a hand-assisted device. Spleens measuring greater than 30 cm leave little room for favorable port placement, limit working space, and often require hand-assisted laparoscopic splenectomy (HALS). Moreover, specimen removal may require either an incision comparable to the "open" technique or the use of a morcellation technique, both with their own risks, and specimen morcellation may have an adverse impact on pathologic analysis. Many surgeons believe that the maneuvers required to remove such large spleens do not warrant these procedures. Special considerations regarding laparoscopy for giant spleens are discussed later in this section.

Preoperative Considerations

Imaging

Preoperative ultrasound or CT imaging is critical for operative planning. As outlined earlier, imaging can not only help with patient selection based on spleen size but also can define useful anatomic relationships that can have an impact on the conduct of surgery, such as nestling of the spleen against the stomach, pancreas, colon, and kidney and the rich, variable blood supply of the spleen. A normal spleen measures about 11 cm in length. Moderate splenomegaly, from 11 to 20 cm, should be noted in the preoperative planning. Massive splenomegaly, greater than 20 cm in length, may alter the preoperative strategy. Preoperative imaging may also identify accessory spleens, which are reported in 10% to 29% of patients.

Though not routinely used with a normal-sized spleen, preoperative splenic artery embolization can be performed in patients with massive splenomegaly to reduce blood loss, reduce the conversion rate, and make laparoscopic splenectomy more manageable. Angiographically guided coil embolization of the proximal splenic artery limits blood flow to the hilum and, in experienced hands, can be a safe and effective way to limit blood loss when preparing for surgery on a giant spleen. If splenic artery embolization is performed, it should be done distal to the great pancreatic artery. This technique is discussed in our image-guided interventional section.

General Considerations

A broad-spectrum antibiotic covering skin flora should be administered approximately 30 minutes before skin incisions. Postoperative antibiotic prophylaxis is discussed later.

Patients being treated by splenectomy for a hematologic disorder should undergo the same preparation that they would for "open" splenectomy, which may include the administration of steroids, globulin, fresh frozen plasma, cryoprecipitate, or platelets. Blood products should be available intraoperatively, especially platelets for intraoperative transfusion in patients with severe thrombocytopenia. In such patients, prophylactic platelet transfusions are typically given only for platelet counts below 50,000 and are typically administered only after the splenic artery has been ligated.[12]

All patients require protection against deep venous thrombosis. We favor knee-high TED hose, sequential compression devices, and if tolerated, preoperative and postoperative heparin prophylaxis according to established national guidelines.

Recommendations regarding bowel preparation for splenectomy remain variable. We favor mechanical bowel preparation the day before surgery or, at a minimum, a cleansing enema the night or morning before surgery to clear the left colon of stool bulk, with the objectives of both improving the ease of intraoperative mobilization of the splenic flexure of the colon and avoiding postoperative constipation.

Immunizations Against Overwhelming Post-Splenectomy Sepsis

Patients who have undergone splenectomy are at increased lifetime risk for overwhelming post-splenectomy infection (OPSI), reported by most experts as occurring in 3% to 5% of patients. The annual incidence of OPSI is reported to be between 0.23% and 0.42%. Risk is highest in three groups:

1. Patients at the extremes of age
2. Immunocompromised patients
3. Those in whom splenectomy was preformed for a hematologic disorder

Trauma patients who require splenectomy are among the lowest-risk groups for OPSI. Cases of OPSI are emergencies, can be lethal, and require immediate parenteral antibiotics and intensive care. Intravenous immunoglobulin may play a beneficial role. OPSI carries a mortality rate of 38% to 69%. The mechanism of OPSI is thought to be decreased antigen clearance in post-splenectomy patients and decreased antigen response. *Streptococcus pneumoniae* is the most common infective agent and is recovered in 50% to 90% of isolates from OPSI patients, followed by *Haemophilus influenzae* type b (Hib), *Streptococcus* group B, *Staphylococcus aureus*, and *Escherichia coli* and coliforms. Increased susceptibility to parasites and malaria is noted in endemic areas. The hypothesized increased risk for *Neisseria meningitides* is unclear.[15]

Optimally, patients should be immunized against encapsulated organisms 14 days before surgery. Recommended immunizations include polyvalent pneumococcal, meningococcal, and *Haemophilus* vaccinations.[16] Pneumovax provides protection against 73% of OPSI-causing organisms. Data on revaccination remain unclear, but current consensus favors a Pneumovax booster every 5 to 10 years, which may be protective against all OPSI bacteria. The benefit of Hib/meningococcal/influenza vaccine is unproven, but it is recommended. For patients who do not receive recommended OPSI immunizations before surgery, we immunize patients just before hospital discharge.

Operative Technique

There is wide variation in the technique of laparoscopic splenectomy with respect to approach, patient positioning, port site placement, port size selection,

number of ports, and instrumentation for controlling splenic vessels. The two most common laparoscopic surgical approaches are the anterior and lateral approaches.

Anatomic Considerations

Laparoscopic splenectomy is not a forgiving procedure. Methodical maintenance of hemostasis, both during division and control of the splenic vasculature and as the spleen is mobilized, is key to a successful minimal access approach. The splenic parenchyma is fragile and particularly vulnerable to capsular tears and procedure-limiting bleeding. Understanding the variable splenic anatomy is essential to intraoperative management. Michels' 1942 review of 100 spleens noted that no two spleens have the same anatomy.[17] Michels divided the splenic blood supply into two types, distributed and magistral, with the distributed type being present in 70% of patients. Splenic size does not correlate with the number or distribution of splenic arteries, although the number of splenic notches and tubercles does. Splenic hilar anatomy can include numerous branches with various division levels. In addition, up to six short gastric arteries may be found in the gastrosplenic ligament arising from the fundus of the stomach. The lienorenal ligament contains hilar vessels and the tail of the pancreas. In nearly three quarters of patients, the tail of the pancreas lies within 1 cm of the spleen, and direct contact between the pancreas and spleen is noted in about a third of patients.

Getting Started—Position, Equipment, "Time-Out," and Team Orientation to the Operative Steps

Minimally invasive surgery is a high-tech environment. The surgeon should review the videoendoscopic equipment required before the procedure starts by systematically going through a checklist to ensure that all needed or potentially needed equipment is available, including video towers with high-fidelity cameras, insufflator, high-intensity light source, video capture device, preferred energy sources (harmonic scalpel, LigaSure, etc.), angled telescope (we favor a 45-degree angled telescope; we also favor having a 5-mm angled telescope for use through 5-mm ports if needed), access device, laparoscopic ports, special laparoscopic instruments (including, for example, preferred dissectors, right-angle dissectors), laparoscopic retractors, specimen retrieval bags, endoscopic staplers, endoclips, and other devices anticipated for the procedure.

The anterior approach was the first laparoscopic splenectomy technique to be described. However, with greater than 15 years of experience with laparoscopic splenectomy worldwide, the procedure has evolved. The most frequent approach to contemporary laparoscopic splenectomy is via a lateral approach.

HALS has been increasingly described for use in complex cases, particularly in patients with splenomegaly.[18]

All patients enter the operative suite and are placed on an electric operative table in the supine position on a beanbag. Pneumatic sequential compression devices are placed before induction of anesthesia. Evidence-based data on prophylaxis for deep venous thrombosis favor the use of perioperative heparin therapy. Perioperative antibiotics are administered. Once anesthesia monitoring devices are placed, general endotracheal anesthesia is established, and the airway is secured, the operative team repositions the patient in the lateral decubitus position with the right side down. Care is taken to ensure that adequate padding is in place. The beanbag is inflated, and additional tape with padding is placed to secure the patient. The security and safety of patient positioning are tested by moving the electric operating table to different planned positions before scrubbing to ensure adequacy of positioning and taping.

A "time-out" is conducted to ensure that the correct patient is in the correct operating room at the correct time for the correct procedure as reflected on the signed informed consent. The "time-out" also affords the operative team the opportunity to familiarize themselves with members of the team, with the objectives of the procedure and key steps, and with special equipment needs. We do not start the procedure unless all equipment requirements have been resolved. The patient is then prepared and draped in the usual sterile manner.

Regardless of approach, performance of laparoscopic splenectomy can be divided into systematic steps, which we review and often write on a white board in the operating room:

1. Positioning and safe access for pneumoperitoneum
2. Diagnostic laparoscopy, including a search for accessory spleens
3. Mobilization of the spleen with dissection of the splenic ligaments
4. Division of the splenic vessels, including the splenic hilum and short gastric vessels
5. Division of the remaining attachments and placement of the spleen in a specimen bag
6. Extraction of the spleen within the specimen bag from the peritoneal cavity
7. Inspection of the operative field
8. Removal of trocars, desufflation of pneumoperitoneum, and closure of the port site

Step 1: Positioning and Safe Access for Pneumoperitoneum

The Anterior Approach Once the standard laparoscopic approach, the anterior approach is now used less frequently because the lateral approach is thought to provide better exposure and more tactical options. The anterior approach may be better suited for dealing with a large spleen, particularly one that has previously undergone splenic artery embolization. It may be preferable for clearance of accessory spleens when suspected. For this group of patients, preoperative imaging with a technetium scan may be helpful, even supplemented by intraoperative localization with a laparoscopic gamma probe. The anterior approach may also be preferable if

other procedures such as diagnostic laparoscopy or cholecystectomy are planned.

For the anterior approach to laparoscopic splenectomy, the patient is placed in either a supine or a modified lithotomy position, with the left side elevated by means of a roll or a sandbag. If the lithotomy position is used, we favor placement of a beanbag to "cocoon" the patient with padding to avoid the patient slipping during intraoperative repositioning. The patient's right arm should be tucked to create more room for the operative team to work opposite the target organ. Equipment is positioned with the understanding that most of the laparoscopic procedure will be conducted from the patient's right, facing toward the patient's left upper quadrant.

Controversy remains regarding the optimal access technique to achieve pneumoperitoneum. Access for pneumoperitoneum is achieved with a "closed" Veress needle, "open" Hasson technique, "direct visualization" device, or a combination of these techniques, depending on the preference of the surgeon and patient characteristics. Despite strong individual surgeon opinion, evidence from tens of thousands of procedures has not provided compelling data favoring one technique over the others with regard to "open," "closed," and "direct visualization" access techniques. We favor the use of a combined Veress "closed" technique, followed by the use of a "direct visualization" device, while taking advantage of the initial pneumoperitoneum as a possible buffer for added safety. We avoid previous scars in the hope of avoiding adherent bowel and minimizing the risk for bowel injury. When we use an anterior approach, initial insufflation is performed at the umbilicus site with a Veress needle, and then the "direct visualization" device is placed in the left side of the abdomen, approximately a third of the distance between the umbilicus and the xiphoid process in the midclavicular line.

We preset the laparoscopic insufflator for an abdominal pressure of 12 mm Hg or less. The objective of laparoscopic insufflation is to establish and maintain a laparoscopic working space. Once this space is established, to minimize the effects of intra-abdominal hypertension, we favor utilization of the lowest insufflation pressure settings that maintain a safe working space and good visualization.

Four or five total laparoscopic ports are placed under direct visualization. Laparoscopic port size is up to the surgeon's choice. We place at least one 10- to 12-mm port to have immediate access for use of either a stapler or a large endoclip device. Current retractor devices often require a 10- to 12-mm port. The configuration of port placement for the anterior approach is typically in a V, with the initial port for the camera located at the base of the V, approximately a third of the distance between the umbilicus and the left costal margin in a line directly toward the splenic hilum. One line of the V extends from the initial port to the xiphoid process; the other line of the V extends from the initial port to the most lateral left subcostal region. After the initial port placement for the camera, all ports are placed under direct visualization. Two dissection ports are placed, one near the midline approximately half the distance between the umbilicus and the xiphoid process and one along the lateral V line in the left midportion of the abdomen at about the midclavicular line. We use a 10- to 12-mm port at this location because it is the probable port for introduction of a stapler or endoclip device. An additional port for retraction is placed further lateral along the lateral V line in the anterior axillary line. If a fifth port is needed for retraction, it is typically placed in the subxiphoid position. The patient is then placed in the reverse Trendelenburg position and tilted slightly to the right. The surgeon stands between the legs if the patient is in the low lithotomy position and adjacent to the patient's right hip if the patient is supine, with the surgeon's video monitor located at the head of the bed to the patient's right. Surgical assistants and the scrub nurse are positioned at the patient's sides.[19]

The Lateral Approach The lateral approach is the most popular for laparoscopic splenectomy, with most surgeons believing that this approach provides better exposure and more intraoperative management options. It is useful for normal and moderately enlarged spleens. Advantages of the lateral laparoscopic approach to splenectomy include the fact that it is technically easier, allows access to the splenic vasculature through the relatively avascular retroperitoneum, and decreases inadvertent trauma to the spleen because gravity is used for retraction more than instruments are. In addition, dissection planes open more easily, thereby enhancing identification of key ligaments, the tail of the pancreas is more accessible and less susceptible to injury, operative times are shorter, and dissection strategy options are increased.

Positioning for the lateral approach to laparoscopic splenectomy is similar to that used for posterolateral thoracotomy or laparoscopic left adrenalectomy, or both. The patient is placed on a beanbag in the right lateral decubitus position. An axillary roll is placed under the shoulders, the kidney rest is raised, and the operating table is flexed. The goal of positioning is to maximize the working space between the left costal margin and the left anterior superior iliac spine. All pressure points must be padded and protected. The patient should be well secured on the operating table; we typically use wide tape and padding. We assess the stability of the patient's position on the electric table by testing the various intraoperative positions that we may use before preparing and draping the patient.

The technique for access to the peritoneal cavity to achieve pneumoperitoneum is the surgeon's choice. As mentioned, we typically use a combination of Veress "closed" and "direct visualization" device techniques. In the lateral decubitus position, however, we avoid the umbilicus and favor placement of first the Veress and then the "direct visualization" device in a position approximately a third the distance from the umbilicus to the splenic hilum in a line between the umbilicus and spleen. After securing access to the peritoneal cavity, typically three additional ports are placed along the costal margin. Depending on spleen size and body habitus, it may be necessary to position the trocars inferiorly or medially to accommodate the size of the spleen. We typically place a

10- to 12-mm port capable of accepting a stapler or large endoclip device for dissection in the left subcostal anterior axillary line, a 5-mm port for dissection in the left subcostal region in the midaxillary line, and a third port, usually 5 mm, in the far left lateral subcostal position. All ports are placed under direct visualization. Occasionally, an additional port is required toward the midline near the xiphoid process for retraction.

Step 2: Diagnostic Laparoscopy, Including a Search for Accessory Spleens After gaining access to the peritoneal cavity, placing all laparoscopic ports under direct visualization, and optimally positioning the patient, diagnostic laparoscopy is performed to survey the abdominal cavity, confirm the location of the spleen, assess anatomic relationships of adjacent organs, search for accessory spleens, and enable the operative team to plan the operative strategy.

The type of splenic vascular anatomy usually can be determined by looking at the inner surface of the spleen. If the vessels appear to cover more than three quarters of the surface, a distributed pattern is present. In this case, the vessels can be dissected and isolated individually and then ligated with clips. If the vessels appear to enter the spleen more uniformly and cover only a third of the splenic surface, a magistral pattern is present. The magistral pattern may be amenable to management with a linear stapler.

Up to 20% of the population may harbor an accessory spleen. The majority of patients with accessory spleens have only one. However, as many as 20% of patients with accessory spleens may have two, and up to 17% may have three or more accessory spleens. Accessory spleens can range in size from 0.2 to 10 cm, but they are typically small, less than 1.5 cm in length, often the size of lymph nodes, and appear as miniature spleens in gross appearance. Approximately two thirds of accessory spleens are located at or near the splenic hilum. Twenty percent are within the substance of the tail of the pancreas. The remainder of accessory spleens are found in the omentum, along the splenic artery, in the mesentery, or along the left gonadal vessels.[20,21]

Operative Strategy of "Opportunity" Within a Systematic Framework Although most surgeons describe a systematic, methodical stepwise approach to laparoscopic splenectomy, the variable splenic anatomy forces a "strategy of opportunity" to guide our systematic framework.

Step 3: Mobilization of the Spleen with Dissection of the Splenic Ligaments Laparoscopic dissection typically begins by partially mobilizing the splenic flexure. This is accomplished by taking down the splenocolic ligament, the distal phrenocolic ligament, and the sustentaculum lienis. Such dissection can be performed with endoshears and the judicious use of electrocautery, one of the harmonic scalpel devices, or the LigaSure device. This dissection creates access to the gastrosplenic ligament, which is then easily separated from the splenorenal ligament. The lower pole of the spleen is carefully elevated. Dissection continues medially and cephalad to open the space like a book, with the spleen gradually rolling laterally as access to the splenic hilum increases. Gentle traction on the spleen is required to avoid a capsular tear and procedure-limiting bleeding. As the spleen is gently elevated and rolled laterally, pertinent dissection targets come into view. Some authors describe a "splenic tent," with the gastrosplenic ligament making up the left side, the lienorenal ligament the right side, and the stomach the floor of the tent. A cautious, stepwise approach is taken to divide the phrenocolic ligament so that the spleen can be rolled laterally away from the tail of the pancreas for visualization of the splenic hilum.

Step 4: Division of the Splenic Vessels, Including the Splenic Hilum and Short Gastric Vessels It is important at this stage to recognize that no two spleens are alike. Spleen size, shape, and vasculature can all vary. Vascular anatomy can be distributed or magistral. In the more commonly encountered distributed variant, defined by a short splenic truck and many long branches entering along the medial surface of the spleen, division of the distributed array of splenic vessels can be performed by sequential applications of an energy source device or endoclips. We typically use the harmonic scalpel device but caution that it must be used to completely traverse each vessel and only a single vessel at a time.

The less common magistral pattern is characterized by a long main splenic artery that divides into short branches close to the hilum.[22,23] The optimal approach for this pattern is to isolate the hilum as much as possible by preparing a window for the application of an endoscopic endovascular linear stapler across the splenic hilum. Before firing the endoscopic linear stapler, careful inspection is necessary to ensure that the tail of the pancreas has been dissected free and is not included within the stapler to avoid possible pancreatic injury or fistula formation.

The short gastric vessels are divided sequentially, individually, to the most cephalad portion of the spleen; one should note that the length of the short gastric vessels often becomes shorter as this dissection proceeds, with progressively less distance between the stomach and the spleen. Care must be exercised when placing energy devices adjacent to the stomach while dividing the short gastric vessels to avoid later gastric necrosis.

Step 5: Division of the Remaining Attachments and Placement of the Spleen in a Specimen Bag Final mobilization of the spleen is completed by dividing the proximal phrenocolic ligament along its entire length to the diaphragm and left crus. Careful inspection ensures complete mobilization and freedom of the now completely detached spleen for safe placement in the specimen bag. Some surgeons prefer leaving the superior-most portion of the phrenosplenic ligament intact until placement of the spleen in the specimen bag. This tactic leaves the spleen tethered to the diaphragm, which can facilitate placement of the spleen in the endoscopic specimen bag.

A large endoscopic specimen bag is introduced through the larger left midabdominal port. Several vendors have designed large endoscopic specimen bags that are especially strong for removal of the spleen. Some surgeons have used sterilized medium-duty or large

heavy-duty plastic freezer bags as an acceptable alternative.[23] The key is to ensure easy retrieval of the spleen and prevent the specimen bag from rupturing during extraction to avoid later splenosis. The spleen is placed in the endoscopic specimen bag under direct visualization.

Step 6: Extraction of the Spleen Within the Specimen Bag from the Peritoneal Cavity Preoperative discussion with the patient care team, including the hematologist and pathologist, should take place to determine whether morcellation of the spleen specimen is appropriate. When laparoscopic splenectomy is performed for malignancy, morcellation of the specimen may make histologic evaluation of the specimen difficult. The result of this discussion will guide the conduct of laparoscopic extraction of the splenectomy specimen.

After the spleen is placed in the endoscopic specimen bag, if the spleen was left tethered to the diaphragm, these final attachments are divided.

The endoscopic specimen bag is grasped and extracted through an appropriate port site. When the anterior approach is used, the extraction site is the umbilicus. When the lateral approach is used, the specimen bag is often extracted through one of the lateral left subcostal ports. Typically, the specimen bag is continuously observed as it is elevated to the abdominal wall. The surgeon can then morcellate the spleen within the bag to allow extraction of the fragmented specimen within the specimen bag through a small incision. Care is taken to not rupture the bag because peritoneal spillage of the fragmented spleen can lead to later splenosis (disseminated splenic implantation). To enable delivery of the spleen and specimen bag, it is rarely necessary to enlarge the extraction port incision more than a few centimeters. For larger spleens, extraction through a Pfannenstiel incision may be preferred or, if HALS has been used, through a hand port incision.

If the decision was made preoperatively to remove the spleen intact within the laparoscopic specimen bag, the surgeon must carefully select the best site for extraction. For larger specimens, most surgeons favor a Pfannenstiel site.

Step 7: Inspection of the Operative Field After the spleen has been successfully delivered or, possibly, before final laparoscopic specimen bag extraction and loss of pneumoperitoneum, the operative field is carefully inspected for hemostasis, previously undetected accessory spleens, or any other unexpected mischief.

No surgical drains are placed, in keeping with the experience established in open surgery.

Step 8: Removal of Trocars, Desufflation of Pneumoperitoneum, and Closure of the Port Site Once the operative team is satisfied with inspection of the operative field, all ports are removed under direct visualization. The pneumoperitoneum is desufflated. Fascia at all port sites greater than 5 mm in diameter is closed. The port sites are irrigated and injected with local anesthetic, the skin edges are approximated with subcuticular closure, and Steri-Strips or tissue sealant is placed, followed by simple dressings.

Minimally Invasive Surgical Approaches to Massive Spleens

Hand-Assisted Laparoscopic Splenectomy

Minimal access splenectomy using hybrid technologies such as HALS is increasingly reported for the management of massive spleens, those significantly larger than 25 cm in length.

HALS is performed via a combination of laparoscopic and "open" splenectomy techniques. It involves the use of a device to enable intra-abdominal placement of a hand and forearm through a small incision, while maintaining pneumoperitoneum, to facilitate the performance of laparoscopic surgery. HALS advocates argue that that use of a hand-assisted device enables tactile feedback (haptics); helps the surgeon judge the extent of disease, identify underlying structures, and palpate anatomic landmarks; augments manipulation of instruments intra-abdominally; assists in restoring depth perception and three-dimensional orientation; and can serve as a bridge to enhance laparoscopic skills. For large spleens, it can help the surgeon manipulate the spleen more safely than laparoscopic instrumentation may allow. Vendors have developed a variety of commercially available hand port devices with a wide range in cost. The length of the hand port incision required correlates mainly with the breadth of the surgeon's palm, with incision length usually approximating the size of the surgeon's glove (6.5 to 8.0 cm). Two centimeters should be subtracted if marking takes place before pneumoperitoneum is established. Surgeon hand and forearm size are key and can be limiting for surgeons with large hands.

Placement of the HALS device is important. A "stand off" distance is needed between the hand port and the target organ so that the surgeon's hand has working room within the abdomen and does not interfere with laparoscopic instruments. Options for hand port placement for left upper quadrant surgery include the midline just above the umbilicus, the lower midline or left lower quadrant via a muscle-splitting incision, or even a Pfannenstiel incision for surgeons with particularly small hands. Patient positioning for either a lateral or an anterior approach can be used for HALS, based on surgeon preference and experience. The most common location for the hand port is in the midline, between the xiphoid and the umbilicus. For massive spleens, use of a Pfannenstiel incision has also been described.[22]

Pneumoperitoneum is established after the hand port is placed. Additional laparoscopic port placement must be planned carefully to enable visualization and working access while maintaining hand port access.

Once the hand port and additional laparoscopic ports are placed and pneumoperitoneum is established, the principles of splenectomy remain the same. The biggest technical challenge is avoidance of hemorrhage. Small series have reported successful performance of HALS for severe splenomegaly (mean spleen length, 27.9 cm; range, 23 to 32 cm), with acceptable operative times, morbidity, and outcomes.[24] This approach combines the advantages of hand assistance with the benefits of mini-

mally invasive surgery and has resulted in shorter operative times, increased safety, and acceptable outcomes.

Robotic-Assisted Laparoscopic Splenectomy

Minimally invasive splenectomy for splenic disorders such as ITP results in the same patient benefits as demonstrated for laparoscopic cholecystectomy. Robotic-assisted laparoscopic splenectomy has been reported and may play a role in future minimally invasive surgical approaches to the spleen.[25]

The benefit of robotic systems for general surgery remains a matter of debate. In a retrospective review, six laparoscopic splenectomies were compared with six robot-assisted laparoscopic splenectomies, all for ITP, with patients matched for age, American Society of Anesthesiologists score, body mass index, and preoperative platelet levels. There were no conversions to open surgery, and no complications were reported. The median postoperative stay was 1 day longer in the robotic group, with mean average costs being almost a third higher. Operative times were about 20% longer in the robotic group. In this analysis, robot-assisted laparoscopic splenectomy resulted in prolonged operative time, length of stay, and procedural costs, and though feasible, no relevant benefit was demonstrated.[26]

With advancement in surgical robotic technology, robotic systems may play a more integral role in future minimally invasive surgery.

Postoperative Care

Postoperative care after laparoscopic splenectomy is straightforward, provided that the procedure was uneventful. The nasogastric/orogastric tube and Foley catheter can be removed immediately after the procedure. We do not leave a nasogastric tube in place overnight. A postoperative chest radiograph is not required in the postanesthesia care unit (PACU) to confirm the absence of pneumothorax. Pneumothorax after laparoscopic splenectomy is rare, and if it was not of consequence intraoperatively, it is unlikely to have clinical impact postoperatively. After meeting PACU discharge milestones, patients recover on the ward. Patients should be encouraged to perform deep breathing with incentive spirometry and begin assisted early ambulation within 8 to 10 hours after surgery. Pain should be well controlled to avoid splinting. Deep venous thrombosis prophylaxis is continued postoperatively with both pneumatic sequential compression devices and heparin, unless contraindicated. A diet is resumed when tolerated. We usually begin with a clear liquid diet the morning after surgery and advance the diet as tolerated.

The typical length of stay after laparoscopic splenectomy is 1 to 3 days. Most laparoscopic splenectomy series report that the length of stay is on average 2 to 3 days.

Counseling, Antibiotics, and Immunizations for Overwhelming Post-Splenectomy Sepsis

All patients undergoing splenectomy should be counseled regarding their increased lifetime risk for OPSI. Lifetime risk data, typically reported at 3% to 5%, were outlined earlier. Patients should be advised to seek medical care immediately if any sort of febrile illness develops.

The use of long-term prophylactic antibiotics after splenectomy remains controversial. Long-term antibiotic therapy risks selection of resistant microbial strains. The lowest-risk groups for OPSI are those whose spleen was removed for trauma. The highest-risk groups include those whose spleen was removed for a hematologic disorder, immunocompromised patients, and patients at the extremes of age. Pediatric hematologists often recommend treatment with a penicillin-based regimen for 2 years after splenectomy. Studies have demonstrated benefit from OPSI antibiotic prophylaxis in children with sickle cell disease, but there have been no studies in adults.

We discharge patients with a supply of oral antibiotics and clear instructions to initiate therapy at the onset of symptoms of infection as they simultaneously arrange to seek urgent medical attention. Though uncommon, when it does develop, OPSI can follow a fulminant, often lethal course and should be treated as a life-threatening emergency requiring immediate parenteral antibiotics and intensive care. Intravenous immune globulin may play a beneficial role. OPSI mortality rates are reported to be 38% to 70%.[15]

Surgical Complications

Surgical complications of laparoscopic splenectomy are similar to those for the "open" procedure.

Early complications include bleeding, pneumonia, left pleural effusions, atelectasis, and injury to other organs (colon, small bowel, stomach, liver, and pancreas).

Late complications include subphrenic abscess, splenic or portal vein thrombosis (or both), failure of the procedure to control the primary disease, recurrent disease as a result of accessory spleens, and OPSI.

Concerns regarding accessory spleens and whether there is a higher likelihood of accessory spleens being missed at laparoscopy versus "open" surgery appear to be unfounded. Data from laparoscopic splenectomy have not found an increased incidence of recurrence of the underlying hematologic disorder when compared with "open" historical controls. Moreover, surgeons experienced in laparoscopic splenectomy report an 18% to 27% incidence of discovering accessory spleens in the anterior and lateral approaches, respectively, as opposed to 15% to 30% with "open" surgery. The key is for laparoscopic surgeons to diligently assess for accessory spleens in the expected locations at the time of laparoscopic splenectomy.

Critical to success in laparoscopic splenectomy is being well organized and prepared, with an emphasis on avoidance of complications and technical misadventures. Laparoscopic splenectomy is unforgiving. Managing intraoperative complications, once they occur, can be challenging, particularly bleeding-related complications. Recognition that the splenic vascular anatomy is variable and complex and that the spleen is a fragile solid organ

with a delicate capsule underscores preemptive efforts to avoid bleeding. Dissection should be methodical, with sequential identification, isolation, and control of vessels individually. The lateral approach decreases traction requirements on the spleen, thereby decreasing traction-related splenic capsular tears. Constant intraoperative monitoring for hemostasis is critical. Energy sources have limitations, as do clip and linear stapler devices. Improper application of cautery can result in iatrogenic injury to organs adjacent to the spleen. Improper harmonic scalpel application can lead to hemorrhage from a partially sectioned vessel. Improper clip application can result in injury to an adjacent vessel. Blind linear stapler application can cause damage to the tail of the pancreas. Never bury the stapler and always visualize the tissue within the stapler and the tip of the linear stapler before firing. Hemorrhage can occur from partial division of a major splenic vessel after release of the stapler. Instruments should be introduced into the operative field under direct visualization to avoid inadvertent injury to the delicate splenic parenchyma.

Patients with persistent postoperative fever, an increased white blood cell count, and abdominal pain should undergo CT of the abdomen. Subphrenic abscesses are treated by drainage and intravenous antibiotics.

Splenic or portal vein thrombosis develops in approximately 6% to 10% of "open" splenectomy patients.[27] The incidence of portal vein thrombosis after laparoscopic splenectomy may be higher. In one series that specifically examined laparoscopic splenectomy patients, 14% were found to have portal vein thrombosis.[28] Another series prospectively investigated "open" splenectomy patients and laparoscopic splenectomy patients with helical CT imaging preoperatively and postoperatively and found portal venous thrombosis in 19% of the "open" splenectomy group and 55% of the laparoscopic splenectomy group. Anticoagulation therapy was initiated once the diagnosis was established, and complete recanalization, except for the distal splenic vein, was observed without adverse events.[29]

Symptoms are vague and include fatigue, nausea, vomiting, and nonspecific abdominal pain. If clinical suspicion is high, anticoagulation therapy should be initiated once the diagnosis is confirmed by imaging studies.

Overview

Laparoscopic splenectomy is an excellent option for an expanding group of indications, but it is best accomplished by an experienced laparoscopic team. Conditions that were once considered either relative or absolute contraindications to laparoscopic splenectomy have become fewer. Advances in surgical technique, evolving instrumentation and energy sources, and improved operative strategies are continuing to expand the indications and making laparoscopic splenectomy feasible with good outcomes and minimal morbidity for an increasing group of patients with a variety of pathologic splenic conditions.

IMAGE-GUIDED INTERVENTIONAL THERAPY FOR THE SPLEEN

By possessing a single, accessible feeding artery with a relatively simple branching pattern, the spleen is well suited to routine, safe catheter access. Its brisk blood flow and richly vascular parenchyma provide high-quality arteriograms, parenchymal opacification, and portal venous imaging with digital subtraction angiography. Minimally invasive vascular interventional techniques for the spleen were rapidly popularized in the 1970s and 1980s and played an increasing role in the algorithm of surgical practice, which saw a shift toward preservation of functioning splenic tissue through nonoperative management.

This section reviews the techniques and clinical applications of image-guided splenic interventions for splenic trauma, splenic artery pseudoaneurysm, hypersplenism, and drainage of splenic collections.

Technique of Transarterial Splenic Embolization

Anatomy

Although surgical splenectomy may be performed efficiently and safely, it is now clear that removal of this reticuloendothelial organ carries with it significant risks for overwhelming postoperative sepsis. The objective of catheter-directed therapy is to achieve the surgical therapeutic goals while preserving adequate functioning splenic tissue for host immunity. The splenic artery is usually a large single vessel arising anterolaterally from the celiac axis trunk. Anatomic variants of the splenic artery are uncommon but include a separate origin from the aorta.[30] The artery corkscrews clockwise or anticlockwise while undulating across the posterosuperior aspect of the pancreas body. It gives off sequentially the dorsal pancreatic and pancreatica magna arteries before dividing into extrasplenic polar branches in the region of the pancreatic tail (Fig. 127–1). The pancreas also receives blood supply from the pancreaticoduodenal and transverse pancreatic arcades, and the spleen has a rich vascular network from the short gastric and gastroepiploic arteries. This anatomy may be depicted on current three-dimensional multidetector row CT angiography and magnetic resonance angiography with a diagnostic quality comparable to that of invasive splenic angiography (Fig. 127–2).

Technique

Most splenic interventions may be performed with conscious sedation, although pediatric patients require general anesthesia. When functional partial or complete splenectomy is anticipated, pneumococcal vaccine and intravenous penicillin, metronidazole, and gentamicin antibiotics are administered. An initial aortogram is performed with a 5-French flush catheter through a 5-French sheath in the femoral artery to globally assess for sites of bleeding and depict normal and variant anatomy

for selective angiography. The celiac axis and splenic artery are selected with a combination of a 5-French Simmons 1 or Cobra glide catheter and an 0.035 glide wire. With proximal placement of the catheter, a selective splenic angiogram is performed with arterial, parenchymal, and portal venous phase timing of the contrast bolus. Smaller, more distal hilar and branch vessels may be selected with the 5-French catheter combined with a 3-French microcatheter over a 0.014 to 0.018 microwire. Standard digital subtraction angiography suffices, although newer three-dimensional fluoroscopy units may be of benefit in patients with difficult anatomy (Fig. 127–3).

Embolization is performed in a distal-to-proximal direction within the artery. Available embolic materials include Gelfoam, particles, and coils. Smaller, more distal arteries and parenchyma may be temporarily embolized with gelatin sponge pledgets or slurry or with autologous blood clot. Permanent distal parenchymal vascular occlusion is achieved with 3- to 900-µm particulate polyvinyl alcohol, silicone, or acrylic embolic spheres. The embolic agents may be soaked in antibiotic to decrease the risk for abscess formation. The splenic artery may be permanently embolized with metallic coils from the second-order branches into the main splenic artery. Coils are deployed distal to the dorsal pancreatic

and pancreatica magna arteries in an effort to avoid splenic infarction by preserving collateral blood supply to functioning splenic pulp.[31] Coils must be sized to the target vessel to avoid inadvertent distal embolization to nontarget vessels or proximal migration into the celiac axis or aorta. Depending on the indication, a combined approach of coil and embolic agents may be used. One must remain cognizant that proximally placed coils may limit future interventions if required.

Splenic Bleeding and Transarterial Splenic Embolization

Most cases of splenic bleeding seen in practice result from blunt or penetrating trauma to a normal-sized spleen. The spleen is the most commonly injured organ for which transarterial embolization is necessary and was first described by Sclafani et al. in 1995.[32] The algorithm for managing a patient with splenic injury is an evolving practice reflected by decreased splenectomies in adults and children and expansion of the number of patients managed nonoperatively by observation and transarterial splenic embolization (TASE). Assignment of patients to operative or nonoperative groups and to interventional and noninterventional groups is best achieved through reconciliation of the clinical picture, imaging findings, and injury scores (American Association for the Surgery of Trauma [AAST], Organ Injury Scale [OIS])[33] by the surgeon and interventionalist.[34] CT has largely eliminated the application of admission diagnostic angiography as routine practice for all splenic injuries. One should bear in mind that grading of the injury is now largely based on CT, which has some interobserver variation, is limited in depicting active bleeding on a single study, and cannot reliably distinguish arterial and venous extravasation. CT findings cannot be viewed in isolation for the management algorithm. A temporal change that is clinically occult may be an indication for intervention, but the presence of less remarkable features should not be used to deny intervention when they are discordant with the clinical picture.

Clinical features of patient age, the grade of splenic injury,[35,36] the amount of retroperitoneal bleeding,[37] the need for resuscitation, and associated injuries[38,39] are no longer absolute indications for surgery, nor do they absolutely preclude an interventional approach.[34,37] Broadly speaking, most would agree that a hypotensive, unstable patient refractory to resuscitation (usually grade 3 to 4 injury) mandates surgical exploration.[33] The majority of injuries occur in hemodynamically stable patients with a grade 1 or 2 injury and no signs of continued bleeding and may be managed conservatively with observation.[40,41] The role of endovascular therapy lies between these broadly defined groups and is still actively debated, and management today largely depends on local expertise and trauma team organization, which evaluates each case on its individual merits. Most splenic injuries treated by embolization are grade 2.8 to 3.[35,37,40] TASE has little role in a shattered or devascularized spleen. In centers with rapid access to interventional services as part of trauma triage, there is some evidence to support TASE in patients who respond transiently to minimal resuscitation[42] and for endovascular treatment of higher-grade injuries. Up to 10% of hemodynamically stable patients may have imaging signs of continued bleeding from grade III injuries and are potential candidates for TASE.

Endovascular therapy for splenic trauma begins with review of contrast-enhanced CT or magnetic resonance imaging (MRI). Aortography may demonstrate generalized vasoconstriction and renal retention of contrast in a patient in shock. Splenic angiographic findings include abrupt termination of vessels, vasospasm, pseudoaneurysm, and arteriovenous fistula formation. Intrasplenic vessels may be displaced and the extrasplenic artery may be accordioned as a result of hematoma. The parenchymal phase may demonstrate contrast extravasation, avascular segments, abnormal accumulation of contrast within the pulp, and loss of the smooth splenic contour. In the setting of large subcapsular hematoma, the spleen will be displaced anteromedially and the left kidney may be displaced inferiorly.

Bleeding may initially be treated with a temporary distal particulate agent to slow bleeding from the cut surface, but definitive therapy is permanent coil embolization of the splenic artery. If there are only two or three identifiable bleeding sites, they may be selectively coiled distally. However, if multiple bleeding sites are present, more proximal embolization will be required. Embolization slows arterial inflow and permits distal clot to form,[31] and Haan et al. noted no difference in outcomes between proximal and distal embolization.[37] After therapy one may see complete stasis or markedly slowed flow. Absence of extravasation at angiography is a reliable sign of successful therapy,[32] and such patients will probably not need laparotomy later.

The success of TASE and its contribution to nonoperative management have largely been determined from retrospective data. Patients failing nonoperative management (3% to 17%) and requiring splenectomy are decreasing.[34,37] The overall success rate of TASE in controlling splenic bleeding and salvaging splenic tissue is quoted at over 80% in adults and children.[33,36,42,43] Haan et al. reviewed 648 patients with blunt splenic injury, 132 of whom underwent embolization, and noted a salvage rate of 90%.[37] The presence of an arteriovenous fistula may predict operative failure,[37] but this will depend on how aggressively the fistula is treated. Those who fail an initial TASE procedure may yet be considered for a second application if they remain stable; such patients account for 2% to 5% of those treated[37] (Fig. 127–4). One would expect failure rates to increase as the technique is increasingly applied to higher injury grades.

Complications of TASE include failure to treat sites where delayed recurrent bleeding occurs because of either continued bleeding through the embolization, lysis of the clot at the injured site, rupture of a pseudoaneurysm, or relaxation of acutely vasospastic vessels.[44-47] Delayed bleeds occur days to weeks after therapy. Postembolization syndrome consists of abdominal pain and fever and may be associated with CT findings of necrotic, air-containing parenchyma and left-sided pleural effusion. This syndrome is usually self-limited unless superimposed on infection. Bacterial peritonitis, septicemia, splenic abscess, and rupture are recognized complications. Hematomas may evolve into calcified splenic hematomas or cysts. Postembolization infarction rates are quoted to be as high as 20% but depend on the site of injury and the extent of embolization required.[44,47,48]

Pseudoaneurysm of the Splenic Artery

The splenic artery is the most common visceral artery affected by aneurysms and pseudoaneurysms and is second only to aortoiliac aneurysm formation. They share some causes with aneurysms elsewhere but are specifically associated with pancreatitis, hypersplenism, and pregnancy. Traumatic pseudoaneurysms presumably occur as a result of deceleration of the spleen on its vascular pedicle during blunt abdominal trauma.[44] It has been suggested that the increased nonoperative management of splenic injuries may lead to a greater prevalence of traumatic pseudoaneurysms that would otherwise have been resected,[49] but there is also increased detection of incidental splenic aneurysms because of the widespread application of cross-sectional imaging. Women have an increased prevalence and are more prone to rupture in pregnancy. Splenic aneurysms are typically saccular and situated in the distal third of the splenic artery. Rarely, intrasplenic aneurysms have been reported.[50] They contain a variable amount of mural thrombus, are frequently calcified, but do not affect splenic perfusion. CT angiography is highly accurate in the detection and characterization of splenic aneurysms, although three-dimensional reconstructions are required to differentiate the false-positive findings of normal vessel tortuosity and atherosclerotic change. There is some debate on which pseudoaneurysms should be treated. Most agree that aneurysms larger than 2 to 2.5 cm and enlarging or symptomatic aneurysms should be treated because up to 60% of those who bleed will be unstable and the mortality rate associated with bleeding is quoted to be as high as 15%.[49] Many also advocate therapy for smaller aneurysms in women considering childbearing. Some argue that lesions less than 2.5 cm and small pediatric splenic aneurysms may be managed conservatively with close follow-up imaging and surveillance, although some authors suggest that all pseudoaneurysms be actively treated given the low morbidity of the procedure.[49,51]

The majority of splenic aneurysms may be treated by embolization of the aneurysmal sac directly or its feeding artery. For broad-necked, saccular, or fusiform aneurysms, coils are deployed in a distal-to-proximal direction within the splenic artery. In saccular lesions with a narrow neck, one may deploy detachable coils or balloons within the aneurysm sac itself (Fig. 127–5). More recently, covered stents placed across the aneurysm neck have been suggested as a form of therapy that will exclude the aneurysm and preserve blood flow and future access.[52] This procedure, however, may be associates with higher risk in very tortuous and diseased arteries and requires careful patient selection. Percutaneous injection of thrombin has been reported but is an uncommon approach and perhaps less controlled because one cannot compress the neck as is done in peripheral arteries.[53] Localized treatment of a pseudoaneurysm and its neck preserves splenic function through more proximal branches. The results of endovascular management have been good, and it is a now a recommended consideration for all splenic aneurysms.[54] It is not clear to what extent splenic artery integrity is undermined by its proximity to the pancreas

in pancreatitis, but it has been suggested that pseudoaneurysms related to pancreatitis may be better treated surgically. If surgery is anticipated, balloon occlusion catheters may control bleeding intraoperatively.[49]

Hypersplenism and Partial Splenic Embolization

Splenic embolization was introduced in the early 1970s and is for the treatment of hypersplenism and pancytopenia with or without massive splenomegaly (e.g., thalassemia, myelofibrosis).[26] As well as improving hematologic parameters and decreasing splenic size, it may improve liver function and decrease gastric or splenic variceal bleeding, but this will depend on the baseline splenic disease and hepatic reserve.[48,55-58] Although complete embolization was performed initially, the combination of antibiotic prophylaxis and partial splenic embolization[59] has been an effective, safer alternative to surgical splenectomy.

Treatment is usually performed with small (3- to 900-µm) permanent particulate embolic agents (e.g., polyvinyl alchohol or silicone or acrylic embolic spheres), which seek to deprive peripheral, intraparenchymal segmental regions of the spleen of their blood flow. Coils are not used because it is harder to gauge and stage the percentage of parenchyma treated and they limit access for future treatments, which are frequently required. The risk for pancreatitis is reduced by placement of the catheter as distal as possible to avoid particulate agents going to nontarget sites, and one may select individual hilar branches to better distribute the embolic agents throughout the spleen. Percent embolization is judged from parenchymal-phase angiography after injection of the particulate agent. It has been suggested that less than 50% embolization predisposes to relapse[48,60] but with over 70% embolization of the splenic pulp, greater long-term efficacy may be achieved.[56] Most achieve this 70% goal in staged applications to limit postembolization syndrome and complications. The response in organ size is best appreciated with CT or MRI and will be noticed within 2 to 4 months of therapy. A hematologic response may be seen within weeks,[61] but a prolonged long-term response has also been demonstrated[62] (Fig. 127–6). Although Nio et al. noted relapse

of thrombocytopenia after a single partial splenic embolization treatment, long-term efficacy was achieved in 70% of patients.[56] Success rates are higher in patients with decreased variceal bleeding and improved liver function. Relapse may be related to the rate of splenic regeneration. Reported complications of the procedure include splenoportal venous thrombosis, splenic necrosis, abscess, and septicemia, which are potentially lethal in this patient population.[48,61]

A similar technique is used for pre-splenectomy splenic embolization. In general, the surgical approach to splenectomy permits good control of bleeding and

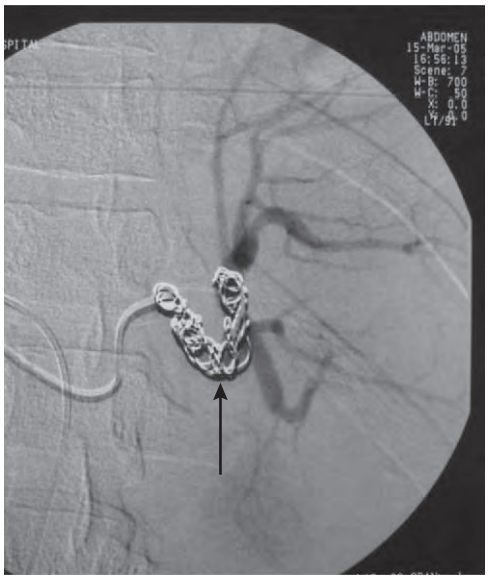

Figure 127–7. Sixty-two-year-old man who underwent preoperative embolization before splenectomy for lymphoma and splenomegaly. Note coils in the splenic artery *(arrow)* and decreased blood flow distally.

limited blood loss. However, it may be more challenging in a patient with massive splenomegaly (lymphoma or leukemia), in whom access to the hilum is more difficult. Coil embolization proximally may limit blood flow into the hilar vessels. Although the coils may affect placement of surgical clamps and ligatures, they can be removed easily if placed near the time of surgery. Intraparenchymal particulate Gelfoam slurry embolization may limit bleeding of an intrasplenic mass (hemangiosarcoma or fibrosarcoma) (Fig. 127–7). Typically, embolization is performed close to the time of surgery.

Splenic Abscess and Pseudocyst

The most common splenic collections include old hematoma, pseudocysts and cysts, (Fig. 127–8) and splenic abscesses (Fig. 127–9). Cysts are commonly seen on cross-sectional imaging and require therapy when they are large enough to cause early satiety or left shoulder pain. Noninfected splenic cysts may be treated by percutaneous puncture and aspiration with sclerosis. The volume of aspirate is replaced with 100% dehydrated ethanol or doxycycline, and the patient is placed in alternate postures for an hour before the fluid is aspirated.[63,64] Repeat therapy may be required. Splenic abscesses may be iatrogenic and may be complicated by a mycotic pseudoaneurysm. They are usually accessed with ultrasound guidance and a single-walled 18-gauge needle. A 10-French drain may then be placed over a 0.035 wire. When the drainage tapers off, repeat imaging will indicate whether the drain may be removed.[65,66] Sterile collections that continue to reaccumulate may be sclerosed with tetracycline.[66]

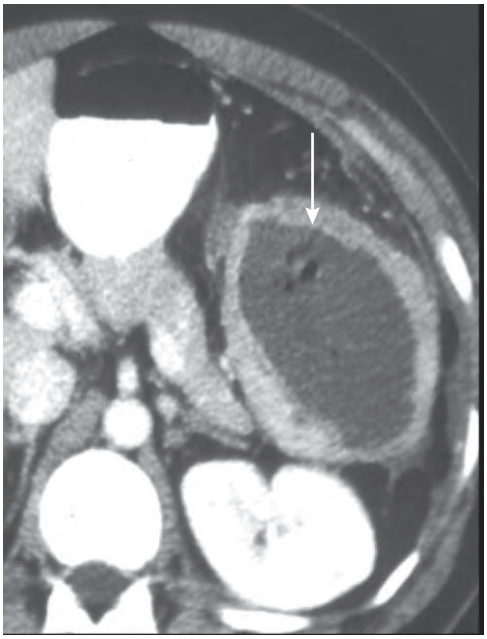

Figure 127–9. Axial contrast-enhanced computed tomography scan demonstrating an air-containing splenic abscess *(arrow).*

CONCLUSION

Splenic diagnostic angiography is shifting from interventional techniques to noninvasive three-dimensional CT and MRI, which produce studies of similar quality. There has been growth in splenic artery therapeutic embolization, which is safe and efficacious. It has expanded the proportion of patients treated by nonoperative management and complements the move in surgery to organ preservation whenever possible. It already has a clear role in trauma, hypersplenism, and splenic artery aneurysm, but with refinement of the algorithms, we will probably see a broadening of patient selection.

Future interventions for splenic disorders will be approached by a multidisciplinary team that includes the surgeon and interventional radiologist.

Management of Splenic Trauma in Adults

Anne Lidor

The spleen, an important component of the reticuloendothelial system in normal adults, is a highly vascular solid organ situated in the left upper quadrant of the abdomen that arises as a mass of differentiated mesenchymal tissue during early embryonic development. The normal adult human spleen weighs between 75 and 100 g; receives an average blood flow of 300 ml/min; and functions as the primary filter of the reticuloendothelial system, sequestering and removing antigens, bacteria, senescent or damaged cellular elements, and other particulate matter from the circulation. In addition, the spleen also plays an important role in humoral immunity, producing immunoglobulin M and the opsonins tuftsin and properdin[1]; is an important component of the complement activation system; and can serve as a source of extramedullary hematopoiesis.

Although the spleen is protected anteriorly, posteriorly, and laterally by the lower rib cage, it is nevertheless frequently subject to both blunt and penetrating trauma. In fact, although the spleen and liver are the two most commonly injured solid organs in the abdomen, splenic injuries are more clinically significant and more frequently require surgical intervention,[2] a reflection of the potential for sudden and catastrophic hemorrhage in splenic trauma. Isolated splenic injury after blunt trauma is common in children, whereas in adults associated injuries are more frequent, including injuries of the thorax, lungs, liver, kidneys, diaphragm, extremities, and head. Blunt splenic trauma is only infrequently accompanied by associated pancreatic or bowel injury, contrasting sharply with the experience seen with blunt liver injury, in which these two organs are frequently also involved.[3] In addition, the spleen is not infrequently the victim of iatrogenic injury: Although splenic injury complicates only 0.01% of all laparotomies, splenic injury may accompany as many as 10% of complex or revisional operations performed in the left upper quadrant.[4]

Clinical indicators of splenic injury depend largely on the mechanism of injury. In blunt trauma, a history of abrupt deceleration may result in vascular torsion of the splenic hilum, shearing of the short gastric vessels within the gastrosplenic ligament, or capsular tearing at sites of ligamentous fixation. Associated fractures of the lower left rib cage, when present, not only serve to indicate the severity of the initial blunt force injury but can also inflict severe laceration on an otherwise uninjured spleen. In instances of penetrating trauma, a wound track traversing the left upper quadrant necessarily raises suspicion for splenic injury. Additional clinical findings pointing toward possible splenic damage include extensive ecchymosis or abrasions of the left upper quadrant or left flank and left shoulder or subscapular pain caused by irritation of the left hemidiaphragm by subphrenic blood (Kehr's sign). Initial laboratory evaluation is that of the standard trauma survey, and it is important to recognize that the initial hemoglobin and hematocrit may be entirely normal and, as such, have little utility in ruling out the possibility of significant splenic injury. Any suspicion for splenic injury should immediately lead to more definitive diagnostic testing (discussed later).

DIAGNOSTIC MODALITIES

Diagnostic peritoneal lavage (DPL) has historically been the cornerstone diagnostic study used to detect significant intraperitoneal injury requiring surgical intervention. This quick, simple procedure can be easily performed in the resuscitation area of the emergency department. DPL is considered to be positive for the presence of significant intraperitoneal injury when more than 10 ml of gross blood is aspirated directly from the peritoneal cavity or when the returned effluent contains more than 100,000/mm^3 of red blood cells, more than 500/mm^3 of white blood cells, or demonstrable bacteria or bile. In cases of significant splenic trauma, the most common findings on DPL are either the return of gross blood or the presence of more than 100,000/mm^3 of red

blood cells. The sensitivity of DPL for detecting significant intra-abdominal injury has been reported to range from 82% to 96%, whereas its specificity ranges from 87% to 99%.[5] Despite this, it has been reported that between 25% and 36% of celiotomies performed solely on the basis of a positive DPL are negative. Moreover, DPL itself carries an incidence of complications approaching 2.5%.[6,7] Because of the inherent inaccuracies of DPL, as well as its invasiveness, this diagnostic modality has now largely been supplanted by the use of noninvasive imaging studies such as ultrasound and computed tomography (CT).

Ultrasonography is readily available, can be performed quickly, and offers a completely noninvasive method for rapidly surveying for intraperitoneal blood or solid organ injury in patients with blunt or penetrating abdominal trauma. The focused abdominal sonography in trauma (FAST) examination, though somewhat lacking in specificity, is nevertheless highly sensitive for detecting intraperitoneal blood—a frequent accompaniment to significant splenic trauma—and has emerged as a useful diagnostic tool in the evaluation of patients with suspected splenic injury. FAST is completely without risk of complications and, moreover, its performance does not preclude the subsequent performance of CT scanning. The sensitivity of FAST has been reported as anywhere between 42% and 93%, whereas its specificity ranges in various reports between 90% and 98%.[8] The primary limitations of FAST (and, no doubt, the reasons for the extraordinary variability of the reported sensitivity of this technique) are (1) the heavy operator dependence of ultrasonographic examinations and (2) the obscuring effect of intestinal gas, which can severely compromise the ability to obtain distinct and useful images. Although FAST has not emerged as the dominant diagnostic imaging modality in the evaluation and management of patients with abdominal trauma, it has proved useful as a preliminary study, helpful in guiding the performance of additional imaging studies (e.g., CT) to determine the need for surgical management.

CT scanning is the diagnostic imaging modality of choice in all hemodynamically stable patients in whom splenic injury is suspected. The sensitivity and specificity of CT scanning (approaching 100% and 98%, respectively)[9] are superior to both FAST and DPL in detecting significant intra-abdominal injury and determining the need for surgery. Moreover, the exceptional resolution afforded by current-generation multislice scanners provides extraordinary detail regarding specific intra-abdominal organs and retroperitoneal structures. CT allows detailed examination of the splenic architecture, enabling the differentiation of simple subcapsular hematomas from more significant intraparenchymal hematomas, splenic fractures, and massive crush injury involving the entire spleen. To maximize the diagnostic accuracy of CT, patients should be given both intravenous and oral contrast to enhance tissue definition. Another advantage of CT scanning is that studies are performed according to predetermined computer-guided protocols, eliminating dependence on individual operator ability. Disadvantages of CT include the administration of ionizing radiation, the potential for nephrotoxic or anaphylactic reactions to the contrast agent, and the time required to transport patients to the scanner and to perform the examination. This latter consideration accounts for the inapplicability of CT scanning in hemodynamically unstable patients. However, the ubiquity of CT scanners, their proximity to the trauma area in well-designed modern emergency departments, and the astonishingly rapid image acquisition times with the newest generation scanning units all are factors continually extending the applicability of CT for evaluation of all but the most unstable patients.

Several grading systems have been employed for classifying the severity of splenic injuries, and these have important implications in guiding both operative and nonoperative management decisions. We have found the system designed by the Organ Injury Scaling Committee (OISC) of the American Association for the Surgery of Trauma[10] to be quite helpful not only in stratifying the severity of splenic injuries and determining proper therapy but also in providing a standardized and reproducible nomenclature for reporting purposes. This grading system incorporates both CT findings and intraoperative assessment of the injured spleen and consists of five levels of splenic injury, as follows:

- Grade I injuries consist of small subcapsular hematomas and capsular tears less than 1 cm in length.
- Grade II injuries comprise subcapsular hematomas involving less than 50% of the surface area of the spleen and parenchymal lacerations 1 to 3 cm in length that do not involve a trabecular vessel.
- Grade III injuries consist of any subcapsular hematoma involving more than 50% of the splenic surface, all expanding (or ruptured) subcapsular hematomas, and parenchymal lacerations longer than 3 cm (with or without involvement of trabecular vessels).
- Grade IV injuries apply to patients with splenic lacerations involving the segmental vessels or with devascularization of more than 25% of the spleen.
- Grade V injuries consist of major hilar disruption, devascularization of more than 50% of the spleen, or complete splenic shatter (Table 128–1).

Such severity grading systems notwithstanding, decisions regarding management of individual patients with specific splenic injuries are not cut-and-dried and involve more than simply assigning a severity score and determining therapy. Other factors, such as the mechanism of injury (blunt versus penetrating), the presence of other associated injuries (both intra-abdominal as well as extra-abdominal), the age and overall condition of the patient, and the presence and duration of hypovolemic shock and/or hypothermia all must be taken into consideration and will influence the choice of management in cases of splenic trauma. Nevertheless, the severity of the splenic injury plays a dominant part in determining whether nonoperative management is appropriate or—if not—whether splenorrhaphy or splenectomy will be the more appropriate surgical option. As a general rule, younger, healthier patients with less severe splenic

Table 128–1 Splenic Injury Scale—1994 Revision

Grade* and Type of Injury	Injury Description
I	
Hematoma	Subcapsular, <10% surface area
Laceration	Capsular tear, <1 cm parenchymal depth
II	
Hematoma	Subcapsular, 10-50% surface area; intraparenchymal, <5 cm diameter
Laceration	1-3 cm parenchymal depth, does not involve trabecular vessel
III	
Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma
Laceration	>3 cm parenchymal depth or involving trabecular vessels
IV	
Laceration	Laceration involving hilar vessels producing >25% devascularization of spleen
V	
Laceration	Completely shattered spleen
Vascular	Hilar vascular injury, spleen devascularized

*Advance one grade for multiple injuries, up to grade III.
Data from Moore EE, Cogbill TH, Jurkovich GJ, et al: Organ injury scaling: Spleen and liver (1994 revision). J Trauma 38:3, 1995.

injuries and fewer associated injuries and comorbidities are more likely to be able to be managed nonoperatively or with splenic repair, whereas unstable, actively hemorrhaging patients with more severe splenic trauma and/or multiple associated injuries are overwhelmingly likely to require splenectomy.

OPERATIVE TREATMENT

The earliest reports on the management of splenic trauma focused almost exclusively on splenectomy, and this constituted the mainstay of treatment of splenic injuries for the first half of the 20th century. Although suture repair of splenic injuries (as well as rudimentary attempts at formal splenorrhaphy) had been described as early as the latter half of the 19th century, these techniques failed to enter the mainstream of surgical management of splenic trauma until a resurgence of interest in them developed in the mid-20th century. By the 1950s, the potentially devastating complications of what would eventually come to be recognized as overwhelming postsplenectomy sepsis (OPSS) were being well documented in infants who had undergone splenectomy,[11] and this led to enthusiasm for nonoperative management of splenic trauma in the pediatric population.[12,13] It was not until the 1980s, however, that a similar emphasis on splenic salvage began to be extended to the management of splenic trauma in adults.[14]

General Principles

If operative management (either splenectomy or splenorrhaphy) has been deemed appropriate, certain standard principles of trauma care are followed. These include the establishment of reliable large-bore intravenous access, aggressive volume resuscitation, preparation of type and cross-matched packed red blood cells for anticipated intraoperative transfusion, nasogastric decompression, and preoperative intravenous antibiotic administration. It is our standard practice to utilize a vertical midline incision for all trauma celiotomies because this affords the quickest access to the peritoneal cavity and allows for thorough examination of the entire abdomen to evaluate for the possibility of concomitant injuries. For improved visualization of the left upper quadrant, the midline incision can be extended cephalad, to the left of the xyphoid process, and the left triangular ligament of the liver may be incised to allow reflection of the liver away from the area of interest. We have found it uniformly helpful to resist the temptation to perform an oblique left upper quadrant incision when an isolated splenic injury is suspected; this approach is invariably more time consuming than a midline approach, and one is spared the occasional embarrassment of attempting to evaluate or repair an unsuspected concomitant injury elsewhere in the abdomen through an awkward point of access.

On entering the peritoneal cavity, a standard initial trauma survey should be performed in all patients, no matter how high the index of suspicion may be that one is dealing with an isolated splenic injury. All four quadrants should be packed and systematically inspected for hematoma, active bleeding, or biliary or intestinal contents. Preoperative imaging studies may have indicated the presence of isolated splenic trauma, warranting a focusing of attention on the left upper quadrant; however, in the event that multiple intra-abdominal injuries are identified, common sense dictates that the most serious and immediately life-threatening injuries be treated first. If other injuries take precedence over the splenic injury, in almost all cases the left upper quadrant

and splenic bed can be packed with laparotomy tapes so that hemorrhage can be sufficiently controlled until such time that definitive treatment of the splenic injury is undertaken.

In all but the most inconsequential instances of splenic trauma, mobilization of the spleen from its deep and protected location in the left upper quadrant is mandatory to be able to assess fully the location and severity of the splenic injuries. The most helpful initial step in this is the liberal placement of laparotomy tapes posterior to the spleen, greatly facilitating its elevation into the operative field where it can then be carefully inspected and palpated to characterize the nature of the lesion(s). Following this preliminary maneuver, the spleen's ligamentous attachments to the diaphragm, kidney, and colon should be sharply incised. These connections are avascular and can be divided with impunity, except in patients with portal hypertension, in whom enlarged collateral veins may become prominent. Doing so will allow the spleen to be rotated to the midline and further elevated, thus enabling complete access to its anterior and posterior surfaces as well as to the hilum. Once accomplished, the operator can easily achieve virtually complete hemostasis of any splenic injury: either by direct manual compression of the splenic parenchyma at the site of bleeding or by direct control of the splenic artery and vein at the hilum. At this point, with the spleen fully mobilized, a judgment is then formulated as to whether splenectomy is required or splenorrhaphy should be attempted. In grade I or II splenic injuries, small surface lacerations can often be successfully treated with some combination of manual compression, the topical application of hemostatic agents (e.g., Surgicel, Gelfoam, Avitene, or fibrin glue), or argon beam coagulation.

Splenectomy

Once the spleen has been fully mobilized as described, if splenectomy is to be performed the short gastric vessels are next individually ligated and divided well away from the surface of the greater curvature of the stomach. This reduces the risk of gastric necrosis, which can occur if insufficient care is taken and a portion of the gastric wall is inadvertently incorporated into the ligatures. It is also at this point—as the short gastrics are divided and the splenic hilum is skeletonized—that particular attention must be directed to avoiding injury to the tail of the pancreas, which is closely applied to the splenic hilum. Inattentiveness here can result in the development of a pancreatic fistula with its attendant morbidity. With the short gastrics completely divided, the splenic artery is then doubly ligated and divided within the splenic hilum, followed by ligation and division of the splenic vein, which completes the splenectomy. Following removal of the spleen, the splenic bed is carefully inspected for hemostasis. If systemic coagulopathy has developed as the result of hemorrhagic shock, consumption of coagulation factors, or hypothermia, the left upper quadrant can be tightly packed with laparotomy tapes while fresh frozen plasma and platelets are administered and efforts are directed at rewarming the patient. Packs are then carefully removed, individual bleeding sites are electrocauterized, and the left upper quadrant is irrigated copiously. These steps are essential to minimize the chances of postoperative splenic bed hematoma, which in turn predisposes to the risk of subphrenic abscess. Although the data are inconclusive regarding the use of drains, we do not routinely drain the splenic bed following splenectomy or splenorrhaphy, preferring instead to emphasize meticulous hemostasis as the best path to avoiding splenic bed complications.

Splenorrhaphy

The term *splenorrhaphy* actually represents a variety of "spleen-sparing" techniques aimed at controlling the hemorrhage from a splenic injury while sparing the patient the long-term immunologic consequences of splenectomy. More often than not, some combination of these techniques is used to achieve this goal. The intraoperative decision to attempt splenorrhaphy should be made only after the spleen has been fully mobilized in the process of assessing the injuries.[15,16] As a general rule, splenorrhaphy is most appropriately considered in cases of less severe splenic injury (e.g., grades I and II, and occasionally grade III). Splenorrhaphy should not be attempted to repair extensive or complex shatter or crush-type injuries of the spleen, nor is it well-advised to undertake splenorrhaphy in the face of multiple concomitant traumatic injuries or associated hypotension. With the spleen fully mobilized and controlled with the surgeon's hand, splenorrhaphy may consist of nothing more than manual compression of the splenic parenchyma between thumb and finger to achieve hemostasis of simple lacerations. If this is insufficient to control bleeding, a variety of topical hemostatic agents may be applied directly to the bleeding surface, as already mentioned. The placement of a simple monofilament suture through the splenic parenchyma (often in a mattress technique and incorporating a piece of Gelfoam or an omental patch placed at the site of bleeding) will often bring about satisfactory hemostasis. Alternatively, wrapping the entire spleen with either absorbable or nonabsorbable mesh has been described as a means of effecting external tamponade and controlling bleeding and has not been associated with significantly increased risk of infectious complications.[15] In their review of a 9-year experience with splenorrhaphy at one trauma center, Feliciano et al.[17] found that, in 92% of cases, splenorrhaphy was accomplished without the need for mesh wrapping or partial splenectomy. The incidence of rebleeding in this series was 1.3% and was due to bleeding from other, initially overlooked, splenic injuries in two patients and rebleeding at the site of prior splenorrhaphy in only one patient.

Finally, and perhaps most important, as nonoperative management of splenic injuries has assumed a greater role in the management of splenic trauma (in large part owing to the increased availability of high-resolution CT scanning), the role of splenorrhaphy has correspondingly waned. As one would expect, as the less severe

splenic injuries (i.e., those most likely, if operated on, to be suitable for splenorrhaphy) are increasingly managed nonoperatively, it is only the most complex and severe injuries (i.e., likeliest to require splenectomy) that are managed surgically.

Laparoscopic Splenectomy

With the introduction and refinement of new technologies such as the harmonic scalpel and endoscopic staplers, laparoscopic splenectomy has become the preferred technique for the elective treatment of splenic disorders in many centers. In addition, laparoscopic performance of all of the aforementioned methods of splenic salvage (e.g., splenorrhaphy, partial splenectomy, hemostatic agent application) has been described in the trauma setting, although this consists mostly of scattered case reports,[18,19] and no one center has reported extensive experience with laparoscopy for splenic trauma. As with all types of laparoscopic surgery, there is a considerable learning curve with laparoscopic splenectomy, and in other than experienced hands, the increased time taken can have deleterious consequences in actively hemorrhaging or hemodynamically unstable patients. This, combined with the increasing role of nonoperative management and angiographic embolization techniques, makes it unlikely that laparoscopic splenic surgery will become the standard of care in the trauma setting.

Autotransplantation

Autotransplantation of splenic tissue has been described as a means of preserving some remnant of the spleen's reticuloendothelial function in cases of severe splenic trauma when splenorrhaphy is not possible and formal splenectomy would be the only surgical option. The efficacy of autotransplantation in maintaining immunologic competence has never been validated, and multiple cases of OPSS have been reported after autotransplanation.[20] Consequently, this technique remains controversial and is not to be endorsed for routine use.

OPSS, first described by Diamond in 1969,[21] is an infrequent but potentially catastrophic complication of splenectomy, resulting from an increased susceptibility to infection by encapsulated microorganisms. Although the precise incidence of OPSS remains ill defined, one retrospective review of 5902 postsplenectomy patients studied between 1952 and 1987 documented an incidence of OPSS of 4.4% in children younger than 16 years of age and 0.9% in adults.[22] Schwartz and coworkers,[23] using actuarial methods, estimated the risk of developing fulminant sepsis following splenectomy to be just 1 case per 500 person-years of observation; however, the cumulative incidence of infections severe enough to require hospitalization was 33% by the end of a 10-year follow-up period. Early reports of established cases of OPSS indicated mortality rates ranging from 50% to 70%, despite the use of intravenous antibiotics and intensive therapeutic intervention. With advances in antibiotic therapy and critical care, more recent evidence suggests that when informed patients seek medical attention promptly, the mortality rate of OPSS can be expected to be approximately 10%, with more than half of all fatalities occurring within 48 hours of presentation.[1,24]

Although no vaccination protocol has ever been proven effective in reducing the incidence of OPSS, it is nevertheless a widely accepted practice to immunize patients with pneumococcal vaccine shortly after undergoing splenectomy prior to discharge from the hospital.[25] The efficacy and clinical importance of meningococcal and *Haemophilus influenzae* type b vaccination in splenectomized individuals is unknown and can be considered in patients who may be more prone to infection with these organisms.[24] Irrespective of the vaccination schedule used, lifelong vigilance against serious infection is mandatory in all patients following splenectomy. Finally, the routine use of prophylactic antibiotics is not necessary after splenectomy in adults.[26]

NONOPERATIVE MANAGEMENT

Over the past several years an increasing number of patients with blunt splenic trauma have been successfully managed nonoperatively. The success of nonoperative management strategies has largely correlated with the increased availability of high-resolution CT scanning and advances in selective arterial catheterization and embolization techniques. In properly selected, hemodynamically stable patients with blunt splenic trauma, nonoperative management consists of bed rest, serial abdominal examinations, and hemoglobin and hematocrit determinations—all best carried out in a monitored setting. Clinical indices associated with failure of nonoperative management include higher grade of splenic injury, increased transfusion requirement, and hypotension at presentation. Patient age (>55 years) has been shown by some to augur poorly for nonoperative management[27,28]; however, the experience of others has failed to validate this.[29-32] The presence of associated intra-abdominal injuries or altered level of consciousness are significant obstacles to successful nonoperative management and should be considered relative contraindications. When proper selection criteria were used, the multi-institutional study of the Eastern Association for the Surgery of Trauma[33] demonstrated that a nonoperative management strategy could be employed in 61.5% of patients with blunt splenic trauma, with a success rate of 89%. Of the 11% of patients who failed nonoperative management in this study, 61% of these failed within the first 24 hours of observation. Similar findings have been reported by others.[34,35]

As vascular interventional techniques have evolved and become more prevalent in recent years, the selective use of splenic embolization as an adjunct to nonoperative management has resulted in improved success rates, with reduced need for delayed operative intervention.[36-38] In a multicenter review of four level I trauma centers,[39] a splenic salvage rate of 87% was achieved in patients undergoing adjunctive splenic embolization

during nonoperative management of splenic trauma, including an 80% success rate among patients with grades IV and V splenic injuries. With these techniques now more readily available and more widely used, even patients with CT findings of active extravasation—previously considered an absolute indication for immediate operative intervention—can often be managed nonoperatively if embolization can be successfully performed.[40,41] Unfortunately, CT or angiographic demonstration of traumatic splenic arteriovenous fistulization continues to be predictive of a high failure rate (40%) of nonoperative management.[35]

Most patients who fail nonoperative management require intervention (splenectomy, splenorrhaphy, or embolization) within 48 to 72 hours, whereas a minority (5% to 6%) develop complications more than 4 days following injury.[31,42] Such complications include delayed hemorrhage requiring operation or embolization, splenic artery pseudoaneurysm formation, and the development of splenic pseudocyst or abscess.

Delayed Splenic Rupture

Delayed splenic rupture, the sudden unheralded rupture more than 48 hours after initial trauma of a demonstrably normal spleen in a hitherto asymptomatic, hemodynamically stable patient, is an infrequent but potentially catastrophic complication of splenic injury. This phenomenon, separate and distinct from late splenic rupture after failed nonoperative management of documented splenic injury or unsuccessful splenorrhaphy, probably represents the late, sudden expansion of an occult subcapsular hematoma not detectable on the initial CT scan.[43] Minor, self-limited subcapsular bleeding that attains initial hemostasis and goes undetected on initial radiographic evaluation is thought to increase suddenly when endogenous thrombolysis is reactivated several days after injury. Increased subcapsular tension may be further aggravated by oncotic forces in the subcapsular space, leading to rupture and massive hemorrhage. Because of difficulties distinguishing this entity from either the missed or delayed diagnosis of a discernable splenic injury, the true incidence of delayed splenic rupture is not known.[44]

Management of Splenic Injury in Children

Paul M. Colombani · F. Dylan Stewart

An injured spleen in a child is a well-known entity to those involved in pediatric trauma care. The majority of children with a splenic injury now receive nonoperative intervention and therapy. This shift from operative to nonoperative treatment over the past several decades is a tremendous success story in which clinical judgment and reason triumphed over standard surgical dogma. Furthermore, this success has prompted surgeons to adopt similar management strategies for other pediatric solid organ injuries, as well as changes in the management of adult trauma patients. Recent work with clinical outcomes data in pediatric splenic trauma has given rise to model clinical practice guidelines. These guidelines serve to standardize and justify management decisions based on the best possible data and accepted clinical parameters. This chapter briefly discusses the history of this remarkable management shift, the immunologic imperative for splenic preservation, and the algorithm for evaluation and treatment of a child with suspected splenic injury.

THE SPLEEN IN HISTORY

Throughout much of the history of medicine, the value of the spleen has been trivialized, thereby contributing to the doctrine that the organ was expendable. That dictum was questioned near the turn of the 20th century by Nicholas Senn, who suggested that the spleen might have an as yet unrecognized function.[1] The first suggestion that the spleen might have important immune function came from Morris and Bullock in 1919.[2] They demonstrated, in well-designed animal experiments, that splenectomized rats were immunocompromised and went as far as to suggest that routine splenectomy might be unwarranted. Surgical opinion, however, did not significantly change until the first report of overwhelming post-splenectomy sepsis by King and Shumaker in 1952.[3] They reported two deaths in five infants in whom a septic syndrome developed after splenectomy for spherocytosis and gave the first description of overwhelming post-splenectomy sepsis. This syndrome was characterized by the subtle manifestation of fever, with rapid decompensation into septic shock, consumptive coagulopathy, and possibly death. First pneumococcus and then later other encapsulated organisms such as meningococcus, *Haemophilus influenzae*, and *Pseudomonas* species were implicated as the pathologic agents. Further experimental studies validated the increased susceptibility of splenectomized animals to pneumococcus.[4] Singer published a large series in 1973 in which it was found that the risk for sepsis in post-splenectomy patients was between 50 and 500 times greater than in the general pediatric population. Furthermore, these patients had a mortality rate of greater than 50% when these infections occurred.[5]

Even before the recognition and awareness of overwhelming post-splenectomy sepsis, sporadic reports of nonoperative management of an injured spleen could be found in the surgical literature.[1] However, none commanded attention until the 1968 publication by Upadhyaya and Simpson of successful nonoperative treatment of selected patients with splenic injury.[6] Remarkably, this very influential report involved only 12 children treated nonoperatively. The authors reviewed case records of 52 children with suspected splenic injury between 1954 and 1965 at Toronto Children's Hospital. Thirty patients had isolated splenic injuries and were treated by splenectomy. Ten children with splenic rupture were operated on and died, but as a result of associated injuries and not necessarily splenic hemorrhage. Twelve children with suspected splenic injuries were never taken to laparotomy and recovered without incident. The authors concluded that isolated splenic injury in children was well tolerated and made the first convincing plea for conservative management. In the

subsequent 10 years, numerous authors reported on successful nonoperative management of pediatric splenic injury, thus validating the early successes reported by Upadhyaya and Simpson. By the early 1980s, conservative management had become the universally accepted practice.[7]

IMMUNE FUNCTION AND CONSEQUENCES OF SPLENECTOMY

The spleen is an effective immune filter against a number of circulating antigens and blood-borne particles. Absence of the spleen results in profound immunologic changes. Defects in both cell-mediated and humoral immune function are present, as well as nonspecific immune defects.[8]

Cellular-mediated immune defects relate mainly to changes in peripheral T-lymphocyte populations and the ability of the host to effectively respond to circulating antigens. Antigens enter a normal spleen and are processed by macrophages of the red pulp.[9] Macrophages and dendritic cells then act as antigen-presenting cells in the periarteriolar lymphoid sheaths, where T cells are activated. These T cells then migrate to the marginal zones, where they may interact with B cells and influence specific antibody responses. Asplenia reduces these T-cell populations, with a resultant decrease in cell-mediated antigen response.

The humoral changes in asplenia involve altered levels of immunoglobulins, particularly significantly decreased IgM levels. The spleen provides the main anatomic site for lymphocyte sequestration during an immune response, and germinal centers in the spleen are the source of memory B cells. Asplenia is thought to attenuate this response.[8]

Nonspecific immune changes relate primarily to the important role that splenic macrophages play in the clearance of blood-borne bacteria and the prominent role that the spleen plays in overall phagocytic capability. Several groups have shown a significant reduction in monocyte-mediated phagocytosis and bacterial killing after splenectomy.[9] Decreases in cytokine production, specifically interleukin-12 (IL-12), may also contribute to susceptibility to pneumococcal infections because of lack of IL-12–mediated helper T-cell activation.[9]

Other studies have shown decreased phagocytic ability of alveolar macrophages in splenectomized animals, thus suggesting a role of the spleen in either alveolar macrophage maturation or activation.[8]

The timing of splenectomy may also be an important determinant in the risk for compromised immune function and overwhelming post-splenectomy sepsis. It has been observed that a younger patient may have a shorter interval before life-threatening infection, as well as a higher incidence of infectious complications in general.[10]

Much work remains before the exact relationship between asplenia and overwhelming sepsis is completely understood. However, the value of an aggressive approach to splenic preservation and salvage can no longer be understated.

EVALUATION OF A CHILD WITH ABDOMINAL TRAUMA

Trauma continues to be the leading cause of morbidity and mortality in the 1- to 18-year-old population in the United States.[11] Blunt trauma accounts for 90% of the injuries in children, with motor vehicle accidents and falls being the most common mechanisms. Head and extremity trauma is by far the most common pattern of injury; however, approximately 8% of children suffering blunt trauma will sustain an abdominal injury.[7] Several factors regarding body habitus make an injured child more likely to sustain intra-abdominal injury, including proportionally larger abdominal organs with respect to adult patients, an incompletely ossified rib cage that sits relatively higher and offers less protection to the intra-abdominal organs, and relatively less musculature and fat to absorb impact forces. The spleen is the most commonly injured solid organ in blunt abdominal trauma in children, followed closely in frequency by the liver and kidney.

The initial evaluation of a child with suspected blunt abdominal trauma follows the well-established advanced trauma life support protocols promulgated by the American College of Surgeons. Airway security plus confirmation of adequate ventilation is always a top priority. After a secure airway is established, the quality of circulation can be assessed. All children with suspected blunt abdominal trauma should have large-bore intravenous access established, preferably in one or both upper extremities. Femoral venous catheters are acceptable when peripheral access cannot be obtained, and intraosseous lines are also acceptable for both fluid resuscitation and administration of medications. Initial boluses of warmed lactated Ringer's solution should be used, typically given at 20 ml/kg. This bolus may be repeated if the child remains hemodynamically unstable, and the child should be prepared for possible blood transfusion, which should be strongly considered if a second 20 ml/kg bolus is not effective.

The secondary survey is begun after the ABCs (airway, breathing, circulation) and the primary survey are complete. Children in whom a strong suspicion of intra-abdominal injury exists should have both bladder and gastric catheters placed early in the resuscitation. The importance of decompressing the stomach, especially in a child who may have received positive-pressure breaths, cannot be overstated because the hemodynamic changes may simply be a result of massive gastric distention and not intra-abdominal hemorrhage. A careful secondary survey is performed to look for outward abdominal signs of internal injury, including contusions and seat belt signs, abdominal distention, and tenderness.

A child with abdominal distention, no response to fluid resuscitation efforts, and continued hemodynamic instability at the completion of the secondary survey should undergo prompt exploration in the operating room. Unfortunately, little further diagnostic work-up can be tolerated, and exploration to stop presumed intra-abdominal hemorrhage may be lifesaving. Of critical importance in this group of patients is early neurosurgical consultation, especially if a depressed Glasgow Coma

Scale score is present or if other signs of neurotrauma are found on the initial evaluation, because computed tomography (CT) scanning of the head is not indicated in an unstable patient.

Fortunately, most children with blunt abdominal trauma will stabilize after fluid resuscitation, and the diagnostic work-up can proceed safely. A lateral cervical spine film, chest radiograph, and pelvic radiograph should be obtained in all trauma patients. These films are unlikely to identify intra-abdominal injury, although left-sided rib fractures may be associated with significant transfer of force to the spleen.

Since the mid-1980s, CT scanning has been the standard of care in evaluating abdominal trauma.[12] Modern CT scanners can detect splenic injury with high specificity and sensitivity. The use of oral contrast agents is controversial, especially in the setting of trauma, where adequate time for small bowel opacification with contrast is not available. Several studies have suggested that detection of small bowel injuries, which may be associated with splenic trauma, is unaffected by the use of oral contrast agents.[13] There are also legitimate concerns regarding aspiration of orally administered contrast. It is our practice to perform the initial abdominal CT scan without oral contrast. If concern for small bowel or other missed injury persists during the patient's evaluation period, further scans with carefully administered contrast are performed.

Intravenous contrast, however, is an important element of quality CT scanning and should be used unless specifically contraindicated (Fig. 129–1). The significance of the "blush sign," or evidence of extravasation of contrast, is controversial in splenic trauma (Fig. 129–2). Cox et al. reviewed a series of patients and suggested that the blush sign might signify the need for early laparotomy.[14] Lutz and colleagues agreed that vascular blush did correlate with a higher degree of injury, but not the need for operative intervention.[15] It seems reasonable that management decisions should be dictated primarily by physiologic parameters, with CT findings serving only as a diagnostic adjunct.

A grading system has been established to further delineate the severity of splenic injury.[16] Grading is from I through V and summarized in Table 129–1. Figure 129–3 depicts five CT scans demonstrating the grades of splenic injury.

Focused abdominal sonography for trauma (FAST) is a relatively new imaging modality that has gained widespread use in adult trauma patients. FAST is sensitive for the detection of free intraperitoneal fluid; however, pediatric trauma patients may sustain significant splenic injury and have no free intra-abdominal fluid.[17] In addition, the presence of intraperitoneal fluid does not mandate operative exploration in the blunt abdominal pediatric population, thus further limiting the usefulness of FAST. It is likely that FAST will become a useful adjunct in blunt abdominal pediatric trauma but will not supplant the usefulness of CT scanning.

Diagnostic peritoneal lavage (DPL) is a time-honored technique that involves invasive evaluation of the peritoneal cavity for blood, bacteria, or particulate matter. It is a relatively simple and fast technique, although its applications are dwindling and surgical trainees are unlikely to be facile with the procedure. A simple positive DPL for hemoperitoneum is unlikely to change clinical management because many children with solid organ injury and hemoperitoneum are managed nonoperatively. DPL's usefulness lies mainly in patients with severe neurotrauma who require immediate neurosurgical intervention before radiographic evaluation of the abdomen can be performed. Given the speed of modern CT scanning, even that population of patients is decreasing because the additional time added by performing abdominal CT scanning in a child already undergoing head CT is minimal. DPL may be indicated for multiply injured patients undergoing surgery on an emergency

Figure 129–1. Abdominal computed tomography scan with intravenous contrast demonstrating a fracture in the upper pole of the spleen.

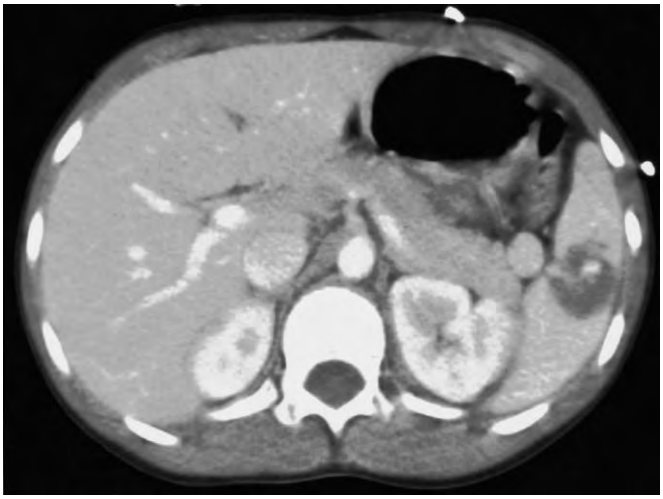

Figure 129–2. Abdominal computed tomography scan with intravenous contrast demonstrating a midsplenic laceration with extravasation of contrast (blush) into a hematoma.

Table 129–1 A Grading System Established to Further Delineate the Severity of Splenic Injury

Grade		Injury Characteristic
I	Hematoma	Subcapsular, nonexpanding, <10% of surface area
	Laceration	Capsular tear, nonbleeding, <1 cm of parenchymal depth
II	Hematoma	Subcapsular, nonexpanding, 10%-50% of surface area; intraparenchymal, nonexpanding, <2 cm in diameter
	Laceration	Capsular tear, active bleeding, 1-3 cm of parenchymal depth, no involvement of trabecular vessels
III	Hematoma	Subcapsular, >50% of surface area or expanding, ruptured subcapsular hematoma with active bleeding; intraparenchymal hematoma, >2 cm or expanding
	Laceration	>3 cm of parenchymal depth or involving trabecular vessels
IV	Hematoma	Ruptured intraparenchymal hematoma with active bleeding
	Laceration	Involves a segmental or hilar vessel and produces major devascularization (>25% of spleen)
V	Hematoma	Completely shattered spleen
	Laceration	Hilar vascular injury that devascularizes the spleen

Adapted from Moore EE, Cogbill TH, Jurkovich GJ, et al: Organ injury scaling: Spleen and liver (1994 revision). J Trauma 38:323-324, 1995.

basis for head or extremity trauma who become unstable in the operating room. DPL could then be used to assess the need for formal laparotomy in a minimally invasive manner.

Radiographic embolization of injured spleens has become commonplace in adult trauma populations. It should be noted, however, that many series report nearly a 10% greater failure rate of nonoperative management of splenic injuries in adults, thus providing a much larger patient population that might benefit from radiographic hemorrhage control. This outcome difference may be related to anatomic differences in the pediatric spleen, such as more efficiently contractile splenic arterioles and a thicker splenic capsule.[18] It seems likely that the already high success rate of nonoperative management of injured spleens in children will not be greatly influenced by the addition of arterial embolization and all its attendant risks. Figure 129–4 depicts the angiographic management of splenic injury in a pediatric patient.

Splenic injuries seen on CT are graded as described earlier. Although the clinical usefulness of splenic injury grade is often not evident, the system is helpful for collecting meaningful data and comparing similar patient injuries, as well as comparing practice guidelines. This usefulness was clearly demonstrated in a report by Stylianos and the American Pediatric Surgery Association (APSA) Trauma Committee in 2000.[19] Case records of 856 children with splenic and liver injury at 32 pediatric trauma centers were reviewed, with the severity of injury classified by standard CT scan. The purpose of the study was to evaluate current clinical practice and develop evidence-based guidelines to best use resources without compromising patient safety or outcomes. The resultant guidelines are presented in Table 129–2. The author concluded that these evidence-based guidelines would need to stand up to prospective validation, and such evaluation was performed in 312 children at 16 pediatric trauma centers between 1998 and 2000.[19] The study concluded that compliance with the proposed guidelines had been high; improved utilization of resources was achieved by decreasing intensive care unit stay, hospital stay, and follow-up imaging; and patient safety had not been compromised.[20-22]

In accordance with the guidelines presented in Table 129–2, most children with splenic trauma have a relatively benign hospital course. Our routine is to maintain NPO status for three consecutive hematocrit determinations over a period of 24 hours. If the blood count remains stable, diet is resumed, bed rest restrictions are implemented for the prescribed period, daily hematocrit determinations are obtained, and discharge is planned at the selected interval based on the grade of injury. We do not obtain follow-up imaging. Resumption of physical activity also follows the APSA guidelines; however, resumption of full-contact sports is usually allowed on a case-by-case basis at the discretion of the attending surgeon.

OPERATIVE MANAGEMENT

It is rare that a pediatric patient with an isolated splenic injury will fail nonoperative management—80% to 90% of children with splenic trauma are stable or respond to the initial fluid bolus.[17] Patients with splenic trauma, however, may also have other serious injuries that require laparotomy, so strategies for control of splenic bleeding and splenic preservation are crucial.

A patient with hemodynamic instability and a distended abdomen (after gastric decompression) should be taken immediately to the operating room. DPL may be useful in an unstable patient without obvious signs of abdominal trauma who has other causes for the hemodynamic changes that do not warrant laparotomy, such as pelvic fracture and bleeding. Large-bore intravenous access and type- and cross-matched blood should be available. Typically, a midline incision is used, with immediate four-quadrant packing after entry into the peritoneum. If the patient is in shock or has other severe injuries and the spleen is found to be the primary source

of the blood loss, it should be removed. The spleen should initially be assessed in situ, with splenic mobilization performed only if visible or palpable parenchymal tears are noted. Splenic mobilization begins with incision of the lateral-most attachments, the lienorenal ligaments. This allows rotation of the spleen medially into the wound, where it can be thoroughly inspected.

Hemorrhage from grade II and III splenic injuries can usually be controlled by direct suture splenorrhaphy with moderately sized absorbable suture. Omentum may also serve as a buttress when securing these sutures, as well as any number of topical hemostatic agents.[23]

Multiple or deeper injuries may be amenable to wrapping the spleen in absorbable mesh, as described by Delaney et al.[24] This mesh creates pressure to tamponade parenchymal bleeding while preserving function. Deeper parenchymal disruption can be treated by anatomic resection and closure of the cut splenic edges with mattress sutures or omental buttressing.

Splenic autotransplantation has been suggested as an alternative for preservation of functional splenic tissue, but no consensus exists with regard to the amount of immunocompetence retained by ectopic splenic fragments. Some surgeons continue to advocate routine reimplantation after splenectomy in adults, and a recent report from Dessouky suggests that some aspects of splenic function are preserved in pediatric patients undergoing splenectomy for thalassemia.[25] No class I evidence exists at this time to guide this practice.

ASPLENIA PROPHYLAXIS

Children with post-traumatic or functional asplenia need antibiotic prophylaxis. All these patients are at increased risk for infection, primarily with the encapsulated organisms *Streptococcus pneumoniae*, *H. influenzae*, and *Neisseria meningitidis*. Life-threatening infections occur with a frequency of approximately 0.3% per year, with a 5% lifetime risk. Fifty percent of all life-threatening infections occur within the first 2 years after splenectomy. Exacting guidelines for immunization and antibiotic prophylaxis do not exist, but an excellent review by Castagnola and Fioredda in 2003 summarized the most current recommendations.[10] Prevention of life-threatening infection in post-splenectomy patients involves vaccination, antibiotics, and education.

Vaccination Vaccination against *S. pneumoniae* is highly recommended in all post-splenectomy patients. Two versions of vaccine exist—the polysaccharide vaccine, which includes 23 serotypes (PPV23), and the tetanus-conjugate heptavalent vaccine (PCV7). The heptavalent vaccine should be given to all children between the ages of 2 and 23 months, with asplenic and other high-risk groups receiving two additional doses after the age of 2 years. Additionally, the polysaccharide vaccine should be given 2 to 3 months after the final dose of PCV7, with consideration of boosters every 6 years. Some authors have advocated determination of antipneumococcal titers to document vaccine response and to identify poor responders, but this practice has not gained widespread acceptance.[10]

Vaccination against *H. influenzae* is thought to be safe and is recommended for all post-splenectomy patients. A course of three separate vaccines is given to infants, but a single dose should be effective for children older than 1 year.[10]

There are relatively few data regarding the response of splenectomized patients to the meningococcal vaccine. However, it has been shown to have an effective safety and immunogenic profile in adults, and many centers, including our own, routinely offer the meningococcal vaccine to asplenic patients.

Antibiotics All asplenic patients should be given daily oral antibiotic prophylaxis. Penicillin V, 125 mg twice daily for children younger than 3 years and 250 mg twice daily for those 3 to 14 years old, is the recommended dosage. The age at which prophylaxis is discontinued is controversial; however, most authors agree that all asplenic children younger than 5 years should receive prophylaxis and all children, regardless of age, should receive antibiotics for at least 2 years after splenectomy, when the risk for invasive infection is the highest.[10]

Education Patient and parental education is probably the most important aspect in preventing serious infection. Without creating paranoia, the surgeon needs to emphasize to parents that any fever in their asplenic

child constitutes a potential life-threatening emergency and medical care should be sought as soon as possible. Dosages of oral antibiotics should be readily available in the home and given to the child en route to seeking formal medical attention. Parents need to be counseled that their child's asplenic state is of utmost importance when presenting the medical history to the primary physician. Early and aggressive parenteral therapy targeted against encapsulated organisms should be standard when concerns of infection exist in this group of patients.

CONCLUSION

Splenic injury is relatively common in pediatric trauma. Isolated splenic trauma is extremely well tolerated; however, the presence of a splenic injury should alert surgeons to the possibility of other associated injuries. The expectation for these patients should be for successful nonoperative management under the watchful eye of the surgical team.

Cysts and Tumors of the Spleen

Michael R. Burgdorf • Douglas P. Slakey

Cysts and tumors of the spleen are rare lesions. Cysts are classified as either "true" cysts containing an epithelial lining or "false" cysts without an epithelial lining (pseudocysts).[1] True cysts are either parasitic or nonparasitic, whereas false cysts mainly arise as a result of blunt abdominal trauma.[2,3] Tumors of the spleen are divided into two categories: nonlymphoid and lymphoid. The most common nonlymphoid tumors are the vascular tumors consisting of benign and malignant hemangiomas, lymphangiomas, and hemangioendotheliomas. Lymphoid tumors are mainly of the Hodgkin and non-Hodgkin variety. Metastasis from melanoma, breast, and lung tumors make up the majority of secondary tumors found in the spleen.[4] Treatment options of cysts and tumors of the spleen have evolved greatly over the past few decades. Recognition of the immunologic function of the spleen and the occurrence of overwhelming postsplenectomy infection (OPSI) has changed the preferred procedure from splenectomy to splenic preservation whenever feasible. Cysts and tumors of the spleen in children pose different challenges for the surgeon, and management is discussed in this chapter.

Splenic surgery has a long and storied tradition. Galen believed that the spleen was an "organ of mystery." Aristotle viewed it as unnecessary, and Pliny the Elder (23-79 AD) among others thought it was where laughter was based. From William Shakespeare's *Twelfth Night,* Act 3, 2, 62-63 is the quote, "If you desire the spleen will laugh yourself into stitches, follow me." Adrian Zacarelli performed the first splenectomy in 1549 for splenomegaly on a 24-year-old Neapolitan woman. Franciscus Rosetti reported the first successful partial splenectomy for trauma in 1590. A total splenectomy for trauma was recorded by Nicolaus Matthias in 1678 in Capetown, South Africa, in a patient whose spleen protruded through a flank wound. In the United States, it was not until 1816 that Royal Navy surgeon O'Brien reported his first successful splenectomy for trauma. His patient was in the act of committing a rape when the female stabbed him on the left side. The protruding portion of the spleen was ligated and the man was discharged 20 days later, having been cured.[5] In England, 1866 marked the first successful splenectomy by Sir Thomas Spencer Wells. After discovering the condition at autopsy in 1829, Andral is credited with the first record of any nonparasitic splenic cyst.[7] Pean described the first splenectomy for a splenic cyst in 1867[2] and Grede, in 1881, performed the first splenectomy for a splenic pseudocyst that occurred after abdominal trauma.[7] In 1952, King and Shumacker described an increased rate of infection in children who had undergone splenectomy and efforts began to treat splenic cysts and tumors without resorting to total splenectomy.[8] Morgenstern and Shapiro are credited with the first successful open partial splenectomy for an epidermoid cyst in 1980.[9] With the advent of laparoscopic surgery in the 1990s, options for splenic preservation surgery increased. Seshadri et al. reported the successful performance of laparoscopic partial splenectomy.[10] Today, reported laparoscopic methods include both traditional and hand-assisted methods for marsupialization of splenic cysts and removal of splenic tumors.

CYSTS

Before one determines the most appropriate treatment, the type of splenic lesion must be determined. Fowler is credited with the first classification system for splenic cysts.[11] Martin revised this to a simpler more practical classification, which is used more commonly today.

Primary (true) splenic cysts are also known as congenital, epidermoid, or epithelial cysts. These true cysts can be divided into parasitic and nonparasitic. Parasitic cysts are more common worldwide, especially in areas endemic for *Echinococcus* such as south central Europe, South America, and Australia, but are extremely rare in

the United States. Two thirds or more of the splenic cysts are caused by echinococci, with *Echinococcus granulosus* as the most common species.[6] The echinococcal cyst is composed of an inner germinal layer and an outer laminated layer surrounded by a fibrous capsule, characteristically multilocular in appearance, and filled with fluid under pressure. It contains daughter cysts and infective scolices. Echinococcal cysts may be asymptomatic or may cause pressure symptoms when they reach a large enough size, become secondarily infected, or rupture. Diagnosis may be established by indirect hemagglutination or enzyme-linked immunosorbent assay tests, which are positive in about 90% of patients with echinococcal cysts. Ultrasound and computed tomography (CT) characteristically demonstrate a cystic mass that is septated and contains daughter cysts. Splenectomy is the treatment of choice. Care must be taken to avoid puncture of the cyst and spillage of the infective scolices, which can cause an anaphylactic reaction and hypotension. Sterilization of the cyst contents by instillation of 3% sodium chloride or alcohol has been attempted, but the potential for systemic absorption limits usefulness of this approach. If intraperitoneal spillage occurs, intravenous epinephrine may be needed to treat the anaphylactic hypotension.

Congenital nonparasitic cysts account for about 10% of all splenic cysts[12] and approximately 25% of nonparasitic cysts. Ough and associates in 1981 examined fetal and adult spleens and proposed that congenital splenic cysts form where there is an invagination of the mesothelium-lined splenic capsule during development.[13] This lining is pluripotential and may undergo metaplastic changes and fluid accumulation with resultant cystic expansion. The neoplastic nonparasitic cysts are less common and include epidermoid cysts, dermoid cysts, lymphangiomas, and cavernous angiomas. Of these, epidermoid cysts are the most common.[12-14]

Overall, the most common type of splenic cyst is the secondary (false) cyst. These cysts do not have a cellular lining and are, therefore, pseudocysts. Excluding parasitic cysts, pseudocysts constitute 75% of all splenic cysts. They are most commonly post-traumatic and most likely arise from encapsulation of a splenic hematoma with subsequent absorption of blood and persistence of a false cyst wall.[12] Eighty percent of splenic pseudocysts are large, solitary, and unilocular, two thirds being of the hemorrhagic variety with one third of the serous type.[7,11] Pachter and colleagues hypothesized that an increase in nonsurgical management of blunt splenic trauma could contribute to the formation of splenic pseudocysts.[3] In fact, 80% of patients with hemorrhagic splenic pseudocysts report a history of abdominal trauma.[3,7,11]

Splenic cysts are most common in the 2nd and 3rd decade of life, although they have been noted in all age groups, including infants. An asymptomatic painless abdominal mass is the presenting feature in approximately 30% to 45% of cases. Splenic cysts may present with localized or referred pain relating to splenomegaly, abdominal distention, and mass effect. The symptoms are primarily gastrointestinal and include vague abdominal pain, early satiety, nausea, vomiting, and dysphagia. The nonspecific symptoms, such as epigastric fullness or pain, may best be related to compression of adjacent organs such as stomach, kidneys, or diaphragm. A recurrent, intermittent, dull pain that is unabated with food or antacids haunts some patients. Other symptoms include left shoulder pain, shortness of breath and pleuritic chest pain, left lower lobe pneumonia, and/or atelectasis. Reversible hypertension due to renal artery compression may be seen. Vague urinary complaints may arise due to compression and/or pressure on the left kidney and ureteropelvic junction.[14] Acute abdominal pain with or without peritoneal signs may be secondary to rupture or infection.[9] Tsakayannis et al., in their study of 19 children with congenital cysts, reported that only those with cysts larger than 8 cm had clinical symptoms, mainly an abdominal mass and/or abdominal pain.[15] Walz et al. reported a 25% risk of rupture when the cyst is greater than 5 cm.[16]

Aside from the occasional abdominal mass, the physical examination is usually normal. Routine laboratory studies are also normal. Tumor markers carcinoembryonic antigen (CEA) and CA 19-9 may be elevated and should be checked if splenic cyst is in the differential diagnosis.[16] Although these are tumor markers associated with pancreatic, ovarian, uterine, and alimentary carcinomas, they may be elevated in patients with benign cystic diseases, such as bronchogenic, pancreatic, retroperitoneal, hepatic, thymic cysts, and true epithelial cysts of the spleen. According to Madia and Trompetas and their coworkers, there is a direct relationship between these tumor marker elevations and the presence of splenic cysts. Studies have demonstrated intense immunoreactivity of the cyst's inner lining to anti–CA 19-9 antibodies.[17,18] Serum levels of these tumors markers may lag behind actual elevations within the cystic cavity. Because increased CEA and CA 19-9 levels may be from benign or malignant processes, preoperative and postoperative levels documenting change are indicated.

Diagnosis of a splenic lesion is easily obtained with noninvasive radiographic imaging. Ultrasound and CT scanning are the diagnostic tools of choice. Ultrasound can distinguish between solid and cystic lesions and accurately measure size. Sonography also may be useful in demonstrating the internal echoes of abscesses and hematomas and differentiate them from cysts. When ultrasound is unsuccessful because of obesity, distortion of the signal from overlying bowel gas or the lower ribs, and/or the presence of small and multiple lesions, CT scan may be a better option. CT scanning can better delineate the trabeculated or septated nature of the cyst wall and wall calcification and has greater specificity in defining whether a lesion is cystic or solid. CT has the advantage of being able to examine the rest of the peritoneal cavity for mass effect, compression, extrasplenic involvement, or other abnormalities.[1,19-21]

Splenic cysts have historically been treated by splenectomy. However, since 1952, with the demonstration of the increased mortality of splenectomized patients due to OPSI, the trend has shifted to more conservative surgery. The incidence of OPSI is reported to be 0.2% to 4.3%, with a lifetime risk of OPSI of 5%.[2,22,23] Although the incidence is low, it still represents a 20- to 50-fold increase in the risk of dying from sepsis compared to the general population with intact spleens. OPSI may be preventable

by several interventions. The surgeon must keep in mind that preservation of at least 25% of the spleen is necessary to maintain protection against pneumococcal bacteria, the most common organism associated with OPSI.[13,15] Immunization against *Streptococcus pneumoniae* is recommended in all patients 10 days to 2 weeks prior to undergoing a splenectomy, with a booster dose in 5 to 10 years. *Hemophilus influenzae* type b and meningococcal immunizations are also available.[23]

Partial splenectomy with a TA-stapler or harmonic scalpel makes organ conservation possible.[24,25] Percutaneous aspiration or percutaneous drainage with an indwelling catheter has also been suggested as a treatment alternative to splenectomy. Pachter et al. believes that this might play a role in management of posttraumatic pseudocysts before surgical treatment is offered.[3] There are no studies to qualify this belief. In fact, one study is of three pediatric patients who were treated in this manner and all resorted to surgical intervention.[26] Laparoscopic puncture and creation of a cyst-peritoneal window has been reported as an alternative to percutaneous drainage.[27] However, one must be cognizant of the possibility of recurrence and, more important, of the presence of an echinococcal cyst with a false-negative serology. Aspiration or percutaneous drainage may also result in a dense inflammatory reaction around the spleen making subsequent surgical treatment that much more difficult, making the possibility of splenic preservation highly unlikely. We believe that attempts at percutaneous aspiration or drainage of splenic cysts should be avoided.

Another technique to avoid splenectomy is partial splenic decapsulation (marsupialization). This approach involves the trocar decompression of the cyst with removal of the outer splenic capsule. A running locking suture in the splenic wall is used to ensure hemostasis. External drainage is also performed. This method is performed with greater ease than a partial splenectomy and may be attractive in cases where previous percutaneous aspiration has been attempted and a dense inflammatory reaction resulted. However, the possibility of a malignancy developing in the splenic remnant raises doubts with this technique.[2,14]

SOLID TUMORS

Tumors of the spleen are uncommon lesions and are categorized as either nonlymphoid or lymphoid. The most common nonlymphoid tumors are the vascular tumors consisting of benign and malignant hemangiomas, lymphangiomas, and hemangioendotheliomas. Other tumors of the spleen such as hamartomas, fibrosarcomas, inflammatory pseudotumors, and lipomas are extremely rare and have been reported only briefly.[4,6,28-30]

Hemangiomas are the most common benign tumor of the spleen. These lesions are primarily asymptomatic and incidentally found at autopsy or in spleens removed for other purposes. Hemangiomas may be singular, multiple, or even involve the entire spleen. Symptoms result when the tumor enlarges to encroach on adjacent organs. Spontaneous rupture can occur in up to 25% of cases. A consumptive coagulopathy may be present due to the platelet trapping in the cavernous spaces of the lesion. Mass effect on the stomach, kidney, and splenic flexure of the colon may be seen with radiographic examination. CT scan demonstrates splenomegaly. Duplex ultrasound or magnetic resonance imaging can be used to establish the diagnosis. Angiography demonstrates a "laking" effect similar to that seen with hepatic hemangiomas. Nonsurgical treatment is employed for small, asymptomatic, incidentally detected hemangiomas, whereas splenectomy is the treatment of choice for larger and symptomatic hemangiomas.[4,6]

Lymphangiomas of the spleen are less common than hemangiomas. They are formed from congenital malformations of the lymphatic system and are composed of cystic lymphatic spaces lined with endothelium. These spaces are filled with eosinophilic proteinaceous material and may account for a significant part of the splenic weight. They may be part of a generalized lymphangiomatosis. Lymphangiomas are found incidentally and only become symptomatic due to their size. This is mainly a benign condition, although there exists one case of malignant degeneration reported from Tel Aviv, Israel, in 1983.[31] CT and angiography are helpful in the diagnosis, the latter revealing the absence of "lakes" characteristic of hemangiomas. Splenectomy is indicated for symptomatic lesions.[4,6,31]

Primary hemangiosarcoma of the spleen, although rare, is considered the most frequent primary malignancy of the spleen. This lesion is synonymous with hemangiosarcoma, angiosarcoma, and hemangioendothelial sarcoma. *Hemangiosarcoma* is the preferred term to distinguish it from lymphangiosarcoma, but *angiosarcoma* seems to be the term most widely used historically. This tumor arises from endothelial or mesenchymal cells, grows rapidly, and metastasizes to regional lymph nodes, liver, bone marrow, and lungs. Clinically, symptoms relating to splenomegaly predominate. Abdominal pain, tenderness over the spleen, general weight loss, and cachexia may be seen. Aranha et al. reported a 20% occurrence of ascites and 16% occurrence of pleural effusion associated with splenic neoplasms.[32] Angiopathic hemolytic anemia may be noted. Spontaneous rupture may be the presenting feature of this tumor. Although it has been the case for hemangiosarcomas of the liver, documentation of exposure to thorium dioxide, vinyl chloride, or arsenic is not associated with splenic cases. Angiographic findings are similar to those seen with hemangiomas. Splenectomy is indicated for hemangiosarcomas. However, prognosis remains poor in almost all cases.[4,6,31-34]

Lymphoid tumors of the spleen are mainly Hodgkin's disease and non-Hodgkin's lymphoma. As primary lesions of the spleen, these tumors are rare; however, the spleen is often the site of secondary involvement. Involvement of the spleen, either primarily or secondarily, is seen first in the white pulp. This process may be diffuse, as seen with nodular lymphoma, or localized with large irregular tumors, as seen with large cell lymphomas. In addition to the palliative attempts of splenectomy for symptomatic splenomegaly or hypersplenism, splenectomy may be performed as part of a staging laparotomy

for Hodgkin's lymphoma. There is considerable controversy regarding the usefulness of a staging laparotomy and splenectomy for Hodgkin's disease; it is beyond the scope of this chapter to explore that topic.

Metastasis from melanoma, breast, and lung tumors make up the majority of secondary tumors found in the spleen.[4] These metastases are relatively uncommon even though the spleen is the most vascular organ in the body. Lam gave the following explanations for this phenomenon: the sharp path of the splenic artery may inhibit tumor emboli from entering the spleen; the rhythmic contractions of the spleen prevent lodging of tumor emboli in the spleen; the lack of afferent lymphatics prevent transport of metastases to the spleen; and the high amount of lymphoid tissue in the spleen allows for high antitumor activity.[35] Lam reports the incidence of splenic metastasis from 0.3% to 7.3%, which seems to be dependent on the location of the primary tumor. This is also dependent on the part of the world in which the patient lives and which cancers are prevalent in that geographic location. It is extremely rare to find metastasis to the spleen in the absence of metastases to other organs. Splenic metastasis often occurs later in the disease process and is found at autopsy in a patient with disseminated disease. The latent period of metastatic lesions is variable and may occur up to 7 years after primary tumor detection. Therefore, a splenic mass seen in a patient with a history of carcinoma, even if a surgical cure had been obtained, should be treated as potentially metastatic disease until proven otherwise. Metastases to the spleen are typically asymptomatic, until they become large enough to cause mass effect symptoms. Spontaneous rupture of the spleen from metastatic tumor is exceedingly rare but may be the solitary presentation.[35]

To establish the diagnosis and to alleviate symptoms, tumors of the spleen should be removed. Surgical removal of a splenic tumor must adhere to the sound surgical principles for removal of any tumor. Good exposure, removal of the entire tumor without rupture, adequate margins, and perfect hemostasis must be achieved for a successful tumor operation. For most splenic tumors, these principles are best achieved with a splenectomy.

A left subcostal incision or midline incision can be used to expose the spleen. Although Morgenstern et al. believe the subcostal incision is the best approach, the midline incision may offer better exposure in the patient with gross splenomegaly.[4] The midline view allows for better isolation of the lower pole if it extends down into the pelvis. The first step is transection of the ligamentous attachments, including the splenophrenic ligament at the superior pole and the spenocolic and splenorenal ligaments at the inferior pole. Either blunt dissection or sharp dissection in the case of thickened ligaments accomplishes this task easily. Early double ligation of the splenic artery allows for possible reduction of the spleen size, decrease in venous outflow, and easier delivery of the spleen into the wound. Ligation of easily accessible veins including the short gastric veins, vessels to the anterior hilum, and lower pole should be accomplished before mobilization is attempted. To ensure gentle mobilization of an intact spleen and capsule, the surgeon should stand on the right side of the table while the assistant retracts the costal margin to the left. This allows for incision of the retroperitoneum parallel to the long axis of the spleen. Rarely, it may be necessary to remove a portion of the parietal peritoneum or diaphragm if the spleen is not easily separable from these areas. Once the spleen has been sufficiently mobilized to the midline and posterior hilar surface exposed, it is advisable to control the large posterior splenic veins. Attempts at control of the fragile veins from the anterior approach may result in venous disruption and massive bleeding. On removal of the spleen, attempts at sampling the hilar lymph nodes should be made. These are usually located near the major hilar vessels and may be useful in the grading of splenic tumors.[4,36]

Laparoscopic splenectomy for splenic tumors has been reported. The principles for open tumor surgery apply for laparoscopy. In the past, opponents of the laparoscopic splenectomy criticized the necessity of splenic morcellation for removal of the spleen from the peritoneal cavity. However, with a small 3-cm extension of one of the trocar sites, most spleens can be removed intact. Carroll et al. proved that the staging surgery for Hodgkin's disease could be performed entirely laparoscopically.[37] It is essential that the spleen be removed intact to avoid peritoneal dissemination of potentially malignant cells. Proponents believe that the spleen can be dissected more precisely and due to better visualization, vessels can be ligated safely and earlier in the course of the operation to prevent hematologic spread with dissection. However, Flowers et al. reported a learning curve of 20 laparoscopic splenectomies before surgeons were comfortable with the technique.[22] Therefore, laparoscopic splenectomy is feasible only if the laparoscopist is expert in advanced laparoscopic surgery.[22,37-39]

Hand-assisted laparoscopic splenectomy might be a practical alternative to pure laparoscopic removal. This offers both the benefits of close inspection with laparoscopy and palpation of the tumor as in open surgery. The hand offers easy exposure, more complete exploration of regional lymph nodes, stomach and pancreas by palpation, and immediate hemostasis with manual compression. Intact removal is easily accomplished through the hand port, and the patient receives much of the same advantages of laparoscopic surgery.[39]

Partial splenectomy has been successfully reported only for cysts of the spleen. However, for staging of Hodgkin's disease, the risk of a negative staging error with partial splenectomy has been reported and is advised against. In patients with splenic metastasis, if the metastasis is clearly part of disseminated metastatic disease, splenic biopsy is sufficient. Splenectomy should not be performed in these cases because there is no survival advantage to justify the risk.

CONCLUSIONS

When faced with a tumor or cyst of the spleen, the surgeon must first narrow the differential diagnosis, paying special attention to the possibility of infections or malignant etiology. Once the cause has been established,

the appropriate operative approach may be chosen. As described, laparoscopic and open techniques are equally effective and safe as long as the surgeon has the requisite experience.

Management of Splenic Abscess

Adheesh A. Sabnis · Jeffrey L. Ponsky

Splenic abscesses are rare, with less than 500 cases cited in the literature.[1] Splenic abscesses were lethal prior to the era of antibiotics and were usually diagnosed at autopsy[2] with incidences of 0.14% to 0.7%.[3,4] In recent times the incidence of splenic abscess has increased due to the growing number of immunocompromised patients.[5] However, with the development of new imaging techniques and improved antibiotics comes an advance in the management and resolution of splenic abscesses.

PRESENTING SYMPTOMS AND SIGNS

The clinical triad of fever, left upper quadrant pain, and leukocytosis is seen only in one third to two thirds of patients with splenic abscess.[6,7] At the time of diagnosis, patients may present with a variety of signs and symptoms or none at all. Reported symptoms and signs include nausea, vomiting, weight loss, decreased left-sided breath sounds, splenomegaly, and a new systolic murmur.[5,8-10] Immunocompromised patients usually present further in the disease process with generalized symptoms and signs such as fever, abdominal pain, and weight loss.[5]

DIAGNOSIS

The diagnosis of splenic abscess can be supported by microbiology and laboratory data. Leukocytosis (white blood cell count >12,000/μl) is reported in 60% of cases.[7] Idiopathic thrombocytosis in septic patients may suggest a splenic abscess.[11] Cultures of abscess fluid identify the offending organism 80% of the time.[7] However, blood cultures isolate the infecting organism in less than half of all cases.[7,8] Moreover, in 66% of cases, different organisms are identified from the abscess and blood cultures.[7,8] These factors need to be considered when choosing a patient's antibiotic regimen. Imaging studies can be invaluable when diagnosing splenic abscess. Plain chest radiographs cannot give a definitive diagnosis, however, because there are nonspecific findings in 33% to 80% of cases.[3,4,8,12,13] These findings include left pleural effusion, pleural thickening, left basilar pulmonary infiltrate, and an elevated left hemidiaphragm.[5,8,13,14] Nonspecific findings are also seen in about 25% to 69% of abdominal radiographs.[3,4,8,12,13] These studies may demonstrate a soft tissue mass, extraluminal gas shadow, or a nongastric air-fluid level in the left upper quadrant.[13,14] There is one reported case of a gas-forming splenic abscess causing pneumoperitoneum and generalized peritonitis in an immunocompromised patient, in which the plain abdominal film showed free air and extraluminal air bubbles in the left upper quadrant.[15] Ultrasound has a sensitivity of 75% to 90% for detecting splenic abscess.[4,13,16] Sonographic findings include an anechoic (13%) or hypoechoic (87%) mass, with an irregular wall, with or without internal echogenic foci that may represent septations, debris, or layering.[7,17-20] Computed tomography (CT) is more accurate than ultrasound, with a sensitivity of up to 96%[4] and specificity of 90% to 95%.[4,7] In addition, CT has a greater specificity over ultrasound in detecting gas, a diagnostic finding for splenic abscess.[7] CT also offers the advantage of being able to localize abscesses as small as several millimeters and enables the examiner to determine whether the abscesses are unilocular (Figs. 131–1 and 131–2) or multilocular (Fig. 131–3). Another advantage is being able to identify the anatomic location of the abscess in relation to the spleen and other organs, thus aiding in determining the appropriate management option. Findings on CT scan include low-density parenchymal areas with peripheral enhancement after intravenous contrast administration.[13,14] These scans can help differentiate splenic abscess from other diseases such as splenic cysts and infarctions and can be used serially to follow abscess response to therapy.[5] Furthermore, CT- or ultrasound-guided intervention can be used for both diagnosis and therapy.

In situations where the diagnosis remains unclear after the imaging and laboratory studies, fine-needle aspiration is recommended.[7]

ABSCESS CHARACTERISTICS

The pathogenesis of splenic abscess include hematogenous spread of a remote infection, hemoglobinopathy resulting in embolization/infarction, chemotherapy and other immunodeficiency states, trauma, and contiguous infection from adjacent organs.[1,3,21,22] Traditionally, the pathogenesis is related to the spread of microorganisms

Figure 131–3. CT of the upper abdomen demonstrating a multilocular splenic abscess after splenic flexure lymphoma resection. There is a Penrose drain centrally.

from an infectious source via a hematogenous route. This route of infection has been reported in 49% to 68% of cases.[1,13,21] Metastatic hematogenous infections from endocarditis account for greater than 66% of splenic abscesses.[9] However, in recent times, 18% to 28% of splenic abscess cases are found in immunocompromised patients.[1,13] In this patient population, splenic abscesses are usually multilocular. Secondary to the increased population of immunocompromised patients, opportunistic pathogens such as fungi and gram-positive aerobes are more often identified than in the past.[1] Splenic abscess due to a contiguous septic process from adjacent organs such as the stomach, colon, pancreas, or kidney is seen less frequently, with an incidence of only 6% to 15% of reported cases.[1,4,13] Hemoglobinopathies such as sickle cell, thalassemia, and leukemia are known to predispose patients to splenic abscess.[13] These disorders are recently reported in 6% or less of cases.[1,4,13,21] Unilocular splenic abscess has an improved prognosis and is usually present with subacute bacterial endocarditis, drug abuse, trauma, or other septic episodes.[7]

There is a large variety of both aerobic and anaerobic bacteria responsible for splenic abscess. The most common being *Staphylococcus aureus, Streptococcus, Salmonella, Escherichia coli,* and anaerobes.[3,4,23] Polymicrobial abscesses have been found in 11% to 36% of cases,[23] with anaerobic bacteria being present most often.[4,23] With the increased number of immunodeficient patients, there has been an increase in fungal abscesses to 25.8% of cases.[1,4,13] *Candida* accounts for more than 70% of fungal abscesses with other isolates including *Aspergillus, Cryptococcus neoformans, Aureobasidium pullulans,* and *Blastomyces dermatitis.*[4,13] Fungal abscesses tend to be multilocular in 90% of patients,[13,24] whereas bacterial abscesses are multilocular in 26% of patients.[4,13,21] Splenic involvement with *Mycobacterium* species was once rare but recently has been reported in 4% to 7.8% of cases, mostly in immunocompromised patients.[4,13]

MANAGEMENT

If left untreated, splenic abscesses are universally fatal. Combined medical therapy and drainage is used to treat many splenic abscesses. Drainage can be accomplished by either splenectomy or percutaneously using radiographic guidance. Medical management alone is ineffective and is associated with a mortality rate as high as 80%.[5] However, splenic abscess caused by *Mycobacterium* species, *Pneumocystis carinii,* or fungal infection can be treated successfully with antibiotics alone.[1]

The traditional treatment for splenic abscess is splenectomy, but this is associated with morbidity and mortality rates of 11% to 28% and 6% to 14%, respectively, secondary to underlying disease and intra-abdominal rupture during operation.[1,4,7,8] Mortality is even greater in critically ill and immunocompromised patients.[1,5,7] Furthermore, splenectomy may be difficult in some patients because of extensive parasplenic inflammation and adhesions. In these situations, ligation of the splenic vessels through an opening in the gastrosplenic ligament may be more desirable prior to splenectomy. After splenectomy, the left subphrenic space should be drained. At the time of exploration, if dense adhesions prevent a safe splenectomy, the abscess can be aspirated and interval splenectomy performed at a later date. Infrequently, it may be necessary to remove the 10th and 11th ribs to gain access to a high-lying abscess, taking caution not to enter the pleural cavity.

Laparoscopic drainage of splenic abscess may be indicated when percutaneous drainage is not an option due to location or access or when prior percutaneous drainage attempts have failed. In such cases, laparoscopic drainage of splenic abscess can offer a minimally invasive alternative to open surgery. Additionally, with laparoscopic drainage, abscesses can be aspirated, larger drains placed, and if warranted, a total splenectomy completed. When using laparoscopic therapy for splenic abscess, the abscess may be aspirated at the onset of the procedure to facilitate splenectomy. Laparoscopic splenectomy[25] or drainage may also be successfully and safely implemented for cases of splenic abscess, with outcomes comparing favorably to open series.

An alternative to open splenectomy is CT- or ultrasound-guided percutaneous drainage. This carries a lower morbidity and mortality rate of 5% and 1%, respectively.[1,4,7] Reported complications associated with this modality include pneumothorax and hemothorax.[1] The advantage of the low mortality rate must be weighed against the disadvantage of the 30% recurrence rate from percutaneous drainage.[4] Multiple catheterizations have been required in some patients for complete resolution of an abscess. Furthermore, percutaneous drainage with serial attempts may be implemented as initial therapy for many cases of unilocular abscesses. Response to therapy is monitored with CT or ultrasound, and failure of response can be followed by splenectomy. Techniques of percutaneous drainage offer more advantages over splenectomy in that the therapy is tolerated even in severely debilitated, elderly, or critically ill patients.[5] Additionally, preservation of the spleen is vital in children and immunocompromised patients.[5] Adequate percutaneous drainage of a splenic abscess can be achieved by using 12- to 14-French catheters.[5,22]

Abscesses appropriate for percutaneous drainage are usually unilocular, solitary, and possess a well-defined wall with homogenous-appearing contents. Proper localization of the abscess is also essential for CT- or ultrasound-guided percutaneous drainage. For abscesses that are multiple, septated, or anatomically inaccessible, percutaneous drainage is relatively contraindicated.[5] Percutaneous drainage is not recommended in patients with coagulopathies, ascites, or associated diseases requiring surgical management.[5,6]

Selection of antibiotics in patients with splenic abscess should be guided by the sensitivity of isolates or by the most likely pathogens in culture-negative isolates.[13] The most common length of antibiotic therapy is 10 to 14 days.[13]

Splenectomy for Conditions Other Than Trauma

Y. Nancy You · John H. Donohue · David M. Nagorney

Splenectomy for nontraumatic disorders demands careful risk-benefit analysis and surgical planning. Crucial factors considered include the nature of the underlying disease, the severity of symptoms, alternative therapeutic options, the operative risk, and the success rate of splenectomy. During the last decade, the underlying diseases have become better understood; more and effective medical therapies have become available; laparoscopic techniques have decreased operative risks; and prophylaxis has minimized the risk of postsplenectomy infections. These advances have challenged some of the traditional concepts regarding splenectomy. This chapter aims to summarize the current indications and contemporary outcomes of splenectomy for nontraumatic conditions encountered by surgeons in consultation. These conditions mainly include hematologic disorders but also splenic mass lesions, splenic vascular disease, iatrogenic injuries, and other rare diseases.

SPLENECTOMY FOR HEMATOLOGIC DISORDERS

The spleen performs important hematologic and immunologic functions. It maintains the circulating blood components by filtering and removing damaged or senescent cells. As the largest aggregate of lymphoid tissue in the reticuloendothelial system, the spleen functions in both antibody production and phagocytosis. Accordingly, cytopenia and splenomegaly are two common manifestations of hematologic disorders involving the spleen. Cytopenia is associated with hypersplenism, the excessive destruction of one or more blood components. Splenomegaly, defined as splenic weight of more than 175 g (normal, 90–150 g), can become massive (>1000–15,000 g). Mechanical symptoms of splenomegaly include pain and early satiety. When the spleen is the sole site of the disease or a major contributor to the underlying pathophysiology, splenectomy is performed with curative intent. In most conditions, it is performed for effective palliation of symptoms and complications.

Disorders Causing Thrombocytopenia

Thrombocytopenia is defined as platelet count less than 150×10^9/L. Patients with platelet counts of 50×10^9/L or greater are usually asymptomatic and are discovered incidentally. Excessive oozing after surgery or bruising after minor trauma usually does not occur until the platelet count is below 30 to 50×10^9/L. Spontaneous internal bleeding may occur with counts of 10 to 20×10^9/L. Response of thrombocytopenia to therapy has been variably defined in previous studies. Complete response (CR) is most commonly defined as achieving platelet counts of 150×10^9/L for at least 30 days after splenectomy without additional therapy. Partial response (PR) results when platelet counts of at least 50×10^9/L are achieved, whereas no response (NR) is defined when counts remain below 50×10^9/L for 30 days. Relapse occurs when thrombocytopenia recurs after achieving a normal platelet count.[1]

Idiopathic Thrombocytopenic Purpura

Idiopathic thrombocytopenic purpura (ITP) is the most common hematologic disease for which splenectomy is indicated. Affected patients may be asymptomatic or may present with petechiae, ecchymosis, epistaxis, gastrointestinal bleeding, or menorrhagia. Subarachnoid or intracranial hemorrhage suggests severe thrombocytopenia. ITP is mediated by autoantibodies, typically against multiple platelet membrane glycoproteins such as IIb/IIIa, Ib/Ix, Ia/IIa, IV, and V. Splenic macrophages clear platelets coated with IgG autoantibodies in an accelerated fashion.[2] When compensatory platelet production is impaired or outstripped, thrombocytopenia ensues. The test for antiplatelet antibodies has a sensitivity of

only 49% to 66% and a specificity of 78% to 92%.[2,3] A positive test does not definitively diagnose ITP, whereas a negative result cannot exclude it. ITP remains a clinical diagnosis of exclusion. A search for a secondary cause for thrombocytopenia should be prompted by a history of drug or toxin exposure, recent viral infections, splenomegaly on physical examination, an abnormal peripheral smear, or a hypoplastic bone marrow. Although peripheral smear has been required as a diagnostic test, bone marrow aspiration is considered for patients older than 60 years of age with atypical presentations and in whom other disorders are suspected and splenectomy is contemplated.[4]

The time of disease onset in childhood or adulthood determines the clinical presentation, natural history, and treatment approaches. Childhood ITP most commonly affects children between 2 and 5 years of age without a gender bias. In approximately 90% of the patients, the disease manifests as acute thrombocytopenia, associated with a sudden onset of petechiae occurring 4 to 8 weeks after the prodrome of viral illness, allergies, or immunizations.[5] Antibodies formed during the preceding illnesses cross-react against platelets. The natural history of childhood ITP is favorable; a vast majority (83%) spontaneously recover within 8 weeks without therapy, with approximately 10% to 15% persisting as chronic ITP.[6] Therefore, aggressive therapy is avoided. Typical management includes observation and avoidance of platelet-inhibiting medications and of activities predisposing to trauma. The decision to initiate any form of therapy is typically driven by a concern for the risk of intracranial hemorrhage, the development of refractory clinical symptoms, and activity restrictions that compromise a child's quality-of-life. First-line therapy is medical and includes intravenous immunoglobulin (IVIG), corticosteroids and, anti-IgD, and platelet transfusion. Splenectomy is delayed for as long as possible.[5] However, when it is performed, response rates of 63% to 76% may be expected. The response is sustained in the long-term in 45% of the patients.[7] Benefit from splenectomy may be predicted by preoperative response to IVIG, with positive predictive values of 74% to 91% and negative predictive values of 75% to 100%.[8-11] In the pediatric population, laparoscopic splenectomy does not compromise the response rates, can be safely performed, and allows faster recovery without increasing costs.[12]

Adult ITP has an insidious onset and affects women between 18 and 40 years of age most commonly. The natural history contrasts with that of childhood ITP in that spontaneous remission occurs only in 2% to 9% of all patients.[13] The majority develops chronic ITP. Although the disease course is usually benign, those with severe or refractory thrombocytopenia face four times the risk of mortality than the general population.[14] The decision to initiate therapy depends on the bleeding risk, estimated from patient's age, life-style, platelet count, and concomitant diseases.[4] Standard first-line options include corticosteroids, anti-IgD, and IVIG. Each therapy suffers from limitations: (1) corticosteroids may induce remission in 66% of the patients initially, but less than 20% maintain remission in the long-term; (2) IVIG is costly and is reserved for when steroids are ineffective or contraindicated (e.g. pregnancy); and (3) anti-IgD is only effective in Rh-D–positive nonsplenectomized patients.[4,14] Splenectomy is the most likely curative therapy for ITP. Currently, it is indicated when disease is refractory to 6 weeks of corticosteroid therapy, when maintenance of platelets is dependent on 10 mg or more of prednisone daily, or when options for alternative therapy are limited.[4]

Outcomes of splenectomy for ITP have been summarized in a systematic review by Kojouri et al. reporting on 130 articles.[1] The overall rate of platelet response to splenectomy is 67% (range, 37%–100%), with a sustained response rate of 64% after 7 years (range, 5–12.75 years) of follow-up. The average relapse rate after splenectomy is 15% (range, 0–51%), most occurring within the first postoperative year. One single-center experience of 140 adults revealed an overall complete platelet response rate of 78% initially and 74% after 1 year.[4] Corticosteroids, danazol, and/or IVIG salvaged 81% of those who relapsed.[15] Factors predictive of successful outcome after splenectomy have also been investigated.[1,13] Younger age (<30 years old) at splenectomy and previous response to glucocorticoids most consistently correlated with good response. Additionally, when platelets are mainly sequestered in the spleen rather than the liver and other lymphoid organs, as identified by indium-labeled platelet scans,[4] a superior response rate has been observed.

Laparoscopic splenectomy has become the gold standard for ITP patients. Operative mortality has decreased from 1% for open splenectomy to 0.2% for laparoscopic splenectomy. Similarly, operative morbidity has decreased from 12.9% to 9.6%.[1] Postoperative recovery is superior with less pain and earlier hospital discharge. These benefits are realized without increased cost and without compromising hematologic response rates.[16] In debilitated patients who are unsuitable for an operation, splenic irradiation or partial splenic embolization may be considered, but the experience with this treatment is limited.

Accessory splenic tissue may be present in 16% to 29% of patients with ITP.[1] The most common locations for accessory splenic tissue include the splenic hilum, the gastrosplenic ligament, gastrocolic ligament, greater omentum, mesentery, and presacral space (Fig. 132–1).[17]

A thorough search should be conducted intraoperatively whether the operative approach is open or laparoscopic, because a missed accessory spleen may be the cause for relapse of ITP. The presence of residual functioning splenic tissue after splenectomy is indicated by the absence of Howell-Jolly bodies on a peripheral smear.

ITP occurs in every 1 or 2 per 1000 pregnancies, with or without a preexisting diagnosis. Differential diagnosis should exclude hereditary thrombocytopenia, gestational thrombocytopenia, and syndrome of hemolysis with elevated liver enzymes and low platelets. In pregnant ITP patients, bleeding risks for both the mother and the fetus must be considered, because maternal IgG antibodies cross the placenta and can cause fetal thrombocytopenia. Treatment consists of careful monitoring of maternal platelet counts that typically reach a nadir in

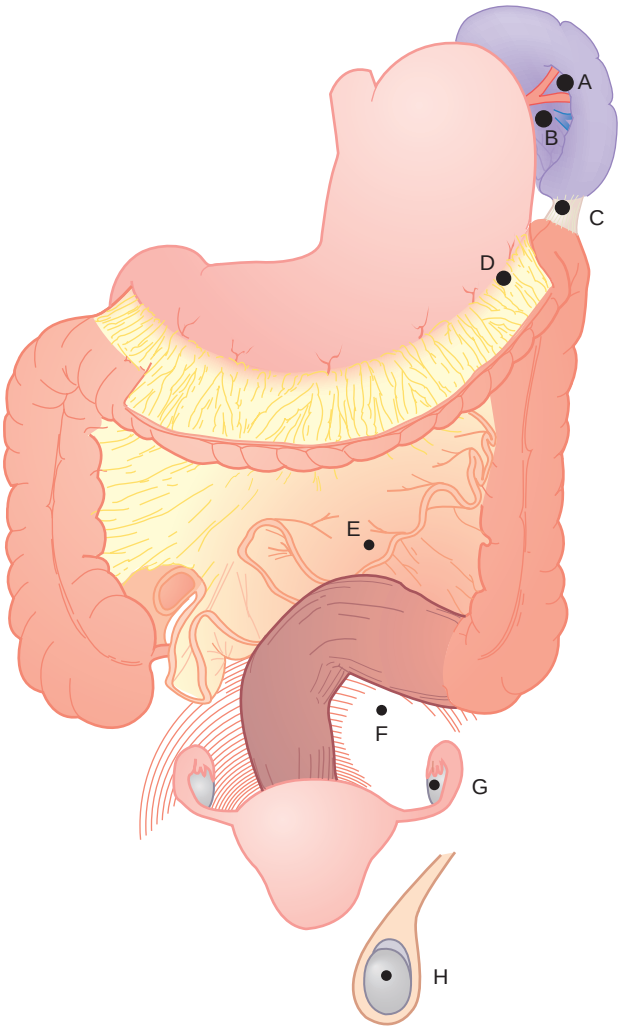

Figure 132–1. Common locations for accessory spleens: hilus of the spleen (A); along the splenic vessels (B); splenocolic ligament (C); omentum (D); mesentery (E); presacral region (F); adrenal region (G); and gonads (H). The weight of the dot corresponds to the frequency an accessory spleen may be found at that location. (From Martin JK: Staging laparotomy. In Donohue J, van Heerden J, Monson J [eds]: Atlas of Surgical Oncology. Cambridge, MA, Blackwell Science, 1995, p 150.)

the third trimester. Intervention is generally not needed in patients with platelet counts greater than 20×10^9/L until prior to delivery. A maternal count greater than 50×10^9/L is considered safe for any mode of delivery and is the goal of therapy. Treatment options of low teratogenic risk include corticosteroids or IVIG, but their side effects may be exacerbated in pregnancy and should be carefully monitored. Splenectomy is usually avoided, but if necessary, splenectomy should be performed during the second trimester. With maternal platelet count greater than 50×10^9/L, the incidence of fetal thrombocytopenia is 10% to 15% and that of fetal hemorrhage is less than 1%.[4,18]

Emergent intervention for ITP is indicated for patients with neurologic symptoms suggestive of intracranial bleeding, with evidence of internal or widespread mucocutaneous bleeding, and for those requiring an emergency operation for other reasons. First-line therapy consists of IVIG (1 g/kg/day for 2 days), intravenous methylprednisolone (1 g/day for 3 days), and platelet transfusions. Emergency splenectomy for refractory patients is rarely needed.[4]

Thrombotic Thrombocytopenia Purpura

Unlike ITP, thrombotic thrombocytopenia purpura (TTP) can be a highly lethal disorder. TTP is characterized by the pentad of thrombocytopenia, hemolytic anemia, fever, renal dysfunction, and, more rarely, neurologic impairment. Characteristic findings include peripheral schistocytes (fragmented erythrocytes) and evidence of microvascular thrombosis. The pathophysiology of TTP involves an undefined trigger of vascular endothelial injury, leading to the release of unusually large forms of the von Willebrand factor. Abnormal platelet agglutination and marked intrasplenic phagocytosis follow. Currently, the first-line therapy consists of total plasma exchange in conjunction with corticosteroids and antiplatelet drugs such as aspirin or dipyridamole. Total plasma exchange has revolutionized the care of TTP by increasing the previously dismal survival rate to approximately 70% to 85%.[19,20] Relapse rates remain as high as 36% over 10 years.[21] Splenectomy has also been advocated for patients who are refractory to or suffer a relapse after plasma exchange. In several small series of patients, splenectomy induced remission of TTP in 50% of refractory patients[22] and reduced the risk of relapse by 70% to 95%.[22-24] However, the operative morbidity in this patient population may be substantial at 17% to 39%. Only recent reports have suggested that laparoscopic splenectomy has lowered these operative risks.[23,25]

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic autoimmune disease of unknown cause. Antiplatelet antibodies are demonstrable in 78% of SLE patients. These pathogenic autoantibodies and immune complexes affect virtually every body system. Destruction of antibody-coated platelets leads to severe thrombocytopenia in 8% to 20% of these patients.[26] The first-line therapy involves agents aimed at reducing the pathogenic immune response: corticosteroids, danazol, IVIG, and immunosuppressive (e.g., CellCept) and antineoplastic (e.g., cyclophosphamide, vincristine) drugs. Response rates to medical therapy have been variable and transient. Splenectomy is considered for patients who are refractory, dependent, or intolerant of medical therapy. Despite previous concerns, the operative risks of splenectomy are acceptable. The most recent single-center experience of 25 patients undergoing splenectomy reported a 30-day mortality of 0% and morbidity of 24%, with bleeding and infection being the most common complications.[26] The hematologic response was comparable to that for ITP alone, with an initial response rate of 88% and a relapse-free long-term response rate of 64%. These are consistent with

previously reported initial response rates of 21% to 93% and exceeded previously reported sustained response rates of 10% to 32%.[26] Although 36% of the patients relapsed after initial response (consistent with previously reported rates of 6%–79%), additional medical therapy successfully salvaged 55% of these patients.[26] Because splenomegaly is typically not present, laparoscopic splenectomy is now the procedure of choice in this patient population.

Human Immunodeficiency Virus

Chronic thrombocytopenia affects approximately 10% of patients infected with the human immunodeficiency virus (HIV) and 33% of those with acquired immunodeficiency syndrome (AIDS). Bleeding complications are infrequent and rarely severe even in the 1% to 5% of the patients with severe thrombocytopenia.[27] Most patients have platelet counts higher than 50×10^9/L; some may even spontaneously correct their thrombocytopenia. The pathogenesis of HIV-thrombocytopenia involves (1) immune-mediated platelet destruction, similar to that in ITP, and (2) impaired platelet production due to infected megakaryocytes in the bone marrow.[27] Accordingly, first-line therapy consists of (1) corticosteroids, IVIG and anti-D, similar to those in ITP, and (2) antiviral agents such as azidothymidine (AZT) or combination highly active antiretroviral therapy to treat the primary disease.[28,29] However, the immunosuppressive effects of corticosteroids make them unsuitable for long-term administration. Splenectomy is indicated in patients unresponsive, refractory, or intolerant of medical therapy. Operative mortality is minimal,[30,31] though the complication rate approaches 24%.[32] Favorable response is achieved in 83% of HIV patients[30,33,34] and slightly fewer AIDS patients.[32] Splenectomy has not been shown to adversely impact the progression to AIDS, overall survival, and AIDS-free survival.[32,34] Despite encouraging results, the timing and patient selection for splenectomy during the course of HIV infection remain controversial.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is an X-linked immunodeficiency disorder characterized by thrombocytopenia, eczema, vasculitis, progressive immunodeficiency, and increased risk for malignancy. Its pathogenesis involves defective cytoplasmic scaffolding proteins.[35] Despite varied phenotypic expressions, thrombocytopenia is the most common manifestation of WAS. For patients with severe symptoms and available HLA-matched donors, bone marrow transplant is performed with curative intent. For symptomatic patients without appropriate donors, splenectomy is indicated in combination with prophylactic antibiotics and immunization. Median survival of up to 25 years has been reported,[36,37] representing substantial improvement over the previously dismal median survival of less than 5 years. IVIG may be used alone or in combination with splenectomy.

Disorders Causing Anemia

Hereditary Anemia

Hereditary anemias can be categorized by (1) defects of the erythrocyte membrane (e.g., hereditary spherocytosis, hereditary elliptocytosis); (2) defects of an erythrocyte enzyme (e.g., pyruvate kinase deficiency, glucose-6-phsophase dehydrogenase deficiency); and (3) defects of hemoglobin synthesis (e.g., thalassemias, sickle cell anemia). All of these mutations result in abnormal erythrocyte morphology and stability and lead to increased hemolysis and phagocytosis by the spleen. The benefit and use of splenectomy vary depending on the diagnosis.

Red Blood Cell Membrane Defects Hereditary spherocytosis (HS) is the most common inherited hemolytic disorder in North America and Europe. It is transmitted mainly as an autosomal dominant trait. The pathogenesis of HS involves deficiencies in membrane structural proteins. The affected family of spectrin proteins, including β spectrin, ankyrin, band 3, and protein 4-2, normally forms the supportive cytoskeleton of the red blood cell (RBC). Dysfunction of these proteins result in abnormal RBC morphology, increased cell membrane fragility, and shortened life span. Clinical findings are variable and include anemia, jaundice, and splenomegaly. Pigmented gallstones form in up to 41% of patients screened with ultrasonography, and their prevalence is higher in patients who coinherit Gilbert's disease.[38] HS is distinguished from other anemias by the findings of elevated reticulocyte counts, hyperbilirubinemia, negative direct antiglobulin test (DAT), spherocytes on peripheral smear, and increased erythrocyte osmotic fragility.[39,40]

The indication for splenectomy is not based on the diagnosis of HS, per se, but on its symptoms and complications (Table 132–1).[41] For patients with mild HS and no gallstones, splenectomy has no benefit.[42] For patients with moderate or severe disease, splenectomy is indicated but usually delayed until after the 6th year of life but before puberty to minimize the risk of postsplenectomy sepsis.[40] Children with accelerating anemia, frequent hemolytic crises, transfusion dependency, or intractable leg ulcers may require earlier intervention.[39] For patients with symptomatic cholelithiasis, splenectomy and cholecystectomy are indicated and can be performed safely together.[43] When gallstones are asymptomatic or found incidentally, the best approach has not been established. Options include observation, cholecystotomy with stone removal, or cholecystectomy.[44,45]

The optimal approach for splenectomy remains controversial. Laparoscopic splenectomy offers a faster postoperative recovery in the pediatric population. It should be the approach of choice when splenomegaly is not present to increase the operative risks.[12,46] Partial (80%–90%) open splenectomy has been advocated for very young patients with severe disease,[46] but preservation of splenic function must be balanced against the risks of disease recurrence. Recently, near-total splenectomy (98%) has been proposed as a means to optimize this balance.[47]

Table 132–1 Classification of Hereditary Spherocytosis

Variable	Trait/Carrier	Mild	Moderate	Severe
Hemoglobin, g/dl	Normal	11-15	8-12	6-8
Reticulocyte, %	<3	3-6	>6	>10
Bilirubin, µmol/L	<17	17-34	>34	>51
Spectrin per RBC, % normal	100	80-100	50-80	40-60
Splenectomy	Not indicated	Usually not indicated	Consider prior to puberty	Usually necessary, delay until age 6 yr if possible

RBC, red blood cell.

Hereditary elliptocytosis is a variant of HS also involving defective spectrin proteins. These patients typically have mild anemia requiring no intervention. Splenectomy does not correct the abnormal RBC morphology but is effective for the rare patient with severe transfusion-dependent anemia. HS must also be differentiated from other rare disorders of RBC membrane permeability, such as hereditary stomatocytosis or cryohydrocytosis. Splenectomy is ineffective and unwarranted and carries a high risk of postsplenectomy venous thrombosis in these patients.[39]

Red Blood Cell Enzymatic Defects Glucose-6-phosphate dehydrogenase deficiency is the most common RBC enzymatic defect. It manifests as a mild anemia and rarely splenomegaly. Experience with splenectomy in this disease is limited. Pyruvate kinase deficiency results in reduced energy generation in RBCs. The homozygous form of this disease results in a severe anemia with splenomegaly. Splenectomy is effective in reducing transfusion requirements.[48]

Hemoglobinopathies Sickle cell disease includes sickle cell anemia (SS), hemoglobin C disease (SC), and the sickle β thalassemia. The inherited point mutation on the sickle gene leads to an abnormal β-chain forming a hemoglobin with decreased solubility in its deoxygenated form. Pathogenesis of sickle disease results from abnormal polymerization of hemoglobin S with low cellular oxygen content. Exponential propagation of this process stiffens and distorts erythrocytes. Further compounding factors include abnormal endothelial adhesion, formation of heterocellular aggregates, dysregulation of nitric oxide–mediated vasodilation, and local inflammation. All of these factors lead to slowed RBC transit and their entrapment in the vasculature and in the spleen.[49] Microvascular occlusion results, and sickle patients suffer from end-organ damage of the eyes, kidneys, subcutaneous tissue, and bone. Splenic sequestration occurs when the RBC is trapped in the enlarged spleen, which then undergoes autoinfarction; it is observed in 7% to 30% of SS patients between 2 and 5 years of life. Acute manifestation, known as *acute splenic sequestration crisis* (ASSC), is potentially fatal. Patients present with profound acute anemia (decrease in hemoglobin by >2 g/dl), reticulocytosis, and thrombocytopenia. Acute therapy requires resuscitation by RBC transfusions. However, recurrence carries a 20% mortality rate and can occur in 50% of those who survive ASSC.[49] As a means to prevent future ASSC, elective splenectomy has been indicated in children older than 2 or 3 years of age after the first episode of ASSC. The operative mortality is 7%, and 5-year mortality is 3.4%.[50,51] The risk of postsplenectomy sepsis is approximately 2% in this patient population but increases substantially if splenectomy is performed prior to 4 years of age.[52-54] Although splenectomy has not been proven to increase survival, its benefits include reducing transfusion dependency, relief from pain from splenomegaly, and treatment of splenic abscesses resulting from splenic infarctions.[50,55]

Patients with thalassemia major (or homozygous β thalassemia) synthesize structurally abnormal hemoglobin that deforms erythrocytes. They typically depend on multiple transfusions to maintain a hemoglobin level above 10 g/dl. When complications of hypersplenism develop, as measured by transfusion requirement of greater than 250 ml/kg/year and iron overload, splenectomy is indicated.[56] Splenectomy reduces the requirements for both transfusions and deferoxamine (an iron chelator) in 32% of patients.[57] More than 80% of children with thalassemia regain normal weight and growth rates after splenectomy.[58] The risk for overwhelming postsplenectomy sepsis (OPSS) is high in this patient population, approximately 10% in the long term.[59] Therefore, splenectomy is usually delayed until after 6 to 8 years of age. Partial splenectomy has been advocated in younger children,[60] and laparoscopic splenectomy is definitely feasible in these patients.[61]

Acquired Hemolytic Anemia

Hemolytic anemia may result from numerous etiologies. Autoimmune hemolytic anemia (AIHA) is an IgG-mediated (so-called warm agglutinin) hemolytic anemia with a positive Coombs' antiglobulin test. Erythrocyte destruction is mediated by splenic macrophages. AIHA may be idiopathic or a manifestation of a systemic disease, such as viral infection, SLE, rheumatoid arthritis, ulcerative colitis, or chronic lymphocytic leukemia (CLL). Splenectomy is indicated when disease is refractory to corticosteroids. It succeeds in up to 64% of patients and reduces the steroid requirement in an

additional 21%.[48] The success rate is higher when AIHA is associated with systemic disease.[62] In contrast, so-called cold agglutinin hemolytic anemia is mediated by IgM. Erythrocytes are sequestered and destroyed in the liver, and splenectomy therefore plays no role in this condition.

Miscellaneous Hematologic Disorders

Evans's Syndrome

Patients with Evans's syndrome present with a combination of autoimmune thrombocytopenia (ITP) and hemolytic anemia (AIHA). Medical therapy typically involves multiple agents, with corticosteroids and IVIG being used most commonly.[63,64] Experience with splenectomy for this rare disease is limited.[65] Although long-term remission has been reported,[65] one study observed the median duration of response following splenectomy to be only 1 month.[64]

Felty's Syndrome

Felty's syndrome, defined as a combination of rheumatoid arthritis, splenomegaly, and neutropenia, affects a small subset of patients, particularly those with destructive rheumatoid arthritis, severe extra-articular symptoms, and an HLA DR4 haplotype.[66] Neutropenic sepsis is the main cause of patient demise. First-line therapy consists of hematopoietic growth factors and often leads to rapid, favorable responses.[67] Splenectomy is indicated when the neutropenia fails to improve adequately or rapidly enough. Neutropenia is corrected by splenectomy in 80% of patients, and active preoperative infections resolve in nearly half of patients.[67]

Autoimmune Neutropenia

Patients affected by autoimmune neutropenia, a rare disorder, usually have neutrophil counts of 500 to 1000/μl but manifest granulocyte-specific antibodies. It commonly presents in infancy as recurrent infections. When present in adults, it may be associated with underlying diseases such as viral infection, collagen vascular diseases, ITP, or AIHA. Autoimmune neutropenia is typically characterized by spontaneous disappearance of autoantibodies and does not require specific intervention. However, for acute infections or operative procedures, granulocyte-colony stimulating factors effectively improve the neutrophil counts. Fifty percent to 60% of the patients also respond to corticosteroids and IVIG.[68] Therefore, the role for splenectomy is limited only to the rare patient who is refractory to medical interventions.

Lymphoproliferative Disorders

Lymphoma

Lymphomas are categorized into two distinct types: Hodgkin's disease (HD) and non-Hodgkin's lymphoma (NHL). The surgeon's role in HD is to provide disease staging, a rare indication for splenectomy today, since most HD patients now receive chemotherapy. Splenectomy provides palliative and therapeutic benefits in several subtypes of NHL.

Hodgkin's Disease The diagnosis of HD is made when a tissue biopsy demonstrates Reed-Sternberg cells surrounded by reactive lymphocytes. Molecular alterations in the BCL2 or the NFκB pathways enable the malignant Reed-Steinberg cells to evade apoptosis and account for the pathogenesis of HD.[69,70] The clinical manifestations and course of HD are largely dependent on its histopathology. Classic HD includes the following histologic subtypes:

1. The most common nodular-sclerosing form affects the mediastinum predominately and carries a favorable prognosis.
2. The mixed-cellularity subtype is the second most common and has a high frequency of abdominal involvement.
3. The diffuse lymphocyte-predominant subtype is distinguished from the nodular lymphocyte-predominant form in its involvement of multiple anatomic regions.
4. The least common, lymphocyte-deplete subtype, is usually a subdiaphragmatic disease characterized by pancytopenia, abnormal liver function, minimal peripheral adenopathy, and poor prognosis.

Apart from classic HD, the nodular lymphocyte-predominant form of HD affects a minority (5%) of patients with limited cervical or inguinal disease and carries a favorable prognosis. Regardless of the histologic type, 30% to 60% of all patients with HD experience systemic symptoms consisting of fever, night sweats, and weight loss.

The therapy of HD depends on its clinical and pathologic stage, according to the Ann Arbor staging system with Cotswold modification (Table 132–2). Patients with advanced disease (stage III or IV) receive combination chemotherapy and radiation. The current gold standard therapeutic regimen is ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine), with more intense drug regimens used for refractory disease. Patients with localized disease (stage I or II) may receive only radiation therapy to the involved fields. Short-cycle chemotherapy (ABVD) is added for high-risk disease.

Clinical staging of HD can be ascertained by physical examination, laboratory tests, bone marrow biopsy, chest radiograph, computed tomographic (CT) or magnetic resonance (MR) imaging scan of the chest, abdomen and pelvis, lymphangiogram, and possibly positron emission tomography. Pathologic confirmation of the disease extent is undertaken only when the information gained might change therapy. Surgical staging is indicated when patients are potential candidates for radiation as their sole therapy based on their clinical stage.[71] The goal of laparotomy is to rule out occult subdiaphragmatic disease that would upstage the disease and require systemic chemotherapy. It has been reported to detect occult splenic or upper abdominal disease in 20% to 35% of the patients with clinical stage I or II disease.

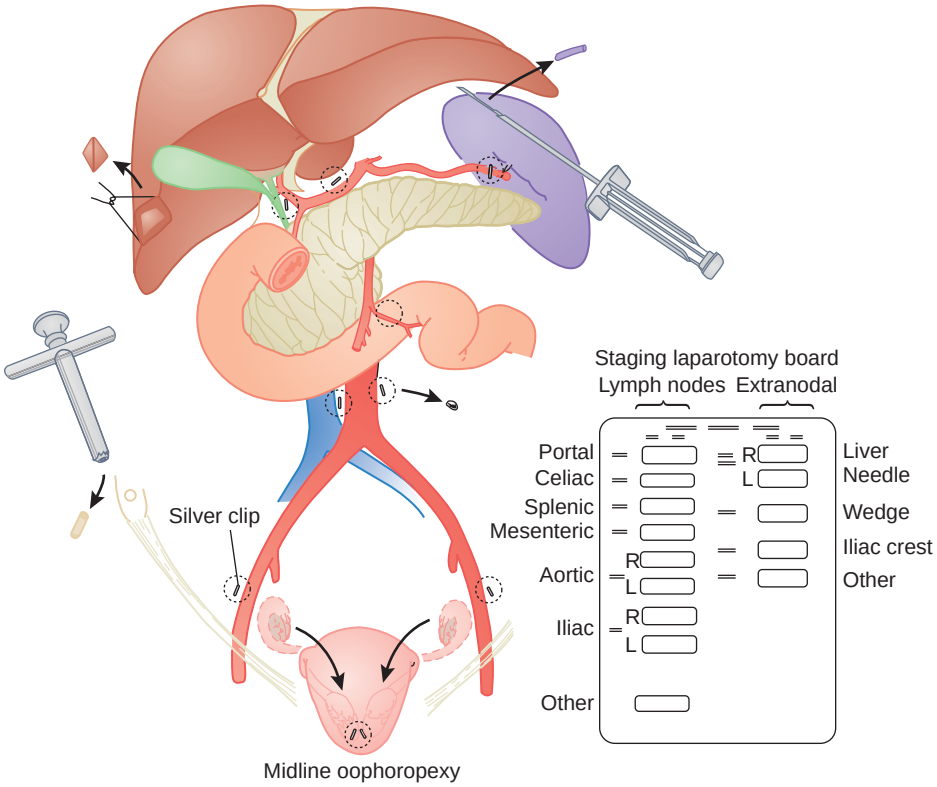

Figure 132–2. Components of a staging laparotomy for Hodgkin's lymphoma. These include splenectomy, bilobar liver biopsies (needle and wedge), and nodal sampling (including celiac, porta hepatitis, mesenteric, para-aortic, and iliac nodes). Oophoropexy to the midline is performed in women to exclude ovaries from the radiation field. Bone marrow biopsy may be performed as a part of the procedure. (From Martin JK: Staging laparotomy. In Donohue J, van Heerden J, Monson J [eds]: Atlas of Surgical Oncology. Cambridge, MA, Blackwell Science, 1995, p 150.)

Table 132–2 Hodgkin's Disease: Ann Arbor Classification with Cotswold Modification

		Modifying Features	
Classification Stage	**Description of Involvement**	*Classification Letter*	*Description*
I	1 lymph node/tissue (e.g., spleen, thymus, Waldeyer's ring)	A	No symptoms
II	≥2 lymph nodes/tissue, on same side of the diaphragm	B	Fever, night sweats, weight loss >10% in 6 mo
III	Lymph node/tissue, on opposite side of the diaphragm	X	Bulky disease
1	Splenic, celiac, portal nodes		
2	Para-aortic, iliac, mesenteric nodes		
IV	Extranodal sites	E	Involves single, contiguous, or proximal extranodal site

Currently, however, surgical staging plays only a limited role in HD because the use of radiation-only treatment regimens has decreased and accurate imaging and percutaneous biopsies are well developed. Current indication for surgical staging is limited to patients in whom acquisition of tissue is inadequate.

The components of staging laparotomy are summarized in Figure 132–2.[17,18,71] Exploration is performed through an upper midline incision and includes palpation of the liver, spleen, bowel, mesentery, and major nodal groups. Splenectomy is performed, with nodal clearance from the splenic hilum. The tied ends of the splenic vessels are marked with metal clips to guide postoperative radiation therapy. Both a wedge and core-needle biopsies are obtained from each lobe of the liver, plus a wedge biopsy of any abnormality. Finally, all abnormal nodes identified by preoperative lymphangiogram are removed. Systemic nodal biopsies then follow with celiac axis, hepatic artery, hepatoduodenal, bilateral para-aortic, and iliac nodes being sampled. All areas are marked with metal clips for future localization. Oophoropexy behind the uterus in the midline has been

Table 132–3 Experience with Splenectomy in NHL, Published Since 1990

NHL, non-Hodgkin's lymphoma; N/A, not available.

recommended for women of child-bearing age to exclude the ovaries from the radiation field. Operative complications (~10%) include small bowel obstruction, venous thrombosis, and subphrenic abscess.[18] Currently, staging laparoscopy is preferred over laparotomy. Adequate tissue biopsies, similar to those of traditional laparotomy, can be successfully obtained.[72] Laparoscopic ultrasonography may supplant digital palpation in doubtful areas. In experienced hands, staging laparoscopy can achieve an accuracy rate of 96% to 100% for primary or relapsed HD, without false-negative results[73,74] and lower complication rates. The reported rates of conversion to laparotomy range from 0 to 20%, mainly due to hemorrhage during splenectomy.[73]

Non-Hodgkin's Lymphoma NHL is a diverse group of more than 20 malignancies originating from B lymphocytes (~80%), T lymphocytes (~15%–20%), or natural killer cells (<5%). A specific NHL diagnosis requires histologic examination of lymphoid tissue plus flow cytometry and molecular marker studies. Patients with NHL frequently present with nonspecific symptoms of fever, night sweats, malaise, and weight loss. Peripheral lymphadenopathy is variably present and lymphatic spread is often noncontiguous. The spleen is involved in 30% to 40% of NHL patients.[74] Although NHL shares the same Ann Arbor staging system as HD, clinical staging is less crucial in NHL treatment because most patients present with advanced disease. There is no role for staging laparotomy in NHL because therapy is seldom redirected by staging information.[71]

There are three indications for splenectomy in NHL patients: (1) to correct hypersplenism and the resultant cytopenia(s), thereby allowing chemotherapy and/or independence from transfusions; (2) to relieve symptoms of splenomegaly from lymphocytic infiltration; and (3) debulking when the spleen is the main site of disease involvement, either as primary treatment or for residual disease. Operative mortality ranges between 0 and 3.5%, and reported operative morbidity is higher at 11% to 37% in studies published since 1990 (Table 132–3).[75-79] The most common severe complications are venous thrombosis and subphrenic abscess. A laparoscopic splenectomy is associated with reduced morbidity but requires technical expertise, particularly when splenomegaly is present.[79] Blood counts normalize in 72% to 89% of patient with NHL within the first postoperative month. A durable response is observed in a substantial proportion of patients (see Table 132–3). Finally, these potential benefits and risks of splenectomy must be balanced against the prognosis of the primary disease. The proposed World Health Organization classification system (Box 132–1)[80] categorizes subtypes of NHL by clinical behavior: Indolent subtypes have mean expected survivals measured in years, but aggressive subtypes generally have survivals measured only in months.

The spleen is the primary site of disease in several subtypes of NHL. Mantle cell lymphoma (MCL), an uncommon type, constitutes only 5% to 8% of NHL. Patients with MCL may have minimal adenopathy but prominent extranodal disease.[81] Up to 60% develop massive splenomegaly.[82] For patients with splenic-predominant MCL, splenectomy should be considered to palliate either or both hypersplenism and splenomegaly. Splenectomy may further benefit patients by stabilizing their disease, delaying the start of chemotherapy, and prolonging survival. A retrospective study of 26 patients[81] found that splenectomy is safe (no operative mortality and morbidity of 24%). Hypersplenism was corrected in 69% of patients with anemia, 90% with thrombocytopenia, and 50% for patients with both. In addition, 90% did not require chemotherapy until at least a year after splenectomy. The median survival is 5.5 years (typically 3 to 4 years), and splenectomy was the sole therapy in 15% of the patients.

The therapeutic role of splenectomy is more prominent in splenic marginal zone B-cell lymphoma (MZL). This primary lymphoma of the spleen comprises only 1% of NHL and is characterized by massive splenomegaly, lymphocytes with villous projections, anemia, thrombocytopenia, and mild monoclonal gammopathy.[83] Reversal of cytopenia occurs in 82% to 95% of patients following splenectomy,[83-87] with a median survival of 8.5 years[84,86] and 3-year survival of 82%[83] in patients with spleen-only MZL. These results suggest that they behave like those with localized stage I NHL. Longer overall survival correlated with prompt correction of cytopenia during the immediate postoperative period.[84] Splenectomy is a treatment of choice in patients with localized MZL.

Box 132–1 Proposed World Health Organization Classification of Lymphoid Neoplasms

Indolent Lymphomas

B-Cell Neoplasms

- Small lymphocytic lymphoma/B-cell chronic lymphocytic leukemia
- Lymphoplasmacytic lymphoma (± Waldenström's macroglobulinemia)
- Plasma cell myeloma/plasmacytoma
- Hairy cell leukemia
- Follicular lymphoma (grades I and II)
- Marginal zone B-cell lymphoma
- Mantle cell lymphoma

T-Cell Neoplasms

- T-cell large granular lymphocyte leukemia
- Mycosis fungoides
- T-cell prolymphocytic leukemia

Natural Killer Cell Neoplasms

- Natural killer cell large granular lymphocyte leukemia

Aggressive Lymphomas

B-Cell Neoplasms

- Follicular lymphoma (grade III)
- Diffuse large B-cell lymphoma

T-Cell Neoplasms

- Peripheral T-cell lymphoma
- Anaplastic large cell lymphoma, T/null cell

Highly Aggressive Lymphomas

B-Cell Neoplasms

- Burkitt's lymphoma
- Precursor B lymphoblastic leukemia/lymphoma

T-Cell Neoplasms

- Adult T-cell lymphoma/leukemia
- Precursor T-lymphoblastic leukemia/lymphoma

Table 132–4 Rai Classification of Chronic Lymphocytic Leukemia

Stage	Description
0	Lymphocytosis (WBC >150,000/ml, >40% lymphocytes in bone marrow)
I	Lymphocytosis and lymphadenopathy
II	Lymphocytosis and splenomegaly/hepatomegaly
III	Lymphocytosis and anemia (hemoglobin <11 g/dl)
IV	Lymphocytosis, lymphadenopathy, anemia, and thrombocytopenia (platelet <100,000/ml)

WBC, white blood cell count.

Leukemias Leukemia is hallmarked by a malignant clonal proliferation of hematopoietic stem cells. For patients with acute lymphocytic or acute myelogenous leukemia, there is consensus that splenectomy plays no role except for splenic rupture with hemorrhage.[18] For patients with chronic forms of leukemia, splenectomy may be indicated to palliate symptoms of splenomegaly or cytopenias. The survival benefit of splenectomy in patients with leukemia remains controversial.

CLL is the most common chronic leukemia. CLL is characterized by the accumulation of morphologically normal but functionally incompetent B lymphocytes. Patients follow either an indolent course requiring no therapy or an accelerated course with severe symptoms that require intervention.[88] CLL patients present with painless lymphadenopathy alone or with additional features including splenomegaly, cytopenia, and constitutional symptoms, as defined by the Rai classification (Table 132–4). Patients with stage 0 disease require no therapy, but selected patients with stages I and II disease and all patients with stage III and IV disease should receive chemotherapy, typically fludarabine.[71] Although cytopenia in CLL may result from bone marrow failure, hypersplenism, autoimmune destruction, chemotherapy, or any combination,[89] splenectomy is an efficacious method of reversing cytopenia (Table 132–5). A durable response of cytopenia in CLL is observed in at least 80% of patients, with higher response rates when splenectomy is performed for thrombocytopenia rather than for anemia.[82,89-94] However, no predicative factor of a hematologic response to splenectomy has been consistently identified.[90] The overall survival is longer in patients with a hematologic response than those who fail to respond,[90,94,95] but the survival benefit of splenectomy in patients with advanced CLL remains controversial. No significant difference in survival was observed in a case-matched study,[94] though in subgroup analysis of patients with severe anemia (hemoglobin <10 g/dl) or thrombocytopenia (platelet count $<50 \times 10^9$/L), splenectomy did significantly prolong median survival (19 versus 10 months and 17 versus 4 months, respectively). These results suggest that splenectomy should be considered

Table 132–5 Experiences with Splenectomy for Chronic Lymphocytic Leukemia, Published Since 1990

for all CLL patients with cytopenia, particularly those with severe anemia or thrombocytopenia.

Chronic myelogenous leukemia (CML) consists of a chronic benign phase followed by an acute blast transformation phase. Patients usually present during the chronic phase with systemic symptoms, splenomegaly, leukocytosis, and cytopenias. Chromosomal translocation t(9;22) (i.e., Philadelphia chromosome) is present in 90% of the CML patients; and treatment efficacy is monitored by decreased expression of the abnormal chromosome.[71] Therapeutic options in CML include chemotherapy (e.g., hydroxyurea or busulfan), interferon-α, and bone marrow transplant.[18] Splenectomy is used only for palliation of refractory cytopenia or painful splenomegaly. Splenectomy does not seem to increase survival or delay the onset of the acute blastic transformation. Acute blastic crisis, hallmarked by prolonged fever of unknown origin, leukocytosis, thrombocytopenia, and greater than 30% blasts in peripheral circulation, carries a grim prognosis, with mean survival measured in months. Splenectomy is contraindicated during the acute phase. However, when necessary for emergency indications, a low 30-day mortality rate of 3.5% can be achieved.[96] Additionally, splenectomy does not have an adverse impact on the incidence of infections, graft versus host disease, or overall survival if a bone marrow transplant is performed after splenectomy.[97]

Hairy cell leukemia (HCL) comprises 2% to 5% of leukemias and is a chronic B-lymphocyte disorder characterized by peripheral cytopenia and massive splenomegaly. The malignant cells have hairlike projections and accumulate mainly in the red pulp of the spleen but can be identified elsewhere by their positive tartrate-resistant acid phosphatase staining.[95] Cytopenia in HCL may result from hypersplenism, bone marrow failure, or other reasons. Prior to 1990, splenectomy was the only known effective therapy for HCL. Cytopenia improved after splenectomy in 60% to 100%,[95] and a survival benefit may even occur.[98] In the early 1990s, interferon-α was shown to be superior to splenectomy for cytopenia in a randomized trial.[98] Currently, medical therapies of interferon-α and purine analogues are efficacious. The indications for splenectomy in HCL are, therefore, limited to those patients with an uncertain diagnosis, emergency splenic rupture, severe splenomegaly with symptomatic cytopenia, or disease refractory to chemotherapy. Resection of residual splenic disease after interferon therapy may prolong progression-free survival.[98] However, the contemporary experience with splenectomy for HCL is limited.

Myeloproliferative Disorders

Chronic myeloproliferative disorders are marked by abnormal clonal proliferation of hematopoietic stem cells. Myelofibrosis with myeloid metaplasia (MMM) occurs when bone marrow develops a fibrotic reaction to the stem cell disease and can be divided into agnogenic (AMM), post-thrombocythemic (PTMM), and postpolycythemic (PPMM) types. PTMM and PPMM are preceded by essential thrombocythemia and polycythemic rubra vera, respectively, and splenectomy generally does not benefit these patients.[18,99,100] AMM is characterized by peripheral cytopenia and progressive extramedullary hematopoiesis in the spleen and the liver. Associated features include painful splenomegaly, increased portal blood flow, portal hypertension from venous thrombosis (~7%),[101] and cytopenia from splenic sequestration. The prognosis of AMM is poor, with a median survival ranging from 3 to 5 years. Nonoperative therapy has been limited.

Bone marrow transplant is frequently not an option for elderly AMM patients. Transfusions, androgens, corticosteroids, and interferon-α are largely palliative, and splenic irradiation is only transiently effective. Therefore, splenectomy should be considered in symptomatic patients. Symptomatic splenomegaly, constitutional symptoms, and portal hypertension improve in 100%, 67%, and 50% of the respective patients at 1 year postsplenectomy. Among those patients with transfusion-dependent anemia, 30% remain independent of transfusions for 6 months. No benefit for splenectomy is seen with thrombocytopenic patients.[102] Despite potential benefits, splenectomy in this patient population is a high-risk procedure.[99] Prior to 1940, operative mortality was prohibitively high at 40%. Currently, it ranges from 8% to 11%, with postoperative morbidity ranging from 31% to 40%.[102-105] Hemorrhage, infection, and thrombosis are the most common nonfatal complications. Several complications characteristic of this patient population have also been described.[102] Progressive hepatomegaly develops in 12% to 29% of the patients after splenectomy; as extramedullary hematopoiesis increases in the liver, 7% develops fatal hepatic liver failure. Severe thrombocytosis affects 18% to 50% of AMM patients after splenectomy, particularly if the preoperative platelet count is greater than 50×10^9/L. Postsplenectomy leukemic transformation occurs in 11.2% to 20% of patients and manifests as an accumulation of blasts in the bone marrow and periphery.[99] Whether postsplenectomy blast transformation affects overall patient survival remains controversial[99,100,102,106] and should not deter the surgeon from performing an otherwise appropriate splenectomy. The median overall postsplenectomy survival is 2.3 years.[102] The main causes of death include infection, thrombosis, bleeding, and acute leukemia. Current indications for splenectomy in patients with AMM remain palliative and include severe constitutional symptoms, mechanical symptoms of splenomegaly, portal hypertension complicated by ascites and variceal hemorrhage, and transfusion-dependent anemia.[99]

SPLENECTOMY FOR TUMORS, CYSTS, AND ABSCESSES

Tumors

Splenic masses are usually discovered incidentally. They present for surgical intervention with an unknown diagnosis, when the spleen ruptures, or when symptoms develop from their large size or associated hypersplenism.

The most common cause of a malignant splenic mass is metastasis from a primary carcinoma. Splenic metastases are present in 7% of patients dying from cancers of the breast, lung, ovary, stomach, and prostate.[18] Melanoma and other skin cancers also spread to the spleen. When the spleen is the only site of metastasis, splenectomy may prolong patient survival.

Primary, nonlymphatic, malignant tumors of the spleen include angiosarcoma, hemangioendothelioma, and malignant fibrous histiocytoma. Angiosarcoma is the most common of these rare tumors. Patients present at a median age of 60 years, with abdominal pain, splenomegaly, and microangiopathic hemolytic anemia. The tumors appear as well-circumscribed nodules with central necrosis or hemorrhage. The prognosis for angiosarcoma patients is dismal. Eighty-nine percent of patients die of metastatic disease, with a median survival of 5 months.[107] Splenectomy is indicated for palliation and for splenic rupture, which may occur in 25% of patients. The rarity of the disease has hindered identification of risk factors, but exposure to thorium dioxide (Thorotrast), vinyl chloride, and anabolic steroids has been implicated in isolated reports.[107]

Benign tumors of the spleen are uncommon and include hamartoma, inflammatory pseudotumor, and vascular lesions (hemangioma, lymphangioma, peliosis). Hemangiomas are the most common benign splenic lesions and arise from the red pulp of the spleen. They can become very large, with prominent cystic components. Nonexpanding and asymptomatic hemangiomas less than 4 cm are safely observed.[108] Splenectomy may be considered to prevent or treat complications such as hypersplenism and splenomegaly. Peliosis of the spleen occurs alone or in association with peliosis of the liver. It occurs more frequently in men and is the result of the ingestion of androgens or oral contraceptives or accompanies chronic debilitation from tuberculosis, diabetes, or a neoplasm.[18] Complications of peliosis include thrombosis and fatal hemorrhage from splenic rupture. Splenectomy is indicated when peliosis is incidentally discovered. Splenic hamartomas as large as 2 kg have been reported and require surgical intervention for diagnosis. Inflammatory pseudotumors are a poorly understood entity. Patients present with fever, night sweats, and weight loss. These tumors must be distinguished from malignant lymphoma by immunohistologic studies, making splenectomy necessary for diagnosis in many patients. Additional rare benign splenic lesions include Littoral cell angioma, hemangioendothelioma, and angiomyolipoma.

Cysts

Parasitic Cysts

Echinococcus cysts are common in endemic areas but rare in the United States. Humans serve as intermediate hosts after ingestion of food contaminated with feces laden with tapeworm eggs. Hydatid cysts most commonly develop in the liver and the lungs; their daughter cysts contain multiplying larvae called *scolices*. Cysts of *Echinococcus granulosus* are unilocular, but those of *Echinococcus multilocularis* and *Echinococcus volegi* are multilocular.[13] Intervention should be considered when disease is refractory to the antiparasitic drug albendazole or when cysts become large enough to risk rupture. Cystectomy or splenectomy should be performed with care to avoid cyst rupture or leakage. Anaphylaxis and disseminated scolices infection are serious operative complications. Administration of albendazole and instillation of hypertonic saline or ethanol prior to cyst manipulation have been advocated to decrease these risks.[13]

Nonparasitic Cysts

Nonparasitic splenic cysts were previously classified as true cysts (~20%) or pseudocysts (~80%) based on the presence or absence of an epithelial lining. True cysts may be epidermoid or, less commonly, dermoid in origin, resulting from splenic inclusion of embryonic tissue. They may also be associated with benign splenic hemangiomas or lymphangiomas. Pseudocysts are typically associated with antecedent splenic trauma or splenic infarction.[18] Splenic infarction occurs with hematologic disorders (most commonly sickle cell disease) in younger patients or with arterial emboli (the most common cause is atrial fibrillation) in patients older than 40 years.[109] Recently, however, the reliability of identifying the cyst lining has been questioned. A newly proposed system classifies cysts based on causes into congenital, neoplastic, true traumatic, and degenerative cysts.[110]

Intervention is not necessary for asymptomatic, small (<5 cm) splenic cysts that have imaging characteristics of a benign cyst, namely a smooth, regular cyst wall, with no solid component within the cyst interior or wall, either with or without calcification.[110] Total splenectomy is typically considered for patients with low operative risk who develop pain or early satiety due to their splenic cysts. Recently developed minimally invasive treatment options include cyst aspiration with sclerosis using alcohol or tetracycline, cyst marsupialization, and local cyst resection with or without a portion of the cyst wall contiguous with splenic parenchyma. However, their use is limited by the risks of cyst recurrence. Laparoscopic or partial splenectomy is now the preferred treatment because of their low complication and cyst recurrence rates.[111]

Abscesses

Although splenic abscess remains a rare entity, it is uniformly fatal if unrecognized or untreated. With an increasing incidence of immunosuppressive diseases and medications, splenic abscesses have become more common.[112] A high index of suspicion is required for timely diagnosis and favorable outcome.[113] Patients able to mount an immune response present with the triad of fever, leukocytosis, and left upper quadrant pain.[114] Chest or abdominal radiographs often show a left-sided pleural effusion, elevated hemidiaphragm, left upper quadrant mass, and extraluminal air. A CT scan has a sensitivity of 96% and is the imaging modality of choice. A splenic abscess typically has a thick, irregular rim with a hypodense center, but multiple or miliary abscesses may be difficult to identify.

Splenic abscesses are classified by their cause.[13,112] The must common cause is primary hematogenous seeding from a distant septic source (common sources include bacterial endocarditis associated with valvular disease, intravenous drug use, bacteremia, and intra-abdominal sepsis postoperatively or primary infection). The most commonly responsible organisms are *Streptococcus* and *Staphylococcus* species, but *Salmonella* species, gram-negative *E. coli,* and *Enterococcus* species, as well as fungal infections also cause splenic abscesses.[115] Although most splenic abscesses are solitary, multiple abscesses more frequently develop from hematogenous spread.[114] Secondary infection of splenic infarction is another cause of splenic abscess. Patients with an architecturally or functionally abnormal spleen are most susceptible to this type of infection. Common associated conditions include sickle cell anemia, lymphoproliferative and myeloproliferative diseases, trauma, and systemic arterial embolic events. Patients with sickle cell anemia characteristically develop splenic abscesses with *Salmonella* species. The direct extension of a local septic focus may also result in a splenic abscess. The infections may originate from a gastric, colonic, pancreatic, or perinephric source. Post-traumatic splenic abscesses occur after conservative management of splenic trauma or an iatrogenic intraoperative injury. Immunocompromised host accounts for up to 35% of patients with splenic abscesses. Associated conditions include malignancy, organ transplantation, chronic steroid use, and HIV/AIDS.

The treatment of choice for splenic abscess consists of broad-spectrum antibiotics, splenectomy, and drainage of the left upper quadrant.[113] Excellent outcome is usually expected. In critically ill patients who are unable to tolerate a surgical procedure, image-guided drainage should be attempted. When the abscess is discrete, unilocular, and filled with thin fluid, the success rate is as high as 51%.[112] Occasionally, dense inflammatory adhesions preclude splenectomy, leaving splenotomy or surgical drainage as the only surgical options. In this setting, delayed splenectomy is necessary since intravenous antibiotics alone are almost never sufficient treatment for a splenic abscess.[114] Mortality from splenic abscess remains substantial and ranges from 0 to 24%. Poor outcome occurs with immunocompromised patients, delayed diagnosis, and postponed operative intervention.[112,113]

SPLENECTOMY FOR VASCULAR DISORDERS

Splenic Artery Aneurysm

Splenic artery aneurysm (SAA) constitutes 60% of all visceral arterial aneurysms and is the third most common abdominal aneurysm after aortic and iliac artery aneurysms. The typical patient with SAA is a multiparous woman (in a series of 87 women, the average number of pregnancies per patient was 4.5).[116] Other associated conditions include portal hypertension, congenital vascular or connective tissue diseases, and trauma. SAA presents (1) after rupture with hemodynamic instability; (2) as a symptomatic mass; or (3) as an incidental finding. Rupture occurs most commonly in the third trimester of pregnancy and may be forewarned by a sentinel hemorrhage in 20% to 30% of patients.[117] In pregnant patients, the mortality rate after rupture is 70% and 100% for the mother and the fetus, respectively[118]; in nonpregnant patients, the mortality rate is 25%.[18] As soon as rupture is suspected, prompt resuscitation, emergent splenectomy, and resection of the aneurysm are indicated. For all symptomatic aneurysms, surgical intervention is indicated. For incidental and asymptomatic aneurysms, an

operation is indicated only if the SAA is longer than 2.5 cm in diameter or if the patient is pregnant or of child-bearing potential.[18,119] Operative treatment differs by location of the SAA. Proximal aneurysms are excised after proximal and distal ligations. Mid-splenic aneurysms are excluded by proximal and distal ligations of the splenic artery and all collateral vessels. The spleen can be preserved by blood flow via the short gastric arteries. Distal or hilar aneurysms are the most common and are treated with aneurysmectomy and splenectomy.[116,118,120] For patients unable to tolerate an operation, transcatheter embolization can be successful. However, it causes splenic infarction and has the risks of distant embolization, arterial disruption, and arterial recanalization with potential for future rupture.[117,119] Laparoscopic ligation and splenectomy have also been reported. The optimal approach to elective treatment of SAA depends on patient variables and physician expertise.

Splenic Venous Thrombosis

Splenic venous thrombosis (SVT) complicates acute pancreatitis and pancreatic neoplasms in 7 to 20% of patients. Nonpancreatic diseases, including primary retroperitoneal fibrosis, peptic ulcer disease, and a hypercoagulable state, may also be associated with SVT.[121] It results in a localized form of portal hypertension termed *sinistral portal hypertension*.[122] Collateral flow through the short gastric vessels leads to engorgement of submucosal veins of the gastric fundus or gastric varices. Esophageal varices may arise when the left gastric vein is also occluded by the thrombus and fails to decompress localized portal hypertension. The diagnosis of SVT should be suspected in patients with upper gastrointestinal hemorrhage following pancreatitis, in patients with splenomegaly but no hepatic or hematological disease, and when isolated gastric varices are noted on upper endoscopy. Ultrasonography, CT scan, and visceral angiography all can confirm the diagnosis. In patients presenting with hemorrhage, urgent splenectomy is indicated. The operative bleeding risk is substantial given the perigastric varices and inflammation. To reduce this risk, some surgeons advocate preoperative embolization of the splenic artery.[122] In unstable patients or those not fit for an operation, endoscopic variceal sclerotherapy or banding may be performed but are usually ineffective.[123]

Splenic artery embolization does not provide a definitive cure but should be attempted. In asymptomatic patients with SVT, the indication for splenectomy is controversial. Prophylactic splenectomy used to be uniformly recommended, because up to 51% of asymptomatic patients with SVT were thought to develop acute variceal bleeding.[124] Recent studies found that the natural history of gastric varices is more benign, with a 4% to 18% prevalence of clinical hemorrhage.[122,124] Expectant management, initially advocated by Loftus et al.,[125] has been more widely adopted. Prophylactic splenectomy should be considered for patients who are noncompliant, those undergoing an abdominal operation for another cause, or for patients who possess endoscopic features such as "red wale markings" indicating high risk for bleeding.[122,123]

Portal Hypertension

Patients with portal hypertension often develop thrombocytopenia from platelet sequestration in the splenic sinusoids.[18] Splenectomy may be considered in conjunction with other devascularization or stenting procedures when the bleeding risk from thrombocytopenia is excessive, when medical therapy cannot be administered, or when the varices are resistant to nonoperative management.[126] Portal hypertension is not an absolute contraindication to laparoscopic splenectomy, but a 9.6% conversion rate and 11% morbidity rate have been reported in this setting.[126]

"Wandering Spleen" and Splenic Torsion

A "wandering spleen" occurs when the spleen is attached only by a long, loose vascular pedicle without the usual peritoneal attachments. The spleen may be ectopic on imaging studies. Two main patient populations are affected. Wandering spleens in children arise from congenital atresia of the dorsal mesogastrium. When found in women between 20 and 40 years of age, wandering spleens result from an acquired tissue laxity associated with pregnancy.[127] The condition is complicated by acute torsion around the vascular pedicle, which manifests with acute abdominal pain, fever, vomiting, acute pancreatitis, and gastric compression. Without detorsion, splenic infarction and gangrene ensue. Chronic torsion typically causes venous congestion and splenomegaly. In children without splenic infarction, the procedure of choice is splenopexy, suturing the spleen to the diaphragm, abdominal wall, or omentum.[128] Traditionally performed as an open procedure, laparoscopic splenopexy has been recently reported.[129] Splenopexy allows for splenic preservation, but the long-term results are unknown. For adults, splenectomy is the preferred therapy.

SPLENECTOMY FOR IATROGENIC INJURY

An iatrogenic splenic injury is an unintentional injury caused by the operator during either an interventional radiologic or surgical procedure. The surgical operation most commonly associated with iatrogenic splenic injury include distal esophageal or gastric procedures, colon surgery, left nephrectomy, and upper abdominal vascular procedures.[18] Risk factors for iatrogenic injury include a prior left upper quadrant operation, malignant or inflammatory diseases, and obese body habitus.[130] The spleen, when tethered by its normal peritoneal ligaments plus additional dense adhesions, becomes prone to injury through inappropriate traction, retractor placement, or instrumentation.

When an iatrogenic splenic injury occurs, exposure to the left upper quadrant should be optimized, blood and clots are gently removed, and severe bleeding is temporized by pressure on the splenic artery at the superior pancreatic margin. Limited splenic capsular tears may not require any treatment or can usually be salvaged by electrocautery, argon beam coagulation, or hemostatic

agents such as fibrin adhesive, thrombin-soaked Gelfoam, and microfibrillar collagen. Deeper lacerations may be salvaged with argon beam coagulation, mattress sutures in the fibrous capsule with or without pledgets, wrapping the spleen in an absorbent mesh, or segmental splenectomy. In patients with severe (>grade 4) splenic injury or hemodynamic instability or in those requiring postoperative anticoagulation, total splenectomy is indicated. Splenectomy for iatrogenic injury prolongs hospital stay and increases morbidity from 0 to 32% to 16% to 84% in various series.[130] Whether incidental splenectomy compromises immune function and decreases survival in cancer patients is uncertain. The incidence of sepsis is low after unplanned splenectomy in adults: 1 per 545 adult years.[130] Measures to prevent iatrogenic injury include placement of the incision to maximize exposure, gentle retraction, careful medial or downward traction of the peritoneal ligaments, and manipulation of stomach and colon only after dividing splenic ligaments and other perisplenic adhesions.[130]

SPLENECTOMY FOR MISCELLANEOUS DISORDERS

Gaucher's disease is an inherited metabolic disorder manifesting with anemia, thrombocytopenia, hepatosplenomegaly, and bone dysplasia. The genetic deficiency in lysosomal glucocerebrosidase leads to accumulation of glucosyl ceramide-laden macrophages in the reticuloendothelial cells of the liver, bone, and spleen. Enzyme replacement therapy (alglucerase or imiglucerase) effectively ameliorates symptoms of Gaucher's disease.[131] Splenectomy is reserved for patients with compressive symptoms from massive splenomegaly or refractory cytopenia. The largest series to date reports operative mortality of 2.1% and morbidity of 27%.[132] In children with Gaucher's disease, partial splenectomy or another spleen-preserving technique is advocated.

Splenomegaly complicates 6% of patients with sarcoidosis and is associated with anemia, neutropenia, or pancytopenia. Most patients have mild and asymptomatic splenomegaly and do not require treatment. Splenectomy is considered for massive or painful splenomegaly, refractory hypersplenism, need to exclude lymphoma or other malignancy, and prophylaxis against splenic rupture. Outcome of splenectomy for sarcoidosis is favorable in isolated case reports.[133]

Amyloidosis is a systemic infiltrative disease. Splenic rupture occurs as amyloid deposits distend the capsule and increase vascular fragility.[134] Emergent splenectomy may be necessary for splenic rupture.

OPERATIVE CONSIDERATIONS FOR SPLENECTOMY

Preoperative Preparation

The indication for splenectomy, the underlying disease, and the patient's comorbidities, hematologic status and previous therapy, must be clearly reviewed.

Vaccinations are indicated whenever splenectomy or impaired splenic function is anticipated. They should be administered at least 2 weeks prior to splenectomy because the vaccine immunogenicity may be reduced if given after the splenectomy.[135] Pneumococcal vaccine is indicated for all patients; meningococcal and *Hemophilus influenzae* vaccinations are added for younger patients and those not previously immunized. The normal host defense against these encapsulated species involves antipolysaccharide antibodies and opsonization. Splenectomy renders both processes deficient and the patient more susceptible without vaccination. If the splenectomy is emergent and preoperative vaccination is precluded, postoperative administration is necessary.

Patients' hematologic reserve and the operative risks must be considered. The need for blood component transfusion is anticipated. Laboratory tests (e.g., crossmatch) are performed and appropriate blood components reserved. One unit of platelets usually elevates the platelet count by 5×10^9/L, whereas 1 unit of erythrocytes elevates hemoglobin by 1 g/dl. In selected high-risk patients with severe thrombocytopenia (platelet count $<20 \times 10^9$/L), transfusion of 6 units of platelets may be considered prior to anesthetic induction to reduce the risk of laryngeal hematoma during endotracheal intubation. Preoperative platelet transfusion should be avoided in patients with ITP because transfused platelets will not survive splenic circulation until the splenic vessels are ligated.[18] In patients with portal hypertension and massive splenomegaly, preoperative splenic artery embolization can be performed to reduce the bleeding risk. However, its potential benefit must be balanced against the risk for pancreatitis, splenic abscess from infarction, hematoma formation, and pain.

Immediately prior to splenectomy, several medications are administered in the operating room. Patients on chronic steroid therapy should receive a bolus of exogenous steroid for operative stress. Prophylactic antibiotics are indicated in immunocompromised patients or when the gastrointestinal tract may be opened. In patients prone to thrombosis (e.g., myeloproliferative disorders), administration of low-dose heparin (5000 IU subcutaneously three times daily) or antiplatelet agent (e.g., aspirin) may be beneficial.[136]

Operative Considerations

Splenectomy can be performed via the open, hand-assisted, or totally laparoscopic approach. This chapter focuses on techniques of open splenectomy, whereas the latter two approaches are discussed in Chapter 127.

The most commonly used surgical incisions for open splenectomy are the left subcostal and the midline incisions. The latter is preferred for patients with narrow costal arches or with marked splenomegaly. A left thoracoabdominal incision with a midline vertical extension has been described but is rarely needed.[136] Most surgeons prefer gastric decompression via an orogastric or nasogastric tube.

The initial steps of splenectomy generally involve mobilizing the spleen. The stomach and the spleen are

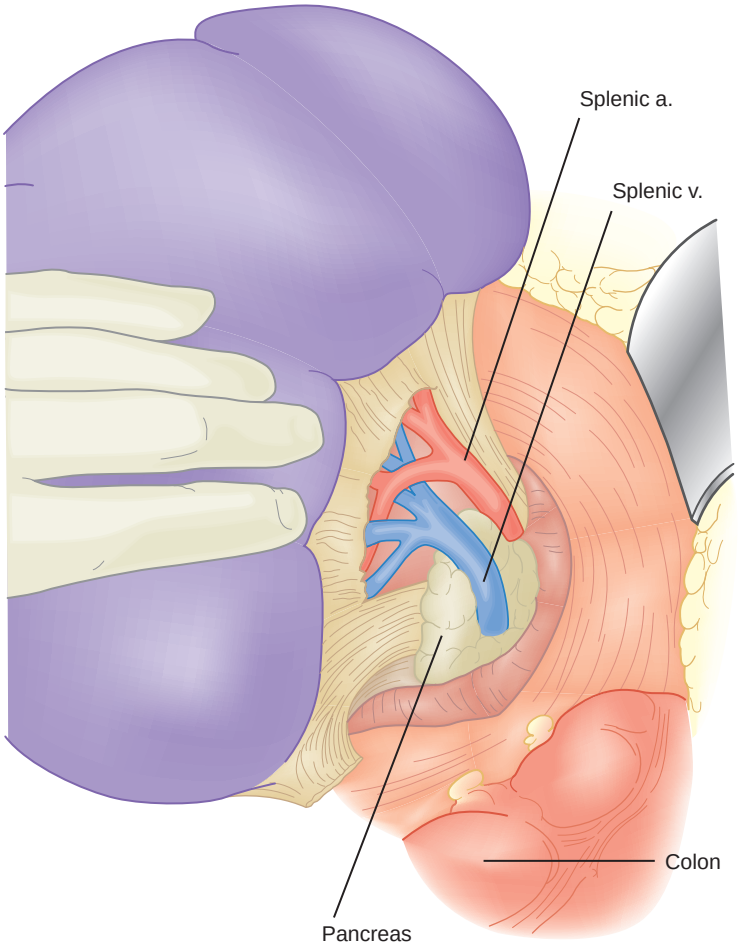

Figure 132–3. Mobilization of the spleen from its peritoneal ligamentous attachments. (From Scott-Conner CEH: Chassin's Operative Strategy in General Surgery: An Expositive Atlas. Stamford, NY, Springer, 2002, p 736.)

retracted medially to expose the splenophrenic and splenorenal ligaments. Unless venous varices are present, the ligaments are avascular and can be divided by blunt or sharp dissection. After the spleen is freed from its posterior attachments to the diaphragm and Gerota's fascia, the splenocolic ligament is divided, releasing the splenic flexure and the omentum from the inferior splenic pole. The spleen can then be lifted into the abdominal incision (Fig. 132–3). This maneuver should not be performed with excessive force, to avoid a capsular tear or avulsion of the splenic vessels. The splenogastric ligament is incised with identification, division, and ligation of the short gastric vessels. Suture ligation of these vessels on the gastric wall has been advocated by some surgeons to prevent postoperative loosening of the ligatures if the stomach becomes distended. At this point, the spleen is attached only by the hilar vessels.

An alternative approach to splenectomy involves control of the splenic vessels at the hilum as the initial step. The gastrocolic omentum is opened outside the gastroepiploic arcade (Fig. 132–4A). The splenic artery is palpated along the superior border of the pancreas. Dissection of the vessels should be carried out close to the splenic hilum to avoid injury to the tail of the pancreas (see Fig. 132–4B to D). The splenic artery and vein may be divided together; however, separate division is preferable to prevent the formation of an arteriovenous fistula. The splenic artery should be controlled by double ligation and suture ligature. The splenic vein is divided after double ligation; a continuous vascular suture or a vascular stapler is used when the vein is substantially enlarged. This approach of initial vascular control may be particularly suitable in the presence of massive splenomegaly, marked hilar lymphadenopathy, or dense perisplenic adhesions. It has also been advocated for ITP, where early ligation of the vessels allows earlier administration of platelet transfusion. Similarly, it may be preferred for splenic malignancies, because it can prevent inadvertent tearing of the vessels during splenic mobilization and spillage of malignant cells.

When a partial splenectomy is considered, branches of the vasculature are identified before they enter the spleen and ligated separately. Once the plane of vascular demarcation is recognized and marked, transection of the splenic parenchyma should be performed with total hilar occlusion to reduce hemorrhage at the surface. Moreover, placement of pledgets under through-and-through sutures during inflow occlusion reduces hemorrhage related to partial splenectomy.

After removal of the spleen for hematologic diseases, the abdomen should be explored for accessory splenic tissues at their common locations (see Fig. 132–1).

Prior to closure, hemostasis of the left upper quadrant should be ascertained by inspection of the inferior

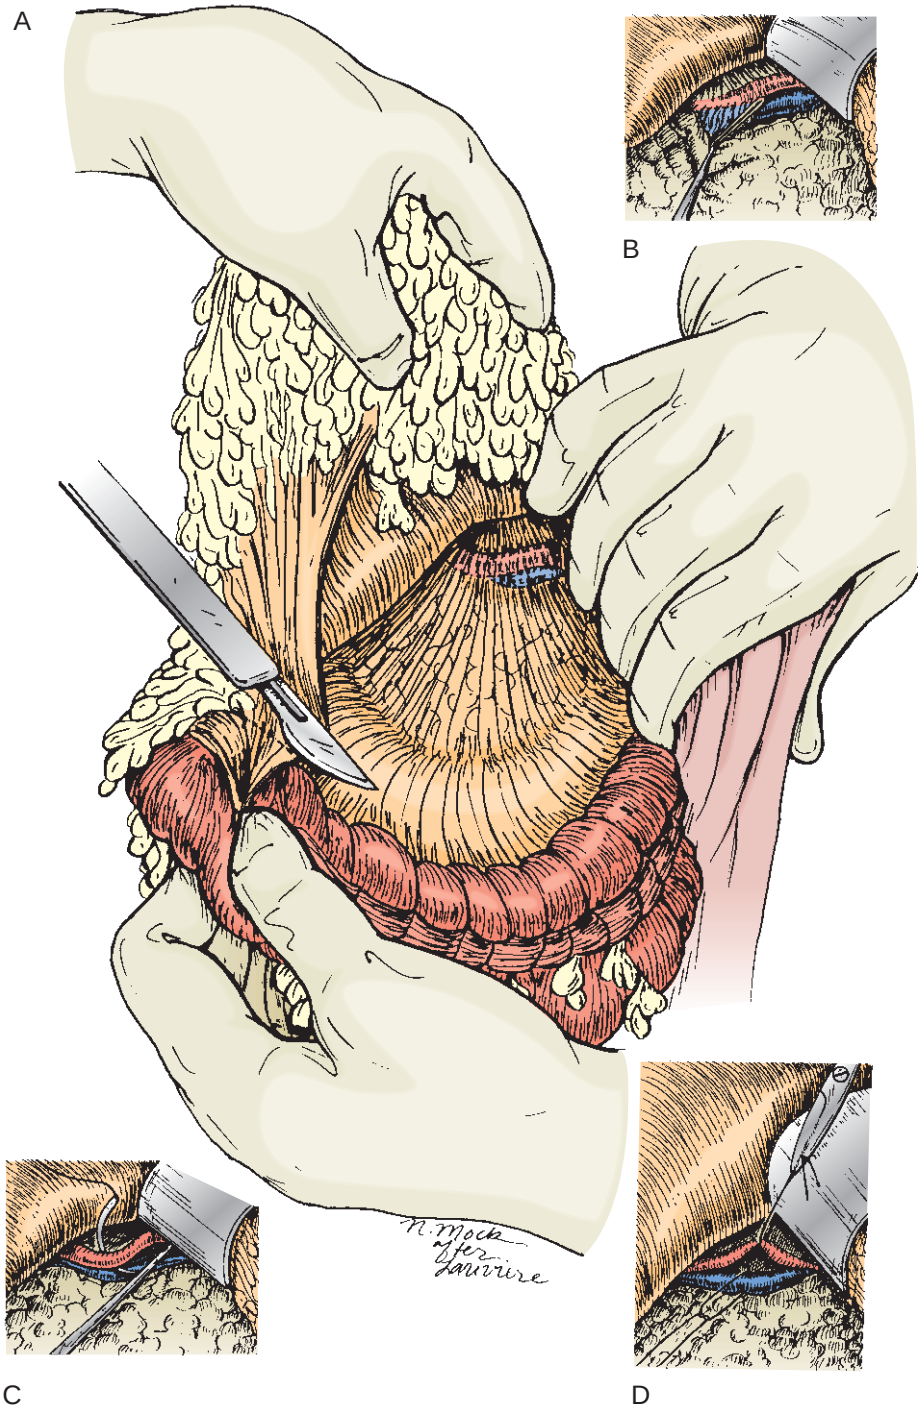

Figure 132–4. Approach to the splenic hilum through the lesser sac **(A)**. Splenic vessels are identified **(B)** and controlled **(C** and **D)** along the superior border of the pancreas. (From Schwartz S: The spleen. In Zinner MJ, Schwartz SI, Ellis H [eds]: Maingot's Abdominal Operations. Stanford, CT: Appleton & Lange, 1997, p 2058.)

surface of the diaphragm, the left cephalad retroperitoneum, the greater curvature of the stomach, and the splenic hilum. The left upper quadrant may be packed to promote hemostasis. The greater curvature of the stomach should be imbricated with interrupted Lembert sutures if any serosal damage is present to prevent a gastric fistula. Closed-suction drainage of the left upper quadrant is not indicated unless injury to the tail of the pancreas is suspected or encountered.

Postoperative Course and Complications

The highest rate of postoperative complications is anticipated in patients with massive splenomegaly (splenic weight >1500 mg) or myeloproliferative diseases, where a morbidity of up to 52% has been reported. [137,138]

All patients are closely monitored during the early postoperative period for hemorrhage. Immediate postoperative bleeding most commonly arises from an

unligated short gastric vessel high on the greater curvature or from small veins around the tail of the pancreas. When indicated by a fall in hemoglobin and signs of hypovolemia, exploration should be performed promptly. Another common complication, pulmonary atelectasis, can be prevented with adequate pain control and incentive spirometry. A subphrenic abscess occurs rarely but may develop with poor hemostasis and clot formation in the splenic bed or when the gastrointestinal tract is opened. Percutaneous or operative drainage plus parenteral antibiotics are required. A gastric or pancreatic fistula occurs in less than 1% of the patients and is associated with iatrogenic injury to these organs.

Leukocytosis occurs as a physiologic response to splenectomy. It may be difficult to distinguish from a septic state. Traumatic splenectomy patients with white blood counts greater than 20×10^9/L after postoperative day 10 are more likely to be septic,[139] but leukocytosis after splenectomy for nontraumatic indications has not been investigated. Similarly, reactive thrombocytosis may occur immediately postsplenectomy, with the platelets peaking at 2 to 3 weeks postoperatively. In the absence of hemostatic or vascular complications, no therapy is indicated for secondary thrombocytosis.

Venous thrombosis involving the mesenteric and portal veins is a serious complication after splenectomy. The incidence of clot formation may be as high as 50% if all patients are screened, but only 8% of these are symptomatic. Predisposing factors include myeloproliferative disease or hemolytic anemia, postoperative thrombocytosis, previously undiagnosed systemic hypercoagulable state, and a long splenic vein stump.[140] Laparoscopic splenectomy may be associated with a higher incidence of portal and splenic vein thrombosis than the open technique (55% vs. 12% in one retrospective series[141]). Patients usually present within 10 days of splenectomy with vague symptoms including generalized abdominal pain and distention, fever, nausea, and anorexia. The diagnosis is best obtained by contrast-enhanced abdominal CT, MR imaging, or ultrasonography, systemic anticoagulation is initiated promptly and maintained for 6 months. Recannulation occurs in 90% of those on appropriate anticoagulation.[142]

All asplenic patients are at risk for OPSS. The incidence of OPSS ranges between 1% and 2.4% and is fatal in 45% to 75% of patients. The elevated risk of mortality is life-long.[47] Any febrile asplenic patient must be promptly evaluated and initiated on a broad-spectrum antibiotic regimen such as a third-generation cephalosporin.[135] Measures to prevent OPSS include vaccination and prophylactic antibiotics.[143] Preoperative vaccination is preferred. When the vaccines are administered postoperatively, they are conventionally given on the day of dismissal to avoid confusing febrile reactions to the vaccine with a postoperative complication. In the absence of established guidelines, repeat vaccination should be considered every 5 years. Prophylactic antibiotics, particularly advocated for children, include two commonly used strategies. First, a daily prophylactic antibiotic is given to asplenic children (<5 years old) for the first 2 years after splenectomy. The traditional regimen has been a single daily dose of penicillin, amoxicillin, or erythromycin. Recently, antibiotics with broader spectrum, including amoxicillin/clavulanic acid, cefuroxime, and trimethoprim/sulfamethoxazole, have been used. Prophylactic antibiotics can reduce the infection rate by 47% and mortality rate by 88%.[144] Concerns of increasing pneumococcal resistance and patient noncompliance have recently brought this practice into question. Alternatively, asplenic adults are given a supply of "standby" antibiotics to be started if symptoms of infection develop. It should be emphasized that such patients should still seek medical attention. All patients and caretakers should be educated regarding OPSS. Documentation of patient's asplenic state and vaccination status should be issued, along with a medical alert bracelet.

Anatomy, Physiology, and Diagnosis of Colorectal and Anal Disease

Chapter

133

Anatomy of the Colon

James M. D. Wheeler · Neal James McCready Mortensen

The colon extends from the end of the ileum to the peritoneal reflection at the junction of the sigmoid colon with the rectum and includes the ileocecal valve and appendix. It may be considered from its proximal end to be made up of *cecum,* which leads into the ascending, transverse, descending, and sigmoid colon. Together with the rectum and anus, they make up the large intestine (Fig. 133–1), which differs considerably from the small intestine. The *large intestine* originates from both the midgut (cecum to distal transverse colon) and the hindgut (distal transverse colon to rectum and anus) embryologic structures. The colon is approximately 150 cm long, and its greatest caliber is 7.5 cm at the cecum, from where it gradually diminishes to 2.5 cm at the rectosigmoid. Although older studies have shown the length of colon to be as much as 180 cm in men and 157 cm in women,[1] other studies that involved the use of laparotomy have shown the colon to be shorter—about 114 cm in men and about 115 cm in women.[2] The longitudinal muscle layer is concentrated to form three linear bands that are equidistant from each other and make up the taeniae coli. These shorter taeniae cause the circular muscle coat to be puckered and thrown into haustral sacculations because the length of the taeniae is less than that of the bowel wall. The taeniae extend from the tip of the cecum to the rectosigmoid and are approximately 6 mm wide. Most of the colon, other than the appendix and cecum, is peppered with peritoneum-covered adipose pieces known as *appendices epiploicae.* They are most numerous along the taeniae and are relatively flat in the right-sided colon, but they are elongated and pedunculated in the sigmoid.

SURFACE ANATOMY

The surface projection of the cecum (Fig. 133–2) is bounded by the right lateral plane, the transtubercular plane, and the inguinal ligament. From here, the ascending colon moves up to the right of the lateral plane until a point midway between the subcostal and transpyloric planes at the hepatic flexure. Here, the ascending colon meets the transverse colon, which drops to the umbilicus before passing upward and to the left to a point (splenic flexure) above and lateral to where the left lateral and transpyloric planes meet. The transverse colon may show both intraindividual and interindividual differences in position, varying by as much as 17 cm in the same person between standing upright and lying flat.[3] The descending colon then passes down just lateral to the left lateral plane to the inguinal ligament, where it becomes the sigmoid colon. Surface projections of the sigmoid colon vary considerably due to its length, movement on its mesocolon, its distention, and the condition of other pelvic viscera (rectum, bladder, and uterus in females).

CECUM

The cecum is the commencement of the large intestine and is the portion located below a transverse line passing just above the ileocecal valve. The ileum, the vermiform appendix, and the ascending colon all are continuous with the cecum. Its average axial diameter is approximately 6 cm, with a breadth of about 7.5 cm. It is related posteriorly to the iliacus and psoas major muscles and to

Figure 133–1. Double-contrast barium enema demonstrating the tortuous route that is commonly followed by the colon.

the lateral cutaneous nerve of the thigh, which lies on the iliacus. Anteriorly, the cecum is in contact with the anterior abdominal wall but may have greater omentum or coils of small intestine overlying it. The cecum is mobile and has a complete covering of peritoneum, although this may be absent at the superior part of the posterior surface, which is then connected to iliac fascia by areolar tissue. Although the mesocecum is usually short, the mobility of the cecum may cause it to twist on its mesenteric axis to form a cecal volvulus or to herniate through the right inguinal canal. The area of tenderness in acute appendicitis may be unusually located if the cecum has a long mesocecum. Several mammals have sphincteric anatomy and function at the cecocolonic junction. Faussone-Pelligrini and associates[4] performed functional anatomy studies on 100 patients (including an endoscopic examination in vivo and both macroscopic and microscopic examinations of the ileocecocolonic region from surgical specimens) and concluded that the cecocolonic junction contained both sphincter morphology and function.

ILEOCECAL VALVE

The ileum opens into the large intestine through the ileocecal valve medially and posteriorly where the cecum joins the ascending colon. This "valve" forms a sphincter as a result of the continuation of the circular and longitudinal muscle layers of the terminal ileum. The valve not only prevents reflux from the cecum into the ileum but probably also acts as a terminal ileum sphincter that prevents small intestinal contents from passing too quickly into the cecum. An absolutely competent ileocecal valve together with a colonic obstruction results in a closed-loop obstruction, and in the absence of surgical intervention this will result in perforation of the colon. Barium enema studies have shown that the ileocecal valve is frequently incompetent in persons without any disease.

VERMIFORM APPENDIX

The vermiform appendix is a blind-ending tube that varies from 2 to 20 cm in length (it is longer in the child), with an average length of about 9 cm. It arises from the posteromedial wall of the cecum about 2 cm below the end of the ileum. Its serous coat is complete except for the attachment of its mesentery. Although the position of the appendix base is constant, the appendix itself may occupy one of the following positions:

1. Posterior to the cecum and lower part of the ascending colon (retrocecal and retrocolic)
2. Descending over the pelvic brim (pelvic/descending)
3. Below the cecum (subcecal)
4. Anterior to the terminal ileum and in relation to the anterior abdominal wall (preileal)
5. Posterior to the terminal ileum (postileal)

Despite much anatomic and surgical literature, there remains debate as to the incidence of each appendix position. In a large study of 10,000 subjects in 1933,[5] the appendix was retrocecal or retrocolic in 65%. *McBurney's point,* the junction of the lateral and middle thirds of the line that joins the right anterior superior iliac spine to the umbilicus, is used as a surface marking for the base of the appendix. The three teniae coli converge at the tip of the cecum to form the continuous longitudinal muscle layer of the appendix. The base of the appendix can be located by tracing the anterior taenia coli to the tip of the cecum. The ileocecal fold of peritoneum, which connects the terminal 2.5 cm of ileum to the cecum, can also be used to locate the base of the appendix. A short, triangular mesoappendix extends along the length of the appendix and connects it to the lower portion of the mesentery of the ileum. The mesoappendix contains the main artery to the appendix, which is a branch of the lower division of the ileocolic artery. The lumen of the vermiform appendix communicates, via an opening, with the cecum below and behind the opening of the ileocecal valve.

ASCENDING COLON

The ascending colon is narrower than the cecum at its origin and is about 15 cm long, ascending to the inferior surface of the right lobe of the liver. It then turns down,

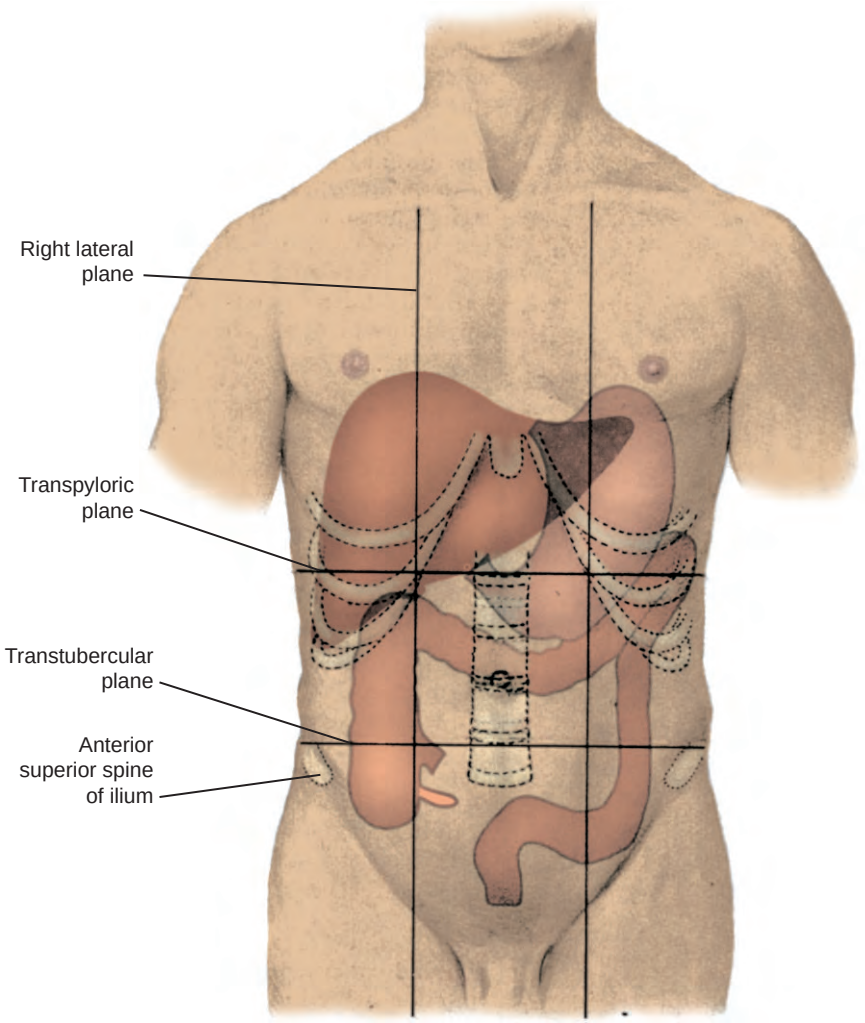

Figure 133–2. Surface projection of the stomach, liver, and colon. The outlines of the lumbar vertebral bodies, lower ribs, xiphoid process, and parts of the iliac crests are indicated. (From Williams PL, Warwick R: Gray's Anatomy, 36th ed. London, WB Saunders, 1980.)

forward, and to the left, forming the *hepatic flexure*. It is related posteriorly to the iliacus, iliolumbar ligament, quadratus lumborum, the origin of the transversus abdominus, the perirenal fascia anterior to the inferolateral part of the right kidney, the lateral cutaneous nerve of the thigh, the fourth lumbar artery, and the ilioinguinal and iliohypogastric nerves. Anteriorly, it is related to the small intestine, the right edge of the greater omentum, and the anterior abdominal wall. The ascending colon is covered on all sides except its posterior surface and is bound by areolar tissue to the posterior abdominal wall (Fig. 133–3). It is not uncommon for it to be completely covered with peritoneum and to contain a narrow mesocolon. Treves[6] found an ascending mesocolon in 12% of cadavers, a descending mesocolon in 22%, and both mesocolons in 14%. The posterior aspect of the hepatic flexure is in direct contact with the inferolateral part of the right kidney, whereas above and anterolaterally, it is related to the right lobe of the liver. The descending portions of the duodenum and fundus of the gallbladder lie anteromedially. The hepatic flexure has a vertical mobility of 2.5 to 7.5 cm with respiration.[7]

TRANSVERSE COLON

The transverse colon begins at the hepatic flexure and passes across the abdomen into the left upper quadrant, where it curves acutely onto itself (more so than at the hepatic flexure), down and backward, to form the *splenic flexure*. It is about 50 cm long, and in its course across the abdomen, it forms an arch with its concavity facing backward and up. The transverse colon is almost completely covered with peritoneum between the head of the pancreas and the splenic flexure. It is attached to the anterior surface of the body of the pancreas and lower pole of the left kidney by the transverse mesocolon, which divides the abdominal cavity into supracolic and infracolic compartments. This division of the abdominal cavity acts as a natural barrier to reciprocal infections between these two areas. The right extremity of the transverse colon is related posteriorly to the front of the descending part of the duodenum and head of the pancreas, being separated by areolar tissue. On its superior aspect, it is related to the liver and gallbladder, the greater curvature of the stomach (to which it is attached by the gastrocolic omentum), and the lateral end of the

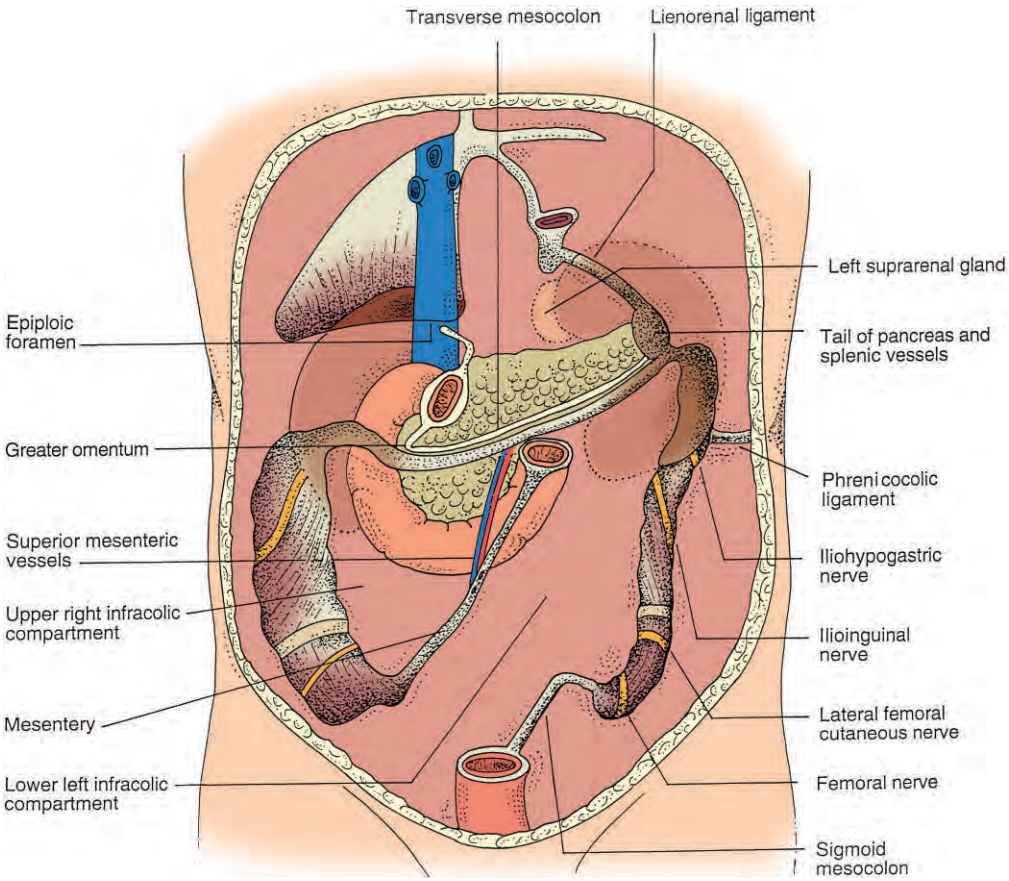

Figure 133–3. Posterior abdominal wall. The colon is removed, demonstrating the attachments of the parietal peritoneum.

spleen. Inferiorly, it is related to the small intestine. It is covered on its anterior surface with the posterior layers of the greater omentum to which it is attached. Posterior to the transverse colon are the descending part of the duodenum, the head of the pancreas, the mesentery, the duodenojejunal flexure, and the small intestine. The transverse colon joins the descending colon at the splenic flexure. This may be so acute that the distal transverse colon lies anterior to the descending colon. Superior to the splenic flexure is the lower part of the spleen and the tail of the pancreas, whereas the anterior aspect of the left kidney lies medially. The splenic flexure is connected to the diaphragm by the phrenicocolic ligament, at the level of the 10th and 11th ribs, and lies at a higher level than the hepatic flexure (Figs. 133–4 and 133–5).

DESCENDING COLON

The descending colon is 25 cm long and extends from the splenic flexure down to the pelvic brim. From the lateral border of the left kidney, it descends between the psoas major and quadratus lumborum to the iliac crest. It then turns medially in front of the iliacus and psoas major to end in the sigmoid colon. Its posterior surface is related to the lower pole of the left kidney, the origin of the transversus abdominis, the quadratus lumborum, the iliacus and psoas major, the subcostal vessels and nerve, the iliohypogastric and ilioinguinal nerves, the fourth lumbar artery, the lateral femoral cutaneous, the

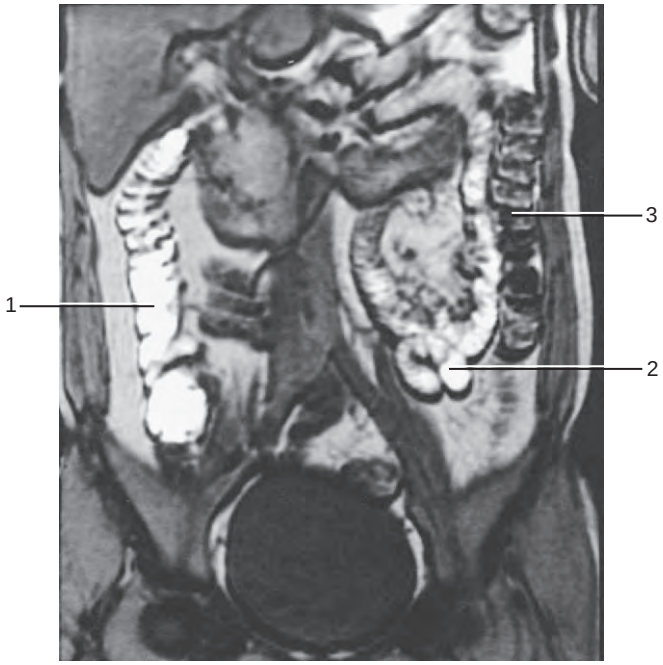

Figure 133–4. Coronal section of MRI: ascending colon (1), small bowel (2), and descending colon (3).

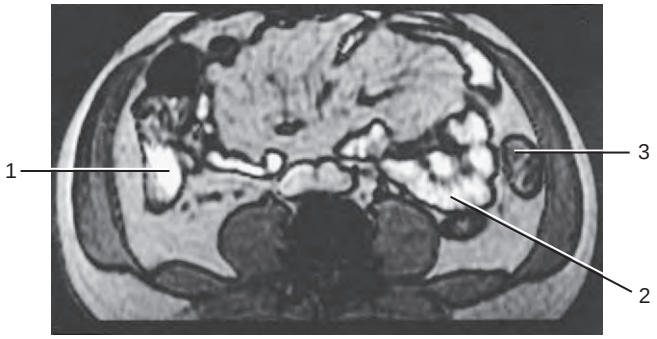

Figure 133–5. Axial section of MRI: ascending colon (1), small bowel (2), and descending colon (3).

femoral and genitofemoral nerves, the gonadal vessels, and the external iliac artery. It is covered by peritoneum over its anterior surface and sides, although like the ascending colon, it may have a narrow mesocolon. On its anterior aspect, it is related to the coils of the small intestine, and in its lower portion, it is related to the anterior abdominal wall. The descending colon is both more narrow and more deeply placed than the ascending colon.

SIGMOID COLON

The sigmoid colon begins at the pelvic brim and forms a loop of about 40 cm (although this may vary greatly) that lies within the pelvis. It becomes continuous with the rectum at the level of the third sacral vertebra and is marked by the lower end of the sigmoid mesocolon. The sigmoid loop is made up of the following parts:

1. *Descending* in contact with the left pelvic wall
2. *Crossing* the pelvic cavity between rectum and bladder (or uterus in the female), where it may reach the right pelvic wall
3. *Arching backward* to reach the median plane

The sigmoid colon is completely surrounded by peritoneum, which forms the sigmoid mesocolon. The sigmoid mesocolon has a V-shaped attachment that is greatest in length at its center and decreases in length toward the end of the loop, so that the sigmoid colon is relatively fixed at its junctions with the descending colon and rectum. The apex of the V is at the bifurcation of the common iliac vessels that overlies the left sacroiliac joint. The left ureter lies between the peritoneum and common iliac artery at this point and is an important landmark for the identification of this structure. The lateral limb of the mesocolon passes forward along the pelvic brim midway to the inguinal ligament. The medial limb slopes down into the hollow of the sacrum, where it reaches the median plane at the level of the third sacral vertebra. As a consequence of the mobility of the loops, the sigmoid colon has variable anatomic relations. On its posterior aspect are the left internal iliac vessels, the ureter, the piriformis, and the sacral plexus. Laterally, it is related to the left external iliac vessels, the obturator nerve, the ovary or ductus deferens, and the lateral pelvic wall. The bladder (and uterus in the female) lies inferior. Above and medially, the sigmoid colon is related to the coils of the small intestine. The rectosigmoid junction has the following six distinguishing features:

1. The diameter of the large intestine narrows.
2. There is an absence of complete peritoneal investment.
3. There is no true mesentery.
4. The three taeniae coli diverge to form a continuous longitudinal muscle coat on the rectum.
5. There are no appendices epiploicae.
6. Endoscopically, an acute angle is encountered at the narrowing of the rectosigmoid and the rectal mucosa is smooth and flat, whereas the mucosa of the sigmoid forms prominent rugal folds.

ARTERIAL SUPPLY

The colon receives its arterial supply from two main branches of the aorta (Figs. 133–6 to 133–8). The *superior mesenteric artery* is the artery of the midgut, and it supplies the colon (and the small intestine from the level of the entrance of the bile duct into the duodenum) to a level just short of the splenic flexure. The *inferior mesenteric artery* is the artery of the hindgut, and it supplies the large intestine as far as the mucous membrane of the upper third of the anal canal.

The superior mesenteric artery arises at the level of the L1 vertebra, approximately 1 cm below the celiac trunk. It descends behind the splenic vein and neck of the pancreas and accompanies the superior mesenteric vein (which lies on its right side) into the upper end of the small intestine mesentery, with the left renal vein, uncinate process of the pancreas, and third part of the duodenum lying behind them. They continue to a point approximately 60 cm from the cecum, passing to the right along the root of the mesentery. The following branches are responsible for supplying the colon:

1. The *ileocolic artery* branches early from the superior mesenteric trunk in the base of the mesentery. Having reached the ileocecal junction, it gives off ileal and colic branches (Fig. 133–9). The colic branch follows the left side of the ascending colon behind the peritoneal floor to anastomose with the right colic artery. The artery then divides into anterior and posterior cecal arteries to supply the cecum. The larger posterior cecal artery supplies the medial, lateral, and posterior walls of the cecum and gives off the appendicular artery, which passes toward the tip of the appendix in the mesoappendix. The appendicular artery is an end artery and does not anastomose with other arteries.
2. The *right colic artery* has its origin at the right side of the root of the superior mesenteric artery in the mesentery. Anatomic studies have shown that this artery originates from the superior mesenteric artery in only 40% of subjects.[8] In 30% of subjects, it arises from the middle colic artery, and in 12% of subjects, it arises from the ileocolic artery. In the

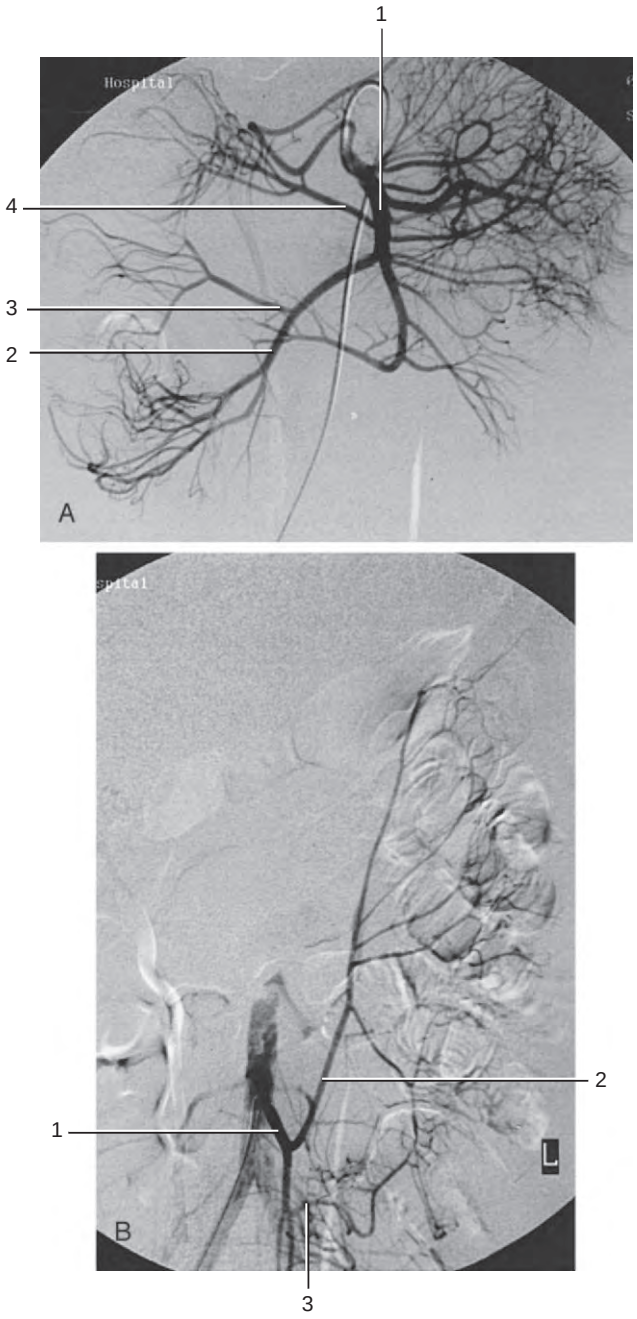

Figure 133–6. **A,** Superior mesenteric angiogram: superior mesenteric artery (1), ileocolic artery (2), right colic artery (3), and middle colic artery (4). **B,** Inferior mesenteric angiogram: inferior mesenteric artery (1), left colic artery (2), and sigmoid artery (3).

remaining 18% of subjects, there was no identifiable right colic artery. It runs behind the peritoneal floor to the ascending colon lying anterior to the right psoas muscle, gonadal vessels, ureter, genitofemoral nerve, and quadratus lumborum. At the left side of the colon, it divides into a descending branch, which anastomoses with the colic branch of the ileocolic artery, and an ascending branch, which runs anterior to the lower pole of the right kidney to the hepatic flexure, where it anastomoses with a branch of the middle colic artery.

3. The *middle colic artery* is the most proximal branch of the superior mesenteric artery, and it arises from the artery at the lower border of the neck of the pancreas, passing into the transverse mesocolon. It travels to the right of the midline in the transverse mesocolon and divides into right and left branches at the transverse colon that run along its length. The right branch anastomoses with the ascending branch of the right colic artery, whereas the left branch anastomoses with a branch of the left colic artery (branch of inferior mesenteric artery) just proximal to the splenic flexure. A large avascular window is left in the transverse mesocolon to the left of the middle colic artery and is often used for surgical access to the lesser sac and posterior wall of the stomach. Unrecognized injury to the middle colic artery will usually result in gangrene of a significant portion of the transverse colon.

The inferior mesenteric artery arises opposite the L3 vertebra from the front of the aorta at the lower border of the third part of the duodenum. It is smaller than the superior mesenteric artery and runs beneath the peritoneal floor of the left infracolic compartment to the pelvic brim. Here, it crosses the bifurcation of the left common iliac vessels and converges on the left ureter. In its descent, it lies anterior to the aorta, left psoas muscle, left sympathetic trunk, left common iliac artery, and hypogastric nerve. On crossing the pelvic brim, the inferior mesenteric artery becomes the superior rectal artery (supplying the rectum) and continues along the pelvic wall in the root of the sigmoid mesocolon. Branches of the inferior mesenteric artery pass to the left in front of the ureter in the floor of the left infracolic compartment. The following branches supply the left side of the colon:

1. The first branch is the *left colic artery,* which, lying beneath the peritoneal floor, passes up and laterally to the splenic flexure. It branches after a short course into the ascending branch, which continues laterally and up, and a descending branch. The ascending branch lies anterior to the left psoas muscle, gonadal vessels, ureter, genitofemoral nerve, and quadratus lumborum and is crossed by the inferior mesenteric vein. It then divides into the upper branch, which crosses the lower pole of the left kidney on its way to the splenic flexure, and the lower branch, which passes across to the descending colon. Both branches further divide into branches that anastomose with the left branch of the middle colic artery. The descending branch passes laterally and down (anterior to the same structures as the ascending branch), and at the pelvic brim, it divides into two or three branches that pass laterally behind the peritoneal floor of the left iliac fossa and form anastomoses with each other to supply the lower portion of the descending colon.
2. The *sigmoid arteries* are three or four branches that arise from a common origin at the inferior

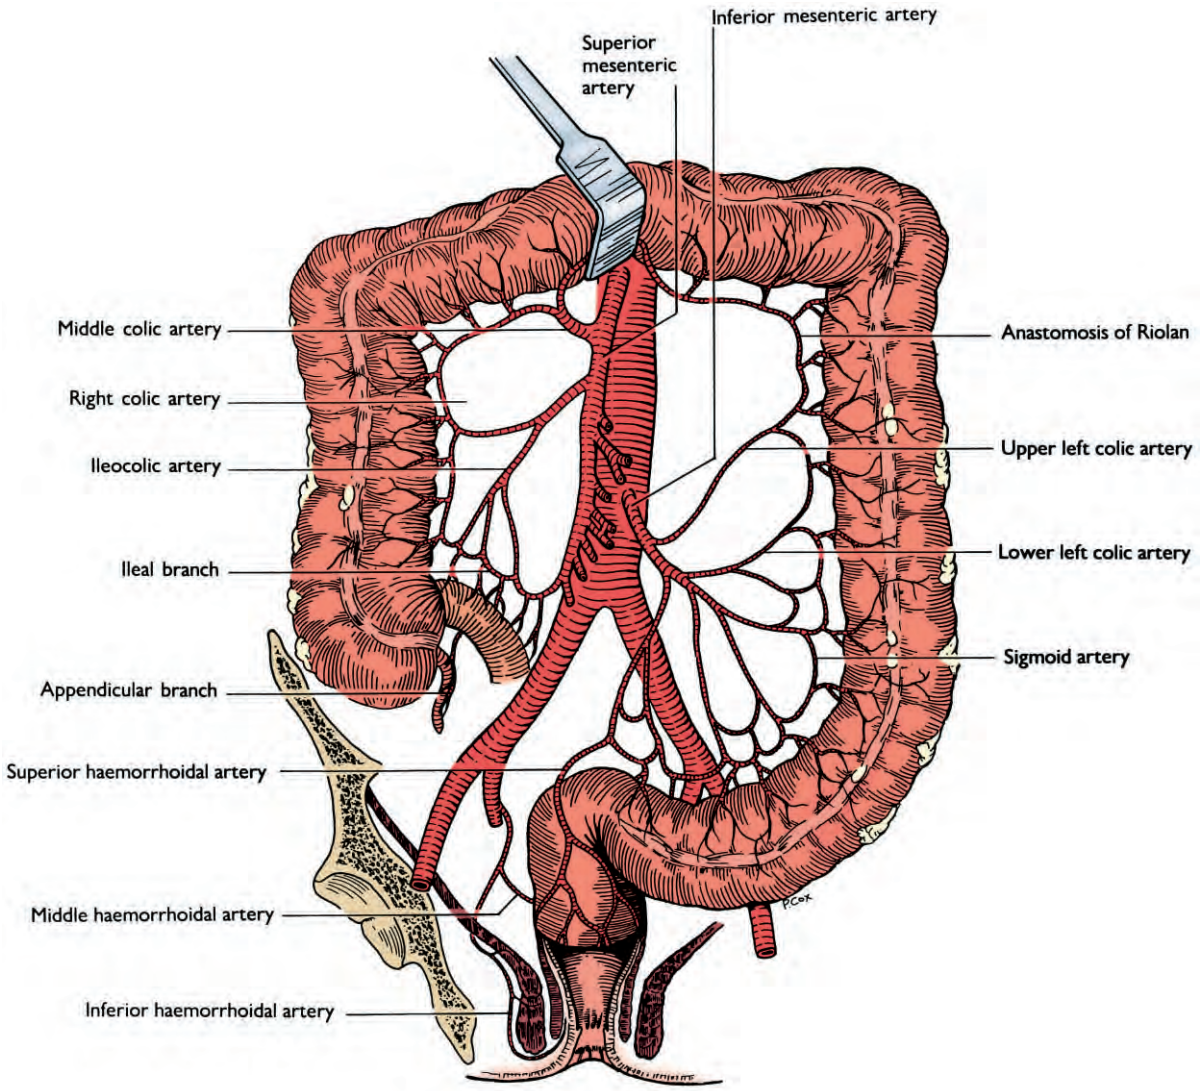

Figure 133–7. The arterial supply to the colon and rectum. The normal distribution of supply to the ileum, right colon, and right side of transverse colon from the middle colic artery and ileocolic arteries is shown. The distribution of the arterial supply from the inferior mesenteric artery to the left side of the transverse colon, the descending colon, the sigmoid, and the upper rectum is also demonstrated. (From Keighley MRB, Williams NS: Surgery of the Anus, Rectum, and Colon. Philadelphia, WB Saunders, 1995.)

mesenteric artery below the left colic artery. They pass forward in the sigmoid mesocolon and supply the sigmoid colon.

The *marginal artery* is the name given to a single arterial trunk made up of anastomoses around the concave border of the large intestine from the ileocecal junction to the rectosigmoid junction. The marginal artery is therefore made up of branches of both the superior and inferior mesenteric arteries. Moynihan[9] remarked that the importance of the marginal artery "cannot be overemphasized." Vessels arise from this artery that run perpendicular to and sink into the walls of the colon to supply the large intestine. Short vessels supply the mesocolic two thirds of the large bowel circumference, whereas the long vessels penetrate the serosa, encircling the bowel to supply the antimesenteric third of the large bowel circumference (Fig. 133–10). The weakest link in this anastomosis is between the middle and left colic arteries in the region of the splenic flexure. Hall and colleagues[10] measured tissue oxygen tension and showed that after "high tie" of the inferior mesenteric artery (flush with the aorta), the marginal artery remains able to adequately supply the transverse and descending colon but not the sigmoid colon. Furthermore, Dworkin and Allen-Mersh[11] demonstrated with the use of laser Doppler flowmetry that there is a *50% reduction* in blood perfusion of the sigmoid colon after ligation of the inferior mesenteric artery.

VENOUS DRAINAGE

Venous blood returns from the colon in veins with names that correspond to those of the artery, having drained an area similar to that supplied with arterial blood (Fig. 133–11).

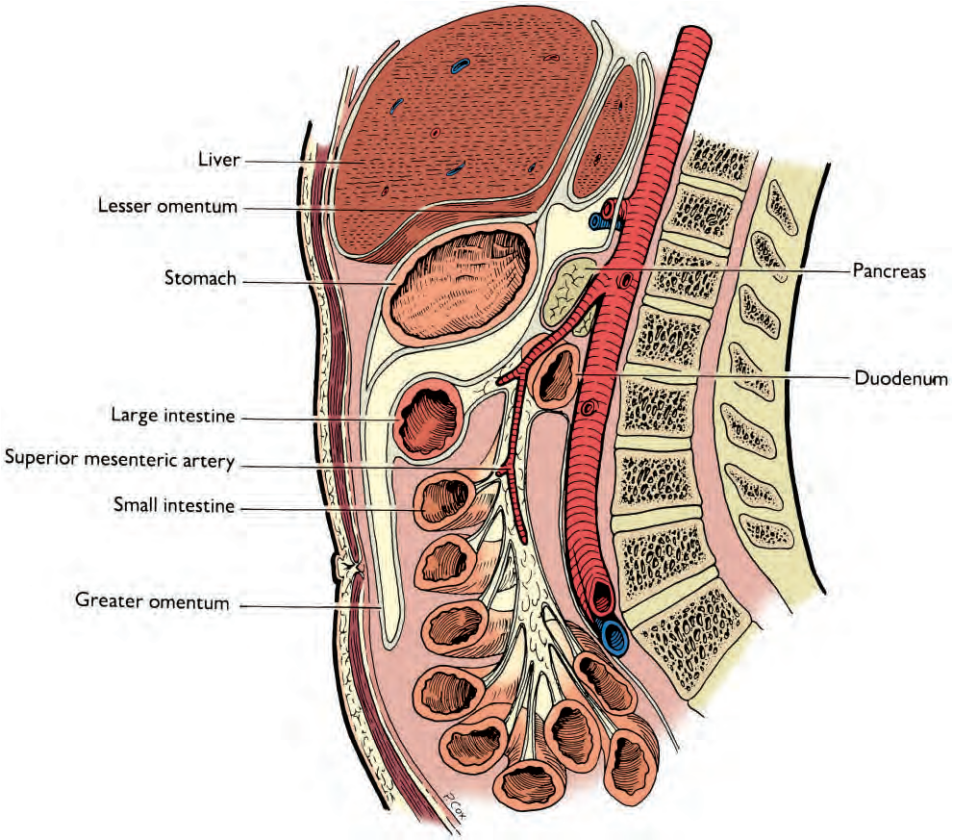

Figure 133–8. Sagittal section of the abdomen to demonstrate the blood supply to the transverse colon and small bowel, the greater omentum, the greater sac, and the lesser sac. (From Keighley MRB, Williams NS: Surgery of the Anus, Rectum, and Colon. Philadelphia, WB Saunders, 1995.)

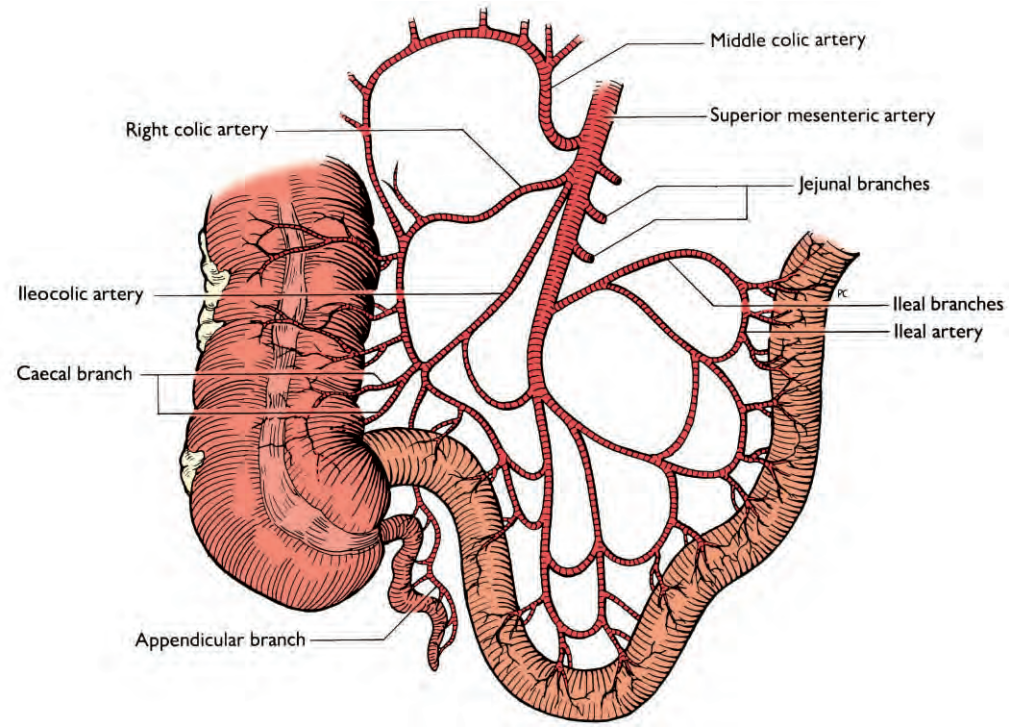

Figure 133–9. Detailed anatomy of the arterial supply to the terminal ileum and right colon is shown. In particular, the normal divisions of the ileocolic artery and arcade with the middle colic artery are demonstrated. (From Keighley MRB, Williams NS: Surgery of the Anus, Rectum, and Colon. Philadelphia, WB Saunders, 1995.)

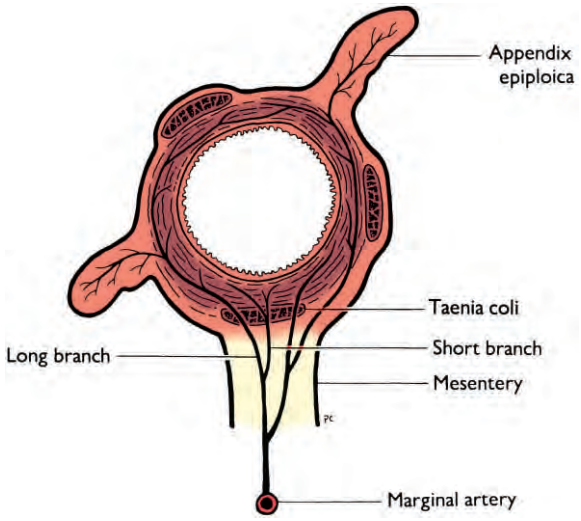

Figure 133–10. The terminal arterial supply to the colon and its relation to the taeniae coli and appendices epiploicae are demonstrated. (From Keighley MRB, Williams NS: Surgery of the Anus, Rectum, and Colon. Philadelphia, WB Saunders, 1995.)

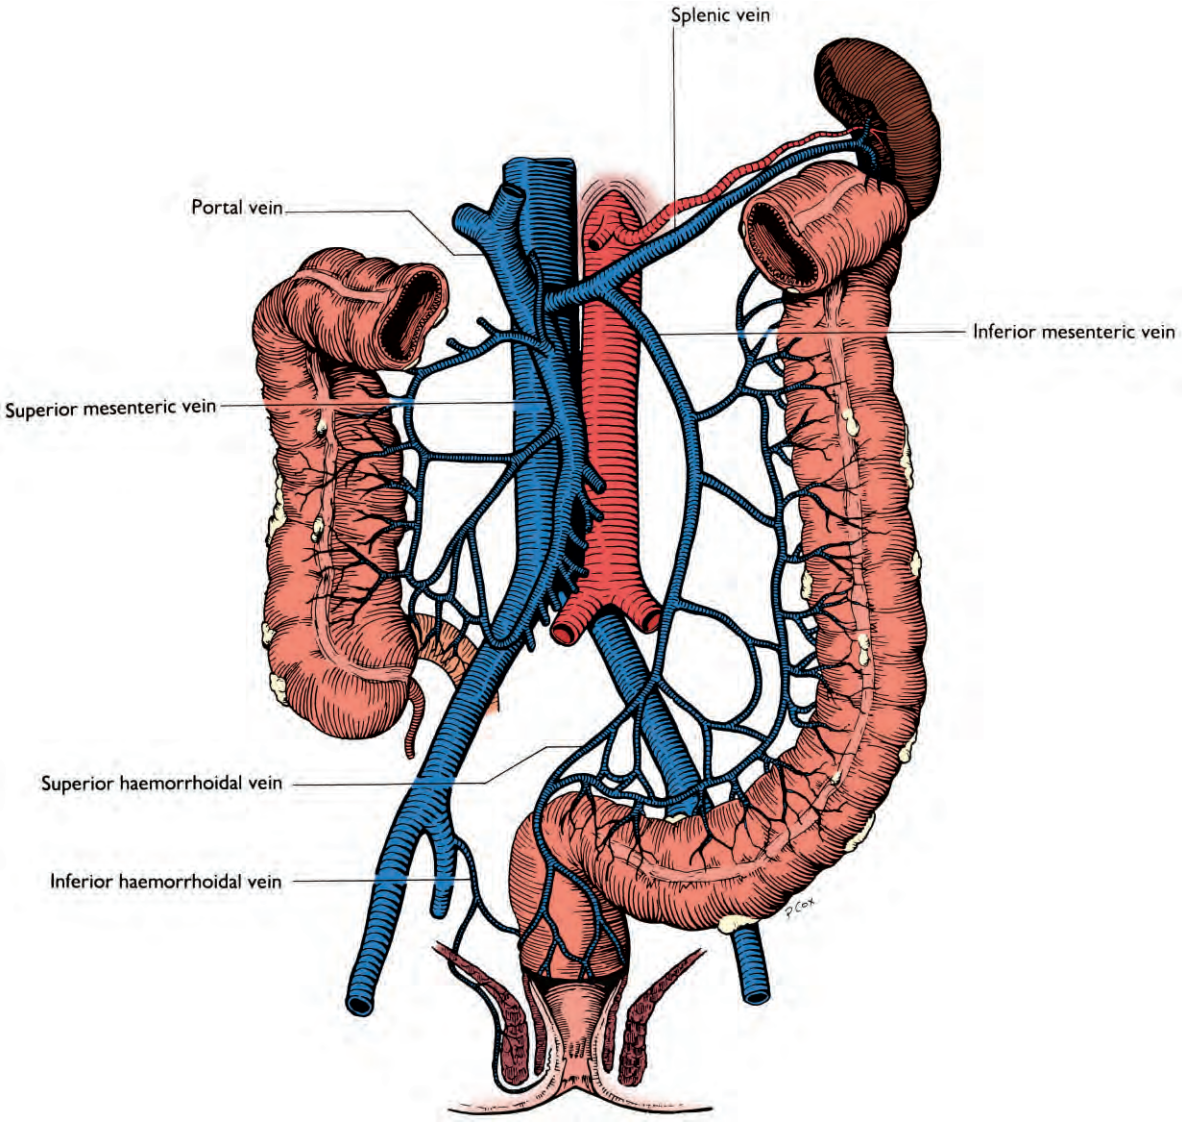

Figure 133–11. The venous drainage of the large bowel and rectum is illustrated; in particular, the drainage of the left colon via the inferior mesenteric vein to the splenic vein is shown. (From Keighley MRB, Williams NS: Surgery of the Anus, Rectum, and Colon. Philadelphia, WB Saunders, 1995.)

Veins from the right side of the colon flow into the superior mesenteric vein, which drains the midgut. This large vein lies to the right side of the artery, crossing the third part of the duodenum and ascending between the uncinate process and the neck of the pancreas to join with the splenic vein and to form the portal vein. The portal vein continues up behind the first part of the duodenum.

Veins from the left side of the colon flow into the inferior mesenteric vein, which drains the hindgut. The inferior mesenteric vein is the continuation of the superior rectal vein, which lies to the left of its artery. The inferior mesenteric vein runs vertically up beneath the peritoneal floor of the left infracolic compartment and is well to the left side of the artery. It lies anterior to the left psoas muscle, gonadal vessels, ureter, and genitofemoral nerve. The vein continues to the left side of the duodenojejunal flexure and passes behind the lower border of the body of the pancreas (anterior to the left renal vein) and joins the splenic vein. The inferior mesenteric vein may open directly into the superior mesenteric vein, having taken a course farther to the right and passing behind the pancreas, below and parallel with the splenic vein.

LYMPHATIC DRAINAGE

Lymph vessels of the gastrointestinal tract run along arteries, in the reverse direction, to their draining lymph nodes, which lie along the aorta at the origin of the relevant artery (Fig. 133–12). The lymphatic vessels of the left colon drain into lymph nodes at the inferior mesenteric trunk, which drain into the superior mesenteric trunk, which drained the right colon (and most of the small intestine). They then pass via efferent lymph vessels to the celiac group of nodes and ultimately into the cisterna chyli.

The appendix drains into lymph nodes in the mesoappendix and from there into paracolic nodes that lie along the ileocolic artery. The cecum and ascending colon drain into epicolic nodes that lie along the left side of the bowel, into the paracolic nodes along the ileocolic and right colic arteries behind the peritoneal floor, and then into the superior mesenteric group of preaortic lymph nodes. The transverse colon drains via epicolic nodes into the paracolic nodes along the middle colic artery in the transverse mesocolon and then into the superior mesenteric nodes.

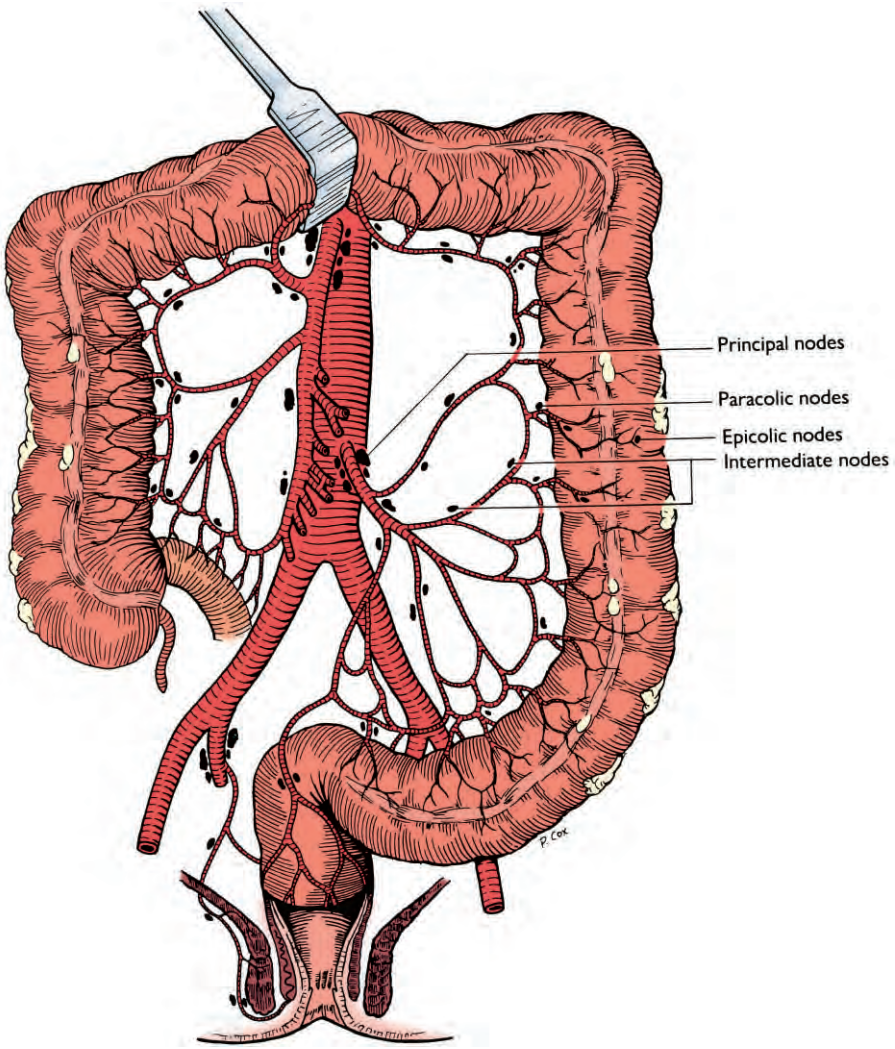

Figure 133–12. The lymphatic drainage of the colon and rectum is illustrated, showing that the lymph nodes are distributed around the arterial supply to the large intestine. Four tiers of nodes are recognized: paracolic, epicolic, intermediate, and principal lymph nodes. (From Keighley MRB, Williams NS: Surgery of the Anus, Rectum, and Colon. Philadelphia, WB Saunders, 1995.)

The lymphatic vessels of the left side of the colon from the splenic flexure to the start of the rectum drain into epicolic nodes along the right side of the bowel. From here, they drain into paracolic nodes that lie along branches of the inferior mesenteric artery behind the peritoneal floor (although the paracolic nodes draining the sigmoid colon lie in the root of the sigmoid mesocolon) and then into the inferior mesenteric nodes.

INNERVATION

The colon is innervated by both the sympathetic (from the 11th and 12th thoracic and 1st and 2nd lumbar nerves) and parasympathetic (from the vagus and 2nd, 3rd, and 4th sacral nerves) divisions of the autonomic nervous system (Fig. 133–13). The sympathetic nerves are thought to have an inhibitory effect on colonic

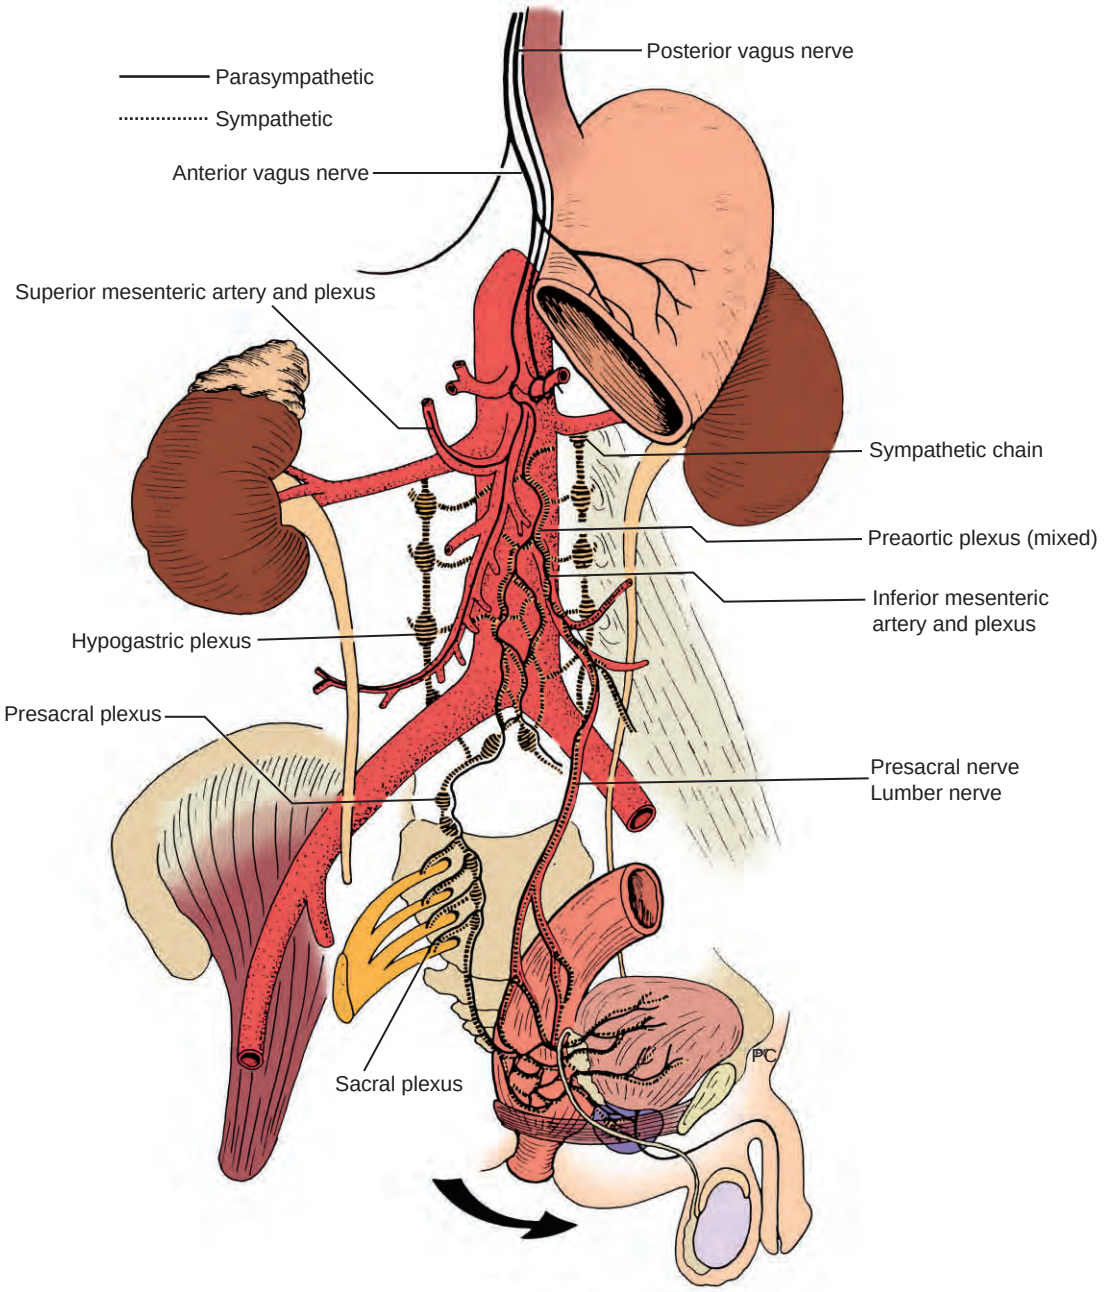

Figure 133–13. The autonomic supply to the colon and rectum is diagrammatically illustrated in an oblique plane. The contribution of the vagus nerve and the nervi erigentes to the parasympathetic supply to the pelvis is demonstrated. The sympathetic chain is shown together with the perivascular plexus to provide the autonomic innervation to the large bowel and rectum. (From Keighley MRB, Williams NS: Surgery of the Anus, Rectum, and Colon. Philadelphia, WB Saunders, 1995.)

peristalsis and secretions, whereas the parasympathetic nerves increase colonic peristalsis and secretions.

The right half of the colon obtains its sympathetic supply via the celiac and superior mesenteric ganglia of the sympathetic trunk, whereas the left side of the colon is supplied with sympathetic fibers from the lumbar part of the sympathetic trunk, via the superior hypogastric plexus, which sends nerves along branches of the inferior mesenteric artery. The parasympathetic supply of the right side of the colon comes from the vagus, and together with the sympathetic supply, the nerves are distributed along branches of the superior mesenteric artery. The parasympathetic supply to the left colon occurs via the pelvic splanchnic nerves (nervi erigentes). Nerves travel up through the superior hypogastric plexus, often referred to as the *presacral nerve* (nerves to the rectum and anus pass to the inferior hypogastric plexus), without interruption and follow branches of the inferior mesenteric artery. The splenic flexure and descending colon also receive branches of the pelvic splanchnic nerves, which have traveled up behind the peritoneal floor and independent of the inferior mesenteric artery.[12]

Colonic pain may be referred to a site distant to the organic insult. Nash[13] described a study of intestinal pain reference in which a balloon was inflated at various points of the gastrointestinal tract. Pain from the cecum is referred to McBurney's point with spread to the epigastrium, whereas pain from the hepatic flexure is referred to the right upper quadrant. Pain from the ascending, transverse, and descending colons is referred to the lower abdomen in the midline and to the left. Rectosigmoid pain is referred to the suprapubic and coccygeal areas.

Embryology and Anatomy of the Colon

Luca Stocchi · John H. Pemberton

EMBRYOLOGY

The colon develops from the primitive midgut, which opens ventrally into the yolk sac. Starting at the 5th gestational week, the midgut rapidly grows and reorganizes to delineate the permanent gastrointestinal tract structures, including the colon. This progression is traditionally divided into three separate stages (Fig. 134–1). In the first stage, the elongated midgut loop enters the extraembryonic celom into the umbilical cord, a process referred to as *physiologic umbilical herniation*. The superior mesenteric artery (SMA) also exits the abdominal cavity along with this bowel loop and within its corresponding mesentery. The SMA thus separates the midgut in a proximal and anterior portion, referred to as *prearterial,* which carries the omphalomesenteric duct at its apex, and a posterior and distal portion. The herniated intestine then rotates counterclockwise by 180 degrees around the SMA axis. In particular, the prearterial segment moves posteriorly and to the left of the SMA and delineates what will become the third and fourth portions of the duodenum.

In the second stage, the primitive intestine returns into the abdominal cavity and undergoes an additional 90 degrees of rotation, thus completing a total of 270 degrees. At this point, the duodenum has rotated counterclockwise around and below the SMA, and the small bowel is located mostly on the right side of the midline. At variance with that, the primitive colon rotates over the SMA, starting from the left. In particular, the cecum is the last segment to reenter the abdominal cavity, where it is initially located right below the liver and then migrates toward its permanent position in the right iliac fossa. Meanwhile, the small bowel elongates while its mesentery shortens, before becoming fixed to the posterior peritoneum.

A number of anomalies of rotation can occur at this stage, including nonrotation, incomplete rotation, reversed rotation, and the range of intermediate conditions collectively considered under the definition of malrotation (Fig. 134–2).[1] In general, individuals with anomalies of rotation are at an increased risk for mesenteric volvulus and extrinsic duodenal compression from abnormal peritoneal attachments, also referred to as *Ladd's bands*. In the nonrotation, the midgut is unable to complete the physiologic 270 degrees of rotation and lies at 0 or 90 degrees with the colon in the left abdomen, the cecum near the midline, and the small bowel to the right. This anomaly can be encountered in approximately 0.2% of radiologic studies and predisposes to midgut volvulus and extrinsic compression of the duodenum. In incomplete rotation, the rotation progresses to approximately 180 degrees. Therefore, the prearterial segment does not reach the posterior location, and the cecum does not rotate anteriorly to the SMA but typically remains in the left upper abdomen. The colon becomes fixed to the posterior wall by abnormal peritoneal bands, which can cause duodenal obstruction. The reversed rotation is the result of a clockwise rotation around the SMA, with the prearterial segment ending up anteriorly to the posterior segment, which can become entrapped in a mesocolic hernia. The transverse colon lies posteriorly to the duodenum and the SMA, in a tunnel beneath the mesentery, which predisposes to the onset intestinal obstruction (Fig. 134–3).

The third and final developmental stage occurs at approximately the 12th week and consists of cecal descent and colon fixation to the posterior peritoneum. In particular, the cecum reaches the right iliac fossa, whereas the ligament of Treitz becomes an identifiable anatomic structure located to the left of the aorta, and the small bowel mesentery retracts in its permanent oblique and broad-based position. When the migration of the colon is complete, the posterior mesentery of the ascending and descending colon fuses with the posterior abdominal wall and forms the fascia of Toldt, also referred to as *white line of Toldt,* which is an essential landmark for a bloodless dissection (Fig. 134–4).

Anomalies of the third phase include undescended, mobile, or hyperdescended cecum; persistent colon

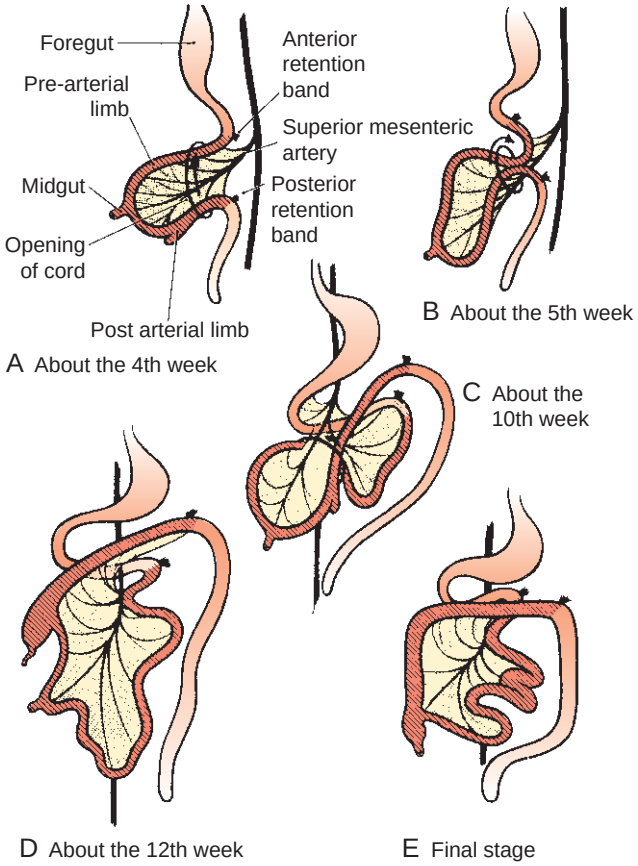

Figure 134–1. Normal rotation. **A,** Human embryo at 4th or 5th week. Note that the midgut supplied by the superior mesenteric artery has "herniated" into the cord. The foregut and hindgut derivatives do not enter this "hernia"; the retention bands are points of fixation. **B,** The prearterial segment of the midgut loop has returned into the abdomen first, as the gut has rotated counterclockwise. The duodenum thus comes to lie behind the superior mesenteric artery. Note the splenic flexure is fixed on the left. **C,** Embryo at the 10th week. The postarterial segment has also reduced and comes to lie in front of the superior mesenteric artery. The cecum is in the upper abdomen and must migrate to the right lower quadrant as counterclockwise rotation continues to 270 degrees. **D,** Embryo at the 12th week. Rotation has been completed; the viscera have attained their normal relationships. **E,** Gradually, fusion of parts of the primitive mesentery occurs fixing the duodenum and ascending and descending portions of the colon to the posterior abdominal wall. (**A**-**E,** From Haller JD, Morgenstern L: Anomalous rotation and fixation of the left colon: Embryogenesis and surgical management. Am J Surg 108:331, 1964.)

mesentery; and ileocecal mesentery. In these anomalies, the laxity of the posterior attachments increases the risk of volvulus.

Anomalies of Fixation

When the posterior fixation of the colon is incomplete, abnormal spaces result that may favor the onset of internal hernias. The most common types of internal hernias are referred to as *mesocolic* or *paraduodenal hernias,* which can occur either on the right or to the left (Fig. 134–5).[2-5] A right mesocolic hernia results from a failure of the prearterial limb to rotate around the SMA so that the intestinal loops become entrapped into the right colon mesentery. Surgical repair is accomplished by mobilization of the right colon and rotation to the left, which is essential to free the small bowel.

The more frequent left mesocolic hernia results from migration and protrusion of the small intestine through the space between the superior mesenteric vein (SMV) and the descending colon mesentery. In this case, the surgical repair consists of mobilization of the inferior mesenteric vein (IMV) and reduction of the hernia through the sac, which is then closed to prevent the creation of an empty space.

Rarely, anomalies of rotation and fixation coexist, and these can occur in the left colon. The primary disorder is fixation of the left colon on the right side, followed by a physiologic counterclockwise rotation of the transverse colon, which concludes its trajectory behind the SMA and the duodenum.

Atresia of the Colon

Atresia of the colon is a rare disorder that resembles the analogous condition of the small bowel and constitutes 5% to 12% of all the intestinal atresias. Three different types have been described. In type I, there is simple mucosal diaphragm, whereas in type II, two blind ends are connected by a fibrous cord derived from the mesentery. In type III, the two blind ends are associated with a corresponding mesenteric gap. The most accepted pathogenetic theory postulates that this disorder originates from an intrauterine derangement in the development of the vascular supply to the involved segment of bowel. A more recent theory supported by experimental evidence correlates colonic atresia to the absence of embryonic expression of fibroblast growth factor or its corresponding receptor.[6] The three types occur with approximately similar frequency without any gender predilection.

In approximately 20% of cases, a number of associated congenital abnormalities have been described, including Hirschsprung's disease, duodenal atresia, bladder exstrophy, and ophthalmic defects. Symptoms are not distinctively different from other types of intestinal obstruction and include bilious vomiting, abdominal distention without bowel movements, and absent or minimal passage of meconium. Barium enema is diagnostic and should be promptly followed by surgery to avoid the risk of necrosis and perforation. A delayed diagnosis predisposes to profound dehydration and electrolyte imbalance.

Duplication of the Colon

A number of different disorders are included in this category; they are basically divided into mesenteric cysts, colonic diverticula, and true colon duplications.

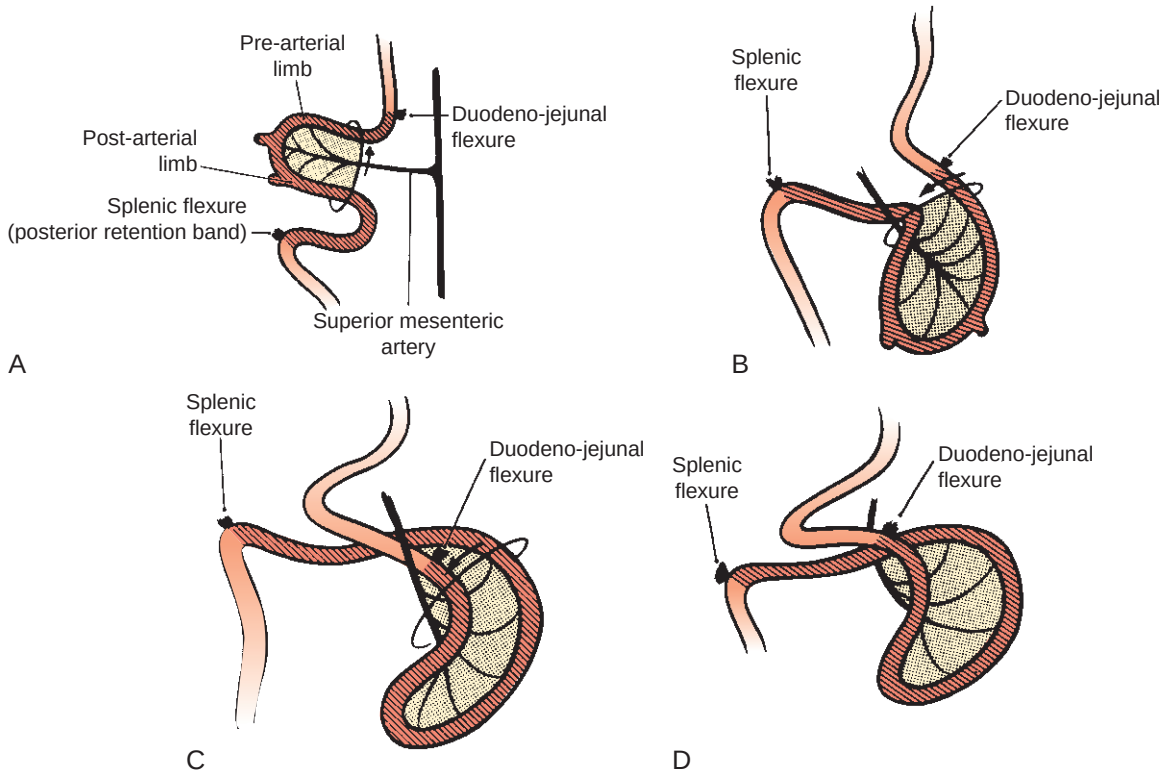

Figure 134–2. Mechanism for producing anomalies of rotation and fixation of the entire left colon. **A,** The splenic flexure fixes on the right side rather than on the left. This is the first and basic anomaly. **B,** Rotation begins in the normal counterclockwise direction. Because the splenic flexure is already fixed on the right, the adjacent segment of bowel, the transverse colon, reduces first and comes to lie behind the superior mesenteric artery. Thus, the first anomaly of fixation has produced the second anomaly of rotation. **C,** The next loop to reduce is the duodenum, as is normal. By projecting from this diagram, one can see that the reduction of the cecum last, as also is normal, will throw the proximal transverse colon in front of all of the other structures. **D,** If duodenal reduction is delayed or its rotation is incomplete, it may reenter the abdomen later and come to lie anterior to the superior mesenteric artery. (**A-D,** From Haller JD, Morgenstern L: Anomalous rotation and fixation of the left colon: Embryogenesis and surgical management. Am J Surg 108:331, 1964.)

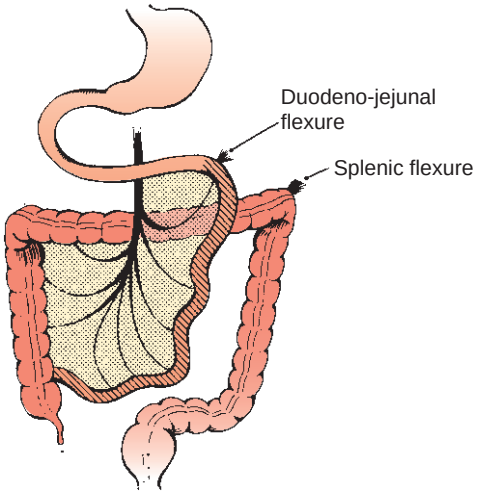

Figure 134–3. Reversed rotation. Note that (1) the locations of all parts of the large and small bowel are normal and (2) the only anomaly is the reversed relationship of the transverse colon and duodenum with the superior mesenteric artery; the colon is posterior and the duodenum is anterior. (From Haller JD, Morgenstern L: Anomalous rotation and fixation of the left colon: Embryogenesis and surgical management. Am J Surg 108:331, 1964.)

Figure 134–4. Mesenteric cysts are generally located in the mesocolon. They can communicate or not with the intestinal lumen and can have an independent blood supply. They are lined with intestinal epithelium and present as palpable masses or with symptoms of intestinal obstruction.[7]

A different variant of colonic duplication is the presence of colonic diverticula. Congenital disorders are often difficult to differentiate from acquired diverticula, a quite common condition in elderly individuals living in Western countries. Acquired diverticula are common and generally located in the sigmoid colon and tend to increase in frequency with age. In contrast, right colon diverticula are much rarer and are equally frequent in elderly and younger patients. Therefore, it has been speculated that right colon diverticula are most likely congenital. In general, congenital diverticula can be located on the mesenteric or antimesenteric border of the colon and can undergo mucosal metaplasia, most frequently gastric or pancreatic. Accumulation of fecal material can increase the dimensions of the diverticulum, which becomes manifest as an abdominal mass. Alternatively, the diverticulum can present with bleeding from gastric ectopic mucosa, or it can prompt colonic intussusception with intestinal obstruction.

A truly bilateral colon duplication is a rare disorder often accompanied by duplication of other structures, most frequently the spine, bladder, and vagina (Fig. 134–6). In its complete form, two distinct gastrointesti-

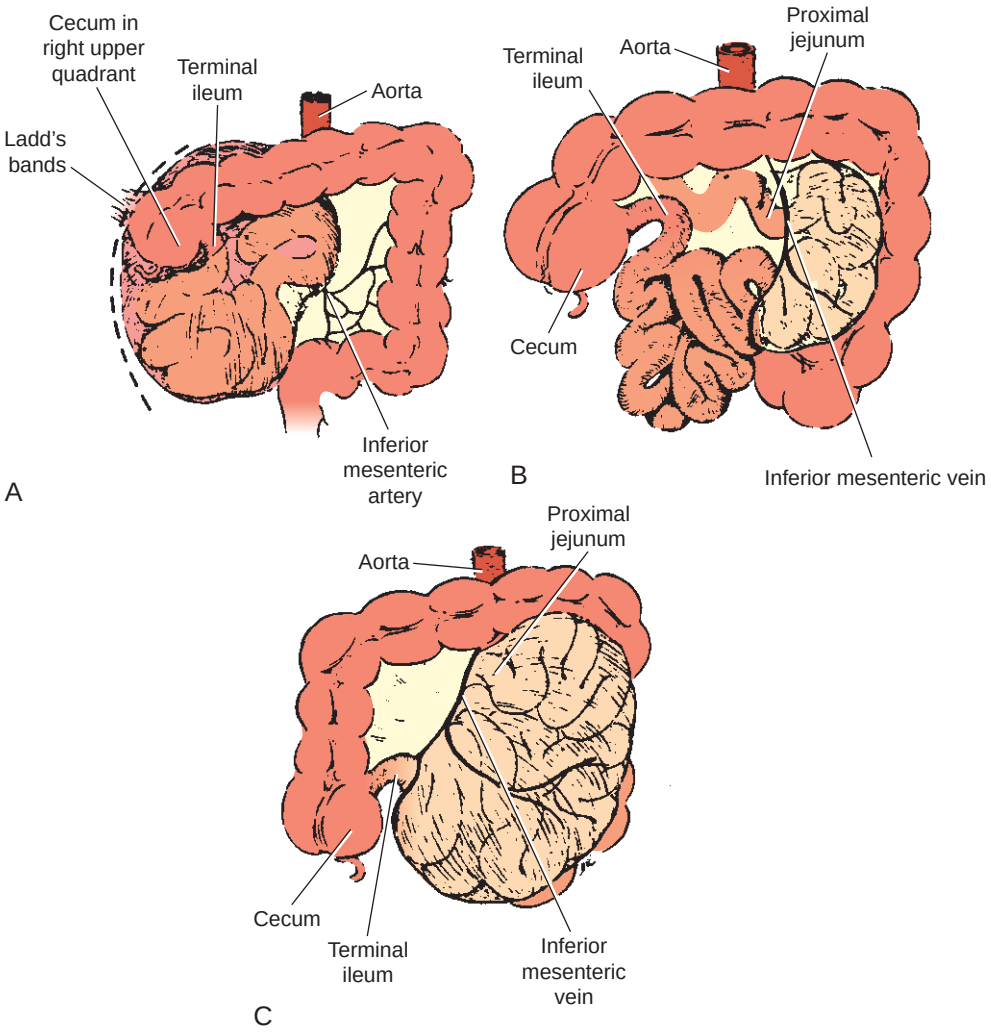

Figure 134–5. Mesocolic hernias. **A,** Right mesocolic hernia. Prearterial segment of the midgut has failed to rotate. Postarterial segment does not rotate and traps most of the small bowel behind the right mesocolon. The *hatched line* indicates the surgical incision used to reduce the hernia. **B,** Left mesocolic hernia. Initial rotation of the small intestine is normal. During migration to the left superior portion of the abdomen, the bowel invaginates an avascular portion of the left mesocolon posterior to the interior mesenteric vein. **C,** Left mesocolic hernia. Small intestine, except for portions of the distal ileum, is trapped beneath the left mesocolon. Note that the inferior mesenteric vein delineates the right margin of the sac and is an integral part of the neck of the sac. (**A,** From Willwerth BM, Zollinger RM, Izant RJ: Congenital mesocolic (paraduodenal) hernias: Embryologic basis of repair. Am J Surg 128:358, 1974; **B** and **C,** Adapted from Callander CL, Rusk R, Nemir A: Mechanism, symptoms, and treatment of hernia into the descending mesocolon. Surg Gynecol Obstet 60:1052, 1935.)

nal tubules are encountered from the terminal ileum to the rectum. The two proceed distally while sharing a common wall and terminate in two separate anal openings.[8] However, in most cases, the duplication is incomplete and involves only a segment of the large bowel, which can terminate in one anus or an anus and a fistula.[9] Other anomalies may coexist, such as horseshoe or absent kidney and clubfoot.

ANATOMY

The colon has been traditionally described as the gastrointestinal segment that extends from the ileocecal valve to the rectum (Fig. 134–7). Whereas these landmarks have been widely accepted, their definition is more controversial. At the proximal end, the term *ileocecal valve* is considered a misnomer by several authors,[10] who postulate that the valve mechanism is located entirely in the terminal ileum. On the other hand, the delimitation between the colon and the rectum is not uniformly accepted. Some surgeons consider the sacral promontory or the changes in the characteristics of the longitudinal muscular layer at the end of the sigmoid to be landmarks. Others simply measure the rectum as the last 10, 12, or 15 cm of the large bowel from the anal verge and consider as colon the entire remaining large bowel. The location of the colon in the peritoneal cavity

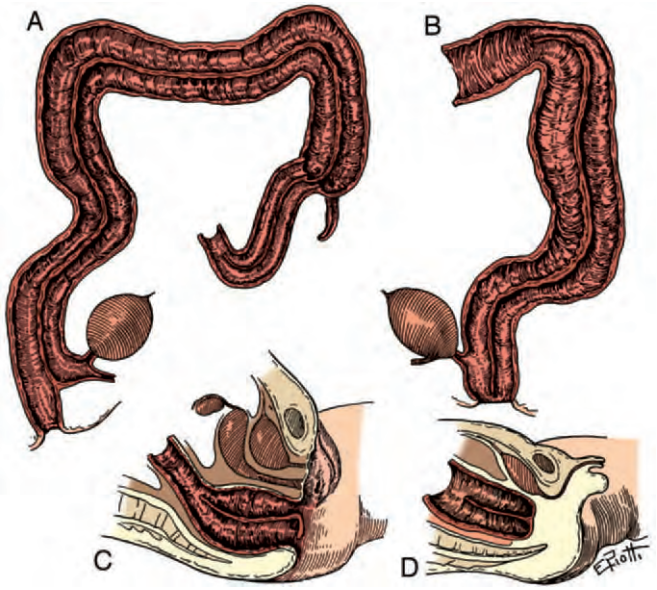

Figure 134–6. Examples of tubular duplications of the intestine. **A,** Duplication from ileum to rectum. One canal ends at a normal anus, and the other ends in a fistula to the urethra. **B,** Duplication of the descending colon with double anus and a fistula to the urethra. **C,** Short duplication of the rectum, with two anal openings. **D,** Duplication of the rectum, with both canals ending blindly (more frequently, the cranial end of the duplication is blind). varies greatly based on individual shape and extent of mesenteric attachments. In most cases, the hepatic flexure lies lower than the splenic flexure, as can be seen on barium enema. In general, the ascending and descending colons are retroperitoneally located, whereas the transverse and sigmoid colons have mesenteries. The colonic length ranges between 120 and 200 cm and depends on gender as well as individual variations. In a study that compared colonic length as measured on barium enema, despite a significantly smaller stature, women had a longer colon than men, with a median of 155 versus 145 cm. In addition, women have a longer transverse colon, which also carries an increased likelihood of location within the pelvis.[11] These anatomic data might explain why colonoscopies are generally more difficult to perform in women than in men. Similarly, there is evidence that Western patients have an increased incidence of sigmoid colonic adhesions and colonic mobility compared with Asian counterparts, which again would confirm the increased technical difficulty in performing colonoscopy that is observed in Western patients.[12] It has been reported that the transverse colon lies below the umbilicus in as many as 10% of women, a detail that might carry importance for laparoscopic surgery.[13]

Three distinctive basic macroscopic features in the colon help differentiate it from the small bowel: the presence of taeniae coli, the presence of haustra coli, and appendices epiploicae, or fatty appendices (Fig. 134–8). The taeniae coli are condensations into three bundles of the longitudinal muscular layer of the large bowel that are macroscopically visible, although a thinner longitudinal layer remains to completely encircle the lumen. The taeniae extend from the cecum to the end of the sigmoid. The taeniae are traditionally named after their location in the transverse colon. The taenia mesocolica is connected to the mesocolon; the taenia omentalis is attached to the greater omentum; and the taenia libera has no attachments and is more clearly identifiable on the surface of the bowel wall. The taeniae contribute to the configuration of the haustra as convex folds of colonic wall, which confer to the colon its saccular appearance. Last, the appendices epiploicae are similar to droplets of yellow adipose tissue that surround the colonic wall. They are especially noticeable in the sigmoid, and they become absent in the rectum.

Cecum

The cecum is the proximal portion of the colon after the ileocecal valve. At this level, it continues into the ascending colon and measures approximately 6 cm in length and 7.5 to 8 cm in width. The cecum is generally covered by peritoneum, although in most cases, there is no distinct mesentery and the mobility is limited. Occasionally, the cecum can be particularly mobile, which facilitates the dissection but predisposes to cecal volvulus and may contribute to unusual clinical presentations of acute appendicitis. Such a varying degree of attachments corresponds to a variable position of the cecum that lies on the iliac muscle but can cover part of the psoas or abut the pelvis. The lowest haustrum corresponds to what can be endoscopically viewed as the cecal fundus, where the appendiceal orifice is generally visible and is a useful indicator of a complete colonoscopic exploration. A mucosal fold referred to as *Gerlach's valve* inconsistently covers the appendiceal orifice. An additional landmark visible endoscopically is the ileocecal valve, with the ileal orifice delimited by two distinct lips: the ileocolic, or superior, lip and the ileocecal, or inferior, lip. Although the term *ileocecal valve* is still largely used, some authors have objected to its accuracy in consideration that the valve mechanism might actually lie in the terminal ileum. Externally, the junction between the ileum and the cecum is associated with a number of peritoneal folds and recesses. The superior ileocecal fold extends anteriorly as a mesenteric appendage where the anterior cecal artery runs. The fold covers the corresponding superior ileocecal recess. Inferiorly, the inferior ileocecal fold connects the antimesenteric aspect of the terminal ileum with the mesenteriolum of the appendix. Because this fold does not contain any vessel, it is also referred to as the *bloodless fold of Treves*. A small inferior ileocecal recess lies inferior and posterior to the corresponding fold.[14]

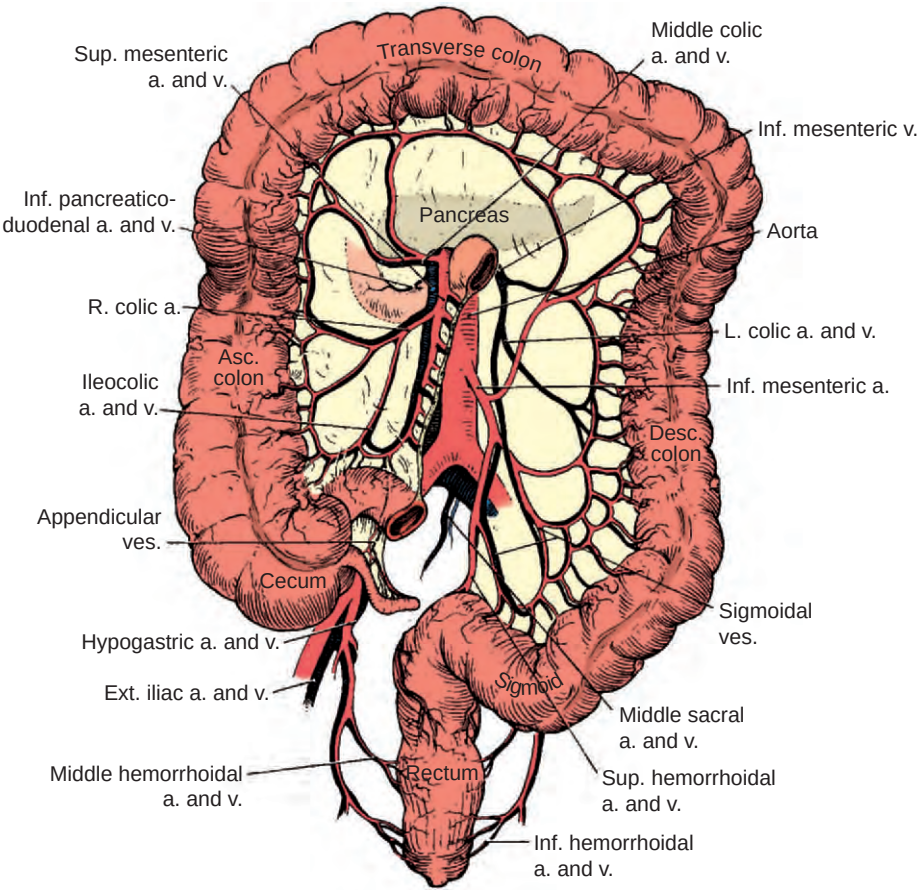

Figure 134–7. The colon, showing its anatomic divisions and its blood supply (the veins are shown in black lines). (Modified from Jones T, Shepard WC: A Manual of Surgical Anatomy. Philadelphia, WB Saunders, 1945.)

Appendix

The vermiform appendix is in continuation with the cecum through the appendiceal orifice and is surrounded by a continuous longitudinal muscular layer, which results from the union of the three taeniae. It is approximately 8 to 9 cm long, although it can range from 5 to 35 cm. It generally originates at the posteromedial border of the cecum, although it can be connected to the cecal fundus or even located in close proximity to the ileocecal valve. In approximately 65% of patients, the appendix courses vertically in the retrocecal recess, whereas in 31%, it descends into the iliac fossa. More rarely, it can course laterally in the retrocecal recess, immediately below the posterior cecal serosa, or it can be encountered in a paracecal, preileal, or postileal location (Fig. 134–9). The appendix is accompanied by its corresponding mesenteriolum, which contains the appendicular artery, a terminal artery without any arterial arcades. It is postulated that this anatomic condition predisposes to inflammatory damages due to the inability to meet the demand for an increased blood supply. Conversely, branches derived from the anterior and posterior cecal arteries provide additional blood supply to the base of the appendix. The venous circulation drains into the ileocolic and the right colic veins, whereas the lymphatics drain into the ileocecal nodes and then along the SMA nodes into the celiac nodes.

Ascending Colon

The ascending colon lies on the right side of the abdominal cavity, in front of the quadratus lumborum and transversus abdominis muscle. It extends from the cecum to the hepatic flexure and averages 12 to 20 in length. The existence of a physiologic sphincter zone at the cecocolonic junction has been suggested based on manometric studies performed during right hemicolectomy.[15] In most cases, the ascending colon is covered by peritoneum on its anterior and lateral aspects and is fixed posteriorly, whereas in about 25% of individuals, mesentery can be identified. Rarely, a tenuous adhesion from the right abdominal wall to the anterior taeniae of the ascending colon has been observed, which is referred to as *Jackson's membrane*. The ascending colon lies anterior to the lower pole of the right kidney, from which it is separated by perirenal fat and Gerota's fascia. It also relates posteriorly to the right ureter and gonadal vessels, which lie on the surface of the psoas muscle (Fig. 134–10). At the lower margin of the liver and lateral or adherent to the gallbladder, the ascending colon turns to the left at the point traditionally described as *hepatic flexure*. The hepatic flexure lies immediately above the second portion of the duodenum, to which it is sometimes attached by a peritoneal fold referred to as *duodenocolic ligament*. In addition, a hepatocolic ligament can be occasionally found, in continuity with the lesser omentum (Fig. 134–11).

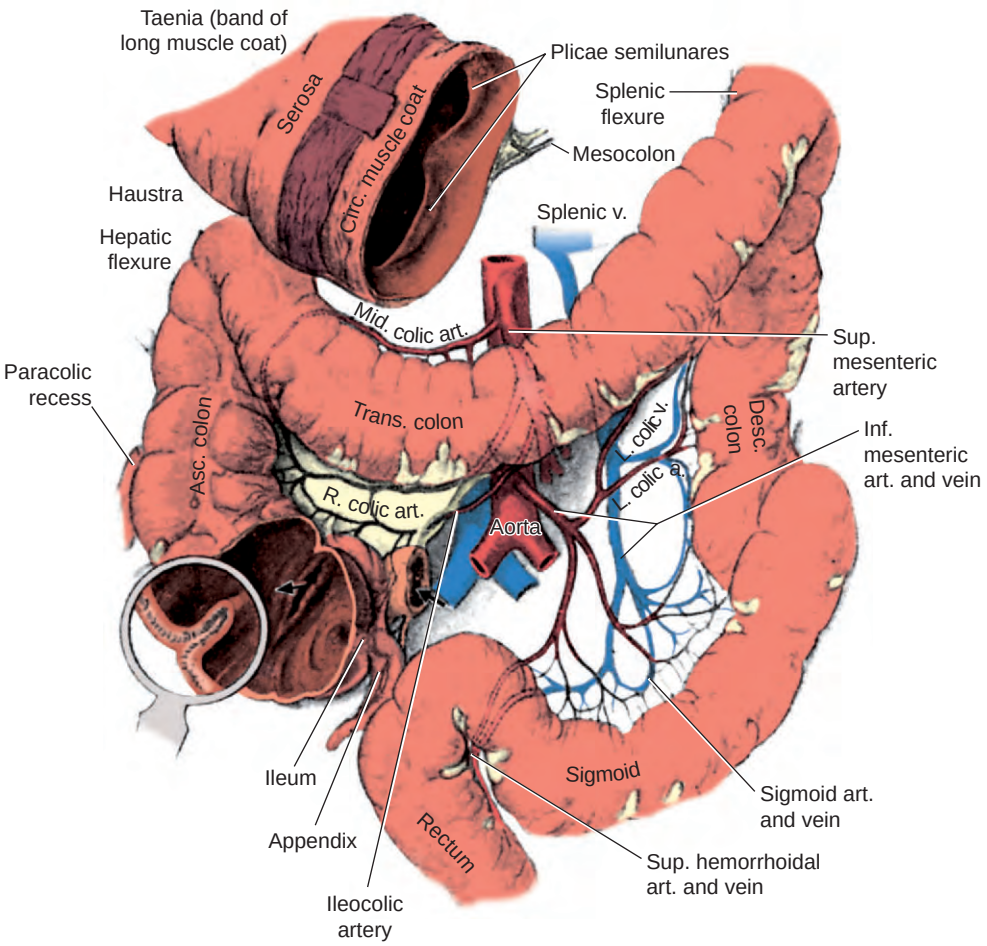

Figure 134–8. The large intestine. The position of the colon as shown is based on radiographic study in living humans. The anterior wall of the cecum is removed to show the ileocolic valve, characteristic folds, and opening of the appendix. Note that the blood supply is from two sources: (1) the superior (sup) mesenteric artery through the middle, right, and ileocolic branches; and (2) the inferior (inf) mesenteric artery through the left colic, sigmoid, and superior hemorrhoidal branches. An enlarged segment of transverse colon is shown above with details of the wall and plicae. A magnified portion of cecum wall is seen at the lower left. (From Bockus HL: Gastroenterology, Vol 2, 3rd ed. Philadelphia, WB Saunders, 1976.)

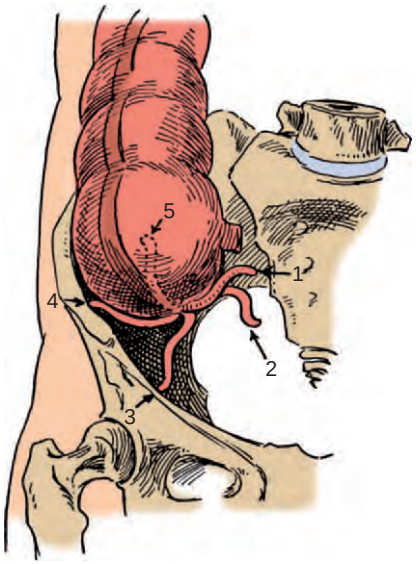

Figure 134–9. Various positions (1 to 5) occupied by the appendix.

Transverse Colon

The transverse colon connects the ascending and descending colon and courses horizontally across the abdominal cavity. It is attached to the posterior abdominal wall by a long mesentery, which renders it extremely flexible. The transverse colon can therefore be quite long, even 40 or 50 cm, and reach the iliac crests or even lie deep into the pelvis. The root of the transverse mesocolon lies anteriorly to the lower pole of the right kidney and extends over the second portion of the duodenum; the head, body, and tail of the pancreas; and, finally, on the hilum of the left kidney. It is generally accepted as the anatomic landmark that separates the supramesocolic from the inframesocolic compartments. The duodenojejunal junction, also referred to as the *ligament of Treitz,* lies just inferior to the root of the transverse mesocolon. The greater omentum covers the transverse colon along almost its entire length and is connected to it by the gastrocolic ligament. This structure is usually dissected in case of transverse colectomy or to obtain access to the lesser sac. The distal transverse colon generally lies in front and above the descending colon and is connected to the diaphragm by the phrenocolic ligament. The splenic flexure generally forms an acute angle in the

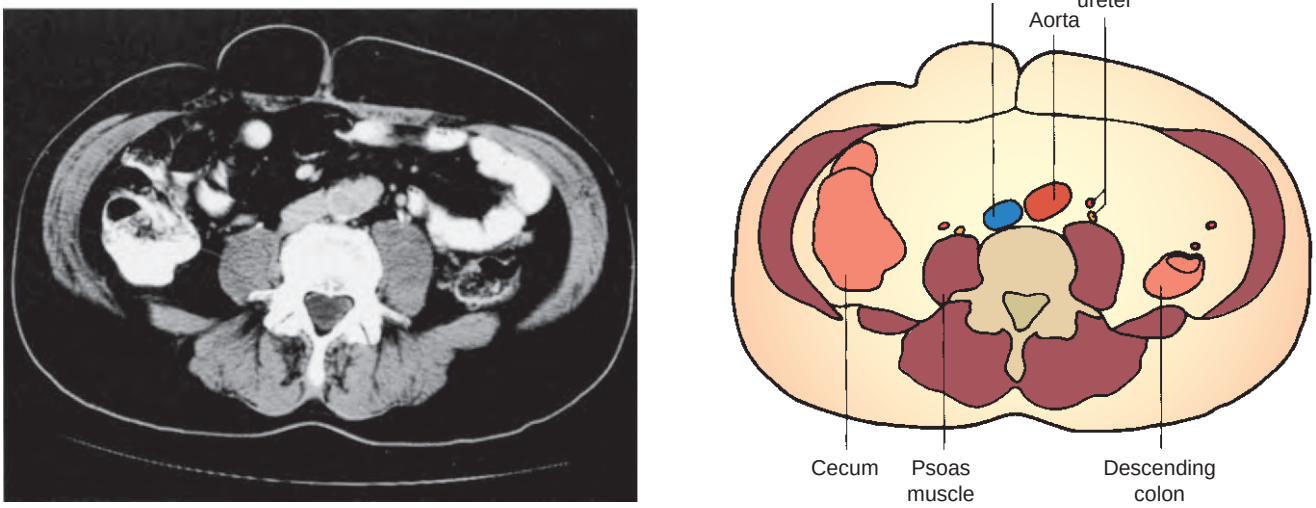

Figure 134–10. **A** and **B,** The right colon is related posteriorly to the right ureter, gonadal vessels, duodenum, and kidney. (**A** and **B,** From Fozard JBJ, Pemberton JH: Applied surgical anatomy: Intra-abdominal contents. left upper quadrant of the abdominal cavity in front of the left kidney, also in close relationship to left adrenal gland, and the tail of the pancreas. It lies higher than the contralateral hepatic flexure and is connected by flimsy adhesions to the lower pole of the spleen, which contributes to render it a fixed bowel segment (Fig. 134–12). Such anatomic location is often difficult to access, which poses the spleen at increased risk of inadvertent tears during surgical dissection of the splenic flexure. A retrosplenic colon variation has been described in 3 of 1000 patients examined by thoracoabdominal CT scan.[16]

Descending Colon

The descending colon extends from the left upper quadrant to the pelvic brim and connects the splenic flexure to the sigmoid colon. It measures approximately 30 cm and descends vertically and slightly toward the midline in the groove between the psoas and the quadratus lumborum. It is surrounded by the peritoneum anteriorly and bilaterally, whereas in most cases, it is fixed on the posterior peritoneum through the Toldt fascia. This is an important surgical plane to allow for a bloodless dissection. The descending colon tends to be in a more posterolateral position in young women.[17]

Sigmoid Colon

The sigmoid starts at the pelvic brim at the point where the descending colon turns medially and acquires a mesentery (Fig. 134–13). It terminates approximately at the level of the sacral promontory where the three taeniae commonly coalesce into a diffuse longitudinal muscular layer devoid of any epiploicae. The presence of a distinct sigmoidorectal sphincter is generally not recognized, although Shafik and colleagues have identified distinct, thickened smooth muscle bundles at the junction of sigmoid and rectum.[18] The diameter of the sigmoid colon decreases along its course, and its length, position, and fixation are extremely variable. It is commonly accepted that a long mesocolon with a short base predisposes to the onset of sigmoid volvulus, whereas a long convoluted sigmoid has been implicated in the origin of constipation. The base of the mesosigmoid generally extends from the left iliac fossa to the pelvic brim and then across the sacroiliac joint at the 2nd or 3rd sacral space, thus having a course described as an inverted V. In a study on the anatomic dimensions of the sigmoid colon of 70 North Indian subjects, the sigmoid colon of females tended to be wider rather than long, whereas the opposite was true for male subjects.[19] The lateral wall of the sigmoid often presents with adhesion to the lateral wall of the iliac fossa (Fig. 134–14), which must be freed to allow mobilization of the left colon. Once lateral adhesions are taken down and the lateral peritoneal reflection is incised, the fascia of Toldt can generally be appreciated. The mesosigmoid contains a recess, referred to as the *intersigmoid fossa,* which can be used as a landmark for identification of the ureter. In fact, the ureter can usually be identified deep to the intersigmoid fossa, where it courses along the surface of the psoas muscle and grossly parallel to the gonadal vessels, as it descends and crosses medially into the pelvis above the common iliac artery bifurcation. However, the intersigmoid fossa can also be the location of internal hernias, when a small bowel loop remains entrapped into this blind pouch.

Endoscopic View of the Colon

The cecum is identified on colonoscopy by the following three distinct features:

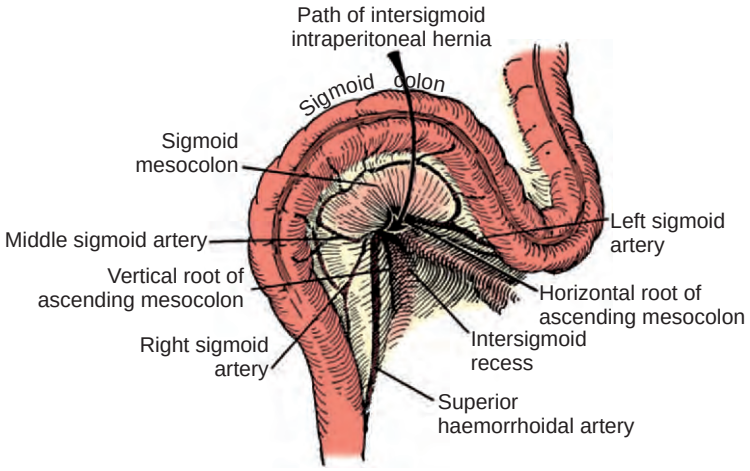

Figure 134–13. Sigmoid colon, its mesentery and arterial supply, and the intersigmoid recess. The sigmoid colon and mesocolon are raised forward and upward to show the vertical and horizontal attachments of its two roots. The *arrow* indicates the apex of the intersigmoid recess into which a loop of small bowel may insinuate and travel up behind a partially unfused descending mesocolon to form an intraperitoneal hernia. The superior hemorrhoidal artery, which is the main arterial supply to the rectum, lies between the leaves of the vertical root of the sigmoid mesocolon.

1. Ileocecal valve—This appears as "pouting lips," which lie transversely. These in part are responsible for the valvular continence in that reflux back to the small bowel is prevented. It is viewed "side on" from the colonoscope. It may have a lobular appearance that resembles a lipoma, and the mucosa appears more velvety, typical of small bowel. It moves rhythmically, and this movement can often be accentuated by inflating and deflating the cecum with the colonoscope. Finally, bile-stained ileal effluent may be seen discharging intermittently.
2. "Mercedes-Benz" sign—The convergence of the three taeniae at the cecum results in a three-pointed star, which has been associated with the German Marque. The three taeniae are located anteriorly, posteromedially, and posterolaterally.
3. Appendiceal orifice—At the site of the convergence of the taeniae should be the orifice of the appendix.

Two of these three signs are usually sufficient for a diagnosis of the cecum endoscopically, because occasionally one of the signs may be obscured by a less-than-perfect bowel preparation.

On withdrawal up the ascending colon, the hepatic flexure may be recognized by the bluish indentation of the liver. In addition, once past the flexure, the easiest way to advance the colonoscope is usually to shorten the endoscope while applying suction. This causes a "paradoxical advance," allowing the ascending colon to concertina over the colonoscope.

The transverse colon has a highly characteristic endoscopic triangular shape. This is the result of the attachment of the peritoneum at three points to the colon (e.g., gastrocolic omentum, greater omentum, and transverse mesocolon). Occasionally, the length of the transverse colon may cause difficulty in advancement of the colonoscope through because of the resulting "looping." External pressure on the colonoscope in the epigastrium often fixes the transverse colon, facilitating intubation. However, the best way to avoid this situation completely is to insufflate the colon minimally, thus avoiding lengthening it. Suction applied here often allows advancement of the colonoscope without pushing. This, in addition to avoiding looping, also makes the procedure less uncomfortable.

Further distally, the splenic flexure may be difficult to negotiate and is marked by a turn at the end of the descending colon as well as the bluish tinge of the spleen.

The sigmoid/descending colon junction is probably the most difficult curve to negotiate endoscopically. It marks the end of the free sigmoid and ends in a tunnel-like appearance of the descending colon.

Finally, the sigmoid is easily identified, because of the multiple turns and bends that occur as soon as the rectosigmoid junction is negotiated. Moreover, the haustra of the sigmoid colon are quite thickened (muscular).

Arterial Blood Supply

The vascular supply of the colon is variable (see Figs. 134–7 and 134–8). It receives its blood supply from both the SMA and the inferior mesenteric artery (IMA) systems. The branches of each system and the connections between the two systems are variable.

As mentioned, the colon receives its blood supply from two arterial systems: the SMA and the IMA. The SMA system supplies the right and the proximal transverse colon, whereas the IMA system send tributaries to the distal transverse, descending, and sigmoid colon.

The SMA arises anteriorly from the aorta at the level of L1. After supplying the small intestine, it terminates into the ileocolic artery, which is constantly present. The ileocolic artery divides into an ascending colonic branch, which anastomoses with a descending branch from the right or middle colic artery (MCA), and a descending branch, which anastomoses with the distal ileal branches. Three additional branches of the ileocolic artery form the anterior and posterior cecal arteries and the appendiceal artery. The right colic artery (RCA) originates 1 to 3 cm below the takeoff of the MCA and supplies the ascending colon with ascending and descending branches. The MCA arises from the SMA posterior to the pancreas and courses superiorly within the mesocolon

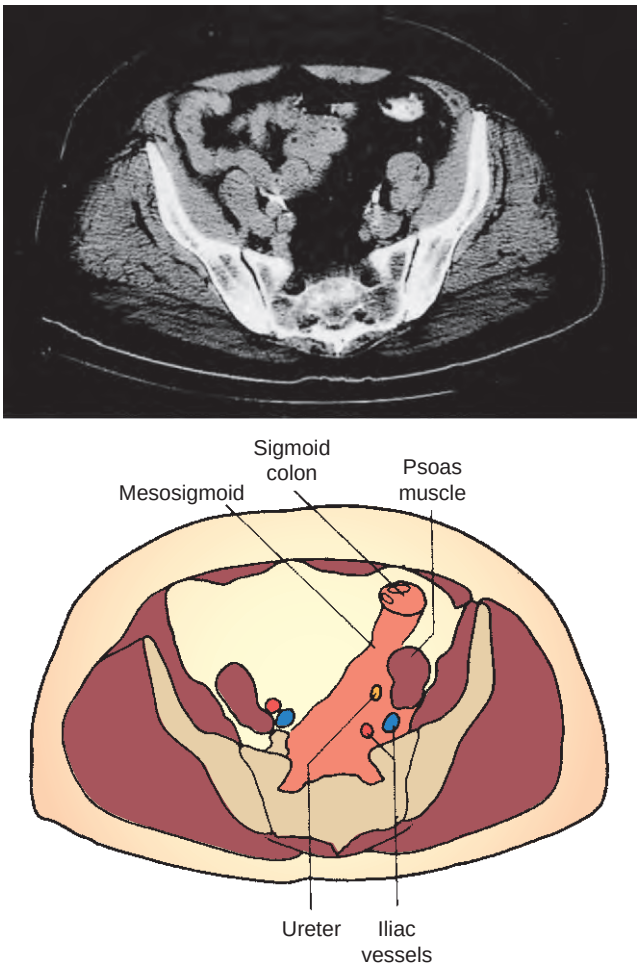

Figure 134–14. Near the pelvic brim, the colon acquires a mesentery. This marks the junction of the descending with the sigmoid colon, which in turn becomes the rectum at the sacral promontory. The sigmoid colon is variable in length and position. A long mesosigmoid colon with a short base predisposes to volvulus. Commonly, the sigmoid colon loops down into the pelvis to lie anterior to the rectum. (From Fozard JBJ, Pemberton JH: Applied surgical anatomy: Intra-abdominal contents. In Fielding LP, Goldberg SM [eds]: Rob and Smith's Operative Surgery of the Colon, Rectum, and Anus, 5th ed. Philadelphia, Chapman & Hall, 1994.)

and toward the hepatic flexure. It divides into right and left branches, which anastomose with the ascending branch of the RCA and the ascending branch of the left colic artery (LCA), respectively.

The IMA originates from the aorta at the level of L3. The LCA originates from the IMA approximately 2 to 7 cm distally and supplies the distal transverse and proximal descending colon. After a brief course directed caudad, the LCA turns cranially toward the splenic flexure and divides into an ascending and a descending branch. The ascending branch anastomoses with the left branch from the MCA, whereas the descending branch contributes to the marginal artery (see later). The sigmoid branches of the IMA supply the sigmoid colon and there are classically three, although their number varies. The descending branch of the IMA continues into the superior hemorrhoidal artery to supply the proximal rectum.

The earlier-mentioned vascular systems are connected by arterial collateral vessels that carry important clinical implications. The marginal artery of Drummond courses in close proximity and parallel to the bowel wall. It is variably anastomosed to the terminal portions of the named colic trunks as well as peripheral branches and gives origin to the terminal vasa recta that directly supply the bowel wall. It has been observed that the marginal artery is less consistently encountered at the level of the splenic flexure, where the vascular arcades connecting the MCA and LCA are often absent, in a critical colonic segment that has been described as the *Griffith's point*. It has been speculated that an inconsistent marginal artery might also enhance a more tenuous vascular supply at the junction of the lowest sigmoid branch and the superior hemorrhoidal artery, referred to as *Sudek's point*.

The meandering artery or Arc of Riolan is an additional collateral branch that can occasionally be observed intraoperatively. This branch connects the proximal MCA to the LCA and runs in the transverse mesocolon parallel to the left branch of the MCA.

Variations in the Arterial Supply Based on Anatomic Studies

Angiographic and autopsy studies have often challenged the vascular anatomy as traditionally accepted. Yada and colleagues[20] reported on 344 patients with colon cancer who were preoperatively studied with angiography. Four possible branching patterns of the RCA were detected. In 41% of cases, the RCA arose from the SMA; in 19%, it originated from the MCA; and in 14%, it arose from the ileocolic artery. It is of note that the RCA was absent in 26% of cases. In two different smaller series, although the ileocolic artery was ubiquitously found, an RCA emanating from the SMA was encountered in only 11% and 30% of cases, respectively.[21,22] Based on a superior mesenteric angiogram conducted in 273 patients, the MCA forked into the right and left branches in 160 cases (59%). Of these, 3 patients had a completely replaced MCA originating from the IMA. The remaining 113 patients had an independent origin for the left branch of the MCA, mainly from the SMA (90%) and less commonly from the IMA, dorsal pancreatic artery, or splenic artery.[20] Rare cases of an MCA originating from the celiac trunk[23] or a common trunk from which celiac, SMA, and IMA originate[24] have been reported. For every possible anatomic configuration, it is important to ensure that before resection of the right colon, the proximal vascular ligation is properly carried out at the level of the ileocolic artery. An excessively proximal ligation would actually occur at the level of the SMA and imperil the blood supply of all or part of the small bowel. Similar anatomic variations have been observed in the distal colon, where three distinct patterns of branching have been observed for the LCA. In the most common, encountered in 58% of cases, the LCA and the first sig-

moidal artery were distinct branches that arose from the IMA. However, in 27% of cases, the LCA and the main sigmoid artery shared a common trunk, and in 15% of patients, the LCA and the first sigmoidal artery arose simultaneously from the IMA.

Venous Return

The venous supply to the colon has been less extensively investigated than the arterial system. It is generally accepted that the venous return corresponds to the arterial supply. In general, although the right side of the colon drains into the SMV and from there into the portal vein, the left colon drains into the IMV, which drains into the splenic vein and only then into the portal system. In particular, the cecum and the appendix drain into the ileocolic vein, which is a tributary of the SMV. The ascending colon and hepatic flexure venous return follows the corresponding arteries and also drain into the SMV. Similarly, the middle colic vein drains into the SMV from the transverse colon and part of the splenic flexure. In a study examining the venous anatomy of the right colon on 58 cadavers, there was a single ileocolic vein in all cases. The right colic vein was absent in 57% of cadavers and single in the remainder. When present, the right colic vein joined the SMV in 56% of cases and the gastrocolic trunk in the remaining 44%. The middle colic vein was double in 50% of cases, but it could also be single or triple. It generally drained in the SMV (85%) but could also drain into the gastrocolic trunk and more rarely into the splenic or IMV.[25] The left colic veins provide additional return from the same area, although their drainage is into the IMV, which is a tributary of the splenic vein and secondarily of the portal system. A similar pathway applies to the venous return from the descending and the sigmoid colon, following the respective arterial distribution.

Lymphatic Drainage

Colonic lymphatics are traditionally divided into four drainage levels (Fig. 134–15). The lymphatic plexuses located on the bowel wall drain first into the epicolic nodes, located in the epiploic appendages and subserosally. The epiploic nodes then drain into the paracolic nodes, which are located behind the peritoneum on the upper border of the transverse and on the mesenteric side of the remaining colon. The intermediate nodes are the third lymphatic station and are encountered along the course of the main colonic vessels, namely, the ICA, RCA, MCA, LCA, and sigmoid branches. The intermediate nodes ultimately drain into the lymph nodes that accompany the two main colonic tributaries, that is, the SMA and IMA. From these two main trunks, the lymphatic drainage continues into the iliolumbar chain and terminates into the thoracic duct. The significance of metastatic involvement of each of these specific stations is controversial. The current TNM classification considers only the number, not the location, of positive nodes as the preferred criterion with which to establish

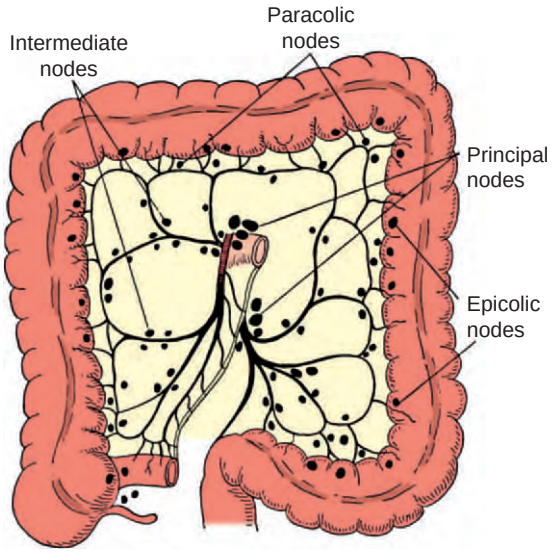

Figure 134–15. Diagram showing the epicolic, paracolic, intermediate, and principal lymph node groups that accompany the vessels of the colon. (From Grinnell RS: Lymphatic metastases of carcinoid of the colon and rectum. Ann Surg 131:494, 1950.)

the N stage. Novel information regarding the lymphatic drainage of the colon might derive from ongoing studies on sentinel lymph node–mapping techniques in relation to colorectal cancer,[26] similar to what has been shown for melanoma and breast cancer.

Innervation

The colon is widely innervated by the autonomic system, which follows the arterial distribution (Fig. 134–16). In particular, the parasympathetic system increases colonic peristalsis and secretion, with simultaneous inhibition of the sphincteric musculature. The sympathetic system acts in an opposite fashion. The sympathetic nerves originate from the intermediolateral neurons of the lower five thoracic segments and the first three lumbar segments. Preganglionic fibers proceed to the respective paravertebral chains of ganglia and then organize themselves into bundles, which give origin to the splanchnic nerves. The splanchnic nerves form distinct network-like structures referred to as *prevertebral ganglia,* such as the celiac, the superior, and the inferior mesenteric ones, which basically follow the course of the respective arteries. In these structures, synapses occur, and the emerging postganglionic fibers travel as mesenteric nerves into the mesocolon to reach the bowel wall. Similar to the arterial distribution, the proximal half of the colon is supplied by the celiac plexus through the superior mesenteric plexus, whereas the distal colon receives its sympathetic fibers from the inferior mesenteric plexus. The parasympathetic innervation of the proximal colon is derived from the celiac branch of the right vagus nerve, which reaches the celiac plexus. Fibers that exit this plexus move to the preaortic and superior mesenteric plexuses

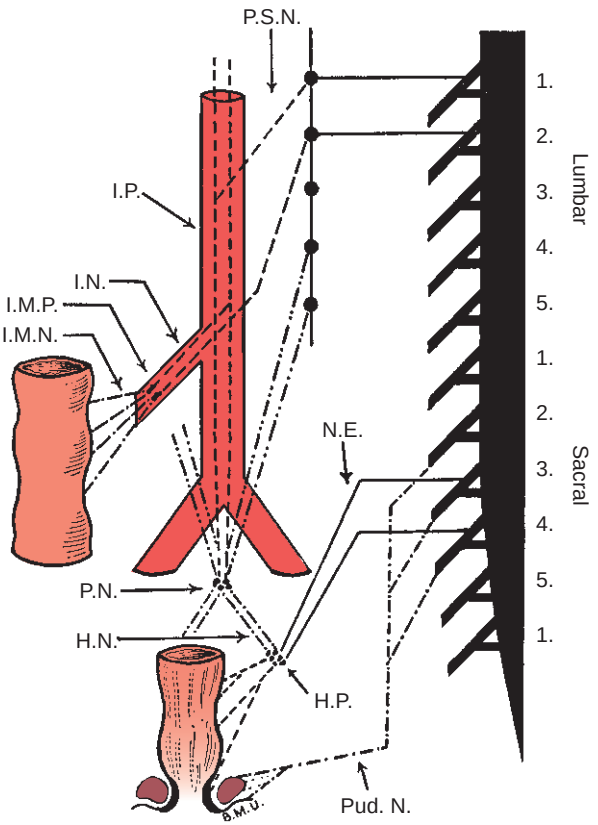

Figure 134–16. Nerve outflow to the distal part of the colon in humans. HN, hypogastric nerve; HP, hypogastric plexus; IMN, inferior mesenteric nerve; IMP, inferior mesenteric plexus; IN, intermesenteric nerve; IP, intermesenteric plexus; NE, nervi erigentes; PN, presacral nerve; PSN, pelvic splanchnic nerve; Pud N, pudendal nerve. and then follow the course of the SMA and its branches and ultimately reach the bowel wall. The distal colon receives its parasympathetic innervation through the nervi erigentes, also referred to as *pelvic splanchnic nerves,* which originate from S2 to S4. Fibers that exit from the nervi erigentes then move cranially into the presacral plexus and supply the distal transverse, descending, and sigmoid colon, traveling in close proximity to the IMA. Preganglionic fibers enter the bowel wall and synapse in the myenteric and submucosal plexuses.

Chapter

135

Physiology of the Colon and Its Measurement

Adil E. Bharucha ▪ Michael Camilleri

The human colon serves to absorb water and electrolytes, store intraluminal contents until elimination is socially convenient, and salvage nutrients after bacterial metabolism of carbohydrates that have not been absorbed in the small intestine. These functions are dependent on the colon's ability to control the distal progression of contents; in healthy adults, colonic transit normally requires several hours to almost 3 days for completion. There are differences in colonic structure and function even among mammals[1]; unless otherwise stated, this chapter focuses on the physiology of colonic function in humans. Although the colon is regarded as a single organ, there are regional differences between the right and left colon, indicated in Table 135–1. The right and left colon are derived from the embryologic midgut and hindgut, and the junction is located just proximal to the splenic flexure.

ANATOMY

In adult cadavers, the colon is approximately 1.5 m long. The musculature in the colonic wall comprises outer longitudinal and inner circular layers. From the cecum to the rectosigmoid junction, the longitudinal layer is organized in three thick bands, the taeniae, with a thin layer of longitudinal muscle in between these bands.[2] At the rectosigmoid junction, the three taeniae broaden to form a uniformly thick layer throughout the rectum. In the anal canal, the longitudinal muscle layer merges with the external anal sphincter while the circular muscle layer extends into the internal anal sphincter. Other than humans, only primates, horses, guinea pigs, and rabbits have taenia coli[3]; the taenia coli are thought to function as suspension cables on which the circular muscle arcs are suspended, facilitating efficient contraction of the circular muscle. Thus, a 17% contraction of circular muscle reduces the luminal diameter of the colon by two thirds.[4] If the longitudinal muscles were arranged concentrically, an identical contraction of circular muscle would only reduce luminal diameter by one third. Whether or not longitudinal and circular muscles contract synchronously during peristalsis is controversial.

The colon is suspended from the posterior abdominal wall by a mesentery. The mesentery is relatively narrow, restricting mobility of the cecum, ascending colon, and descending colon. Around the transverse and sigmoid colon, the mesentery is broader, permitting considerable movement and contributing to the tendency in some individuals to have a pendulous transverse colon. This also partly contributes to the fluctuations associated with looping of the colonoscope during examination.

The colon is innervated by extrinsic and intrinsic nerves.[1] The extrinsic input includes sympathetic and parasympathetic components. In several species, including primates, the vagus innervates the proximal colon. The parasympathetic input to the distal colon is derived from the sacral (S2 to S4) segments of the spinal cord via the pelvic plexus. After entering the colon, these fibers form the ascending colonic nerves, traveling orad in the plane of the myenteric plexus to supply a variable portion of the left colon. The sympathetic fibers originate in the paravertebral "chain" ganglia, segments from the T12 to L4 levels of the spinal cord, and are conveyed to the colon via arterial arcades of the superior and inferior mesenteric vessels. The sympathetic nervous system provides excitatory input to the sphincters and a tonic inhibitory input to nonsphincteric muscle. Norepinephrine is the major neurotransmitter released by sympathetic nerves throughout the small and large intestine. The intrinsic or intramural nerves are organized into myenteric and submucous plexuses and the interstitial cells of Cajal (ICCs). The myenteric plexuses and interstitial cells are primarily responsible for controlling motility; the submucous plexus regulates mucosal absorption. The extrinsic nerves modulate the intrinsic neural activity. For example, the sympathetic nervous system exerts a tonic inhibitory input on colonic motor function, primarily via stimulation of α_2-adrenergic receptors, which hyperpolarize cholinergic neurons in

Table 135–1 Comparison of Right and Left Colon

Feature	Right Colon	Left Colon
Embryologic origin	Midgut	Hindgut
Blood supply	Superior mesenteric vessels	Inferior mesenteric vessels
Extrinsic nerve supply		
Parasympathetic	Vagus	Pelvic nerves from sacral S2-4 segments
Sympathetic	Superior mesenteric ganglion	Inferior mesenteric ganglion
Function	Mixing and storage	Conduit

the myenteric plexus. Thus, the α_2 agonist clonidine decreases colonic tone whereas the α_2 antagonist yohimbine increases colonic tone in humans[5]; clonidine also enhances mucosal absorption of fluid and salt.

FUNCTIONS

Regional Heterogeneity in Colonic Function

Although the colon is regarded as a single organ, there are regional differences in normal motor function and mucosal absorption: the right colon functions primarily as a reservoir for mixing and storage processes, the left colon as a conduit, and the rectum and anal canal enable defecation and continence. The ileocolonic sphincter regulates the intermittent aborad transfer of ileal contents into the colon, mainly after meals. The rate of delivery of liquids into the proximal colon can influence colonic transit. Thus a liquid marker injected directly into the proximal colon is emptied more rapidly than after oral ingestion of the same marker.[6] There is evidence for adaptation in these regional functions. Within 6 months after a right hemicolectomy, isotope movement from the small to the large bowel normalizes in response to the augmented storage capacity in the residual transverse and descending colon.[7] In humans, the ileocolonic sphincter plays only a minor role in regulating ileocolonic transit.

Colonic Fluid and Electrolyte Transport

Under basal conditions, the healthy colon receives approximately 1500 ml of chyme over 24 hours, absorbing all but 100 ml of fluid and 1 mEq of sodium and chloride, which are lost in the feces.[8] Colonic absorptive capacity can increase to 5 to 6 L and 800 to 1000 mEq of sodium and chloride daily when challenged by larger fluid loads entering the cecum, as long as there is a slow infusion rate (i.e., 1 to 2 ml/min). In addition to the ascending and transverse colon, the rectosigmoid may also participate in this compensatory absorptive response.[9] For 25 years, secretory and absorptive processes were believed to be segregated to crypt and surface epithelial cells, respectively. It is now recognized that absorptive mechanisms are constitutively expressed in crypt epithelial cells; secretion is regulated by one or more neurohumoral agonists released from lamina propria cells, including myofibroblasts.[10]

When the colon is perfused with a plasma-like solution, water, sodium and chloride are absorbed, whereas potassium and bicarbonate are secreted into the colon.[11] Absorption of sodium and secretion of bicarbonate in the colon are active processes occurring against an electrochemical gradient. There are several different active (transcellular) processes for absorbing sodium, and these show considerable segmental heterogeneity in the human colon. The regional differentiation of colonic mucosal absorption is also demonstrated by regional effects of glucocorticoids and mineralocorticoids on sodium and water fluxes. For example, in the *distal* colon, epithelial Na^+,K^+,ATPase is activated by mineralocorticoids.[12] On the other hand, the Na^+/H^+ exchange is activated in *proximal* colonic epithelium by the mineralocorticoid aldosterone.[13] Specific channels are involved in water transport across surfaces and epithelia. These water channels, or aquaporins, are a diverse family of proteins, of which aquaporin-8 is expressed preferentially in colonic epithelium and small intestinal villus tip cells.

Potassium is absorbed and secreted by active processes; it is unclear if chloride is absorbed by an active process. In contrast with the small intestine, glucose and amino acids are not absorbed in the colon.

Colonic conservation of sodium is vital to fluid and electrolyte balance, particularly during dehydration, when it is enhanced by aldosterone.[14] Patients with ileostomies are susceptible to dehydration, particularly when placed on a low-sodium diet or during an intercurrent illness. In addition to glucocorticoids and mineralocorticoids (aldosterone), other factors enhancing active sodium transport include somatostatin, α_2-adrenergic agents and short-chain fatty acids (SCFAs). Clonidine mimics the effects of adrenergic innervation by stimulating α_2 receptors on colonocytes. In contrast, stimulation of mucosal muscarinic cholinergic receptors inhibits active NaCl absorption and stimulates active chloride secretion. Somatostatin, a peptide released by submucosal and myenteric nerves, also has potent antisecretory effects.

Colonic Metabolism

In the proximal colon, bacteria ferment organic carbohydrates to SCFAs, predominantly acetate, propionate, and butyrate.[15] There is a low, normal rate of SCFA production from "malabsorbed" (≤10% of ingested) carbohydrates; diets high in fiber, beans, resistant starches, and complex carbohydrates increase the production of SCFA. SCFA are rapidly absorbed from the colon, augment sodium, chloride, and water absorption and constitute the preferred metabolic fuel for colonocytes. SCFA may also serve to regulate proliferation, differentiation, gene expression, immune function, and wound healing in the colon.

Colonic Motility

Assessment of Colonic Motor Function

Radiopaque Marker Methods of Colonic Transit Since the original description by Hinton and colleagues, there have been several refinements to the radiopaque marker technique for measuring colonic transit.[16] In the modification described by Metcalf, a capsule containing 20 radioactive markers is ingested at the same time on each of 3 consecutive days; a plain abdominal radiograph is taken on the 4th day. The number and distribution of markers in the abdomen provide a measure of overall and regional colonic transit (Fig. 135–1). The maximum whole-gut transit time with a single plain radiograph on day 4 is 72 hours, which is barely 2 SDs above the mean for healthy controls. This upper limit can be extended to 120 hours by administering a capsule containing 24 radiopaque markers once daily for 5 days and taking a plain abdominal radiograph on the 6th day, 24 hours after the last capsule.[17]

Scintigraphic Techniques of Colonic Transit Colonic transit can also be assessed by scintigraphy (Fig. 135–2).[16] To avoid dispersion of the radiolabel during passage through the gastrointestinal tract, the isotope is delivered into the colon by orocecal intubation or a delayed-release capsule. The delayed-release capsule contains activated charcoal or polystrene pellets radiolabeled with ^{99m}Tc or ^{111}In and covered with a single coating of a pH-sensitive polymer, methacrylate. The capsule dissolves at a pH between 7.2 and 7.4, generally within the distal ileum, releasing the radioisotope within the ascending colon. The colonic distribution of radioisotope on scans taken 4, 24, and 48 hours after administration of the capsule is highly sensitive and specific for identifying rapid or slow colonic transit. The proportion of counts in each of four colonic regions of interest (i.e., ascending, transverse, descending, and rectosigmoid colon)

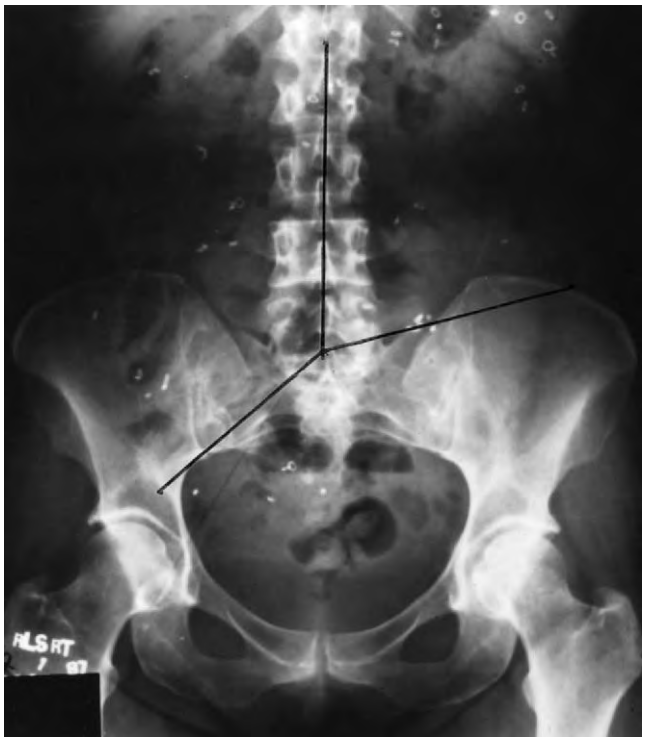

Figure 135–1. Abdominal radiograph demonstrating radiopaque markers and lines used to demarcate markers in the left, right, and sigmoid colon/rectum.

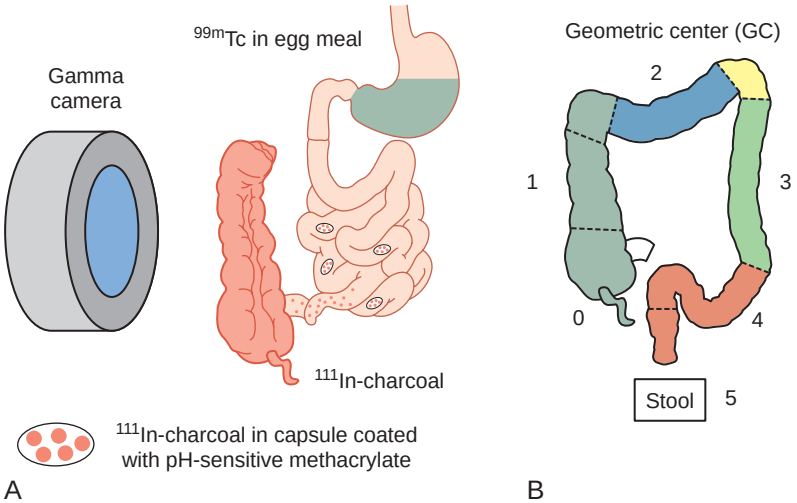

Figure 135–2. Scintigraphic assessment of gastrointestinal transit. **A,** Gastric emptying and small intestinal transit are assessed with ^{99m}Tc-labeled polystyrene pellets while ^{111}In-labeled charcoal in delayed-release capsules measures colonic transit. **B,** Proportion of ^{111}In counts in each of four colonic regions of interest and stool is multiplied by the appropriate weighting factor, ranging from 1 to 5.

and stool is multiplied by a specific weighting factor that ranges from 1 (for the ascending colon) to 5 (for stool), respectively. The aggregate of these products (proportion of counts × weighting factor), provides the geometric center of overall colonic transit. A low geometric center implies that most radiolabel is close to the cecum, whereas a high geometric center implies that most radiolabel is close to stool.

Both radiopaque markers and scintigraphy are sensitive for identifying colonic transit delays in patients with slow-transit constipation. Colonic transit measurements by radiopaque markers and scintigraphic techniques are correlated with each other and involve similar total-body radiation exposure (i.e., 0.08 rad for the radioactive capsule and for each abdominal radiograph). Scintigraphy is a useful research tool that allows more thorough assessment of regional colonic functions.

Recording Techniques of Colonic Motility Colonic motor activity can be assessed by recording electrical signals or variations in luminal pressure by pressure transducers, either water perfused or solid-state, or, a balloon controlled by a barostat.[18,19] There are several limitations to recording colonic motor activity in humans. Intraluminal colonic recording devices can only be positioned using flexible colonoscopy, per oral intubation, or per nasal intubation techniques. Cleansing of the rectosigmoid and occasionally the entire colon is necessary to facilitate placement and accurate recording. Cleansing can accelerate colonic transit but does not, with the exception of more frequent high-amplitude propagated contractions (HAPCs), fundamentally alter motor activity.[20]

Recording myoelectrical activity with serosal, mucosal, or intraluminal electrodes is fraught with technical difficulties and has fallen out of favor. Currently, few centers utilize manometry to record colonic motor activity in clinical practice. Although manometry is reasonably reliable for identifying the colonic motor response to a meal (see later) or to a stimulatory agent such as neostigmine or bisacodyl, intraluminal pressure changes may not necessarily reflect colonic contractions. Indeed, simultaneous endoscopic and manometric recordings in the human colon suggest that most manometric deflections coincide with relaxation rather than colonic contraction or real-time observation.[21] The barostat system appears to have the potential to overcome this limitation, since the balloon is continuously apposed to the colonic mucosa and haustrations, permitting identification of colonic contractions and relaxation (Fig. 135–3).

The barostat system comprises an infinitely compliant polyethylene balloon connected by tubing to the barostat. The barostat is a rigid piston within a cylinder that can adjust either the pressure or volume within the bag using a servomechanism. When the balloon is inflated to a low constant pressure, colonic contraction is accompanied by expulsion of air from the balloon into the barostat. Conversely, when the colon relaxes, the balloon volume increases to maintain a constant pressure. The advantages of the barostatic balloon over manometry are greater sensitivity for recording contractions that do not occlude the lumen, particularly when the colonic diameter is larger than 5.6 cm.[22] Moreover, a barostat can record changes in baseline balloon volume and phasic fluctuations, colonic relaxation, and colonic pressure-volume relationships. Thus, the barostat is primarily a research tool that has been introduced into clinical practice in selected centers.

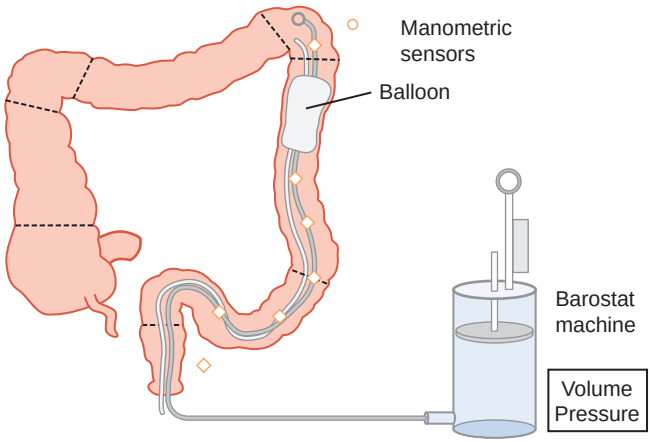

Figure 135–3. Barostat-manometric assembly positioned in the descending colon with polyethylene balloon in apposition with colonic mucosa.

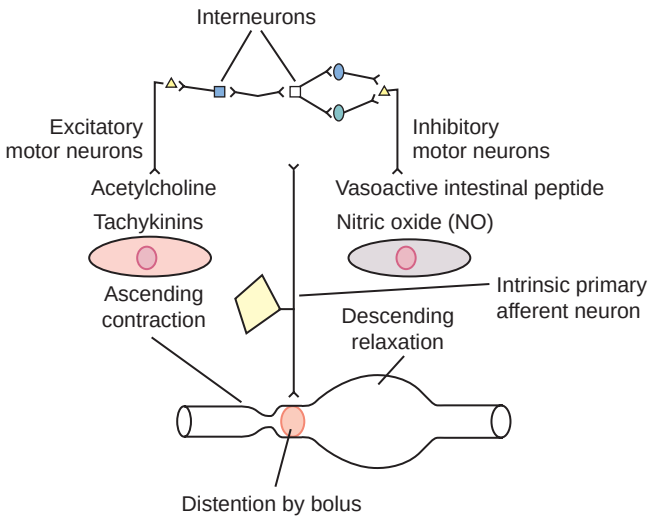

Figure 135–4. Schematic representation of major neurotransmitters mediating peristaltic reflex. Mechanical distention activates sensory neurons, whereas interneurons transmit messages between sensory and motor neurons.

Peristalsis

Distention of a viscus evokes the peristaltic reflex, characterized by coordinated contraction of the orad segment and relaxation of the distal gut, facilitating propulsion. The neural pathways and neurotransmitters mediating this reflex are depicted in Figure 135–4. In the human colon, the principal excitatory neurotransmitter

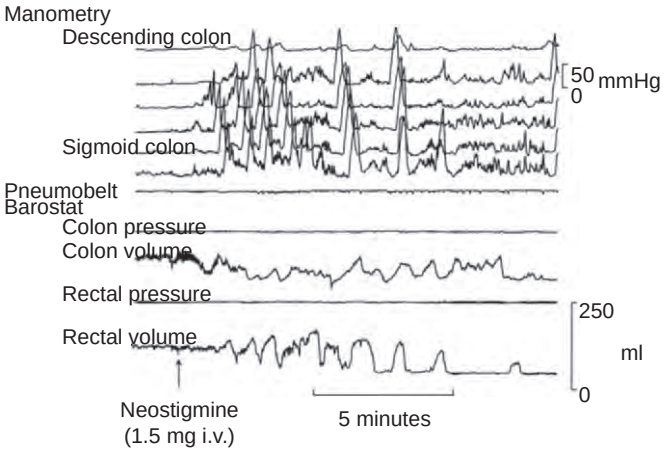

Figure 135–5. High-amplitude propagated contractions induced by neostigmine. (From Law NM, Bharucha AE, Undale AS, et al: Cholinergic stimulation enhances colonic motor activity, transit, and sensitivity in humans. Am J Physiol Gastrointest Liver Physiol 281:G1228-G1237, 2001.)

is acetylcholine, whereas in vitro studies suggest that NO and ATP are inhibitory neurotransmitters in the human colon.

Cellular Basis for Motility

Contraction of smooth muscle results from interactions between smooth muscle, the ICCs, the intrinsic or enteric nervous system, and the extrinsic nervous system. ICCs are the pacemaker cells, responsible for generating slow-wave activity which drives smooth muscle contraction. ICCs also amplify neuronal input, act as mechanotransducers, and regulate smooth muscle membrane potential. ICCs are located in two networks: one in the myenteric plexus region and the other in the submucosa. They are also found interspersed in longitudinal and circular muscle layers (Fig. 135–5). The three basic electrical events recorded from human colonic circular smooth muscle in vitro are (1) slow-wave activity with a frequency of two to four contractions per minute, originating along the submucous plexus border of the circular muscle layer; (2) membrane potential oscillations (MPOs), with a frequency of about 18 contractions per minute, originating in the myenteric plexus border of circular muscle; and (3) action potentials superimposed on slow waves and MPOs.[23]

Slow waves and MPOs summate in the central region of circular muscle, producing a complex pattern of activity that regulates contractile amplitude and frequency. The predominant contractile rhythm recorded from the human colon in vitro and in vivo corresponds to the slow-wave frequency of two to four per minute. Repolarization of membrane potential during slow waves result in opening of L-type Ca^{2+} channels and, when a firing threshold is reached, action potentials. The result is Ca^{2+} influx through L-type Ca^{2+} channels initiating smooth muscle contraction. L-type Ca^{2+} channels are blocked by nifedipine. In the presence of nifedipine, smooth muscle contraction is inhibited and action potentials are absent. Tonic contractions are generated by continuous action potentials. In contrast to regular cyclical contractile activity in the stomach and small intestine, colonic motility is markedly irregular. This irregularity is partly attributable to the variable frequency and duration of action potentials but is not well understood.

Colonic Motor Function in Health

In contrast with the canine colon, contractile activity in the human colon is not cyclical. Colonic motor activity may vary from no activity or quiescence, isolated contractions, bursts of contractions, or propagated contractions. Irregular phasic activity constitutes a major proportion of colonic motor activity and probably serves to segment and mix intraluminal contents. Combined assessments of motor activity and transit in the cleansed colon of healthy subjects reveal that transit is associated with nonpropagated and propagated contractions; propagated contractions propel contents over longer distances than nonpropagated contractions.[24] However, only one third of propagated contractions are accompanied by propulsion of colonic contents. Propagated contractions are subclassified as low (5 to 40 mm Hg) or high amplitude (>75 mm Hg). In ambulatory, prolonged colonic manometry studies, HAPCs occur on an average of six times per day, originate predominantly in the cecum/ascending colon, and migrate over a variable distance. These HAPCs are probably responsible for mass movement of colonic contents. HAPCs occur more frequently after awakening and after meals and may account for the urge to defecate in healthy subjects and in patients with irritable bowel syndrome (IBS) (see Fig. 135–5). The mechanisms that underlie HAPCs are poorly understood. In addition to occurring spontaneously, HAPCs can be induced by luminal distention, by the parenteral administration of cholinesterase inhibitor neostigmine, or by intraluminal stimuli (i.e., glycerol, bisacodyl and oleic acid).

Eating is accompanied by a brisk increase in tone and phasic activity throughout the colon (Fig. 135–6).[25] Because this response is preserved even after a gastrectomy, the term *colonic motor response to eating* is preferred to *gastrocolonic reflex*. The response may begin within a few seconds after eating and last, to a varying degree, for up to $2^1/_2$ hours. A biphasic response with early (first 60 minutes) and late (120 and 150 minutes) components has also been described.[26] Meal composition and caloric content both influence the response. A mixed meal containing more than 500 kcal predictably elicits a response. Gastric distention and chemical stimulation by nutrients elicit comparable responses; lipids are the most potent stimuli, whereas amino acids appear to inhibit the response.[27]

The precise mechanisms mediating the response are uncertain, but neural and hormonal mechanisms have been implicated. It is conceivable that different mechanisms regulate the early and late components.[28] The early, particularly the immediate, component is likely to be neurally mediated. The later component temporally

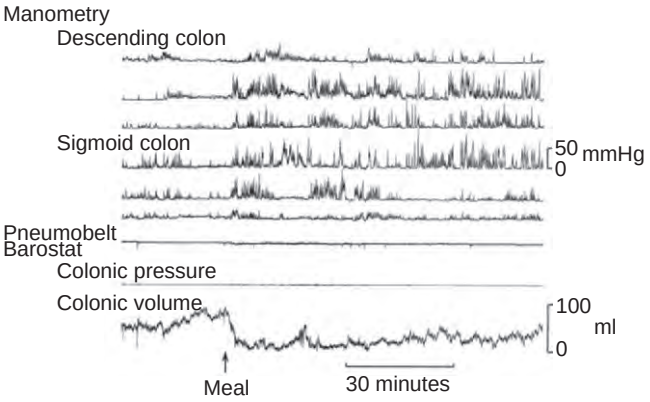

Figure 135–6. Colonic motor response to a 1000-kcal meal. Note the increased phasic pressure activity recorded by manometric sensors and reduction in barostat balloon volume maintained at constant pressure, indicating increased tone.

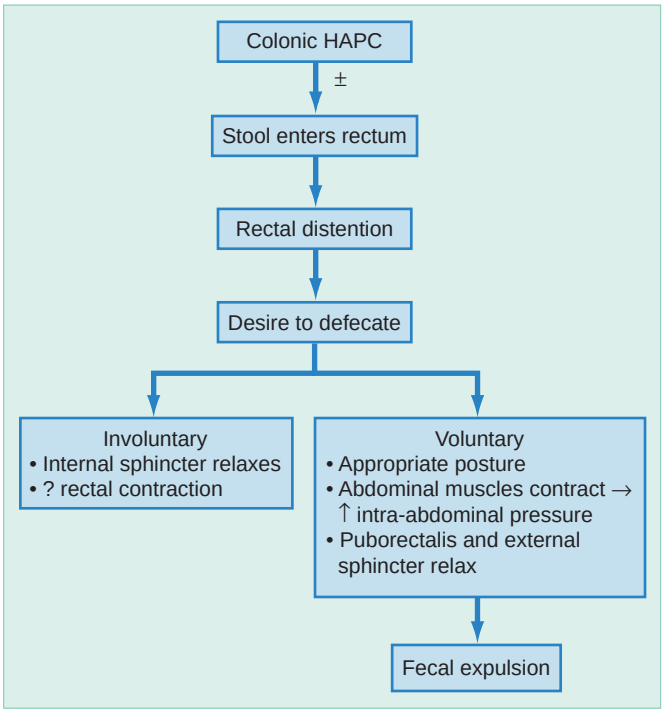

Figure 135–7. Schematic representation of events preceding defecation. HAPC, high-amplitude propagated contraction.

coincides with arrival of chyme into the ileum and may be mediated by humoral factors such as peptide YY, neuropeptide Y, and neurotensin released from the ileal mucosa. Although serum levels of gastrin and cholecystokinin rise after a meal, intravenous cholecystokinin actually induces colonic relaxation.[29] Atropine, naloxone, and the 5-hydroxytryptamine-3 (5-HT_3) antagonist ondansetron inhibit the response indicating that cholinergic, opiate, and serotoninergic 5-HT_3 receptors may be involved in mediating the response.[30] There is also evidence to suggest that efferent vagal fibers contribute to the colonic motor response in primates.[31]

The colon relaxes during sleep, after intraluminal administration of SCFAs or glycerol, during balloon distention of the rectum, and in response to parenterally administered pharmacologic agents. In addition to the α_2-adrenergic agonist clonidine, morphine, atropine, the 5-HT_{1A} agonist buspirone,[28] and the 5-HT_{1D} agonist sumatriptan all reduce colonic tone in humans.[32-34] Rectal distention by a balloon to subnoxious levels induces colonic relaxation in humans.[35] Colocolonic reflexes mediated via local nervous pathways through the prevertebral ganglia and independent of central nervous system activity have been well characterized in animal preparations.[36] This propensity for colonic relaxation, particularly that induced by sympathetic stimulation and opiates, may be relevant to the pathophysiology of acute colonic dilation or pseudo-obstruction.[37] Colonic relaxation induced by rectal distention may explain left-sided colonic transit delays in patients with obstructed defecation since restoration of normal defecation tends to restore colonic motility to normal.[38]

There are regional and age-related differences in biomechanical properties of the colon.[4] These biomechanical properties can be assessed by stress-strain relationships in vitro and by the pressure-volume relationships during balloon distention by a barostat in vivo. In ex vivo and in vivo studies, stiffness declines from the rectum to the transverse colon. These observations are probably relevant to the segmental heterogeneity in function depicted in Table 135–1 and to the pathophysiology of diverticulosis, as discussed later. Thus, the compliant ascending and transverse colon are ideally suited to function as a reservoir. Conversely, the descending and sigmoid colonic segments are suited to function as conduits, tend to have lower compliances, and are the primary sites of diverticula since intraluminal pressures are transmitted to weak points in the colonic wall.

Defecation

In health, rectal distention evokes the desire to defecate and reflex relaxation of the internal anal sphincter (Fig. 135–7). If social circumstances are conducive, defecation is accomplished by adoption of a suitable posture and contraction of the diaphragm and abdominal muscles to raise intra-abdominal pressure. Concomitant relaxation of the puborectalis and external anal sphincter, both striated muscles, enables widening of the anorectal angle by 15 degrees or more, reduction of pressure within the anal canal, and perineal descent. Appropriate coordination between abdominal contraction and pelvic floor relaxation is crucial to normal fecal expulsion. In addition, there is evidence to suggest that these somatic processes are integrated with visceral components such as colonic HAPCs during defecation.

Colonic Sensation

Healthy individuals, for the most part, do not perceive physiologic processes within the gut except for the

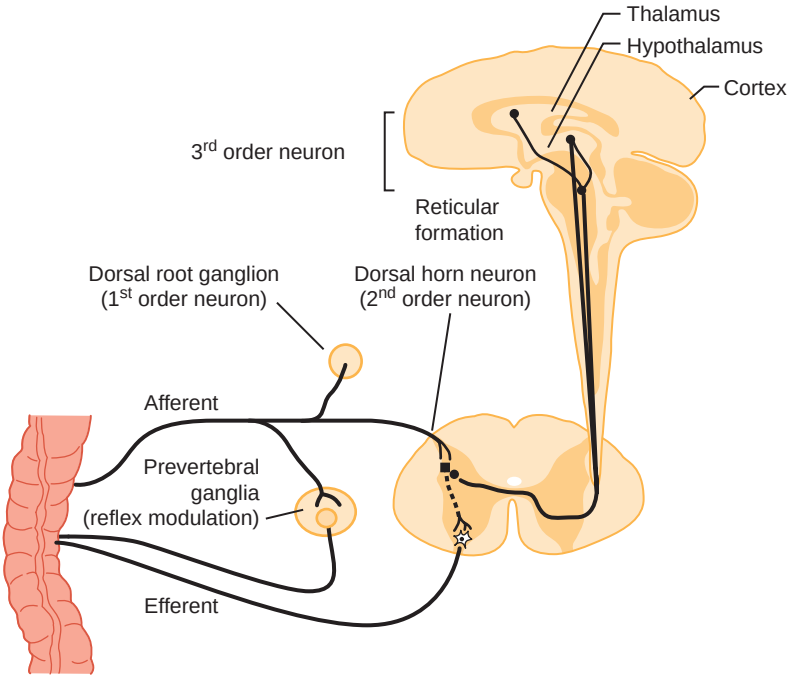

Figure 135–8. Visceral sensory pathways include reflexes mediated through prevertebral and other autonomic ganglia and a third-order neuron chain that ultimately projects to supraspinal centers. Convergence of visceral and somatic afferents at the dorsal horn explains referral of visceral discomfort to the body surface. Third-order neurons originating in thalamus project to the cerebral cortex; those from the reticular formation project to the thalamus and hypothalamus. (From Camilleri M, Saslow SB, Bharucha AE: Gastrointestinal sensation: Mechanisms and relation to functional gastrointestinal disorders. Gastroenterol Clin North Am 25:247-258, 1996.)

Table 135–2 Visceral Afferent Pathways

Functions	Discriminative	Affective-Motivational
Afferent fibers	Rapidly conducting Aδ fibers	Unmyelinated C fibers
Thalamic nuclei	Lateral	Medial
Cortical area	Somatosensory cortex	Frontal, parietal, and limbic regions

sensation of fullness and the desire to defecate. Over the past few years, it has been proposed that symptoms associated with functional gastrointestinal disorders are partly related to enhanced sensory perception.[39] Visceral sensation is perceived in peripheral receptors and conveyed centrally by a three-neuron chain (Fig. 135–8).[40] Although visceral afferents can respond to one or more stimulus modality (e.g., tension, temperature, osmolarity), mechanoreceptors are particularly important in the context of functional gastrointestinal diseases. Mucosal mechanoreceptors respond to mucosal pinching or stroking, whereas serosal mechanoreceptors respond to movement or strong distention of a viscus. Visceral perception is characterized by discriminative (localizing, precise) and affective-motivational (diffuse, emotional) aspects, which are conveyed by discrete mechanisms, demonstrated in Table 135–2.

The predominant afferent fibers are rapidly conducting myelinated Aδ fibers and slowly conducting unmyelinated C fibers. The Aδ fibers convey the sensation of first pain, which is well localized and lasts as long as the stimulus. The C fibers convey the "second" pain, which is diffuse, lasts longer than the duration of the stimulus, and is associated with the affective-motivational aspects of pain. In the spinal cord, visceral afferents project centrally via spinothalamic and spinoreticular tracts and a nociceptive dorsal column. The spinothalamic tracts project to the medial and lateral thalamic nuclei, which are associated with affective-motivational and discriminative aspects of pain, respectively. These thalamic nuclei project to the cortical areas indicated in Table 135–2. Descending (chiefly serotoninergic and adrenergic) pathways originating in the frontal cortex, hypothalamus, and brain stem reticular formation inhibit spinal cord dorsal horn neurons, thereby reducing pain perception.

In humans, colonic (and rectal) perception is assessed during balloon distention. The rate and pattern of balloon distention are important parameters. Perception is assessed by asking subjects to indicate when they perceive a given sensation, such as first threshold, desire to defecate, or discomfort. To avoid bias resulting from gradually increasing stimuli, the distending stimuli can be randomized. The contractile response is more pronounced during fast than during slow distention. It is conceivable that this partly explains why rapid rectal distention is more likely than slow distention to be perceived in healthy subjects and to evoke visceral hypersensitivity in IBS.[41,42]

An alternative method involves asking patients to rate the intensity of perception during balloon distentions of standardized intensity delivered in random order.[43] Perceptual intensity is recorded on separate visual analog scales for gas, desire to defecate, and discomfort. With this technique, subjective perceptual ratings are

proportional to the intensity of the stimulus. Moreover, this technique is responsive to alterations in visceral perception induced by psychological stress and relaxation, by the α_2 agonist and antagonist clonidine and yohimbine, respectively, and by the cholinesterase inhibitor neostigmine.

In humans, balloon distention of the left colon evokes abdominal discomfort in the midline or left iliac fossa. The rectum is more sensitive than the colon and can distinguish between flatus and feces. Rectal distention induces rectal or sacral discomfort, akin to the desire to defecate, or urgency. The anal canal is exquisitely sensitive, with sensitivity to touch, pain, and temperature comparable to the dorsum of the hand.

Perturbations of Colonic Physiology in Disease States

Examples of illnesses that derange colonic physiology, as discussed in the following sections, include constipation, obstructed defecation, acute colonic pseudo-obstruction, chronic megacolon, functional diarrhea or diarrhea-predominant IBS, other diarrheal illnesses, and diverticulosis.

Constipation

Constipation may result from alterations of colonic transit and pelvic floor function; an algorithmic approach for the management of constipation includes tests of both physiologic processes (Fig. 135–9).[44] Colonic transit is frequently delayed in patients with obstructed defecation, which should be considered in all patients with delayed colonic transit. Patients with normal-transit constipation usually respond to dietary fiber supplementation[45]; those with slow-transit constipation frequently require judiciously administered laxatives, and pelvic floor retraining is necessary to reverse pelvic floor dysfunction in patients with obstructed defecation. In patients with chronic constipation, intraluminal measurements may demonstrate fewer HAPCs over a 24-hour period and/or a reduced colonic motor response to eating.[46] Thus, intraluminal measurements are useful for confirming the presence of severe colonic motor dysfunction prior to surgery in patients with slow-transit constipation. Patients with colonic inertia represent one end of the spectrum of slow-transit constipation that is characterized by absence of a colonic motor response to a meal or a stimulatory agent such as bisacodyl or neostigmine. Detailed histopathologic studies with special stains reveal a marked loss of nerves and ICCs throughout the colon in slow-transit constipation and megacolon (Fig. 135–10).[47] Rarely, constipation may be the presenting manifestation of a generalized gastrointestinal motility disorder resulting from a paraneoplastic syndrome, (e.g., due to small cell carcinoma of the lung).[48]

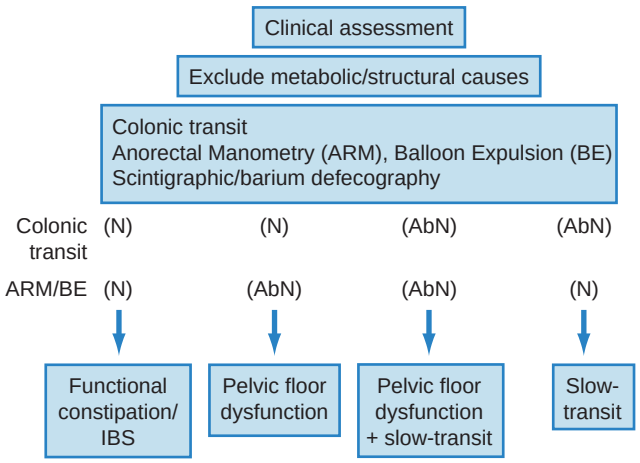

Figure 135–9. Diagnostic tests in the management of constipated patients in clinical practice. Note that these simple tests permit categorization of patients and choice of therapy. AbN, abnormal; IBS, irritable bowel syndrome; N, normal.

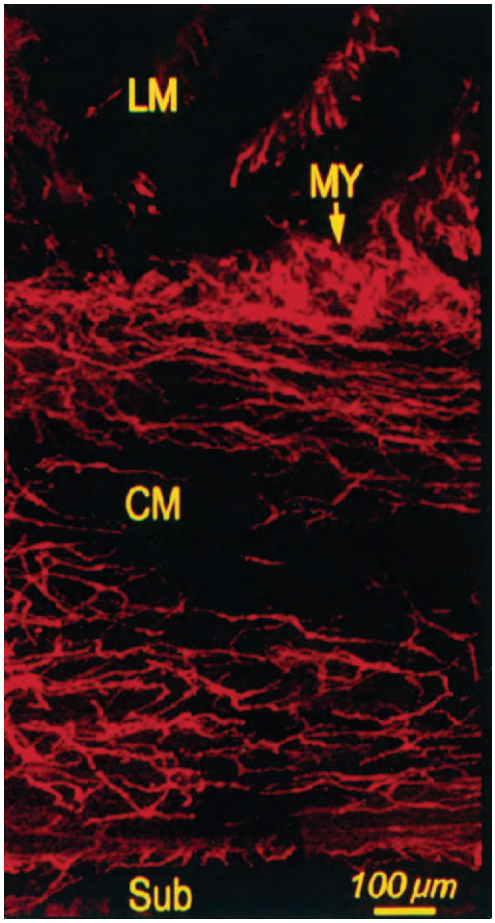

Figure 135–10. Distribution of interstitial cells of Cajal (ICC) as demonstrated by c-*Kit*–positive immunoreactivity, in the normal human sigmoid colon. Sections were cut parallel to the longitudinal muscle layer. CM, circular muscle; LM, longitudinal muscle; MY, myenteric plexus region; Sub, submucosal border. (From He CL, Burgart L, Wang L, et al: Decreased interstitial cell of Cajal volume in patients with slow-transit comstipation. Gastroenterology 118:14, 2000.)

Obstructed Defecation

Patients with obstructive defecation strain excessively to overcome the functional obstruction caused by inadequate relaxation of the external anal sphincter and/or puborectalis muscle sling.[49] The distinction between these two components (i.e., puborectalis and external anal sphincter) is often blurred by the term *anismus* to describe pelvic floor dyssynergia. Symptoms that are suggestive, but not necessarily specific, of obstructed defecation include frequent straining, a sensation of incomplete evacuation, dyschezia, and digital evacuation of feces. The physical examination may reveal high resting anal sphincter tone, failure of puborectalis relaxation and/or perineal descent during simulated defecation, or anatomic abnormalities such as anal fissure or rectocele. The latter may occur alone or may be accompanied by pelvic floor laxity and organ prolapse (descending perineum syndrome). The clinical impression can be corroborated by objective assessments of pelvic floor function, beginning with anal manometry and a rectal balloon expulsion test (Box 135–1). With anal manometry or sphincter electromyography, paradoxical sphincter contraction or anismus can be observed in up to 20% of healthy subjects with no symptoms of obstructed defecation. This underscores the importance of considering clinical features in diagnosing obstructed defecation. The rectal balloon expulsion test, performed by measuring the time required to expel, or external traction required to facilitate expulsion of a rectal balloon filled with water or air, is a useful, highly sensitive (89%) and specific (84%) test for evacuation disorders.[50] The balloon expulsion test is a useful screening test but does not define the mechanism of disordered defecation nor does a normal balloon expulsion study always exclude a functional defecation disorder.[51] Anal manometry and an abnormal balloon expulsion test suffice to confirm the diagnosis of an evacuation disorder in most patients with typical symptoms and reduced perineal descent (i.e., <1 cm) at clinical examination. However, if the results of anal manometry and the rectal balloon expulsion test are discrepant, or conflict with the clinical impression, then anorectal imaging may be necessary to clarify the diagnosis. Defecography is a dynamic technique to evaluate rectal and pelvic floor motion during attempted defecation. This test can detect structural abnormalities (rectocele, enterocele, rectal prolapse) and assess functional parameters (anorectal angle at rest and during straining, perineal descent, anal diameter, indentation of the puborectalis in the posterior aspect of the recto-anal junction, degree of rectal emptying).[52,53] The diagnostic value of defecography has been questioned primarily because normal ranges for quantified measures are inadequately defined and because some parameters such as the anorectal angle cannot be measured reliably because of anatomic variations in rectal contour and location (e.g., in the presence of perianal discomfort). Magnetic resonance imaging (MRI) is the only imaging modality that can visualize both anal sphincter anatomy and global pelvic floor motion (anterior, middle, and posterior compartments) in real time without radiation exposure. Dynamic MRI depicts the heterogeneity in functional defecation disorders and may be useful for clarifying the diagnosis in selected patients.[54,55] Patients with obstructed defecation may also have delayed left colonic transit, attributable to obstruction of luminal contents by retained stool, colonic motor dysfunction unrelated to obstructed defecation, rectocolonic inhibition, or decreased colonic motor response to a meal. The latter is reversible after biofeedback therapy.[38]

Box 135–1 Diagnostic Tests for Obstructed Defecation*

- Anorectal manometry/anal sphincter EMG—would show failure of anal canal pressure/EMG activity to decline
- Balloon expulsion—would show an inability to expel the rectal balloon within established norms for weight to facilitate expulsion
- Barium/scintigraphic defecography—would show (1) an increase in rectoanal angle of <15 degrees; and (2) perineal descent by <1 or >4 cm

*During simulated defecation.
EMG, electromyography.

Acute Colonic Pseudo-obstruction (Ogilvie's Syndrome)

In *acute megacolon* (Ogilvie's syndrome), colonic dilation is attributed to a sympathetically mediated reflex response to a number of serious medical or surgical conditions in elderly patients.[37] Cholinesterase inhibitors such as neostigmine enhance colonic contractility, reducing colonic distention in patients with acute colonic pseudo-obstruction by increasing the availability of acetylcholine in the myenteric plexus and neuromuscular junction.[56]

Chronic Megacolon

Chronic megacolon may be congenital (due to Hirschsprung's disease) or may represent the end stage of any form of refractory constipation. The initial treatment for Hirschsprung's disease is surgery. In chronic idiopathic megacolon, medical measures such as colonic evacuation with enemas, fiber supplementation, and laxatives may suffice; if severe motor dysfunction is confined to the colon, a subtotal colectomy with an ileorectal anastomosis or an ileostomy may be necessary.

Functional Diarrhea or Diarrhea-Predominant Irritable Bowel Syndrome

A subset of patients with functional diarrhea or diarrhea-predominant IBS have accelerated proximal colonic transit,[57] more frequent HAPCs,[58] and an exaggerated colonic motor response to eating. These result in

postprandial abdominal discomfort and urgency to defecate in some patients with diarrhea-predominant IBS. Other studies have shown that approximately 50% of patients with diarrhea-predominant IBS have rectal hypersensitivity or project sensation to a wider cutaneous area during balloon distention. However, the significance of visceral hypersensitivity during balloon distention to symptoms in patients with IBS is unclear and several methodologic issues need clarification.[59] Moreover, the association between rectal hypersensitivity and intensity of symptoms in patients with IBS is weak, and rectal hypersensitivity does not accurately predict the response to therapy.

The etiopathogenesis of IBS is still incompletely understood. In some patients, symptoms may be preceded by acute gastroenteritis, psychological stress, or pelvic surgery. In a prospective study, hypochondriasis or a recent stressful life event predicted which patients would have abnormal colonic physiology and IBS symptoms after an attack of acute gastroenteritis.[60]

Other Diarrheal Illnesses

In carcinoid syndrome there is accelerated small intestinal transit and increased jejunal secretion. However, there is also evidence for altered *colonic* physiology. Increased delivery of contents to the colon is compounded by reduced capacitance in the ascending colon and an exaggerated colonic motor response to eating, causing rapid proximal colonic emptying.[61] 5-HT_3 antagonists, such as ondansetron and alosetron, reduce the colonic tonic response to eating and the rate of emptying, respectively, suggesting that 5-HT_3 receptors may partly mediate the motor dysfunction in these patients.[30]

Disturbances in motility and NaCl absorption have been described in patients with *ulcerative colitis*. Patients with active proctitis have a stiff, noncompliant rectum, which may explain the enhanced sensation of urgency prior to defecation.[62]

Diarrhea after *ileal resection* of less than 100 cm is induced by the secretory effects of bile acids, associated with mild steatorrhea (<20 g/day), and responsive to cholestyramine (4 to 6 g/day).[63] After more extensive ileal resection (>100 cm) steatorrhea is severe (>20 g of fat/day) and attributable to fat maldigestion and malabsorption secondary to low jejunal concentrations of bile acids. Cholestyramine will not ameliorate and may aggravate diarrhea in these patients.

Clonidine ameliorates the diarrhea related to *diabetic neuropathy* by restoring the α_2-mediated sympathetic "brake," such as promoting intestinal and colonic absorption of NaCl and inhibiting motility.[64]

Diverticulosis

Considerations relevant to the pathophysiology of diverticulosis include the orientation of taeniae coli, the course taken by perforating arteries supplying the colonic wall, and changes in the biomechanical properties of the colon that accompany diverticulosis. Colonic diverticula are mucosal pouches that are pushed out between arcs of circular muscle at weak points, such as where arteries pierce the muscularis propria in the spaces between the mesenteric taenia and the two antimesenteric taeniae. Thus, diverticula do not occur where the taeniae fuse to form a longitudinal muscle layer surrounding the rectum.[65]

Thickening of the colonic circular and longitudinal muscle layers, partly due to elastin deposition with shortening of taeniae coli, may narrow the colonic lumen in diverticulosis. Recent studies also reveal colonic motor disturbances (i.e., more propulsive activity, more 2- or 3-cycle/min regular, phasic, nonpropagated activity) and heightened perception of colonic distention in patients with uncomplicated, symptomatic diverticulosis.[66] Thus, it is conceivable that increased motor activity, particularly rhythmic contractions, may lead to mucosal outpouching and formation of diverticula, particularly when the colon is less compliant and/or narrower, such as in the sigmoid colon or in the presence of long-standing disorders of defecation. These motor disturbances may be partly attributable to cholinergic hypersensitivity.[67] It has been speculated that a low-residue diet with diminished fecal bulk predisposes to colonic luminal narrowing and ultimately diverticulosis. However, there is no direct evidence to corroborate a cause-effect relationship between lack of dietary fiber and luminal narrowing or elastin deposition in the taeniae coli.

Implications of Colonic Physiology for Surgical Practice

The physiological concepts discussed earlier have considerable implications for colorectal surgical practice. For example, it is crucial to treat pelvic floor dysfunction in patients with severe constipation prior to considering colectomy in those with delayed colonic transit. A colectomy with ileorectostomy is the preferred procedure for patients with intractable constipation and adequate anal sphincter function.[68] Assessment of gastric and small intestinal transit or motor activity may permit recognition of patients with generalized gut dysmotility disorders in whom long-term success rates after a colectomy for constipation are lower than in patients with selective colonic dysmotility. Left-sided colectomy may result in postoperative colonic transit delays in the unresected segment; this likely represents parasympathetic denervation, since ascending intramural fibers travel in retrograde manner from the pelvis to the ascending colon. The sigmoid colon and rectum are also supplied by descending fibers that run along the inferior mesenteric artery. These nerves may be disrupted during a low anterior resection, leaving a denervated segment that may be short or long depending on whether the dissection line includes the origin of the inferior mesenteric artery.[69] A long denervated segment is more likely to be associated with nonpropagated colonic pressure waves and delayed colonic transit than a short denervated segment. In addition to colonic denervation, a low anterior resection may also damage the anal sphincter and reduce rectal compliance[70]; in contrast to anal sphincter injury, rectal compliance may recover with time.[71] Physiologic assessments confirm clinical observations suggesting that colonic

motor function recovers more rapidly after laparoscopic-assisted compared with open sigmoid colectomy.[72]

Surgeons should also be aware of the fluid-absorptive capacity of the colon and its importance in fluid and electrolyte homeostasis. The retention of a segment of colon can make an enormous difference to the postoperative management of short bowel syndrome after massive resection for mesenteric vascular thrombosis or Crohn's disease.

Motor disorders of the colon may manifest with colonic dilation. Not all dilation is secondary to obstruction and, in the presence of comorbidity or electrolyte imbalance, megacolon should be considered early, particularly since it can be treated medically or endoscopically without resorting to resection.

Finally, colorectal surgeons, like gastroenterologists, encounter many patients in their practice in whom the diagnosis is functional diarrhea, constipation, or fecal retention. These patients deserve a compassionate, careful appraisal and advice on how to restore normal colonic physiology. Avoidance of unnecessary colonic or other surgery is the best course of management—*primum non nocere*.

Diagnosis of Colon, Rectal, and Anal Disease

Julie K. Marosky Thacker ▪ Scott A. Strong ▪ James M. Church

It is self-evident that the appropriate treatment of diseases of the colon, rectum, and anus relies on a correct diagnosis. A correct diagnosis is built on three pillars: history, examination, and investigation. Taking a good, accurate, and targeted history; performing a careful and revealing physical examination; and choosing the right investigations require skill and acumen. The wisdom that comes with experience is of great value in perfecting these diagnostic techniques. Clinical diagnostic skills have, in general, been less valued as part of a diagnostic work-up since the 1980s, as easy access to a plethora of imaging techniques has tended to encourage taking "the easy way out." As clinicians are asked to account for the costs of every investigation, we are reminded to begin with as thorough a clinical assessment as possible, saving expensive investigative tests for well-defined indications. We need to ask the right questions of our patients, know what to look for on examination and how to look for it, and choose only tests that will make a difference. In this chapter, we hope to provide some directions toward attaining these goals. We consider diagnosis under the broad headings of history, examination, and investigation, and because other chapters follow a disease-oriented approach, we focus on symptoms.

HISTORY

General Principles

The history of a patient with colon, rectal, or anal disease can be the key to the diagnosis. When the patient describes symptoms, the likely site and nature of the problem direct the remainder of the history. Keeping an open mind is important, though, as a patient may use diagnostic terminology in a lay application and misguide the investigation. For example, "hemorrhoids" could mean rectal prolapse, an abscess, or a fissure. Basic history-taking skills are important and are refined by a mental differential diagnosis that impels specific questions. The astute clinician should inquire about the patient's bowel habits, typical diet, and use of medications. Apart from the history of the presenting complaint, it is important to document comorbid diseases, medication use that includes over-the-counter drugs, drug allergies and intolerances, past operations, and family history of related diseases or colorectal cancer (CRC). Anal disorders in particular may be sexually transmitted and a history of sexual practices might be necessary. After a thorough history, the differential diagnosis should be fairly well established. Examination and investigation can therefore be planned to confirm or exclude some of the possible diagnoses and to exclude other common complicating conditions.

Symptoms

Bleeding

Rectal bleeding can be categorized as typical outlet bleeding, suspicious bleeding, or hemorrhage. *Outlet bleeding* is bright red, seen only on the toilet paper or in the water, and not associated with any risk factors for colorectal neoplasia (e.g., past history or family history for colorectal neoplasia). *Suspicious bleeding* includes dark blood, blood associated with mucus, blood on or in the stool, and blood associated with either a personal or familial risk or a change in bowel habits. *Hemorrhage* is an acute, large-volume blood loss; this is discussed in detail in Chapter 145.

Outlet bleeding is usually associated with an obvious anal cause. The history provides important clues. If the bleeding is associated with pain, suspect fissure, or excoriation. If it is painless, consider internal hemorrhoids or brim irritation. Suspicious rectal bleeding has a wider differential diagnosis than outlet bleeding. Internal hemorrhoids are still a likely cause, but rectal mucosal prolapse, occult full-thickness rectal procidentia, and even solitary rectal ulcer may present in this way.

Constipation, difficult defecation, and rectal pain can be highly suggestive of one or all of these conditions.

Anorectal Pain, Itching, and/or Swelling

Anal pain is a common symptom in Western societies, because the modern Western diets' effect on bowel function places a strain on the anal canal. The pattern of the pain is usually highly suggestive of the cause, and this is confirmed on examination. Burning pain after a bowel movement that lasts for 30 minutes to 2 hours and is often accompanied by traces of blood suggests an anal fissure. The pain can be quite severe and is sometimes traced to an episode of diarrhea or constipation. Alternatively, burning pain may be due to perianal excoriation, which can also bleed if the perianal skin becomes ulcerated. A history of itching, mild incontinence, seepage, or an anastomosis that involves the anus suggests that excoriation may be present. A pressure-type pain associated with a tender lump could be either a thrombosed external hemorrhoid or a perianal abscess. Hemorrhoid pain is of sudden onset, usually occurring after an episode of difficult defecation. Acutely thrombosed hemorrhoids can be suspected when there is a history of a reduction in pain accompanied by bleeding independent of bowel motions. Abscess pain is more insidious, with slowly but relentlessly increasing severity.

Itching, or pruritus ani, has a wide differential diagnosis list. Clues in the history include the timing of the pruritus, its relationship to food and clothing, the use of specific soaps, and its response to topical medications. Patients who are obsessed with cleanliness are prone to damaging the perianal skin, as are those who are unable to keep their perianal skin clean. Frequent stooling, especially when the stool is liquid, is also a risk factor for pruritus. In the absence of specific causes, nonspecific pruritus can be diagnosed.

Nonpainful lumps include skin tags, fibrous anal polyps, or a large rectocele. Anal swellings that are reducible may be prolapsing internal hemorrhoids or full-thickness rectal prolapse.

A patient with rectal pain carries a complex differential diagnosis of poorly defined conditions. History taking establishes the pattern and nature of the pain. A constant, gradually worsening pain may indicate a tumor or an abscess; both should be palpable or visible on imaging or proctoscopy. A pressure-like pain that worsens on sitting is likely to be levator syndrome. Sharp, fleeting pains like electrical shocks are suggestive of proctalgia fugax. Constant anterior pain in a man may suggest prostatitis, whereas painful defecation in the absence of anal problems may imply a solitary rectal ulcer. Tenesmus is a type of rectal pain best described as a feeling of intense rectal contraction that is associated with rectal mucosal inflammation; it is typically associated with acute proctitis or a low-lying rectal tumor.

Abdominal Pain and/or Distention

Abdominal pain is a common symptom that has a vast differential diagnosis. This differential diagnosis can be considerably focused by analyzing the pain according to its timing, nature, pattern, site, and context. Sharp, steady pain is likely to be due to some infectious process or a tumor, whereas colicky pain or intermittently crampy (pain that builds to a crescendo, then eases, and then builds again) is due to either obstruction or spasm. When a constant pain is made worse by breathing or moving, infection is likely. Pain associated with diarrhea may be due to colitis, irritable bowel, diverticulitis, or a stenosing tumor. When painful diarrhea is bloody, colitis is more likely. Pain associated with abdominal distention and reduction in bowel movements may be caused by a large bowel obstruction. Sudden-onset pain indicates an acute event (e.g., perforation, volvulus); gradually increasing pain is more likely due to contained sepsis or tumor. Colonic pain may be felt anywhere in the abdomen, chest, back, or pelvis. Pain from an infectious process is generally felt near the site of the sepsis. Pain from spasm of the sigmoid colon is commonly felt in the lower abdomen. Patient age, gender, and past history are important in setting the differential diagnosis for a patient who presents with abdominal pain. For example, colon cancers are more common in elderly patients, and colitis is more typical in the young.

Abdominal distention may be a sign of colonic distention. If it is associated with pain, the distention is likely to be due to a mechanical obstruction. If there is no pain, there may be a colonic ileus (i.e., pseudo-obstruction). Distal small bowel obstruction may also produce considerable distension but is more often associated with nausea and vomiting.

Constipation

The word *constipation* has many definitions, and patients may imply different things by its use. Constipation may be used to describe small stools, hard stools, large stools, stools that are difficult to pass, stools that come infrequently, or stools that are incompletely passed. Patients need to realize that the range of normal stool frequency is three times per day to three times per week. Persons do not need to have a stool every day to be normal.

Small, hard stools are usually a result of lack of fiber. "Pebbles" may come from inside diverticula. Hard stools have been in the colon too long and have become inspissated. Infrequent stools may be caused by a lack of bulk in the diet or decreased colonic peristalsis due to one of a number of causes (see Chapter 135). A full history of medications and coexisting diseases may reveal the cause.

Serious constipation, with stools passed once a week or less often, is usually due to either colonic inertia or rectal outlet obstruction. Patients with colonic inertia usually do not feel the urge to defecate. As time passes, they become more uncomfortable and distended. They may try to strain and pass stool, but this is usually unsuccessful. These patients typically ingest high doses of laxatives to initiate their bowel motions. Contrarily, with rectal outlet obstruction, stool reaches the rectum and is often sensed but cannot be passed. Affected persons classically report difficult defecation as their main symptom, but they may experience abdominal cramps due to colonic contractions. They commonly spend prolonged

periods on the toilet straining to pass stool and often need to use their finger or some other instrument to push on the perineum or into the anus to help evacuate the stool. The most common causes of rectal outlet obstruction are a nonrelaxing puborectalis and rectal mucosal prolapse. Some patients may develop secondary colonic inertia after years of rectal outlet obstruction, in which case the clinical presentation may be confusing.

A feeling of incomplete defecation may be due to truly inefficient evacuation of stool. It may, however, be due to a rectal tumor or redundant rectal mucosa as occurs in occult rectal prolapse. Incomplete defecation differs slightly from frequently repeated calls to stool. If a patient appears to completely evacuate but then is called to stool again soon, this suggests either stool stacking (fragmentation) or a rectocele. Stool stacking is common after a proctosigmoidectomy, which interrupts the normal defecation mechanism. The collection of stool in a rectocele can be sensed and is often associated with a feeling of perineal fullness or bulge. The use of a finger to splint the vagina or perineum to aid defecation is characteristic of persons with a symptomatic rectocele.

Diarrhea

Many causes of diarrhea exist; some are disorders of the small bowel, and others involve the large intestine. An analysis similar to that presented for abdominal pain may be helpful. Constant diarrhea is usually due to an infectious or inflammatory process in either the small or large bowel. Endoscopy of the colon usually excludes a colonic cause or establishes the diagnosis. Postprandial diarrhea usually suggests some form of malabsorptive illness (e.g., celiac disease, lactose intolerance) but may also reflect short bowel syndrome. Intermittent diarrhea associated with abdominal cramps is a common variant of irritable bowel syndrome. Diarrhea with blood implies some variant of colitis such as infectious, ischemic, ulcerative, or Crohn's disease. Sometimes blood associated with diarrhea is secondary to internal hemorrhoids or anal fissure/irritation. Diarrhea associated with abdominal pain may indicate ischemic colitis if it is of abrupt onset or an inflammatory colitis if it is chronic. The extent of disease in colitis can somewhat be predicted by the presence of diarrhea; generally patients with distal colitis or proctitis have formed stool, whereas pancolitis leads to diarrhea. A history of a trip abroad or the ingestion of questionable food raises the possibility of infectious diarrhea. The sensation of impending loss of control or the urgent need to use the lavatory is usually associated with rectal inflammation or strong muscular contractions characteristic of irritable bowel syndrome. Sometimes the well-meaning patient reports diarrhea when he or she actually has urgency.

Urgency and Incontinence

Urgency of stool is a sensation of impending defecation (see Chapters 135 and 138). It is associated with increased sensitivity of the rectal mucosa due to inflammation (e.g., proctitis) or an increased pressure of stool (e.g., irritable bowel syndrome). Intermittent urgency is more likely due to irritable bowel syndrome, whereas constant urgency, especially in association with rectal bleeding, signifies proctitis.

Fecal incontinence can be defined as an inability to defer passage of stool to a socially acceptable time and place. The history is crucial to making an initial diagnosis as to the cause of incontinence. A history of trauma or irradiation to the anal sphincter mechanism suggests sphincter damage. Classically, this is caused by obstetric trauma but may be secondary to surgical injury or other physical damage. Neurologic diseases may also contribute to or cause incontinence, whereas concomitant chronic bowel disease (e.g., inflammatory bowel disease, irritable bowel syndrome) is also important to document. *Urge incontinence,* defined as an inability to control the urge to defecate, implies external sphincter dysfunction, whereas the loss of control of stool unrelated to an urge (i.e., seepage) implicates the internal sphincter. Involuntary loss of stool suggests a loss of rectal sensation or fecal impaction with overflow of liquid waste.

EXAMINATION

General Principles

Examination is primarily directed to the region of the body responsible for the presenting problem, but persons seen for the first time or in the remote past should undergo a more generalized physical examination. Along with a general survey and recording of vital signs, this procedure typically includes an examination of the eyes, mouth and pharynx, thorax and lungs, heart, peripheral vascular system, gross neurologic function, and mental status. Patients examined for colorectal symptoms should have a digital rectal examination. An abdominal examination is required for older patients (>50 years) or for younger persons whose symptoms are not obviously caused by an anorectal disorder. The abdomen examination is conducted with the patient supine and should include inspection from the xyphoid to pubis with particular attention to scars, deformities, distention, and masses. Auscultation characterizes the quality of the bowel sounds and identifies any bruits. Percussion helps differentiate among distended bowel, ascites, and solid masses and identifies hepatomegaly or splenomegaly. Palpation of all four abdominal quadrants should identify abnormal masses that are evaluated for size, mobility, and pulsation. Last, the groins should be palpated for hernias and significant adenopathy.

Patients with a disease of the colon, rectum, or anus bear the burden of embarrassment in addition to concerns about their symptoms, likely diagnosis, and prognosis. They appreciate a professional attitude, consideration to covering sensitive areas where possible, and a minimal number of observers in the room. A nurse should be present during the examination and ideally should be of the same gender as the patient. Gentleness in examination is paramount to minimizing discomfort, especially when performing anal examinations. Maximum information can be gleaned only if the patient is able to tolerate the examination and relax. Anoscopy

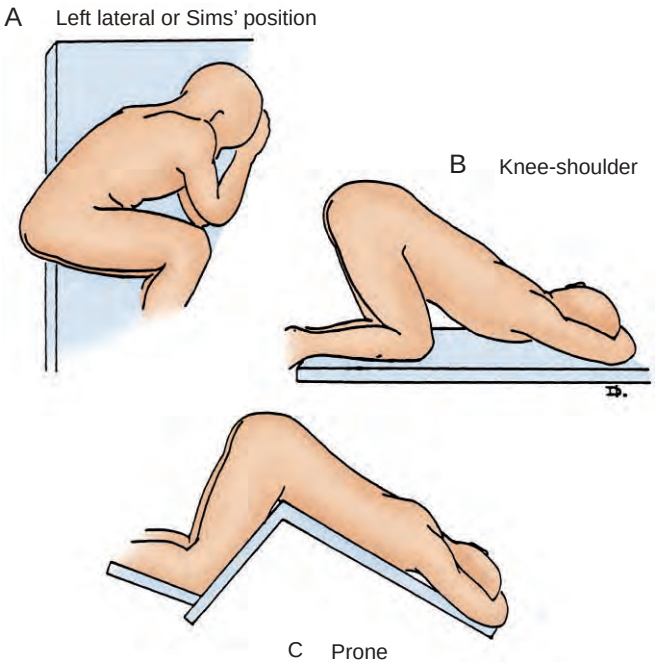

Figure 136–1. Positions of patient for anorectal examination. **A,** Left lateral (Sims') position. **B,** Knee-shoulder position. **C,** Prone (jackknife) position using proctoscopy table. (**A** to **C,** From Hill GJ II: Outpatient Surgery, 2nd ed. Philadelphia, WB Saunders, 1980.)

allows visual evaluation of anal complaints, and proctosigmoidoscopy is similarly important if rectal symptoms predominate.

Position

Most patients undergo anorectal examination in the prone jackknife or left lateral decubitus position (Fig. 136–1). The former position provides the examiner with the greatest comfort, whereas the latter is easiest for the patient.

The prone jackknife position requires a special examination table that can be flexed to 90 degrees and tilted head-down. The patient kneels on a shallow ledge that is height adjusted to allow comfortable hip flexion and lowers his or her clothing and undergarments while shielded from direct view by a sheet held between the patient and examiner. The patient then lays his or her chest flat on the table, and the table is tilted to bring the anoperineum into clear vision after adjustment of the sheet. This position allows the rectum to fill with air while the liquid and solid luminal contents will dependently settle into the rectosigmoid region.

If a specialized table is unavailable, colonoscopy is planned, or the patient is more easily positioned from prior abdominal examination, a left lateral decubitus position is recommended. With the patient covered with a sheet and lying in the left lateral decubitus (Sims') position, the hips and knees are flexed, and the patient's hips are positioned on the edge of the table. The head, knees, and feet are situated opposite the examiner, angling the patient's body across the table. The anoperineum is then undraped to allow isolated exposure of the examination area.

Inspection and Palpation

Examination of the perineum and anus must be systematic, incorporating both inspection and palpation, and the patient should be informed of all maneuvers before they occur to minimize anxiety, discomfort, and the potential for harm. The physician and assistant should position themselves on opposite sides of the patient and then gently separate the buttocks, with the examiner leaving his or her dominant hand free. The sacrococcygeal region is first surveyed to exclude pilonidal disease. The skin overlying the ischioanal fossae is then inspected for abnormalities that include excoriation, maceration, ulceration, drainage sites, lesions, and masses. The perianum is observed for external hemorrhoids, skin tags, scarring, and deformity. Last, retraction allows inspection of the anal verge and distal canal for a fissure, ulcer, and prolapsing anal papillae or internal hemorrhoids. If rectal procidentia is suspected, the patient is asked to perform the Valsalva maneuver while the examiner watches for prolapsing mucosa or rectal wall. The position of the anus and quality of the perineal body, including descent of these structures, should be consciously noted when a woman is inspected, especially when the presenting complaint is seepage, urgency, or incontinence.

Palpation of the perineum is performed next. This tactic may elicit tenderness and detect fluctuance or induration suggestive of an abscess. Fistula tracts can be felt as they course from an external os toward the anal canal. After palpation of the skin overlying the external sphincter, an anal wink is elicited by drawing a finger quickly across the sphincter while applying light pressure. A well-lubricated finger is then gently and slowly inserted into the anal canal to assess sphincter tone. As the pad of the finger passes along the anoderm above the intersphincteric groove, the canal should feel smooth and nonulcerated. The examiner might encounter scarring or stricturing at this level; pain may preclude further examination except under anesthesia. The dentate line can be appreciated as the mucosa transitions into more irregular tissue. Hypertrophied anal papillae and masses can be best appreciated by slowly rotating the digit around the circumference of the canal. Internal hemorrhoids are rarely palpable unless they are hypertrophied due to chronic prolapse. Before the examination continues above the anorectal ring, the patient is asked to squeeze around the examining finger to assess external sphincter and puborectalis function. The thumb of the examining hand should be placed into the posterior vaginal fourchette to permit bidigital appreciation of an anterior anal sphincter defect. For patients who complain of nonspecific pelvic pain, the puborectalis and levators should be firmly palpated bilaterally and the coccyx bimanually manipulated, while the patient is

asked whether the various maneuvers reproduce his or her presenting pain.

The distal rectum is examined last, beginning with palpation of the prostate or cervix through the anterior rectal wall; laxity of the rectal wall with significant anterior bulging is suggestive of a symptomatic rectocele. Bidigital examination of the rectovaginal septum often allows the identification of an enterocele that is palpable with straining. Like the anal canal, the rectum is circumferentially palpated to exclude tenderness, induration, polyps, and masses. The velvety soft texture of a large, sessile villous adenoma can be easily missed if the examiner is unaware of the subtle mucosal changes associated with these lesions. Any neoplasms that are encountered should be characterized according to size, position, and location relative to the anorectal ring to assist in planning the appropriate operative approach. In addition, palpation of the tumor for firmness, mobility, and ulceration that predict wall invasion and palpation of the posterior rectal wall for retrorectal lymph nodes that suggest local nodal metastases are pivotal for accurate clinical staging.

Examination of Specific Complaints

Anorectal Pain and/or Swelling

Examination of the painful anus must be done gently, duly warning the patient of what can be expected. Typically, a patient with a fissure has a "shy" anus that resists distraction. However, the fissure, or its external component, usually can be seen with the use of gentle pressure to pull the anus slightly open. An acute fissure has no tags or rolled edges; these are signs of chronicity. If the principal complaint is that of mild pain or itching, specific causes of pruritus should be sought, such as infections, infestations, dermatitis, allergies, and mucus leakage due to prolapsing hemorrhoids or rectal mucosa. Examination of the perianal skin may show minor excoriations that can be quite tender or the whitish appearance of lichenified skin that has been subjected to chronic wetness and irritation. Bowen's disease may appear as asymmetrical patches of discolored skin, whereas a reddish hue is more suggestive of Paget's disease and must be excluded by biopsy in any patient with unremitting pruritus and discolored perianal skin. Last, painful perianal ulcerations in the appropriate setting may be due to herpes simplex infection, and a swab sample should be taken for culture.

A thrombosed external hemorrhoid appears as a swelling at the anal verge and may be small or involve nearly half of the anal circumference. A bluish tinge is usually visible as the clot shines through the skin. The skin over acutely thrombosed hemorrhoids is tight with edema and appears smooth. As days pass, the edema tends to disappear and the skin starts to wrinkle, whereas the clot occasionally erodes through the skin. An abscess is typically visible as a localized swelling in the perianal or ischioanal area. Fluctuance, erythema, tenderness, and sporadic skin discoloration may or may not be present because the deeper the sepsis, the less obvious are the signs. For instance, a deep postanal space abscess classically presents with pain and toxicity but a normal-appearing anal area. Examination under anesthesia and needle aspiration of the postanal or perianal space is the best method of diagnosis.

Although a painful perianal lump is usually a thrombosed external hemorrhoid or an abscess, nonpainful lumps may include skin tags, fibrous anal polyps, or a large rectocele. Anal swellings that are reducible may be prolapsing internal hemorrhoids or full-thickness rectal prolapse. Perianal condylomata are usually obvious, but anoscopy is necessary to exclude intra-anal condylomata or prominent hemorrhoids.

Rectal pain can be poorly defined and difficult to treat. Again, taking a detailed history leads the direction of the necessary examination. Tumors and abscesses causing constant or gradually worsening pain should be palpable or visible on proctoscopy or imaging. Digital rectal examination may reveal an asymmetrically tender levator muscle in levator syndrome. The prostate is usually tender on digital rectal examination when prostatitis is causing constant anterior rectal pain. Although a digital examination is limited to the length of the examining finger, it is usually adequate to diagnose or exclude a mass lesion or sepsis in or around the lower rectum. Regardless, when a patient who complains of anal or rectal pain cannot be adequately examined or when the examination reveals no abnormalities, examination under anesthesia is warranted.

Bleeding

Perineal excoriation, anal fissure, internal hemorrhoids, or a low-lying neoplasm can cause outlet rectal bleeding. Excoriation and fissures can be identified through simple inspection of the perineal skin and anal verge. Inspection of the perianum may reveal grade III or IV internal hemorrhoids, especially if the hemorrhoids remain prolapsed after an enema. Although they are occasionally associated with external skin tags, internal hemorrhoids are rarely palpable unless they are hypertrophied due to chronic prolapse. Instead, symptomatic internal hemorrhoids are best diagnosed with anoscopy and appear as bulging mucosal cushions, often with prominent veins or arteries that tend to lie anteriorly and posterolaterally on both sides of the anal canal. Chronically prolapsing internal hemorrhoids develop a whitish-gray lining, *pseudoepitheliomatous hyperplasia.*

Suspicious rectal bleeding has a wider differential diagnosis than outlet bleeding. Internal hemorrhoids are still a likely cause, so anoscopy is important. Rectal mucosal prolapse, occult full-thickness rectal procidentia, and even solitary rectal ulcer may present in this way. Proctoscopy may show erythematous, redundant rectal folds that descend into the anus with a Valsalva maneuver. Suspicious bleeding may also herald neoplasia, and evaluation of the proximal colon is required. It is always important to recall that rectal bleeding is never normal and invariably requires further investigation because it should never be assumed that the cause is "merely" hemorrhoids.

Urgency and Incontinence

Examination of the anus and rectum confirms the diagnosis suggested by the history. The sensation of the perianal skin and the wink reflex of the corrugator cutis ani muscle can be tested with a light touch. This simple maneuver provides useful information about the innervation of the external sphincter. Perianal scarring suggests previous trauma, and a sphincter defect is usually visible or palpable. The thickness of the perineum in women provides a clue to sphincter bulk.

Constipation

Once the diagnosis of an outlet obstruction is suspected on the basis of the history, examination can often suggest which of the common causes contributes. The ability of the puborectalis to relax while bearing down can be assessed during a digital examination. At the same time, laxity of the rectal mucosa or tendency of the rectal wall to prolapse can be noted. Similarly, a digital examination can exclude an anal stricture or a rectocele. If a rectocele is present, it will be noted as an anterior defect in the rectal wall, bulging into the perineum. Rectoceles are usually asymptomatic, and the mere presence of a rectocele does not mandate treatment.

Examination of the anus may reveal a rectocele in women, or a megarectum may be identified. Careful inspection can expose prolapse of the rectal mucosa during a Valsalva maneuver, or, occasionally, the pelvic floor fails to relax when the patient bears down.

INVESTIGATION

Blood and Stool Testing

Routine blood and stool tests are helpful in the evaluation of some disorders of the large bowel and anus. Occasional abnormalities in blood levels directly cause a malady; some are signs that are associated with the disease that causes symptoms and others are the result of the disorder itself. For instance, serum electrolyte abnormalities can affect bowel frequency with few other systemic manifestations. Alternately, altered thyroid-stimulating hormone levels may identify the cause of intestinal symptoms related to thyroid dysfunction. Contrarily, a bleeding colorectal neoplasm may be the cause of a microcytic, hypochromic anemia. Infectious and neoplastic abnormalities of the colon and rectum are also investigated by stool and blood studies.

Stool tests for ova, parasites, and other pathogens can lead to the diagnosis of infectious colitides. Examples of common pathogens include *Giardia* and *Clostridium.* Giardiasis, acquired from contaminated water, is more likely found in the younger outpatient population. *Clostridium difficile* colitis has a particularly high prevalence in the older, institutionalized, or hospitalized population, though; the stool of any patient with colitis after antibiotic use should be tested for the *C. difficile* antigen.

Serum and stool tests are used in the evaluation of CRC. Screening tools for new and recurrent cancers include serum carcinoembryonic antigen (CEA), a glycoprotein found in the cell membrane of CRCs that is the tumor marker most often used clinically. The marker enters the circulation and can be detected by radioimmunoassay in 70% of patients with CRC but in fewer than half of patients with localized disease.[1] Unfortunately, CEA is not specific for the gut epithelium or malignant neoplasms and is not useful as a screening tool. Preoperative CEA levels herald postoperative disease recrudescence and recurrence. If an elevated preoperative level does not return to normal, undetected disease is suspected; if the level normalizes but begins to return to abnormal range, recurrence will likely be discovered with further investigation.[2]

Although colonoscopy, discussed in a later section, is considered the gold standard as screening for CRC, several less invasive screening modalities exist. A common test is guaiac-based fecal occult blood testing, (FOBT). Despite onerous dietary restrictions and collection processes, FOBT has been used widely for more than 30 years. The low cost of FOBT does not compensate for the spot test low sensitivity, low specificity, and inconvenience, but FOBT is the only noninvasive screening test shown, as of yet, to decrease mortality from CRC. Sensitivity of FOBT is slightly higher with serial examinations; however, newer stool studies, applying innovative DNA testing, promise to greatly improve noninvasive CRC screening.

Selected DNA alterations, (i.e., K-*ras, p53, APC,* BAT-26, and "long" DNA) are seen in sloughed colonocytes collected in stool sampled of CRC patients. Multitargeted DNA-based stool testing for these alterations has been shown to be four times more sensitive (52% compared to 13%) and just as specific at screening for invasive CRC than guaiac tests.[3] As with all DNA-based tests, however, costs are currently prohibitive outside of the experimental setting.

Blood testing for gene abnormalities can be used for persons with particular forms of inherited CRC, such as familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC). Although a specific adenomatous polyposis coli *(APC)* gene mutation is identified in approximately 80% of FAP families, the mismatch repair germline mutation is demonstrated only in approximately 50% of families meeting HNPCC criteria.[4,5] Because of heterogeneity of the mutations of mismatch genes, tests for the disease-causing mutation is first sought in a family member clinically known to have the disease. Once a mutation is found in the index case, other family members can be tested with about 100% accuracy, as all affected family members would have the same mutation. A negative result on genetic testing only rules out FAP or HNPCC if an affected family member has an identified mutation.

Stool tests for ova, parasites, and other pathogens can lead to the diagnosis of infectious colitides. *C. difficile* antigen can be detected in the stool of patients with this bacterial colitis, which causes diarrhea after antibiotic use. Stool assays are also used to help diagnose large bowel neoplasms. The FOBT, however, is a relatively insensitive and nonspecific marker for large (>1 cm) polyps (sensitivity of 12%) and CRC (sensitivity of 22% to 28%).[6] In fact, FOBTs fail to detect most asymptomatic

cancers and the vast majority of large adenomas; most positive FOBT results are due to non-neoplastic causes. A new stool assay panel of selected DNA alterations (i.e., K-*ras, p53, APC,* BAT-26, "long" DNA) does hold promise as a potential screening tool. In a study, the sensitivity of this panel was 91% for cancers and 82% for large (>1 cm) adenomas, whereas the specificity was 93%.[7]

Endoscopy

Anoscopy Inspection of the anal canal is best performed with an anoscope. Various types of anoscopes are manufactured but are described on the basis of size and whether they are disposable, lighted, and bivalved, slotted, or beveled (Fig. 136–2). Regardless of the type of instrument that is used, digital examination should always precede insertion of the anoscope. The patient is informed of the ensuing procedure, the well-lubricated anoscope is gently applied against the anus, and gradual pressure is applied to pass the scope into the canal. If resistance is encountered because of increased sphincter tone, the patient is asked to strain because this will involuntarily relax the sphincter and allow passage of the anoscope. Continued difficulties are suggestive of anal stenosis, mandating the use of a smaller-caliber anoscope, or of anal pathology that necessitates examination under anesthesia. Once the anoscope is appropriately inserted, it is used to circumferentially inspect the anal canal and, occasionally, the lower rectum. The scope is partially withdrawn in each quadrant to allow visualization of all mucosa.

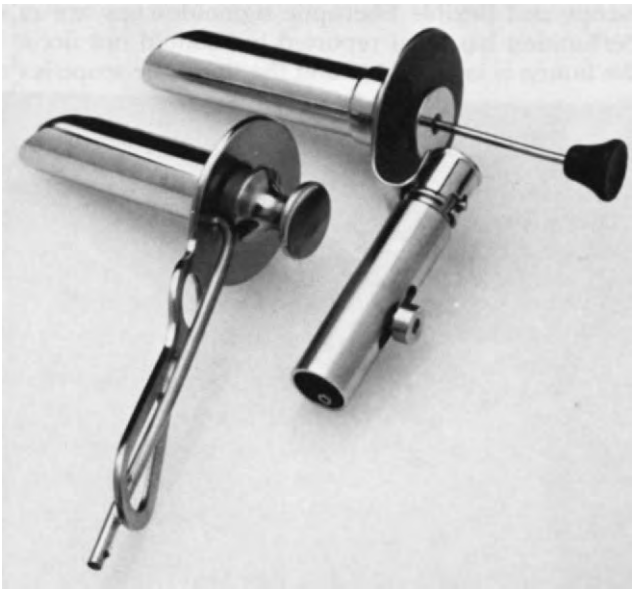

Figure 136–2. Large modified Hirschman anoscopes.

Rigid Proctosigmoidoscopy Historically, rigid proctosigmoidoscopy was used for routine visualization of the rectum and distal sigmoid colon. Rigid endoscopy remains the procedure of choice for evaluation and treatment of distal rectal lesions. In addition, a rigid scope more accurately measures the location of a tumor relative to the anal verge than a flexible endoscope, which adds at least 3 cm of length to the distance in 80% of patients.[8] The rigid instruments are 25 cm long and have a diameter of 11, 15, or 19 mm (Fig. 136–3). The smaller instruments are used in patients with strictures, whereas the larger proctosigmoidoscopes enable the evacuation of stool or blood and the treatment of larger polyps. The scope is inserted after anoscopy has been completed and is passed similarly to the anoscope. After the rigid proctosigmoidoscope has passed through the sphincters while typically directed toward the umbilicus, the obturator is removed, and the scope is advanced under direct visualization. Luminal contents that obscure adequate inspection are aspirated or swabbed as the examination progresses, but close mucosal examination is best performed during scope withdrawal. If stool obscures significant segments of mucosa, the procedure is halted until an enema is delivered to clear the lower bowel.

Although the direction of rigid proctosigmoidoscope passage must be individualized, the general route is directed posteriorly along the sacral hollow, around the inferior (left posterior), middle (right anterior), and upper (left posterior) valves of Houston. The rectosigmoid junction will come into view after the proctosigmoidoscope has been inserted 17 to 19 cm. At this point, further insertion will cause many patients to experience

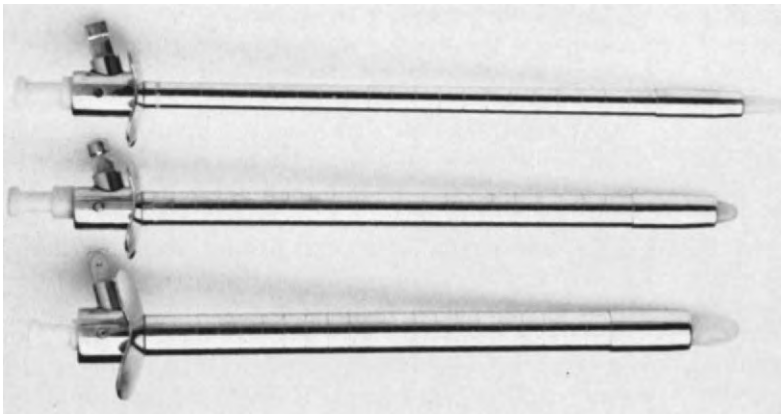

Figure 136–3. Large-, medium-, and small-diameter Welch-Allyn rigid sigmoidoscopes.

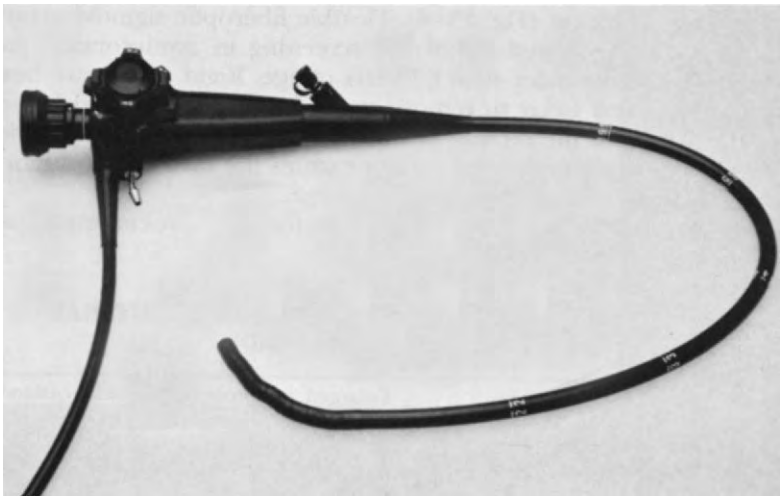

Figure 136–4. Pentax 65-cm flexible fiberoptic sigmoidoscope.

crampy visceral pain that resolves with instrument withdrawal. The angulated rectosigmoid may appear as a blinded end to the rectum with no visible rectum. Gentle manipulation to the left and then to the right will often open the sigmoid lumen to inspection. Moderate air insufflation facilitates the procedure, but excessive use is painful and interferes with the examination. Examination is performed during withdrawal while sweeping the scope around to allow careful inspection of all mucosal surfaces, flattening the rectal valves to survey their cephalad components.

Biopsy samples are obtained posteriorly along the folds of the valves if possible to minimize the risk of perforation. Small lesions can be fulgurated, and larger polyps can be excised with a Frankfeldt snare. Anterior biopsies above the middle rectal valve are especially prone to intraperitoneal perforation because this area is situated above the peritoneal reflection; perforation complicates 0.005% to 0.01% of rigid procedures.[9] Perforation by the tip of the scope occurs at areas of angulation, bowel wall weakness, and intestinal fixation. Bleeding after biopsy with the larger forceps or snare rarely occurs and usually spontaneously ceases. In the event that hemorrhage persists, a small artery is usually implicated, but it can be controlled by a combination of pressure and coagulation. Explosion has occurred during electrocoagulation in the presence of methane and hydrogen gases.[10] Fortunately, the lumen of the rigid scope is vented to room air, which prevents explosion.

Flexible Proctosigmoidoscopy In many units, flexible proctosigmoidoscopy has replaced rigid examination for most clinical indications, with the exception of those mentioned earlier. This shift in practice is because the length, flexibility, magnification, and optics of the newer instruments make flexible proctosigmoidoscopy better tolerated and more sensitive in detecting distal large bowel lesions while allowing greater length of intestine to be inspected (Fig. 136–4). After at least one hypertonic sodium phosphate enema, the scope is inserted into the rectum, and air insufflation is used to open the ampulla. The scope is advanced to the rectosigmoid, where the lumen can be difficult to visualize. Passage through this area requires a combination of torque and in-out motion to avoid loop formation that causes discomfort, precluding further examination. Through a straightened sigmoid colon, the flexible instrument is advanced with care taken to avoid intubation of wide-mouthed diverticula. Patience is required to allow segmental spasms to resolve. The descending colon can usually be negotiated with ease but occasionally requires the assistant to splint the abdominal wall to avoid looping. In most patients, the flexible proctosigmoidoscope can be inserted to at least 50 cm but should be halted earlier if the patient becomes too uncomfortable.

Biopsy samples are obtained from haustral folds, but electrocoagulation should be avoided because of the risk of explosion. Alternatively, polyps can be "cold biopsied" or snared when the risk of hemorrhage is small. If a polyp is better treated with electrocautery, exceeds 1 cm in size, or appears adenomatous on biopsy, complete colonoscopy is recommended to safely remove the lesion and to exclude synchronous neoplasms. Perforation occurs in 0.01% of patients, whereas other complications such as infection transmission and bleeding are quite rare.[9,11,12]

Colonoscopy Colonoscopy is essential in the diagnosis of several benign and any malignant diseases of the colon and rectum. Routinely used in the asymptomatic patient as screening for early neoplasms, colonoscopy is an important diagnostic tool in adenomatous, bleeding, and inflammatory conditions.

In the acutely bleeding patient, emergent colonoscopy can identify the bleeding source in 70% to 92% of patients with moderate or severe lower gastrointestinal hemorrhage (LGIH). Endoscopic management of LGIH can be achieved in many cases with coagulation, injection, and occlusion devices.[13]

For screening or nonemergent diagnostic colonoscopy, the patient is usually prepared with clear liquids and aboral gut lavage with polyethylene glycol or sodium

phosphate during the 12 to 24 hours before examination. Prophylactic antibiotic therapy is warranted if the individual has a history of prosthetic heart valve, endocarditis, surgically constructed systemic-pulmonary shunt, complex cyanotic congenital heart disease, or vascular graft within the past 6 months.[15] Although colonoscopy can be safely and comfortably performed without medication in many persons, most individuals prefer to receive a sedative, analgesic, or both. Regardless, monitoring of blood pressure, pulse, and oxygen saturation is necessary in all instances because cardiopulmonary adverse effects complicate 2% of all colonoscopies.[14]

The technique of colonoscopy is beyond the scope of this chapter, but the procedure is performed in a manner similar to flexible proctosigmoidoscopy. Cold biopsy, brushing, and cytologic washing are used for diagnostic colonoscopy in appropriate individuals. Moreover, the therapeutic endoscopist's armamentarium must include competency with hot biopsy and snare polypectomy. Expert endoscopists possess further experience with hydrostatic balloon dilation for short benign strictures and endoscopically dispatched stents used to palliate selected malignant obstructions.

The risks of colonoscopy include diagnostic and therapeutic perforation, as well as hemorrhage related to polypectomy or splenic injury. A review of more than 10,000 scopes performed over 10 years was completed at the Mayo Clinic. Twenty perforations (0.19%) occurred during colonoscopy; 65% of these occurred in the sigmoid colon. This larger review confirms previously reported iatrogenic perforation rates of 0.09% to 0.3%.[15,16] Increased risks include female gender, diagnostic or therapeutic electrocoagulation, and colitis or obstruction symptoms of any etiology.[17,18] Patients with perforation but no peritoneal signs can be safely managed with careful monitoring. Operative intervention is warranted if peritonitis develops.

Intestinal hemorrhage complicates 0.7% to 3.3% of colonoscopies.[19] Immediate bleeding usually follows inadequate control of an artery during polypectomy, whereas delayed bleeding results from subsequent clot retraction and dislodgment 1 to 2 weeks after polypectomy. Delayed hemorrhage occurs more commonly with hot biopsy than with snare polypectomy and on the right side of the colon than on the left side. Immediate hemorrhage or moderate delayed bleeding usually can be controlled by endoscopic techniques, whereas severe delayed bleeding may require assistance from the interventional radiologist. Surgical intervention is necessary only when these other modalities fail or the hemorrhage is life-threatening.

Radiologic Tests

Plain Films Plain film radiography of the abdomen and pelvis requires interpretation of varying radiolucency that is characteristic of the different structures (Fig. 136–5). This differentiation depends on the gas (intestine), water (fat, muscle, hollow organs, solid organs), and calcium (bones, calculi, nodes, thrombi, plaques)

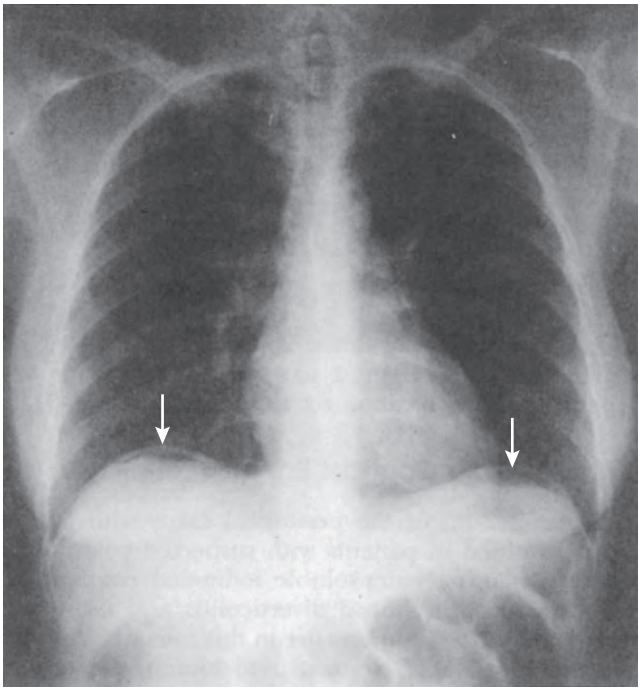

Figure 136–5. Erect chest film showing free air in the abdomen under the diaphragm *(arrows).* (Courtesy of Ruedi F. Thoeni, MD.)

content of the structures. Normally, the stomach contains at least some gas, whereas a fair amount is distributed throughout the large bowel, especially the hindgut portion. In the healthy ambulatory adult, the small intestine occupies the center of the peritoneal cavity and contains little or no gas, but bedridden adults often demonstrate considerable amounts of small bowel gas without any causative abdominal pathology. The large bowel usually frames the abdomen, and parts of colon sometimes contain semisolid feces mixed with bubbles of gas that create a distinctive speckled shadow; these speckled fecal shadows are not seen in the small intestine. Abnormalities in the usual character and pattern of radiolucencies should alert the physician to potential intra-abdominal disease processes.

Colonic Transit Study The indications for and interpretation of a colonic transit study are thoroughly discussed in Chapter 135. Briefly, the test was initially designed as a method to measure whole and segmental gut transit with radiopaque markers and serial plain radiographs. Alternatively, radioisotopes that emit gamma radiation can be used, but this method is more time-consuming.

Single-Contrast Barium Enema As alluded to earlier, soft tissue differentiation is limited on plain radiography by subtle differences in radiolucency. A radiopaque agent can enhance the interpretation of these studies by outlining the large bowel and its mucosa (Fig. 136–6). A liquid that contains low concentrations of barium sulfate has been used for nearly a century to visualize the colon and rectum and to demonstrate its configuration. The

Figure 136–6. Single-contrast barium enema demonstrating Crohn's disease involving right colon and distal ileum (oblique view). (Courtesy of Henry I. Goldberg, MD.)

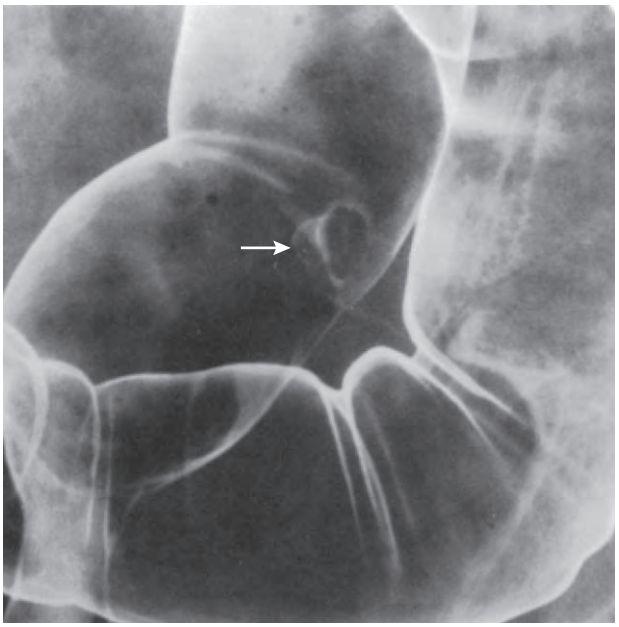

Figure 136–7. Double-contrast barium enema showing a colonic polyp *(arrow).* (Courtesy of Ruedi F. Thoeni, MD.)

bowel must be viewed in different projections, and subtle abnormalities are discernible only when the beam is passing tangential to the bowel edge. Otherwise, lesions are visible only if they are large enough to displace enough barium that the beam absorption is significantly reduced. Compression of the bowel and postevacuation films can somewhat compensate for this limitation, but the results are still less than desirable. Nearly one third of filling defects seen on single-contrast barium enema are found to represent mere artifacts when colonoscopy is subsequently performed. Similarly, a large number of lesions are missed by the technique, especially smaller (<1 cm) polyps.[20] Good bowel preparation is pivotal to an accurate examination because retained residue and stool reduce the specificity of the study. The procedure is still used routinely for patients who would have difficulty with colonoscopy or double-contrast barium enema, such as the aged, seriously ill, and disabled persons. Moreover, a single-contrast barium enema is the procedure of choice for the evaluation of fistulas and the exclusion of obstruction, assuming that concomitant perforation is unlikely. Perforation is the most common (0.01%) complication associated with barium enema, and it usually occurs when there is weakness of the bowel wall secondary to the underlying disease, traumatic insertion of the enema tip, overinflation of the rectal balloon, or excessive hydrostatic pressure associated with the study. Unfortunately, perforation and barium peritonitis confer a high mortality rate because barium concretions that contain small foci of viable bacteria are dispersed through the peritoneal cavity and cannot be adequately cleared.

Double-Contrast Barium Enema The double-contrast barium enema was designed to overcome some of the shortcomings associated with the single-contrast study, such as identification of small polyps and diagnosis of colitis (Fig. 136–7). Even more than the earlier-generation single-contrast study, the double-contrast barium enema relies on good bowel preparation to clear all stool and residue. A combination of dietary manipulation, oral hydration, cathartics, and optional enemas is recommended. The procedure is performed in a relatively standard manner in which barium is run into the transverse colon and the bowel is then distended with air. The patient is rolled into various positions so gravity and palpation can manipulate the barium column around the entirety of the large bowel that is continuously distended with air. Multiple spot and overhead films are generated and collected to create a composite evaluation of the adherence of the contrast agent to the large bowel.

Few clinicians will argue that double-contrast barium enema is simpler, safer, and less expensive than colonoscopy. However, even under ideal conditions with interpretation by experienced radiologists, the double-contrast barium enema is inferior to colonoscopy for the detection of CRC and polyps. Historically, the sensitivity of the procedure for detecting polyps smaller than 5 mm was poor, improving with polyps of 5 to 9 mm and best for polyps larger than 1 cm. According to a literature

review, the sensitivity for these larger polyps is approximately 80% and the specificity is approximately 95%.[21] Although the overall sensitivity of a double-contrast study for the detection of CRCs ranges from 80% to 100%, nearly one fourth of the rectosigmoid carcinomas will be missed. The combination of sigmoidoscopy with double-contrast barium enema overcomes some of the deficiencies but adds costs and risks to screening.[22]

As part of the National Polyp Study, a prospective, blinded trial studied the relative accuracy of double-contrast barium enema compared with colonoscopy in 580 patients.[23] The sensitivity for the detection of advanced (>1 cm) adenomas of the contrast study and colonoscopy was 46% and 100%, respectively. The investigators concluded that colonoscopy detects many more adenomas than double-contrast barium enema and that the combination of the two studies adds little to the use of colonoscopy alone. The benefits and limitations associated with imaging and endoscopy will continue to fuel the debate that ensues when the indications for double-contrast barium enema and colonoscopy are discussed.

Water-Soluble Contrast Enema A water-soluble contrast enema with Gastrografin or Urografin is favored over a barium study when the risk of perforation is at all likely because the water-soluble compounds will not cause the peritonitis mentioned earlier. Instead, the water-soluble agents are absorbed so that no peritoneal reaction ensues. The low viscosity of the agents makes them more likely than barium to identify fistulas and anastomotic leaks, but the clarity of the images is compromised, because these hypertonic, water-soluble compounds quickly become diluted. This hypertonicity feature can also be therapeutic, because diarrhea usually occurs after the study, which may be helpful in patients with pseudo-obstruction. However, for the same reason, the agent can be detrimental in persons with obstruction because rare perforation might result from the massive amounts of fluid that can be drawn into the closed segment of bowel proximal to the obstructing lesion. In addition, dehydration might result in some individuals but is unlikely when small (<500 ml) volumes of contrast material are used.

Contrast Fistulography Contrast fistulograms may provide valuable information and alter the treatment of select patients. Anal fistulas are rarely assessed with fistulography, but the modality can be useful for persons with chronic complex fistulas and suspected extrasphincteric fistulas. More often magnetic resonance (MR) imaging or endorectal ultrasound (ERUS) is used to best discern anal fistula anatomy.[23] Conversely, reliable information can be gleaned from fistulography performed for an enterocutaneous fistula. The test is usually part of a group of investigations and should be performed before any other imaging examinations because retained barium can obscure the fistulography results. A small Foley catheter is inserted as deep as possible into the tract, and the balloon is inflated to secure the position of the catheter, seal the tract against reflux of contrast medium, and allow opacification of the entire proximal tract. Water-soluble contrast material should be used, and spot films are obtained perpendicular to the fistula tract.

Vaginography is indicated when a rectovaginal or colovaginal fistula is suspected and a water-soluble enema failed to identify the communication. The test is performed in a manner similar to fistulography with a large Foley catheter used to occlude the vaginal introitus. Cystograms uncommonly identify enterovesical or colovesical fistulas. Instead, a bladder deformity is often seen, which suggests an extrinsic mass or inflammatory process that often accompanies the fistula. Again, MR and ERUS are more sensitive imaging modalities.

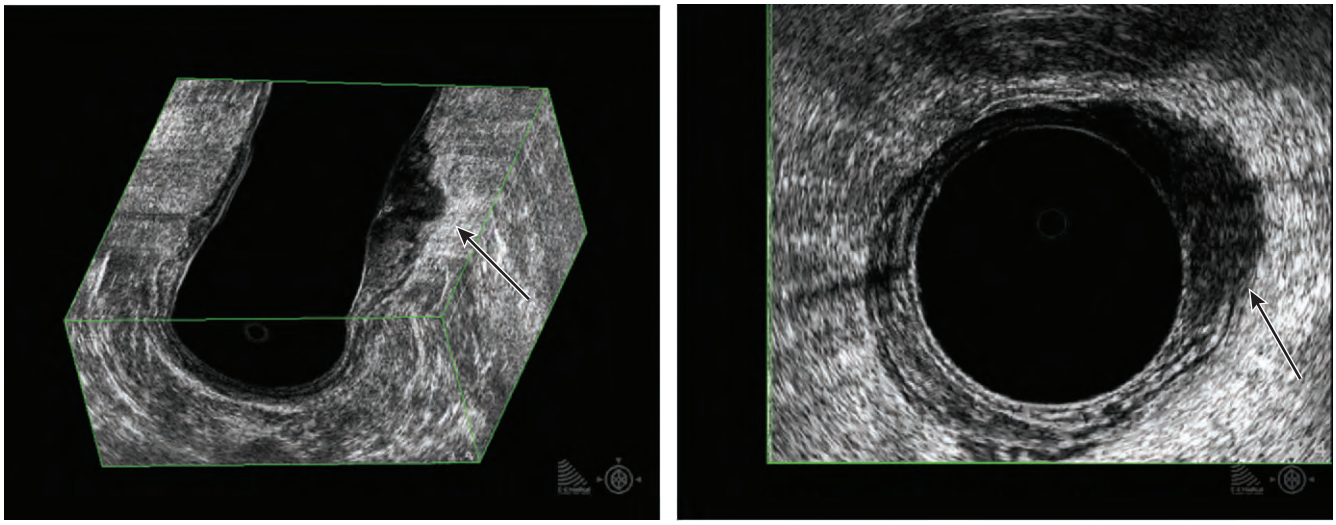
Defecography Evacuation proctography is used to study the dynamics of voluntary rectal evacuation, and techniques vary considerably. The indications for and interpretation of defecography are thoroughly discussed in Chapter 139.

Endoluminal Ultrasound Without radiation exposure, ERUS provides excellent evaluation of the distal colon, rectum, and anal canal. Rivaled only by MR with endorectal coil, ERUS shows details of anorectal anatomy, benign disorders, and malignant tumors (Fig. 136–8).

Typically performed after an enema preparation, rigid, 10-MHz endoscopy using endoluminal contact for structure definition is used to evaluate fecal incontinence, rectal cancers, and perianal inflammatory conditions. Evaluation of ill-defined anal pain and anal cancers are also indications. Obstetric injuries to the sphincters, occult and complex fistula tracts, and perianal Crohn's disease additionally are clarified by ultrasound examination.

In regard to cancer, ERUS is used for tumor staging. The examination is performed with either a rigid or flexible probe and stages all cancers with more than 70% accuracy compared to surgical specimen. Ultrasound is the least accurate for bulky T4 tumors, and nearly 20% of all tumors may be over-staged. But as an available modality used to guide preoperative neoadjuvant therapies, ultrasound is the gold standard.[24] The flexible endoluminal ultrasound allows for evaluation of low colon cancers and higher rectal tumors than the rigid transducer probe. By this flexible probe technique, the iliac nodal basin is also evaluated. Biopsy of tumors and suspicious nodes is possible through a side port on either the rigid or flexible probe. The flexible probe technology is less widely available and performed than the rigid method. Radiologists, gastroenterologists, and colorectal surgeons perform the rigid examination, whereas the flexible method is predominantly performed by gastroenterologists at larger centers.

CT Scanning Computed tomographic (CT) scanning is useful in the diagnosis of benign and malignant diseases of the colon, rectum, and anus (Fig. 136–9). Its role in the diagnosis and management of diverticulitis is unparalleled because it identifies extraluminal disease and features of severe inflammation (e.g., extraluminal gas and contrast, abscess) that predict or define a complicated disease course. Inflammatory bowel diseases are associated with nonspecific findings such as bowel wall



A B

thickening on CT scanning, but again, extraluminal disease can be visualized. Right lower quadrant masses in Crohn's disease, for instance, caused by terminal ileal inflammation can be readily distinguished from abscesses related to perforative disease. Last, the role of CT in the diagnosis and treatment of complex anoperineal sepsis is evolving as experience grows but is typically disappointing because the levators are not well defined and sphincter resolution is poor.

Although conventional CT scanning is insensitive for the diagnosis of intraluminal CRCs, it is still useful in evaluation of the patient with a known malignancy because it can demonstrate extracolonic spread to adjacent and remote organs. This knowledge might significantly alter the planned clinical and operative management of the primary lesion. CT scanning also might play a role in the postoperative surveillance and identification of suspected disease recurrence (see later).

CT Enterography CT enterography and CT colonography (so-called virtual colonoscopy) provides an effective means of imaging the bowel. The procedure requires adequate bowel preparation and low-dose, high-resolution helical CT imaging. The patient is initially placed in the supine position, and a barium enema tip is placed transanally to allow inflation of the large bowel with air or carbon dioxide to maximum patient tolerance. After adequate distention is ensured with a localizing CT scout, a helical CT scan of the abdomen and pelvis is performed. The procedure is then repeated in the prone position.

This minimally invasive approach to bowel evaluation provides information about the entire bowel, particularly sensitive for inflammatory abnormalities and larger cancers. Crohn's disease and rare tumors of the small bowel may be found with this modality (Fig. 136–10). Used for CRC screening, CT colonography has the advantages of no sedation or recovery time. Only low-dose radiation exposure is required for this test, which can also provide three-dimensional reconstructions of the bowel and any observed abnormalities.

Reports of sensitivity for lesions greater than 1 cm have ranged from 55% to 90% when compared with colonoscopy. Flat lesions, easier to miss on colonoscopy, are reportedly detected with nearly 70% sensitivity, 100% greater than 4 mm being detected.[25] A review from St. Mark's Hospital reports the American Cancer Society Colorectal Cancer Advisory Group recommendations of CT colonography as a promising technique, which is not yet endorsed as a screening tool.[26]

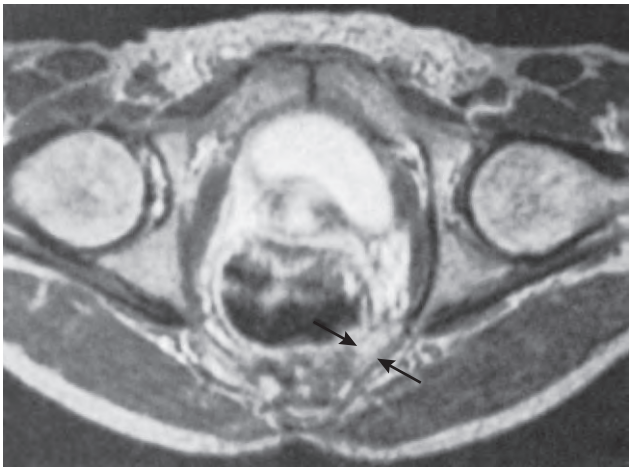

Figure 136–11. MR imaging of pelvis demonstrating recurrent carcinoma *(arrows)* after anterior resection of rectal adenocarcinoma. (Courtesy of Ruedi F. Thoeni, MD.)

MR Imaging MR imaging is one of the more recent modalities used to study structural and functional disorders of the anus, rectum, colon, and surrounding structures (Fig. 136–11). The examination is typically used to focus on an area of abnormality rather than to survey the entire abdomen and pelvis, like CT scanning. Usually, T1- and T2-weighted images are obtained in the axial plane with coronal, oblique, and sagittal planes selected when necessary to view a particular area of interest. Gradient-echo images depict flowing blood and make lesions more distinct, whereas chemical shift images determine the fat content of a lesion. Similar to contrast-enhanced CT scans, gadolinium-based contrast agents are used intravenously to demonstrate vascularity and enhance lesion patterns. In addition, various radiofrequency coils can be used depending on the anatomic structure that is to be imaged. External and internal coils that are relevant to imaging in this area include the body, surface (abdomen- or pelvis-phased multicoils), and endorectal coils. In general, higher resolution is seen with the smaller viewing fields because the dedicated coils are placed closer to the region of interest and this increases the signal-to-noise ratio.

MR imaging is used in the diagnosis of benign colorectal conditions. MR imaging more accurately delineates structural defects of pelvic floor disorders and of anal fistulous disease than does plain film or CT.[23] In addition, MR imaging is more useful than digital examination in the diagnosis and differentiation of ischioanal and perirectal abscesses.[27] MR imaging is also commonly used in the diagnosis of malignant colorectal disease. Staging of rectal cancer by MR is used to guide neoadjuvant therapy and allows for accurate restaging preoperatively.[28] This modality is also efficacious in the evaluation of metastatic liver disease and recurrent rectal cancer, especially when adjacent organ or bony invasion is suspected.

Positron Emission Tomography Just as MR can provide a three-dimensional image through reconstruction, emission imaging allows for a three-dimensional representation of distribution to be created. If a single photon emission is studied, such as technetium or thallium, a single-photon emission CT (SPECT) test is possible. The details of tests such as a SPECT are discussed with nuclear medicine tests.

PET using ^{18}F-fluorodeoxyglucose (FDG-PET) is indicated in the evaluation of patients with known or suspected recurrent CRC. Because positron emission tomography (PET) images can help differentiate postoperative changes from recurrent or residual tumor, this modality is particularly useful in the early postoperative period. FDG-PET can be used as a screening tool, though prohibitive costs and restricted availability have led to limited indications including evaluation of increased CEA levels without an obvious tumor recurrence or preoperatively for the exclusion of widespread disease in a patient with one known area of recurrence. Where available, CT-PET fusion tests provide the most powerful integrated images (Fig. 136–12).[29]

Nuclear Medicine Imaging Nuclear medicine imaging uses various radioisotopes (e.g., ^{131}I, ^{111}In, ^{99m}Tc) that are bound to a variety of materials and cells, including monoclonal antibodies, leukocytes, and erythrocytes (Fig. 136–13). After intravenous injection or ingestion of the radiolabeled compounds, the patient is imaged with a gamma camera designed for the 140-MeV energy at one or several time points. This modality can be used to evaluate a variety of disease processes, including the detection of metastatic cancer, the identification of bowel infection or inflammation, the localization of intestinal hemorrhage, and the measurement of colonic transit.

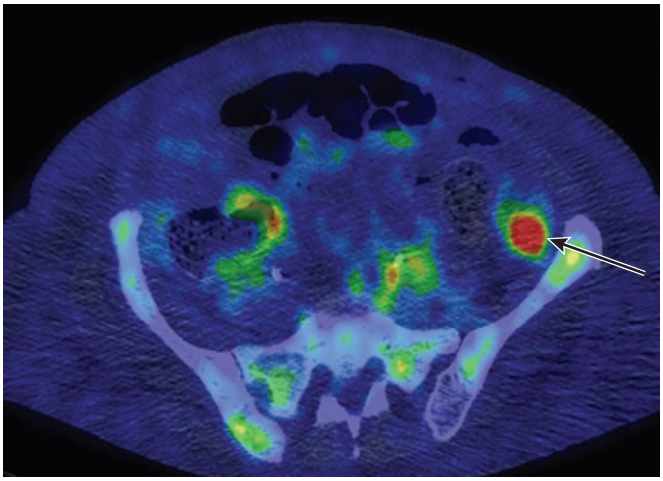

Figure 136–12. Left pelvic tumor *(arrow)* seen by positron emission tomography–CT adjacent to the descending colon at the level of the iliac spine, which was found after normal colonoscopy and examination in a patient with a history of colorectal cancer and a rising carcinoembryonic antigen level.

These uses are discussed elsewhere in detail, but their use in the diagnosis of disease deserves brief comment.

Radionuclide imaging of colon malignancies must be interpreted in conjunction with review of findings from physical examination and other investigative studies. The reported sensitivities of monoclonal antibody staging of CRC varies from 65% to 86%, with specificities for the detection of primary, metastatic, and recurrent disease ranging from 77% to 92%.[30] Thus, this principal contribution of the modality in the management of CRC lies in its ability to target potential sites of occult tumor and confirm the absence of distant metastases in persons with disease amenable to resection. At this time, most clinicians would not base treatment solely on the outcome of a nuclear medicine scan.

Radiolabeled white blood cell scans can reliably contribute to the evaluation of a postoperative patient who develops fever and in the assessment of inflammatory bowel disease,[31] but the use of other radiolabeled agents in these scenarios is still under investigation. Similarly, radionuclide-based colonic transit assessment may contribute to an improved understanding of normal and abnormal colonic motility and might assist in the management of disorders such as idiopathic constipation, fecal incontinence, and megarectum.

For many surgeons, the most common indication for radionuclide imaging involves the management of intestinal hemorrhage. Most early series reported sensitivities of more than 90% for the detection of bleeding with radionuclide scans.[32] Because this sensitivity was higher than that reported with angiography, it was recommended that a radionuclide study be performed before arteriography to identify a source of bleeding. The implication was a negative scan would dismiss the usefulness of emergent angiogram. However, several reports have produced compelling data (radionuclide scan sensitivity of 20% to 46%) that contradict this practice.[33] These series suggest that the value of the ^{99m}Tc-labeled red blood cell scan as a screening tool before arteriography is questionable and that the scan is a poor diagnostic test for the localization of LGIH. This apparent discrepancy arises from the manner in which the sensitivity rate was calculated in the early compared with the late studies. In the early reports, patients who presented with bleeding but whose scans were negative and did not rebleed were assumed not to be bleeding and were excluded from the sensitivity denominator. Conversely, the late series included all patients with documented significant hemorrhage, regardless of the scan result. This latter practice clearly lowers the sensitivity rate but probably is a more reliable measurement. A yield of less than 50% accuracy for a study with possible complications (most important, delayed diagnosis) has led to the abandonment of scintigraphy in the management of lower intestinal hemorrhage in favor of mesenteric angiography or colonoscopy, which can be both diagnostic and therapeutic.[34]

Intestinal transit can be measured using a radiolabeled nonabsorbable marker in solid food. The particulars of this method are thoroughly discussed in Chapter 135.

Mesenteric Angiography Mesenteric angiography may be performed by specially trained vascular surgeons or interventional radiologists and is commonly used to identify the source of intestinal hemorrhage and to determine acute arterial occlusion of the main visceral trunks (Fig. 136–14). Discussed in Chapter 145 on gastroin-

Figure 136–14. Selective inferior mesenteric arteriogram demonstrating bleeding site in sigmoid colon *(arrow).* (Courtesy of Ernest J. Ring, MD.)

testinal bleeding, the application of mesenteric angiography specific to colorectal bleeding is briefly covered here. The important role of mesenteric angiography in the management of lower intestinal hemorrhage is as a diagnostic and possibly interventional tool. The key to successful localization of bleeding is early, prompt arteriography in the face of active, massive bleeding. The timing is crucial because angiography best identifies the site of bleeding when the bleeding occurs at a rate exceeding 0.5 ml/min. Aggressive pharmacologic techniques with systemic heparinization, selective intra-arterial vasodilators, and/or thrombolytic agents have been used to prolong or reactivate bleeding in an attempt to improve the diagnostic yield.

Although the yield of bleeding site localization by angiography in acute lower gastrointestinal bleeding is low relative to the reported complications, if selective embolization is possible, clear benefits exist. Local injection of vasopressin at the mesenteric site of hemorrhage can be attempted. This technique can successfully arrest bleeding in more than 80% of cases, although rebleeding occurs in nearly half.[35,36] Selective transcatheter coil embolization is successful in at least 70% of cases, but there is a 6% to 22% risk of clinically significant ischemia and infarction. Stabilization in the acutely bleeding patient by interventions in the angiography suite may allow for medical optimization and bowel preparation before an urgent, rather than emergent, surgery.[37,38]

Arteriography also is the procedure of choice for the diagnosis of acute mesenteric ischemia. MR arteriography and CT arteriography are sensitive for diagnosis and carry less risk than arteriography, but the ability to perform simultaneous diagnosis and therapy initiation in the emergent setting make arteriography superior. Flush abdominal aortography with anteroposterior and lateral projections may visualize the main vascular trunks, but selective angiography, especially with digital subtraction, defines the artery and its branches. Moreover, this latter modality can differentiate among the three principal causes of acute ischemia and allows medical or mechanical revascularization without laparotomy in some instances. Chronic mesenteric ischemia, however, is better evaluated with noninvasive procedures such as abdominal duplex ultrasonography, laser Doppler flow analysis, and MR imaging.

Tests of Pelvic Floor Function The diagnosis and treatment of pelvic floor dysfunction are discussed more thoroughly in Chapter 139. Anorectal manometry quantifies the luminal pressures in the anus and rectum to provide a direct measure of internal and external sphincter function. Microballoon systems, water-perfused catheters, or solid-state transducers can be used to measure these pressures, but each laboratory should establish its own standards. Balloon distention or mucosal electrosensitivity testing can evaluate rectal sensitivity. Defecography is used to diagnose anatomic abnormalities such as symptomatic internal intussusception and rectocele. Pudendal nerve damage can accompany chronic defecation disorders and is best elucidated with tests of motor and sensory conduction. Colonic inertia must also be excluded in these patients, and normal colonic transit should be documented.

Ultrasonographic Diagnosis of Anorectal Disease

Dimitra G. Barabouti · W. Douglas Wong

Endorectal ultrasound (ERUS) is the diagnostic procedure of choice in the evaluation of many anorectal disorders. It is the best imaging modality for local staging of rectal and anal cancer and has an important role in surveillance for local recurrence. ERUS is used in the diagnosis of benign mucosal lesions, extrarectal masses, anal incontinence, fistula-in-ano, and anorectal abscesses. It is a valuable tool in the office setting, where it is performed by the surgeon, providing information essential for treatment decisions. In this chapter, we focus on the role of ERUS in the evaluation of benign and malignant conditions of the rectum and anus.

Technique

ERUS requires minimal patient preparation with two enemas the morning of the examination. The test is well tolerated, without need for sedation. Patients are preferably examined in the left lateral decubitus position. For rectal cancer staging, we perform a digital rectal examination (DRE) to determine the location of the tumor and its relation to the anorectal ring. We then evaluate the rectum using a 20-mm wide rigid proctoscope (ElectroSurgical Instrument Company, Rochester, NY) to document the morphologic characteristics of the lesion (size, distance from the anal verge, location on the rectal wall, and appearance) and to ensure that a complete sonographic evaluation can be performed. At this time residual stool, mucus, and enema effluent are removed to avoid image artifacts.

It is important to advance the proctoscope proximal to the lesion, to facilitate complete imaging of the lesion from its most proximal to its most distal extent. The examination is complete only when the entire length of the tumor is imaged, because the findings at the lower end of the tumor may differ markedly proximally. Moreover, positive lymph nodes, when present, are most commonly found in the mesorectum proximal to the lesion. Blind insertion of the ultrasound probe into the rectum may distort the lesion, miss proximal areas of the tumor and surrounding mesorectum, and cause discomfort to the patient.

At Memorial Sloan-Kettering Cancer Center (MSKCC) we use a Brüel & Kjaer (B & K) 2101 Hawk (Naerum, Denmark) scanner with an 1850 rotating endosonic probe and a 10-MHz 6004 transducer (Fig. 137–1). We also use a 2050 probe with capability for 10-, 12- or 16-MHz (multifrequency transducer). The 10-MHz transducer with a focal length of 1 to 4 cm is the one most commonly used, providing superior near-image clarity and excellent visualization of the perirectal tissues. A 7.0-MHz transducer, which provides a focal length of 2 to 5 cm, may be used if there is a need to evaluate deeper structures. A 90-degree scanning plane is rotated at four to six cycles per second to provide a 360-degree radial scan of the rectum and surrounding structures. We use the rigid ultrasound probe, because we find it provides better maneuverability and optimizes the image. However, a rigid probe cannot evaluate areas more than 12 to 15 cm from the anal verge. Flexible endosonoscopes are also available. Steele et al. compared the two probes, with results suggesting a more reliable learning curve for the rigid devices and less accuracy of the flexible devices for visualizing depth of invasion.[1]

Once the proctoscope is advanced above the tumor, the ultrasound probe is lubricated and inserted gently through the proctoscope, allowing the transducer to be advanced above the cancer. The proctoscope is then pulled back and the balloon over the ultrasound crystal is instilled with fluid. The amount of fluid is estimated based on the luminal diameter from proctoscopy, patient discomfort, and ability to pass the balloon beyond the lesion. For the 1850 probe, 30 to 60 ml is used on average, whereas the 2050 probe usually requires between 90 and 120 ml. It is important to make sure no air bubbles are present, to minimize acoustic impedance.

The key to the procedure is to keep the probe centered in the lumen of the rectum. Scanning is best conducted from proximal to distal. The probe and attached

proctoscope are slowly withdrawn together, assessing the mesorectum for evidence of nodal metastases and the tumor for depth of penetration. Optimal evaluation often requires several passes back and forth across a lesion or a suspected lymph node. Measurements of lymph nodes' size and tumor dimensions are made, including any radial extension of tumor into the perirectal fat.

Endoanal ultrasound (EAUS) is used to evaluate disease in the anal canal. In the case of malignancy, EAUS follows the assessment of the mesorectum with the balloon for nodal metastases. A fluid-filled, hard translucent plastic cap is used rather than the balloon. The ultrasound transducer is then inserted into the anal canal without a proctoscope.

Ultrasonographic evaluation of the anorectum is based on real-time imaging. We routinely videotape all examinations and have found this to be helpful in the review of difficult cases. Spot images may be copied and printed. These are useful for documentation and for following suspicious areas.

Normal Endorectal Ultrasound Anatomy

The five-layer model for ERUS anatomy was proposed by Beynon et al. in 1986 and is the one used today. Beynon and colleagues demonstrated that the proposed five ultrasonic layers correspond to the anatomy of the rectal wall by correlating in vitro ultrasound scanning and sequential microdissection of the normal layers of the rectum from operative specimens.[2]

In this model, the first and innermost line encountered is hyperechoic (white), representing the interface between the fluid-filled balloon and the mucosa. Next is the first hypoechoic (black) line, which represents the mucosa and the muscularis mucosa. The middle hyperechoic (white) line represents the submucosa. The next hypoechoic line correlates to the muscularis propria. The third and outermost hyperechoic line represents the interface between the muscularis propria and the perirectal fat (Fig. 137–2). Occasionally, a seven-layer model may be visualized in which the muscularis propria is observed as two black rings separated by a white ring. In this case, the inner circular and outer longitudinal layers of the muscularis propria appear as two distinct hypoechoic (black) layers, separated by a hyperechoic interface. In addition to the rectal wall, the mesorectum, urinary bladder, cul-de-sac and its contents, seminal vesicles, prostate, uterus, vagina, and cervix are visualized with ERUS. The ultrasonographic appearance of the normal rectal wall is depicted in Figure 137–3.

RECTAL CANCER

Accuracy of ERUS in the Local Staging of Rectal Cancer

Accurate preoperative staging is necessary to determine prognosis and select optimal treatment for patients, in terms of cure and quality of life, for patients with rectal cancer. Knowledge of the depth of rectal wall invasion and perirectal lymph node involvement is essential to

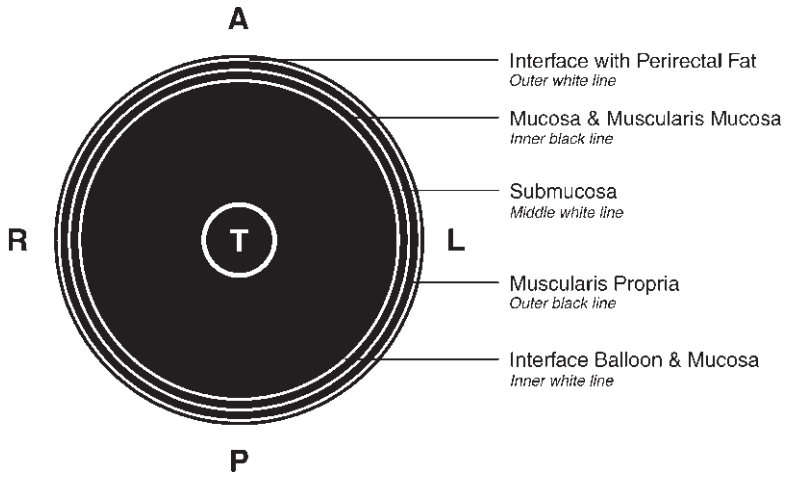

Figure 137–2. Five-layer anatomic model for interpretation of endorectal ultrasonographic scans. Three hyperechoic (*white*) layers and two hypoechoic (*black*) layers can be visualized. A, anterior; L, left; P, posterior; R, right; T, transducer.

select early cancers amenable to local excision and identify locally advanced cancers that are treated with neoadjuvant chemoradiotherapy. DRE, ERUS, computed tomography (CT), and magnetic resonance imaging (MRI) have been applied in the local staging of rectal cancer, and their diagnostic accuracy has been evaluated by comparing results to the final pathologic staging from surgical specimens.

DRE by an experienced surgeon is an important part of the evaluation of the patient and may predict pathologic stage, particularly for advanced tumors. However, DRE is subjective; it cannot assess tumors in the proximal third of the rectum, and it is unreliable in staging early lesions. The accuracy of DRE versus ERUS for the staging of rectal cancer was compared in a prospective study by Rafaelsen et al.[3] They found that ERUS demonstrated significantly more accuracy in staging rectal cancer, particularly in the setting of less advanced tumors. Moreover, ERUS successfully detected 11 out of 19 regional lymph node metastases as opposed to DRE, which detected none. Beynon studied 100 patients with ERUS; 76 had palpable tumors, but only 46 of these were also assessed by DRE for depth of invasion. The accuracy of DRE was 58% compared to the 93% accuracy shown by ERUS.[4] The accuracy of ERUS in predicting nodal involvement was 83%. Other studies have also demonstrated an accuracy with DRE in the range of 68% to 88% for reachable lesions.[5-8] Overall, it is well established that DRE is less accurate compared to other methods and should rarely be used alone in the local staging of rectal cancer.

CT is routinely used in the preoperative staging of rectal cancer and is particularly useful in detecting contiguous organ involvement and distant metastases. Its accuracy in local staging, however, appears to be relatively low. Beynon reported an accuracy for CT of between 74%[4] and 82%[5] for depth of invasion and 57% for nodal involvement.[4] Goldman et al. compared CT and ERUS in 32 patients and found accuracy rates of 52% and 81%, respectively, for perirectal fat invasion, and 64% and 68%, respectively, for lymph node involvement.[9] Similar results were reported by Herzog et al.[10] In 87 patients, ERUS was accurate 91% of the time in assessing depth of invasion, whereas CT was accurate 74% of the time. ERUS was 81% accurate in predicting nodal disease. It is possible that advances in technology will increase the accuracy of CT in detecting local invasion and nodal disease. Recently, Kulinna et al. evaluated the accuracy of multislice CT (MSCT) with double-contrast (rectal and intravenous) and three-plane reconstruction in 92 patients.[11] A subgroup of 63 patients was also evaluated with ERUS. The accuracy of MSCT for depth of invasion was 86%, compared with the 60% accuracy of ERUS. The accuracy rate of MSCT for nodal disease was 81%, compared with 65% for ERUS.

MRI is another modality used in the staging of rectal cancer. Starck et al. compared plain MRI with ERUS in 35 patients in 1995.[8] MRI had lower accuracy than ERUS in the detection of tumor penetration (66% vs. 88%, respectively), and similar accuracy in nodal evaluation

(72% and 71%, respectively). The addition of new technology to conventional MRI has improved its anatomic definition and diagnostic accuracy. Schnall et al. examined 36 patients using MRI with endorectal coil (ERC-MRI).[12] The MRI stage agreed with pathologic findings in 81% of the cases. Although sensitive for demonstrating perirectal lymph nodes (nodes as small as 2 mm were visualized), ERC-MRI had a specificity of only 72% for nodal disease.

In 1999, Kim et al. reported on 89 patients; ERUS and ERC-MRI were equivalent, and superior to CT, with an accuracy of 81% versus 65% in staging depth of invasion.[13] In staging lymph node metastasis, the rates were 63% (ERUS and ERC-MRI) versus 56% (CT). In 2000 the same group published their experience with contrast-enhanced MRI for the preoperative staging of 217 patients with rectal cancer and reported similar accuracy rates (81% for T stage, 63% for N stage).[14] Hunerbein et al. compared ERUS, three-dimensional ERUS (3D-ERUS) and ERC-MRI in 25 patients and found comparable accuracy between the three modalities for evaluating depth of invasion (84%, 88%, and 91%, respectively).[15] ERUS and ERC-MRI assessed the lymph node status correctly in 80% and 89% of the patients, respectively. The duration of the MRI examination, including placement of the coil and application of the contrast agent, was between 60 and 75 minutes. The time required for ERUS and the acquisition of 3D scans was shorter, ranging from 10 to 15 minutes.

The endorectal coil device has larger diameter than the ultrasonic probe. This sometimes limits its use in the setting of locally advanced rectal cancers. New MRI techniques aiming to avoid the disadvantages of the endorectal coil have been developed and evaluated in small studies. Pelvic phased-array coil (PA) MRI uses external coils without an endorectal probe to assess rectal tumors. Matsuoka et al. in 2003 compared the ERC-MRI with PA-MRI in 19 patients.[16] Only 10 patients were evaluated with the ERC-MRI, because of difficulties in the placement of the endorectal coil. The PA-MRI could be obtained in all patients. In the 10 patients examined with both modalities, the diagnostic accuracy of depth of invasion was the same (80%). In lymph node staging, ERC-MRI yielded an accuracy of 70%, and PA-MRI yielded an accuracy of 90%. In 2004 the same group evaluated 54 patients with rectal cancer (4 with gadolinium-enhanced endorectal coil and 50 with an air-enema technique).[17] Gadolinium-enhanced ERC-MRI accurately diagnosed depth of tumor invasion in all 4 patients and accurately diagnosed nodal disease in 75% of cases. The air-enema MRI had promising results, with an accuracy of 82% in staging depth of invasion and 72% in detecting lymph node metastasis.

There are two meta-analyses in the literature comparing ERUS, MRI, and CT in rectal cancer staging. In 2000, Kwok et al. published a systematic review of 83 studies conducted between 1980 and 1998, with data on 4897 patients.[18] The authors used descriptive analysis of pooled data, with no statistical analysis, due to the diversity of the studies. The overall pooled results indicated that ERUS had the highest sensitivity, specificity, and accuracy (93%, 78%, and 87%, respectively) in assessing depth of invasion, compared with MRI (86%, 77%, and 82%, respectively) and CT (78%, 63%, and 73%, respectively). For assessment of nodal status, the sensitivity, specificity, and accuracy were similar between ERUS (71%, 76%, and 74%, respectively) and MRI (65%, 80%, and 74%, respectively). CT had the lowest sensitivity, specificity, and accuracy for assessing nodal involvement (52%, 78%, and 66%, respectively). Subgroup analysis showed that ERC-MRI had sensitivity, specificity, and accuracy similar to ERUS for assessing T stage (89%, 79%, and 84%, respectively) and a higher sensitivity, specificity, and accuracy for assessing N stage (82%, 83%, and 82%, respectively). For T1 lesions the accuracy of ERUS was 96%, versus 91% for MRI and 94% for ERC-MRI.

Recently, Bipat et al. published a meta-analysis of 90 articles written between 1985 and 2002, to compare ERUS, CT, and MRI in rectal cancer staging.[19] Statistical analysis of their data revealed that ERUS had sensitivity similar to that of MRI for detecting T2 stage but significantly higher specificity (86% vs. 69%). For evaluating perirectal tissue invasion (T3 stage), the sensitivity of ERUS (90%) was significantly higher than that of CT (79%) and MRI (82%); specificities were comparable. Sensitivity and specificity for adjacent organ invasion (T4 stage) were similar between the three modalities. For lymph node involvement, the analysis did not show any difference in sensitivity, specificity, or accuracy between ERUS, CT, or MRI. Compared to MRI and CT, ERUS is more readily available, portable, and less expensive. It requires the least amount of time and causes minimal patient discomfort. In addition, ERUS is performed by the surgeon, who can direct the examination with specific operative considerations in mind, in the preoperative setting as well as during postoperative surveillance. Over the past 15 years, ERUS has become the standard of care in local staging of rectal cancer. Table 137–1 cites many of the studies that have evaluated the diagnostic accuracy of ERUS, alone or in comparison with other modalities. In the hands of experienced clinicians, ERUS has a reported accuracy of up to 80% to 90% in preoperative assessment of T stage and up to 70% to 80% in assessment of N stage for rectal cancers.[3-6, 8, 10, 11, 14, 16, 19-27]

The technique involved in ERUS is highly operator dependent, with a significant learning curve. This was demonstrated by Orrom et al., who evaluated 77 patients with rectal cancer staged by ERUS and assessed the accuracy of the examination over three time periods.[23] In the first time period, examinations were performed by several clinicians, including nonsurgical staff. The accuracy of ERUS for determining the T stage during this period was only 58%, with 37% of lesions overstaged and 4% understaged. In the second and third time periods, all examinations were performed by one surgeon, and the use of a rigid proctoscope for the introduction of the ERUS probe was instituted. Accuracy of assessment during the second time period increased to 77%, with 20% overstaging and 3% understaging. In the third time period, all scans were interpreted according to the five-layer model of ERUS anatomy. Accuracy increased to 95%, with only 5% overstaging and no understaging. The accuracy for determining N stage also improved from

71% for the first period to 88% for the second and third periods.

In 2002, Garcia-Aguilar et al. published the largest single-institution study to date, based on 10 years of ERUS experience at the University of Minnesota.[26] From a population of 1184 rectal cancer patients who had ERUS staging, they focused on 545 patients who underwent surgery without neoadjuvant chemoradiotherapy (307 were treated with local excision and 238 with radical surgery). Of the remaining 639 patients who were excluded for various reasons, 270 had preoperative chemoradiotherapy. Three surgeons performed 97% of the examinations. The overall accuracy of ERUS in assessing T stage was 69%, with 18% overstaging and 13% understaging. The accuracy of ERUS in diagnosing nodal disease was 64%, based on assessment of the 238 patients who underwent radical surgery. These rates are lower than those of previous reports. However, it is possible that this study underestimated the overall accuracy of ERUS, due to the exclusion of patients with locally advanced cancers who underwent neoadjuvant treatment. ERUS was most accurate in detecting benign villous adenomas.* Contrary to the suggestion of earlier, smaller studies,[24,28] the distance of the tumor from the anal verge did not influence the accuracy of the examination. Only the T stage of the tumor, and the surgeon performing the ERUS, were independent factors affecting T stage accuracy.

*Stage-specific accuracy: T0, 87%; T1, 47%; T2, 68%; T3, 70%; T4, 50%.

Table 137–2 Ultrasound Staging Classification (uTNM) for Rectal Cancer

Classification	Criteria
uT0	Noninvasive lesion confined to the mucosa
uT1	Tumor confined to the mucosa and/or submucosa
uT2	Tumor confined to the muscularis propria
uT3	Tumor extending into the perirectal fat
uT4	Tumor involving adjacent structures
uN0	No evidence of lymph node metastasis (no definable lymph nodes by ultrasound)
uN1	Evidence of lymph node metastasis (ultrasonographically apparent lymph nodes)

uTNM, ultrasonographic staging of tumor, node, metastasis.

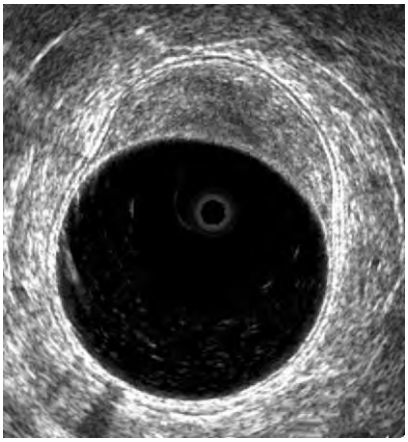

Figure 137–4. Benign villous tumor of the rectum (uT0). The middle white line is intact around the entire breadth of the tumor, indicating that the submucosa is not involved. (From Wong WD, Orrom WJ, Jensen LL: Preoperative staging of rectal cancer with endorectal ultrasonography. Perspect Colon Rectal Surg 3:315, 1990.)

Depth of Invasion

In 1985 Hildebrandt and Feifel introduced the ultrasonographic staging of rectal cancer as a modification of the TNM staging system.[7] This is depicted in Table 137–2. The prefix "u" denotes ultrasound staging, as opposed to the prefix "p," which denotes pathologic staging. Sonographically, a rectal cancer appears as a hypoechoic mass that causes disruption of the layers of the rectal wall. The depth of tumor invasion is classified as follows:

- uT0 lesions are benign, noninvasive lesions, confined to the mucosa
- uT1 cancers invade the submucosa
- uT2 lesions invade into but not through the muscularis propria and remain confined to the rectal wall
- uT3 lesions penetrate through the entire thickness of the bowel wall and invade the perirectal fat
- uT4 lesions invade an adjacent organ (i.e., uterus, vagina, cervix, bladder, prostate, seminal vesicles), the pelvic sidewall, or the sacrum

uT0 Lesions

Lesions staged as uT0 are noninvasive and confined to the rectal mucosa. Benign villous adenomas are uT0 lesions. On ERUS imaging, the mucosal layer is expanded but the middle white line (submucosa) remains intact. The middle white line is the key to determining whether a lesion is benign (Fig. 137–4). Benign lesions accurately identified by ERUS may be treated with local excision in the submucosal plane. ERUS is reliable in distinguishing benign lesions, with accuracy ranging from 87%[26] to 96%.[29] On biopsy of villous tumors, foci of malignancy may not be detected due to biopsy sampling error. However, ERUS can detect a malignant focus within a villous adenoma.[30] Worrell et al. performed a meta-analysis on the data for 258 biopsy-negative rectal adenomas from five studies. Focal carcinoma was detected in 24% of these tumors on histopathology. ERUS correctly established a diagnosis of cancer in 81% of these cases, thus decreasing the misdiagnosis rate from 24% to 5%. ERUS should be routinely used in the preoperative work-up of rectal villous adenomas.[31]

uT1 Lesions

A uT1 lesion is an early cancer that invades the mucosa and submucosa but not the muscularis propria. The ERUS finding is an irregular middle white line (submucosa) without alteration of the outer black line (muscularis propria) (Fig. 137–5). Irregularities of the middle white line are seen as a thickening or stippling but must not constitute a distinct break. If a break is seen in the submucosa, the muscularis propria has been invaded and the tumor is a T2 lesion. Garcia-Aguilar et al. reported 47% accuracy in the subgroup of 105 patients with T1 stage disease.[26] In their meta-analysis, Kwok et al. reported a 96% accuracy rate for T1 lesions.[18]

Accurate staging of uT1 lesions is important, because select uT1 lesions are amenable to local therapy. However, lymph node involvement occurs in 6% to 15% of T1 rectal cancers.[32,33] ERUS may identify this subgroup of patients with uT1 tumors and metastatic lymph nodes, for whom local therapy is contraindicated. Accurate staging of uT1 lesions with ERUS is particularly important if endocavitary radiation therapy is elected, because pathologic staging cannot be obtained with this technique. In the setting of favorable tumor characteristics and proper patient selection, local resection with negative margins can lead to low recurrence, survival rates comparable to radical surgery, and excellent quality of life.[34-36] We approach these patients with curative intent. Use of adjuvant chemoradiotherapy is based on the pathology of the excised tumor.

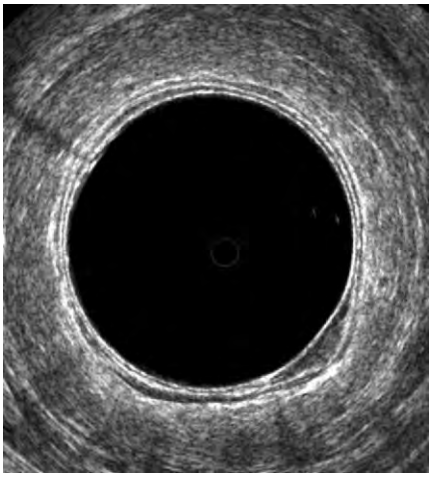

Figure 137–5. A uT1 lesion. There is invasion into the submucosa, and although the middle white line is not disrupted, it is thickened and irregular. The muscularis propria (outer black line) is not expanded, and the outer white line is intact.

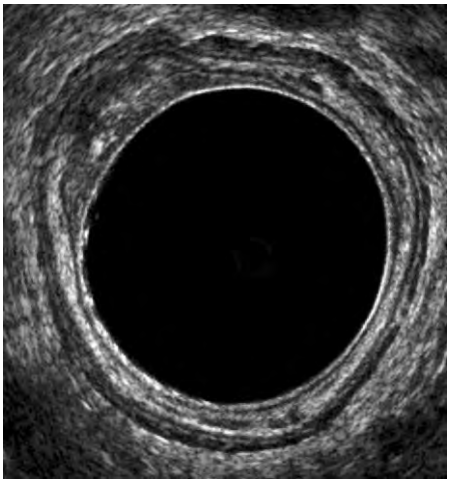

Figure 137–6. A uT2 lesion. The submucosa (middle white line) is disrupted, and there is expansion/invasion of the muscularis propria (outer black line). The outer white line (perirectal fat) is intact, demonstrating that the tumor is confined to the bowel wall.

uT2 Lesions

A uT2 cancer disrupts the middle white line and invades the second hypoechoic layer (muscularis propria) but remains confined to the rectal wall. Characteristically there is expansion of the muscularis propria, but the interface between the muscularis propria and perirectal fat (outermost white line) remains intact. The expansion of the muscularis propria may be variable, depending on the degree of invasion. "Early" uT2 lesions may just penetrate the muscularis propria with minimal expansion of this layer. A distinct break in the middle white line must be identified. "Deep" uT2 lesions have a significant degree of expansion of the muscularis propria that may also appear as "scalloping," but they do not invade the perirectal fat. There is a significant tendency to overcall deep T2 lesions as T3 cancers because of their "scalloped" appearance. An example of a uT2 lesion is shown in Figure 137–6.

Accuracy of ERUS in detecting T2 stage is in the range of 68%.[26] Lymph node metastases occur in up to 17%[32] to 28%[37] of patients with T2 tumors. Local recurrence rates of T2 tumors treated with local surgery alone have reportedly been as high as 47%, with survival rates as low as 65%.[35,36,38] We recommend radical surgery (either a sphincter-sparing resection or abdominoperineal resection) for patients who are acceptable surgical candidates and for whom there is a curative intent. Local therapy is reserved for patients with uT2 tumors who are poor-risk surgical candidates, those approached with palliative intent, or those who require an abdominoperineal resection but refuse a permanent colostomy despite appropriate counseling. When local therapy is used for the treatment of uT2 lesions, postoperative chemoradiation treatment is recommended to lower the risk of local recurrence.[34]

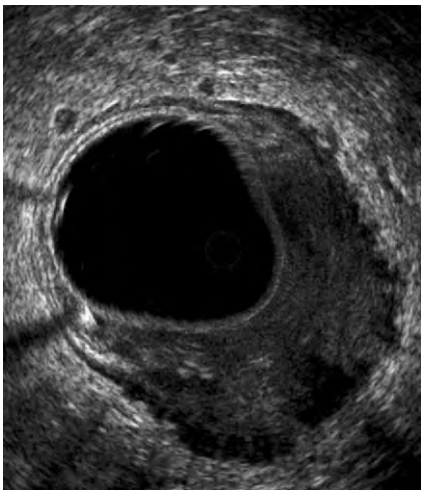

Figure 137–7. A uT3 lesion. The interface between the muscularis propria and perirectal fat (the outer white line) is irregular and interrupted, indicating extension of tumor into the perirectal fat.

uT3 Lesions

A uT3 lesion is a locally advanced cancer that penetrates through the full thickness of the rectal wall and invades into the perirectal fat. Contiguous structures are not involved. The ERUS findings are a disruption of the outer white line, with extension (like a thumbprint) of the tumor into the perirectal fat. An example of a uT3 lesion is shown in Figure 137–7.

The accuracy of ERUS in detecting T3 stage is reportedly between 70%[26] and 81%.[10] Early superficial uT3 lesions can be difficult to distinguish from deep uT2 lesions. Deep uT3 lesions with extensive invasion into the perirectal fat are readily recognized and reliably staged.

Patients with uT3 lesions are candidates for neoadjuvant chemoradiotherapy, followed by surgery. Local therapy is not appropriate treatment for uT3 lesions because lymph node metastases may occur in up to 66%[33] of cases, and local surgery carries a high rate of local recurrence, even with the addition of adjuvant therapy.[39,40]

uT4 Lesions

uT4 cancers are locally advanced tumors that invade into adjacent structures such as the bladder, uterus, cervix, vagina, prostate, or seminal vesicles. These tumors are clinically fixed. Sonographically, there is loss of the normal hyperechoic plane between the tumor and the adjacent organ. Specifically, Denonvilliers's fascia, which normally appears as a hyperechoic interface between the rectal wall and prostate gland in men, becomes obscured by a uT4 tumor with prostatic invasion. Similarly, obliteration of the distinct hyperechoic plane between the rectum and vagina in women is characteristically seen with a uT4 rectal tumor invading the posterior vaginal wall. An example of a uT4 rectal cancer invading the posterior vaginal wall is shown in Figure 137–8.

The treatment of uT4 tumors requires neoadjuvant chemoradiotherapy and in-continuity organ resection for potential cure. However, uT4 rectal cancers are resectable for cure in fewer than half of the cases. The use of preoperative chemoradiotherapy can shrink the tumor, allowing for increased resectability and decreased local recurrence rates. Intraoperative radiation therapy is used in some specialized centers; when used in combination with preoperative radiation, this appears to improve local control in T4 rectal cancers.[41]

Nodal Involvement

ERUS is used to detect potentially malignant mesorectal lymph nodes in patients with rectal cancer. However, the accuracy of ERUS in identifying metastatic lymph node involvement has been lower than its accuracy in determining depth of tumor invasion and is in the range of 64%[26] to 83%.[4] Undetectable or benign-appearing lymph nodes are classified as uN0. Malignant-appearing lymph nodes are classified as uN1. Normal, nonenlarged lymph nodes are generally not seen with ultrasound. Inflamed, enlarged lymph nodes appear hyperechoic, with ill-defined borders. Metastatic lymph nodes that have been replaced by tumor appear hypoechoic, with an echogenicity resembling that of the primary tumor. Malignant lymph nodes tend to be round rather than oval, have discrete borders, and are most commonly found in the mesorectum adjacent or proximal to the primary tumor.[42] Distal lymphatic spread in rectal cancer is unusual without the involvement of proximal lymphatics. An example of a metastatic lymph node detected on ERUS is depicted in Figure 137–9.

Both size and echogenic pattern of the lymph nodes have been evaluated as indicators of metastatic nodal involvement. Tio and Tytgat first recognized the hypoechoic pattern of malignant lymph nodes on ERUS imaging.[43] Hildebrandt et al. demonstrated that two main groups of lymph nodes are visualized on ultrasound: hyperechoic nodes and hypoechoic nodes.[22] In vitro, it has been shown that the ultrasound properties of involved and uninvolved lymph nodes differ significantly. Lymph nodes involved by tumor appear hypoechoic because less sound energy is reflected from the homogeneous tumor tissue. Uninvolved lymph nodes appear hyperechoic because most of the sound energy is reflected if the lymphatic structure remains unchanged. ERUS cannot detect lymph nodes with micrometastases, however, because these do not significantly alter the sound-reflecting characteristics of lymph node tissue. This limitation of ERUS explains, in part, its lower rates of accuracy detection of nodal disease.

We consider lymph nodes seen on ERUS as potentially positive if they are larger than 3 mm in diameter, round, hypoechoic, and in an appropriate location. Sunouchi

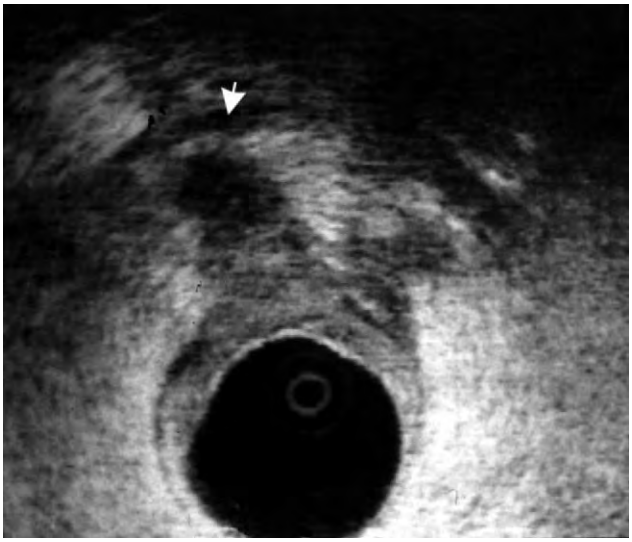

Figure 137–8. A uT4 lesion. There is invasion of the posterior vaginal wall *(arrow).*

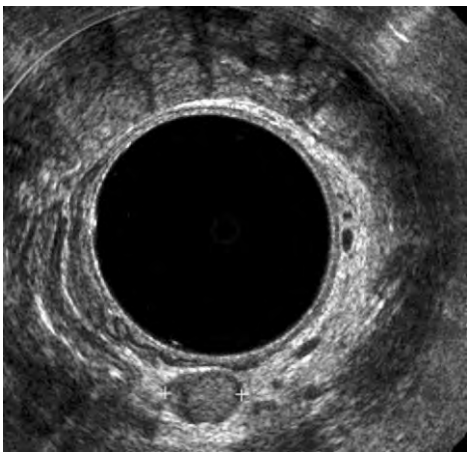

Figure 137–9. Metastatic lymph node (1.2 cm) detected with endorectal ultrasound.

et al. studied hypoechoic lesions larger than 5 mm, reporting that 20% were tumor deposits and 68% were metastatic lymph nodes.[44] It is possible that nodal size alone may not be an accurate predictor of metastatic disease. Akasu et al. found that approximately 50% of lymph nodes with diameters of 3 to 5 mm harbored metastases, making prediction based on size difficult.[25] In a pathologic study by Herrera-Ornelas et al., two thirds of metastatic lymph nodes from colorectal cancer were smaller than 5 mm in diameter.[45] Sunouchi et al. also described a "small-spot sign" for lesions identified in the mesorectum measuring 1 to 3 mm in diameter and suggested that small hypoechoic spots may correlate with tumor deposits or massive lymphovascular invasion histologically. The finding of small spots may indicate a high risk of hematogenous metastasis and local recurrence.[46]

The major error in the diagnosis of lymph node metastases has been with false-positive results (overstaging). False-positive results may occur due to inflammatory lymph nodes. The cross-sectional appearance of blood vessels in the perirectal fat may also be confused with positive lymph nodes. Careful, repeated scanning of the area in question can demonstrate the sonographic continuity of hypoechoic vessels over a distance greater than the cross-sectional diameter, thus distinguishing them from hypoechoic lymph nodes. Another criterion is that blood vessels branch or extend longitudinally. Additionally, it may be difficult to differentiate the appearance of islands of tumor outside the bowel wall from that of involved nodes. Demonstrating continuity with the main tumor is helpful in making this distinction.

False-negative results (understaging) are also a problem. This is partially due to the presence of lymph node micrometastases, which current ERUS technology cannot detect. Moreover, involved lymph nodes may be missed when they lie beyond the imaging range of the ultrasound transducer. This is particularly true for nodes in the proximal mesorectum, above the reach of the rigid probe. Advances in technology and increased operator experience will likely improve the sonographic accuracy and sensitivity of metastatic lymph node detection.

Proposed Modification of the ERUS Staging System

We have modified the uTNM classification into a treatment-oriented staging system to address clinical considerations for each stage (Table 137–3). In this system, uTw lesions include uT0 and uT1 tumors which are amenable to local excision. The second group, uTy, consists of uT2 and select superficial uT3 lesions; the recommended treatment for this group is radical surgery without neoadjuvant therapy. The third group, uTz, includes deep uT3 and uT4 lesions, which are best treated with neoadjuvant therapy followed by radical resection. The stratification of rectal tumors into groups amenable to specific treatment plans constitutes the major advantage of this modified system. We are currently using this system at MSKCC, along with the uTNM classification, to stage our rectal cancer patients.

Table 137–3 Proposed Modified Endorectal Ultrasound Staging System (uTNM) for Rectal Cancer

Classification	Criteria
uTw: uT0/uT1	Amenable to local excision
uTy: uT2/superficial uT3	Recommend radical surgery
uTz: Deep uT3/any uT4	Recommend neoadjuvant treatment followed by radical surgery
uN1: probable or definite	Recommend neoadjuvant treatment
uNx: equivocal	Base treatment on T stage and pathologic features

uTNM, ultrasonographic staging of tumor, node, metastasis.

Limitations of ERUS

The ERUS technique is highly operator dependent and requires experience in accurate interpretation of the results, with a significant learning curve.[23] Overall staging accuracy improves with adequate training and experience, optimal technique, and high-quality equipment. Overstaging has been reported in the range of 11%[18] to 18%[26] for depth of wall invasion. Understaging occurs less frequently, with rates between 5%[18] and 13% (see Table 137–2).[26] Understaging is significantly more serious than overstaging because it may result in inadequate management; with overstaging potentially more aggressive management is advised than might be required. Overstaging depth of invasion may result from inflammation at the deep edge of the tumor, preoperative radiation, hemorrhage in the rectal wall following biopsy, or a tendency of the observer to fear understaging depth of invasion. ERUS tends to understage disease in the setting of stenotic, near-obstructing tumors; examination may not be possible or complete in the setting of lesions that cannot accommodate passage of the endosonic probe.

Overstaging of lymph node involvement occurs between 5%[4] and 22%[20] of the time. This is due to the presence of inflammatory lymph nodes, blood vessels, or tumor deposits in the mesorectum. Understaging occurs between 2%[4] and 25%[13] of the time and is partially due to the inability of ERUS to detect lymph node micrometastases.

It is particularly important to recognize factors that affect the accuracy of ERUS and may lead to misinterpretation of ultrasound images.[47] For example, if the ultrasound probe is not at a 90-degree angle with the region of interest, balloon-wall separation may occur, mimicking a (nonexistent) rectal lesion. Poor bowel preparation or retained air can produce shadowing artifacts. Finally, cautery burns from endoscopic biopsies or excisions may alter the image and significantly affect the accuracy of sonographic assessment.

Accuracy of ERUS After Neoadjuvant Therapy

Neoadjuvant chemoradiotherapy is used to treat locally advanced rectal cancers, producing a complete pathologic response in up to 30% of cases.[48] Radiation causes inflammation, edema, and fibrosis and obscures differentiation of the layers of the rectal wall, making sonographic distinction between residual tumor and radiation-induced changes difficult. Re-evaluation of rectal tumors with ERUS after neoadjuvant chemoradiotherapy is inaccurate, with high rates of overstaging.[49]

ERUS after chemoradiotherapy appears to be least accurate in patients with visual and sonographic evidence of response. Rau et al. used ERUS to evaluate 84 patients with locally advanced rectal cancers following completion of neoadjuvant chemoradiotherapy and found that the misinterpretation of T stage, including overstaging and understaging, correlated with downstaging.[50] Accuracy of ERUS for assessing T stage in the 51 downstaged patients was only 29%, whereas 82% of the 33 nonresponders were correctly staged ($P < 0.001$). Gavioli et al. suggested that, after radiation therapy, ERUS no longer stages the tumor but rather the fibrosis that takes its place.[51] They concluded that the extent of fibrosis in the rectal wall is a direct indication of the depth of residual cancer and that residual tumor, when present, is always present within the fibrosis. However, they were unable to correlate the echo-pattern changes they recorded on ERUS with response of the tumor to treatment.

Unfortunately, all the conventional imaging modalities (ERUS, CT, MRI) are unreliable in the detection of complete response following neoadjuvant treatment and cannot identify a subgroup of patients who might safely avoid radical surgery.[52] Imaging modalities such as positron emission tomographic scan[53] and 3D-ERUS are currently being evaluated in the setting of post-chemoradiotherapy staging of rectal cancer.

ERUS for Postoperative Follow-up

Local recurrence rates of rectal cancer have decreased significantly over the last decade, with use of improved surgical technique and combined-modality therapy. Nevertheless, the detection and treatment of local recurrence continues to represent a challenge. Mellgren et al. reported local recurrence rates of 4% for T1 and T2 rectal cancers after radical surgery, and 28% after local excision.[36] Steele et al. reported a local recurrence rate of 9% for T1 and T2 cancers treated with local excision and adjuvant therapy.[34] Local recurrence rates for locally advanced rectal cancer treated with combined-modality therapy and total mesorectal excision are in the range of 6%.[54] Early detection of recurrence is clearly important, and follow-up programs should address this issue if they are to be successful. Such programs should focus on detection of resectable anastomotic and locoregional failures, in addition to treatable systemic metastases and metachronous colonic tumors.

A number of methods have been used to detect local recurrence at an early stage. Clinical evaluation, including history, physical examination, sigmoidoscopy, and serial carcinoembryonic antigen (CEA) determinations will detect local recurrences, but often at a late, unresectable stage.[55] CT is useful in the assessment of local recurrence, especially in the case of bulky lesions, but it is not sufficiently accurate in distinguishing recurrent tumor from inflammation or fibrosis. For accurate diagnosis of tumor recurrence with CT, lesions generally must be a minimum of 1 to 1.5 cm in diameter.[56] MRI is not used routinely for postoperative surveillance. However, if local recurrence is suspected, MRI may be superior to CT because there is more accurate tissue characterization.[57] The main problem with most follow-up modalities (including CT and MRI) is that they rarely detect local recurrence in the asymptomatic patient at an early and treatable stage.

ERUS has been used to follow patients after local excision or low anterior resection for rectal cancer. Transvaginal ultrasound may be performed in female patients after abdominoperineal resection. ERUS is also used to follow patients treated with chemoradiation therapy for anal canal carcinomas. Both hand-sewn and stapled anastomoses may be identified with ERUS, and staples do not interfere with the sonographic image. ERUS cannot establish that a recurrent lesion is malignant with absolute certainty, so biopsy of suspicious lesions is recommended for definitive diagnosis. It is recommended that a "baseline" ultrasound be performed approximately 3 months after surgery, with future comparisons at 3- to 4-month intervals. A good baseline examination is useful in documenting postoperative scarring and evaluating possible changes over time. Serial ultrasound evaluations may identify and confirm suspicious areas, which may then be biopsied via a transrectal, ultrasound-guided approach.[58]

Locally recurrent cancer that is advanced and detected by digital and endoscopic examination has hypoechoic ultrasound characteristics similar to those of primary rectal cancers. Tumor recurrence is often first identified outside of the rectal wall, in an area adjacent to the anastomosis. Extrarectal recurrent tumor often appears on ERUS as a circumscribed, hypoechoic lesion in the para-anastomotic extrarectal tissues, with all or a portion of the rectal wall intact on the luminal aspect. Furthermore, ERUS may identify metastatic lymph nodes that develop in the mesorectum after local excision of a rectal cancer. An example of a locally recurrent tumor detected by ERUS is illustrated in Figure 137–10.

ERUS has been shown to be particularly useful in the evaluation of asymptomatic patients for evidence of early local recurrence. Lohnert et al. followed 338 patients, after curative resections for rectal and left colon cancers, with DRE, endoscopy, CEA levels, and ERUS.[59] All cases of local recurrence (116 patients [34%]) were identified by ERUS; additionally, local recurrence was proven by ultrasound-guided needle biopsy in all cases showing unclear pararectal structures that could not be verified by endoscopic biopsy. In 28% of local recurrence cases, both DRE and endoscopy results were normal. These results indicate that ERUS is able to detect local recurrence at an earlier and asymptomatic stage, compared with other surveillance methods. Similar results were obtained by De Anda et al., in a study of 275 patients

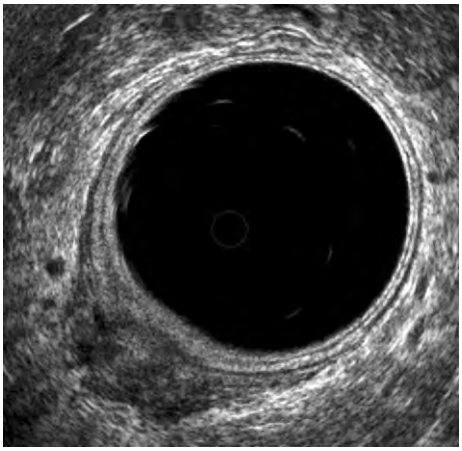

Figure 137–10. Locally recurrent rectal cancer. There is a hypoechoic mass in the extrarectal tissues, and the inner rectal wall appears normal. Sigmoidoscopy revealed normal rectal mucosa.

placed on ERUS surveillance after curative surgery for rectal cancer.[60] ERUS identified one third of asymptomatic local recurrences missed by DRE or proctoscopic examination. The impact of earlier diagnosis of local recurrences in patient survival has not been documented due to the lack of large, prospective, randomized trials; however, aggressive surveillance seems reasonable for patients who may be candidates for salvage treatment.[61] ERUS follow-up is particularly useful for patients treated with local therapies for early rectal cancers, because early diagnosis of tumor recurrence is critical if curative salvage surgery is to be considered.

Although the optimal interval for repeat follow-up examinations has not been determined, and the cost-effectiveness of follow-up ERUS has not been assessed, ERUS is recognized as an important and accurate test for postoperative follow-up. Certainly, ERUS should not be considered the sole constituent of any follow-up program; rather, ERUS should complement clinical examination, proctoscopy, and serum CEA levels as part of a comprehensive rectal cancer surveillance strategy. At MSKCC, we perform ultrasound examinations every 4 months for the first 3 years after local excision for rectal cancer and every 6 months for the next 2 to 3 years.

Three-Dimensional Endorectal Ultrasound

Three-dimensional ERUS is a novel technique that provides high-resolution multiplanar images. The examination displays volume data in three orthogonal planes as a three-dimensional view, closely resembling the original anatomy. This is particularly valuable for assessment of small structures (e.g., lymph nodes). This study has the potential to improve the examiner's understanding of spatial relations between the tumor and anatomic structures and to increase the diagnostic accuracy of ERUS.

Initial small reports on 3D-ERUS have suggested an accuracy for T and N stage similar to that of conventional ERUS.[62,63] Hunerbein has compared 3D-ERUS to endorectal coil-MRI in the staging of 25 rectal cancer patients; both methods showed equivalent accuracy in the assessment of rectal wall invasion.[15] Three-dimensional ERUS has also been evaluated in the staging of obstructive, stenotic rectal cancers[64] and in diagnosis of locally recurrent rectal cancer,[65] with promising results. At MSKCC, we have ongoing studies assessing the value of 3D-ERUS in the staging of rectal cancer following neoadjuvant chemoradiotherapy.

ENDOANAL ULTRASOUND: ENDOSONOGRAPHY OF THE ANAL CANAL

EAUS is the diagnostic test of choice for evaluation of anal sphincter anatomy and the identification of sphincter defects associated with fecal incontinence. It has particular value in the diagnosis of complex perianal fistulas. Furthermore, EAUS is used in staging and follow-up of both benign and malignant anal neoplasms.

The equipment used is the same as the equipment used for ERUS, with a minor modification. A translucent plastic cap (Brüel & Kjaer WA0453) is placed over the transducer and is filled with water, which provides the acoustic medium. A pinhole in the apex of the plastic cap allows for removal of the air bubbles through displacement with water. The technique for EAUS is similar to that for ERUS. Patients should be reassured that this examination will be no more uncomfortable than a DRE. The patient is examined in the left lateral decubitus position. Inspection of the perineum and digital examination precede EAUS assessment. The probe is lubricated with water-soluble jelly and gently inserted into the anus to the level of the upper anal canal. The entire length of the anal canal is evaluated while the probe is withdrawn slowly.

Normal Endoanal Ultrasound Anatomy

The anatomy of the anal canal is generally imaged sonographically at three levels (upper, mid, and distal anal canal).[66] The upper anal canal is illustrated in Figure 137–11. The puborectalis muscle is an important landmark for the upper anal canal and is seen as a horseshoe-shaped white structure (hyperechoic striated muscle) that forms the lateral and posterior portions of the upper anal canal.

In the mid-anal canal, the internal anal sphincter appears as a complete dark band around the probe (hypoechoic smooth muscle), surrounded by the hyperechoic external anal sphincter. A hyperechoic ring is seen between the transducer and the internal sphincter, representing subepithelial, hemorrhoidal, and submucosal tissues. The mid-anal canal is illustrated in Figure 137–12. The internal anal sphincter is most prominent at the level of the mid-anal canal. The perineal body is usually measured at this level. With the ultrasound probe in place, the index finger of the examiner's right hand is simultaneously inserted into the vagina. The distance between the ultrasound reflection of the finger and the

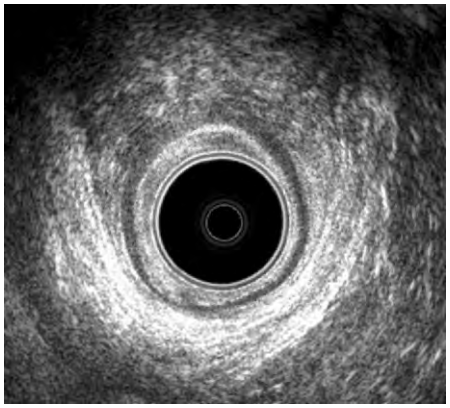

Figure 137–11. Upper anal canal. The puborectalis muscle is seen as a horseshoe-shaped hyperechoic structure and is an important landmark for the upper anal canal.

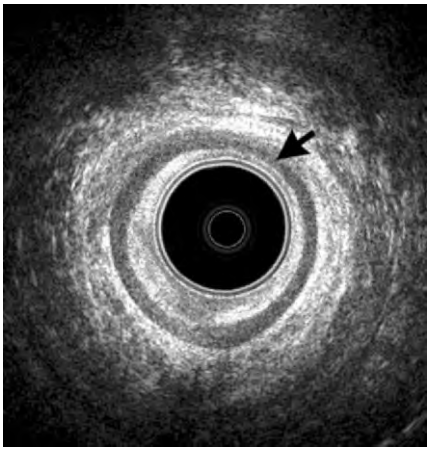

Figure 137–12. Mid-anal canal. The internal anal sphincter appears hypoechoic *(arrow)* and is surrounded by the hyperechoic external anal sphincter.

inner aspect of the internal sphincter may be measured and corresponds to the perineal body, as illustrated in Figure 137–13. Normal values for perineal body thickness (PBT) are approximately 10 to 15 mm.[67] Measurement of the perineal body is useful in evaluation of women with incontinence from anterior sphincter defects and pelvic floor disorders.

In the distal anal canal (Fig. 137–14), the internal anal sphincter is not seen. Only the hyperechoic external anal sphincter and surrounding soft tissues are visualized.

Anal Sphincter Defects and Fecal Incontinence

EAUS is a valuable tool in the work-up of fecal incontinence, detecting anatomic anal sphincter defects and identifying patients who would benefit from surgery. Causes of sphincter defects include obstetric injury, perianal trauma, anorectal surgery, and congenital abnormalities.

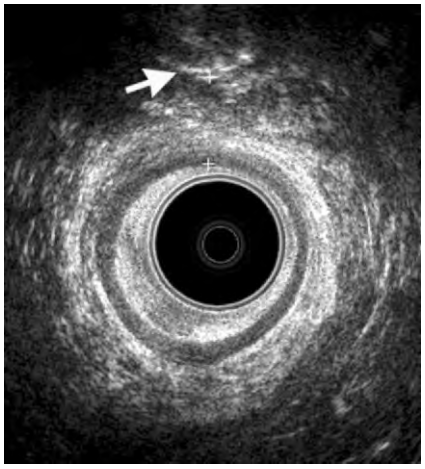

Figure 137–13. Perineal body measurement. The distance between the hyperechoic reflection of the examiner's finger *(arrow)* and the inner aspect of the internal sphincter is measured.

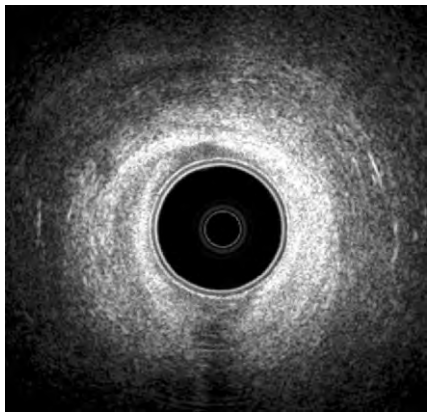

Figure 137–14. Distal anal canal. The internal anal sphincter is not seen, and only the hyperechoic external anal sphincter and surrounding soft tissues are visualized.

Obstetric injury to the anal sphincter is the most common cause of incontinence in young women. Most patients will have had primary repair of a fourth-degree tear at the time of vaginal delivery, with subsequent fecal incontinence. However, in some patients, a tear injury may remain asymptomatic and initially unrecognized, due to sufficient residual sphincter function. Sultan et al. prospectively studied 202 women before and after delivery, using EAUS and anorectal neurophysiologic tests.[68] They found that occult sphincter defects were common after vaginal delivery (especially forceps delivery), with an incidence of 35% in the primiparous women evaluated. Similarly, Zetterstrom et al. demonstrated a significant frequency of sphincter injuries (20%) after vaginal delivery.[69] Oberwalder et al. performed a meta-analysis of 717 vaginal deliveries that revealed a 27% incidence of anal sphincter defects in primiparous women and an

8.5% incidence of new sphincter defects in multiparous women.[70] Overall, 30% of anal sphincter defects were symptomatic. Three percent of women without an anal sphincter defect experienced postpartum fecal incontinence.

Patients often develop delayed symptoms of incontinence several years following an unrecognized sphincter injury.[71] Since the peak incidence of fecal incontinence among women occurs in the 5th and 6th decades, the effects of aging, menopause, and progression of a neuropathy all may contribute to sphincter weakness in the long term. It appears that nerve damage is cumulative, whereas direct sphincter damage most likely occurs on first delivery.

Defects in the external anal sphincter muscle usually appear sonographically as hypoechoic defects, although some may be hyperechoic or may demonstrate mixed echogenicity. In the case of complete sphincter disruption, the ends of both internal and external sphincter muscles are widely separated and bridged by scar tissue. In many patients, complete sphincter disruption is not seen; rather, significant attenuation of the sphincter muscle is present anteriorly, suggestive of a significant deficit. Zetterstrom et al. have shown that perineal body measurement as part of the EAUS can help to identify anterior sphincter defects in most patients.[67] Normal values for PBT are approximately 10 to 15 mm. However, Oberwalder et al. recently evaluated 89 patients with fecal incontinence and found that PBT of 10 to 12 mm was associated with a sphincter defect in one third of the patients, whereas patients with a PBT of 12 mm or more were unlikely to harbor a defect.[72]

The importance of EAUS in the diagnostic evaluation of fecal incontinence has been demonstrated in several studies.[73,74] Other anorectal physiologic tests, such as anorectal manometry and electromyography, are complementary. Women with symptoms of fecal incontinence and history of vaginal deliveries should be evaluated with EAUS for an anatomic sphincter defect that might account for the incontinence. This is important, since some defects are amenable to surgical repair.[75] EAUS is well tolerated, produces minimal discomfort, and provides high-resolution images of both the external and the internal sphincter. EAUS identifies sphincter injuries with a very high degree of accuracy when these injuries are present; however, it may falsely identify anterior sphincter injuries in normal, intact sphincters. By recognizing a potential high false-positive sphincter injury rate, and limiting evaluation of the anal canal to the most distal 1.5 cm, Sentovich et al. were able to decrease the rate of false-positive findings to a range between 5% and 25%.[76] An anterior internal and external anal sphincter defect is depicted in Figure 137–15.

Other causes of anal sphincter defects are perianal trauma and anorectal surgery. Major blunt and penetrating perineal trauma often involves the anal sphincter. Fecal diversion is often required, in addition to débridement, in the case of major soft tissue perineal injuries. After the injuries have healed, EAUS may be used to assess the remaining anatomy and to determine whether reconstructive surgery is necessary before stomal closure. Fecal incontinence may also occur after anorectal surgery. Most of the time this is transient, but occasionally it persists, warranting evaluation. EAUS has been used to evaluate potential sphincter defects associated with postoperative fecal incontinence following hemorrhoidectomy, lateral internal sphincterotomy,[77] or sphincteroplasty.[78]

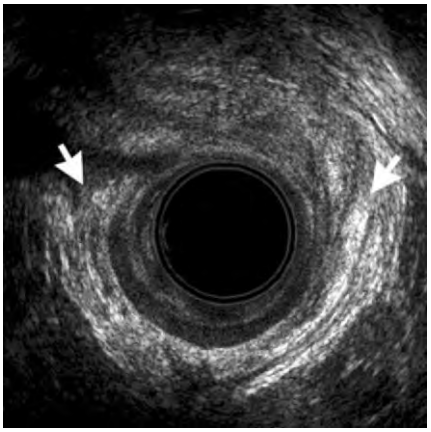

Figure 137–15. Anterior anal sphincter defect in a woman with incontinence. The distance between the two *arrows* represents an anterior defect in both the internal and external anal sphincters.

Perianal Sepsis and Fistula-in-Ano

The diagnosis of a perianal abscess is usually made by clinical examination and requires only proper recognition and prompt drainage. However, sometimes an abscess is strongly suspected by history but is not readily evident on physical examination. EAUS may be used intraoperatively or in the office to localize an obscure abscess and aid in planning the appropriate incision for drainage.[79] Such an example is an intersphincteric abscess, which is often difficult to diagnose clinically but may be suspected due to a history of severe anal pain. Abscesses appear on EAUS as hypoechoic areas, often surrounded by a hyperechoic border.

EAUS may be applied in the evaluation of complex and recurrent fistula-in-ano. It can anatomically delineate the fistula tract in relation to the anal sphincters. Sonographically, fistula tracts are generally hypoechoic defects and can be followed for direction and extent. Examination should include ultrasound scanning of the anal canal, as well as the distal rectum, to search for high blind tracts. An example of a fistula-in-ano demonstrated with EAUS is illustrated in Figure 137–16.

Deen et al. reported a 94% correlation between EAUS and operative findings in 18 patients with complex anal fistulas. EAUS was highly accurate in identifying fistula tracts, horseshoe tracts, and fluid collections but was less accurate in identifying internal fistula openings.[80] Seow-Choen et al. proposed criteria for identification of the internal opening that included a hypoechoic gap in the subepithelial layer, a defect in the internal anal sphincter, and a hypoechoic area in the intersphincteric space.[81]

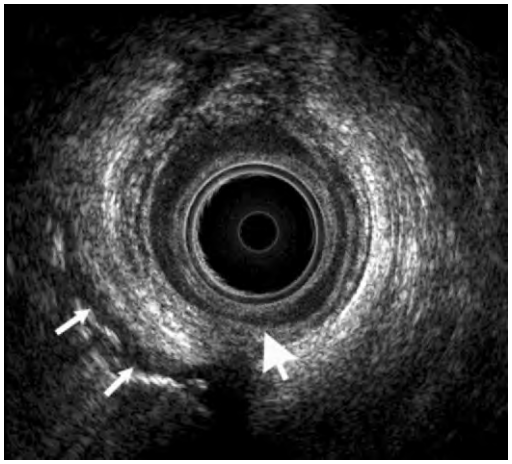

Figure 137–16. Fistula-in-ano. The fistula tract appears hypoechoic *(small arrows)*. The internal opening was identified in the midline posteriorly *(large arrow)*.

Cho et al. defined the following three criteria for localization of the internal opening[82]: I, a rootlike budding, formed by the intersphincteric tract, that contacts the internal sphincter; II, a rootlike budding with an internal sphincter defect; and III, a subepithelial breech connecting to the intersphincteric tract through an internal sphincter defect. The combination of these criteria produced a sensitivity of 94%, a specificity of 87%, and positive predictive value of 81%. In a more recent study of 151 patients with fistula-in-ano, Lengyel et al. reported an 82% concordance of EAUS with the operative findings and a 93% accuracy of the test in predicting the internal opening of the fistula.[83]

EAUS is useful in patients with Crohn's disease, where it can delineate complex fistula tracts and abscesses. Schratter-Sehn et al. compared EAUS and CT in the evaluation of 25 patients with perianal Crohn's disease and suggested that EAUS was superior to CT in diagnosing fistulas and inflammatory infiltration of the lower pelvic muscles.[84] The two methods were equivalent in diagnosing perianal abscesses. Solomon et al. performed EAUS, pouchography, and CT in patients with dysfunctional ileoanal pouches and inconclusive clinical and endoscopic examinations.[85] Their results suggested higher sensitivity of EAUS in the detection of anastomotic leaks and peripouch sepsis.

A variety of techniques are used alone or in conjunction with EAUS in the identification of complex fistulous tracts. These include careful probing; fistulography; and injection with methylene blue dye, milk, hydrogen peroxide, or contrast agents such as Levovist.[86] Hydrogen peroxide injection is used along with EAUS to enhance the imaging of complex and recurrent anal fistulas.[87] The release of oxygen accentuates the fistula tract, which shows as a brightly hyperechoic image on the sonogram. An example of a fistula-in-ano visualized on EAUS with hydrogen peroxide enhancement is depicted in Figure 137–17.

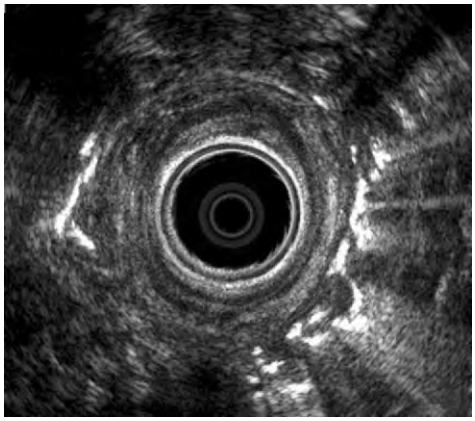

Figure 137–17. Fistula-in-ano. Hydrogen peroxide injected into the external orifice of the fistula appears brightly hyperechoic and outlines the fistulous tract.

Rectovaginal Fistula

EAUS can be used in the diagnosis of a suspected rectovaginal fistula (RVF) when clinical examination fails to identify a communication.[88] Furthermore, EAUS is valuable in the preoperative work-up of patients with RVF. Tsang et al. reviewed the experience of the Minnesota Group with RVF repair.[89] EAUS or anal manometry was used preoperatively to detect sphincter defects. If a defect was found, then endorectal advancement flap was more likely to fail and overlapping sphincteroplasty was more likely to be successful, although this difference did not reach statistical significance. The authors proposed that all patients with RVF undergo preoperative evaluation for occult sphincter defects. This becomes especially important if the patient has symptoms of fecal incontinence or if the cause of the RVF is obstetric trauma.

Anal Canal Neoplasms

EAUS shows the anal canal anatomy well and has an important role in the evaluation of benign and malignant anal neoplasms. Lesions of the anal canal appear as hypoechoic areas on EAUS, and the size and extent of lesions can be detailed. Tissue confirmation may be obtained with ultrasound-directed needle biopsies, if needed. Benign neoplasms such as lipomas and leiomyomas can be visualized with EAUS, and their relationship to other structures of the anal canal can be defined.

Malignant neoplasms of the anal canal include squamous cell carcinomas, adenocarcinomas, leiomyosarcomas, and melanomas. Squamous cell or epidermoid carcinoma is the most common anal canal malignancy. EAUS is effective in the initial evaluation and follow-up of patients with squamous cell carcinoma of the anal canal.[90] Because this cancer is primarily treated with combined chemoradiotherapy, an accurate method of staging the tumor and assessing response to treatment is essential.

EAUS complements the DRE in determining actual size and circumferential involvement of anal canal

Table 137–4 Ultrasound Staging Classification (uTNM) for Anal Canal Cancer

Classification	Criteria
uT1	Maximal diameter <2 cm
uT2	Maximal diameter 2-5 cm
uT3	Maximal diameter >5 cm
uT4	Adjacent organ invasion
uN0	No evidence of lymph node metastasis
uN1	Evidence of lymph node metastasis

uTNM, ultrasonographic staging of tumor, node, metastasis.

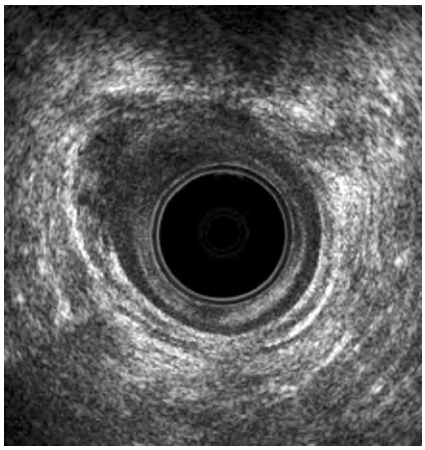

Figure 137–18. Squamous cell carcinoma of the anus. The lesion measured 2.4 cm in maximal diameter, indicating a uT2 anal canal tumor involving both internal and external anal sphincters.

tumors. EAUS staging (uTNM) of anal canal cancers corresponds to TNM (International Union Against Cancer [UICC]) staging (Table 137–4). EAUS accurately measures the greatest diameter of the tumor, which is the basis of T staging for anal canal cancer. Furthermore, EAUS can demonstrate the extent of sphincter muscle involvement. ERUS should always be performed to assess the mesorectum for metastatic lymph nodes. An EAUS image of a squamous cell carcinoma of the anal canal is depicted in Figure 137–18.

Some authors have proposed that ultrasound-based staging systems for cancers of the anal canal include depth of tumor invasion. Tarantino and Bernstein proposed a modified endoscopic staging system that emphasized depth of penetration over size of the tumor and used it to distinguish early lesions that might be amenable to less aggressive treatment.[91] In this system, a uT1 tumor was confined to the submucosa; a uT2a lesion invaded only the internal anal sphincter; a uT2b lesion penetrated into the external anal sphincter; a uT3 lesion invaded through the sphincter complex into the perianal tissues; and a uT4 lesion invaded adjacent structures. They demonstrated that EAUS was highly accurate in determining depth of penetration into the sphincter complex and assessing response of the tumor to chemoradiotherapy. Giovannini et al. proposed a different ultrasound staging system (with a uT2 lesion defined as involving the internal sphincter and a uT3 lesion defined as invading the external sphincter).[92] In a multicenter study of 146 patients, they compared this system with the UICC staging (done by clinical examination only). Their results suggest that ultrasound staging is superior to clinical staging in predicting local recurrence and patient survival.

The value of EAUS in detecting residual tumor as well as early local recurrence after treatment has been supported by small prospective[93] and retrospective[94] studies. Conversely, Lund et al. performed a retrospective study to evaluate the necessity of EAUS in detecting local recurrence.[95] They focused on 52 patients followed by EAUS out of 82 patients treated in their institution for anal canal cancer; 9.6% developed local recurrence, all of which were detected by clinical examination prior to EAUS. The authors concluded that EAUS was unnecessary in the follow-up of anal cancer.

Currently, EAUS is part of most surveillance programs for anal cancer. The small percentage of these patients who fail chemoradiotherapy may undergo abdominoperineal resection for salvage, with a reasonable chance for cure.[96]

Miscellaneous Anorectal Conditions

Retrorectal Tumors

Retrorectal tumors are rare and include developmental cysts, teratomas, chordomas, meningoceles, and miscellaneous neurologic and osseous tumors. CT and MRI are the best imaging modalities for identifying these tumors and their relationships to adjacent anatomic structures, such as the sacral nerves. However, ERUS is useful in assessing possible involvement of the rectal wall and may help in planning the appropriate surgical approach. An ultrasound image of a retrorectal tumor is depicted in Figure 137–19.

Solitary Rectal Ulcer Syndrome and Colitis Cystica Profunda

ERUS can be used in the evaluation of patients with solitary rectal ulcer syndrome or colitis cystica profunda. These conditions are uncommon, but it is important for them to be accurately recognized and not mistaken for malignancy. The endoscopic appearance of a solitary rectal ulcer ranges from that of a typical ulcer with a fibrinous central depression to that of a polypoid lesion. It is always located on the anterior aspect of the rectum, 4 to 12 cm from the anal verge. The fold with the ulcer is thought to represent the lead point of an intussusception into the anal canal. Chronic, repeated straining or prolapse of this lead point result in ischemia and ulceration. Pathologic evaluation reveals obliteration of the lamina propria by fibrosis. In the case of colitis cystica profunda, pathologic examination reveals mucin-containing glands

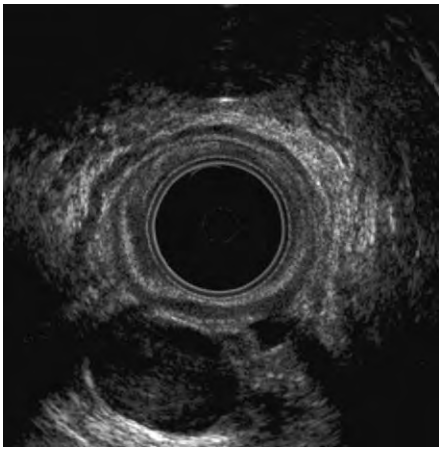

Figure 137–19. Retrorectal/presacral tumor. Note that the rectal wall is not involved on the basis of ultrasound assessment.

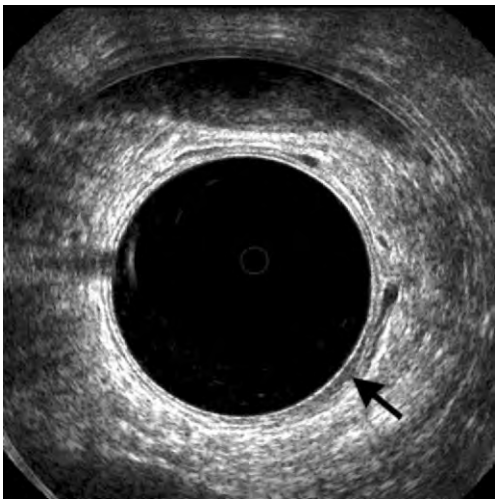

Figure 137–20. Solitary rectal ulcer syndrome. There is thickening of the mucosa and irregularity of the submucosa *(arrow).*

misplaced in the submucosa and lined with normal colonic epithelium.

Sonographically, a solitary rectal ulcer appears as an area of thickened submucosa. The submucosa appears hyperechoic in patients with solitary rectal ulcer due to fibrosis. In contrast, in patients with colitis cystica profunda, the submucosa appears hypoechoic due to mucus-filled cysts.[97] An example of a solitary rectal ulcer identified on ERUS is depicted in Figure 137–20.

SUMMARY

ERUS has proved to be a valuable tool in the diagnosis and management of many anorectal disorders. The accuracy of examination is operator dependent and improves with experience. ERUS is the best available imaging modality for preoperative local staging of rectal and anal canal cancers. Moreover, it has an important role in surveillance after treatment of rectal and anal cancers. ERUS is the diagnostic test of choice for evaluation of fecal incontinence and can be used in the diagnosis of several other benign anorectal conditions. The use of endorectal ultrasonography by surgeons has contributed greatly to the understanding and management of anorectal disease.

Diagnosis and Management of Fecal Incontinence

Susan C. Parker ▪ Robert D. Madoff

Fecal incontinence is the inability to defer the passage of feces until a desired time and place. Although incontinence of gas, liquid, or solid stool is not a life-threatening disorder, it can dramatically affect an individual's lifestyle and lead to social isolation. Fortunately, most incontinence is amenable to medical or surgical therapy.

The prevalence of fecal incontinence depends on the definition used and the population under study. Community prevalence has been estimated to range from 0.5% to 11%.[1] A Wisconsin telephone survey reported that 2.2% of the general population experienced fecal incontinence of varying degrees.[2] The prevalence increases to 13.4% in outpatients seeing their primary care physicians and 26% in outpatients seeing their gastroenterologist.[3] The highest rates of incontinence are seen in institutionalized individuals; a survey of 18,000 Wisconsin nursing home residents found that 47% of them had fecal incontinence.[4]

EVALUATION

The causes of fecal incontinence are divided into factors that alter anorectal anatomy (trauma, surgery), overwhelm physiologic control mechanisms (diarrhea, secretory tumors, fecal impaction), or interfere with neurologic function (diabetes, spinal cord injury, pudendal nerve injury). In many cases, a combination of factors leads to incontinence (Box 138–1). For example, incontinence associated with rectal prolapse is due to excessive physical stretching of both the anal sphincter and pudendal nerves. Similarly, diminished sphincter strength associated with aging can unmask a previously well-compensated obstetric sphincter injury.

Initial evaluation of the incontinent patient is performed in the physician's office and requires only careful elicitation of pertinent history and performance of a directed physical examination. However, while the initial evaluation can indicate the probable cause of incontinence in many patients, further testing is used to confirm the initial clinical impression. Pudendal nerve injury is not in and of itself visible, and sphincter injury due to surgery or childbirth can be undetectable on later examination after healing has occurred. Laboratory evaluation is also used to quantify the severity of the physiologic deficit, identify specific anatomic abnormalities, and elucidate the causes of incontinence when the diagnosis is obscure or there are multiple abnormalities.

History

Fecal incontinence is embarrassing, and many patients are reluctant to discuss their condition or even identify it by name. Accordingly, one of the first steps in evaluating the incontinent patient may be getting the patient to admit to the problem. Many patients present with complaints of "diarrhea," which on close questioning turns out to be involuntary loss of normal stool. It is also common for a patient to complain of the sudden onset

Box 138–1 Causes of Fecal Incontinence

Normal Pelvic Floor

- Diarrheal states
  - Infectious diarrhea
  - Inflammatory bowel disease
  - Short-gut syndrome
  - Laxative abuse
  - Radiation enteritis
- Overflow
  - Impaction
  - Encopresis
  - Rectal neoplasms
- Neurologic conditions
  - Congenital anomalies (e.g., myelomeningocele)
  - Multiple sclerosis
  - Dementia, strokes, tabes dorsalis
  - Neuropathy (e.g., diabetes)
  - Neoplasms of brain, spinal cord, cauda equina

Abnormal Pelvic Floor

- Congenital anorectal malformation
- Trauma
  - Accidental injury (e.g., impalement, pelvic fracture)
  - Anorectal surgery
  - Obstetric injury
- Aging
- Pelvic floor denervation (idiopathic neurogenic incontinence)
  - Vaginal delivery
  - Chronic straining at stool
  - Rectal prolapse
  - Descending perineum syndrome

From Madoff RD, Williams JG, Caushaj PF: Fecal incontinence. N Engl J Med 326:1002, 1992.

of fecal incontinence and, on careful questioning, reveal that a change in stool consistency preceded the onset of incontinence. Certain risk factors or associated conditions should alert the physician to the presence of fecal incontinence: anal trauma or surgery[5]; vaginal deliveries,[6] especially multiple, difficult, or traumatic ones; pelvic radiation[7,8]; diabetes mellitus, especially with neuropathy; chronic diarrheal states; congenital conditions,[9] such as imperforate anus and spina bifida; urinary incontinence; or complaints of rectal prolapse or anal protrusion.[10,11]

The extent of incontinence should also be quantified. The key components of severity assessment include the nature of the material being lost (flatus, liquid stool, or solid stool), the frequency of loss, and the need to wear a pad. Although it is agreed that solid stool incontinence reflects a greater degree of physiologic impairment than incontinence for liquid stool only, it is noteworthy that patients perceive liquid stool incontinence to be more of a problem because it is more difficult to manage. Numerous scoring systems have been proposed for the evaluation of incontinence, but none has achieved universal acceptance to date.[12] However, the Fecal Incontinence Severity Index (FISI) is being used increasingly because its scores were derived from both patient and colorectal surgeon-based weighting of severity.[13]

Quality-of-life assessment is a critical component to the evaluation of fecal incontinence and the success of its management. The concept itself is obvious, but quantification has proved to be difficult. General scales such as the SF-36 have not proved to be sufficiently sensitive to reflect real changes in patient status. Several incontinence scales combine a subjective quality-of-life assessment with a quantitative severity score to produce a single global incontinence score, an approach that, despite providing a single score per patient, combines two distinctly separate variables.[14] A validated fecal incontinence-specific quality of life score (FIQL) has been developed and is now enjoying widespread use.[15]

Physical Examination

Physical examination of the patient with fecal incontinence begins with external examination of the perianal area. Profuse incontinence, particularly of liquid stool, can lead to excoriation of the surrounding perianal skin. The perianal area should be inspected for scars from previous trauma, episiotomies, or anal surgery. The "keyhole deformity" is a groove in the anal canal, most commonly seen in the posterior midline, caused by a sphincterotomy, fissurectomy, or fistulotomy, that permits seepage of stool or mucus. The female patient with an obstetric injury may have a thin perineal body, an associated rectovaginal fistula, or a cloacae due to loss of the distal portion of the rectovaginal septum and perineal body.

The patient with rectal prolapse may have a visibly patulous anus or one that gapes with traction. The prolapse itself, with its characteristic concentric folds, can be demonstrated by asking the patient to bear down, optimally while seated on a commode. Rectal mucosal prolapse, characterized by radial folds, can cause mucus seepage and staining but is not a cause of more severe incontinence.

The anocutaneous reflex is a test of perianal sensation that is elicited by stroking the perineal skin and observing an anal "wink" due to sphincter contraction. This spinal reflex has its afferent and efferent pathways in the pudendal nerve and is abolished if S4 is transected.

The findings to note on digital examination are the tone of the anal canal, the strength of the squeeze, and whether it seems symmetrical. A strong contraction of the gluteal muscles should not be confused with contraction of the external anal sphincter muscle. Voluntary contraction of the external anal sphincter normally fatigues to a basal level over 3 minutes. A more rapid fatigue may be elicited in the incontinent patient.[16] Puborectalis function is evaluated separately from the external anal sphincter. This muscle forms a sling at the top

of the anal canal that the examining finger can hook around posteriorly. Contraction of the muscle lifts the examining finger or is felt as a generalized tightening at the top of the anal canal. Fecal impaction leading to overflow incontinence should be evident on the initial digital examination. If there is a history of obstetric trauma, the examiner should palpate for a rectal vaginal fistula along with assessment of the perineal body width. Obstetric tears usually occur in the anterior midline, leaving a thin perineal body due to retraction of the sphincter muscle posterolaterally. A rectocele is present if there is a weakness in the rectovaginal septum that allows a digit placed in the rectum to push into the vagina. If a large rectocele is present, the posterior wall of the vagina can be pushed out the introitus.

The anoscope is used to look for prolapsing hemorrhoids, scarring in the anal canal from previous surgery, internal fistula openings, and mucosal inflammation. Any patient under evaluation for fecal incontinence should undergo a flexible sigmoidoscopy to exclude proctitis, cancer, or a benign secretory tumor such as a large rectal villous adenoma. A full colonic or small bowel evaluation is not usually necessary unless there is a history of diarrhea in addition to incontinence.

Laboratory Assessment

In most patients, the history and physical examination determine the cause of fecal incontinence. For the patient with a minor degree of fecal incontinence, medical management is instituted and further testing can be deferred. For most patients, testing at an anorectal physiology laboratory documents the degree of dysfunction, fully determines anatomic defects, and better directs the treatment plan.[17-19] Relevant tests include anal manometry, pudendal nerve latency testing or more advanced electrodiagnostics, endoanal ultrasound, and defecography or peritoneography.

Manometry

Anal manometry determines anal canal pressure to provide an assessment of internal and external anal sphincter function. The entire length of the anal canal is evaluated, using either a "station" or continuous pull-through technique, and any one of a number of available catheters (e.g., water perfused, microballoon, and solid state). Despite the lack of methodologic standardization, the essential measurements are resting pressure, squeeze pressure, and rectoanal inhibitory reflex. The internal anal sphincter tone supplies 55% to 85% of the resting pressure,[20] and accordingly, manometric resting pressure, whether expressed as a maximum or mean, is an indication of internal anal sphincter function. Squeeze pressure reflects external anal sphincter function but, because it is under voluntary control, requires a cooperative patient to be accurate. Both resting and squeeze pressures are higher and sphincter length is longer in males than in females and pressures decrease with age.[21,22]

Rectal sensation is determined by inflating a rectal balloon with air and recording the volume of first sensation, sensation of fullness (urge to defecate), and maximum tolerated volume. Abnormal rectal sensation can lead to incontinence in two ways. Hyperacute sensation is seen when proctitis is present, typically due to inflammation or radiation therapy. Under these circumstances, the rectum is unable to tolerate an adequate volume of stool, and reservoir function is lost. Conversely, dulled sensation, as is seen in megarectum and some neurogenic disorders, leads to overflow incontinence.

The rectoanal inhibitory reflex is a decrease in resting pressure that occurs in response to rectal distention (accomplished in the laboratory by inflation of a rectal balloon). It is absent in Hirschsprung's disease and immediately after rectal resection with coloanal anastomosis, and it can be difficult to detect in the presence of a megarectum or when resting pressures are very low. The rectoanal inhibitory reflex has been postulated to permit anal "sampling" of rectal contents to determine the appropriate sphincter response, such as expelling gas or withholding feces.[20] The exact nature of this sampling, however, has yet to be determined.

Pudendal Nerve Terminal Motor Latency

The pudendal nerve provides motor innervation to the external anal sphincter and sensory innervation to the perineum. Pudendal nerve injury is caused by traction on the nerve during straining (as seen during childbirth or prolonged efforts at defecation), and it results in denervation and subsequent reinnervation of the external anal sphincter and pelvic floor musculature. This reinnervation can be documented with needle electromyography (EMG), which demonstrates polyphasic motor unit action potentials and an increase in fiber density.[23] However, because the examination is uncomfortable, needle EMG is not widely used. Additional useful tests include the pudendoanal and anal reflex (or anal "wink"). The levels of the sacral cord involved in sacral reflexes are S2 to S4. The pudendoanal reflex is elicited by stimulating the dorsal nerve of the penis or clitoris. The pudendoanal reflex is absent or delayed in many patients with fecal incontinence. The absence of an anal wink can also indicate injury, but it is more unreliable.[24]

Pudendal nerve integrity is now most commonly assessed by determination of pudendal nerve terminal motor latency (PNTML). PNTML is measured using the finger-mounted St. Mark's electrode, which stimulates the pudendal nerve at the level of the ischial spine and records the conduction time to the sphincter.[25] Prolonged conduction times are indicative of pudendal neuropathy, which is caused by traction injury to the nerve from vaginal childbirth, prolonged straining, rectal prolapse, or excessive perineal descent.[25] The test is affected by the skill of the examiner and body habitus of the patient; therefore, the significance of an undetectable PNTML is uncertain. Furthermore, because the test evaluates the function of the fastest remaining nerve fiber, incomplete nerve injuries can be missed with this technique. Indeed, fiber density but not pudendal nerve latency correlates with clinical and manometric variables in patients with fecal incontinence.[26] Some investigators

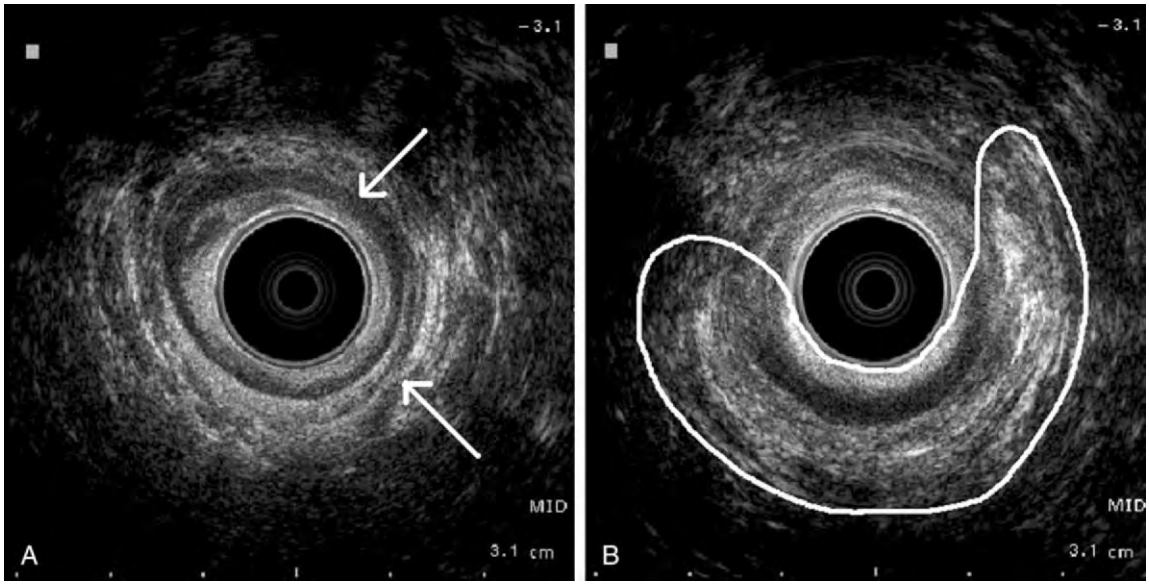

Figure 138–1. Endoanal ultrasound. **A,** Normal sphincter, mid-anal canal: the *arrow* at 1 o'clock indicates the internal anal sphincter, and the *arrow* at 4 o'clock points to the external anal sphincter. **B,** Disruption of anterior internal and external anal sphincter muscles with posterior retraction of muscles. The *line* indicates retracted muscle.

have found an abnormal PNTML to be highly predictive of failure after sphincteroplasty,[27,28] but many others have observed no such correlation.[29,30]

Endoanal Ultrasound

Sphincter mapping helps the surgeon by confirming the presence of a sphincter defect and localizing the site and severity of the defect (Fig. 138–1). The preferred method for sphincter mapping is endoanal ultrasound, optimally using a 360-degree rotating transducer probe that images through a plastic cap. The usual finding after an obstetric injury is an anterior (between rectum and vagina) disruption of the anal sphincters. Other common findings are disruptions of the internal anal sphincter after hemorrhoidectomy or sphincterotomy and disruptions of both sphincter muscles after fistulotomy or trauma. Endoanal ultrasound, in conjunction with manometry, can be particularly useful when evaluating trauma patients for continence before reversing a diverting stoma, because the degree of anal sphincter injury can be difficult to determine at the time of the initial trauma. Sphincter mapping is also described using magnetic resonance imaging (MRI), but its use is limited and MRI may be less accurate at detection of internal anal sphincter defects.[31]

Defecography

Defecography, also termed *evacuation proctography,* is a dynamic study of rectal emptying. The rectum is filled with thick barium paste, which the patient is asked to evacuate under videofluoroscopy. Defecography is useful for evaluation of suspected rectal prolapse, including both internal intussusception and true procidentia. Patients with severe incontinence may be unable to hold the contrast agent without involuntary leakage, a finding that confirms the presence of a severe functional deficit. Defecography is also useful in demonstrating associated pelvic floor disorder that may be seen in the incontinent patient. The failure of appropriate pelvic floor relaxation is well visualized on defecography along with the degree to which flow of contrast is impeded. Although this is more often of significance in the evaluation of constipation, defecography can be helpful to identify a patient with overflow incontinence or incontinence due to a poorly emptying rectocele, especially if the patient also has sphincter dysfunction. Visualization of other associated disorders, such as enteroceles and pelvic floor hernias, can be optimized by the addition of a vaginal, small bowel, or peritoneal contrast agent.[32]

Benefits and Limitations of Physiology Testing for Incontinence

Over the years, many surgeons have argued that anorectal physiology tests add little to the "educated finger" in the evaluation of the incontinent patient. It is true that much can be learned by a careful physical examination and equally true that physiologic findings do not necessarily correlate with clinical status, but we believe that the appropriate use of anorectal physiology testing does improve the care of the incontinent patient. An early branch point in the algorithm for incontinence therapy is the presence or absence of a sphincter defect. Sphincter defects may be clinically obvious, or they may be subtle and difficult to detect. Anal ultrasonography

provides a rapid and definitive answer. Anal manometry provides an objective assessment of internal and external sphincter function, even if there is an underlying broad range of normal. Mild unilateral pudendal neuropathy may not accurately predict functional failure after sphincteroplasty, but the presence of severe bilateral neuropathy may help surgeons pick the best therapy for a given patient or at least counsel the patient regarding a diminished likelihood of success. In short, we believe that careful and complete patient evaluation leads to accurate categorization, appropriate treatment, and optimized outcome.

TREATMENT

Medical Therapy

Because fecal incontinence can be exacerbated by abnormal bowel function, initial treatment efforts should be directed at correction of any associated underlying disorders. Severe diarrhea can overcome even a normal sphincter mechanism, and even mild chronic diarrheal states can be sufficient to tip a marginally compensated individual with abnormal sphincter function into frank clinical incontinence. Incontinent patients with loose stool should be evaluated for a cause of their diarrhea, including infection, malabsorption syndromes, and, in particular, occult inflammatory bowel disease. Irritable bowel syndrome is an important related entity. Although this disorder alone is not a cause of incontinence, it is widely prevalent and often complicates the management of patients with incontinence due to other disorders.

Management of the incontinent patient depends on the severity of his or her symptoms. Mild incontinence is usually best treated by conservative medical management. Food intolerance causing malabsorption can contribute significantly to symptoms, and patients should be alerted to this possibility. The classic example of this phenomenon is occult lactose intolerance, which can lead to liquid stool and excessive flatulence with consequent urgency and diminished bowel control.

Because solid stool is easier to control than liquid and because liquid stool incontinence is more distressing to patients than solid, all efforts should be made to optimize stool consistency. This goal is often best achieved by the consumption of adequate quantities of dietary fiber. Although 30 g/day of dietary fiber is most commonly quoted as the therapeutic goal, many patients find this level unachievable, and for most, 20 to 25 g/day is a reasonable target. Patients are able to best reach this goal with appropriate dietary counseling and the use of a stool-bulking supplement such as psyllium or methylcellulose. Increased dietary fiber and supplemental psyllium should be gradually instituted to diminish the side effects of bloating and increased flatulence.

Patients with mild to moderate incontinence frequently improve with antidiarrheal medicines such as loperamide or diphenoxylate with atropine. Loperamide is related to haloperidol and decreases intestinal motility and secretion. Diphenoxylate with atropine has a mode of action similar to that of other related narcotics, such as morphine. Of these, only loperamide is a sphincter agonist that can increase sphincter pressure.[33] These drugs are often best used prophylactically when patients can predictably expect difficulty, such as at bedtime for patients with nocturnal incontinence and before leaving the home for patients with limited ability to defer evacuation. Patients with mild seepage may also benefit from several simple ancillary measures, including tap water irrigation of the rectum after bowel movements using a bulb syringe, use of a small absorbent cotton wick placed adjacent to the anal orifice, and regular application of a barrier cream to the perianal skin.

Biofeedback

Although Kegel exercises have been a popular approach to the incontinent patient, especially in the postpartum period, results for patients with significant incontinence are unimpressive. One reason for this may be that patients attempting to strengthen their pelvic floors may or may not be exercising the muscles they intend to exercise. In addition, because fecal incontinence is often related to several physiologic abnormalities, it is reasonable to suspect that addressing voluntary sphincter contraction alone may not improve a problem that is multifactorial in origin.

Biofeedback describes a class of techniques that use monitoring devices to provide information regarding a physiologic function so an individual may voluntarily alter or control that function. In the case of the anorectum, patients attempting to activate their sphincter mechanisms receive feedback confirming the extent to which muscle contraction is actually occurring.

Although initially popularized using the Schuster three-balloon system,[34] most centers now use either EMG or standard anal manometric approaches. Sensory training is variably provided, either to improve rectal sensation or to increase maximally tolerated rectal volume. Some stress the importance of coordinating appropriate sphincter contraction to rectal sensation.[34,35] However, the physiologic mechanism by which biofeedback exerts its effect is uncertain. Although much biofeedback training is directed at improving voluntary sphincter contraction, successful results appear to correlate more with improved sensation[35,36] than improved motor function.[37,38]

Incontinent patients are candidates for biofeedback if they are adequately motivated and intellectually capable of following instructions. It is commonly held that they should have some ability to contract their anal sphincter and at least some rectal sensation, but these latter qualifications are vague and poorly substantiated in the literature. The cause of incontinence does not appear to affect the outcome of therapy, although patients with keyhole deformities do poorly because of continued stool leakage through the anatomic defect.[37]

A systematic review of biofeedback and pelvic floor exercises for treating fecal incontinence in adults identified 46 studies involving 1364 patients[39]; 49% of patients were reported cured, and 72% improved or cured. However, only 8 of the 46 studies reviewed included a

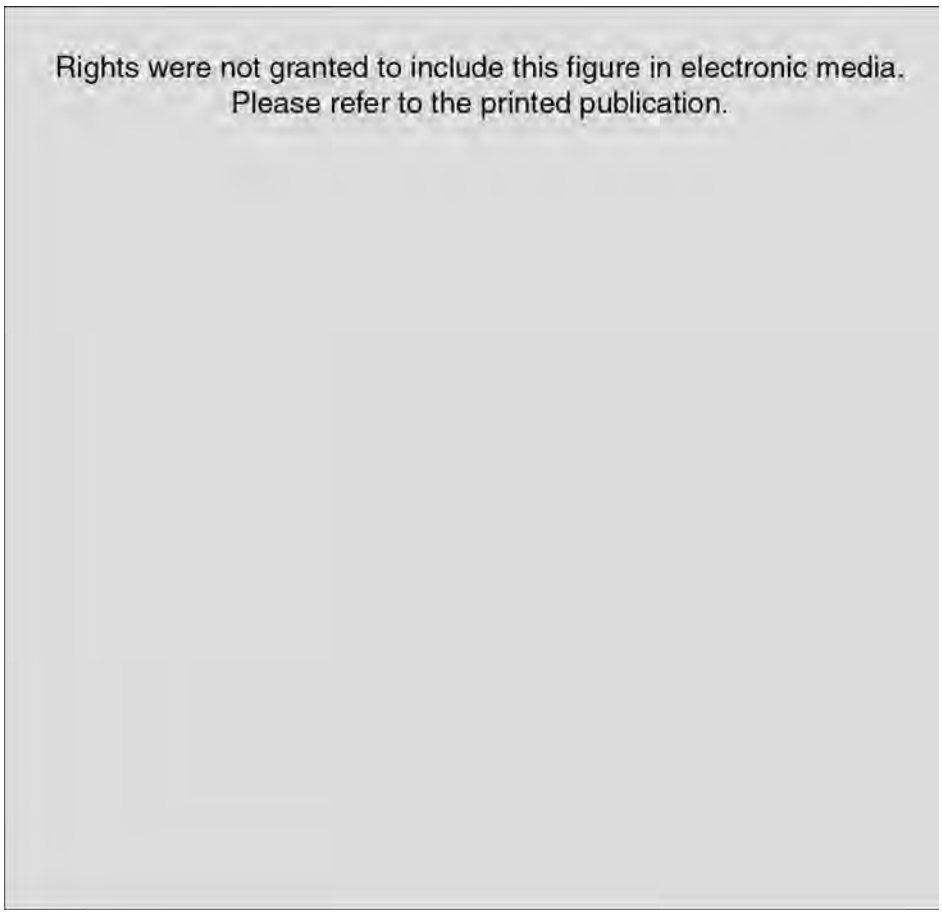

Figure 138–2. Sphincteroplasty. **A,** With the patient in the prone jack-knife position, a curvilinear incision is made. Inferior rectal nerves cross the ischiorectal fossa posterolaterally. **B,** Anterior levatoroplasty is performed, and overlapping sphincter repair is then initiated. **C,** Sphincter repair is completed. **D,** The incision is closed, with drains in place (optional), and V-Y plasty is done to restore the perineal body. (**A-D,** From Baxter NN, Madoff RD: Motility disorders. In Souba WW, Fink MJ, Jurkovich GJ, et al [eds]: ACS Surgery: Principles and Practice, section "Alimentary Tract and Abdomen." New York, WebMD, 2005.)

control group, and most individual reports are subject to criticism due to small patient numbers, short follow-up periods, heterogeneous patient groups, poor quantification of incontinence severity, and the addition of concurrent therapy (e.g., dietary counseling) and physician encouragement, each of which may alone lead to clinical improvement. Indeed, a recent randomized, controlled trial called the efficacy of biofeedback into question because it showed no benefit when biofeedback was added to standard medical care (advice from a nurse specialist) or standard care plus sphincter exercises.[40] Despite these caveats, many clinicians continue to believe that biofeedback is an effective treatment option for patients with fecal incontinence. Indeed, there are few contraindications to a trial of biofeedback, and the technique is painless and risk free. It plays a particularly important role in the treatment of patients with minor degrees of incontinence in whom no anatomic sphincter defect is present and for whom surgery is therefore not indicated. Biofeedback has also been shown to be useful to improve the function of patients with suboptimal results after sphincteroplasty.[41]

Surgery

Surgery for fecal incontinence varies considerably depending on the clinical situation. Traumatic sphincter disruptions are repaired. Should sphincter repair not be indicated or fail, salvage procedures including insertion of an artificial anal sphincter, placement of a sacral nerve stimulator, or injection of sphincter-bulking agents are new options. For patients with persisting refractory incontinence, fecal diversion remains an excellent choice.

Sphincter Reconstruction

Direct sphincter repair (Fig. 138–2) can be performed in the acute setting in the presence of an isolated and easily definable sphincter disruption; this scenario most often occurs in the delivery room after obstetric injury. These injuries are typically repaired with simple sphincter apposition, but up to 70% of women have persisting sphincter defects and 50% persisting incontinence after repair in this setting.[42] Nonoperative traumatic injuries can

often be treated in a similar fashion; however, when severe associated pelvic injuries are present, when the patient is unstable, or when long-standing local contamination is present, débridement with the placement of a diverting stoma plus planned delayed sphincter repair is a better option. Delayed sphincter repair is also required to treat unrecognized sphincter injuries, failed primary repairs, and incontinence after fistulotomy. In each of these cases, definitive surgery should be delayed 3 to 6 months until all local inflammation has resolved.

Patients undergoing elective sphincter repair should have a complete mechanical bowel preparation preoperatively. The operation is best performed with the patient in the prone jack-knife position with the buttocks taped apart. General or regional anesthesia may be used. For anterior defects, a curved circumanal incision is performed along the perineal body and extended laterally over the ischiorectal fossae. A flap of anoderm and, proximally, rectal mucosa is raised along the length of the anal canal anteriorly. Next, the external anal sphincter is mobilized from the vagina anteriorly and laterally until the retracted scarred ends can be easily overlapped to form the repair. Posterior dissection of the sphincter muscle should not extend beyond the mid-lateral line to avoid potential injury to the pudendal nerves, which enter the sphincter posterolaterally. Proximal dissection continues until a proximal nonscarred plane is reached or the inferior fibers of the puborectalis are encountered as they run anteriorly to the pubis.

The midline scar is divided but not excised to minimize the risk of suture pull-through. The buttock tapes are released. Many surgeons perform an anterior levatoroplasty in an effort to lengthen the functional high-pressure zone. Some also advocate reefing of the rectovaginal septum to provide additional anterior support. The divided sphincter is then overlapped to create a "snug" wrap, and this is secured with a series of interrupted 2-0 polydioxane or polyglycolic acid horizontal mattress sutures. Most surgeons perform a "mass" overlap of the combined internal and external sphincter muscles. Others advocate individual dissection and repair of the internal and external sphincter muscles, but the hypothetical superiority of this approach remains to be clinically demonstrated.[27] The skin is loosely closed in a T-shaped configuration, vertically in the anterior aspect to provide adequate length for the perineal body and transversely in the posterior aspect adjacent to the anal verge. No covering stoma is raised.

Results of incontinence surgery vary with definitions of success and closeness of patient follow-up. For many years the reported results after overlapping sphincteroplasty were remarkably consistent: approximately 60% to 75% of patients achieved a "good to excellent" surgical outcome, which in practice entailed perfect or near-perfect control of solid stool, occasional difficulties with control of liquid stool, and episodic "minor" accidents such as seepage or uncontrolled passage of flatus. An additional 15% to 20% of patients achieved lesser degrees of improvement, whereas the remaining 15% to 20% were unchanged or, rarely, worse.[27,29,43,44] Recent series, however, have raised questions about the quality and durability of results following sphincteroplasty.[45-48] Karoui et al. found that 49% of patients were completely continent 3 months after sphincteroplasty, but only 28% were completely continent 40 months after surgery.[47] Halverson and Hull reported that 54% of patients were incontinent to liquid or solid stool 69 months after sphincteroplasty, and only 14% were completely continent.[46] Malouf et al. found that no patients were fully continent 77 months after sphincteroplasty; 84% had fecal urgency and 79% had passive soiling.[45] At the University of Minnesota, we assessed long-term results in 191 consecutive patients after sphincteroplasty. At 10 years' follow-up, just 6% were completely continent, 57% were incontinent of solid stool, and 16% were incontinent of gas only. Results worsened significantly between 3 and 10 years after the procedure.[48]

Salvage Therapy: Postanal Repair and Anal Encirclement

There are a number of options available as salvage therapy for incontinent patients who have failed or are not candidates for standard therapy. The Parks postanal repair was initially devised as an operation for patients with intact but poorly functioning sphincters.[49] The procedure, a posterior plication of the levatores ani and external sphincter, is performed via an intersphincteric dissection. Although once popular in the United Kingdom, the operation never gained widespread acceptance in North America and is performed relatively infrequently. Long-term results from St. Mark's Hospital showed that 26% of patients were continent to stool at a median follow-up of 6 years.[50] However, despite imperfect continence, most patients were improved from baseline.

Anal encirclement in a variety of forms has been used to treat fecal incontinence. The simplest form of this operation, using silver wire, was described by Thiersch in the 19th century.[51] Despite a trend toward the use of softer and more pliable encircling materials, the operation has been plagued by a high local complication rate due to erosion and infection. In 1952, Pickrell et al. devised an operation in which the anal canal was encircled by a transposed gracilis muscle whose neurovascular bundle was maintained intact in the proximal thigh.[52] Pickrell's operation was attractive both because it avoided foreign material and because it created a sphincter that the patient could voluntarily contract (by abducting the thighs). Unfortunately, functional results were generally poor with this procedure, and it never gained widespread acceptance. Several modifications of gluteus maximus transposition have also been described, with highly variable functional results being reported.[53-55]

Dynamic Myoplasty

Interest in gracilis transposition was renewed with the introduction of electrical stimulation by means of an implantable pulse generator.[56] Electrical stimulation is used first to convert the gracilis from predominantly type 2 ("fast-twitch," fatigable) to predominantly type 1 ("slow-twitch," fatigue-resistant) muscle fibers. The stimulator is

Figure 138–3. Acticon neosphincter. (Courtesy of American Medical Systems, Inc., Minnetonka, MN. *www.AmericanMedicalSystems.com*)

Figure 138–4. Artificial anal sphincter. The recommended placement of the artificial anal sphincter device in the patient is shown. (From Baxter NN, Madoff RD: Motility disorders. then used to maintain tonic contraction of the transposed muscle, thereby providing continuous sphincter function. Defecation is effected by switching off the stimulator with a hand-held programmer.

Baeten et al. reported a continence rate of 73% in 52 patients who underwent dynamic graciloplasty for refractory fecal incontinence. The success rate was highest (92%) in patients with sphincter trauma (including obstetric, operative, and accidental) and lowest in patients with anal atresia (50%).[57] Similar success rates were documented in two multicenter trials of dynamic graciloplasty, but both also documented a prohibitively high rate of operative morbidity.[58,59] Because of this high morbidity rate, dynamic graciloplasty has not been approved for use in the United States, and its use worldwide is limited to a small number of specialty centers.

Artificial Anal Sphincter

The artificial anal sphincter (Figs. 138–3 and 138–4) provides an alternative option for patients with severe refractory fecal incontinence. Compared with dynamic graciloplasty, it offers the advantages of simplicity, placement in a single operation, and use of the device 6 weeks after placement without the need for muscle conditioning.

The artificial anal sphincter in use is a modification of an artificial urinary sphincter. It is an implantable device composed of a silicone elastomer that maintains continence via a fluid-filled cuff that surrounds and compresses the anal canal. The patient controls the device via a pump placed in the scrotum or labia. Squeezing the pump 9 to 12 times forces the fluid from the cuff into a reservoir balloon, which is implanted in the space of Retzius. This deflates the cuff and opens the anal canal, allowing the passage of stool. The cuff then automatically slowly reinflates and occludes the anal canal, providing continence until defecation is again desired.

The implantation of an artificial anal sphincter for fecal incontinence was first reported by Christiansen and Lorentzen in 1987.[60] Reported results reflect the early use of the modified urinary sphincter (AMS 800) and the later use of a similar device (Acticon neosphincter) with additional modifications for use around the anal canal.[61-63] Wong et al. performed a multicenter prospective trial of the Acticon neosphincter in 115 patients[64] and found that 46% of implanted patients required revisional surgery, frequently because of infectious complications; 41% of patients required device explantation (17% of these were able to be reimplanted); and 85% of patients who retained their device had a successful outcome, but intention-to-treat success was only 53%. There is some evidence that results improve with surgical experience,[65] but the long-term explantation rate is 40% or greater.[61,66,67] A multicenter study using a specific antibiotic regimen decreased the infection rate of 25%, experienced in the initial multicenter trial, to 9%.[68] Despite several single-center series that have reported successful results in the majority of patients,[65,69,70] a recent systematic review concluded that implantation of the artificial anal sphincter was "of uncertain benefit."[71]

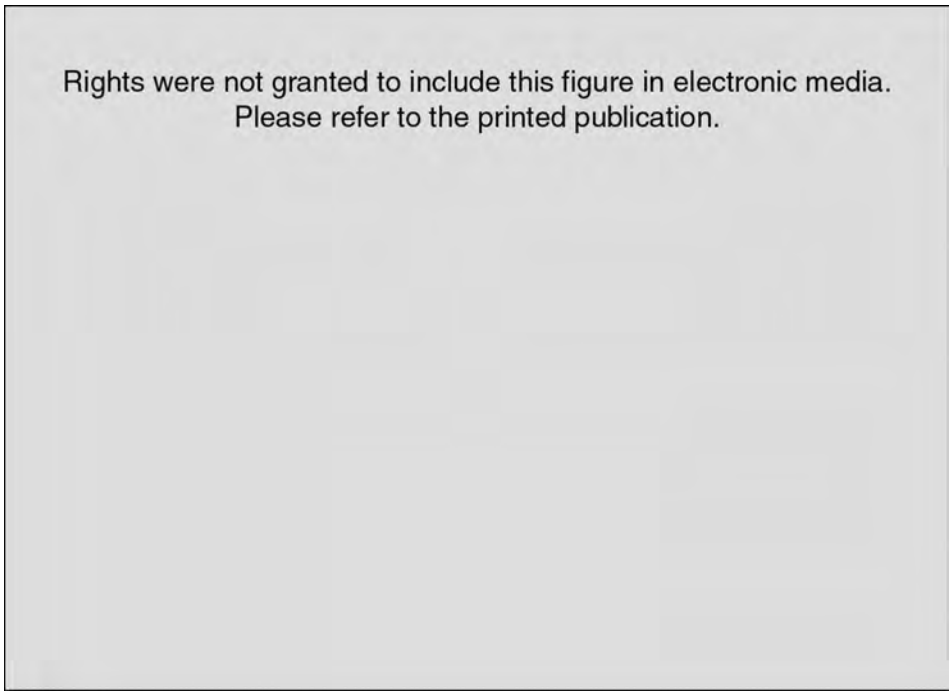

Figure 138–5. Sacral nerve stimulation (SNS). **A,** A lead containing four electrodes is used for SNS. **B,** The sacral foramina are identified; in most cases, S3 is the optimal choice for stimulation. **C,** The quadripolar lead is shown in position. (**A-C,** From Baxter NN, Madoff RD: Motility disorders. In Souba WW, Fink MJ, Jurkovich GJ, et al [eds]: ACS Surgery: Principles and Practice, section "Alimentary Tract and Abdomen." New York, WebMD, 2005.)

Sacral Nerve Stimulation

Sacral nerve stimulation (Fig. 138–5) represents a novel alternative approach to the management of fecal incontinence in highly selected patients. The technique, like the artificial anal sphincter, was initially devised for urinary incontinence. The pudendal nerve is composed of fibers emanating from S2, S3, and S4, and each of these sacral nerves is evaluated using a percutaneous electrode via the sacral foramen. Because these sacral nerves also contribute fibers to the nerves of the lower extremity, it is not surprising that their stimulation leads to the contraction of both the pelvic floor and various leg and foot muscles. It is important that the sacral foramen selected provides maximal pelvic floor and minimal lower extremity stimulation. In clinical practice, this site is most often S3. Once the optimal site has been selected, patients undergo a test period of stimulation with an external pulse generator. If function has improved adequately at the end of the test period, implantation of the permanent leads and pulse generator is performed.

The clinical use of sacral nerve stimulation was pioneered by Matzel et al. in Erlangen.[72] Vaizey and associates reported the results of short-term stimulation for patients with fecal incontinence, a structurally intact external anal sphincter, and manometrically weak internal or external anal sphincters.[73] Successful results, with a marked decrease in incontinent episodes, occurred in 11 of 12 patients. Physiologic studies demonstrated an increase in resting and squeeze anal pressures and a decrease in rectal sensitivity. Ambulatory manometry showed a qualitative decrease in rectal motor complexes and episodes of spontaneous anal relaxation, effects suggesting autonomic nerve effects. However, the mechanism of improvement after sacral nerve stimulation remains unknown. Possible alternatives include a decrease in gastrointestinal transit, decrease in rectal contractility, altered rectal sensation, improved coordination of sensorimotor function, and alterations in anal tone and pressures. The exact nerves that effect changes in incontinence in response to sacral nerve stimulation are unknown. Which nerves are stimulated depends both on the placement of electrode and on the diameter of the nerve in the vicinity of the electrode. Because the largest nerves have the lowest stimulation thresholds, it is most likely that somatic motor efferents and sensory afferents are involved. However, the physiologic findings also suggest that smaller autonomic nerve fibers are also being stimulated.

Sacral nerve stimulation is widely used for urinary incontinence, with more than 15,000 operations worldwide. As the operation is identical for the patient with fecal incontinence, safety and complications are well documented, whereas efficacy is still unknown. To date, most single-center reports of sacral nerve stimulation have reported small cohorts of patients with limited follow-up periods.[74-76] However, a recent prospective, multicenter trial demonstrated a dramatic decrease in incontinent events at 12 and 24 months' follow-up in a cohort of 34 patients who underwent implantation.[77] Quality of life as measured by the FIQL score significantly improved. A multicenter trial is underway in the United States, and results are expected in 2006.

Injectable Biomaterials

Several recent studies have investigated the role of injectable biomaterials in the management of fecal incontinence.[78,79] To date, only relatively small series with limited follow-up have been reported, but success rates have generally been good. Injected materials have

included autologous fat, cross-linked collagen, silicone Bioplastique, and carbon-coated beads. Potential advantages of this technique include simplicity and the ability to offer treatment in an outpatient setting. A successful result can require repeated injections and migration of the injected material is reported. Manometric pressures are not significantly altered. Controlled trials with long-term follow-up are needed.

Fecal Diversion

Despite the broad range of therapies available to the incontinent patient, there inevitably remains a subgroup of patients who fail therapy or simply are not candidates for major reconstructive surgery. In most cases, unmanageable anal incontinence can be converted to a manageable situation by the creation of a stoma, most often a sigmoid colostomy. Although many patients shy from this approach, the loss of body image is generally more than compensated for by the gain in control, self-esteem, and freedom of action. Although available data are quite limited, one questionnaire study of patients who underwent colostomy for fecal incontinence documented marked improvement in subjective quality-of-life assessment after surgery.[80] Counseling by an enterostomal therapist and discussion with other ostomates are invaluable resources in assisting the patient to make an appropriate and informed choice regarding stoma creation. Furthermore, because patient satisfaction is critically dependent on the quality of the stoma provided, preoperative stoma site selection and careful attention to the technical details of stoma creation are mandatory.

CONCLUSIONS

Fecal incontinence is a clinically important disorder whose impact on the individual can range from distressing to devastating. An orderly approach to patient history and physical examination will lead to the diagnosis and its cause in most patients. Patients with mild incontinence often improve with medical therapy. Those with more severe symptoms or an uncertain cause or who are medically refractory should undergo formal physiologic evaluation to optimize their treatment. Most of these patients are successfully treated using biofeedback or standard surgical approaches. For those for whom these strategies fail, salvage therapy with what are now investigational techniques will increasingly become an option in the future.

Surgical Treatment of Constipation

David J. Maron · Steven D. Wexner

Constipation is one of the most frequently experienced gastrointestinal complaints and one of the most common indications for medical consultation.[1] It is estimated that more than 4 million patients in North America suffer from constipation, and laxatives are prescribed for 2 million individuals annually at a cost of more than $800 million.[2] In the United States, more than 90,000 patients are hospitalized each year for constipation-related problems.[3] Constipation has been shown to be more prevalent in persons of lower socioeconomic background,[3,4] females,[5] and the elderly.[3]

The definition of constipation includes both subjective and objective aspects. In addition to decreased frequency of defecation, patients may present complaining of incomplete or difficult evacuation, abdominal or rectal pain, hard stools, decreased stool bulk or caliber, straining for evacuation, nausea, bloating, and tenesmus. Whitehead et al.[6] proposed that at least two of the following need to be present in a patient who has not used laxatives for at least 12 months: (1) straining during more than 25% of bowel movements; (2) feeling of incomplete evacuation after more than 25% of bowel movements; (3) hard stool on more than 25% of bowel movements; and (4) bowel movement frequency of less than two per week with or without symptoms of constipation. Agachan et al.[7] proposed a scoring system that includes frequency of bowel movements, painful evacuation, incomplete evacuation, abdominal pain, length of time per attempts, assistance for defecation, unsuccessful attempts for evacuation per 24 hours, and duration of constipation. After evaluating more than 230 patients, the authors concluded that a score of 15 or greater represents constipation.[7] However, the Rome II criteria are probably the most widely used set of definitions for constipation.[6]

ETIOLOGY

Numerous diseases can cause constipation. Therefore, before attributing constipation to functional or idiopathic reasons, other diagnoses (Box 139–1) must be excluded.

EVALUATION

History and Physical Examination

The significant and critical information obtained from a highly detailed clinical history is mandatory. Thorough abdominal and perineal examinations must be undertaken, with the performance of an inspection of the anal region, including a digital examination, anoscopy, and a rigid or flexible sigmoidoscopy. The abdominal examination should identify any masses, distention, scars, or tenderness. A digital examination can exclude distal obstructive causes of constipation and unveil the presence of any hard stool in the rectum. This latter finding may be common in patients who present with irritable bowel syndrome, inadequate fiber intake, or adequate fiber intake with suboptimal fluid ingestion.

Diagnostic Studies

Barium Enema/Colonoscopy

No patient who complains of constipation should be considered to have a functional cause until mechanical and extracolonic causes are excluded. Therefore, sigmoidoscopy or proctoscopy should be supplemented by a double-contrast barium enema. Although colonoscopy

is a better means of excluding neoplasia, it may be technically challenging due to the redundancy associated with constipation. Alternatively, a barium enema gives the physician a view of the anatomic configuration of the colon, including its size and length.[8] Both constipated and nonconstipated persons can present with large, dilated colons (megacolon) and dolichocolon (Fig. 139–1).

Clinical Approach

Before referral for expensive and invasive physiologic testing, all anatomic and extracolonic causes of constipation must be excluded. Therefore, after the initial office evaluation and air-contrast barium enema, the aim of the general evaluation should be to exclude all of the extracolonic entities listed in Box 139–1. After such

Figure 139–1. Barium enema of a patient with chronic constipation. Typical findings of megarectum include a very elongated and redundant colon.

exclusion, a 6-month course of fiber supplementation, dietary measures, and exercise should eliminate patients who have inadequate fiber or water intake as the source for their constipation.[9] The patient should strive to develop regular bowel habits and try to have a bowel movement in the morning or after meals to take advantage of the gastrocolic reflex. The prompt discontinuation of any stimulant laxative is generally advised, because the earlier mentioned measures should suffice. If laxatives must be prescribed, stool softeners and lubricants are the preferred choices (Box 139–2).

The failure of such measures should prompt physiologic investigation. Rantis et al.[10] reviewed 51 patients with chronic constipation regarding the cost of the diagnostic evaluation and treatment outcome. Fiber, cathartics, and biofeedback therapy were successful in 33 (65%) of 51 patients, and 12 of the 18 remaining patients underwent surgery, with 10 achieving good results. Although an average of $2752 was charged during extensive diagnostic testing, ultimately only the 12 patients who underwent surgery truly benefited from the workup. This study was small and included an analysis of charges rather than of costs; therefore, it does not allow elucidation of the problem or even support the authors' claims. In our department, constipated patients undergo a colonic transit time study, manometry, defecography, and anal electromyography (EMG). The distinction between colonic inertia and a pelvic outlet obstruction syndrome is crucial, because it will have a direct influence on therapy.

Box 139–2 General Classification of Laxatives

Bulk-Forming Agents
- Dietary
- Synthetic or processed
- Methylcellulose
- Polycarbophil
- Psyllium

Lubricants
- Mineral oil

Emollients
- Docusate (calcium, sodium, or potassium)

Saline Laxatives (osmotic agents)
- Magnesium-containing compounds (citrate, hydroxide, sulfate)
- Sodium phosphate

Physiology Laboratory

Colonic Transit

Colonic motility studies have demonstrated that electric activity occurs in the colon as rhythmic or sporadic nonpropagating bursts and sporadic propagating bursts (mass movements) that occur approximately six times per day.[11] Colonic motility is modulated by gastrointestinal hormones such as gastrin, serotonin, vasoactive intestinal peptide, and substance P, as well as by a number of local colon reflexes.

The measurement of colonic transit through the ingestion of radiopaque markers has been used and often modified since 1981.[12-15] In its most "user-friendly" form, the test includes the ingestion of a single capsule containing 24 radiopaque markers (Sitzmarks) followed by radiographs taken on the 5th day after the capsule ingestion. All laxatives, enemas, and suppositories must be discontinued prior to the examination. The diagnosis of colonic inertia is made if 20% or more of the markers are found to be diffusely scattered throughout the colon by the 5th day (Fig. 139–2).[16] Pelvic retention of the markers is consistent with the diagnosis of outlet obstruction.

Advantages of this method determining colonic transit are simplicity, reproducibility, and low cost. Nam and associates[17] studied a group of 51 patients with

Figure 139–2. The radiograph shows the markers distributed diffusely throughout the colon on the 5th postingestion day. The diagnostic finding is consistent with colonic inertia.

chronic idiopathic constipation, each of whom underwent two colonic transit studies. Patients were divided into three groups: colonic inertia, anismus, and chronic idiopathic constipation. In 35 patients (69%), the results were equal between the two studies, and in 16 patients (31%), the results were disparate (gamma correlation coefficient [CC] = 0.53, $P < 0.01$). When the tests were repeated within 1 year, the CC was 0.38 ($P < 0.05$), whereas for periods of more than 1 year, the CC was 0.79 ($P < 0.01$). The authors concluded that colonic transit studies are reproducible, despite the duration between tests. In an attempt to study segmental colonic transit, some authors have used different types of markers administered on successive days with plain abdominal films taken either serially[12,13] or on a single day.[14] Because there is no evidence that segmental colonic resection is an appropriate option in the treatment of colonic inertia, however, the determination of segmental transit does not justify the increased complexity of this approach.

Scintigraphy can also be applied to the measurement of colonic transit. A method of delivery by orocecal intubation was devised to avoid dispersion of the radiolabeled material (In-DTPA) during its passage through the stomach and small intestine.[18] The need for orocecal intubation, however, is eliminated when labeled pellets are incorporated into a gelatin capsule coated with a methacrylate polymer[19] or activated charcoal.[20] Images can be obtained at three time points: 28, 52, and 60 hours after ingestion.[21] Disadvantages of this method include less-than-ideal image resolution and the difficult interpretation of the anatomy of the colon.

Small Bowel Transit

Studies have indicated that there may be a subset of constipated patients in whom orocecal transit time is delayed.[22] When a subtotal colectomy is being planned, measurement of small bowel transit is important to distinguish between isolated colonic inertia and panenteric inertia. The first group of patients are known to benefit from colectomy; the second group may remain constipated even after colectomy.

The breath hydrogen test was first described in 1975 by Bond et al.[23] to measure orocecal transit time. This test is based on the principle that the bacterial metabolism in the colon produces hydrogen. Hydrogen is insoluble in water and highly diffusible; therefore, it is promptly absorbed by the intestinal mucosa, transported to the lungs, and then exhaled. An expiratory breath specimen is measured by means of a gas chromatograph analyzer after the patient ingests a dose of 10 g of lactulose diluted in 100 ml of water; breath samples are taken every 10 minutes for a minimum of 2 hours. The time between the ingestion of the lactulose and the first breath hydrogen peak should represent the time of arrival of the substrate to the colon. This test can be altered by smoking or exercise,[24] as well as by small bowel bacterial overgrowth.

A standard meal labeled with mTc-DTPA can also be used to measure gastric emptying and small bowel transit; other radioisotopes may also be used (iodine, indium). The patient must ingest the meal after an overnight fast, and a gamma camera is used to obtain the images until the meal arrives in the cecum. The actual small bowel transit is determined as the time between 10% gastric emptying and the appearance of scintigraphic activity in the cecum. Apart from the exposure to radiation generated by this examination, the major disadvantage of this method is the difficulty in identifying cecal filling due to the overlap of small bowel loops. Bonapace et al.[25] evaluated 73 patients with chronic constipation using whole-gut transit scintigraphy. Nineteen percent of patients were found to have delayed gastric emptying, and 7% had delayed small bowel transit time.

The detection of plasma sulfapyridine after the ingestion of sulfasalazine has also been described and corresponds to orocecal transit.[26] This technique has not been widely accepted due to its complexity and cost and the requirement for a nuclear camera. The use of a barium-labeled test meal to assess small bowel transit is not recommended, because alterations in small bowel physiology can be caused by barium. Moreover, radiation exposure is significant.

Manometry

Anorectal manometry measures intra-anal and intrarectal pressures by means of a transanally inserted catheter. Measurements can be taken in either a stationary pull-through or a motorized continuous withdrawal technique. We use a water-perfused catheter and measure

pressures at 1-cm increments, in a proximal-to-distal orientation. With this method, we are able to establish the anal canal length (high pressure zone), resting and squeeze pressures, and rectal capacity volume to first sensation. Most important in constipated patients, we are also able to elicit the rectoanal inhibitory reflex (RAIR). Because of the diversity of methods used in performing anorectal manometry, normal values do not always coincide among institutions; however these parameters should remain identical within the same laboratory.[27]

Despite these pressure variations, the absence of the RAIR is abnormal. The lack of this reflex in patients with chronic constipation may suggest Hirschsprung's disease. In addition, the same absence is noted in patients with Chagas' disease and should be suspected in patients from endemic countries. An abnormal reflex may also be encountered in patients with dermatomyositis or scleroderma and after any coloanal or ileoanal anastomosis[28]; elicitation of the RAIR is qualitative and not quantitative.

Defecography

Defecography is a method to assess simulated evacuation under direct real-time fluoroscopic visualization.[29-32] The rectum is filled with a radiopaque material similar in consistency to stool, and the patient is seated on a water-filled commode. The evacuation process is then observed under fluoroscopic guidance. Radiographs and videos are taken during four distinct activities: at rest, during squeeze, while pushing, and after evacuation. The radiographs allow the measurement of the anorectal angle, perineal descent, and puborectalis length. Because the study is dynamic, one of the criticisms has been the reproducibility of the test. However, Pfeifer et al.[33] from the Cleveland Clinic Florida confirmed an 83% accuracy rate for the examination when four independent observers used the same definition for each of the pathologic findings.

Under normal circumstances, the rectum is emptied during straining within 8 to 12 seconds, depending on the viscosity of the contrast medium.[33] Even though the examination may disclose multiple abnormalities such as rectoceles and sigmoidoceles, intussusception, or perineal descent, one should be cautious to not attribute clinical significance to normal anatomic variants.[34] Jorge et al.[35] found that because defecography had the ability to detect associated abnormalities, it was superior to anal EMG in the diagnosis of nonrelaxing puborectalis syndrome.

The failure to eliminate rectal contents during defecography may not be due to obstructed defecation but rather to the patient's inhibition to evacuate in the presence of an audience. To overcome potentially false-positive results, other methods have been devised, such as attempting the evacuation of a balloon from the rectum.[36-38] Radioactive isotopes can also be used to quantitatively assess evacuation.[39] The introduction of a radiolabeled artificial stool into the rectum is followed by the capture of images with a standard gamma camera, and the percentage of emptying is calculated using an equation. Even though this test provides good qualitative information about the percentage of rectal content evacuated, the low resolution of scintigraphic defecography does not permit the detection of abnormalities such as intussusception, mucosal prolapse, or many rectoceles.

Recently, dynamic pelvic magnetic resonance (MR) imaging has been used to diagnose pelvic floor disorders.[40,41] Matsuoka et al.[40] compared MR defecography with conventional videoproctography. Although all 22 patients preferred MR defecography to videoproctography due to greater comfort, MR defecography was inferior in detecting rectoceles, rectoanal intussusception, and perineal descent. The authors concluded that the routine use of MR defecography in the work-up of constipated patients could not be justified by the high cost of the test.

Electromyography and Pudendal Nerve Terminal Motor Latency

EMG and pudendal nerve terminal motor latency (PNTML) are the only methods available to analyze the neurologic status of the striated component of the anal sphincter muscles and its neural supply, respectively. This examination is based on the concept of the motor unit,[42] which consists of an anterior horn cell, its axon and axonal branches, motor end plates, and muscle fibers innervated by that cell. The examination is undertaken with the patient in the left lateral decubitus position, using concentric needle EMG to study the four quadrants of the external anal sphincter, during rest, squeeze, cough, and simulated defecation. A disposable anal plug electrode may also be used for anal EMG. This technique has the advantage of being less invasive; however it is not as accurate as the needle examination. The electrical activity of the muscular action potentials is recorded and analyzed by means of a computer-assisted system (Nicolet Viking II EMG System).

The number of muscle fibers in the anal sphincter innervated by each axon is small due to its fine, continuously contracted activity. In a normal anal EMG, continuous electrical activity may be seen even at rest,[43] with an increase in its activity during squeezing and coughing; it should return to its resting pattern during evacuation. Its role in the evaluation of constipation is that it can help diagnose paradoxical puborectalis contraction (PPC), and it can be used as a tool in its treatment.[44,45]

The PNTML technique was described by Kiff and Swash in 1984.[46] It can be measured with an electrode mounted on the examiner's finger and introduced into the rectum. The examiner's index finger is positioned so that the electrode is brought into contact with one of the ischial spines. The time between the application of the electric stimulus and the external sphincter contraction is called the *terminal motor latency of the pudendal nerve.* Initially, in small series some authors argued for a correlation between the chronic straining encountered in constipated patients and abnormally prolonged PNTML.[47-49] Significantly larger series, however, have not substantiated this theoretical correlation between increased perineal descent and pudendal neuropathy.[50]

Regarding the sensory components of the anal canal, two techniques have been described: temperature sensation[51] and mucosal electrosensitivity.[52] The first consists of a water-perfused thermode to assess the thermal sensitivity of the anorectum. Even though the ability to discriminate temperature has been implicated in fecal continence, no studies have shown any aberration in constipation. For the assessment of mucosal electrosensitivity, a specially constructed probe that generates constant current is applied to the upper anal canal. The stimulus is increased until the patient feels a tingling sensation, which is recorded as the threshold of sensation. The use of rectal electrosensitivity in constipation[53] is based on the fact that rectal sensation may be decreased in these patients, although this observation may be due to damage to sensory innervation of the surrounding muscles or to feces that prevent optimal mucosal contact.[54]

Minnesota Multiphasic Personality Inventory Assessment

The Minnesota Multiphasic Personality Inventory (MMPI) assessment was created in 1943 by Hathaway and McKinley.[55] It has been used to compare the psychological function of patient populations with different medical diagnoses. It describes how effectively the individual is functioning on an interpersonal and intrapersonal level. The test consists of 550 questions, which must be answered on a "true or false" basis. All scale scores are based on a mean of 50 and a standard deviation of 10, whereas 2 standard deviations from the mean is indicative of psychopathology.[56] When Devroede and associates[57] compared constipated women and women with arthritis, they found a "conversion V" pattern on the MMPI of the constipated patients, a pattern indicating the presence of a somatization defense structure for dealing with psychological distress.

Heymen et al.[58] used MMPI to analyze three groups of patients who complained of constipation, fecal incontinence, and rectal pain. They found that constipated patients showed an elevation in the hypochondriasis, depression, and hysteria scales, which are referred to as the *neurotic triad*.[57] This indicates that these subgroups of patients use somatization as a defense mechanism, which is a good prognostic factor for psychotherapy. For these reasons, we believe that constipated patients who are candidates for colectomy should undergo the MMPI assessment before surgery, since they may benefit from preoperative psychotherapy or psychotropic medications.

Interpretation of Results

The aim of the diagnostic evaluation is to determine whether the patient who presents with constipation has any objective abnormalities. As mentioned previously, the initial strategy should therefore be to exclude extracolonic and structural disorders with a barium enema or colonoscopy. If no cause for constipation is identified, a colonic transit study should be performed. If transit is normal, an assessment of the pelvic floor should be undertaken with defecography and EMG. Recurrent volvulus, Hirschsprung's or Chagas' disease, and systemic sclerosis must be excluded in patients who present with megabowel.

After completing the diagnostic evaluation, functional constipation can be categorized as follows:

1. Colonic causes—colonic inertia, idiopathic megabowel, adult Hirschsprung's disease
2. Pelvic outlet obstruction—pelvic floor dysfunction, PPC, combined pelvic floor dysfunction and PPC
3. Combined colonic inertia with pelvic outlet obstruction
4. Normal transit constipation (usually as a result of irritable bowel syndrome)

TREATMENT

Surgical Approach

Colonic Inertia

Patients with abnormal transit and normal pelvic floor physiology who do not respond to conservative therapy are candidates for surgery. Surgical management for clinically intractable constipation was first attempted more than 90 years ago.[59,60] Three surgical techniques have been described to treat colonic inertia: subtotal colectomy with ileorectal anastomosis (IRA), ileosigmoid anastomosis, and cecorectal anastomosis (CRA). Many series have been reported, with variable results (Table 139–1). Despite early suboptimal results, the development and availability of anorectal physiologic testing have made better results possible during the past decade. Subtotal colectomy with IRA has been established as the current procedure of choice for the treatment of colonic inertia. Pikarsky and associates[61] assessed by telephone interview a group of 30 patients who underwent IRA at a minimum of a 5-year follow-up. All 30 patients rated their outcome as excellent, although during this period, 6 patients (20%) required hospitalization for small bowel obstruction, of whom 3 (10%) required laparotomy. In this series, 2 patients (6%) still required assisted bowel movements, 1 patient used laxatives, and 2 patients needed antidiarrheals to control frequency. FitzHarris et al.[62] recently reported on 75 patients who underwent IRA. Eighty-one percent were at least somewhat pleased with their bowel movement frequency; however, 41% had persistent abdominal pain and 21% reported incontinence.

Subtotal colectomy with CRA has the theoretical advantage of retaining the ileocecal valve to improve the absorption of water. Patients who undergo this procedure, however, may suffer from persistent cecal dilation.[73] Most series reporting results of CRA have been small. Yoshioka and Keighley[82] compared results of 5 patients who underwent CRA with 34 patients who underwent IRA and found no difference in the success rate. Sarli et al.[102] recently reported the results of 26 patients. At 1-year follow-up, the mean number of bowel movements per day was 1.7. and all 26 patients were satisfied with the results of their surgery.

Adapted from Pfeifer J, Agachon F, Wexner SD: Surgery for constipation: A review. Dis Colon Rectum 39:444, 1996.

Because some patients may experience diarrhea or frequent bowel movements after subtotal colectomy with IRA, some authors have proposed segmental colectomy to avoid these unwanted side effects. The results of these procedures, however, have been less impressive, with an overall success rate of less than 70%. In addition, up to half of patients will develop megabowel of the remaining colon.

The use of laparoscopic surgery for diseases of the colon and rectum began in the early 1990s and has now become standard of care in some disease states. Several authors have reported on the use of laparoscopy in the treatment of colonic inertia.[103-105] Ho et al.[104] compared 7 patients who underwent laparoscopic-assisted colectomy with 17 patients who underwent open colectomy. Operative time was significantly longer in the laparoscopic group, but functional outcome was equal in both groups. Complications and length of stay were also equal in both groups; however, patients who underwent open surgery were less satisfied with the cosmetic outcome.

Regardless of the type of surgery selected to treat constipation, patients must understand the risks. In addition to the standard risks such as anastomotic leak and postoperative bowel obstruction, problems specific to colectomy for constipation also exist. Specifically, although frequency of bowel movements will probably improve, bloating, pain, nausea, and other constitutional symptoms may persist or even worsen. Furthermore, patients without these symptoms preoperatively may develop them following surgery. No patient should undergo colectomy for constipation without understanding that the operation will not help ameliorate these associated symptoms. In addition, patients must also be aware of the possible need for a stoma at any time following surgery. Patients with unrealistic psychological expectations, no matter how well suited by physiologic testing for surgery, are not surgical candidates.

Pelvic Outlet Obstruction

Sigmoidocele may account for symptoms of obstructed defecation, particularly in patients who have previously undergone hysterectomy. The mechanism of pelvic outlet obstruction is believed to be caused by collapse of the rectal wall as a result of extrinsic compression of the hernia contents and stasis of the sigmoid loop. Jorge et al.[106] elaborated a classification system for sigmoidoceles based on the degree of descent of the lowest portion of the sigmoid: first degree, above the pubococcygeal line; second degree, below the pubococcygeal line and above the ischiococcygeal line; and third degree, below the ischiococcygeal line (Fig. 139–3). First- and second-degree sigmoidoceles may represent normal anatomic variants, although a nonemptying sigmoidocele can be the cause of sensation of incomplete evacuation. Patients with first- and second-degree sigmoidocele can be treated conservatively with biofeedback therapy, whereas third-degree sigmoidoceles may benefit from operative therapy.

Jorge et al.[106] reported their experiences with 9 patients who had first-degree sigmoidocele, 7 patients with second-degree, and 8 patients who had third-degree sigmoidocele. Impaired rectal emptying was present in 16 patients (67%). Five of 8 patients with third-degree sigmoidocele underwent colonic resection with or without rectopexy, whereas the other 3 patients were managed conservatively. One of 7 patients with second-degree sigmoidocele underwent colectomy, and the other 6 were managed conservatively, as were all 9 patients with first-degree sigmoidocele. Post-treatment improvement was noted in all patients who underwent resection, but in only 6 (33%) of 18 patients treated conservatively. Furthermore, the clinical significance of third-degree sigmoidocele is supported by the fact that all 5 of the patients with third-degree sigmoidocele who underwent colonic resection reported symptomatic improvement at a mean follow-up period of 23 months.

Rectocele is a protrusion of the rectal wall into the vagina during defecation. It may be commonly seen in healthy women,[107] but is also associated with multiparity,[108] obstetric damage, and the presence of PPC.[109] Rectoceles can be classified as high level (usually due to stretching or disruption of the upper third of the vaginal wall and the cardinal and uterosacral ligaments), mid level (usually caused by loss of pelvic floor support secondary to parturition), or low level (usually the consequence of perineal body defects).

The clinical significance of rectoceles is uncertain. Rectoceles may cause mild to severe anorectal symptoms, such as perineal pressure, the sensation of a pouch in the vagina, or incomplete evacuation requiring rectal or vaginal digitation.[34] In our institution, patients are chosen for surgery according to the size of the rectocele (>2 cm), the inability to empty the rectocele at defecography, and the use of digitation or perineal support to empty the rectum (Fig. 139–4). Rectoceles can be repaired via a transvaginal[110,111] or transrectal[112-114] approach. Overall success rates range from 65% to 100%.

Rectal intussusception is an infolding of the rectum into but not beyond the anal verge. Although rectal intussusception is a common finding in defecography (Fig. 139–5), it is not usually the cause of constipation. Treatment should consist of adequate fiber intake and the use of enemas or laxatives to assist in evacuation, as well as biofeedback. Surgical repair including rectopexy has had poor long-term results.[115,116] Choi et al.[117] compared patients with large rectal intussusception treated with conservative dietary therapy, biofeedback, or surgery. Although 60% reported subjective improvement following surgery, half of these patients developed new symptoms such as rectal bleeding or pain, incomplete evacuation, or liquid stools. In addition, biofeedback showed a significant improvement in number of bowel movements per week when compared to a high-fiber dietary regimen alone.

Paradoxical Puborectalis Contraction

The normal evacuatory mechanism includes the voluntary relaxation of the external anal sphincter and the pelvic floor muscles, thus increasing the anorectal angle. However, failure of relaxation or paradoxical contraction of the puborectalis muscle during evacuation is

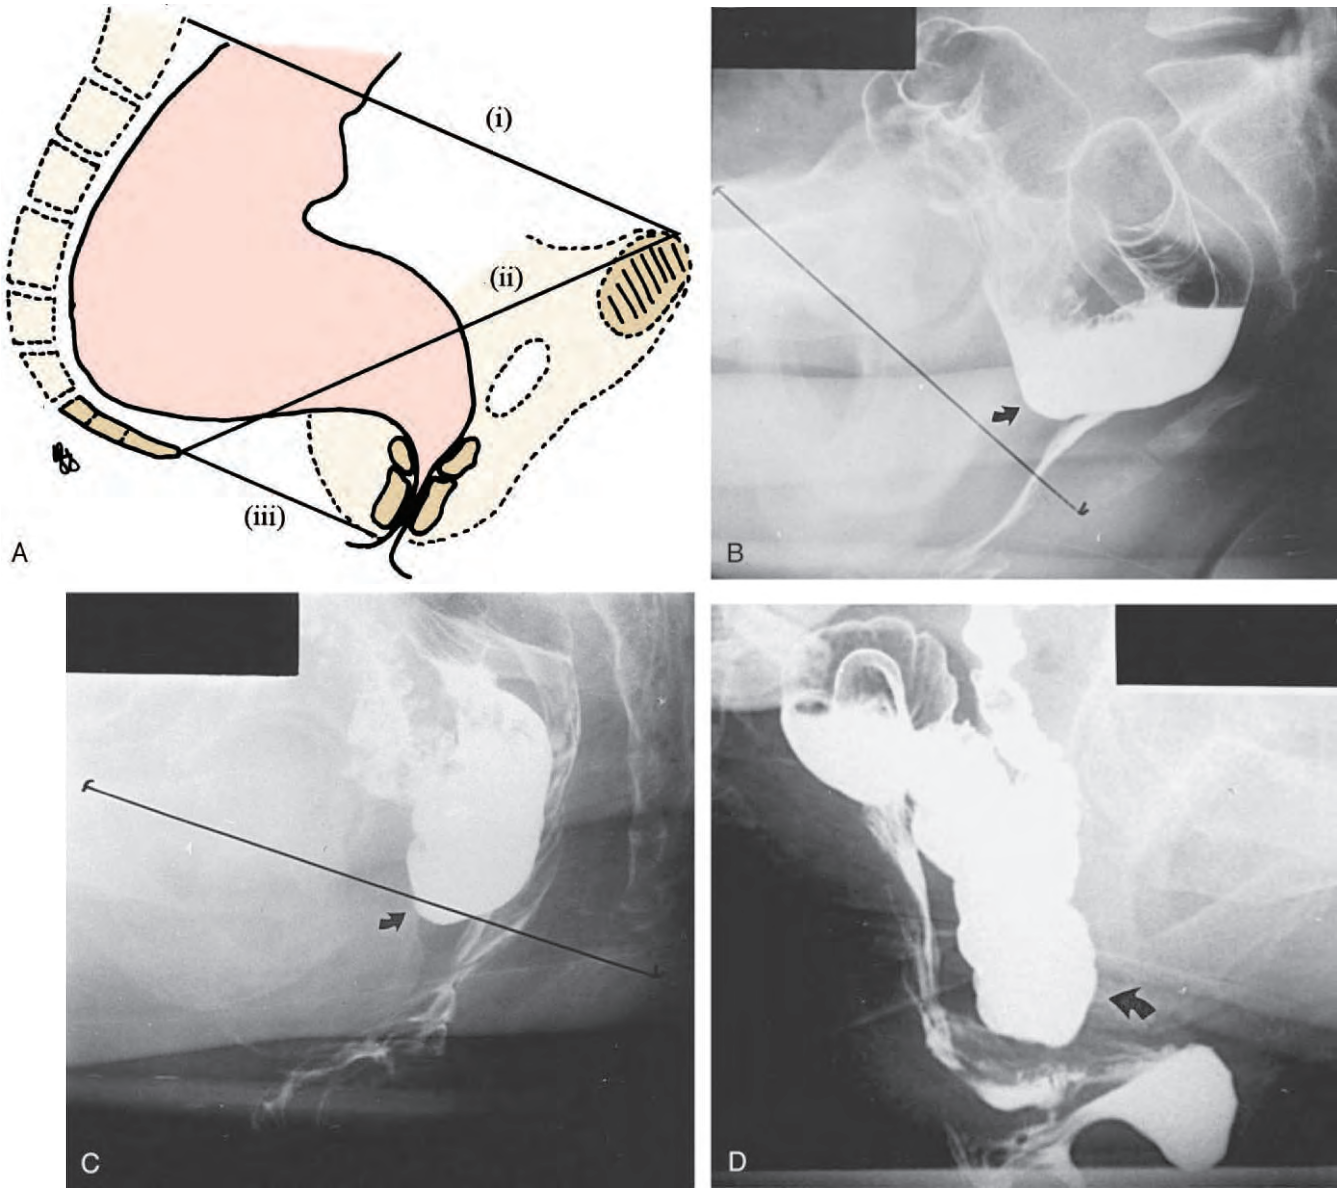

Figure 139–3. **A,** Schematic of the three degrees of sigmoidocele: (i) pubosacral line, (ii) pubococcygeal line, and (iii) ischiococcygeal line. **B,** First-degree sigmoidocele is the descent of the lowest portion of the sigmoid to above the pubococcygeal line. **C,** The second degree is to below the pubococcygeal line but above the ischiococcygeal line. **D,** The third degree is below the ischiococcygeal line.

responsible for obstructed defecation,[118] a condition that is termed *PPC*. This syndrome has also been termed *anismus*, *nonrelaxing puborectalis syndrome*, *spastic pelvic floor syndrome*, and *rectal dyschezia*. The cause of this entity is unclear and may involve a generalized pelvic floor disorder with a strong psychological component.[119] Patients typically complain of straining, tenesmus, and the sensation of incomplete evacuation, as well as the frequent need for suppositories, enemas, or digitation.

Diagnosis is achieved with a combination of defecography (Fig. 139–6) and EMG (Fig. 139–7) to assess the function of the puborectalis muscle. The use of one test does not always ensure a diagnosis (the patients' inhibition may lead to nonrelaxation of the pelvic floor during defecography),[118] and pain may have the same effect during EMG,[70] both of which will lead to false-positive results. Jorge and associates[35] prospectively assessed the role of defecography and EMG in the diagnosis of PPC in 112 constipated patients. In this series, EMG had a sensitivity of 67%, a positive predictive value of 70%, and a specificity of 83%, whereas the values for defecography were 70%, 66%, and 80%, respectively. The authors concluded that although these parameters are suboptimal for both examinations, defecography may be a superior test due to its ability to detect associated abnormalities. Moreover, the inability to relax the puborectalis muscle has been demonstrated in normal control subjects[120]; the diagnosis of PPC, therefore, must be consistent with the

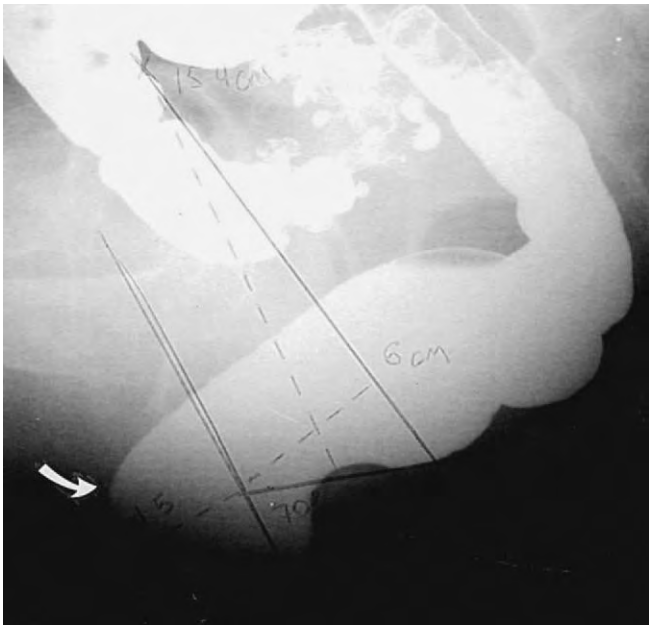

Figure 139–4. A nonemptying anterior rectocele is shown *(arrow)*.

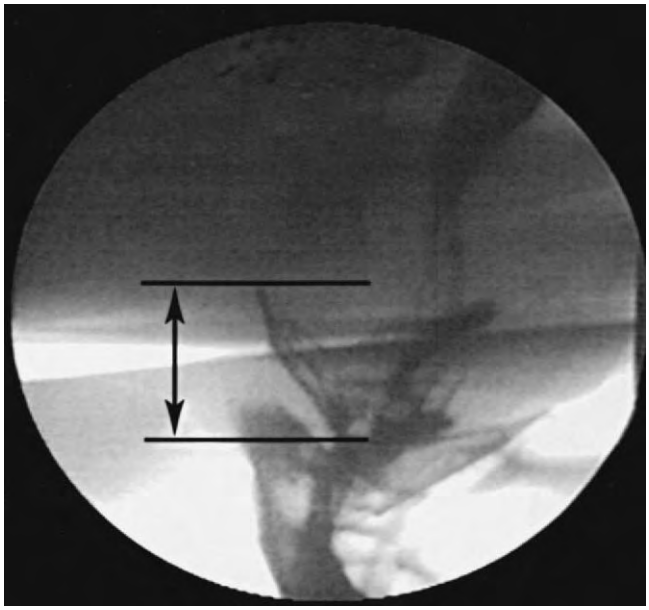

Figure 139–5. Rectoanal intussusception is shown.

clinical findings and the results of more than one physiologic test.

Because of the intense psychologic component in PPC, the treatment of choice for these patients is pelvic floor retraining with biofeedback. The success rate for this modality of treatment applied to PPC ranges from 29% to 100% depending on the series and the techniques that are used (Table 139–2). Attempts have been made to treat PPC through surgical division of the puborectalis muscle. Independent of the site of division on the muscle, either posteriorly or laterally, symptoms of obstructed defecation did not improve and adverse results including fecal incontinence occurred in a high number of patients.[80,121]

Pelvic Floor Retraining and Biofeedback

Biofeedback is based on the concept that patients can be taught to recognize bodily functions of which they were not previously aware. Achieving control of such functions can be translated into visual or aural stimuli by means of different electronic devices. Electrical and hydrostatic information is displayed in such a way that patients can better understand the contraction and relaxation process. Both pressure-based (manometry) and electrical signal-based (EMG) systems have been used.[122,124,130,142] Heymen et al.[143] recently performed a meta-analysis and found that the mean success rate of pressure-based biofeedback was 78%, whereas the success rate for EMG feedback was only 70%. In addition, there was no significant difference between the success rates using either intra-anal sensors or perianal EMG sensors. These modalities have also been combined with rectal sensation training,[122,142] in which patients with a poor recognition of the rectal urge were taught to perceive progressively decreasing volumes of distention. In addition to these methods, portable units are available for use at home, which allows training in a friendly, familiar environment.[127,128,130,131]

Biofeedback training consists of 3 to 10 1-hour-long sessions under the supervision of a biofeedback therapist. The patients are also instructed to keep a daily record of bowel movements, medications, and the use of enemas, laxatives, or digitation. The training is done on an outpatient basis, with the patient dressed and seated on a chair after insertion of the anal plug. Patients are taught to recognize three events: rest, push, and squeeze. The push exercises are done only under supervision during the biofeedback session, whereas the squeeze and rest exercises (Kegel maneuvers) should be practiced at home as well. Discharge conditions include the demonstration of control of pelvic floor musculature as shown with EMG, a reduction in the use of cathartics, and objective resolution of constipation as indicated in a bowel habit diary. Gilliland et al.[136] reviewed the outcome of 194 patients who underwent biofeedback therapy; patients who self-discharged from therapy had a success rate of only 29% compared with patients who were discharged by the therapist, who had a 63% success rate ($P < 0.0001$). In this multivariate analysis, which included duration of symptoms, age, gender, and multiple other variables, the self-discharge rate was the only predictor of successful outcome. The results of biofeedback are dependent both on the expectations of the patient and the expertise of the therapist. Currently, a multicenter prospective, randomized trial is underway to assess the placebo effect of biofeedback.

For the subset of patients who do not benefit from biofeedback, the use of *Clostridium botulinum* type A (BTX-A) in the treatment of PPC has been reported.[144-147] This potent neurotoxin causes paralysis of

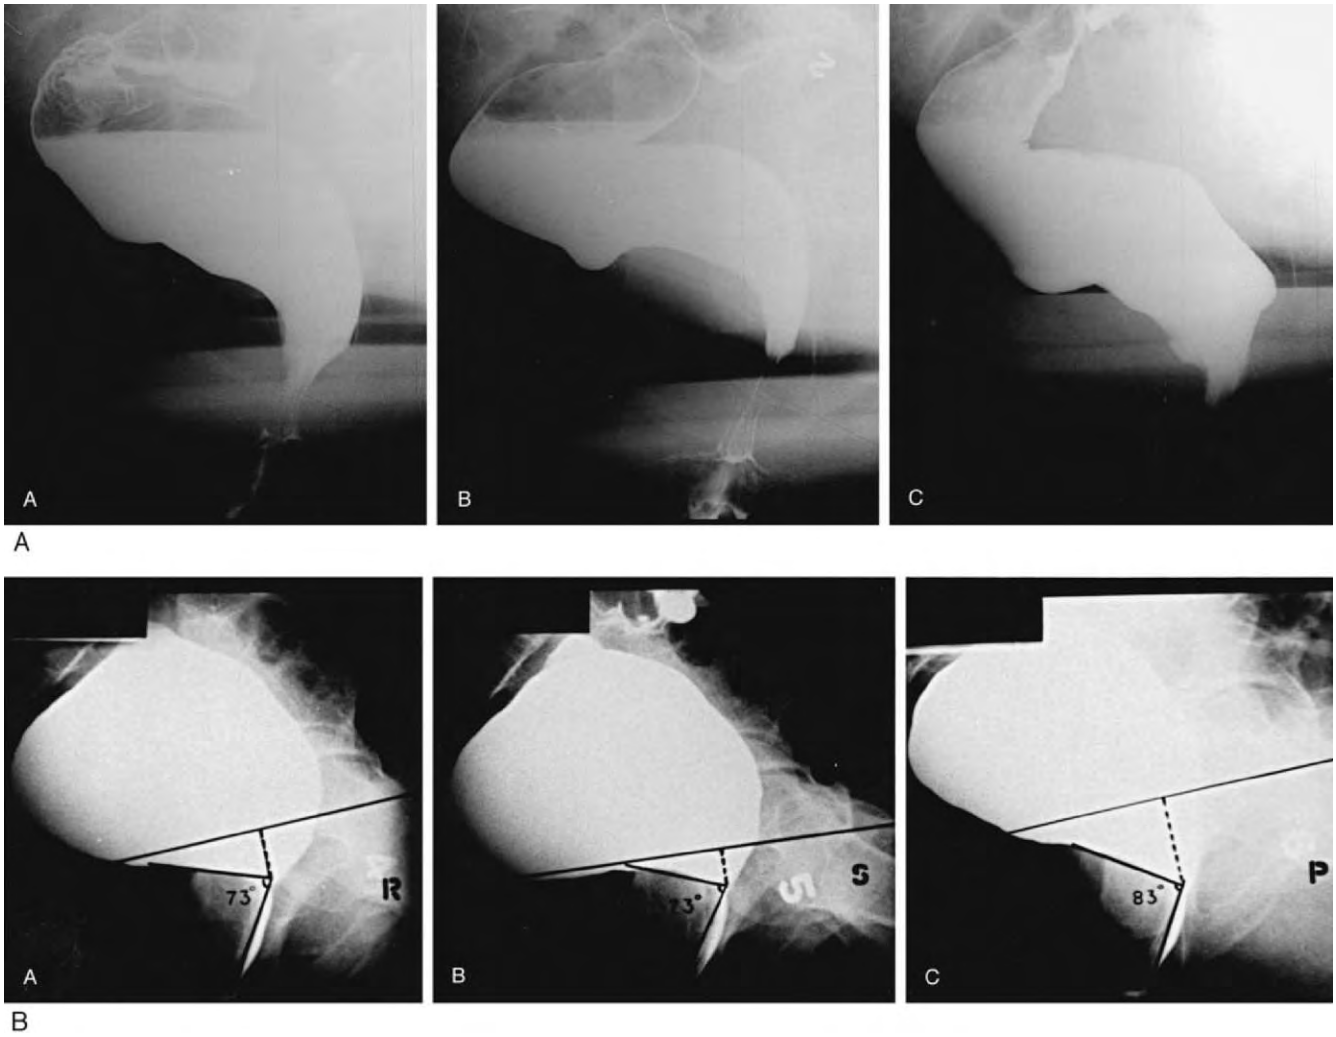

Figure 139–6. **Top Row (A),** Normal cinedefecogram sequence at rest (A), squeeze (B), and attempted evacuation (C). **Bottom Row (B),** Cinedefecogram shows paradoxical puborectalis contraction at rest (A), squeeze (B), and attempted evacuation (C). Contrasting these cinedefecograms, it can be seen that a normal sequence includes shortening of the anal canal and flattening of the anorectal angle with evacuation of barium contents. In comparison, paradoxical puborectalis contraction includes maintenance of the length of the closed anal canal and the anorectal angle or, in some instances, accentuation of these features by an even longer, more closed anal canal and an even more acute anorectal angle.

muscles through presynaptic inhibition of acetylcholine release. Joo and associates[145] treated a group of 4 patients diagnosed with intractable constipation due to PPC with BTX-A injections for a maximum of three sessions during a 3-month period. Under EMG guidance, the BTX-A was injected into the left and right sides of the puborectalis muscle. All patients were relieved of constipation between 2 and 4 days after BTX-A injection without any local or systemic side effects. However, 3 months after BTX-A injection, 2 of the 4 patients experienced symptomatic recurrence. Maria et al.[147] recently reported improvement in 13 of 15 patients treated with injection of 25 units of BTX-A. Improvement, however, was maintained for a mean of only 5 months, requiring reinjection of the toxin.

CONCLUSIONS

Although only a small group of patients may benefit from surgical intervention, the evaluation of these patients must be extensive to ensure both the inclusion of appropriate candidates as well as the exclusion of inappropriate candidates.[148] In addition, the psychological status of these patients requires thorough assessment and often requires treatment. Through careful testing and selection, satisfactory results can be obtained in more than 90% of patients. Patients must understand, however, that although bowel frequency will improve and dependence on laxatives will be eliminated or significantly reduced, other symptoms such as abdominal bloating and pain may persist, develop anew, or become exacerbated.

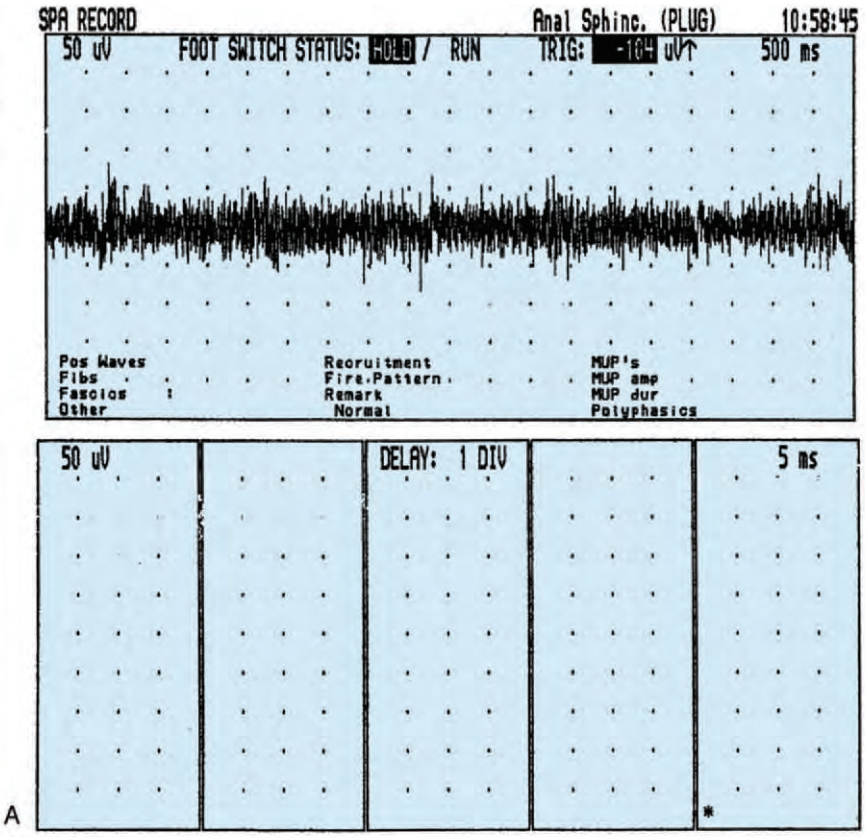

Figure 139–7. **A,** Normal electromyography during attempted evacuation is compared with paradoxical puborectalis contraction **(B). B,** Paradoxical increase in the recruitment of the external anal sphincter muscle and puborectalis is noted during attempted evacuation. The normal study shows appropriate external anal sphincter and puborectalis relaxation.

PPC, paradoxical puborectalis contraction; EMG, electromyography.

Patients must also realize that they may eventually require a stoma as well.

Rectovaginal and Rectourethral Fistulas

Patricia L. Roberts

RECTOVAGINAL FISTULAS

Rectovaginal fistulas are epithelial-lined communications between the rectum and vagina. Although they are relatively uncommon, accounting for approximately 5% of all anorectal fistulas, they may cause significant physical symptoms in addition to adversely affecting intimate relationships and sexual function. The operative approach to such fistulas depends on a variety of factors, including the size, location, condition of the surrounding tissues, and association with concomitant disease, such as inflammatory bowel disease.

ETIOLOGY

Rectovaginal fistulas may occur from both congenital and acquired disorders.

The most common cause of a rectovaginal fistula is obstetric trauma. A prolonged second stage of labor with ischemic necrosis of the rectovaginal septum may contribute to development of a fistula. Other risk factors include a high forceps delivery, shoulder dystocia, midline episiotomy, and third- or fourth-degree perineal laceration.[1] Although fistulas after prolonged labor are rare in developed countries, they are still a relatively frequent occurrence in undeveloped countries.[2] There are few reliable data on the prevalence of obstetric fistula from underdeveloped countries; however in 1989, the World Health Organization estimated that 2 million women and girls had the condition and 50,000 to 100,000 cases were added each year.[3,4] The backlog of unrepaired cases is believed to approach 1 million in such areas as northern Nigeria alone.[2,5] For every 100 obstetric fistulas encountered, 74% are vesicovaginal, 21% are vesicovaginal and rectovaginal, and 5% are rectovaginal alone.[6] In one series in the United States, rectovaginal fistula after vaginal delivery occurred in 25 women out of 22,050 vaginal deliveries (0.1%).[2] A single rectovaginal fistula was reported after 2635 deliveries in another series.[7] Crohn's disease, a transmural inflammatory disease of the bowel, is associated with rectovaginal fistula in more than 10% of women with the disease.[8] Anorectal suppurative disease, including abscesses in the rectovaginal septum and anterior horseshoe abscesses, may be associated with rectovaginal fistulas.

Rectovaginal fistulas can occur as a postoperative complication after a variety of rectal, vaginal, and pelvic operations, including hysterectomy, low anterior resection with stapled anastomosis, ileal pouch–anal anastomosis, and stapled hemorrhoidectomy.[9] The complication occurs more commonly after stapled than hand-sewn anastomoses and may result if the stapler incorporates a portion of the vaginal wall or surrounding perivaginal tissues or as a consequence of an anastomotic leak. Rectovaginal fistulas have been reported in 2.9% to 9.9% of women undergoing resection for rectal cancer and are more common if concomitant vaginectomy has been performed.[10,11] Pouch-vaginal fistulas occur in 2.6% to 16% of women undergoing the ileoanal pouch procedure and may be caused by unsuspected Crohn's disease or other technical problems such as sepsis, ischemia, or tension on the anastomosis.[12-17]

Rectovaginal fistulas are also associated with malignant disease of the cervix, rectum, uterus, or vagina and may be a manifestation of recurrent disease but may also occur after radiation therapy; although radiation delivery techniques have improved, the incidence of rectovaginal fistulas ranges between 0.3% and 6%.[18-20]

Less common causes of rectovaginal fistulas include fecal impaction, long-standing pessary usage, sexual assault, bacterial and viral infections associated with human immunodeficiency viral disease, and ergotamine suppository usage.[21,22]

DIAGNOSIS, CLASSIFICATION, AND CLINICAL EVALUATION

Presentation

The chief presenting complaint of women with a rectovaginal fistula is the passage of stool or air per vagina. On occasion, foul-smelling vaginal discharge with recurrent vaginitis or urinary tract infections may be the presenting complaint. In women with rectovaginal fistulas from an obstetric injury, the incidence of incontinence is close to 50%.[23] The true incidence of incontinence is difficult to determine because passage of air and stool through the vagina may be interpreted as fecal incontinence. Associated symptoms, such as diarrhea, abdominal pain, or mucous discharge, are suggestive of inflammatory bowel disease and should be investigated accordingly. Although many women will seek medical attention immediately, it is not uncommon for some patients to delay evaluation because of social embarrassment, the desire to have more children, or the belief that such symptoms "are to be expected" after childbirth.

Although rectovaginal fistulas occur anywhere along the rectovaginal septum, they most commonly arise from the region of the dentate line and communicate with the posterior vaginal fornix.[24] Fistulas distal to the dentate line are more appropriately termed *anovaginal fistulas* but common usage terms all such fistulas as *rectovaginal fistulas.*

Fistulas are classified in addition as low, mid, or high. In *low fistulas,* the opening is near the posterior vaginal fourchette; in *high fistulas,* the opening is behind or near the cervix; and *mid rectovaginal fistulas* are midway between the two. From a practical standpoint, fistulas may be classified as those palpable on digital examination and within view of an anoscope or those that are not. Simple fistulas arise from obstetric trauma or infection and are relatively small, whereas complex fistulas are caused by inflammatory bowel disease, irradiation, cancer, or failed prior repairs. Complex fistulas may also result from complications of surgery such as after low anterior anastomosis (as a consequence of anastomotic leak) or after hysterectomy (as a result of unrecognized injury to the rectum).

Some authors have suggested a classification scheme based not on the location of the fistula but on the underlying cause since this may provide the best tool for the treating physician as it assesses the integrity of the surrounding tissues and the overall medical condition of the patient.[25]

Examination and Diagnosis

The initial approach to rectovaginal fistula is not only identify the fistula but also to assess the surrounding tissues particularly with respect to any inflammatory change. In addition, the entire rectovaginal septum should be assessed; patients with an obvious sphincter repair require both repair of the sphincter for improvement of continence and also to bring healthy tissue into the repair. Patients with significant scarring, stenosis and tissue defects may require tissue transfer techniques to maximize the change of success with repair.

Low rectovaginal fistulas are easily visualized and palpated on examination. A dimple is felt on digital rectal examination and confirmed on anoscopic or speculum examination. This method results in confirmation of the fistula in most low fistulas, and other diagnostic modalities are rarely needed. A probe can generally be passed quite easily through a short tract into the vagina. Examination with one finger in the rectum and one in the vagina assists in assessing the surrounding tissues and the bulk (usually quite attenuated) of the rectovaginal septum. The size and location of the fistula are noted. An attenuated or absent perineal body and anterior sphincter defect are often noted in patients with previous obstetric injury.

If a fistula is not seen on initial examination but is suspected on clinical grounds, a variety of other maneuvers may be performed to diagnose the fistula. Limited barium enema examination with a lateral view may be performed. It is important to visualize the distal rectum and anal canal because the balloon of the catheter may obscure a fistula. Alternatively, a tampon may be placed in the vagina and a dilute methylene blue enema instilled in the rectum, with care not to contaminate the string of the tampon. The presence of methylene blue on the tampon confirms the fistula is present and open. Another method is to examine the patient in the lithotomy position. Water is placed in the vagina, and air is insufflated into the rectum with a sigmoidoscope. The presence of air bubbles in the vagina indicates a fistula. Imaging studies, such as transrectal ultrasound with use of hydrogen peroxide, vaginography, and magnetic resonance imaging (MRI), may also demonstrate a rectovaginal fistula; however, information from such studies must then be used transformed into in vivo identification of the fistula in the affected patient.

It is essential to assess the anatomy and function of the sphincter muscles, especially in patients who have a rectovaginal fistula resulting from obstetric injury. In one study of primiparous women who had undergone a vaginal delivery alone,[26] 28% had a sphincter defect on ultrasound examination 6 weeks after delivery. One study suggested a 100% incidence of sphincter injuries on endoanal ultrasound in patients who sustained a rectovaginal fistulas after vaginal delivery.[27] Furthermore, in one series of 52 women who had a rectovaginal fistula from obstetric injury,[23] 50% had preoperative incontinence. If available, preoperative studies, including ultrasound and anal manometry with pudendal nerve terminal motor latency studies, are helpful in evaluating patients with associated incontinence. A poorer outcome of repair has been associated with prolonged pudendal nerve terminal motor latency, although this has been questioned recently.[28]

TREATMENT OPTIONS

Although most rectovaginal fistulas require surgical management, there are a few exceptions. A small number of fistulas may close spontaneously after obstetric trauma. Case reports have used of hyperbaric oxygen to heal fistulas in very small series of patients with rectovaginal fistulas from obstetric trauma.[29]

Patients with Crohn's disease and rectovaginal fistulas may be treated with antitumor necrosis factor, or infliximab; such fistulas may either spontaneously or with the use of infliximab become relatively asymptomatic. The natural history of rectovaginal fistulas in Crohn's disease has not been well documented in terms of how many patients ultimately require surgery and how many can be treated medically. In one recent series, 60% of women with rectovaginal fistulas required fecal diversion.[30] The ACCENT II trial treated 25 patients with rectovaginal fistulas with infliximab infusion.[31] Use of infliximab for rectovaginal fistulas in the ACCENT II trial was associated with healing in 60.7% of patients at 10 weeks and 44.8% of patients at 14 weeks. Use of MRI has shown that although fistulas have apparent healing, they may actually simply become less symptomatic with less drainage as tracks persist on radiographic studies. Furthermore, closure of the fistulas was associated with the development of an abscess in 10% of patients presumably since the external opening heals over before the tract has healed.[32] Poritz and colleagues have suggested that use of infliximab does not avoid the need for surgery in more than 70% of patients; however, such patients may be rendered relatively asymptomatic and have reasonable quality of life before requiring surgical intervention.[33] Infliximab has been used as an adjunct to surgery, with some evidence that injection into the tracts may improve healing.[34]

A number of surgical options are available for patients with rectovaginal fistulas (Box 140–1). Local repairs are performed through a rectal, vaginal, or perineal approach and may be augmented with tissue transfer, such as gracilis and bulbocavernosus muscle, if the surrounding tissues are deficient or unsatisfactory. High rectovaginal fistulas or those associated with previous surgery or radiation therapy generally require an abdominal approach. Local repairs and abdominal repairs can be performed with fecal diversion, and fecal diversion may also be used, in selected patients, as the sole treatment for rectovaginal fistula. The choice of repair depends on a variety of factors, including the presence of associated incontinence, the size and location of the fistula, the degree of complexity of the fistula, and the status of the surrounding tissues.

All procedures for rectovaginal fistula repair have a not insignificant failure rate; many reported series measure ultimate success rates and not initial success rates. Preoperative discussion should focus on the anticipated results and at times abnormally high patient expectations need to be adjusted.

Box 140–1 Treatment Options for Rectovaginal Fistulas

Local Repair

- Transanal approach
  - Advancement flap
  - Advancement sleeve flap
- Vaginal approach
  - Advancement flap
- Perineal approach
  - Sphincteroplasty
  - Perineoproctotomy and layered closure
  - Fistulotomy
- Other
  - Injection of fibrin sealant
  - Repair with interposition of polyglycolic acid mesh

Abdominal Procedures

- Low anterior resection
- Coloanal anastomosis
- Onlay patch anastomosis
- Abdominoperineal resection
- Fecal diversion

Tissue Transposition

- Bulbocavernosus
- Gluteus maximus
- Gracilis
- Pudendal thigh
- Sartorius

Other

- Hyperbaric oxygen
- Infliximab (for Crohn's rectovaginal fistulas)

Timing of Surgery

The timing for when to perform a repair for a rectovaginal fistula remains controversial and there is no level I evidence comparing immediate repair with secondary repair particularly with respect to immediate outcome and long-term outcome and continence. For obstetric fistulas, primary repair is generally under the purview of the obstetrician at the time of the delivery.

In general, surgery may be performed for rectovaginal fistulas as long as the surrounding tissues are soft and pliable. The convention, particularly for fistulas of obstetric origin, has been to wait approximately 3 months, to maximize the condition of the surrounding tissues and also since a small percentage of fistulas close spontaneously. Data from series of patients with rectovaginal fistulas who have undergone MRI have challenged this dogma, since obstetric fistulas have short tracts and little associated inflammatory change on MRI compared with perianal fistulas.[35]

For patients whose previous repair has failed, a waiting period of 3 to 6 months has been advocated that permits some healing of the surrounding tissues and often decreases the size of the recurrent fistula.[36] Waiting for 3 to 6 months may also give both surgeon and patient a much needed reprieve from further surgical intervention.

Local Repair

Sliding Flap Repair

The sliding flap repair for the treatment of patients with rectovaginal fistulas was first reported by Noble[37] in 1902. He advocated splitting the rectovaginal septum, dissecting the lower end of the rectum from the vagina, and drawing the anterior wall down through and external to the anus. Since that time, many modifications of the sliding flap technique have been proposed. In 1948, Laird[38] described the use of a flap of mucosa, submucosa, and some fibers of the internal sphincter. Kodner et al.[39] advocated the use of a flap similar to the Laird technique. Other authors[40] have advocated the use of a flap of mucosa, submucosa, and the full thickness of the internal sphincter. Regardless of the thickness of the flap used, the procedure is generally used for patients with simple low fistulas who have not had previous repairs.

Patients undergo a full mechanical and antibiotic bowel preparation the day before surgery. This practice may be re-examined in view of accumulating evidence that mechanical bowel preparation is maybe unnecessary and does not reduce infectious complications after elective bowel resection.[41] The patient is placed in the prone jack-knife position, with the buttocks taped apart and the anal canal and fistula tract exposed (Fig. 140–1). A urinary catheter is placed. The intersphincteric groove is infiltrated with a combination of saline solution and epinephrine.

A trapezoidal flap composed of mucosa, submucosa, and a portion of the internal sphincter is raised. The base of the flap should be at least twice the width of the apex, and mobilization should be continued for at least 4 cm. Before the flap is advanced, the internal sphincter is mobilized and approximated over the fistula. The flap is then advanced down the anal canal and secured with absorbable sutures. If the patient is incontinent or has a sphincter defect, a concomitant sphincteroplasty is performed. Patients are observed overnight if a sliding flap has been performed. A longer hospitalization period is generally required if concomitant sphincteroplasty is performed. Vaginal intercourse is avoided for 6 to 8 weeks.

Other modifications in flap construction have been reported. Ozuner and colleagues[42] have recommended a curvilinear flap incorporating mucosa, submucosa, and internal sphincter to avoid ischemia at the angled corners. Advancement of the entire rectal wall has been advocated by Fazio and colleagues for treatment of rectovaginal fistulas associated with Crohn's disease with extensive scarring of the anal canal and multiple fistula tracts.[43,44] The influence of the technical nuances of flap construction including the thickness of the flap on the outcome of repair has not been determined.

Potential advantages of a sliding flap include the fact that no perineal wound is created and therefore pain is minimized, no sphincter (other than the internal sphincter if this is used for the flap) is cut, other procedures such as a concomitant sphincter repair can be per-

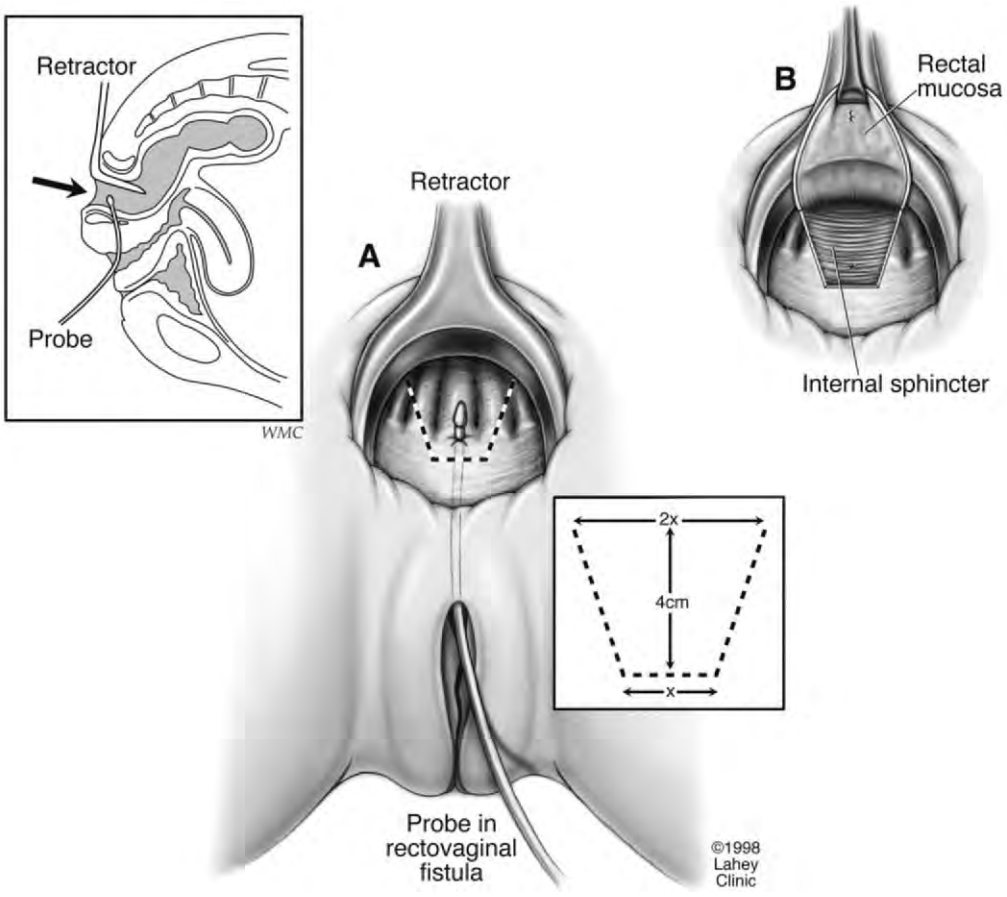

Figure 140–1. Endorectal sliding flap. The patient is placed in the prone jack-knife position, and the fistula is demonstrated *(inset, arrow)*. **A,** The flap should extend for at least 4 cm, and the base should be at least two times the width of the apex. **B,** The flap should include mucosa and submucosa in addition to a portion of the internal sphincter muscle.

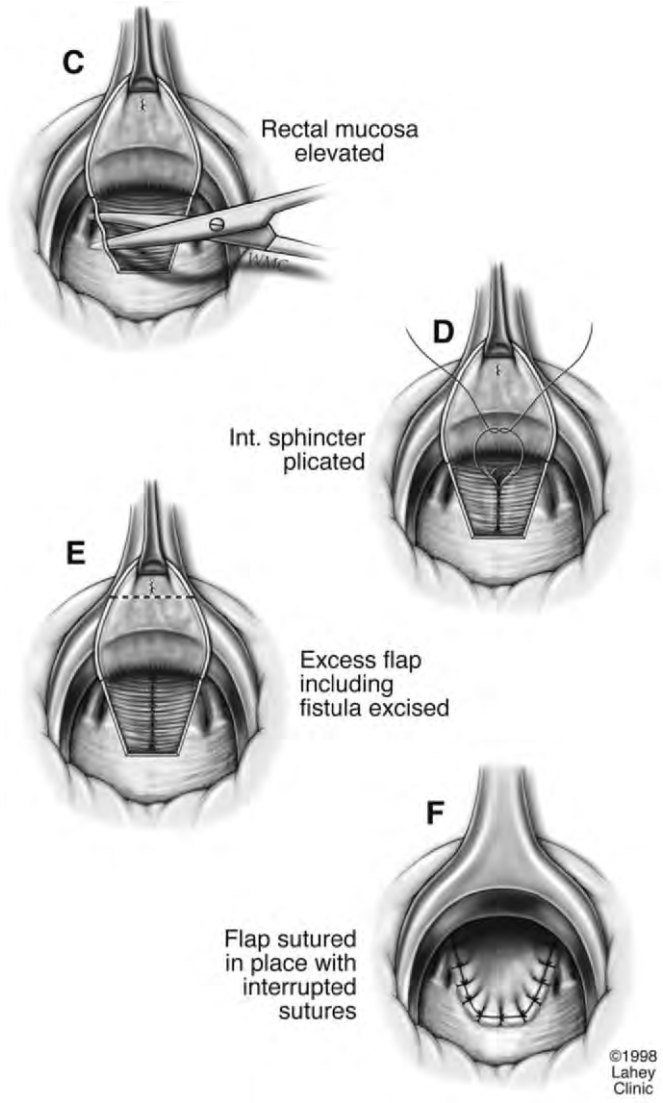

Figure 140–1, cont'd. **C,** The flap is raised, and dissection is performed laterally to permit a tension-free closure. **D,** The internal sphincter muscle is plicated over the area of the fistula. **E,** Excess flap, including the site of the internal opening of the fistula, is trimmed. **F,** The flap is secured with absorbable sutures. formed, a diverting stoma is not necessary, and deformities such as a keyhole deformity, which may occur from fistulotomy, are avoided.

The success rate varies considerably, from 29% to 100% (Table 140–1).[23,39,40,45-56] Common causes of flap failure include ischemia of the flap and hematoma and/or the development of infection under the flap. Considerable variation has even been reported in the same group of surgeons, with a success rate of 41% to 78%.[23,40] A variety of factors most likely account for the differing success rates after sliding flap repair, including the number of previous repairs, whether the initial or ultimate success rate was reported, the presence of a concomitant sphincter defect, and the cause of the rectovaginal fistula. If a patient has had one[48] or two[40] previous rectovaginal fistula repairs, the success rate with a sliding

flap repair decreases significantly; therefore, a sliding flap repair should generally not be considered in a patient whose previous repairs have failed. Assessment of sphincter function and repair of sphincter defects appear to improve the outcome of sliding flap repair. The success rate for patients undergoing flap repair and sphincteroplasty with or without levatoroplasty was significantly higher than the success rate for patients who underwent flap repair only (80 vs. 41%; $P = 0.02$).[23] As a result, some surgeons have advocated that anal ultrasonography and manometry be performed to detect occult sphincter defects in patients undergoing repair of rectovaginal fistulas; sphincter defects, however, in the majority of cases, can be determined by a thorough history and physical examination and then confirmed on manometry and ultrasound.[27] The underlying cause of the fistula may also determine the success of a flap repair. Patients with obstetric injuries as the cause of the rectovaginal fistula have a better outcome than patients with inflammatory bowel disease.

A transvaginal approach for sliding flap may also be used to repair rectovaginal fistulas. Although a transvaginal approach addresses the fistula from the lower pressure vaginal side, not the higher pressure rectal side, this technique allows for good exposure and, as with transrectal advancement flap, the ability to perform a concomitant sphincteroplasty if needed. An incision is made in the posterior vaginal wall by the introitus, and the flap is raised in a similar manner on the vaginal side

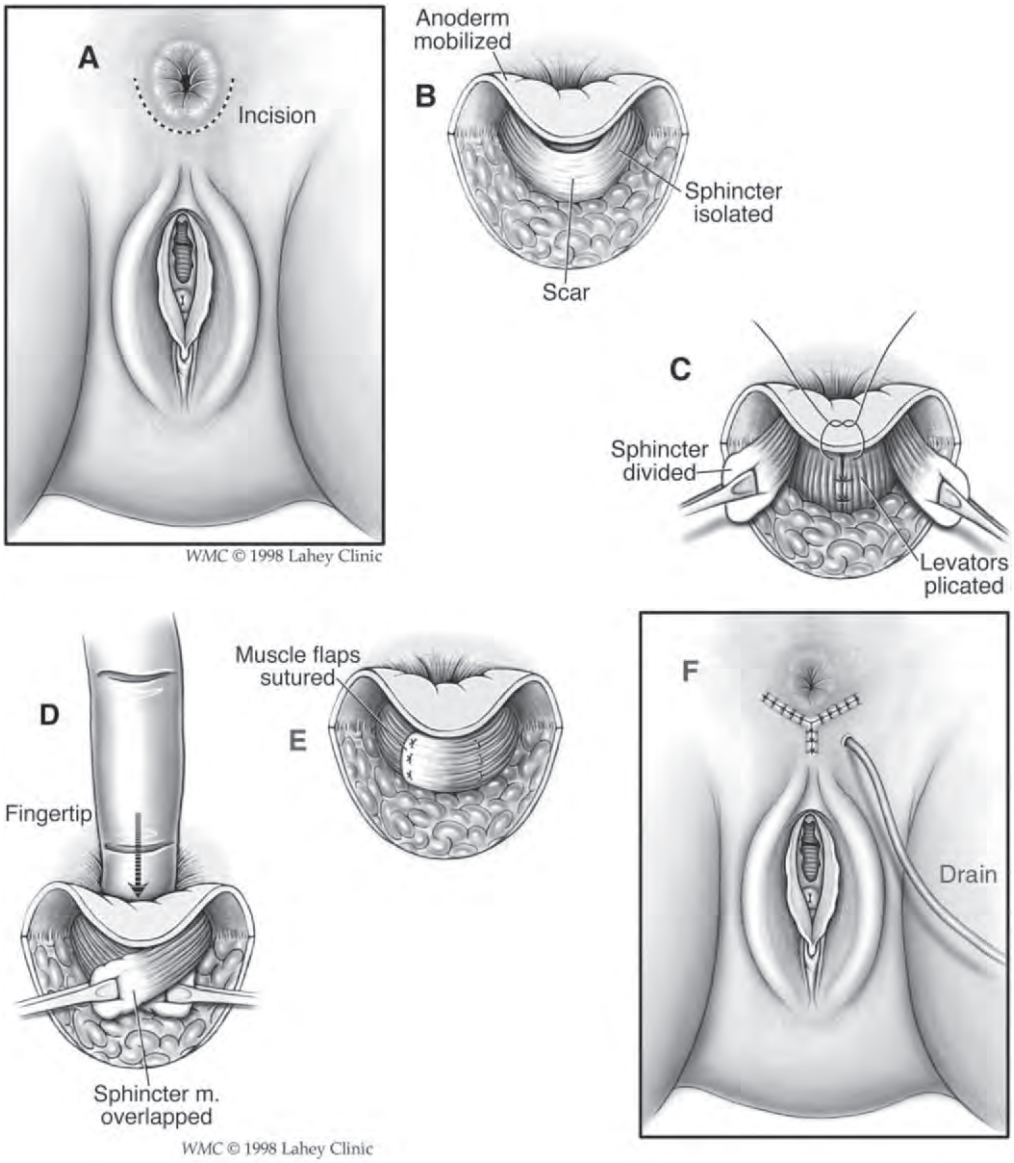

Figure 140–2. Overlapping sphincteroplasty. **A,** The patient is placed in the prone jack-knife position, and a curvilinear incision is made approximately 180 degrees around the anus. **B,** Dissection is carried out medial to the ischiorectal fat, and the external sphincter is identified. **C,** Dissection is carried up to the level of the levatores, which are plicated. **D,** If sufficient muscle is present, an overlapping sphincter repair is performed. If not, simple apposition of the sphincter muscle is performed. **E,** The completed repair. **F,** The perineal body is reconstructed, and the wound is secured in a Y configuration. A drain may be placed. (**A-F,** ©1998, Lahey Clinic, Burlington, MA.)

and advanced. As with a rectal flap, the flap should be wide enough to ensure good blood supply and mobility. This approach may have an advantage in selected patients, especially patients with Crohn's disease, because nondiseased, pliable vaginal tissue is used to form the flap, and there is little manipulation or dissection in the diseased rectum. Using this technique, Bauer et al.[58] reported cure of the rectovaginal fistulas in 12 of 13 women with Crohn's disease, with mean follow-up time of 50 months. Plication of the levator muscles was believed to be crucial to the repair. A transvaginal flap may also be useful in patients with pouch-vaginal fistulas after ileoanal pouch construction, obviating the need for a potentially difficult transanal approach.

There is a limited experience with use of anocutaneous flaps, raising anoderm and perianal skin and advancing this into the anal canal.[59] This technique may be used for very distal fistulas but has limited application because of the lack of adequate perineal skin between the rectum and vagina in most patients with rectovaginal fistulas.

Sphincteroplasty

An overlapping sphincteroplasty is one of the most common operations performed for rectovaginal fistula and may be performed as the sole procedure or combined with sliding flap repair. It corrects any underlying sphincter defect in addition to providing good muscle bulk to interpose in the rectovaginal septum (Fig. 140–2). It is indicated for simple rectovaginal fistulas with an associated sphincter defect. A curvilinear incision is made in the perineum around the anus, and the edges of the external and internal sphincter muscles are identified and mobilized. Scar tissue is usually left in place on the muscle and not débrided. Care is taken to preserve the pudendal nerves that enter posterolaterally; however, a significant sphincter injury usually causes retraction of

the nerves to a more posterior location and, therefore, injury is usually easily avoided. In the course of the dissection, the fistula is identified, and the dissection is carried cephalad, separating the rectum and vagina for several centimeters until soft pliable tissue is reached. The levator muscles are identified and plicated, which adds to the muscle bulk and appears to provide better results from a continence standpoint.[23,60] The perineal skin may be either closed loosely or left open. The vaginal mucosa is left open for drainage. Combining sphincteroplasty with an anoplasty for further separation of the distance between the rectum and vagina has also been advocated.[61]

Sphincteroplasty for rectovaginal fistula is associated with success rates of 65% to 100% (Table 140–2).[23,36,40,45,46,48]

Advancement Sleeve Flap

It is estimated that a rectovaginal fistula will develop in up to 10% of women with Crohn's disease. These fistulas can be difficult to treat. For patients with associated severe anorectal and colonic disease, proctocolectomy with ileostomy is the best option. In selected patients with Crohn's disease and a normal rectum, a local procedure can be considered. Although a sliding flap may be performed in selected patients, for patients with anal canal ulceration, a normal rectum, and rectovaginal fistula, an advancement sleeve flap may be performed (Fig. 140–3). Hull and Fazio[43] initially reported the use of the advancement sleeve flap in 5 women with anorectal ulceration, Crohn's disease, and rectovaginal fistulas. The fistula eventually healed in four patients with this technique, and one patient subsequently required proctocolectomy and ileostomy. In a subsequent report,[44] which included patients with Crohn's disease and a rectovaginal fistula in addition to other complex fistulas, a successful outcome was achieved in 8 of 13 patients. The advancement sleeve flap is a good option for patients in whom the only other option is fecal diversion.

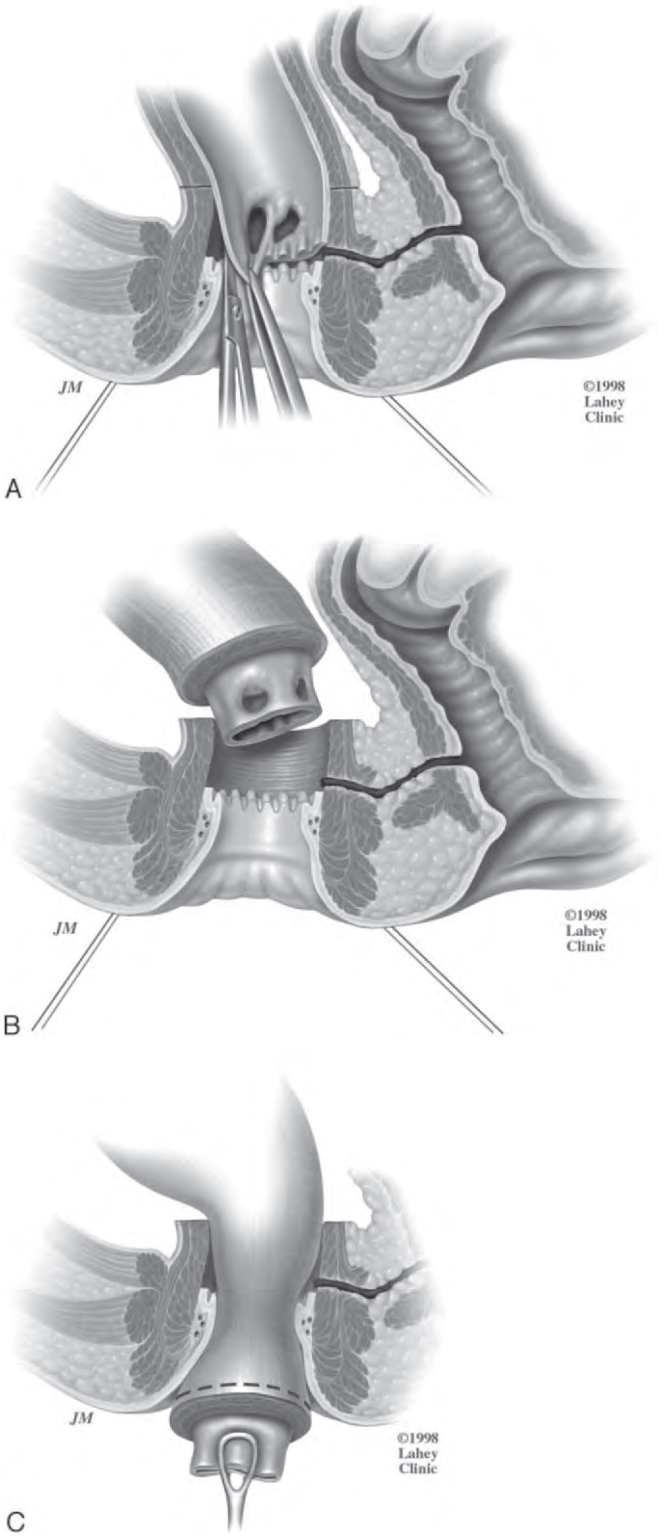

Figure 140–3. Advancement sleeve flap. **A,** Commencing at the level of the dentate line, a circumferential dissection of mucosa and submucosa is performed, thus excising the ulcerated areas of the anal canal. **B,** The dissection is continued cephalad and into the supralevator space, completing rectal mobilization. **C,** The fistula can then be cored out and closed, and the distal cuff *(dotted line)* of the rectum is trimmed and secured to the anoderm. (**A-C,** ©1998, Lahey Clinic, Burlington, MA.)

Perineoproctectomy with Layered Closure

In this procedure, the fistula is converted to a fourth-degree perineal laceration. The tract is then excised, and the vagina, sphincter muscles, and rectal mucosa are identified, mobilized, and repaired in layers. Excellent results have been reported in several series.[7,49,62] Mazier and colleagues[49] reported a success rate of 100% in 38 patients who underwent perineoproctectomy.

Fistulotomy

Simple fistulotomy for the treatment of patients with rectovaginal fistula is mentioned only to be condemned because it is associated with significant incontinence. In a small series[28] of eight patients who underwent this procedure, all patients had postoperative incontinence and required a second procedure.

Autologous Fibrin Glue

Autologous fibrin tissue adhesive initially appeared to have some success in the treatment of patients with rectovaginal fistulas and is used for selective anal fistulas, particularly those with a long tract. The advantage of fibrin glue or treatment of fistulas is that it can be done as a minimally invasive technique without significant complications. However, the technique has, with the exception of one series, has a high failure rate because the tract is characteristically too short to hold the glue for any length of time.[64-66] Modifications in the technique including closure of the internal opening and use of use of intra-adhesive antibiotics have not improved the outcome.[67]

Fibrin glue has also been used as an adjunct with other procedures such as endorectal advancement flap; in one series[54] fibrin glue was combined with endorectal advancement flap in 12 patients; the failure rate was 50% which was not significantly different than patients who had endorectal advancement flap alone.

Miscellaneous

Some authors have reported use of a folded polyglycolic (Vicryl) mesh interposed between the vaginal and rectal suture line.[68] Four patients had successful repair by this technique. The concern with such a technique is possible infection of the mesh.

Tissue Transfer Procedures

Tissue interposition for the treatment of patients with rectovaginal fistula is intended to interpose normal well-vascularized healthy tissue between suture lines. Although several types of tissues have been used, such as the gracilis, sartorius, and gluteus maximus muscles, the most commonly used is the bulbocavernosus muscle. This technique was first described by Martius[69] in 1928 and was originally used for the repair of vesicovaginal fistulas; however, it is also useful for radiation-induced rectovaginal fistulas, large obstetric fistulas, those for which previous repairs have failed, and pouch-vaginal fistulas after restorative proctocolectomy. Details of the procedure are outlined in Figure 140–4. Since the description by Martius,[69] Elkins et al.[70] have shown that the bulbocavernosus muscle itself does not need to be included in the graft since the labial adipose tissue has excellent blood supply, thus decreasing the morbidity of using the bulbocavernosus muscle and reducing the operative time. Using this technique for complex fistulas, Pinedo and Phillips reported healing in 6 of 8 patients.[71] Modifications in surgical technique have been outlined by Hoskins et al.,[72] who used a full-thickness island graft from the labia majora, and Symmonds and Hill,[73] who used a full-thickness graft from labia minor and majora. Boronow[74] reported a success rate of 84% in 25 women with rectovaginal fistulas. Dyspareunia, infrequently reported as an outcome variable, but noted in 25% of women in one series of bulbocavernosus flaps, is a potential concern with the procedure.[56]

Abdominal Procedures

Complex fistulas, particularly those secondary to radiation or previous pelvic surgery, are generally not suitable for a local repair. Fistulas may occur after operations that involve anterior rectal mobilization and mobilization of the rectovaginal septum, such as low anterior resection, coloanal anastomosis, and ileal pouch–anal anastomosis. After colorectal procedures, such fistulas arise from dehiscence of the anastomosis, with subsequent tracking into the vagina. Previous hysterectomy appears to predispose the patient to this complication, presumably because of the difficulty with adhesions between the anterior rectal wall and vaginal cuff.[75] Although rectovaginal fistula is reported after both hand-sewn and double-stapled anastomosis, the double-staple technique seems to be implicated in most cases. The most likely reason is that the staple line includes an edge of vagina. Gynecologic surgery, such as hysterectomy, rectocele repair, and vaginal vault prolapse suspension, may also be complicated by rectovaginal fistula. In one series,[76] rectovaginal fistulas occurred in 1.2% of women undergoing repair of vaginal vault prolapse. These fistulas tend to be higher than obstetric fistulas and have surrounding tissues that are abnormal and poorly vascularized. Abdominal procedures permit excision of abnormal tissue, with interposition of well-vascularized normal tissue to correct the fistula. Preservation of the sphincter is possible with such procedures as coloanal anastomosis and onlay patch anastomosis.

Coloanal Anastomosis

Patients with radiation proctitis and rectovaginal fistula may be treated by resection and coloanal sleeve anastomosis as first reported by Parks and colleagues.[77] The technique involves proximal loop diversion, rectal resection below the level of the fistula, and mobilization of the left colon. Although Parks and colleagues described a distal mucosectomy followed by a coloanal anastomosis, a double-staple technique (as is used for the ileoanal

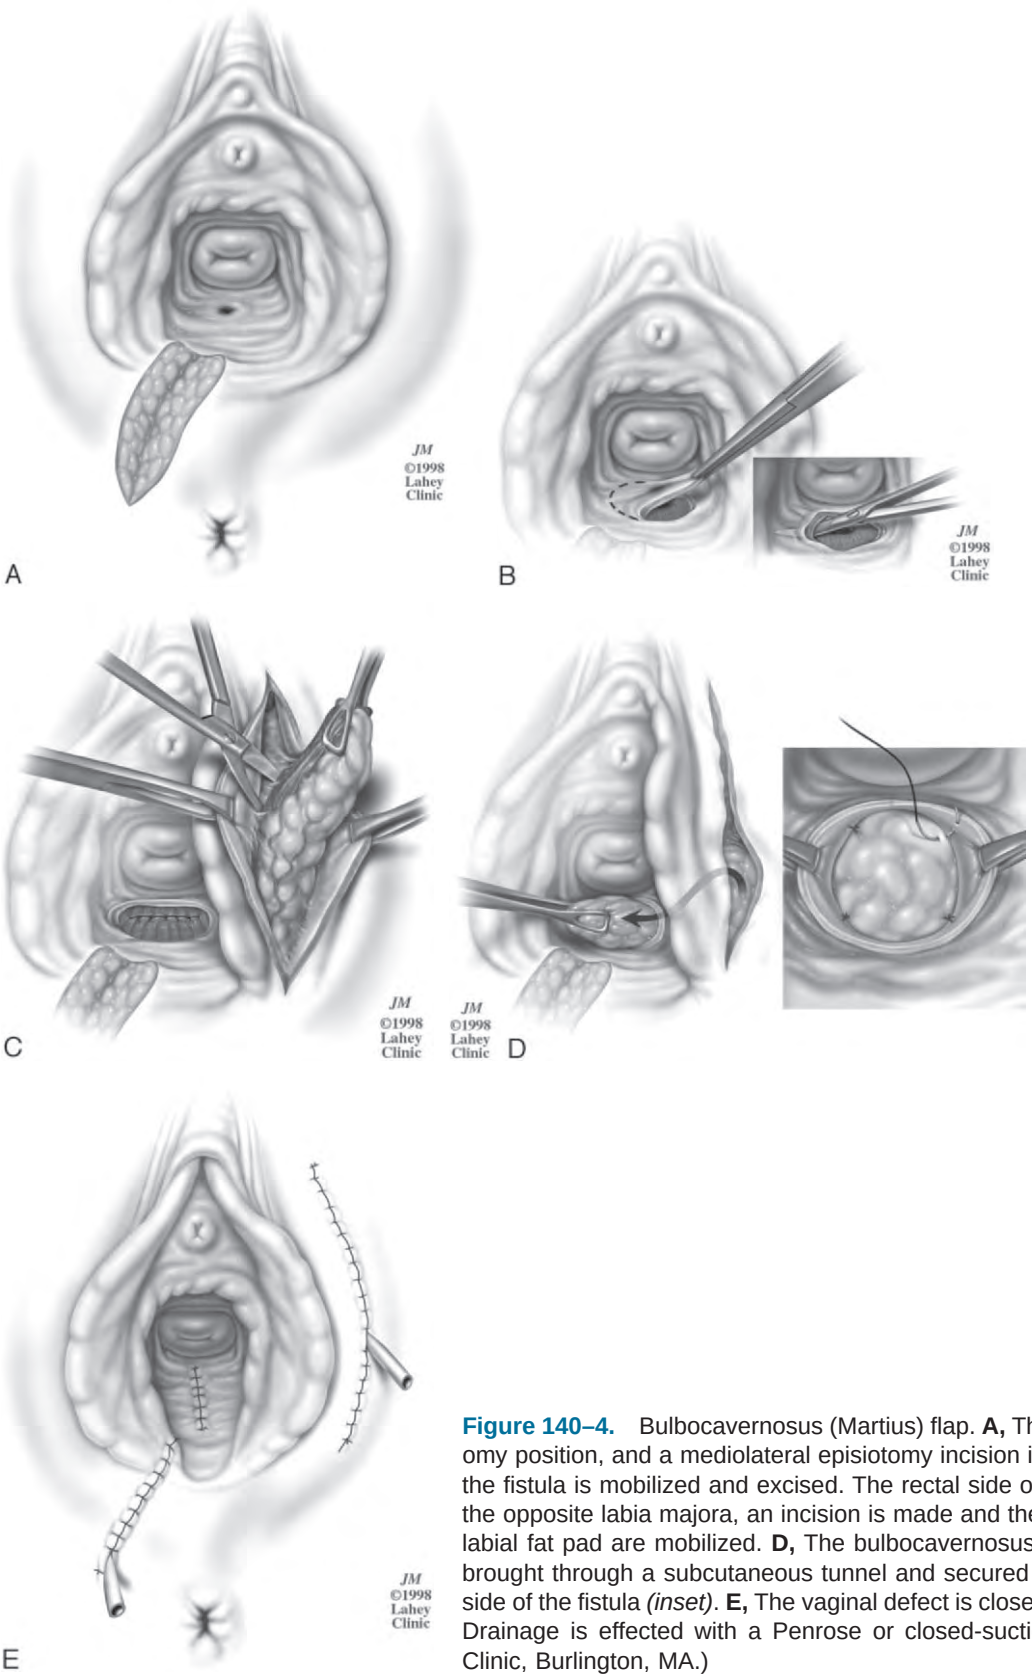

Figure 140–4. Bulbocavernosus (Martius) flap. **A,** The patient is placed in the lithotomy position, and a mediolateral episiotomy incision is made. **B,** The vaginal side of the fistula is mobilized and excised. The rectal side of the fistula is closed. **C,** Along the opposite labia majora, an incision is made and the bulbocavernosus muscle and labial fat pad are mobilized. **D,** The bulbocavernosus muscle and labial fat pad are brought through a subcutaneous tunnel and secured to the previously closed rectal side of the fistula *(inset)*. **E,** The vaginal defect is closed, and the incisions are closed. Drainage is effected with a Penrose or closed-suction drain. (**A-E,** ©1998, Lahey Clinic, Burlington, MA.)

pouch procedure) may also be used, and a colonic J-pouch may be added to improve neorectal function. If available, omentum is interposed between the anastomosis and the vagina. Using the coloanal anastomosis, Cooke and Wellsted[78] reported a 93% success rate in 55 patients. A modification of the coloanal technique has been reported by Simonsen and colleagues,[79] who used the anterior rectal wall to construct a neovagina. The authors reported no operative deaths and no recurrent fistulas in 19 patients.

Onlay Patch Anastomosis

Bricker and Johnston[80] described an alternative approach for radiation-induced rectovaginal fistulas and particularly fistulas that involve large portions of the vagina. Although several modifications of the procedure have been described, the procedure involves mobilization of the rectosigmoid and exposure of the fistula. After transection of the rectosigmoid, an end stoma is formed. Subsequently, the distal rectosigmoid is rotated down, and the open end is anastomosed to the débrided edges of the fistula opening in the rectum. After healing has been confirmed with radiographic studies, the proximal sigmoid is sutured in end-to-side fashion to the loop in the rectosigmoid. The advantage of this procedure is that posterior rectal mobilization and entry into the presacral space are not necessary; however, it is still a technically difficult procedure and a disadvantage is that a portion of the diseased rectum is left in place for the anastomosis. Using this technique, Bricker and Johnston[80] reported excellent or satisfactory results in 19 of 20 patients.

Role of Diversion

For a patient with a rectovaginal fistula who is a poor medical risk and cannot tolerate major surgery, simple fecal diversion with either a loop ileostomy or colostomy may provide good symptomatic relief and return to a reasonable quality of life.

Fecal diversion also has a role in patients who have undergone repair of complex fistulas by coloanal anastomosis or Bricker onlay patch anastomosis. Patients who have Crohn's disease and patients whose multiple previous local repairs have failed may also benefit from fecal diversion as an adjunct to primary repair or as a primary procedure.

SUMMARY

The optimal treatment for patients with rectovaginal fistulas depends on a number of factors, including the site of the fistula, the cause of the fistula, surgical expertise, and the presence of an associated sphincter defect and incontinence. With thorough preoperative evaluation, consideration of optimal treatment options, and meticulous surgical technique, a successful outcome is achieved in the majority of patients.

RECTOURETHRAL FISTULAS

Rectourethral fistulas are rare and may occur from either congenital or acquired causes. Congenital fistulas are often associated with other anorectal abnormalities, whereas acquired fistulas may result from trauma, previous surgery, Crohn's disease, infection, and malignancy, especially prostate cancer. Fistulas arising from prior surgery have previously been noted after such procedures as surgery for benign prostatic hypertrophy, perineal prostatectomy, and perineal biopsy of the prostate; however, the last 2 decades have seen a shift in cause due to increasing numbers of patients undergoing high-dose or salvage brachytherapy, cryotherapy, and radical prostatectomy by either an open or laparoscopic approach for prostate cancer. Thus, there has been a shift from relatively simple small fistulas to larger, more complex fistulas often associated with necrosis, substantial tissue defects, urethral strictures, and radiation effects. This shift in cause has mandated a shift in the surgical treatment of such fistulas. The diagnosis and approach to such fistulas are discussed, and further details are outlined in the Suggested Readings list.

Rectal injury is a well-recognized complication of prostate surgery occurring in 1% to 11%,[81,82] with the subsequent development of a rectourethral fistulas reported in 0.4% to 8.8% of patients undergoing brachytherapy.[83,84] A higher incidence of fistulas has been noted in patients undergoing salvage therapy and patients who have rectal biopsy after brachytherapy.

The clinical presentation of such fistulas is generally straightforward, with most patients complaining of passage of urine per rectum and a number complaining of fecaluria and pneumaturia. Patients who develop fistulas after brachytherapy or cryotherapy may initially complain of severe pain. Retrograde urethrography, voiding cystourethrography, and urethroscopic cannulation and injection of the fistula may help define the fistulas. Digital examination, anoscopy, and either flexible sigmoidoscopy or colonoscopy help identify the rectal opening, assess the anal sphincter and assess the rectum for evidence of intrinsic rectal disease such as inflammatory bowel disease and radiation proctitis.

There are a number of surgical procedures for repair of rectourethral fistulas, and determining the optimal repair must take into account the complexity of the fistulas, the status of the surrounding tissues, the size of the defect, and prior radiation treatments. Although small simple fistulas in patients who have not had previous radiation may be repaired without fecal diversion, this procedure is performed in most complex fistulas and particular those associated with previous failed repairs, complex causes (including radiation), cryotherapy, or large fistulas and those that cannot be repaired without use of patch graft and/or interposition muscle flap. Our preference is the performance of a loop ileostomy, ideally performed by a laparoscopic approach.

One of the most widely used techniques for repair in the last decade has been the York-Mason posterior transanosphincteric approach. The approach, performed in the prone jack-knife position with posterior midline division of the sphincter muscles, allows for good

exposure through unscarred planes and allows for adequate closure. A one-stage procedure without fecal diversion can generally be performed. Excellent results were reported by Renschler and Middleton, who repaired 22 of 24 fistulas with such an approach.[85] Low, simple fistulas may also be repaired by an endorectal sliding flap. The main advantage of such a repair is minimal morbidity and a fairly quick recovery, whereas the main disadvantage of this procedure is that the high-pressure urethral side is not addressed and a period of prolonged catheter drainage is needed. Using such an approach, an initial closure was achieved in 8 (67%) of 12 patients with an ultimate success rate of 83%.[86]

The York-Mason approach and sliding flap do not allow for repair of large complex fistulas, which may require an interposition flap, concurrent urethral reconstruction, or buccal patch graft for large defects or associated urethral strictures. Large fistulas and large defects require interposition of additional tissue, and the gracilis muscle is ideally suited for this technique. The gracilis has been used extensively in colorectal surgery for construction of a neosphincter around the anus, for treatment of unhealed wounds after proctectomy for cancer and Crohn's disease, for treatment of rectourethral fistulas. Gracilis muscle transposition has been reported with good success for rectourethral fistula.[87,88]

These large, complex fistulas are increasingly the type of fistulas seen, and those fistulas associated with urethral defects or strictures require repair of the urethral defect also. These fistulas pose difficult surgical challenges, and few surgeons have significant expertise with repair. At the Lahey Clinic, a variety of surgical techniques, perfected by Dr. Leonard Zinman, have been used. The procedures have previously been reported.[89] The approaches used have included an anterior perineal approach with division and subsequent reapproximation of the sphincter, an anterior sphincter–preserving perineal approach through a classic inverted U-shaped incision, and an anterior perineal approach with preservation of the sphincter with use of a gracilis buttress and of a buccal mucosa graft if required for a urethral defect. From 1980 to 2003, a total of 68 rectourethral fistulas have been treated with these techniques, including anterior perineal repair with interposition of gracilis ($n = 28$), anterior transanosphincteric repair with interposition of gracilis ($n = 9$), anterior perineal repair with buccal graft patch and muscle flap ($n = 27$), and rectal excision and urethral repair with either gluteus maximus or rectus abdominis ($n = 4$).

Patients with rectourethral fistulas are a heterogeneous group, and consideration for treatment needs to address both rectal and urinary function. Large tissue defects associated with radiation require interposition of muscle, ideally gracilis, for treatment and significant urethral defects or stricture require repair and are addressed with buccal grafts.

Complete Rectal Prolapse

Amir L. Bastawrous · Herand Abcarian

Complete rectal prolapse or procidentia is a circumferential, full-thickness descent of the rectum (and maybe the sigmoid colon). Classically, eversion of the rectum is externally visible. The spectrum of associated disorders linked with the putative pathophysiology of rectal prolapse includes lesser degrees of "hidden" prolapse and solitary rectal ulcer syndrome. True rectal prolapse should be distinguished from rectal mucosal prolapse and hemorrhoidal disease. On examination the former has thick, concentric, circumferential folds while the latter has radial folds often shaped like a three-pointed star (Figs. 141–1 and 141–2).

HISTORICAL PERSPECTIVE

Rectal prolapse has been described for centuries. In the Ebers Papyrus the ancient Egyptians described honey-containing suppositories, laxatives, and enemas in the treatment of rectal prolapse. The ancient Greeks used the method of hanging a patient by the heels and shaking to reduce a prolapse. Rectal prolapse was recognized as an intussusception of the colon in the 18th century. Moschocowitz identified rectal prolapse as a sliding perineal hernia on identifying a deep cul-de-sac in affected patients.

PATHOPHYSIOLOGY

The anatomic defect of complete rectal prolapse is relatively easy to describe. The pathophysiology, however, has been more difficult to define. The development of rectal prolapse occurs over a period of years making it difficult to identify a specific cause. It is unclear whether the intussusception of the rectum is the main responsible factor or the result of some other anatomic or physiologic defect. Several findings have been associated with rectal prolapse. These include weak levator ani and anal sphincter muscles, a redundant rectosigmoid colon, a deep cul-de-sac, and loss of fixation of the rectum to the sacrum.

Regardless, the prevailing theory is one of distal intussusception of the rectum. Numerous diseases have been linked to rectal prolapse including connective tissue disorders, pelvic outlet obstruction, pelvic floor laxity, spina bifida, multiple sclerosis, cystic fibrosis, anorexia and bulimia nervosa, and excess straining or Valsalva maneuver. A history of mental illness has been linked to rectal prolapse with a four-fold higher rate in that population.

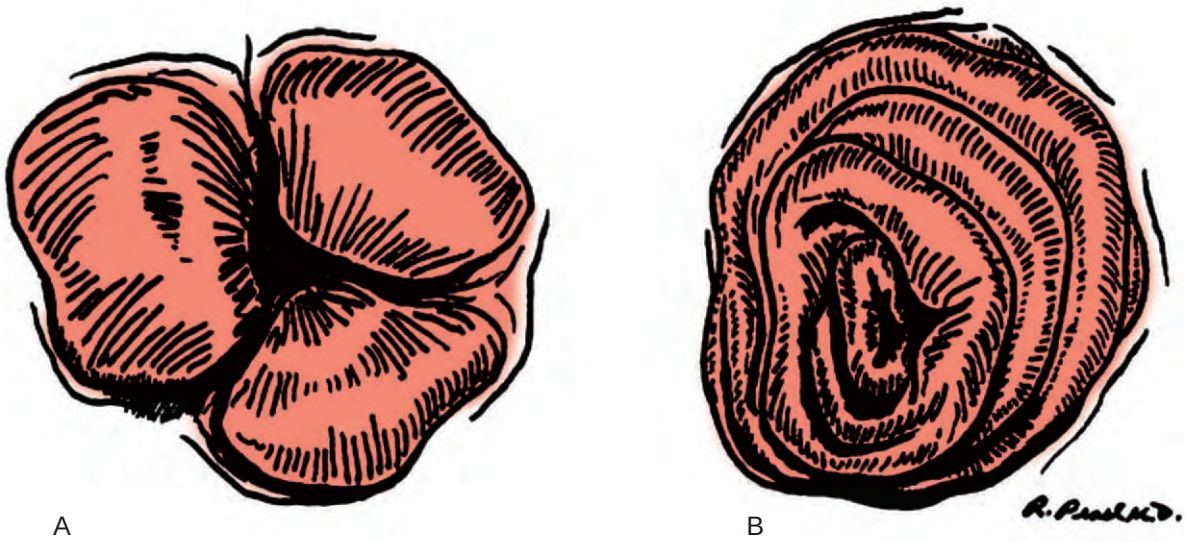
Straining at stool is often associated with rectal prolapse. A history of constipation is seen in up to 67% of patients and diarrhea in 15%. Paradoxically, incontinence is reported to be present in up to 70% of patients with rectal prolapse. Women are six times more likely than men to develop rectal prolapse. There is also a different age distribution in women and men, with men presenting in their twenties and thirties while women present more commonly after the sixth decade. Most patients who require surgery for rectal prolapse are elderly.

PHYSICAL EXAMINATION

The typical patient with complete rectal prolapse will present with a history of bleeding and a "bulge" in the anal region after bowel movements. The rectum is often obvious on inspection. Occasionally, the prolapse may become evident only when asking the patient to squat or sit on a toilet and strain. An evaluation of resting anal tone and squeeze pressures is important in the workup. Identification of other concomitant pelvic floor defects including rectocele, cystocele, vaginal prolapse, and enterocele is necessary and may influence the operative approach.

DIAGNOSIS AND TESTING

Patients with a history of incontinence associated with rectal prolapse should be evaluated with anal manometry, ultrasonography, and pudendal nerve terminal motor latency to document baseline anorectal anatomy



A B

Figure 141–1. Prolapsing hemorrhoids **(A)** and complete rectal prolapse **(B).**

Figure 141–2. Prolapsing hemorrhoids **(A)** and rectal prolapse **(B).**

and function prior to repair.[1] Plain radiographs of the sacrum are useful to identify patients with occult spina bifida. Cinedefecography can be useful to diagnose "hidden" rectal prolapse or internal intussusception for patients in whom the rectum is not visible externally. Colonoscopy is essential to rule out synchronous or causative neoplasm prior to a planned surgical repair.

Colonic transit time should be evaluated with marker studies for patients with a history of constipation and rectal prolapse. This subgroup of patients may benefit from an abdominal approach with resection as rectopexy alone typically worsens the constipation.[2]

If a perineal approach is planned and associated urinary or uterine prolapse is seen, intravenous pylogram will help identify course of the ureters, which may travel quite low in the pelvis. Combined repair of enterocele, cystocele, and rectal prolapse has been described.

TREATMENT

Acute Management of Rectal Prolapse

The acute treatment of complete rectal prolapse involves early reduction. Often, especially in the mentally ill in whom persistent straining or valsalva has contributed to the prolapse, the rectum will immediately re-prolapse. Gentle constant pressure is often successful in reducing the prolapse and if the rectum continues to prolapse after reduction, taping the buttocks together may help temporarily.

If the prolapse has been neglected or unrecognized for a prolonged period, it may not easily reduce. Unless the rectum is frankly non-viable or necrotic, a few techniques may help return the bowel to its anatomic position. Sedation, placing the patient in the Trendelenburg

position, and placement of salt or sugar topically can decrease the bowel edema and assist reduction.[3] Injection of hyaluronidase has also been described in the acute situation. These maneuvers can often be done at the bedside, but may need to be done in an operating room setting in certain cases.

If the incarcerated rectum cannot be reduced, or if there is evidence of ischemic compromise, then operative resection, typically a perineal proctosigmoidectomy is indicated.

Surgical Treatment of Rectal Prolapse

A surgical intervention is nearly always necessary to correct rectal prolapse. The "perfect" treatment should offer safe, complete and durable resolution of the anatomic and physiologic problems.[4] The current treatment modalities all have a recurrence rate, albeit low and decreasing. The search for the best surgical treatment of rectal prolapse spawned a multitude of approaches beginning in the 19th century. Over 100 different procedures or modifications have been described in the medical literature. In fact newer innovations continue to appear in the literature.[5-9] The spectrum of current operative techniques includes both abdominal and perineal procedures. Laparoscopic approaches have gained popularity as surgeons have become comfortable operating on the colon laparoscopically.[10-14] Generally, patients who can tolerate laparotomy should be offered an abdominal approach to correct their prolapse, while elderly or debilitated patients are better managed with a perineal procedure. The exception may be young men who may prefer to accept the higher risk of recurrence of their prolapse with a perineal procedure over the increased risk of impotence or infertility with an abdominal procedure.

As is generally accepted at this time, all patients receive a mechanical bowel preparation the day prior to surgery, perioperative antibiotics, and prophylaxis against deep venous thrombosis.

Abdominal Approaches

General anesthesia is usually employed, but regional anesthesia has been successfully used. Patients are placed in low dorsal lithotomy position for all laparoscopic or open laparotomy procedures. For laparoscopic approaches, the patients' arms are tucked at the side. Furthermore, it is important to place the patient on a torso-sized beanbag with which to cradle the body, as it will be tilted into a steep Trendelenburg position. This will help prevent the patient from sliding on the operative table.

Rectopexy The various modifications of the technique described by Ripstein[15-20] all have in common a posterior mobilization of the rectum to the level of the coccyx. Ripstein's approach was to wrap a 5-cm wide non-absorbable polytetrafluoroethylene (Teflon) mesh around the anterior rectum, then suture it to the presacral fascia on the sides of the rectum 5 cm below the sacral promontory. The Well's modification (Fig. 141–3) places the Ivalon sponge posteriorly, leaving a 2 cm gap anteriorly to allow for rectal compliance. Successful rectopexy has been

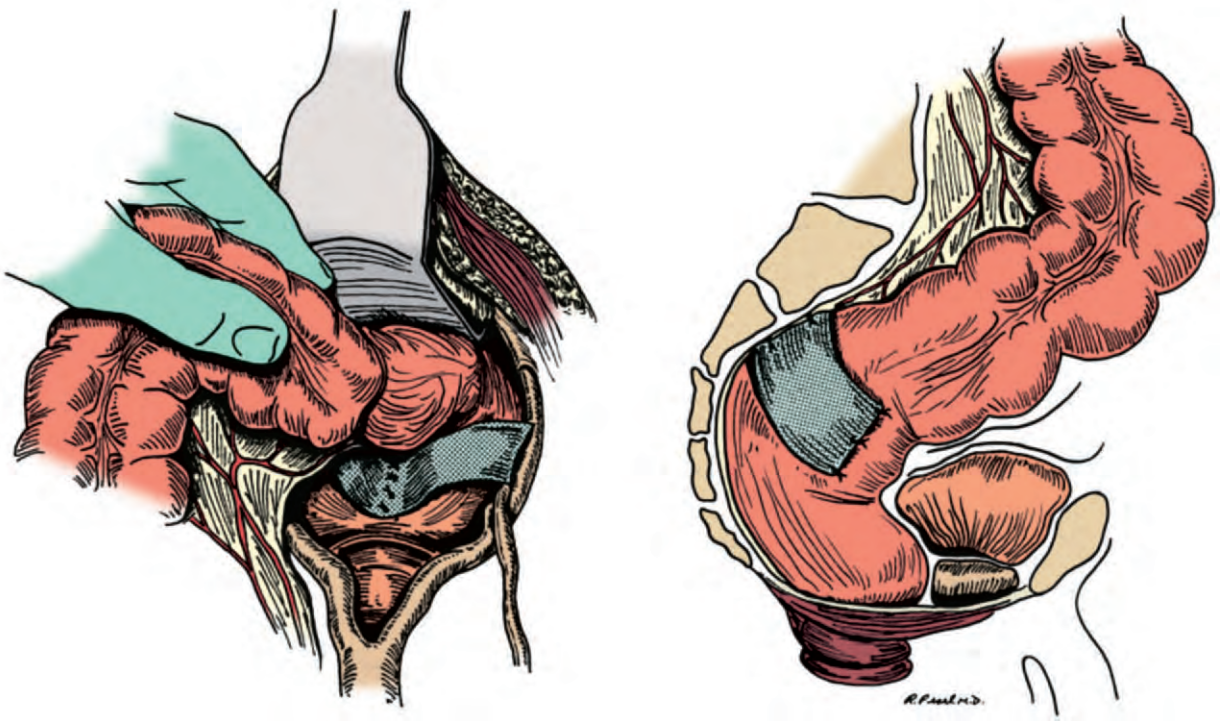

Figure 141–3. Rectopexy (Ripstein procedure).

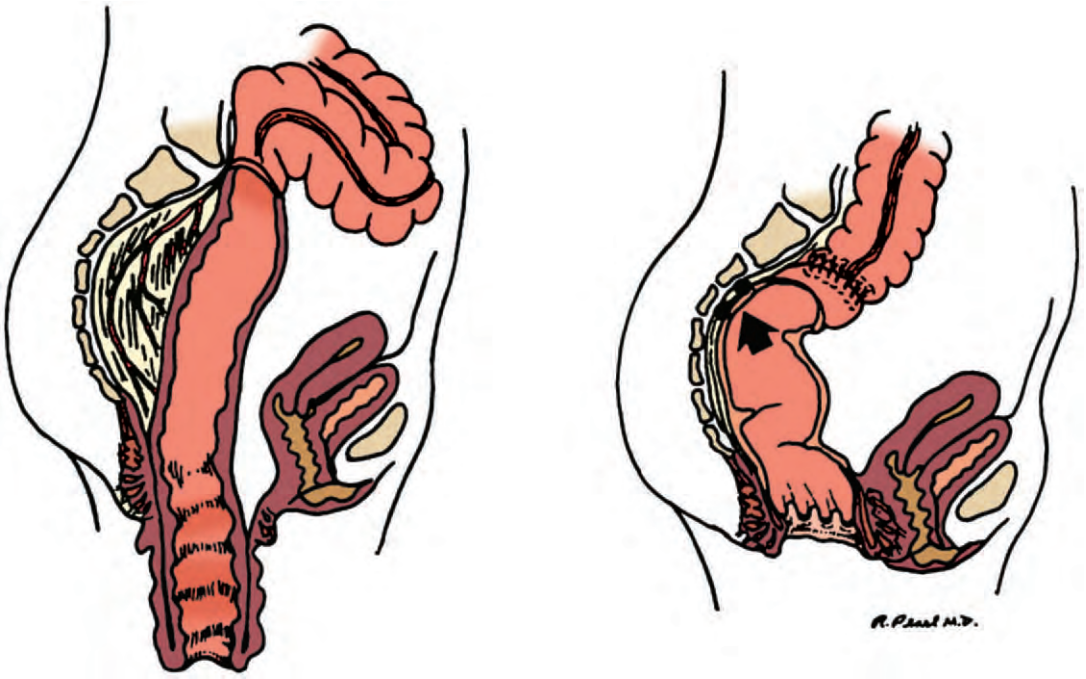

Figure 141–4. Sigmoid resection plus rectopexy (Fuykwan procedure).

described with simply using non-absorbable suture or metal staples to fix the rectum to the sacrum and thus re-create the normal rectal angulation. Recently it was suggested that mobilization of the rectum itself is sufficient to produce enough fibrotic scar to fix the bowel to the sacral curvature.[19] Patients with constipation preoperatively will have worsening of their symptoms with rectopexy alone, because it results in acute angulation of the rectosigmoid position by allowing the sigmoid colon to fall anteriorly into the pelvis. Speakman et al. have reported that division of lateral stalls will allow for better rectal mobilization and fixation and prevents recurrence but at a cost of worsening constipation.[20]

Resection Anterior resection of the colon and rectum is familiar to most general, laparoscopic, and colorectal surgeons. This may partially explain the popularity of this approach. Through a low midline or transverse incision or laparoscopically, the rectum is mobilized to the level of the coccyx to produce fibrotic fixation to the sacrum. Next, the redundant sigmoid colon and rectum are resected and re-anastomosed. The anastomosis should be at the level of the sacral promontory. The splenic flexure should not be mobilized as lack of left upper quadrant fixation may theoretically contribute to recurrence of the prolapse. Resection procedures tend to alleviate preoperative constipation symptoms.

Resection-Rectopexy The technique of resection plus rectopexy combines the benefits and risks of both procedures. Resection rectopexy has the advantage of removing excess bowel and restoring the normal rectal angulation (Fig. 141–4). There are reports that this approach improves symptoms of both incontinence and constipation.[22]

Laparoscopy Laparoscopic approaches to rectal prolapse have gained popularity as surgeons have obtained expertise at laparoscopic colon surgery in general and as safety concerns have abated.[10-14] Proponents describe a lower perioperative morbidity than open procedures.[14] The key steps of the operation should be the comparable to the open technique.

Randomized, controlled trials by Solomon et al.[13,14] comparing laparoscopic and open rectopexy showed both a lower cost and improved clinical outcome with the laparoscopic technique. Laparoscopic resection and resection-rectopexy can be performed with or without hand assistance. The resected colon can be removed from the abdomen either through a hand port or through an extension of a port incision.

Perineal Approaches

Many general surgeons shy away from perineal approaches to complete rectal prolapse because of a lack of training in and understanding of the anorectal anatomy and physiology. Nevertheless, many patients won't tolerate laparotomy or laparoscopy. These patients are better served with the minimally invasive approach of perineal proctosigmoidectomy (Altemeier), anorectal mucosectomy with muscular plication (Delorme procedure) or anal encirclement (Thiersch). Furthermore, recurrence rates in some series approach those described in abdominal treatments of rectal prolapse. Given that most patients with rectal prolapse are elderly women (many with multiple co-morbidities) and young men (who may fear the risk of sexual dysfunction with injury of the hypogastric nerves during an abdominal approach) some argue that perineal procedures are the preferred operations for most patients with procidentia.

The various perineal procedures can be performed either in the lithotomy position, or preferably in the prone jack-knife position. Regional anesthesia is typically used, but some patients may require general anesthesia. A self-retaining–type retractor (e.g. Lone Star) helps with exposure (Fig. 141–5).

Perineal Proctosigmoidectomy Altemeier popularized the technique of resecting the prolapsed bowel directly.[23,24] The Prasad modification is the only surgical approach to correct each of the anatomic defects associated with rectal prolapse.[23] The first step is to completely prolapse the redundant rectum by gently pulling on the rectal wall. The dentate line will be easily visible on the everted rectum (see Fig. 141–5). A dilute epinephrine solution is injected 1 to 2 centimeters proximal to the dentate line in the prolapsed rectal wall. Next, the rectal wall is incised full thickness, circumferentially with electrocautery at the level of the injection. The vascular supply to the prolapsed rectum and sigmoid is then carefully ligated. Nonabsorbable suture is used to fix the non-prolapsing bowel to the pre-sacrococcygeal fascia reproducing the normal posterior fixation of the rectum. The widely open pelvic floor is closed with a posterior levatorplasty. This recreates the normal anorectal angulation. The excess bowel is resected and a coloanal anastomosis is performed. The anastomosis can be hand sewn with absorbable suture or stapled by any of several stapling techniques.

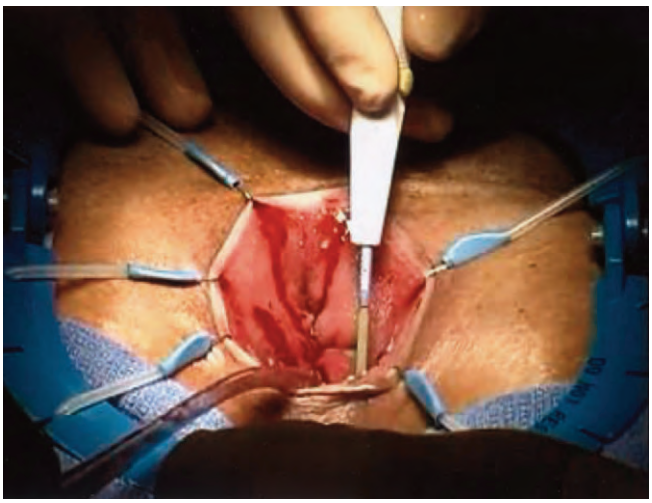

Figure 141–5. Lone Star retractor and incision for Delorme or perineal proctectomy.

Anorectal Mucosectomy with Muscular Plication (Delorme) The Delorme procedure first described in 1900 continues to be employed in select situations. The advantage of the procedure is that no bowel resection and anastomosis is needed.[9,25,26]

Once the bowel is completely prolapsed, a dilute epinephrine solution is injected judiciously in the submucosal plane (Fig. 141–6). The mucosa is circumferentially incised 1 cm proximal to the dentate line with electrocautery. The incision is deepened only to the level of the submucosa. The muscular layers are left intact. The mucosa is then stripped off the rectal wall musculature, continuing proximally to the extent of the redundant bowel (Fig. 141–7). The mucosal sleeve is then excised. Longitudinal plicating sutures are placed along the length of the rectal wall musculature approximately 1 cm apart. The sutures are tied once all 6 to 8 rows have been placed. Next, the proximal mucosal edge is re-sutured to the initial mucosal incision with absorbable sutures.

A modification utilizing a double purse-string suture and a circular stapler has been described.[6] The Delorme

Table 141–1 Procedures for Rectal Prolapse

Procedure	Major Risks	Major Benefits	Best for
Rectopexy	Higher operative risk, presacral bleeding, pelvic abscess	Lower recurrence rate	Young, healthy patient without redundant sigmoid or constipation
Resection	Higher operative risk, anastomotic leak	Lower recurrence rate, correction of constipation	Young, healthy patient with redundant sigmoid and constipation
Resection-rectopexy	Higher operative risk, anastomotic leak, presacral bleeding, pelvic abscess	Lower recurrence rate, correction of constipation	Young, healthy patient with redundant sigmoid and constipation
Perineal proctosigmoidectomy (Altemeier)	Higher recurrence rate, technique unfamiliar to many surgeons	Lower operative risk, correction of incontinence, may be combined with other pelvic floor reconstructive procedures	Older patient with comorbidities, and long-segment rectal prolapse
Anorectal mucosectomy with muscular plication (Delorme)	Higher recurrence rate, technique unfamiliar to many surgeons	Lower operative risk, correction of incontinence, may be combined with other pelvic floor reconstructive procedures	Older patient with comorbidities, and short-segment rectal prolapse
Anal encirclement (Thiersch)	High recurrence rate, mesh infection, erosion into bowel	Lower operative risk	Elderly poor risk patient, short life expectancy

procedure can be combined with posterior levatorplasty[9] in an attempt to improve continence (Fig. 141–8).

Anal Encirclement (Thiersch) Some surgeons have stated that anal encirclement[27,28] is a procedure which should be relegated to historical interest only. However, for the bed-ridden patient with short life expectancy, multiple co-morbidities and possible dementia or Alzheimer's disease and who may not tolerate even a perineal resection of rectal prolapse, the Thiersch technique can still be useful. It may also have a place after failure of the perineal procedures. This simple

procedure can be performed quickly, with very low morbidity.

Two perianal skin incision 180-degrees apart and lateral to the midline are made. The incisions are connected with a tunnel through the ischiorectal fossa. A strip of polypropylene mesh 1.5 cm wide is placed around the deep external sphincter. The mesh is passed around the anus from one incision to the second and then back to the first to completely encircle the anus (Fig. 141–9). The mesh is tightened and sutured to itself allowing an anal diameter only large enough to admit one finger in the anus. The risks of the procedure include erosion of the mesh into the rectum, infection of the mesh, recurrence of the prolapse, and impaction secondary to tight encirclement.

RESULTS AND PATIENT SELECTION

Proponents of abdominal rectopexy in its various forms claim lower recurrence rates (0-5%) than perineal procedures (10-15%). Surgeons with a preference for perineal proctosigmoidectomy and Delorme's procedure point to their relative safety and ease of reoperation in the event of recurrence. Most likely, each clinical situation will favor one approach from the other (Table 141–1). As such, proficiency in each approach is necessary.

Caution must be employed if a perineal approach is contemplated for recurrent rectal prolapse previously treated with an abdominal resection or, alternatively, if an abdominal resection is planned after a perineal resection. Unless the prior anastomotic line is resected, there is a risk of ischemia and necrosis of the intervening bowel between the two anastomoses can occur.[29]

Pilonidal Disease

Debra Holly Ford · H. Randolph Bailey

Pilonidal disease is a common recurring chronic disease. Since its first description in the early 1800s,[1,2] pilonidal disease and its treatment have been the subject of debate and controversy. It is believed to be an acquired infectious process leading to high rates of morbidity. This condition often results in discomfort and inconvenience. Patients are often prevented from working or attending school for extended periods. Although pilonidal disease has been described in other parts of the body, such as the hands, umbilicus, axillae, and external genitalia,[3] our discussion focuses on the disease as it affects the gluteal cleft region.

Sacrococcygeal pilonidal disease occurs predominately in young males at a ratio of 3:1. The peak incidence is between 15 and 24 years of age. Symptoms rarely present before 15 years of age or after the age of 40.[3,4] The disease is most common in whites; however, all ethnic groups can develop the condition.[5] Other factors affecting its incidence are obesity, poor personal hygiene, increased sweating activity, and local trauma.

ETIOLOGY

The pathogenesis of pilonidal disease remains the subject of debate. Approaches to the treatment of pilonidal disease have closely paralleled the theories of its development. For many years, the cause of pilonidal disease was thought to be congenital in origin. The *congenital theory*, which describes the pilonidal tract as a caudal remnant of the medullary canal or as a faulty coalescence of caudal dorsal ectodermal segments, still has its proponents.[6-8] Although true pilonidal cysts have been reported, such cysts are quite rare. Most well-informed surgeons treat the disease as an acquired condition. Patey and Scarff,[9] with additional evidence from Bascom,[10] have provided a plausible explanation in support for the acquired theory.

The *acquired theory* emphasizes the role that hair plays in the development of pilonidal disease. Bascom's histologic studies demonstrate a sequence of stages in the development of this condition (Fig. 142–1).[10] He describes a folliculitis that leads to the development of small subdermal abscesses that increase in size to form a large abscess cavity. He also explains that hair is drawn into the pilonidal cavity through the suction effect of gluteal movement. Other factors believed to contribute to the creation of pilonidal disease are related to the condition of the gluteal cleft, including a catch basin effect, the depth of the gluteal cleft, and gluteal cleft friction.[10]

The uncertain etiology of pilonidal disease has led surgeons to approach this condition in various ways, from the most conservative approaches to extensive plastic procedures.[6]

PATHOLOGY

Pilonidal disease is essentially a foreign body reaction. Midline pits are lined with squamous epithelium. Although 1% of the tracts associated with these pits may be completely lined with squamous epithelium, most are lined with only granulation tissue.[3] Hair, in the form of broken hair shafts, is found in the cavities at least 50% of the time. Typical pilonidal cavities do not contain epidermis, sweat glands, or hair follicles. The tracts usually extend cephalad and lateral from the midline pits. Pilonidal tracts have, however, been described as extending toward the anus and being misdiagnosed as fistula-in-ano in 7% of cases.[3]

CLINICAL PRESENTATION

The prevalence of pilonidal disease is not accurately known. Patients may present to the surgeon with findings of asymptomatic small midline pits in the gluteal cleft (which may contain hair) or as an obvious, painful abscess. After surgical or spontaneous drainage, chronic pilonidal disease may result. The presentation that is most distressing and challenging for the surgeon is recurrent pilonidal disease or an unhealed wound after prior surgical treatment.

The patient with a pilonidal abscess typically presents with a history of increasing pain and the eventual

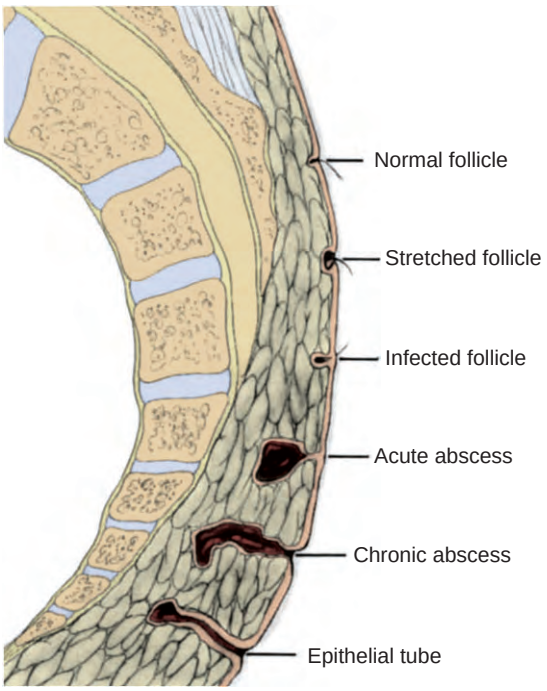

Figure 142–1. Pathogenesis of pilonidal abscess and sinus. (From Bascom J: Pilonidal disease: Origin from follicles of hairs and results of follicle removal as treatment. Surgery 87:567, 1980; redrawn in Nivatvongs S: Pilonidal disease. In Gordon PH, Nivatvongs S [eds]: Principles and Practice of Surgery for the Colon, Rectum, and Anus, 2nd ed. St. Louis, Quality Medical, 1999, p 288.)

development of a tender fluctuant mass in the sacrococcygeal area, often situated slightly off the midline. Cellulitis of the surrounding skin, as well as fever and leukocytosis, is occasionally present. An acute abscess is the presenting finding in approximately 50% of patients with pilonidal disease.[3,11] Most patients with chronic pilonidal disease have pain, intermittent discharge, or both. They may present with recurrent bouts of infection. Rarely, they present with fever and chills. On physical examination, there may be evidence of past drainage with or without cellulitis and induration. The midline pit or pits are usually present, and hair may be protruding from the orifice. The differential diagnosis of sacrococcygeal pilonidal disease includes furuncle, hidradenitis suppurativa, fistula-in-ano, perianal abscess, sacral osteomyelitis with draining sinus, tuberculosis, and actinomycosis.

TREATMENT

Many operations have been proposed for the definitive management of pilonidal disease. These treatment options have paralleled the theories of pilonidal development. During the period when widespread acceptance of the congenital theory prevailed, procedures were described that completely removed all tissue down to the sacral fascia.[7,8,12] These operations were done under general anesthesia and resulted in lengthy inpatient hospitalization. These aggressive operations produced wounds graphically described as "shark bites" that in many instances failed to heal properly and were the source of prolonged disability and discomfort.

Acceptance of the acquired theory has led to a "less is best" approach.[11,13,14] Current emphasis is placed on the elimination of factors that favor pilonidal development. In caring for patients with pilonidal disease, the surgeon should strive for complete wound healing with minimal patient disability, a low recurrence rate, and early return to activities of daily living. Contemporary management of pilonidal disease is frequently performed in an ambulatory setting.

Acute Pilonidal Abscess

An acute pilonidal abscess usually presents as a painful fluctuant mass located in the sacral midline or lateral to the midline. Immediate incision and drainage provide prompt relief of symptoms. Although anaerobic and aerobic bacteria have been cultured from these abscess cavities, antibiotics are not required in the management of most cases of pilonidal abscess.[15] Drainage may be performed in the emergency department or the office using only local anesthesia. A large abscess may require drainage in the operating room using intravenous sedation or general anesthesia. Because the abscess and the surrounding edema often obscure the midline sinus (the source of the abscess), performing a definitive procedure must usually be delayed until the edema subsides.

Technique of Drainage

Essentially all operations for pilonidal disease are best performed in the prone jack-knife position with the buttocks taped apart for better exposure. After preparation of the skin and infiltration with local anesthesia containing epinephrine, the gluteal area is shaved and a cruciate lateral incision is made over the abscess cavity with excision of the four corners of skin to allow for adequate drainage. Bascom favors a linear incision off the midline.[16] All debris and hair should be removed from the cavity if possible. Electrocautery usually suffices for hemostasis. On occasion, temporary light packing may be required. The patient is instructed to take warm tub baths at least twice daily and to return weekly for wound care and shaving. After simple incision and drainage, healing may take as long as 4 to 10 weeks.[3,17]

Several reports have favored immediate unroofing of tracts during the initial drainage of the pilonidal abscess.[3,14,18] If the midline pits can be identified, a probe is inserted through the orifice into the cavity. The abscess cavity and associated tracts are unroofed with cautery. The cavity is débrided, and wound edges are loosely packed apart to facilitate drainage and healing of the wound. Hair remaining in an inadequately drained abscess cavity is the major factor for persistence or recurrence of the abscess. The hair must be shaved surrounding the edges of the wound.[13,19] We have achieved an unreported 80% "cure" rate with this simple technique.

Chronic Pilonidal Disease

The progression to chronic pilonidal disease is expected in 40% to 60% of patients after incision and drainage.[3,5,11,17,19,20] Because of this high rate of continued or recurrent disease, Bascom[10,16] has suggested that incision and drainage be followed by a definitive surgical procedure.

As mentioned earlier, the midline pits, which are the origin of pilonidal disease, lead into a cavity lined with granulation tissue. The removal of all involved tissue is unnecessary. There is no clear consensus as to the preferred definitive treatment; however, acceptance of the acquired theory of origin has led to more operations with a minimalist approach and a strong emphasis on meticulous postoperative wound care. The treatment options usually fit into one of the following categories: conservative, nonresectional approach[12]; midline follicle excision and lateral drainage[2,16,21]; incision and curettage with minimal excision followed by marsupialization or saucerization of the wound[5,13,22]; and excision with or without primary closure.[23,24]

It is desirable to select an approach that can be carried out in an ambulatory setting with minimal patient inconvenience and disability. The role of antibiotics is not clear; there have been reports that have suggested antibiotics directed at anaerobic bacteria may improve healing rates.[15]

Conservative, Nonresectional Approach

Armstrong and Barcia[12] advocated conservative, nonexcisional therapy consisting of meticulous hair control by shaving, good perineal hygiene, and limited lateral incision and drainage for abscesses. There have been reports describing the instillation of liquid or crystalline phenol into the pits.[5,25] Healing rates have been reported from 59% to 95% in an average of 40 days.[25] Laser depilation of the natal cleft is now commonly available. Odet et al.[26] have reported 14 patients with recurrent pilonidal disease, all of whom were successfully healed by laser hair removal. We have no experience with this technique.

Technique of Midline Follicle Excision and Lateral Drainage

Although popularized by Bascom,[10] a similar technique was originally described by Lord and Millar.[2,21,27] The patient is re-examined in an outpatient setting approximately 5 days after drainage of the abscess when the edema and induration from the abscess have subsided. After the patient's gluteal cleft region is infiltrated with local anesthesia and shaved, a long, laterally placed incision is made over the previously drained cavity. The cavity is wiped clean with gauze or curetted and left open. The midline epithelium-lined pits are excised, leaving small wounds. These midline wounds are primarily closed with fine suture material (Fig. 142–2). The patient is instructed to keep the wound clean and to return for weekly visits for shaving and débridement, if necessary, until the wound has healed. Bascom[16] reported a 15% recurrence rate with minimal disability and healing within 3 weeks. However, other surgeons have not been as successful with this approach.[11]

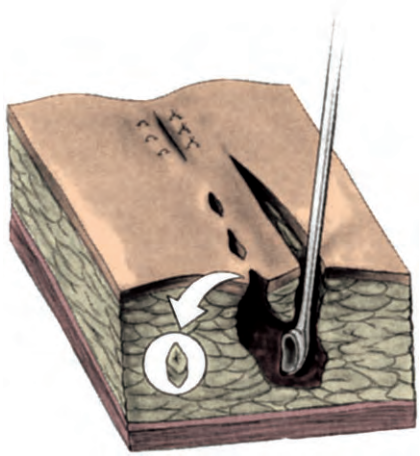

Figure 142–2. Treatment of pilonidal abscess by lateral incision into the abscess with curetting of granulation tissues and excision of midline pits. (From Bascom J: Pilonidal disease: Origin from follicles of hairs and results of follicle removal as treatment. Surgery 87:567, 1980; redrawn in Nivatvongs S: Pilonidal disease. In Gordon PH, Nivatvongs S [eds]: Principles and Practice of Surgery for the Colon, Rectum, and Anus, 2nd ed. St. Louis, Quality Medical, 1999, p 293.)

Technique of Incision and Curettage with Marsupialization or Saucerization

The option of laying open of tracts, minimal excision with marsupialization, or saucerization of the wound edges is commonly selected by surgeons.[6,13,14,18,28] The patient is prepared in the ambulatory setting. Local anesthesia with or without intravenous sedation is appropriate; rarely is general anesthesia needed. A probe is introduced into the midline pit or pits, and all primary and secondary tracts are opened. The resulting small open cavity is cleared of debris and hair, usually with a curette. The wound edges are beveled or saucerized to create a skin-level opening that is larger than the base of the cavity. The edges and base of the cavity are not disturbed except for the curettage. This allows for adequate drainage and prevents premature healing of the edges of the wound.

Marsupialization involves a similar technique, except that the skin edge is not saucerized but rather sutured to the lateral wall of the cavity. Recurrence rates with this procedure have ranged from 1% to 19%, with healing time averaging 34 days.[5,6] It has been our experience that suturing the skin edges to the wound does not consistently result in primary healing. Patients also seem to complain of more pain after marsupialization than after saucerization. For these reasons, we prefer to manage the skin edges with saucerization.

Technique of Excision With or Without Closure

Surgical procedures that involve the radical bloc excision of the pilonidal cavity with secondary healing of the

wound or primary closure are, unfortunately, still performed frequently.[29,30] Because pilonidal disease does not involve a true cyst, there is little justification for removal of the entire cavity. Wide excision of all affected pilonidal tissue down to the sacral fascia is unnecessary for treatment of this disease and has resulted in a high rate of unhealed wounds and prolonged morbidity. Rarely, the chronic cavity may be lined with epithelium, and in this instance the entire cavity may have to be excised.

It is difficult to interpret the literature with regard to recurrence rates after such excision. The extent of excision is usually unclear. In those situations where wide excision down to the sacral fascia with primary closure is performed, recurrence rates have been reported as high as 38%.[23,24,29] Reports have suggested that limited excision encompassing only the involved cavity followed by primary closure is a reasonable option for definitive treatment.[23,24] Primary healing is reported to occur within 2 weeks in 90% of cases.[3] Recurrence rates of 2% to 20% have been reported.[23,24,29,31] Failure of healing after primary closure is about 12%, and the incidence of wound infections varies among reports.[24] As mentioned, excision is usually not required to control chronic pilonidal disease. Although the concept of excision and primary closure is appealing and parallels the approaches that surgeons take to most other problems, the high rate of recurrence and the significant pain experienced due to the sutures make this approach low on our list of treatment choices. Anecdotally, almost all patients who we see with recurrent pilonidal disease have wounds with the telltale cross-hatches typically produced by primary closure.

Postoperative wound care requires diligent attention to gluteal hygiene to reduce the incidence of secondary hair (i.e., scalp hair) from invading the healing wound. Local hair is shaved at weekly office visits. The patient is instructed to take warm tub baths twice a day. Dry gauze or wet-to-dry dressings are used to prevent premature healing and to minimize granulation tissue in the open wound. The use of a Water-Pik[32] or hand-held showerhead will aid in cleaning the cavity. It is well documented that without careful follow-up even the best operation will have a poor result.

Recurrent or Unhealed Pilonidal Disease

Recurrence rates following primary surgical treatment of pilonidal sinuses range from 3% to 40%.[5] Most recurrences respond to reoperation using one of the earlier mentioned techniques. The patient with the unhealed chronic wound after multiple attempts at eradication of disease usually presents with significant tissue loss. These situations are probably best treated by excision, débridement, and closure with myocutaneous or cutaneous flaps. Many procedures have been described, including Z-plasty,[33] V-Y fasciocutaneous flap,[33] Limberg flaps,[33-35] gluteal myocutaneous flaps,[33] advancement flap[4,8] (Karydakis' operation), and the cleft lift (closure) procedure (Fig. 142–3).[36,37] These procedures have a recurrence rate in the range of 2% to 11%. However, these flap procedures carry significant morbidity and require hospitalization. They should be reserved for highly complex pilonidal disease. The cleft lift or closure operation as described by Bascom takes into account the problems of a healing wound in the midline with its associated negative factors, such as a deep cleft in an anaerobic environment. Therefore, the goal of the cleft closure technique is to place the final incision lateral to the midline and to flatten the gluteal cleft.

Technique of Cleft Lift

With the patient in an ambulatory setting and in the prone jack-knife position, the buttocks are held together and the area of contact is marked (see Fig. 142–3A). The buttocks are then taped apart. (see Fig. 142–3B). The gluteal cleft region and buttocks are shaved, prepped, and generously infiltrated with 1% lidocaine containing 1:100,000 epinephrine. To raise a skin flap, an incision is made above the top of the cleft and then crosses the midline at the top of the unhealed wound at an acute angle. Below the wound, the incision again crosses the midline at a right angle and then circles around cephalad to the anus. The lower end of the incision points to the anus. The unhealed wound is excised in a triangular shape (see Fig. 142–3C). A skin flap is then created out to the marked line (see Fig. 142–3D). The tapes are then released. The skin flap is positioned to overlie the edges of the wound on the opposite side. Excess skin is excised. A closed-suction drain is placed in the subcutaneous tissue and brought out through a separate stab wound. The subcutaneous tissue is approximated with 3-0 absorbable sutures (see Fig. 142–3E). The skin is closed in a subcuticular fashion, and adhesive strips are applied. A light dressing is applied. Complete healing is expected, and recurrence rate is reported at 3.3%.[36,37]

The concept of reverse taping to promote wound healing in the obese patient has met with some success.[38] This technique involves taping the buttocks apart by passing tape from one buttock anteriorly around to the other buttock. The tape keeps the buttocks apart promoting drainage of the wound and reducing the anaerobic environment. Meticulous shaving and reapplication of the tape on a weekly basis are important for successful healing. A few patients may benefit from this technique.

PILONIDAL DISEASE AND CARCINOMA

Malignant degeneration of chronic pilonidal wounds is a rare complication.[27,39,40] Such patients have had long-standing disease, averaging 23 years' duration. Most tumors are squamous cell carcinoma. Approximately 80% of these malignancies have been described in men in their 50s. The tumors are aggressive and locally invasive. Inguinal lymph node metastasis is present in 14% of patients. The presence of carcinoma in a pilonidal wound *is* an indication for wide en bloc excision of the mass including the sacral fascia. Flap techniques are usually required to close the defect. Recurrence rates have been reported at 38%. With a mean follow-up time of 28 months, 20% of all patients died as a result of the

neoplasm.[5,39] Local recurrence rates seem to be lower when radiation therapy is added to surgical resection. There also appears to be some advantage to adding chemotherapy to the treatment regimen.[5,39]

SUMMARY

Sacrococcygeal pilonidal disease is a potentially disabling disease that is often made worse by overly aggressive treatment. Understanding the pathophysiology helps the surgeon manage the problem with less destructive techniques than were used previously. Treating pilonidal disease as an abscess with a feeding sinus tract instead of as a "cyst" allows treatment approaches that can be performed with satisfactory results, often on an ambulatory basis.

Traumatic Colorectal Injuries, Foreign Bodies, and Anal Wounds

Susan Galandiuk ▪ Jeffrey R. Jorden ▪ Hiram C. Polk, Jr.

COLORECTAL TRAUMA

The management of injuries to the colon and in particular to the rectum may create problems for general and trauma surgeons who are not completely familiar with the advanced concepts and techniques that are associated with anorectal physiology and reconstruction. Similarly, even the most skillful colorectal surgeon may be presented with major problems in the overall management of diseases associated with that organ in the multiple trauma scenario. The purpose of this chapter is to describe the treatment of injuries to the colon, rectum, and anus, in which the best skills of both the trauma surgeon and the colorectal surgeon will be brought to bear in managing an individual patient.

The history of colon trauma is old, with at least one reference to it in the Old Testament (2 Samuel 20:9-10). Colorectal trauma was nearly uniformly fatal during the American Civil War, but the mortality rate began to decline during World War I. In World War II, the mortality rate declined again to about 25% to 30% as a result of the availability of blood transfusion and the standard practice of fecal diversion. Patient transportation during the Korean and Vietnam wars, as well as the continued refinement of resuscitation and the judicious individualization of colorectal wounds, also increased survival rates. Currently, the mortality rate is about 3% in the civilian scenario. In the United States, trauma is the major cause of death in people younger than 40 years and accounts for nearly 150,000 deaths a year, with a lower life expectancy rate than for cardiovascular disease and cancer combined.

Trauma-related deaths have a tripartite distribution. There are *immediate deaths* that occur soon after injury and before hospital transport and, typically, in association with major neurologic and cardiovascular injury. There are *early deaths* that occur at and about the time of transfer to the hospital and within a few hours after injury due to major hemorrhage, such as hemorrhage in the chest and abdomen, and due to severe blood loss from multiple, less-specific injuries. The third time of trauma death occurs *secondary to infection,* beginning toward the end of the first week of hospitalization and continuing well into the 2nd and 3rd months after injury. Infection, overt sepsis, and multiorgan failure are special problems in colonic injury because of the bacterial contamination that frequently coexists with hemorrhagic shock. In civilian practice in the United States, a gunshot wound to the colon is the most common cause of penetrating injury, with stab wounds being second, and shotgun wounds being third. Blunt trauma occasionally causes colorectal trauma and presents special diagnostic problems (discussed later).

Table 143–1 provides a summary of selected studies from the past 30 years that lists the collective causes of penetrating colonic injury.[1-9] With the increasing use of therapeutic endoscopy that is often performed by nonsurgeons, iatrogenic or unintentional perforation of the colon has become a special problem that deserves separate comment in terms of overall management (see "Iatrogenic Injury"). The frequency of iatrogenic injury, especially in tertiary centers, is vastly underestimated.

Colonic injury, when combined with other injuries such as to parenchymal organs (i.e., liver, pancreas, spleen), is especially important in contributing the second part of the "two-hit" hypothesis (i.e., bacterial contamination combined with hemorrhagic shock). It therefore has a substantial influence on survival rate and an even greater effect on infectious morbidity rates. Table 143–2 provides a summary of associated injuries for gunshot wounds to the colon, which again emphasizes

Table 143–1 Collected Causes of Penetrating Colonic Injuries

Types of Injury	Flint et al., 1981[1]	Samhouri et al., 1979[2]	Bartizal et al., 1974[3]	Wiener et al., 1981[4]	Kirkpatrick and Rajpal, 1975[5]	Steele and Blaisdell, 1977[6]	Thomson et al., 1996[7]	Stone and Fabian, 1979[8]	Jacobsen et al., 1997[9]	Totals

the influence of the small bowel, liver, stomach, major vessels, and pancreas.[4,9-11]

The major factor in the assessment of patients with colorectal injuries, which is discussed in detail in "Intraoperative Management," depends on the severity of injury. Table 143–3 provides a grading system for both intra-abdominal colon and rectal injuries that is helpful in recognizing the severity of the injury and in determining preferred therapy.

All of these factors contribute significantly to the possibility of infectious complications and in turn are closely related to the likelihood of late death.[12] For example, there is a steady increase in infectious complications that parallel the number of units of blood transfused during a laparotomy for colon injury, rising to as much as 60% when more than 10 units of blood have been transfused. Similarly and not surprisingly, the risk of infection approaches 100% when more than five organs have been injured, but the risk is only half that when four or fewer organs have been injured. Patient age also has a substantial effect on the infectious complications rate. Patients younger than 30 years have only a 12% to 15% infection rate, whereas those older than 30 years have an infection rate that exceeds 40%.

INITIAL RESUSCITATION AND ASSESSMENT

It is appropriate to review the important issues of the basic principles of care of the trauma patient.[13]

Care of the trauma patient begins at the scene. Before transport, the patient must receive basic emergency medical services such as the use of a cervical collar, stabilization with a spinal board, and endotracheal intubation with in-line cervical traction if the patient is not breathing spontaneously. Attention to the cervical spine is critical. Intravenous access should be obtained and

Table 143–3 Gradation of Injuries to Colon and Rectum

Injured Structure	Grade	Characteristics of Injury	AIS-90 Score
Colon	1	Contusion or hematoma; partial-thickness laceration	2
	2	Small (<50% of circumference) laceration	3
	3	Large (>50% of circumference) laceration	3
	4	Transection	4
	5	Transection with tissue loss; devascularized segment	4
Rectosigmoid and rectum	1	Contusion or hematoma; partial-thickness laceration	2
	2	Small (<50% of circumference) laceration	3
	3	Large (>50% of circumference) laceration	4
	4	Full-thickness laceration with perineal extension	5
	5	Devascularized segment	5

AIS-90, Abbreviated Injury Score, 1990 version.

crystalloid solutions should be infused during transport. Extremity fractures are splinted with pneumatic devices or other kinds of rigid support system.

On arrival at the treatment facility, the old adage of *ABC* (airway, breathing, and circulation) remains the fundamental catechism of the advanced trauma life support system of the American College of Surgeons.[14]

The presence of a patent airway must be redefined at every step in the process. If intubation is not technically feasible, cricothyrotomy may be required, especially if there has been associated trauma to the head, such as a mid-face fracture. Correct positioning of the endotracheal tube must be determined with chest films, and intubation of the right main stem bronchus should always be considered if no left-sided breath sounds are heard. Hemothorax must be excluded on the basis of chest films and physical examination. The adequacy of circulation is determined through a variety of measures, including blood pressure and assessment of capillary refill. If the patient is hypovolemic, two large-gauge peripheral intravenous lines must be established, and lactated Ringer's solution must be infused rapidly, pending the availability of type-specific blood.

Further assessment of individual injuries should be undertaken once the airway is secured, breathing is accomplished, and circulatory resuscitation is under way. Penetrating injuries to the abdomen, including ecchymoses, must be noted. If an intra-abdominal injury is likely, a broad-spectrum, safe cephalosporin should be administered with one of the first liters of intravenous fluid. We continue to believe that the scenario of trauma with shock and resuscitation is ideal for the use of very large doses of safe antibiotics[15] and their continuous infusion.[16] As part of the care of the trauma patient, an evaluation of pelvic fractures is especially important with respect to bladder injuries or laceration to the anus or rectum. It is important to examine the perineal area and to determine the presence or absence of blood at the urethral meatus or on rectal examination. If there is blood at the urinary meatus or if the prostate is not palpable on rectal examination, one must especially consider transection of the urethra, and a urethrogram should be done *before* Foley catheter insertion.

Depending on the patient's stability, if a pelvic fracture is present, it must be stabilized with an appropriate external fixator or with a military antishock trouser (MAST) device after the Foley catheter has been inserted. This will stabilize the fracture and provide some control of the hemorrhage, which may complicate pelvic fractures.[17]

While resuscitation and the initial assessment are ongoing, the insertion of a nasogastric tube, by nose or mouth, will permit the detection of blood within the stomach, as well as decompress the patient in preparation for an anesthetic. Any penetrating wound below the level of the nipples must be considered a possible intra-abdominal injury.

The evaluation of the abdomen in the unconscious patient continues to represent a serious problem. Diagnostic peritoneal lavage (DPL) has been a reliable procedure for nearly 3 decades; it is performed under direct vision, with care. If no gross blood is encountered, lavage of the peritoneal cavity with saline is performed. DPL is considered positive and indicative of intra-abdominal injury if the effluent contains more than 100,000 red blood cells/mm^3 or more than 500 white blood cells/mm^3, with a hematocrit value of more than 2, or in the presence of bile, bacteria, and vegetable or fecal matter. If DPL is negative but there still is suspicion of intra-abdominal injury, further evaluation by ultrasound examination or computed tomography (CT) scanning may be helpful. Ultrasound examination, when carried out by the examining surgeon, is a most efficient, inexpensive, and reliable aid to patient care.[18,19] Ultrasound has replaced DPL and CT studies,[20] and the focused abdominal ultrasound for trauma (FAST) has replaced DPL in most trauma centers.[21,22] Focused abdominal ultrasound includes evaluation of the pericardium, right

and left upper quadrants, and pelvis. Skills in ultrasound evaluation of the acute abdomen have become as important as laparoscopy to the contemporarily trained general surgeon. Needless to say, FAST should always be performed by the operating surgeon.

The overall priorities of trauma care are important and are dealt with elsewhere.

SPECIAL DIAGNOSTIC PROBLEMS

Colorectal injury associated with *blunt trauma* is especially treacherous and is uncommon enough to worry even the most experienced trauma surgeons. It represents only about 1 in 30 such injuries, and the diagnosis is often made only at the time of laparotomy for other injuries. The diagnosis will often not have been made, and the surgeon will have to be alert intraoperatively to take appropriate measures. Reported data regarding these injuries are suspect in the sense that diagnosis is often delayed and then involves the treatment of a late-recognized colon perforation as opposed to the more frequently and promptly diagnosed penetrating trauma.[23]

There is a 1% incidence of hollow viscus injury with blunt trauma and approximately a 0.3% incidence of colon or rectal injury.[24] No diagnostic test or combination of findings reliably excludes blunt colon injury. This diagnosis is often made at the time of laparotomy for other injuries. The presence of colonic injury at laparotomy is associated with an increased risk of complications but not necessarily mortality.[24]

The proposed mechanisms of colon injury during blunt abdominal trauma are several. This injury is most commonly thought to occur secondary to direct compression between the blunt object and the vertebral column or bony pelvis. This compression produces a tearing or lacerating effect. A second mechanism of injury is thought to involve sudden deceleration, producing bowel-mesenteric disruption and subsequent devascularization. This makes the transverse and sigmoid colon most vulnerable during sudden deceleration injuries because these segments are on a mesenteric stalk.[25]

A further opportunity for diagnostic error regarding injury to the large bowel is the failure to carry out a careful, well-illuminated, and detailed perineal examination in the often unstable multitrauma victim. Lacerations of the perineum or rectum must be presumed to be associated with open pelvic fractures. Shards of bone associated with some pelvic fractures can readily lacerate all pelvic structures, including major blood vessels. The careful examination of the perineum and the rectum, including an examination for occult blood, is important in this scenario and can be difficult. There is no substitute for a careful examination by a person who is knowledgeable of and especially suspicious of the bizarre ramifications of perineal lacerations and pelvic fractures. The standard of care often includes the use of sigmoidoscopy, but this can be technically difficult in the trauma patient. Triple-contrast CT scanning with intravenous, peroral, and rectal contrast medium can identify many rectal extraperitoneal injuries.

Diagnostic dilemmas occur in several typical scenarios, most commonly when a retroperitoneal portion of the colon has been injured and the patient presents with few anterior peritoneal signs, no pneumoperitoneum, and symptoms that may be masked by other overt manifestations of trauma or by treatment. Opening of the peritoneal reflection usually discloses the true nature of the problem.

GENERAL PRINCIPLES OF PREOPERATIVE MANAGEMENT

The fundamental principles of preoperative management are, of course, securing and maintaining an airway and restoring vital organ perfusion. This is ordinarily possible, but there may be circumstances of major vascular injury or liver trauma in which a patient may need to undergo emergency surgery while incompletely resuscitated. Under these circumstances, the injury to the large bowel is seldom the major contributor to hemorrhage. Control of the site of primary blood loss and stabilization of the patient take first priority. Resectional débridement of the colon, or its simple stapling, as an early part of a procedure to control contamination while ongoing hemorrhage is being addressed may be a wise and proper choice. The most significant advance in this field in the past decade has been the recognition that the secure packing of some parenchymal organ injuries often can be the best possible temporizing measure. It will allow the patient to return to the operating room in 24 to 48 hours for more definite management of a variety of injuries when he or she is hemodynamically stable, no longer coagulopathic, and warm. The concept of the damage control laparotomy as a staged approach to severe trauma and associated shock has been a major advance for trauma care in the past decade.[26]

Notwithstanding these circumstances of near exsanguination, one of the most important points in the early care of the trauma patient is the intravenous administration of a broad-spectrum antibiotic. The agent of choice should be a safe drug such as a second- or third-generation cephalosporin. Antibiotic regimens should *seldom* include nephrotoxic aminoglycosides or unnecessary and occasionally harmful agents aimed at anaerobic bacteria. We believe the continuous infusion of a relatively large dose of antibiotics is warranted, given the hemodynamic instability, shock, and transfusion.[15,16] As soon as the condition of the patient has stabilized and contamination is controlled, antibiotics often can be discontinued. If contamination is minimal, antibiotics can be discontinued postoperatively. If contamination is moderate, an antibiotic probably should be continued for 72 hours. Regardless of the degree of contamination, antibiotic administration should not continue beyond 7 days. There is little evidence that continuing use of such drugs for 7, 10, or 14 days accomplishes anything but predisposition to the development of resistant bacterial forms for later infection. Table 143–4 provides a

Table 143–4 Antibiotic Priorities

Factor	Authors, Year	Recommendation
Timing	Richardson et al., 1987[27]	First intravenous infusion solution
Duration	Polk and Christmas, 2000[43]	Single dose to 24 hours when favorable; never longer than 5 days
Doses	Livingston and Wang, 1993[16]	Very large if a cephalosporin is chosen and/or hemorrhage and transfusion are significant
Route	Livingston and Wang, 1993[16]	Parenteral; continuous infusion may be better
	Galandiuk et al., 1997[28]	Special role for prolonged antibiotic beads in wound if closed and high risk
Drug preferences	Price and Polk, 1994[44]	Cefotetan or ceftriaxone; aztreonam for gram-negative coverage
		Metronidazole if overt evidence of established anaerobic infection
		Seldom: clindamycin/amikacin/tobramycin-gentamicin only for rare allergy and/or positive culture scenarios
Cost-control issues	Author's choice, 2005	Safest antibiotic is always the best choice; drugs that require monitoring of levels are prohibitively expensive

summary of our views and practices with respect to the use of antibiotics in colorectal trauma.[16,27,28]

INTRAOPERATIVE MANAGEMENT

If the abdomen is the site of injury, our preferred approach for virtually all patients with such trauma is through a midline abdominal incision that can be extended in either direction depending on the nature of the intraoperative findings. The laparoscopic approach to major abdominal injury is still evolving as are the requisite skills for minimal access surgery among younger surgeons; selected applications in experienced laparoscopic hands may become more acceptable. The burden of proof of overlooked injury is obviously substantial. We emphasize the need to stabilize the patient intraoperatively and to control or ameliorate ongoing blood loss. When that is accomplished, one is ready to turn attention to the possibly injured colon. A system of grading colon injuries is especially helpful to the surgeon (who is not often in this situation) in making a wise choice regarding options, ranging from primary repair to occasional resection and anastomosis, with or without protective proximal stoma. Just as the surgeon must begin to make that determination, he or she must constantly be alert to the stability of the patient and the patient's capacity to tolerate a preferred method of repair. The choices may include rapid stapling and discarding of a section of colon in a patient with a massive liver injury and multiple transfusions who is being packed to control a major hepatic parenchymal hemorrhage. The other end of the spectrum is represented by a stable patient who has an isolated injury of the lower sigmoid and is an excellent candidate for excision of the injured segment and primary repair in the best of circumstances.

In general, options for the treatment of colon injury include (1) proximal diversion and repair, (2) exteriorization of the wound itself as a colostomy, (3) simple suture of even lengthy colon lacerations, and (4) resection and anastomosis. The latter should be applied only with special thought. The patient with injuries requiring resection often has associated injuries and therefore is seldom a candidate for an extensive and complex operation and may be better suited for resection and temporary diversion. On the other hand, if contamination is not extensive, the patient is hemodynamically stable and well-vascularized colon is available, then resection and anastomosis may be suitable. The algorithm (Fig. 143–1) is especially helpful to a surgeon who is unfamiliar with the treatment of colonic injury. It is clear that many tangential, and even penetrating, wounds of the colon can be dealt with safely by primary suture in a stable patient. Even longitudinal tears can be repaired safely. A recent meta-analysis of currently published randomized trials favors primary repair over fecal diversion for penetrating injuries of the colon.[29] The method of anastomosis following colon resection for penetrating trauma does not seem to affect the incidence of abdominal complications.[30] There are special technical considerations, depending on the site of injury. We and others have debated the relative merits of different standards for the management of right and left colon injuries. Resection and anastomosis in the injured right colon have almost identical mortality and morbidity rates as the more conservative procedure of resection and ileostomy. Anastomotic failure is an uncommon phenomenon in the judicious management of right colon injury. Table 143–5 lists the main issues of some studies.[31-35] In 1994, Stewart et al.[35] examined penetrating injuries of the colon in patients with significant risk factors (preoperative or intraoperative transfusion of more than 6 units of packed red blood cells, significant comorbid diseases) and identified a leak rate of 42% in this high-risk group. Based on this and other data, one should avoid an anastomosis in such a severely injured patient.[36]

IATROGENIC INJURY

Colonoscopic perforation is remarkably infrequent, and, even then, it is clear that many patients tolerate delayed

performed if there is blood within the rectum on digital examination or if there is evidence of a bladder or urethral injury, blood within the vagina, severe pelvic fracture, or bullet trajectory above the mid thigh and below the pelvic rim.[40] If a rectal injury is suspected, the patient should be positioned in stirrups so there is free access to the perineum. In general, if such an injury has been complicated by delayed diagnosis, then diversion is preferred, complemented by the removal of palpable rectal fecal material, rectal "washout," and drainage of the presacral space. The efficacy of rectal washout has not been demonstrated prospectively. Rectal washout can be performed via sterilized ventilator tubing inserted transanally after anal canal dilation. A large Foley catheter (e.g., 24 French) can be inserted into the distal rectum, and irrigation is performed until the effluent is clear.[41] Saline is most frequently used, often with a final irrigation of povidone-iodine.

Contrary to common attitudes among trauma surgeons, the promptly diagnosed anorectal injury is often best treated by a definitive early repair, assuming the patient is otherwise stable. This in particular applies to lacerations of the anal sphincter and anal valve region. Obviously, if the patient is badly hurt or in shock or the diagnosis is delayed, diversion becomes part of the care plan for the patient. The operating surgeon must be particularly careful that drainage of the area does not produce further sphincter injury. It requires the best of the trauma surgeon's overall assessment and the colorectal surgeon's anatomic expertise to optimize results in these challenging wounds.

POSTOPERATIVE COMPLICATIONS

Complications that may follow colorectal injury encompass the surgeon's entire repertoire. Bacterial contamination, if accentuated by diagnostic delay, hemorrhage, transfusion, or other major organ damage, is the overriding concern once the ABCs of trauma care have been established. Infection is both the most frequent and the most dangerous problem. The specter of multisystem organ failure and its supportive and definitive care are always the first priority. If the patient does not thrive after treatment, the surgeon must reassess the patient and must be certain that an error in diagnosis or treatment has not occurred. In general, mechanical treatment (drainage and diversion) is far better than reliance on medications and organ system support.

Colostomy is a special complication of several of the therapeutic options in colorectal trauma.[13] In a comparison of outcomes—morbidity and mortality—as well as cost, the closing of a complementary stoma must always be considered. We examined our practices and provide some highlights of that experience in Table 143–6. Colostomy closure requires as much mental preparation for the surgeon as it does technical expertise. The practice in many respected residency programs of assigning "simple" colostomy closure to junior staff is a case in point. Furthermore, choosing a time to perform the closure has become especially contentious in this cost-obsessed era. Surely, if the stoma is complementary (i.e., to a primary repair or for exteriorization of an injury), then early closure is feasible. Although that might safely and wisely be performed within 8 weeks, the stoma constructed as part of the care of a rectal laceration produced by a major pelvic fracture or for a complicated sphincter repair secondary to a straddle injury is another matter, and structural and functional healing for 90 days or more may well be in order before the closure of a stoma. It should not be forgotten that one of the most common complications after blunt or penetrating colonic trauma is development of pneumonia, which may significantly affect mortality. The incidence of intra-abdominal abscess formation ranges from approximately 8% to 12%[24,42] but may be even higher with multiple other injuries.

Psychologically, the surgeon who plans a colostomy closure of a Hartmann-style stoma must also be ready to perform a major laparotomy, and the patient should be prepared as well. Our practice has been to either perform this within 2 weeks or delay it for 90 days, with a hope of minimizing technical issues and errors.

Table 143–6 Lessons Regarding Colostomy Closure in the Trauma Patient

Issues	Comment
Timing	Despite preferences, little differences in morbidity rate can be attributed to early vs. later closure
Preoperative contrast study of distal bowel	Assuming the patient is well physically and no lesions were detected at first operation
Management of the stoma site	Delayed primary or secondary closure often never occurred Closure with prolonged local antibiotic instillation is safe
Home health care follow-up	Home care leads to uniform prolongation of wound closure and increases in cost

Colonic Intussusception and Volvulus

Robin P. Boushey · David J. Schoetz, Jr.

INTUSSUSCEPTION

The invagination of one segment of the intestine into another is defined as *intussusception*. This disease entity is the most common cause of bowel obstruction in children. On the other hand, only 5% to 10% of intussusceptions occur in adults, and it is a rare cause (<1%) of adult bowel obstructions.

Types of intussusception include *enteric* (small bowel into small bowel), *ileocolic* (small bowel into colon), and *colonic* (colon into colon). Although colonic intussusception is rare in children, it accounts for approximately 50% of adult cases.[1] The clinical presentation is that of mechanical bowel obstruction: crampy abdominal pain, nausea, vomiting, and subsequent obstipation or diarrhea. Subacute or recurrent acute attacks are not uncommon in adults compared with children. Radiographic investigation of an individual with recurrent episodes of bowel obstruction should include barium contrast radiography or computed tomography (CT) scanning during an acute episode (Fig. 144–1). The demonstration of an invaginated portion of the bowel secures the diagnosis.

Unlike in children, in whom more than 80% of episodes are idiopathic, in adult patients with intussusception there is a demonstrable pathologic process acting as a lead point, causing the condition in 80% to 90% of patients.[1-4] Potential causes include benign and malignant tumors of the small and large bowel, inflammatory lesions, appendiceal disease, and Meckel's diverticulum. Consequently, all adults who have been demonstrated to have intussusception should be offered operative resection of the involved bowel. This may be necessary in the acute setting because of bowel ischemia or nonresolution of the obstructive episode. In patients in whom the condition spontaneously resolves, elective resection should be performed after appropriate investigation of the gastrointestinal tract to exclude synchronous disease.

If intussusception is present at the time of exploration, an assessment is made regarding the length of bowel that would be required to be resected without reducing the invaginated segment. Nonviability mandates resection with primary anastomosis in most instances. Attempts to reduce the nonviable bowel risks intraoperative rupture and contamination of the peritoneal cavity with both succus entericus and tumor cells. Debate continues as to whether reduction should be attempted in patients without ischemia, with concerns regarding rupture being weighed against the resection of excessive bowel length. Patients with colonic intussusception can most often be treated successfully with subtotal colectomy because involvement of the descending colon and sigmoid is rare. If the lead point is in the left colon and preoperative mechanical bowel preparation cannot be achieved, resection with end colostomy and Hartmann's closure of the rectum or on-table lavage with primary anastomosis should be considered.[5]

VOLVULUS

Volvulus is derived from the Latin word *volvere,* which means "to twist upon." In the colon, it refers to a condition in which the colon is twisted on its mesentery causing acute, subacute, or chronic colonic obstruction. For a volvulus to occur, the colon must be mobile and have sufficient length to rotate around a relatively narrow and fixed mesenteric base. As a result, the most commonly involved sites are the sigmoid colon and the cecum. Volvulus of the colon accounts for approximately 5% of intestinal obstructions and 10% to 15% of colonic obstructions in patients in the United States.[6,7] Ballantyne in a series of 546 cases of colonic volvulus in the United States found the incidence of colonic volvulus to be cecum, 34.5%; transverse colon, 3.6%; splenic flexure, 1%; and sigmoid colon, 60.9%.[8]

The clinical presentation of volvulus of the colon is similar regardless of the site of the twist. Crampy abdominal pain, distention, diminished stool output, and nausea and vomiting consistent with obstruction are the

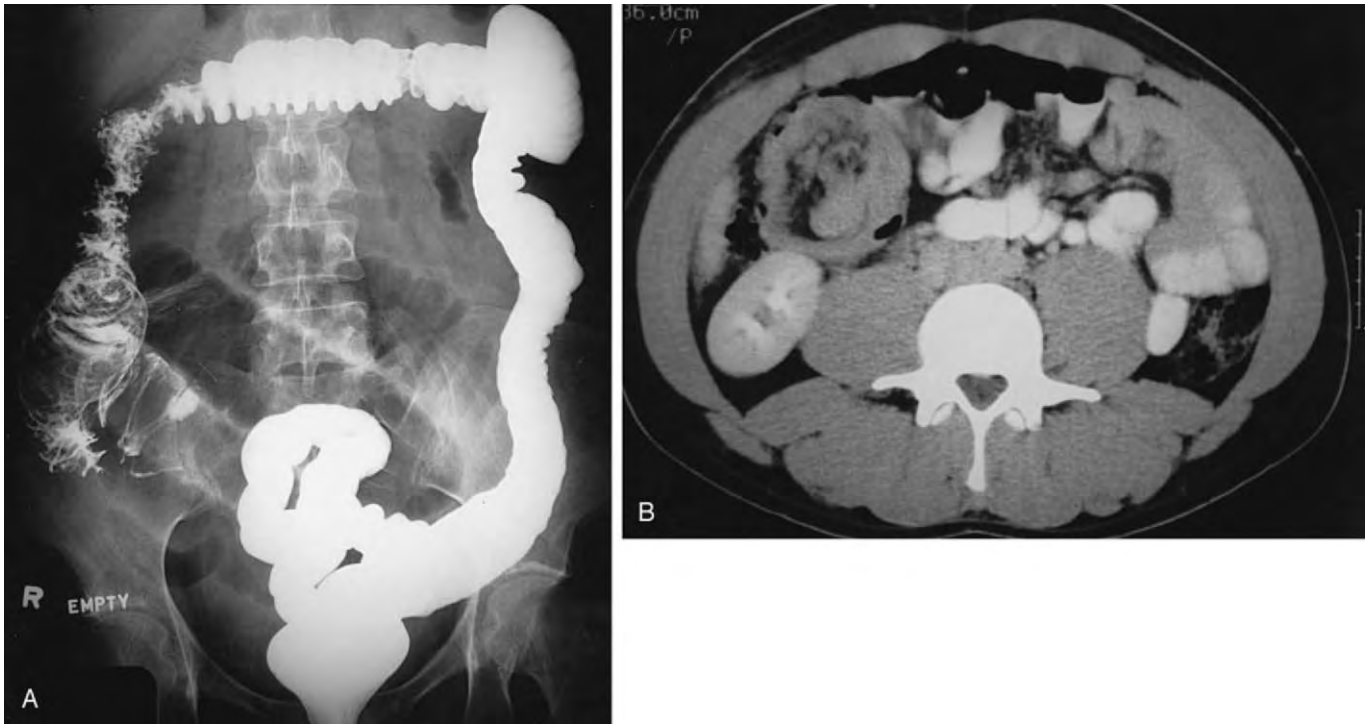

Figure 144–1. **A,** Barium enema of ileocolic intussusception demonstrating an invaginating mass into the right colon with the "coiled-spring" appearance of proximal small bowel obstruction. **B,** CT scan showing ileocolic intussusception, with the typical "bull's eye" appearance of bowel within bowel in the right abdomen.

hallmark complaints. Progression to constant abdominal pain implies the development of serositis of the involved segment, which may act as a closed-loop obstruction with increasing intraluminal pressure that leads to ischemia. Furthermore, the mesenteric vasculature may be compromised by mechanical torsion of the volvulus around the mesenteric pedicle. Acute presentations such as this represent more than half of the total episodes of volvulus. A subgroup of patients with colonic volvulus describes similar episodes in the past that resolved spontaneously, often with an associated explosive bowel movement or passage of gas. Patients with recurrent volvulus need a careful assessment to rule out the diagnosis of colonic inertia and megacolon, which may mandate a more extensive colonic resection.

Predisposing factors common to all sites of volvulus include previous abdominal surgery and a history of chronic constipation. A detailed history should include potential comorbidities that must be incorporated into the overall treatment plan as many of these patients are elderly, debilitated, and have multiple coexisting medical conditions. Examination of the abdomen reveals abdominal distention, varying degrees of tenderness over the obstructed segment, a tympanic mass, and, in instances of vascular compromise or perforation, fever and hypotension.

After physical examination, plain radiographs of the chest and abdomen are obtained. An upright radiograph of the chest excludes the presence of free intraperitoneal air, and abdominal films generally demonstrate a massively distended segment of colon with obstruction proximal to the twist (Fig. 144–2). Lower gastrointestinal contrast radiography should be obtained to confirm the diagnosis. A barium enema should be used only if there is no evidence of peritonitis and in the patient fit enough to undergo the procedure. The classic finding is a "bird's beak" deformity or mucosal spiral pattern at the site of the volvulus (Fig. 144–3). When performing a contrast enema, minimal contrast should be used. Excessive use of rectal contrast may temporarily reduce the volvulus, which may quickly reform, trapping contrast and further dilating the proximal colon. As well, the presence of barium can make subsequent endoscopic reduction of the volvulus difficult. CT scan can also be used to diagnose a volvulus and usually demonstrates a "whorl sign," that is, mesenteric fat with engorged vessels that converge toward the center.

The management of volvulus of the colon, regardless of site, is by either nonoperative or operative means (Fig. 144–4). Evidence of gangrene or perforation is a surgical emergency that necessitates prompt preoperative preparation and laparotomy. The types of available nonoperative therapy depend on the site of the volvulus and are discussed individually.

Sigmoid Volvulus

Etiology and Pathophysiology

In the United States, the sigmoid colon is the most common site of volvulus and sigmoid volvulus is the

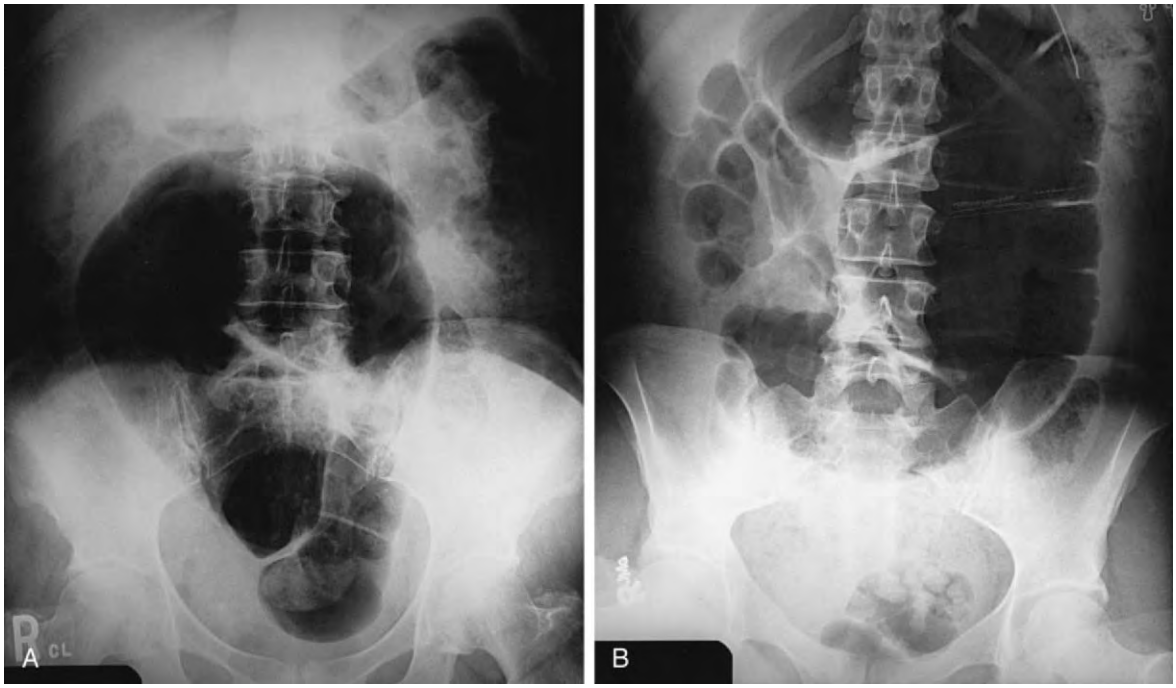

Figure 144–2. **A,** Plain abdominal radiograph of a sigmoid volvulus with the "bent inner tube" sign. The colon is the shape of a coffee bean, with proximal fecal impaction. **B,** Plain radiograph of a cecal volvulus with the kidney bean–shaped rotated ileocecal region and proximal small bowel obstruction.

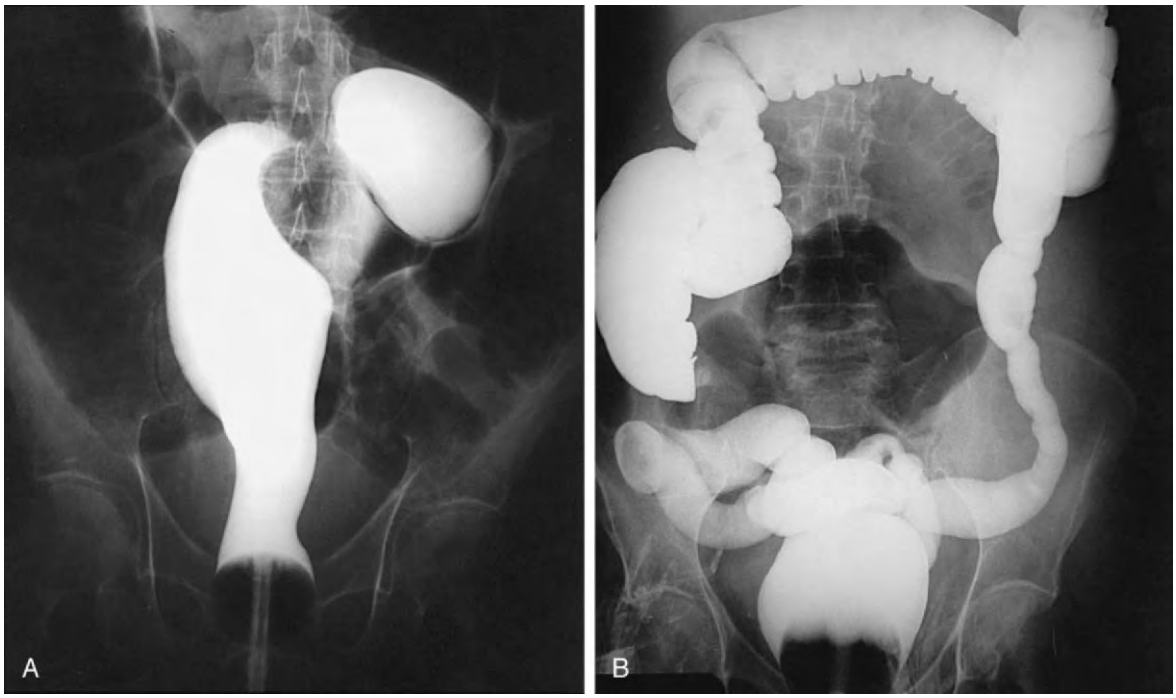

Figure 144–3. **A,** Barium enema of sigmoid volvulus demonstrating the classic "bird's beak" at the point of the twist. **B,** Barium enema of cecal volvulus, with the bird's beak in the ascending colon and proximal colonic distention.

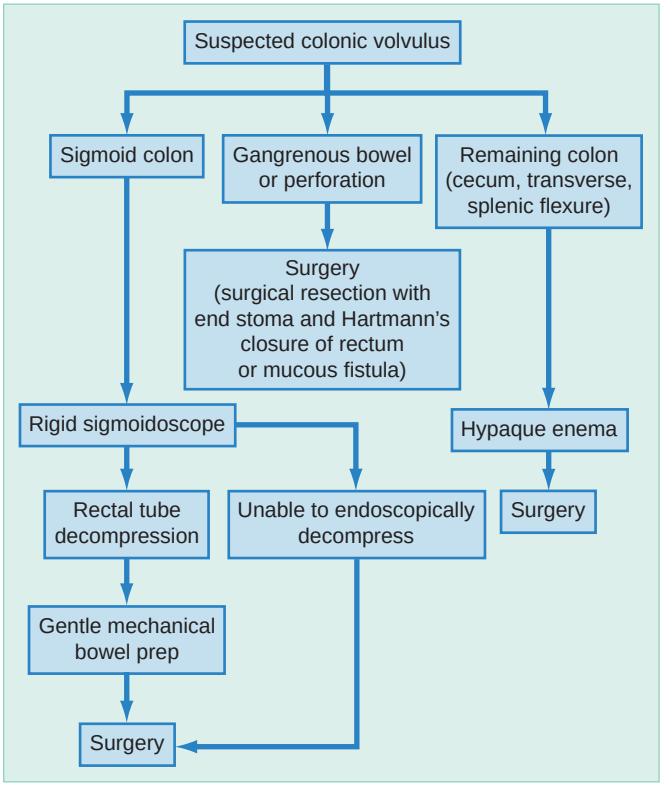

Figure 144–4. Treatment algorithm for patients with suspected volvulus.

second commonest cause of large bowel obstruction following colon cancer. Geographic variations in incidence are well established, with a much higher frequency in countries whose inhabitants consume a high-fiber diet, such as Africa, India, Pakistan, Middle East, and eastern Europe.[8-10] High-fiber diet is thought to lengthen the colon, with resulting elongation of the sigmoid mesentery. A genetic predisposition has also been identified within certain families and tribes.[11,12]

The average age of patients with sigmoid volvulus in the United States is in the 60s and 70s, whereas patients in endemic areas tend to be younger. The two sexes are equally affected in English-speaking countries, but males predominate in other parts of the world. It has been suggested that there is a higher prevalence of neuropsychiatric disorders in patients from Western countries with sigmoid volvulus. In a collected series of 244 patients, Ballantyne[8] found that 32.4% of patients were admitted from mental institutions and 12.7% were admitted from nursing homes. In addition, sigmoid volvulus is more common in patients with conditions associated with a redundant sigmoid colon such as Chagas' disease, Parkinson's disease, chronic neurologic disorders, diabetes, chronic constipation, laxative abuse, and previous surgery involving mobilization of the sigmoid colon. It is the second commonest cause of intestinal obstruction following adhesions in pregnant women, presumably because a redundant sigmoid colon is prone to torsion as the uterus grows out of the pelvis during the second and third trimester. A high index of suspicion is needed in this patient population as symptoms of nausea, vomiting, and abdominal pain can often be incorrectly attributed to pregnancy. Urgent surgical intervention is often required because of the risk to both the mother and fetus.

Torsion of the sigmoid colon involves at least 180 degrees of rotation usually in a clockwise direction around its vascular pedicle, resulting in a closed-loop obstruction of the sigmoid colon and possibly a second closed-loop obstruction of the proximal colon if the ileocecal valve is competent. As a result, intestinal ischemia and necrosis may result in both closed-loop segments either indirectly as a result of significant luminal distention and venous compromise or as a result of arterial vascular compromise resulting from torsion and occlusion of vessels within the sigmoid mesocolon. Plain abdominal radiographs reveal a dilated sigmoid colon that takes the appearance of an "ace of spades" or "bent inner tube" or "omega loop" which arises from the left lower quadrant (see Fig. 144–2A).

Treatment

Nonoperative The initial treatment in the patient with no evidence of bowel necrosis based on history and physical examination should involve an urgent nonoperative endoscopic attempt at reduction of the volvulus.[13] Rigid sigmoidoscopy is the preferred diagnostic and therapeutic modality that can be easily performed with minimal air insufflation in the emergency department. This modality allows for direct visualization of the rectal mucosa to exclude the presence of tissue necrosis and a distal neoplastic lesion. The sigmoidoscope can usually be gently passed through the narrowed edematous twisted point of obstruction to reduce the volvulus. A well-lubricated large-diameter rectal tube (No. 30 to 36 French) is then inserted through the sigmoidoscope across the twisted segment and secured to the skin for several days to maintain colonic decompression. An abdominal radiograph should be obtained following endoscopic detorsion to confirm resolution of the volvulus. Ballantyne[9] reported a success rate of 59% in a series of 352 consecutive patients with sigmoid volvulus living in the United States. Alternatively, flexible endoscopy using minimal air insufflation and manipulation has been used to permit inspection of the mucosa at and proximal to the point of obstruction; again, a rectal tube is left in place in patients with viable bowel.[14,15] At the time of flexible endoscopy, a blunt-ended guidewire can be inserted under direct visualization proximal to the volvulus and a rectal tube passed over the guidewire following removal of the endoscope. To a much lesser extent, reduction with enemas and the blind insertion of a rectal tube are techniques that can avoid urgent surgery.

Operative Following initial reduction of the sigmoid volvulus by sigmoidoscopy, the volvulus will recur in at least 40% of patients.[14-17] Such a high recurrence rate justifies an elective prophylactic sigmoid resection *during the same hospitalization* after the first episode of volvulus in all patients except in high-risk surgical candidates. Under

these circumstances, a mechanical bowel preparation can be administered and a primary anastomosis performed. Laparoscopic resection can be attempted in patients managed conservatively with adequate colonic decompression and in those able to tolerate both pneumoperitoneum and steep Trendelenburg positioning. In patients with significant comorbidities, our bias has been to use a transverse muscle-splitting incision to perform a sigmoid resection combined with postoperative epidural analgesia.

Failure to successfully reduce the volvulus endoscopically or clinical evidence of vascularly compromised bowel mandates emergent celiotomy. Resection of gangrenous bowel is required, with the creation of an end colostomy and Hartmann's or mucous fistula being the safest option in the absence of formal mechanical bowel preparation. If the bowel is of questionable viability, derotation usually in a counterclockwise manner with observation for the return of adequate perfusion may avoid resection. Often the use of a Doppler probe or Wood's lamp following intravenous administration of fluorescein can help in further evaluating for bowel viability. Under these circumstances, a colopexy involving fixation of the sigmoid to the anterior abdominal wall to prevent recurrent volvulus can be performed but is associated with a high incidence of recurrence.[16] Alternatively, single-stage resection with on-table lavage and primary anastomosis may be considered. In our experience, this is performed in only a small subgroup of patients that are hemodynamically stable and otherwise healthy individuals that are able to tolerate the added operative time and the potential risk of anastomotic dehiscence. In the presence of associated megacolon, total colectomy with ileorectal anastomosis may be considered, again with a goal of avoiding a multistage operative approach that requires a temporary stoma.

Outcomes Following Treatment

Operative mortality rates for emergent surgery for sigmoid volvulus are considerably higher in the presence of intestinal gangrene or failed nonoperative reduction, approximating 40%.[9] In comparison, the mortality rate for an elective resection following successful endoscopic reduction is less than 10%.[9]

Ileosigmoid Knot

Ileosigmoid knotting is an unusual entity that is most often confused with sigmoid volvulus.[18,19] In this condition, a loop of ileum wraps around the base of a redundant sigmoid loop, causing a double obstruction of both the colon and the small bowel. Attempts at endoscopic reduction of the volvulus are always unsuccessful, and this diagnosis should be considered in the subgroup of patients in whom endoscopic decompression is not possible. Rapid progression to gangrene of the colon and small bowel is the rule, necessitating urgent operative intervention. Resection of the involved small bowel is added to whatever procedure is dictated by the condition of the sigmoid.

Cecal Volvulus

Etiology and Pathophysiology

In the United States, the cecum and right colon represent the second most common site of volvulus but only account for 1% of all intestinal obstructions. The lack of retroperitoneal fixation of the right colon during fetal development predisposes to axial rotation of the ileocolic junction most commonly in a clockwise direction resulting in a cecal volvulus. The term *cecal volvulus* is misleading as this process is often not limited to the cecum alone but usually involves terminal ileum, ileocecal valve, cecum, and ascending colon. Clinical presentation and evaluation are as outlined earlier and mimic small bowel obstruction. Typically, plain abdominal radiographs reveal a dilated kidney bean–shaped ileocecal region with associated proximal small bowel dilation (see Fig. 144–2B).

A variant of cecal volvulus termed *cecal bascule*, is a condition in which a mobile cecum folds anteriorly and superiorly over a fixed ascending colon without rotation on the vascular pedicle. Consequently, this is not a true volvulus since axial rotation of the intestine is not associated with twisting of the associated mesentery and blood vessels. Although local ischemia and infarction have been reported, vascular embarrassment occurs less frequently. Radiographic investigation with barium enema is useful in diagnosing a cecal bascule, which accounts for 10% of instances of cecal volvulus.[7,10]

Although cadaveric dissections estimate that between 11% and 22% of adults have a sufficiently mobile right colon to allow for development of a cecal volvulus, it remains a rare condition. Predisposing epidemiologic factors are similar to those discussed for sigmoid volvulus and include a history of chronic constipation, obstructing colon lesions, malrotation, use of cathartics, pregnancy, and previous abdominal surgery. Cecal volvulus occurs more commonly in females and has been reported in all age groups, with an average age of presentation in the 40s.[10]

Treatment

Nonoperative Nonoperative treatment of cecal volvulus with endoscopy is much less successful than in patients with sigmoid volvulus. Colonoscopy is usually reported to be successful in fewer than 30% of patients.[15,20] Debate continues as to whether it should even be attempted because the procedure insufflates air into the obstructed segment and may precipitate ischemic changes by increasing the intraluminal pressure. Colonoscopic decompression with minimal air insufflation and manipulation can be effective in high-risk surgical patients with no clinical or biochemical evidence of bowel ischemia to avoid or temporarily defer surgery. A contrast enema is often useful in establishing a diagnosis of cecal volvulus as well as ruling out a distal partially obstructing colon lesion that may have predisposed to cecal distention; however, attempts at reduction using barium insufflation pressure enemas are contraindicated and potentially dangerous.

Operative Cecal volvulus is usually treated by urgent celiotomy. Controversy exists regarding the most appropriate procedure for viable bowel: detorsion alone (usually in a counterclockwise manner), detorsion with fixation, detorsion with cecostomy, and segmental resection all have been advocated.[21-23] This controversy relates in part to the lack of prospective data comparing the various surgical approaches. Resection of the involved bowel is required for ischemic or perforated colon, usually with a primary ileocolonic anastomosis. An ileostomy rather than an anastomosis may be required in selected circumstances. Cecal bascule can often be managed with a well-performed cecopexy as long as there is no evidence of bowel necrosis or gangrene.

Outcomes Following Treatment

When surgical resection has been performed, the recurrence rate for volvulus is nearly 0% compared with approximately 15% for cecopexy or detorsion alone. Cecopexy involves suturing the right colon to the lateral peritoneal surface and risks the sutures pulling though the thin-walled, distended cecum. Although the recurrence rate is low after cecostomy, postoperative management of a cecostomy tube is associated with a high incidence of abdominal wall and wound complications, as well as a persistent fecal fistula in up to 50% of patients.[24] Furthermore, this is not an option in the presence of nonviable bowel. As a result, our preference has been to perform a resection and primary anastomosis in most patients with cecal volvulus. Operative mortality rates are substantially higher in the presence of intestinal gangrene or perforation.[25]

Transverse Colon and Splenic Flexure Volvulus

Etiology and Pathophysiology

Volvulus of the transverse colon or splenic flexure is rare, accounting for fewer than 5% of all cases.[7,10] Presumably, the broad mesenteric attachment of the transverse colon combined with fixation at the hepatic and splenic flexures precludes rotation of the transverse colon in most patients. Epidemiologic studies suggest that the incidence increases in patients with chronic constipation, distal obstructing lesions, previous abdominal surgery, pregnancy, and hypermobile colonic flexures. Hypermobile colonic flexures can occur as a result of congenitally absent or surgically divided important support structures that include the gastrocolic, lienocolic, and phrenocolic ligaments.

Clinical presentation is, again, as outlined earlier and cannot be distinguished from other causes of large bowel obstruction. However, vomiting is thought to be an earlier symptom due to twisting of the transverse mesocolon and compression of the duodenojejunal junction.

Treatment

Nonoperative Plain abdominal radiographs show nonspecific colonic dilation and are frequently misread as a sigmoid volvulus due to the variable position of the transverse colon. As a result, patients are frequently colonoscoped with no clear transition point evident in the sigmoid colon. Under these circumstances, further attempts to identify a transition point should be terminated and a contrast enema study obtained. Although successful colonoscopic decompression has been previously described, there is a risk of excessive insufflation resulting in increased cecal distention and vascular compromise.

Operative Confirmation of transverse or splenic colon volvulus by contrast enema study is generally followed by surgical intervention. Resection of the involved segment is usually required, with primary anastomosis when possible. This can be accomplished with either an extended right hemicolectomy, partial left colectomy, or segmental transverse colectomy. Subtotal colectomy with ileocolonic anastomosis is an attractive single-stage option in the unprepared bowel if the sigmoid colon is not long and tortuous. A technique of fixation without resection has been described in which the redundant transverse colon is sutured to the ascending and descending colon.[26] Derotation followed later by elective resection offers the disadvantage of a second laparotomy. Perforation may require an end colostomy and mucous fistula because of concerns regarding anastomotic security.

Outcomes Following Treatment

Given the rarity of both transverse and splenic flexure volvulus, limited data are available regarding long-term results following the various surgical interventions. Anderson et al. reported a 75% recurrence rate in patients treated with colopexy alone.[27] As a result, our bias has been to perform either an extended right hemicolectomy or subtotal colectomy with ileocolonic anastomosis.

Colonic Bleeding and Ischemia

Ronald Kaleya · Scott J. Boley

During the past 4 decades, vascular lesions of the colon have been recognized as a major cause of rectal bleeding, especially in the geriatric patient population. However, despite the plethora of articles published on these vascular abnormalities, confusion and controversy remain concerning the pathogenesis, natural history, appropriate therapy, and proper naming of these lesions. Although many reports have grouped them together, several distinct entities can be identified (Box 145–1), each having as its common feature the passage of blood via the rectum.

VASCULAR ECTASIAS

Vascular ectasias of the colon are by far the most common vascular lesions found in the colon and are probably the most frequent cause of recurrent lower intestinal bleeding after 60 years of age.[1] They are distinct pathologic[2] and clinical[3] entities, and in our concept of their pathogenesis, they arise from age-related degeneration of previously normal colonic blood vessels. Vascular ectasias almost always occur in the cecum or the proximal ascending colon, are usually multiple, are less than 5 mm in diameter, are rarely identified with gross inspection or routine pathologic examination, are diagnosed with colonoscopy or angiography, and unlike many congenital or neoplastic vascular abnormalities, are not associated with synchronous angiomatous lesions of the skin, mucous membranes, or other viscera.

Incidence and Pathophysiology

There is no sex predilection for the development of vascular ectasias. Most patients are older than 50 years and two thirds are older than 70. Mucosal vascular ectasias of the right colon can be found in more than 25% of asymptomatic patients older than 60 years who undergo routine colonoscopy.[4]

Any hypothesis concerning the formation of colonic vascular ectasias must account for their prevalence in elderly persons, their small size and multiplicity, and their preponderance in the cecum and right colon. Although the cause of these lesions has not been definitively established, injection and clearing studies have led us to postulate that vascular ectasias are degenerative lesions associated with aging and represent a unique entity distinct from previously described intestinal vascular abnormalities. We believe that over time, normal contraction and distention of the colon cause repeated, partial, intermittent, low-grade obstruction of submucosal veins, especially at the point where they pierce the muscular layers of the colon. These repeated episodes of transiently elevated venous pressure initially cause dilation and tortuosity of the submucosal veins and then, in a retrograde manner, of the venules and the arteriolar/capillary/venular units draining into them. Ultimately, the capillary rings surrounding the crypts dilate and the competency of the precapillary sphincters is lost, thereby creating a small arteriovenous communication (Fig. 145–1). The latter produces an early-filling vein, which was the original angiographic criterion for diagnosis of this lesion. These abnormal submucosal veins, found in the absence of a mucosal lesion or underlying a minute mucosal ectasia supplied by a normal artery, suggested that submucosal vein dilation was the primary pathologic change rather than arterialization from an arteriovenous communication. The theory that intramural veins are partially obstructed by functional colonic activity is supported by several earlier studies. Venous flow in the bowel is diminished by colonic motility, increased wall tension, and increased intraluminal pressure.[5-7] Rhythmic alterations in venous blood flow and venous pressure related to colonic contractions have also been demonstrated.[8] The presence of these degenerative lesions in the cecum and right colon may be explained by Laplace's law; specifically, during periods of colonic distention, wall tension will be greatest in the portion of bowel with the widest diameter (cecum and right colon).

Box 145–1 Vascular Lesions of the Colon

- Vascular ectasia
- Hemangioma
- Congenital arteriovenous malformation
- Colonic varices
- Telangiectasia
- Syndrome-related lesions (e.g., Klippel-Trénaunay-Weber syndrome, Maffucci's syndrome)
- Others
  - Vascular spiders and venous stars of liver disease
  - Degenerative phlebectasia of the elderly
  - Vasculitic lesions
  - Focal hypervascularity of ulcerative, Crohn's, and ischemic colitis
  - Neovascularity of radiation colitis
  - Angiosarcoma (e.g., Kaposi's sarcoma)

Approximately 25% of patients with bleeding ectasias have a diagnosis of aortic stenosis. Some investigators ascribe a causative role for ectasias to aortic valvular disease. We do not believe that there is an etiologic relationship between aortic stenosis and the development of colonic ectasias. Rather, there may be some feature of aortic stenosis, perhaps the low pulse pressure or decreased systemic perfusion characteristic of this disorder, that can increase the chance of bleeding in individuals who have vascular ectasias. For instance, a low-flow state may lead to ischemic necrosis of the single endothelial layer that separates the ectatic vessels from the colonic lumen. Alternatively, a roughened or stenotic aortic valve could produce a mild consumptive coagulopathy or a subtle alteration in platelet function, and these defects, combined with a thin-walled, dilated, mucosal vascular lesion, may cause an ectasia to bleed.[9]

In view of these factors and contradictory evidence concerning the beneficial effect of aortic valve replacement in the treatment of bleeding ectasias, it seems prudent to consider cardiac disease and colonic lesions as separate and only potentially related entities. A rational approach appears to be that initial therapy should be directed to the colonic lesion if the patient's cardiac status does not require surgical correction. If valvular replacement is indicated, however, it should be done first and treatment of the colonic ectasia deferred unless or until there is continuing or recurrent postoperative bleeding.

Histologic identification of vascular ectasia is difficult without special techniques, as demonstrated by our early experience. Of seven patients with angiographically demonstrated colonic ectasia who were studied only by routine gross examination and microscopic study of random or selected colonic sections, a mucosal ectasia could be identified in only two patients. Our technique for localization and identification of vascular ectasia consists of injection of a silicone rubber compound (Microfil) through catheters placed in one or more of the arteries supplying the colon. Specimens are then dehydrated in increasing concentrations of ethyl alcohol and are cleared with methyl salicylate. This process produces a transparent specimen with a filled vascular bed that is studied by dissection microscopy under direct light, as well as transillumination. In the first 25 colons in which we used this technique, one or more mucosal ectasias, measuring 1 mm to 1 cm in diameter, were identified in all of the specimens (Fig. 145–2). Seven colons contained two lesions, and 11 colons contained three or more lesions. The ectasias were all located within the cecum and the proximal part of the ascending colon; the most distal one was 23 cm from the ileocecal valve. All the cleared specimens had prominent dilated and tortuous submucosal veins, both beneath the ectasias and in areas in which the mucosal vessels appeared normal (Fig. 145–3). The colon from the oldest patient, an 88-year-old man, contained approximately 50 mucosal ectasias of various size.

Microscopically, vascular ectasias consist of dilated, distorted, thin-walled vessels, mostly lined only by endothelium and, less frequently, by a small amount of smooth muscle. Structurally, they appear to be ectatic veins, venules, and capillaries. The degree of distortion of the normal vascular architecture varies in different lesions, but the most consistent and apparently the earliest abnormality noted in all of the lesions we have studied is the presence of dilated, often huge, submucosal veins (Fig. 145–4A). Progressively more extensive lesions show increasing numbers of dilated and deformed vessels traversing the muscularis mucosa and involving the mucosa until, in the most severe lesions, the mucosa is replaced by a maze of distorted, dilated vascular channels (see Fig. 145–4B).

Clinical Aspects

Except for lower intestinal bleeding, vascular ectasia of the colon is asymptomatic. Bleeding from ectasias is usually recurrent and low grade. Approximately 15% of patients, however, have massive hemorrhage and, less frequently, are in hemorrhagic shock. During repeated episodes, bleeding in an individual patient may range from gross hematochezia to maroon-colored stools, melena, and occult blood in the stool. Tarry stools are passed in 20% to 25% of episodes, and blood loss is manifested as iron deficiency anemia and stools that intermittently contain occult blood in 10% to 15% of patients. This spectrum reflects the varied rate of bleeding from the ectatic capillaries, venules, and in advanced lesions, arteriovenous communications. In more than 90% of patients, the bleeding stops spontaneously.

In the early series, as many as 30% of patients with colonic vascular ectasia had previously undergone surgery for other suspected sources of intestinal bleeding, including partial gastrectomy, vagotomy with antrectomy or pyloroplasty, and left colon resection for purported diverticular bleeding. None of the patients in our series who underwent left colectomy had angiographic or histologic documentation of a bleeding site at

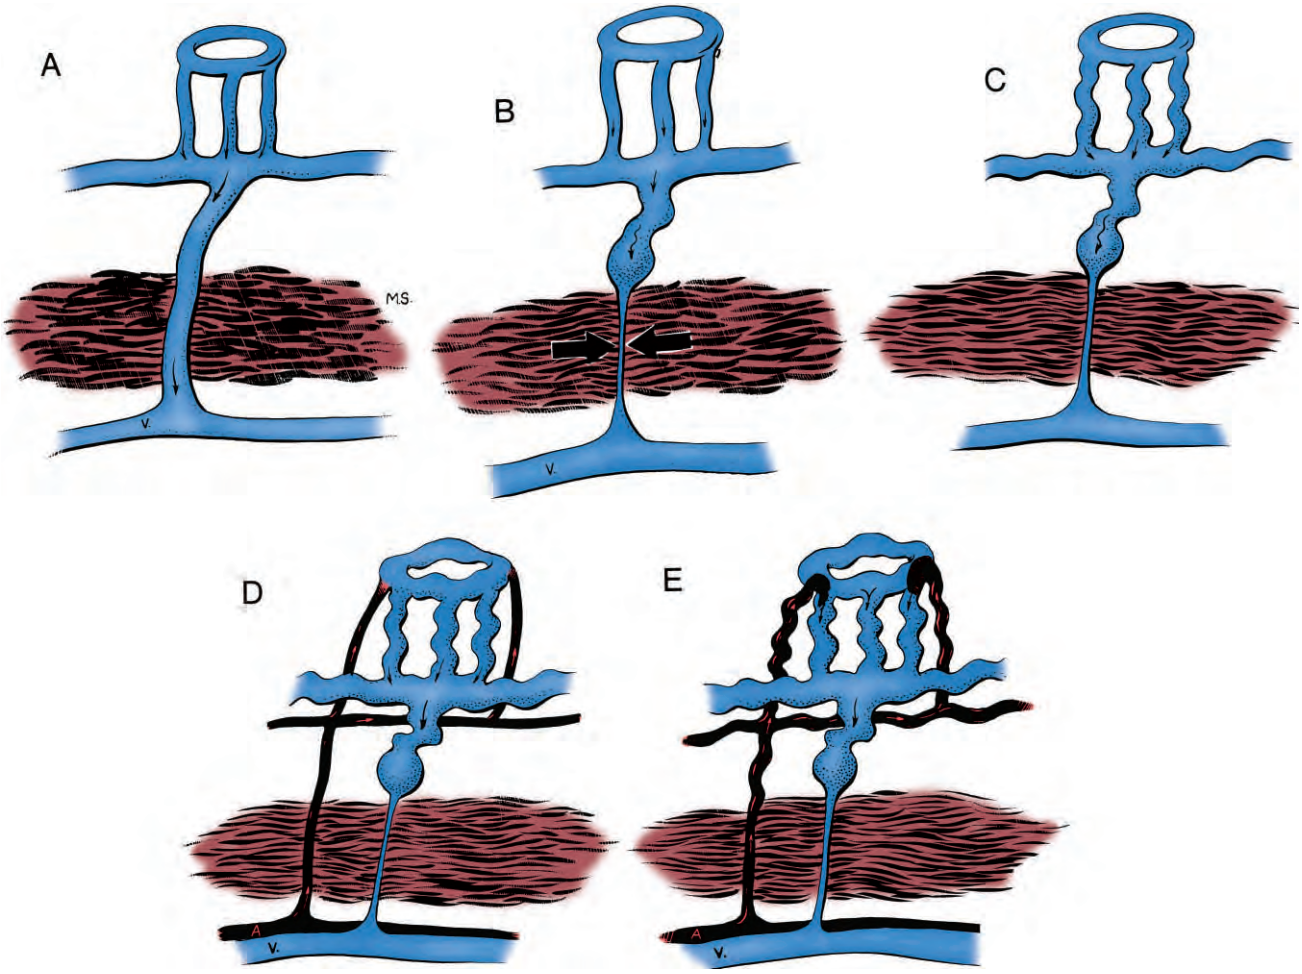

Figure 145–1. Diagrammatic illustration of a proposed concept of the development of cecal vascular ectasia. **A,** Normal state of a vein perforating the muscular layers. **B,** With muscular contraction or increased intraluminal pressure, the vein is partially obstructed. **C,** After repeated episodes over a period of many years, the submucosal vein becomes dilated and tortuous. **D,** Later, the veins and venules draining into the abnormal submucosal vein become similarly involved. **E,** Ultimately, the capillary ring becomes dilated, the precapillary sphincter becomes incompetent, and a small arteriovenous communication is present through the ectasia. (From Boley SJ, Sammartano RJ, Adams A, et al: On the nature and etiology of vascular ectasias of the colon: Degenerative lesions of aging. Gastroenterology 72:650, 1977, with permission.)

the time of the previous operations. However, the proportion of patients who have undergone previous operations has decreased because the diagnosis is established earlier and physicians are more willing to refer patients for endoscopic ablation or surgery before repeated episodes of bleeding occur.

The problem of differentiating blood loss from vascular ectasias or diverticulosis when bleeding is not demonstrated endoscopically or angiographically is compounded by the frequent occurrence of these lesions without bleeding in persons older than 60 years. Diverticulosis occurs in up to 50% of persons older than 60 years, and nonbleeding mucosal vascular ectasias of the right colon have been found in more than a fourth of persons of the same age. Therefore, in the absence of a demonstrated site of hemorrhage, bleeding can be attributed to an ectasia or diverticulosis only indirectly by observing the course of the patient after resection of the suspected lesion. Furthermore, in some patients with angiographically confirmed vascular ectasias, another unrelated and undetected nondiverticular lesion may be responsible for the blood loss.[10,11] The prevalence of a second type of lesion in patients with vascular ectasias is not known. However, recurrent lower intestinal bleeding is noted in 15% to 20% of patients who have undergone right hemicolectomy for angiographically proven vascular ectasias,[12,13] thus suggesting that a second source may have been present in as many as a fifth of affected patients.

Diagnosis

The diagnostic approach that we use in patients with lower gastrointestinal (LGI) bleeding (Fig. 145–5) varies with their age, the presence or absence of active

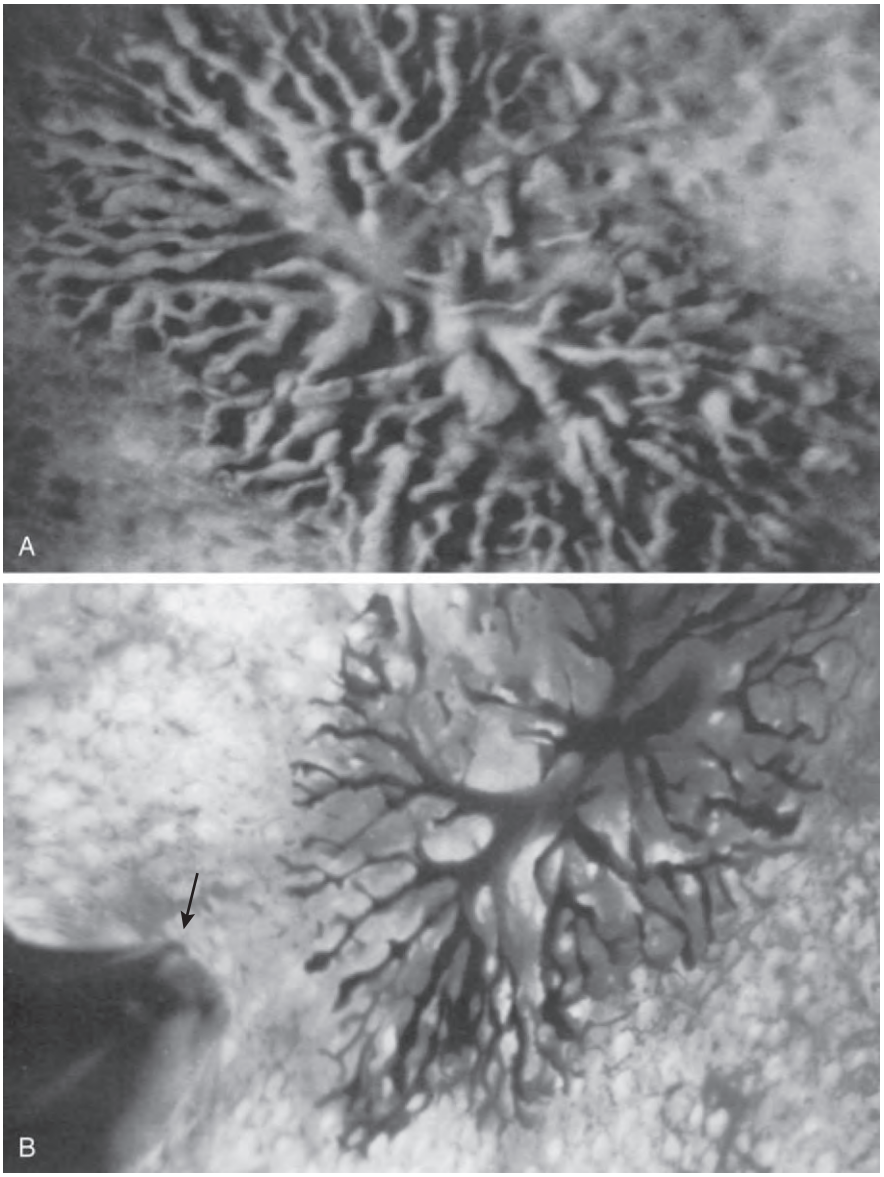

Figure 145–2. **A,** "Coral reef" appearance of an ectasia in an injected, but not cleared colon. bleeding, and the severity of hemodynamic compromise caused by the blood loss. All patients with LGI bleeding should have a coagulation profile performed, including a platelet count, prothrombin time, and partial thromboplastin time, to identify clotting abnormalities. Further evaluation of patients with LGI bleeding depends on the rate of blood loss.

Major Bleeding Major bleeding is defined as (1) acute blood loss causing hemodynamic signs of hypovolemia or (2) the sudden passage of large amounts of bloody, maroon, burgundy, or melenic stools in the absence of hemodynamic compromise.

Because 10% to 15% of major LGI bleeding begins in the upper gastrointestinal (UGI) tract,[14] nasogastric lavage follows assessment of the coagulation status and digital rectal examination. A bloody aspirate indicates UGI bleeding in most cases, whereas the absence of blood and the presence of bile in the aspirate virtually exclude bleeding proximal to the ligament of Treitz. A clear, nonbilious aspirate is, however, an indication for UGI endoscopy in actively bleeding patients because there may be a lesion distal to a closed pylorus. A blood urea nitrogen level of less than 30 mg/dl occurs in approximately two thirds of patients with major bleeding proximal to the colon and may help guide the clinician toward a putative bleeding site. A standard proctosigmoidoscopic examination is conducted to exclude anorectal and distal sigmoid pathology.

Rigid sigmoidoscopy is followed by abdominal scintigraphy in actively bleeding patients because the latter may localize the bleeding site or, alternatively, confirm the cessation of bleeding, thereby enabling the clinician to choose colonoscopy or angiography as the next diagnostic modality. Scintigraphy is noninvasive, safer than angiography and colonoscopy, more sensitive in detecting active bleeding than angiography is, and capable of identifying bleeding over a 24-hour period, not just during the brief period of a colonoscopic examination or injection of an angiographic contrast agent.[15,16] Two

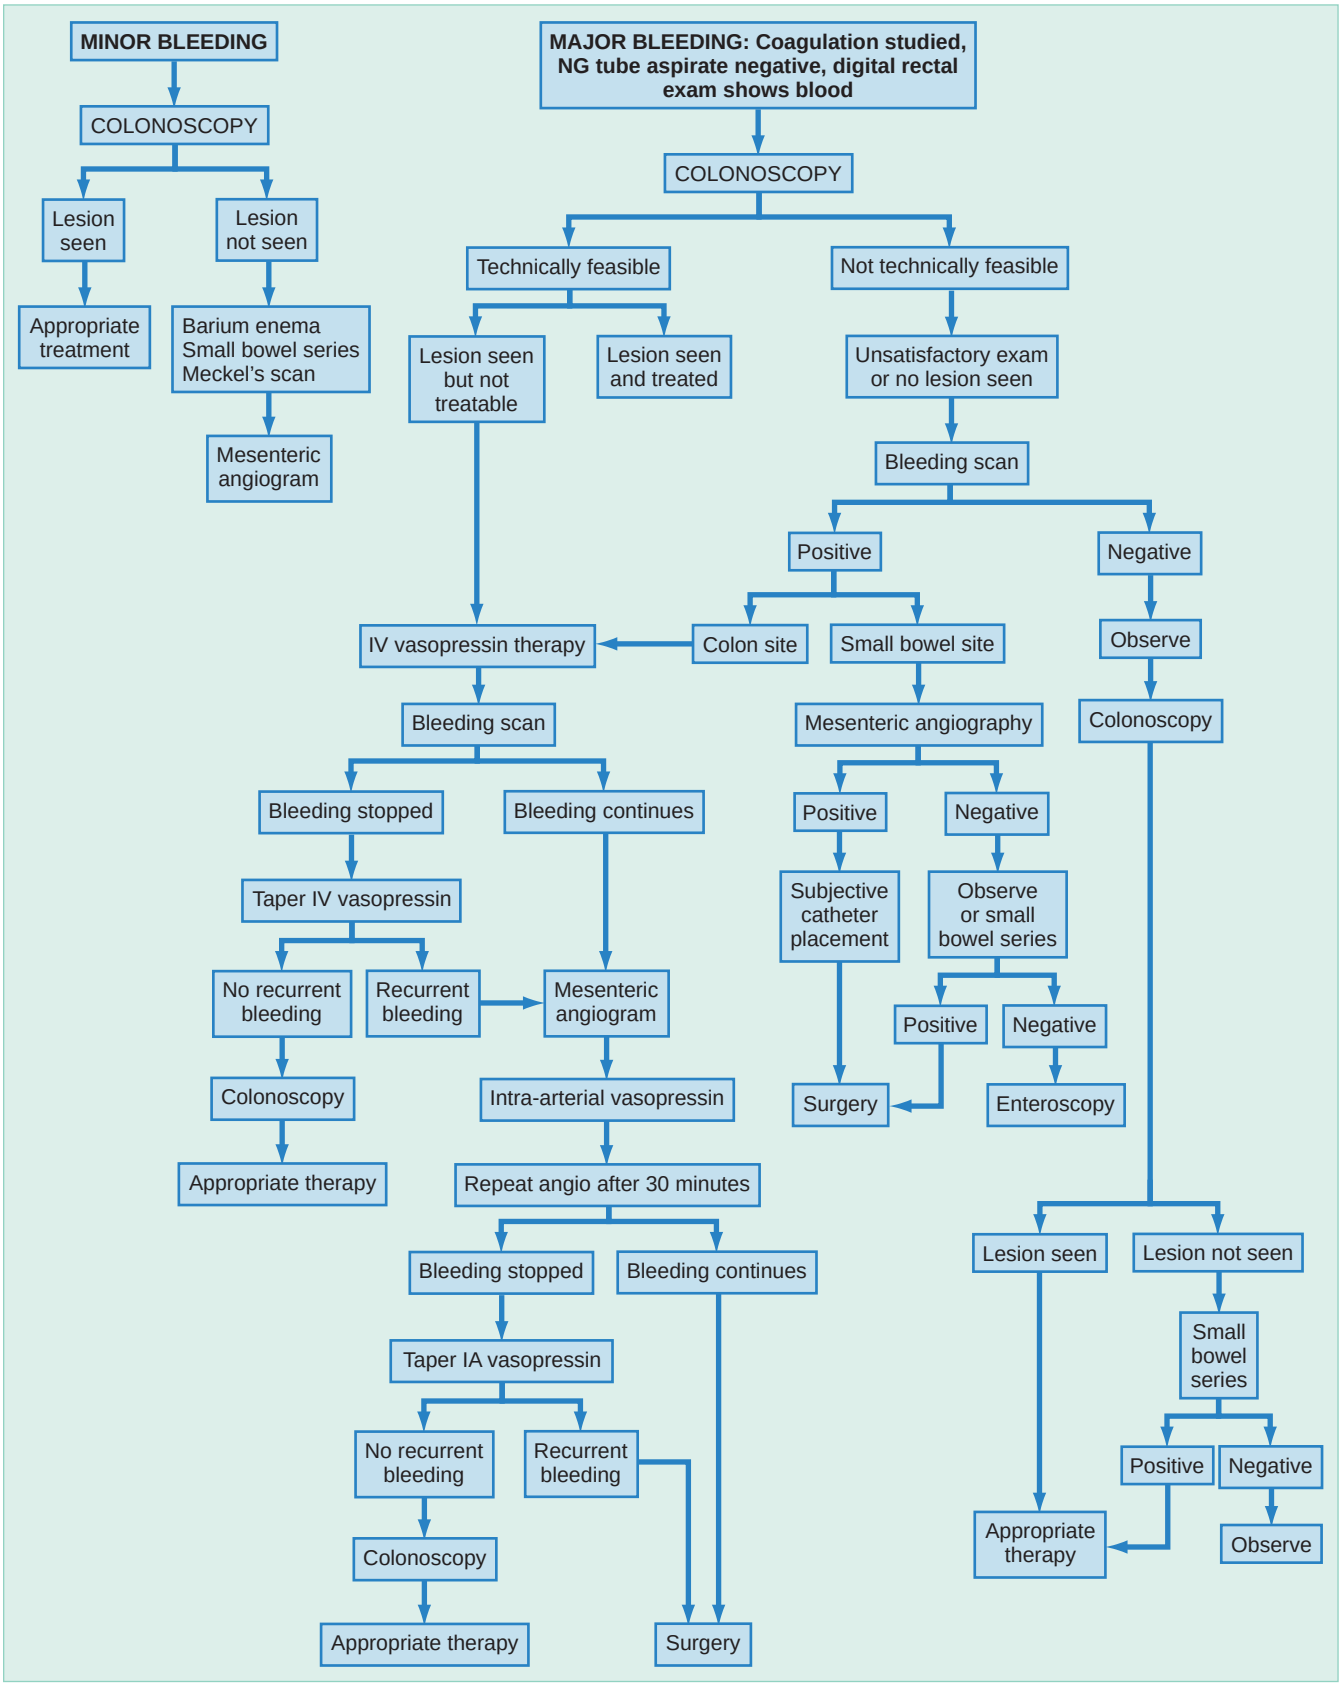

Figure 145–5. Diagnostic algorithm for lower intestinal bleeding. IA, intra-arterial; IV, intravenous; NG, nasogastric.

radionuclides commonly used to detect intestinal bleeding are ^{99m}Tc-labeled sulfur colloid and ^{99m}Tc-labeled red blood cells (RBCs). Previously, ^{99m}Tc–sulfur colloid scanning was considered the more sensitive of these two techniques and, because it is rapidly cleared from the circulation (plasma half-life of only 2 to 3 minutes), the best agent for detecting active bleeding. Although it was thought to be less sensitive than sulfur colloid scanning, ^{99m}Tc-RBC scanning was considered very useful for detecting intermittent bleeding, primarily because of the 24-hour half-life of Tc-labeled RBCs. It now appears that only ^{99m}Tc-RBC labeling is necessary because both clinical[17] and experimental[18] studies have found that it is as sensitive as sulfur colloid and can reliably detect active bleeding even at rates below 0.1 ml/min. Unlike sulfur colloid scanning, with RBC scintigraphy, serial studies can be obtained for up to 36 hours after a single injection of the radionuclide, thus detecting lesions that bleed intermittently. Furthermore, unlike sulfur colloid, ^{99m}Tc-labeled RBCs are not cleared by the liver and spleen, so bleeding in the area of these organs, which is often obscured with sulfur colloid, can be visualized.

Active Major Bleeding If scintigraphy demonstrates a bleeding site in the colon and the patient is hemodynamically stable, colonoscopy is performed. In this circumstance, clotted blood within the colon often obscures visibility and increases the risks associated with the procedure. Because of this increased risk, if the bleeding site is shown by the scan to be proximal to the midportion of the transverse colon, colonoscopy should be abandoned if technical difficulties are encountered. If a site of hemorrhage is identified distal to the midportion of the transverse colon, extra effort to cleanse the bowel and proceed cautiously is usually rewarding.

Although colonoscopy is playing an increasing role in the diagnosis of colonic vascular lesions, the endoscopist's ability to diagnose the specific lesion is limited by the similar appearance of many vascular, inflammatory, neoplastic, and iatrogenic abnormalities. Indeed, vascular ectasias can be mimicked by any of the lesions listed in Box 145–1. Thus, vascular lesions should preferably be evaluated on entering the colon rather than on withdrawal to avoid traumatic and suction artifacts that limit the endoscopist's ability to identify and differentiate these lesions.[19]

Angiography is performed if neither scintigraphy nor colonoscopy reveals the bleeding site, if colonoscopy is not technically feasible, if scintigraphy demonstrates bleeding within the small bowel, or if the patient continues to bleed actively. A selective superior mesenteric arteriogram is the initial study performed because 50% to 80% of all LGI bleeding occurs in the vascular bed fed by the superior mesenteric artery (SMA). Selective inferior mesenteric artery (IMA) and celiac axis (CA) studies are performed in that order if the initial superior mesenteric arteriogram does not identify the lesion. Flush aortography is of no use in identifying bleeding lesions and is not performed.

Mesenteric arteriography may be productive both in patients with active bleeding and in those who have stopped bleeding. Extravasation of contrast material is the angiographic hallmark of active hemorrhage and can be seen with bleeding rates as low as 0.5 ml/min.[20] Angiographic signs of tumor neovascularization or vascular ectasias may identify a presumed cause and location of the hemorrhage.

Angiography can be diagnostic and provide access for treatment. In 80% of cases, active bleeding can be at least temporarily stopped by the transcatheter infusion of vasopressin. Transcatheter embolization of ectasias has been reported but should be used only in desperate situations because it may result in bowel infarction.

Angiography successfully identifies the source of lower intestinal bleeding in approximately two thirds of patients. Pooling of extravasated contrast material in a diverticulum is the angiographic sign of diverticular bleeding and was present in 75% of patients with diverticular bleeding in the series reported by Welch and colleagues.[21] In contradistinction, extravasation has been shown in only 10% to 20% of patients bleeding from vascular ectasias of the colon because the bleeding is usually episodic. However, the presence of other angiographic signs enables the diagnosis of colonic ectasia or other vascular lesions of the small and large bowel to be made even in the absence of active bleeding. There are three major angiographic signs of ectasia (Fig. 145–6). The earliest sign to develop in the evolution of an ectasia, and hence the one most frequently seen, is a densely opacified, dilated, *tortuous, slowly emptying intramural vein* that reflects ectatic changes in the submucosal veins. This sign is present in more than 90% of patients with ectasias. A *vascular tuft*, present in 70% to 80% of patients, represents a more advanced lesion and corresponds to extension of the degenerative process to mucosal venules. An *early-filling vein* is a sign of even more advanced changes and reflects an arteriovenous communication through a dilated arteriolar/capillary/venular unit. It is a late sign, present in only 60% to 70% of patients. All three angiographic signs are present in more than half of patients with bleeding ectasias. Intraluminal extravasation of contrast material alone is inadequate to diagnose an ectasia, but when seen in conjunction with at least one of the three signs of ectasia, it is indicative of a ruptured mucosal lesion.

On rare occasion, vigorous resuscitation with intravenous fluids and blood products may fail to stabilize a patient with major bleeding. Colonoscopy is best avoided in hemodynamically unstable patients, and therefore emergency angiography is the procedure of choice. Transcatheter or intravenous vasopressin will usually control such bleeding and convert an emergency situation into an elective one, thus saving the patient unnecessary and potentially debilitating surgery.

Major Bleeding That Has Ceased In patients with major LGI bleeding in whom proctosigmoidoscopy and nasogastric aspiration are negative and bleeding has ceased, scintigraphy is not performed and colonoscopy is the initial diagnostic procedure. Again, the presence of blood clots may severely limit visualization, obscure lesions, and make passage of the colonoscope technically difficult and hazardous. In these instances, enemas delivered through the colonoscope can be used to clean the

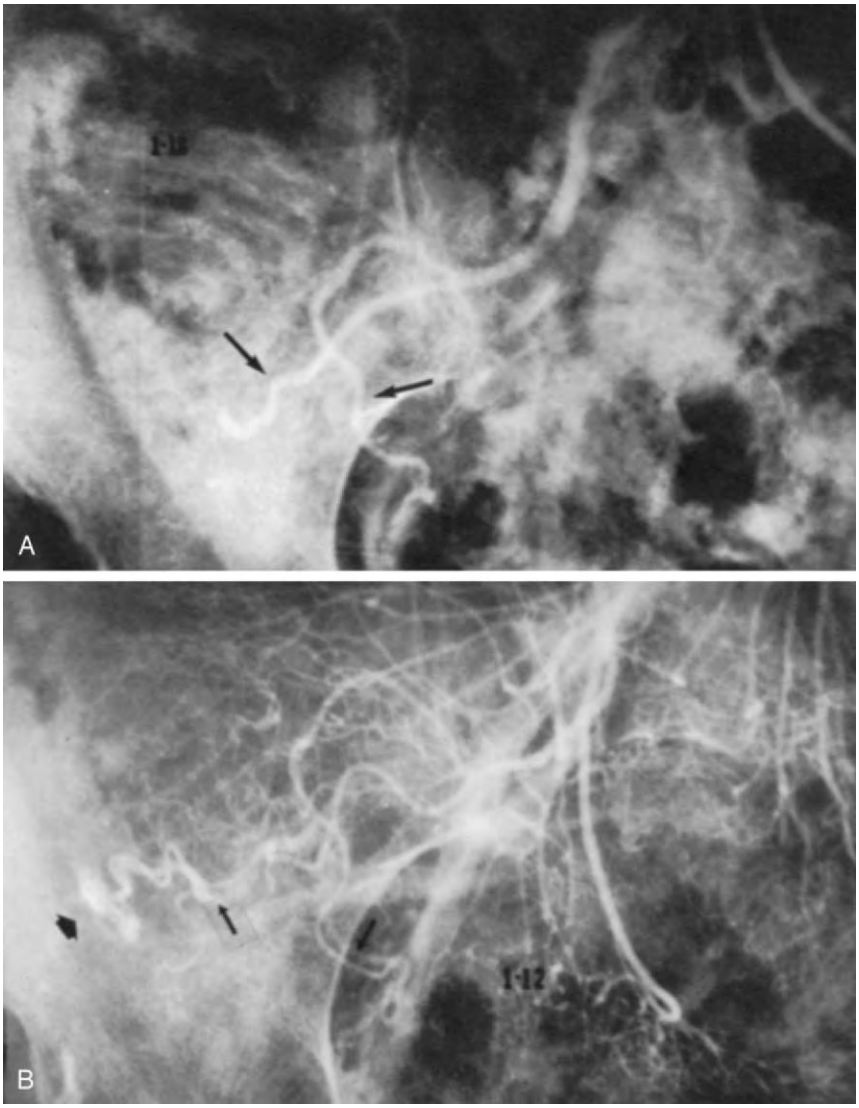

Figure 145–6. **A,** Superior mesenteric arteriogram from a patient with vascular ectasias showing only two densely opacified, slowly emptying, dilated, tortuous cecal veins (*arrows*) at 14 seconds. Note the late visualization of the ileocolic vein after other veins have cleared. **B,** Arterial phase from the same arteriogram showing an avascular tuft (*large wide arrow*) and two early-filling veins (*small arrows*) at 6 seconds. (From Boley SJ, Sprayregen S, Sammartano RJ, et al: The pathophysiologic basis for the angiographic signs of vascular ectasias of the colon. Radiology 125:615, 1977, with permission.)

lumen and bowel wall. If these efforts fail, the examination is postponed to prepare the patient with a polyethylene glycol–based agent (GoLYTELY, Colyte).

If complete and satisfactory colonoscopic examination reveals no explanation for the bleeding other than diverticulosis, double-contrast barium studies of the colon, the UGI tract, and the small bowel are indicated. If both colonoscopy and barium opacification studies are normal or show only the presence of diverticula, selective mesenteric angiography has been the most informative study in our experience. During angiography, the SMA, IMA, and CA are injected, in that order. Arteriography, when performed in patients whose bleeding has stopped, is used primarily to diagnose tumor neovascularity or vascular lesions, many of which have characteristic angiographic findings, thereby permitting them to be identified in the absence of extravasation. Other techniques, such as sequential long-tube aspiration of the intestine and small bowel enteroscopy, may also be of value.

Occasionally, an initially negative ^{99m}Tc-RBC study, performed because it was not clinically apparent whether the bleeding had stopped, may reveal extravasation during serial scanning and localize a lesion that bleeds intermittently. Patients with recurrent or persistent major bleeding for which no site of hemorrhage is found may require exploratory laparotomy with attempts at intraoperative localization (e.g., intraoperative enterocolonoscopy) to avoid blind resection of part or all of the colon.

Nonmajor Bleeding Nonmajor bleeding is defined by (1) a chemical test for blood in stool (occult LGI bleeding) or (2) the passage of hemodynamically insignificant amounts of either gross blood per rectum or melena. Although bleeding of this type has been identified in 25% to 30% of patients with ectasias, it is probably less common. Evaluation of patients with minor bleeding had consisted of rigid proctosigmoidoscopy, followed by single-contrast barium enema. However, this approach is

inadequate because (1) even flexible fiberoptic sigmoidoscopy cannot visualize the right colon and will therefore miss 40% of mass lesions and all vascular ectasias and (2) double- or air-contrast barium enema will be equivocal in 20% of cases and will regularly miss 40% of polyps, a third of cancers, 60% of discrete ulcerations and colitides, and all mucosal or submucosal vascular lesions.[22-24] Conversely, colonoscopy can reliably visualize the entire mucosal surface of the colon and should be the initial diagnostic study in patients with nonmajor bleeding. Retroflexion of the colonoscope in the rectal vault combined with meticulous examination of the anus during withdrawal of the instrument will provide sufficient examination of the anorectum to eliminate the need for rigid proctosigmoidoscopy. Barium enema is necessary only when the entire colon cannot be visualized endoscopically.

If colonoscopy is negative, esophagogastroduodenoscopy is performed, preferably on the same day, to examine the UGI tract. Negative esophagogastroduodenoscopy is followed by double-contrast radiography of the UGI tract and small bowel. On rare occasion, repeat endoscopic studies or barium enema may be contributory. If these studies are repeatedly normal but occult or slow bleeding continues, small bowel enteroscopy,[25] ^{111}In-labeled platelet scintigraphy,[26] or mesenteric angiography may at times be helpful. Less commonly, exploratory laparotomy with attempts at intraoperative localization may be the only alternative.[27]

Treatment

Once a colonic vascular ectasia has been identified, management consists of control of the acute hemorrhage and then definitive treatment of the lesion itself. Major changes in management have occurred since the original descriptions of vascular ectasia and include the increasing roles of radionuclide scanning and colonoscopy in identifying the cause and site of bleeding and transcolonoscopic ablation of focal lesions.

Control of Acute Hemorrhage

In most patients, acute hemorrhage can be controlled by nonoperative means, and an emergency operation, with its increased morbidity and mortality rates, can be avoided. In patients in whom colonoscopy has been successful and an actively bleeding ectasia or fresh mucosal thrombus (i.e., a sentinel clot) has been identified, transendoscopic ablation of the lesion is an effective mode of therapy. In patients who undergo angiography because colonoscopy was unsuccessful or not technically feasible, vasopressin infusions, either intravenously or intra-arterially through the angiographic catheter, successfully arrest hemorrhage in more than 80% of patients in whom extravasation is demonstrated. The intravenous route appears to be as effective as the intra-arterial route when the bleeding is in the left colon, but intra-arterial administration has been more successful when the bleeding is from the right colon or small bowel.

Definitive Treatment

During the first 15 years after vascular ectasias were described, definitive treatment consisted of some type of colon resection. Endoscopic electrocoagulation was a therapeutic option reserved mainly for elderly persons with complicated medical illnesses. Today, use of the argon laser, neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, endoscopic sclerosis, monopolar electrocoagulation, bipolar electrocoagulation, and the heater probe for miscellaneous vascular lesions throughout the gastrointestinal (GI) tract is well described. In institutions where physicians experienced in endoscopic surgery are available, a greater number of patients can be managed endoscopically, and resection is often reserved for patients whose bleeding cannot be stopped or in whom endoscopic treatment is unsuccessful.

Asymptomatic vascular ectasias are frequently noted incidentally during colonoscopy in many elderly patients. Most surgeons do not recommend treating asymptomatic cecal vascular lesions, but if increasing experience demonstrates some of the newer modes of therapy (e.g., bipolar electrocoagulation and the heater probe) to be safe, a more aggressive approach to these lesions may be warranted.

In patients who have bled and in whom an ectasia of the right colon has been identified by either colonoscopy or angiography, right hemicolectomy remains the treatment of choice if (1) the bleeding cannot be stopped, (2) an endoscopist experienced in transcolonoscopic ablation is not available, and (3) endoscopic ablation has been unsuccessful or is not feasible for technical reasons, such as large or multiple lesions. In the latter two situations, right hemicolectomy is performed as an elective procedure once active bleeding is controlled. The extent of colonic resection is not altered by the presence or absence of diverticulosis in the left colon; only the right half of the colon is removed. It is important that the entire right half of the colon be removed to ensure that no ectasias are left behind. Because up to 80% of bleeding diverticula are located in the right side of the colon, the risk of leaving the left colon is far outweighed by the increased morbidity and mortality rates for subtotal colectomy. Recurrent bleeding can be expected in up to 20% of patients so treated and was observed in 4 of our first 27 patients with angiographically proven ectasias. Subtotal colectomy should be performen only in patients with persistent colonic bleeding and normal colonoscopy and selective angiograms.

OTHER VASCULAR LESIONS

As shown in Box 145–1, many vascular lesions other than ectasias can affect the LGI tract—some as part of a syndrome or systemic disease and others as single or multiple lesions unrelated to disease elsewhere in the body.

Hemangiomas

The second most common vascular lesion of the colon is hemangioma. Although these lesions are considered by

some to be true neoplasms, they are generally thought to be hamartomas because of their presence at birth in most cases. Colonic hemangiomas may occur as solitary lesions, as multiple growths limited to the colon, or as part of diffuse GI or multisystem angiomatoses. Individual hemangiomas may be broadly classified as cavernous, capillary, or mixed. Most hemangiomas are small and range from a few millimeters to 2 cm. Larger lesions do occur, however, especially in the rectum.

Clinically, bleeding from colonic hemangiomas is usually slow and produces occult blood loss with anemia or melena. Hematochezia is less common, except in the case of large cavernous hemangiomas of the rectum, which can cause massive hemorrhage. The diagnosis is best established by colonoscopy; roentgenologic studies, including angiography, may be normal. In the presence of GI bleeding, hemangiomas of the skin or mucous membranes should suggest the possibility of associated bowel lesions.

Pathologically, hemangiomas are well circumscribed but not encapsulated. Grossly, cavernous hemangiomas appear as polypoid or mound-like reddish purple lesions of the mucosa. Sectioning of the lesion reveals numerous dilated, irregular blood-filled spaces within the mucosa and submucosa, sometimes extending through the muscular wall to the serosal surface. The vascular channels are lined by flat endothelial cells with flat or plump nuclei. Their walls do not contain smooth muscle fibers but are composed of fibrous tissue of various thickness (Fig. 145–7). Capillary hemangiomas are plaque- or mound-like reddish purple lesions composed of a proliferation of fine, closely packed, newly formed capillaries separated by very little edematous stroma. The endothelial lining cells are large, usually hypertrophic, and in some areas may form solid cords or nodules with ill-defined capillary spaces. There is little or no pleomorphism or hyperchromasia.

Small hemangiomas that are either solitary or few in number can be treated by colonoscopic laser coagulation. Large or multiple lesions usually require resection of either the hemangioma alone or the involved segment of colon. The hemangioma can either be palpated directly or be revealed by transilluminating the bowel wall with an operative endoscope. The affected area can be resected, which can frequently be accomplished without opening the bowel.

Cavernous Hemangiomas of the Rectum

A distinct form of colonic hemangioma is a cavernous hemangioma of the rectum. These lesions are not usually associated with other GI hemangiomas and are extensive, with involvement of the entire rectum, portions of the rectosigmoid, and the perirectal tissues. They cause massive, sometimes uncontrollable hemorrhage, often beginning in infancy. The diagnosis can generally be suggested on plain films of the abdomen by the presence of phleboliths and by displacement or distortion of the rectal air column.[28] A barium enema study showing narrowing and rigidity of the rectal lumen, scalloping of the rectal wall, and an increase in size of the presacral space further supports the diagnosis. Endoscopically, elevated nodules or vascular congestion causing a plum-red coloration is seen. Ulcers and signs of proctitis may be evident. Angiography can be used to demonstrate these lesions but is rarely necessary to establish the diagnosis.

The massive bleeding resulting from these rectal hemangiomas often necessitates excision of the rectum by either abdominal perineal or low anterior resection, but because lesions occasionally involve the perirectal tissues, attempts at maintaining continence via pull-through procedures may fail. Ligation plus embolization of major feeding vessels has been used with varying degrees of success, and although local measures (e.g., electrocoagulation, sclerotherapy) are usually only temporarily effective, they have been of value in some instances.

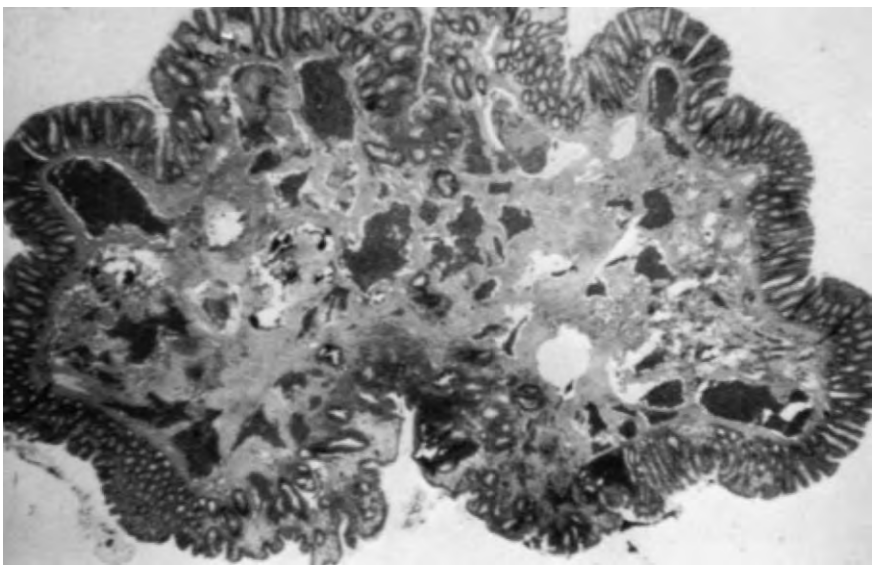

Figure 145–7. Polypoid cavernous hemangioma located in the submucosa with focal extension into the mucosa. Note the large, irregular vascular channels with fibrous walls of various thickness (hematoxylin-eosin stain, ×20). (From Boley SJ, Brandt LJ, Mitsudo S: Vascular lesions of the colon. Adv Intern Med 29:301, 1984.)

Colonic and Extracolonic Involvement

Diffuse Intestinal Hemangiomatosis

This condition is characterized by numerous, as many as 50 to 100, lesions involving the stomach, small bowel, and colon.[29] Bleeding or anemia generally leads to the diagnosis in childhood. Hemangiomas of the skin or soft tissues of the head and neck are frequently present. Continuous slow, but pernicious, bleeding requiring transfusions or intussusception led by one of the lesions may necessitate surgical intervention. The diagnosis may be made by endoscopy and barium studies; angiographic findings can be normal despite numerous lesions. The hemangiomas are similar in appearance to solitary lesions and are generally cavernous, although some have the histologic appearance of hemangioendotheliomas (benign lesions in children). At surgery, all identifiable lesions should be excised either through enterotomies or by limited bowel resections. Transillumination and compression of the bowel wall are helpful in finding small lesions. When they are multiple, the colon can be opened along a taenia and then intussuscepted on itself. Each hemangioma can be ligated with a surgical clip or polyglycolic acid sutures. Unfortunately, repeated operations may be necessary to control blood loss.

Universal (miliary) hemangiomatosis is usually fatal in infancy. It is, fortunately, a rare condition in which there are hundreds of hemangiomas involving the skin, brain, lungs, and abdominal viscera. Death results from congestive heart failure secondary to large arteriovenous shunts, or it may be due to local effects of the lesions. Colonic lesions are rarely of significance.

Blue Rubber Bleb Nevus Syndrome (Cutaneous and Intestinal Cavernous Hemangiomas)

In 1860, Gascoyen reported an association between cutaneous vascular nevi, intestinal lesions, and GI bleeding. Bean[30] later coined the name blue rubber bleb syndrome and distinguished it from other cutaneous vascular lesions. A familial history is infrequent, although a few cases of transmission in an autosomal dominant pattern have been reported.

The lesions in this syndrome are distinctive. They vary in size from 0.1 to 5.0 cm, are blue and raised, and have a wrinkled surface. Characteristically, the blood contained in the lesion can be emptied by direct pressure such that a wrinkled sac remains. The hemangiomas may be single or innumerable and are usually found on the trunk, extremities, and face, but not on mucous membranes. They increase in size and number with advancing age and do not undergo malignant transformation.[31] They may be present in any portion of the GI tract but are most common in the small bowel. In the colon, they occur more commonly on the left side and in the rectum. They are infrequently seen by barium opacification or angiographic studies and are detected best by endoscopy if they are proximal to the ligament of Treitz or in the colon. Microscopically, they are cavernous hemangiomas composed of clusters of dilated capillary spaces lined by cuboidal or flattened endothelium with connective tissue stroma. In the bowel, they are located in the submucosa. Resection of the involved segment of bowel is recommended for recurrent hemorrhage, although endoscopic laser coagulation is an attractive therapeutic option.

Less Common Vascular Lesions

Congenital Arteriovenous Malformations

Congenital arteriovenous malformations are embryonic growth defects and are considered to be developmental anomalies. Although they are found mainly in the extremities, they occur anywhere in the vascular tree. In the colon, they may be small, similar to ectasias, or they may involve a long segment of bowel. The more extensive lesions are most often seen in the rectum and sigmoid.

Histologically, arteriovenous malformations are persistent communications between arteries and veins located primarily in the submucosa. Characteristically, there is arterialization of the veins: tortuosity, dilation, and thick walls with smooth muscle hypertrophy and intimal thickening and sclerosis (Fig. 145–8). In longstanding arteriovenous malformations, the arteries are dilated with atrophic and sclerotic degeneration.

Angiography is the primary means of diagnosis. Early-filling veins in small lesions and extensive dilation of arteries and veins in large lesions (Fig. 145–9) are pathognomonic of arteriovenous malformations. Patients with significant bleeding should undergo resection of the involved segment of colon.

Colonic Varices

Varices of the colon are very rare but may be a cause of hematochezia or melena. In most cases, the varices are located in the rectosigmoid; they are found progressively less often in the more proximal portion of the colon. The most common cause of colonic varices is portal hypertension, with congenital anomalies, mesenteric venous obstruction, congestive heart failure, and pancreatitis accounting for the other causes.[32] Why varices form so rarely in the colon and why they bleed are unclear. Varices are easily diagnosed by proctosigmoidoscopy, colonoscopy, or angiography and may even be seen on conventional barium studies of the colon. Therapy consists of segmental colonic resection, portocaval shunting, or local ligation or sclerosis.

Telangiectasia

Telangiectases are small vascular lesions found on cutaneous, mucocutaneous, and mucosal surfaces throughout the body. Grossly and at endoscopy, they are millet seed sized and appear as cherry-red spots, vascular spiders, smooth hillocks, or lesions resembling ectasias. They may be hereditary or acquired and have been

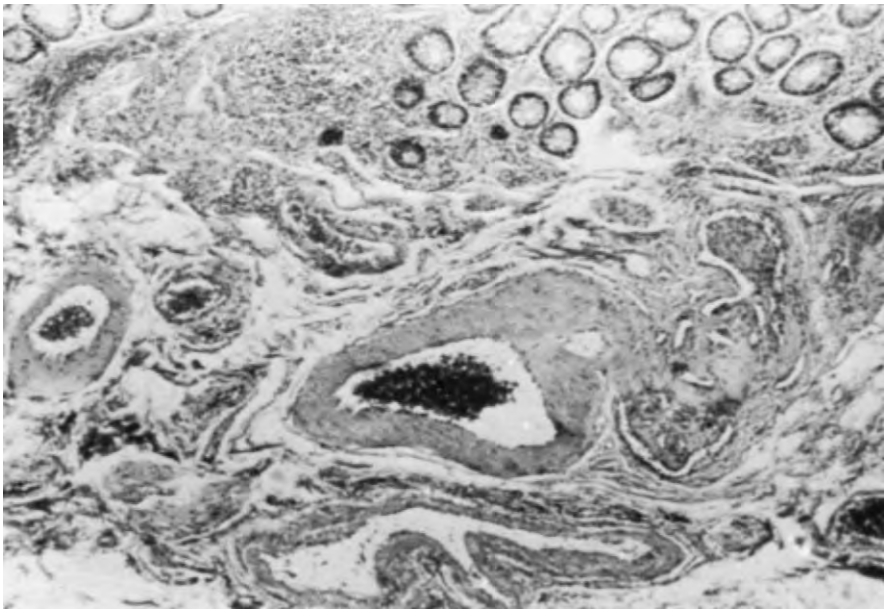

Figure 145–8. Arteriovenous malformation characterized by tortuous veins with sclerotic intima, hypertrophied smooth muscle, and thick-walled sclerotic arteries (hematoxylin-eosin stain, ×100). (From Boley SJ, Brandt LJ, Mitsudo S: Vascular lesions of the colon. Adv Intern Med 29:301, 1984.)

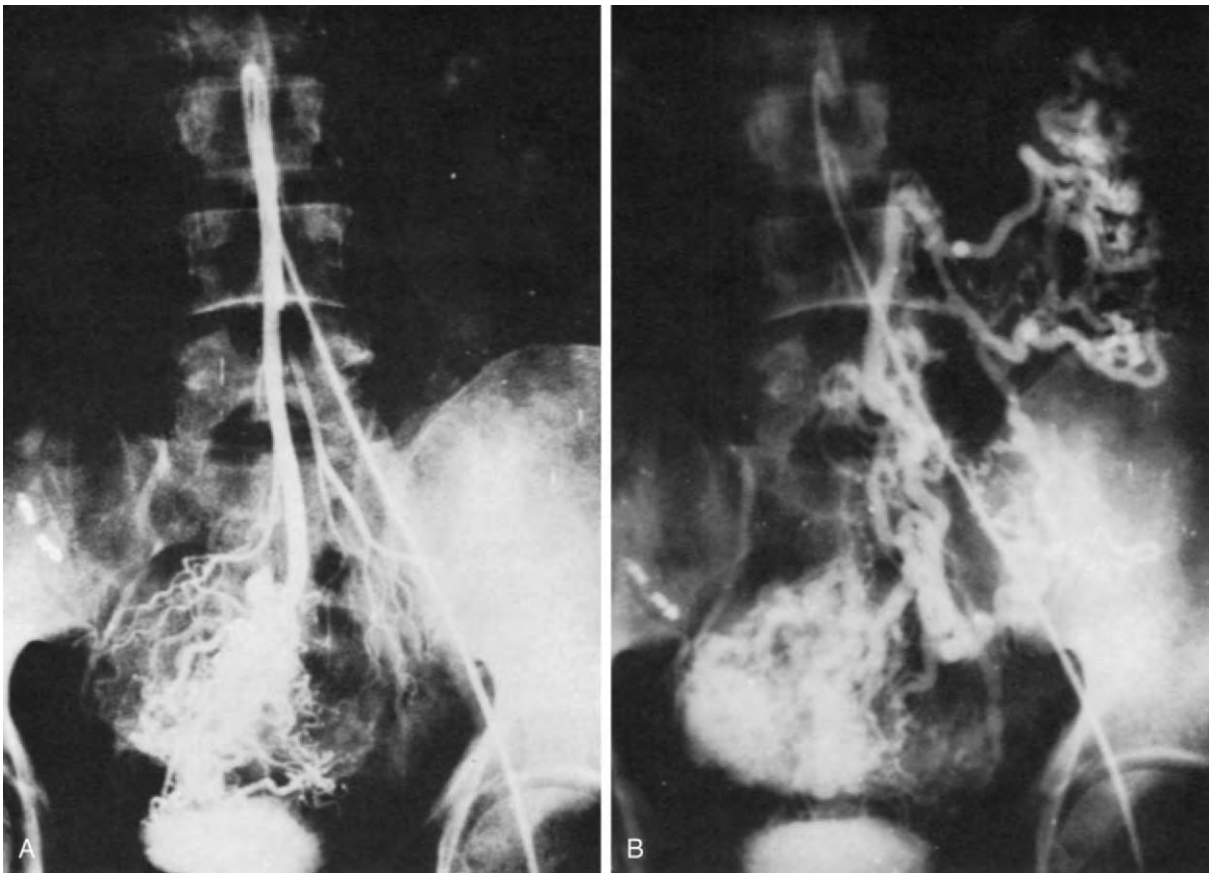

Figure 145–9. **A,** Arterial phase of an inferior mesenteric arteriogram from a patient with a congenital arteriovenous malformation showing multiple dilated arteries going to a large segment of the rectosigmoid. **B,** Venous phase of the same arteriogram showing dilated tortuous vessels to the same segment, as well as to other more proximal areas. (From Boley SJ, Brandt LJ, Mitsudo S: Vascular lesions of the colon. Adv Intern Med 29:301, 1984.)

described in association with many disorders (e.g., chronic renal failure, progressive systemic sclerosis, von Willebrand's disease, CREST syndrome [calcinosis cutis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia])[33-35] but are best known as part of Osler-Weber-Rendu disease, or hereditary hemorrhagic telangiectasia.

Hereditary hemorrhagic telangiectasia is a familial disorder characterized by telangiectases of the skin and mucous membranes and recurrent GI bleeding. Lesions are frequently noticed in the first few years of life, and recurrent epistaxis in childhood is characteristic of the disease. By the age of 10 years, about half of patients will have had some bleeding, but severe hemorrhage is unusual before 30 years of age and has a peak incidence from 50 to 60 years. In almost all patients, bleeding is manifested as melena, whereas epistaxis and hematemesis are less frequent. Bleeding may be quite severe, and patients commonly receive more than 50 transfusions in a lifetime. A family history of disease has been reported in 80% of patients with the disorder, but less commonly in those with bleeding, especially when the bleeding occurs later in life.

Telangiectases are almost always present on the lips, oral and nasopharyngeal membranes, tongue, or hand, and lack of involvement of these sites casts suspicion on the diagnosis. Lesions on the lips are more common in patients with GI bleeding than in those without. Telangiectases occur in the colon but are far more common in the stomach and small bowel. UGI lesions are more apt to cause significant bleeding.

Telangiectases are not demonstrable on barium enema examination but are easily seen on endoscopy. Occasionally, in the presence of severe anemia and blood loss, they transiently become less visible, but with blood replacement they again increase in prominence. Findings on angiography are usually normal, but it may demonstrate arteriovenous communications or small clusters of abnormal vessels.

Pathologically, the major changes involve the capillaries and venules, but arterioles may also be affected. The lesions consist of irregular, ectatic, tortuous, blood-filled spaces lined by a delicate single layer of endothelial cells and supported by a fine layer of fibrous connective tissue. No elastic lamina or muscular tissue is present in these vessels. The arterioles show some intimal proliferation and often have thrombi in them, suggestive of vascular stasis, but the most conspicuous findings are in the venules. In contrast to those in vascular ectasia, these venules are abnormally thick and have very prominent, well-developed longitudinal muscles. Apparently, these abnormal venules play a major role in regulating blood flow to the telangiectases.

Many treatments have been recommended, including oral and parenteral estrogen therapy and multiple resections of involved bowel. Endoscopic electrosurgery or laser coagulation appears to be most promising and may be performed during active bleeding or before any bleeding episodes. Although endoscopic therapy has diminished the need for resecting bowel in some cases, long-term follow-up studies are needed to evaluate the ultimate course of patients so treated.

Klippel-Trénaunay-Weber Syndrome

Originally described by Klippel and Trénaunay in 1900, this syndrome is characterized by unilateral congenital lesions of the lower extremities, including (1) cutaneous hemangiomas, usually of the flat, diffuse capillary type; (2) varicose veins dating from childhood; and (3) soft tissue hypertrophy and bony elongation. Involvement of the colon is uncommon and poorly defined, but when LGI involvement does occur, the rectum or rectosigmoid is generally affected.[36]

The cause of the syndrome has been variably ascribed to congenital arteriovenous fistulas or to aplasia, hypoplasia, dysplasia, atresia, or obstruction of the deep venous system. Rectal lesions usually cause bleeding during childhood and have been described by some as being cavernous hemangiomas or varicosities of the rectal veins.[37] Computed tomography scanning and ultrasonography were found helpful in determining the extent of colonic and other visceral disease.[38]

Major rectal or bladder bleeding has occurred in a few children, with one reported death. Ligation of bleeding hemorrhoids or sclerosis of rectal veins is often temporarily effective, but proctectomy may be necessary in some patients.

COLONIC ISCHEMIA

Before 1950, colonic ischemia (CI) was considered synonymous with colonic infarction or gangrene. Since that time, CI has become recognized as one of the more common disorders of the colon in elderly persons and the most common form of ischemic injury of the GI tract. CI is used to describe a general pathophysiologic process that leads to varied clinical outcomes. The spectrum includes (1) reversible ischemic colopathy (submucosal or intramucosal hemorrhage), (2) reversible or transient ischemic colitis, (3) chronic ischemic ulcerative colitis, (4) ischemic colonic stricture, (5) colonic gangrene, and (6) fulminant universal colitis (Fig. 145–10).

Colonic Circulation

The colon is normally protected from ischemia by its abundant collateral circulation. Communications between the CA, SMA, IMA, and iliac artery beds are numerous. Collateral flow around small arterial branches is made possible by the multiple arcades within the colonic mesentery, and SMA or IMA occlusions are bypassed via the arch of Riolan, the central anastomotic artery, and the marginal artery of Drummond. In addition, within the bowel wall there is a network of communicating submucosal vessels that can maintain the viability of short segments of the colon when the extramural arterial supply has been compromised.

The colon has inherently lower blood flow than the small intestine does and is therefore more sensitive to injury during acute reductions in blood flow. Moreover, experimental studies have shown that functional motor activity of the colon is accompanied by decreased blood flow. In contrast, blood flow to the small intestine

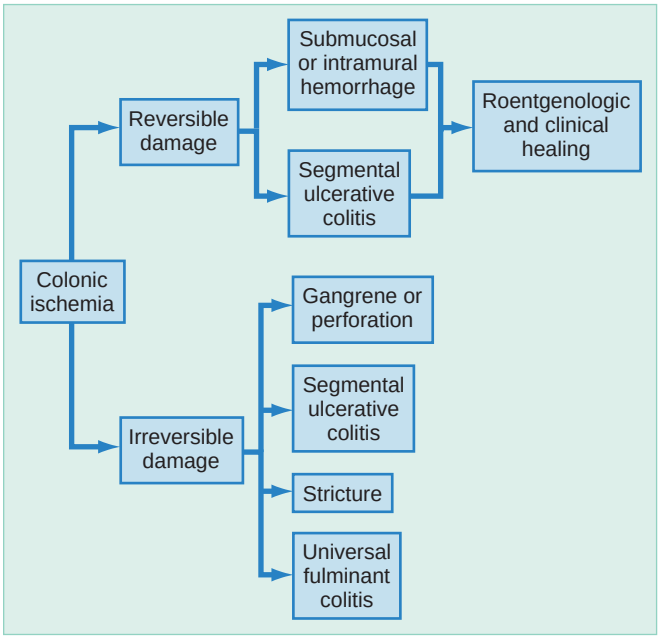

Figure 145–10. End results of colonic ischemia.

increases markedly during periods of increased peristalsis and digestion. In addition, the pronounced effect of straining on systemic arterial and venous pressure in constipated versus normal patients provides indirect evidence that constipation may accentuate the adverse circulatory effects of defecation. Geber[39] postulated that "the combination of normally low blood flow and decreased blood flow during functional activity would seem to make the colon (1) rather unique among all areas of the body where increased motor activity is usually accompanied by an increased blood flow and (2) more susceptible to pathology." Other factors that decrease colonic blood flow include changes in the environment, digestion, and emotionally stressful situations. Experiments evaluating the hypothalamic influence on GI blood flow in the awake cat model suggest that "of the entire GI tract, the colon blood flow is most affected by autonomic stimulation."[40]

Pathophysiology of Colonic Ischemia

What ultimately triggers the episode of CI remains conjectural in most instances. Whether it is increased demand by colonic tissue superimposed on already marginal blood flow or whether the flow itself is acutely diminished has not been determined. However, because CI is a disease of the elderly, an association with degenerative changes of the mesenteric vasculature has been postulated. Histologically, narrowing of small arteries, arterioles, and veins is evident in colons resected for nonocclusive CI. Autopsy studies have also shown abnormal musculature in the wall of the superior rectal artery in the elderly population, which confirms an age-related alteration in the mesenteric vasculature.[41] In addition, postmortem angiographic studies have revealed an age-related tortuosity of the longer colonic arteries that may cause increased resistance to colonic blood flow, thus predisposing the patient to ischemia.[42]

Despite this suggestive evidence for a vascular or autonomic cause of CI, most cases have no identifiable cause. These spontaneous episodes are thought to be the result of local nonocclusive ischemia in association with small vessel disease. Colonic blood flow can be further compromised by alterations in systemic perfusion. The inadequate systemic perfusion accompanying congestive heart failure, digitalis toxicity, or arrhythmias is a rare cause of CI. Many other conditions, spontaneous or iatrogenic, have been associated with CI, although a direct cause-and-effect relationship has not been established (Box 145–2). Two specific and well-recognized exceptions include the development of CI proximal to a potentially obstructing stricture—carcinoma or diverticulitis—and after aortic reconstruction.

Box 145–2 Causes of Colonic Ischemia

- Inferior mesenteric artery thrombosis
- Arterial embolus
- Cholesterol emboli
- Cardiac failure or arrhythmias
- Shock
- Digitalis toxicity
- Volvulus
- Periarteritis nodosa
- Systemic lupus erythematosus
- Rheumatoid arthritis
- Necrotizing arteritis
- Thromboangiitis obliterans
- Strangulated hernia
- Drug induced (e.g., oral contraceptives, cocaine)
- Polycythemia vera
- Parasitic infestation
- Allergy
- Trauma—blunt and penetrating
- Ruptured ectopic pregnancy
- Iatrogenic causes
  - Aneurysmectomy
  - Aortoiliac reconstruction
  - Gynecologic operations
  - Exchange transfusions
  - Colon bypass
  - Lumbar aortography
  - Colectomy with inferior mesenteric artery ligation

Demographics

The diagnosis of CI is usually made after the period of ischemia has passed and blood flow to the affected segment of colon has returned to normal. Many cases of transient or reversible ischemia are probably missed because the condition resolves before medical attention is sought or because a barium enema or colonoscopy is not performed early in the course of the disease. In addition, many cases of CI are misdiagnosed as infectious colitis or inflammatory bowel disease. Thus, to date, no study has provided an accurate determination of the incidence of CI.

Several retrospective reviews of older clinical material have revealed many cases of CI that were either undiagnosed or misdiagnosed because the various clinical manifestations of this disorder were not recognized. Using the modern clinical, roentgenologic, and pathologic criteria for the diagnosis of CI, two retrospective reviews of 154 patients in whom colitis was identified after the age of 50 revealed that approximately 75% of the patients had probable or definite CI.[43,44] In half of these patients, inflammatory bowel disease had been erroneously diagnosed.

At Montefiore Medical Center, approximately 50 cases of GI ischemia are seen each year, and of these cases, 50% to 60% are CI. Acute mesenteric ischemia accounts for an additional 30% to 40% of cases, and focal segmental ischemia or chronic mesenteric ischemia makes up the remainder.[45]

In our experience with more than 300 cases of CI, there was no significant sex predilection. Approximately 90% of patients are older than 60 years and have other evidence of systemic atherosclerotic disease. This prevalence has been confirmed in other reports.

CI affecting young individuals has been recognized more frequently in case reports or small series. Causes in the younger population include vasculitis (especially systemic lupus erythematosus),[46] medications (estrogens,[47,48] danazol,[49] vasopressin,[50] gold,[51] psychotropic drugs[52]), sickle cell anemia,[53] coagulopathies (thrombotic thrombocytopenic purpura,[54] protein C and protein S deficiency,[55] antithrombin III deficiency[56]), competitive long-distance running,[57] and cocaine abuse.[58]

Clinical Manifestations

Symptoms

CI is usually manifested as a sudden onset of mild, crampy abdominal pain, usually localized to the lower left quadrant. Less commonly the pain is severe, or conversely, in other patients the description of pain can be elicited only retrospectively, if at all. An urgent desire to defecate frequently accompanies the pain and is followed, within 24 hours, by the passage of either bright red or maroon blood in the stool. The bleeding is not vigorous, and blood loss requiring transfusion is so rare that it should suggest an alternative diagnosis. Physical examination may reveal mild to severe abdominal tenderness elicited in the location of the involved segment of bowel.

Distribution of Colonic Ischemia

Any part of the bowel may be affected, but the splenic flexure and descending and sigmoid colon are the most common sites (Fig. 145–11). Although specific causes, when identified, tend to affect defined areas of the colon, no prognostic implications can be derived from the distribution of the disease. Nonocclusive ischemic injuries generally involve watershed areas of the colon—the splenic flexure and the junction of the sigmoid and rectum—whereas ligation of the IMA produces changes in the sigmoid. Similarly, the length of bowel affected varies with the cause. For example, atheromatous emboli

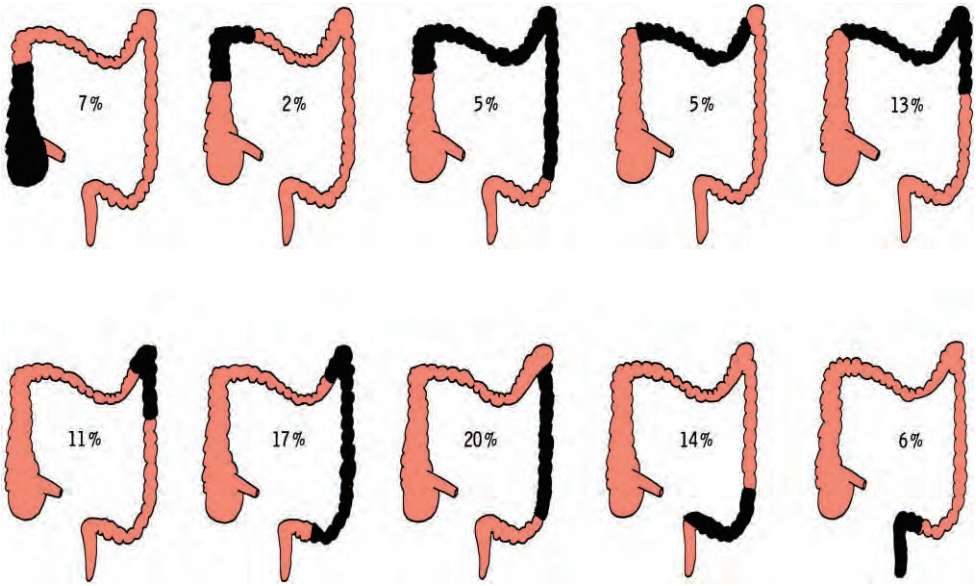

Figure 145–11. Distribution and length of involvement in 250 cases of colonic ischemia. More frequent involvement of the left half of the colon is apparent.

result in short segment changes, and nonocclusive injuries usually involve much longer portions of the colon. Depending on the severity and duration of the ischemic insult, fever or leukocytosis may develop. There is generally no acidemia, hypotension, or septic shock. In more severe ischemia, signs of peritonitis may develop.

Natural History of Colonic Ischemia

Despite similarities in the initial manifestation of most episodes of CI, the outcome cannot be predicted at its onset unless the initial physical findings indicate an unequivocal intra-abdominal catastrophe. The ultimate course of an ischemic insult depends on many factors, including (1) the cause (i.e., occlusive or nonocclusive), (2) the caliber of an occluded vessel, (3) the duration and degree of ischemia, (4) the rapidity of onset of the ischemia, (5) the condition of the collateral circulation, (6) the metabolic requirements of the affected bowel, (7) the presence and virulence of the bowel flora, and (8) the presence of associated conditions, such as colonic distention.

Most commonly, symptoms subside within 24 to 48 hours, and clinical, roentgenographic, and endoscopic evidence of healing is seen within 2 weeks (Fig. 145–12). More severe, but still reversible ischemic damage may take 1 to 6 months to resolve. The majority of patients with reversible disease exhibit only colonic hemorrhage or edema, whereas transient colitis develops in about a third. At times, with more severe yet reversible ischemia, the entire mucosa may slough as a tube. In half of patients with CI, the ischemic damage is too severe to heal, and irreversible disease ultimately develops. In approximately two thirds of these patients, CI follows a more protracted course and develops into either chronic segmental ulcerative colitis or ischemic stricture. In the remaining third, signs and symptoms of an intra-abdominal catastrophe develop, such as gangrene with or without perforation, and become obvious within hours of the initial manifestation.

Patients in whom CI develops as a complication of shock, congestive heart failure, myocardial infarction, or severe dehydration have a particularly poor prognosis. These are typically elderly patients taking digitalis preparations, which may act as potent splanchnic vasoconstrictors and exacerbate the already compromised colonic perfusion. In one series, these factors were present in a fourth of patients with CI, and 12 of 13 patients who were initially seen in shock died.[59]

Because the outcome of an episode of CI cannot usually be predicted, patients must be examined serially for evidence of peritonitis, rising temperature, elevation of the white blood cell count, or worsening symptoms. In patients with diarrhea or bleeding that persists beyond the first 10 to 14 days, perforation or, less frequently, a protein wasting enteropathy generally develops. Strictures may develop over a period of weeks to months and may be asymptomatic or produce progressive bowel obstruction. Some of the asymptomatic strictures resolve spontaneously over a span of many months.

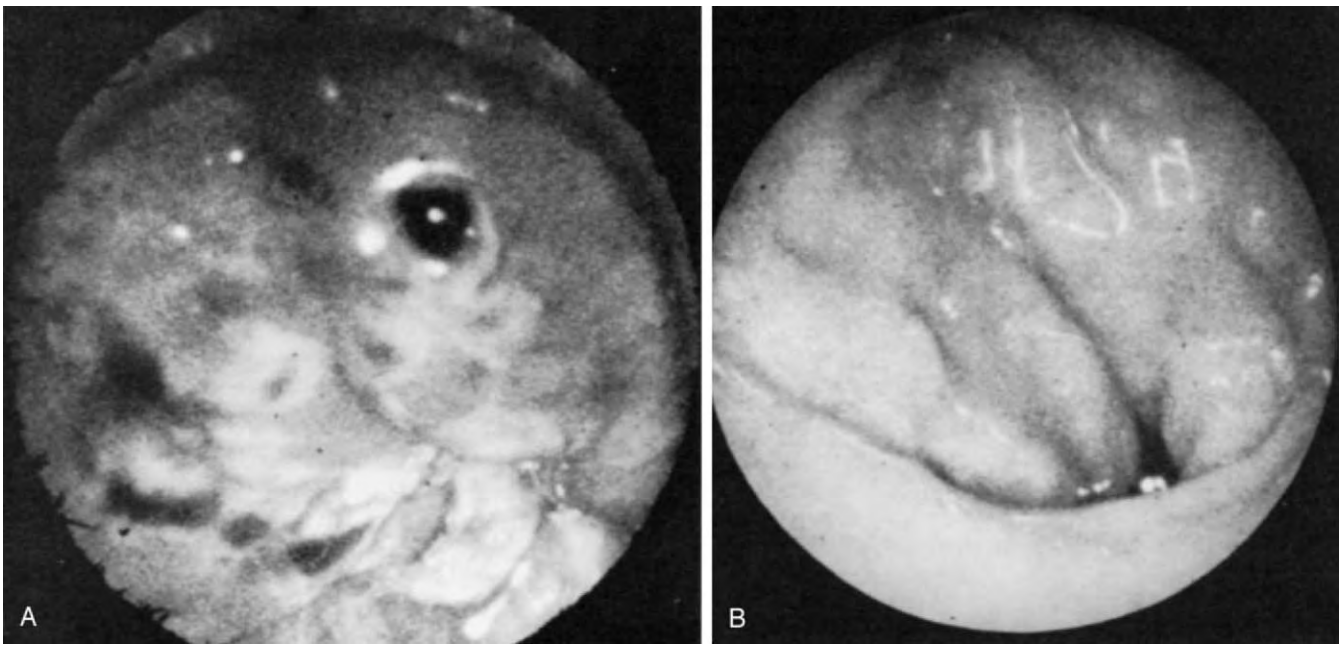

Figure 145–12. **A,** Endoscopic appearance of the colon during the initial evaluation of a patient with colonic ischemia. The dark nodular mass is a submucosal hemorrhage below which are ulcerations where other areas of hemorrhage have broken down. **B,** A follow-up study 3 weeks later demonstrates complete healing of the colonic mucosa. (From Littman L, Boley SJ, Schwartz S: Sigmoidoscopic diagnosis of reversible vascular occlusion of the colon. Dis Colon Rectum 6:142, 1963, with permission.)

Diagnosis

Early and appropriate diagnosis of CI depends on serial radiographic or colonoscopic evaluation, or both, of the colon, as well as repeated clinical evaluations of the patient. More severe cases of CI may be difficult to distinguish from acute mesenteric ischemia, whereas patients with less severe cases may have findings similar to those with acute or chronic idiopathic ulcerative colitis, Crohn's colitis, infectious colitis, or diverticulitis. A combination of radiographic, colonoscopic, and clinical findings may be necessary to establish the diagnosis of CI.

In a patient with suspected CI, if abdominal radiographs are nonspecific, sigmoidoscopy is unrevealing, and there are no signs of peritonitis, a gentle barium enema or colonoscopy should be performed in the unprepared bowel within 48 hours of the onset of symptoms. The most characteristic finding on barium enema is "thumbprinting" or "pseudotumors" (Fig. 145–13) and on colonoscopy is hemorrhagic nodules or bullae. Hemorrhagic nodules seen at colonoscopy represent bleeding into the submucosa and are equivalent to the "thumbprints" seen on barium enema. Segmental distribution of these findings, with or without ulceration, is very suggestive of CI, but the diagnosis of CI cannot be made conclusively on the basis of a single study. In fact, persistence of the thumbprints suggests a diagnosis other than CI, such as lymphoma or amyloidosis.

Repeated radiographic or endoscopic examination of the colon together with observation of the clinical course is necessary to confirm the diagnosis. Segmental colitis associated with a tumor or other potentially or partially obstructing lesions is also characteristic of ischemic disease. The radiographic findings of universal colonic involvement, loss of haustrations, or pseudopolyposis are more typical of chronic idiopathic ulcerative colitis, whereas the presence of skip lesions, linear ulcerations, or fistulas suggests Crohn's colitis.

It is imperative to perform the diagnostic study early in the course of the disease because the thumbprinting disappears within days as the submucosal hemorrhages are either resorbed or evacuated into the colon when the overlying mucosa ulcerates and sloughs. Barium enema or colonoscopy performed 1 week after the initial study should reflect the evolution of the disease, either by return to normal or by replacement of the thumbprints with a segmental ulcerative colitis pattern.

If colonoscopy is chosen as the initial study, caution is indicated. Distention of the bowel with air to a pressure greater than 30 mm Hg diminishes colonic blood flow, shunts blood from the mucosa to the serosa, and causes a progressive decrease in the arteriovenous oxygen difference.[60] If intraluminal pressure exceeds 30 mm Hg during routine endoscopic examination of the colon,[61] colonoscopy can potentially induce or exacerbate CI. This risk can be minimized by insufflation with carbon dioxide, which increases colonic blood flow at similar pressures. Furthermore, carbon dioxide is rapidly absorbed from the colon, thus decreasing the duration of distention and elevation of intraluminal pressure.[62]

Biopsies of nodules or bullae identified endoscopically early in the course of CI reveal submucosal hemorrhage, whereas biopsies of the surrounding mucosa usually show nonspecific inflammatory changes.[63] Histologic evidence of mucosal infarction, though rare, is pathognomonic for ischemia. Angiography seldom shows significant occlusions or other abnormalities and is not indicated in patients suspected of having CI. Computed tomography may show thickening of the bowel wall, but this finding is not specific for CI.

When the clinical findings do not allow a clear distinction to be made between CI and acute mesenteric ischemia and plain films of the abdomen do not show the characteristic thumbprinting pattern of CI, an "air enema" performed by gently insufflating air into the colon under fluoroscopic observation is obtained. The submucosal edema and hemorrhages that produce the thumbprinting pattern of CI can be accentuated and identified in this manner.

Once the provisional diagnosis of CI is made, a gentle barium enema is performed to determine the site and distribution of the disease, as well as to determine any associated lesion that predisposes to the episode of ischemia (i.e., carcinoma, stricture, or diverticulitis). If, however, thumbprinting is not observed and the air enema does not suggest the diagnosis of CI, a selective mesenteric angiogram is immediately performed to exclude the diagnosis of acute mesenteric ischemia. Because acute mesenteric ischemia progresses rapidly to an irreversible outcome and because optimal diagnosis and treatment of this condition require angiography, the diagnosis of acute mesenteric ischemia must be established or excluded before a barium study. Residual barium from a contrast study of the colon may obscure the mesenteric vessels and therefore preclude adequate angiographic examination and intervention.

Management of Colonic Ischemia

General Principles

Once the diagnosis of CI has been established and the physical examination does not suggest intestinal gangrene or perforation, the patient is treated expectantly. Parenteral fluids are administered, and the bowel is placed at rest. Broad-spectrum antibiotics that provide coverage of *Enterococcus* and anaerobic organisms are administered. Antibiotic therapy has been shown to reduce the length of bowel damaged by ischemia, although it will not prevent colonic infarction. Cardiac function is optimized to ensure adequate systemic perfusion. Medications that cause mesenteric vasoconstriction (e.g., digitalis and vasopressors) should be withdrawn if possible. Urine output is monitored and maintained with parenteral isotonic fluids. If the colon appears distended, either clinically or radiographically, it can be decompressed with a rectal tube, with or without gentle saline irrigation. Contrary to their efficacy in ulcerative colitis, parenteral corticosteroids are contraindicated because they increase the possibility of

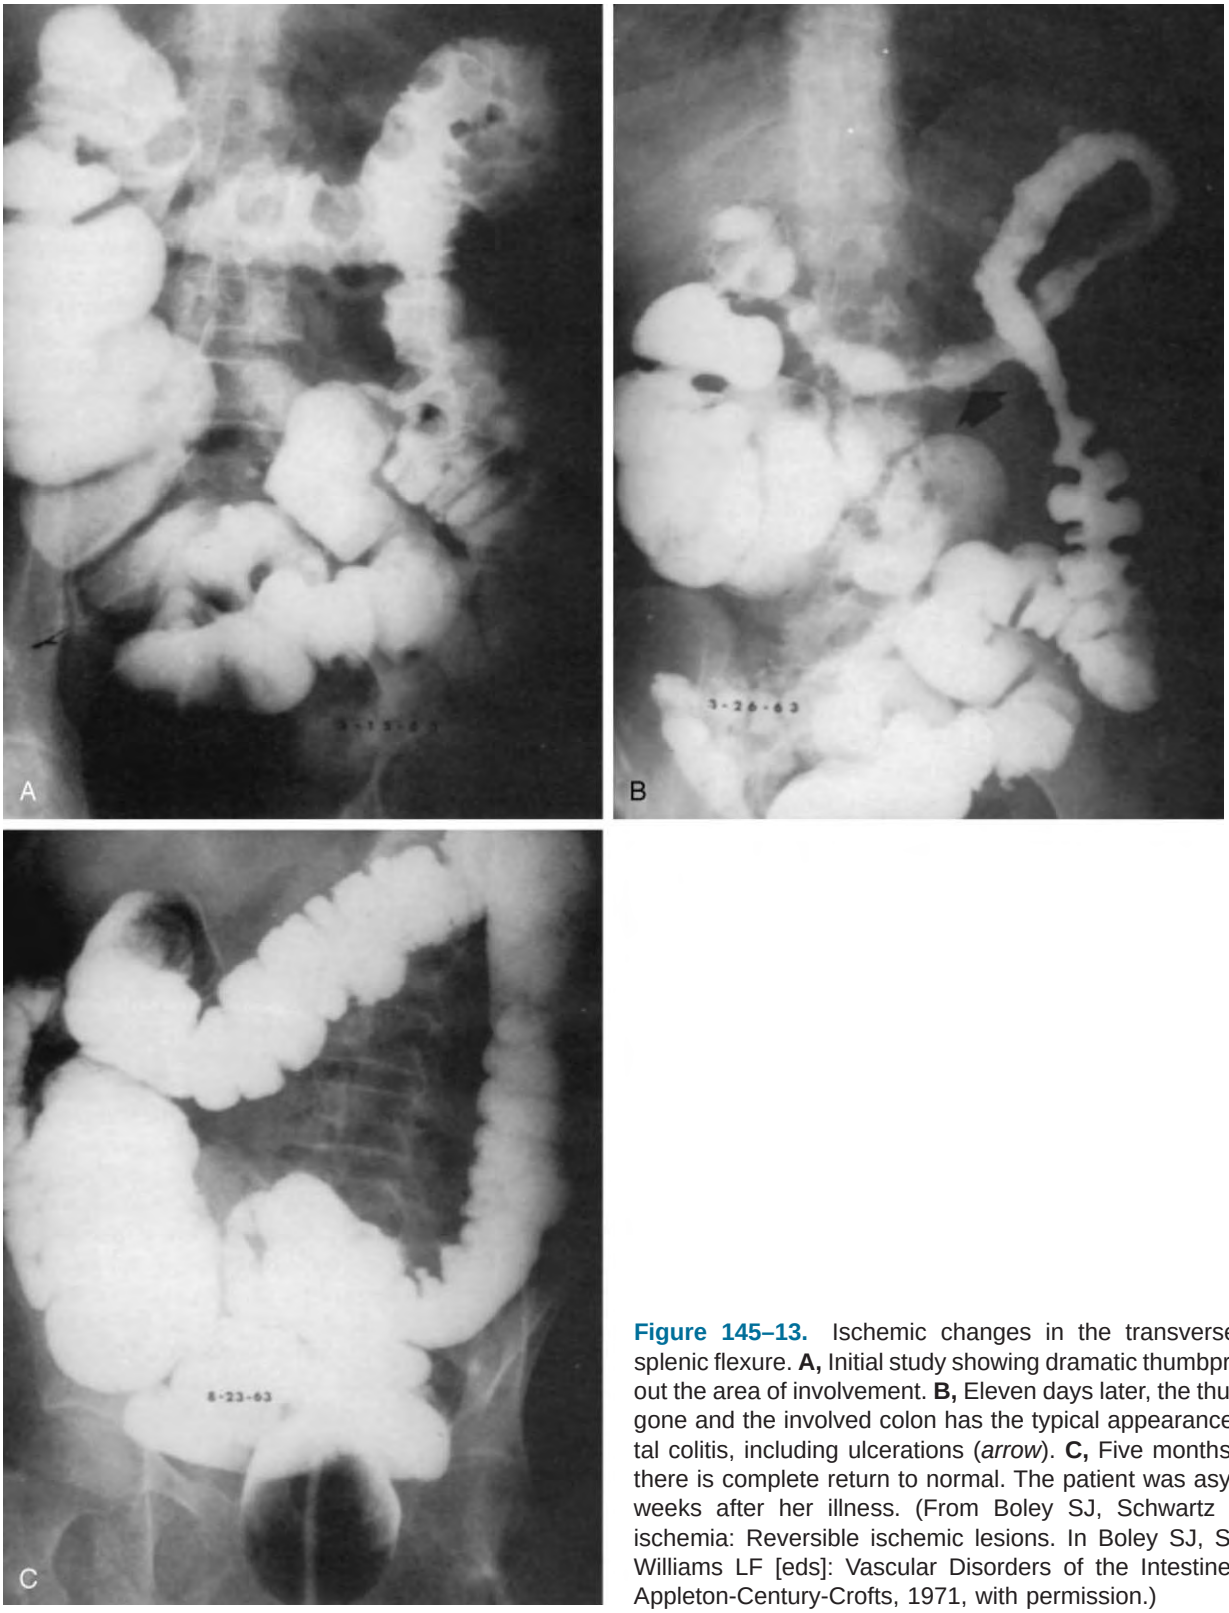

Figure 145–13. Ischemic changes in the transverse colon and splenic flexure. **A,** Initial study showing dramatic thumbprints throughout the area of involvement. **B,** Eleven days later, the thumbprints are gone and the involved colon has the typical appearance of segmental colitis, including ulcerations (*arrow*). **C,** Five months after onset, there is complete return to normal. The patient was asymptomatic 3 weeks after her illness. (From Boley SJ, Schwartz SS: Colonic ischemia: Reversible ischemic lesions. In Boley SJ, Schwartz SS, Williams LF [eds]: Vascular Disorders of the Intestine. New York, Appleton-Century-Crofts, 1971, with permission.)

perforation and secondary infection. Appropriate management of patients seen during or soon after the ischemic episode requires serial radiographic or endoscopic evaluation of the colon and continued monitoring of the patient.

Determination of the white blood cell count, hemoglobin, and hematocrit should be repeated frequently during the acute episode. Though rarely needed, blood products should be administered according to the patient's requirements. Serum potassium and magnesium levels must be monitored because the levels of these electrolytes may be disturbed by the associated diarrhea and tissue necrosis. Systemic levels of lactate dehydrogenase, creatine phosphokinase, aspartate aminotransferase, and alanine aminotransferase may reflect the degree of bowel necrosis, but these serum markers are neither sensitive nor specific for CI. Patients with significant diarrhea are started on parenteral nutrition early. Narcotics should be withheld until it is clear that an intra-abdominal catastrophe is not present and that the patient is clinically improving. Cathartics are contraindicated. No attempt should be made to prepare the bowel for surgery in the acute phase because such preparation may precipitate a perforation.

Increasing abdominal tenderness, guarding, rebound tenderness, rising temperature, and paralytic ileus during the period of observation suggest colonic infarction. These signs, though not distinct indicators of transmural CI or infarction, dictate the need for expedient laparotomy for resection of the affected segment of colon. At laparotomy, the serosal appearance of infarcted colon ranges from wet tissue paper to mottled, thickened, aperistaltic bowel. The resected specimen should be opened in the operating suite and examined for mucosal injury, and if the margins are involved, additional colon should be removed until the margins appear grossly normal.

Management of Reversible Lesions

In the mildest cases of CI, in which the signs and symptoms of illness disappear within 24 to 48 hours, submucosal and intramural hemorrhages are resorbed, and there is complete clinical and radiographic resolution within 1 to 2 weeks (see Fig. 145–13), no further therapy is indicated. More severe ischemic insults result in necrosis of the overlying mucosa with ulceration and inflammation and the subsequent development of segmental ulcerative colitis. Various amounts of mucosa may slough, which may ultimately heal over a period of several months. Patients with such protracted healing may be clinically asymptomatic, even in the presence of persistent radiographic or endoscopic evidence of disease. These asymptomatic patients are placed on a high-residue diet, and frequent follow-up evaluations are performed to confirm complete healing or the development of a stricture or persistent colitis. Recurrent episodes of sepsis in asymptomatic patients with unhealed areas of segmental colitis are generally caused by the diseased segment of bowel and are an indication for elective resection.

Management of Irreversible Lesions

Perforation usually develops in patients with persistent diarrhea, rectal bleeding, protein-losing enteropathy, or recurrent sepsis for more than 10 to 14 days. Hence, early resection is indicated to prevent this complication. A polyethylene glycol bowel preparation is administered along with oral and intravenous antibiotics before surgery. Again, enemas should not be used to prepare the bowel.

Despite a normal serosal appearance, there may be extensive mucosal injury, and the extent of resection should be guided by the distribution of disease as seen on preoperative studies rather than by the appearance of the serosal surface of the colon at the time of surgery. As in all resections for CI, the specimen must be opened at the time of surgery to ensure normal mucosa at the margins. If at the time of surgery the segmental ulcerative colitis is found to involve the rectum, a mucous fistula or Hartmann's procedure with an end colostomy should be performed. The mucous fistula can be fashioned through diseased bowel, and in some cases, this segment will heal sufficiently to allow subsequent restoration of bowel continuity. Local steroid enemas may be helpful in this setting; however, parenteral steroids are, again, contraindicated. Simultaneous proctocolectomy is rarely indicated except in the case of CI after abdominal aortic replacement.

In instances in which the patient has suffered a concurrent or recent myocardial infarction or if the patient has major medical contraindications to surgery, a trial of prolonged parenteral nutrition with concomitant intravenous antibiotic therapy may be considered as an alternative, albeit less optimal, method of management.

Management of Late Manifestations of Colonic Ischemia

CI may not be accompanied by clinical symptoms during the acute insult but may still produce chronic segmental ulcerative colitis. This form of CI may frequently be misdiagnosed if not seen during the acute episode. Barium enema studies may show a segmental colitis pattern, a stricture simulating a carcinoma, or even an area of pseudopolyposis (Fig. 145–14). The clinical course at this stage of disease is often indistinguishable from that of other causes of colitis or stenosis unless the patient has been observed from the time of the acute episode. Crypt abscesses and pseudopolyposis, generally considered histologically diagnostic of chronic idiopathic ulcerative colitis, can also be seen in ischemic colitis. Regardless, the de novo occurrence of a segmental area of colitis or stricture in an elderly patient should be considered to most likely be ischemic and be treated accordingly.

The natural history of noninfectious segmental colitis in the elderly is that of ischemic colitis; the involvement remains localized, resection is not followed by recurrence, and the response to steroid therapy is usually poor. Patients with chronic segmental ischemic colitis are initially managed symptomatically. Local steroid enemas may be helpful, but parenteral steroids should be avoided. In patients whose symptoms cannot be

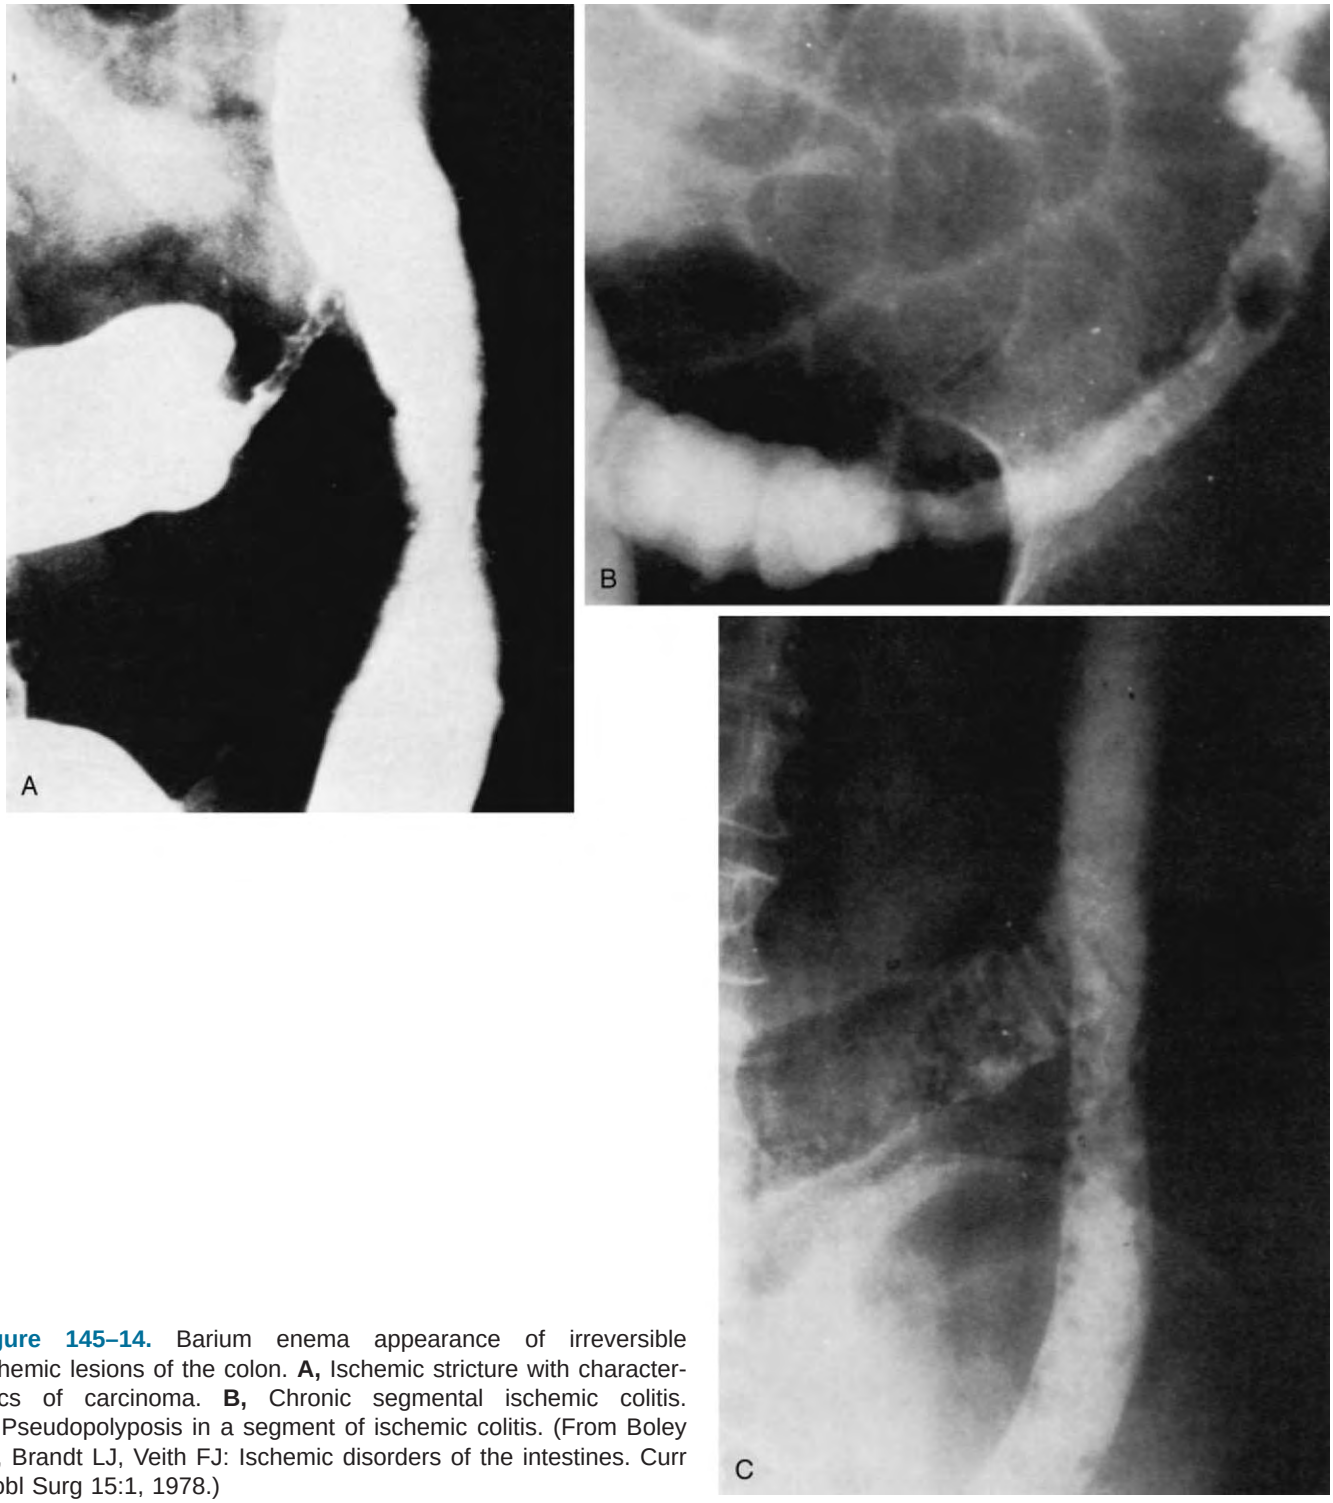

Figure 145–14. Barium enema appearance of irreversible ischemic lesions of the colon. **A,** Ischemic stricture with characteristics of carcinoma. **B,** Chronic segmental ischemic colitis. **C,** Pseudopolyposis in a segment of ischemic colitis. (From Boley SJ, Brandt LJ, Veith FJ: Ischemic disorders of the intestines. Curr Probl Surg 15:1, 1978.)

controlled by medication, segmental resection of the diseased bowel should be performed.

Management of Ischemic Strictures Stenosis or stricture of the colon may develop in patients with asymptomatic segmental ulcerative colitis (Fig. 145–15). Strictures that produce no symptoms should be observed, and some of them will return to normal over a 12- to 24-month period with no further therapy. If, however, symptoms of obstruction develop, segmental resection is required.

Management of Specific Clinical Problems

Colonic Ischemia Complicating Abdominal Aortic Surgery Mesenteric vascular reconstruction is not indicated in most cases of CI, but it may be required to

Figure 145–15. **A,** Ischemic stricture of the sigmoid colon. **B,** Eighteen months later, the stricture is still obvious. **C,** Two years after the initial study, the colon has almost returned to normal. (From Boley SJ, Brandt LJ, Veith FJ: Ischemic disorders of the intestines. Curr Probl Surg 15:1, 1978.)

prevent CI during and after aortic reconstruction. After elective aneurysmectomy, colonoscopic evidence of CI develops in 3% to 7% of patients.[64,65] The incidence of CI after repair of ruptured aortic aneurysms has been reported to be as high as 60%.[66] Although clinical evidence of this complication occurs in only 1% to 2% of patients, when it does occur, it is responsible for approximately 10% of the deaths that take place after aortic replacement.[67] Factors that contribute to the occurrence of postoperative CI include rupture of the aneurysm, hypotension, operative trauma to the colon, hypoxemia, arrhythmias, prolonged cross-clamp time, and improper management of the IMA during aneurysmectomy.

The most important aspect of management of CI after aortic surgery is its prevention. Collateral blood flow to the left colon after occlusion of the IMA comes from the SMA via the arch of Riolan ("the meandering artery") or the marginal artery of Drummond and from the internal iliac arteries via the middle and inferior hemorrhoidal arteries. If these collateral pathways are intact, postoperative CI can be minimized. Therefore, aortography and full mechanical and antibiotic bowel preparation are essential before aortic reconstruction. Aortography is advised to determine the patency of the CA, SMA, IMA, and internal iliac artery. The presence of a meandering artery does not, in and of itself, allow safe ligation of the IMA because blood flow in the meandering artery frequently originates from the IMA and reconstitutes an obstructed SMA. Ligation of the IMA in the latter circumstance can be catastrophic and result in infarction of the small and large bowel (Fig. 145–16). Ligation of the IMA is safe only when it has been confirmed angiographically that blood flows in the meandering artery from the SMA to the IMA. Reimplantation of the IMA and revascularization of the SMA are therefore required in instances in which the SMA is occluded or tightly stenosed and the IMA provides inflow to the meandering artery (Fig. 145–17).

Occlusion of both hypogastric arteries on the preoperative arteriogram indicates that rectal blood flow is dependent on collateral flow from the IMA or from the SMA via the meandering artery. In this circumstance, reconstitution of flow to one or both hypogastric arteries is desirable at the time of aneurysmectomy (Fig. 145–18).

At surgery, cross-clamp time should be minimized, and hypotension must be avoided. If a meandering artery is identified, it should be carefully preserved. Because the serosal appearance of the colon is not a reliable indicator of collateral blood flow, several methods have been suggested to determine the need for IMA reimplantation. Stump pressure greater than 40 mm Hg in the transected IMA or a mean IMA stump pressure–to–mean systemic blood pressure ratio of greater than 0.40 indicates adequate collateral circulation and can be reliably used to avoid IMA reimplantation.[68] The presence of Doppler ultrasound flow signals at the base of the mesentery and at the serosal surface of the colon with temporary occlusion of IMA inflow also suggests that the IMA can be ligated safely without reimplantation.

Tonometric determination of the intramural pH of the sigmoid colon has been used to identify inadequate colonic blood flow during aneurysmectomy.[69,70] A tonometric balloon is passed into the sigmoid colon through the anus before cross-clamping the aorta to enable one to evaluate the effect that occlusion and restoration of aortic flow have on colonic intramural pH. Intramural pH is a metabolic marker of tissue acidosis and will reflect any clinically significant ischemia, thus indicating the need for revascularization while the abdomen is open. An abnormal tonometric study of the sigmoid colon, loss of arterial pulsation, or decreased transcolonic oxygen saturation after aortic surgery is an indication for reimplantation of the IMA. When IMA reimplantation is deemed necessary, the IMA should be excised with a patch of aortic wall (Carrell patch), and this patch should be sutured into the side of the aortic prosthesis.

If it is occluded, the SMA can be revascularized by reimplantation into the graft wall or, alternatively, by creating a lateral extension of the prosthesis and performing an end-to-side anastomosis to the SMA. Liberal use of these adjunctive procedures has, in one prospective

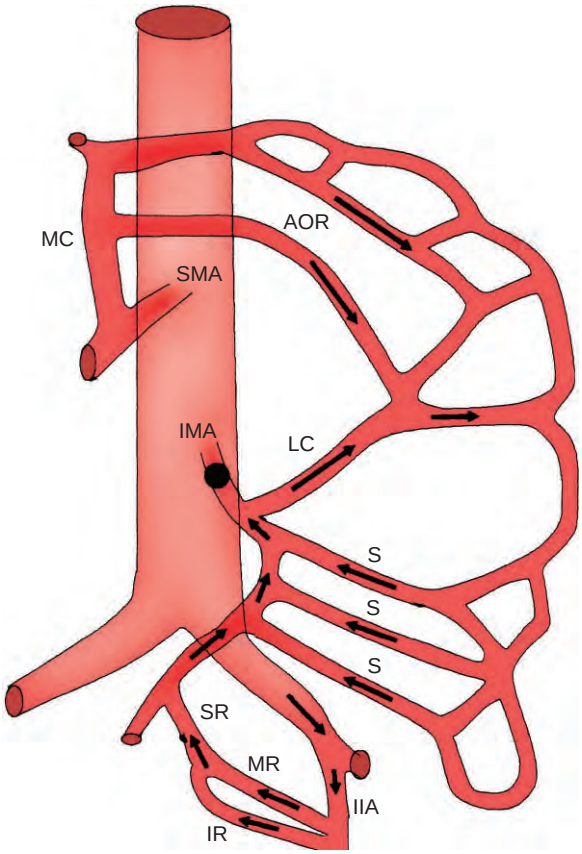

Figure 145–16. Collateral blood flow to the colon from the marginal artery, arch of Riolan, and internal iliac artery via the inferior and middle rectal arteries to an occluded IMA. AOR, arch of Riolan; IIA, internal iliac artery; IMA, inferior mesenteric artery; IR, inferior rectal artery; LC, left colic artery; MC, middle colic artery; MR, middle rectal artery; S, sigmoid arteries; SMA, superior mesenteric artery; SR, superior rectal artery.

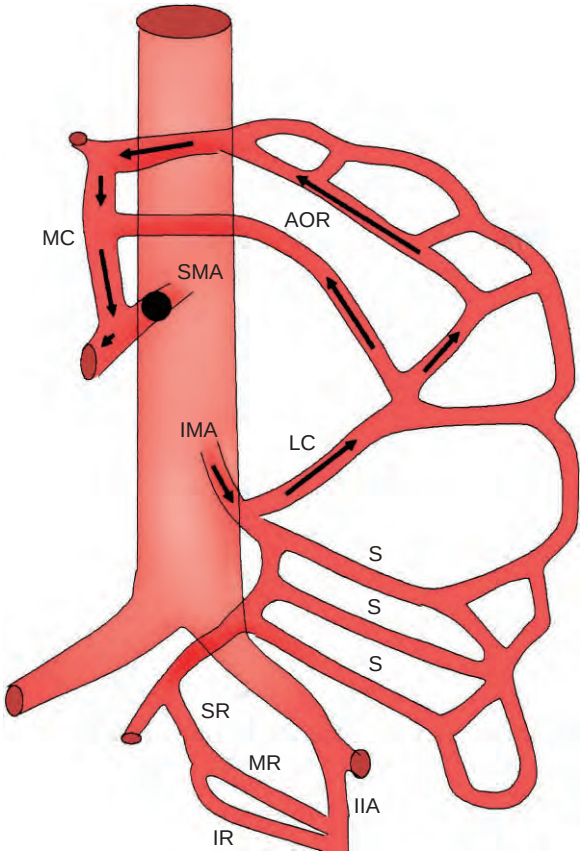

Figure 145–17. Collateral blood flow from the IMA via the marginal artery and arch of Riolan to an occluded SMA. AOR, arch of Riolan; IIA, internal iliac artery; IMA, inferior mesenteric artery; IR, inferior rectal artery; LC, left colic artery; MC, middle colic artery; MR, middle rectal artery; S, sigmoid arteries; SMA, superior mesenteric artery; SR, superior rectal artery.

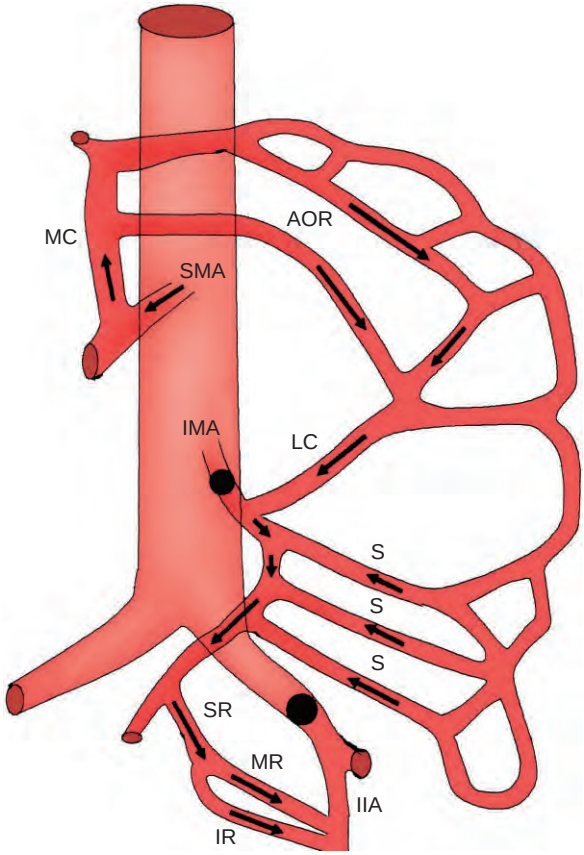

Figure 145–18. The entire rectal blood flow is dependent on collateral flow after occlusion of both internal iliac arteries. In this figure, the IMA is also occluded, so rectal blood flow is dependent on collateral flow from the SMA via the arch of Riolan and the marginal artery and then via the superior rectal vessel to the middle and inferior rectal arteries. AOR, arch of Riolan; IIA, internal iliac artery; IMA, inferior mesenteric artery; IR, inferior rectal artery; LC, left colic artery; MC, middle colic artery; MR, middle rectal artery; S, sigmoid arteries; SMA, superior mesenteric artery; SR, superior rectal artery.

study, both substantially reduced the incidence of CI and eliminated it as a cause of death after aortic surgery.

The difficulty in accurately assessing CI after surgery and the significant mortality rates associated with its occurrence mandate that postoperative colonoscopy be performed in high-risk patients. Patients at high risk for the development of postoperative CI after aortic reconstruction are those with ruptured abdominal aortic aneurysms, prolonged cross-clamping time, a patent IMA on preoperative aortography, nonpulsatile flow in the hypogastric arteries at surgery, and postoperative diarrhea. In these cases, colonoscopy is routinely performed within 2 to 3 days of the operation, and if CI is identified, therapy is begun before major complications develop. Clinical deterioration indicating progression of the ischemic insult to transmural necrosis necessitates reoperation. These patients should undergo resection and colostomy. Primary anastomosis is contraindicated because of potential contamination of the aortic prosthesis in the event of an anastomotic leak. If the rectum is involved, it must also be resected. Every effort should be made to protect the aortic graft from contamination; as such, the retroperitoneum overlying the graft should be reperitonealized with local tissues or omentum.

Fulminating Universal Colitis A rare fulminating form of CI involving all or most of the colon and rectum has been identified in a few patients. These patients experience the sudden onset of a toxic universal colitis. Bleeding, fever, severe diarrhea, and abdominal pain and tenderness, often with signs of peritonitis, have been noted. The clinical course is rapidly progressive. Management of this condition is similar to that for other forms of fulminating colitis. Total abdominal colectomy with an ileostomy is generally required. A second-stage proctectomy has been necessary in some patients within 1 month of the original surgery. The histologic appearance of the resected colon is a combination of ischemic changes, severe ulcerating colitis, and necrosis.

Lesions Mimicking Colon Carcinoma Ischemic colitis can be accompanied by lesions that appear, on barium

enema and colonoscopy, to be colon carcinoma. Colonoscopy may be able to distinguish malignant lesions from those resulting from ischemic cicatrization and is advisable when an annular lesion is identified on barium enema. Treatment is local resection with immediate restoration of bowel continuity.

Colitis Associated with Colon Carcinoma Acute colitis in patients with carcinoma of the colon has been recognized for many years.[71] The colitis is usually, but not always, proximal to the tumor and occurs with and without clinical obstruction. It is of ischemic origin and has the radiologic and endoscopic appearance of ischemic colitis. Clinically, patients may have symptoms of CI or symptoms related to the primary cancer (i.e., crampy pain of a chronic nature, bleeding, or acute colonic obstruction). In most cases, however, the predominant complaints are related to the ischemic episode—sudden onset of mild to moderate abdominal pain, fever, bloody diarrhea, and abdominal tenderness.

It is imperative for both the radiologist and surgeon to be aware of the frequent association of CI and colon cancer. The radiologist must be careful to exclude cancer in every case of CI, and for the surgeon, it is vital to examine any colon resected for cancer to exclude the presence of an ischemic process in the area of the anastomosis because involvement may lead to stricture or a leak.

Colonic Ischemia as a Manifestation of Acute Mesenteric Ischemia CI localized to the right side of the colon may be a manifestation of acute mesenteric ischemia. If a thumbprinting pattern or colonoscopy reveals evidence of CI isolated to the right colon, we consider this an indication for selective mesenteric angiography before discharge to evaluate the status of the SMA. Demonstration of a partially or completely obstructed SMA is an indication for revascularization of this artery.

Diverticular Disease

Jeffrey L. Cohen · John P. Welch

Diverticular disease refers to a spectrum of clinical scenarios that can vary from an asymptomatic state to life-threatening peritonitis. This chapter gives a clinical overview of the pathophysiology, diagnosis, and clinical management of a wide variety of complications of the disorder.

PATHOPHYSIOLOGY AND EPIDEMIOLOGY

Colonic diverticulosis refers to the presence of 0.5- to 1-cm saccular outpouchings termed *diverticula*. Anatomically, diverticula are situated between the single mesenteric taenia and one of the antimesenteric taeniae (Fig. 146–1). Virtually all patients with diverticulosis have sigmoid involvement (95%), although other segments may be affected as well. About 5% have cecal diverticula.[1]

At least two factors account for formation of diverticula: weak areas in the colonic wall, and a pressure differential between the colonic lumen and the serosa. Diverticula may form in response to development of localized high-pressure zones or segments in the colon and hence the term *segmentation* has been coined (Fig. 146–2). Typically they are "pseudodiverticula," with a thin-wall component of a flattened mucosa and submucosa and an attenuated or absent muscularis propria. Diverticula are essentially herniations through the muscular wall of the colon. In addition, there may be gross thickening of the less compliant colonic wall and derangement of the collagen fibers. Increased elastin content in the taeniae may cause shortening of the taeniae, which in turn leads to corrugation of the circular muscle. A defect in cholinergic innervation of the colon has been identified in patients with diverticulosis.[2]

Ten percent to 20% of patients with diverticula develop symptoms from them. Inflammation of one or more diverticula (diverticulitis) sometimes develops, with spread of infection into adjacent or less commonly distant sites. The diverticular wall may be devitalized, due to mechanical trauma from fecaliths or from high intracolonic pressures in the presence of an overgrowth of bacteria. Perforation of a diverticulum may be facilitated by commonly ingested nonsteroidal anti-inflammatory drugs (NSAIDs) such as low-dose aspirin.[3] Smoking,[4] corticosteroids, opioid analgesics,[5] and alcoholism have also been associated with diverticular complications. "Diverticular colitis" has occurred in the presence of diverticular disease, even in the absence of inflammation of the diverticula themselves.[6] Diverticula can bleed as well, since they occur at sites where intramural vessels penetrate the colonic wall.

Diverticular disease is an affliction that reached prominence in the 20th century. The incidence of diverticulosis increases linearly with age after 20 years of age, and hospitalized patients tend to be elderly. The prevalence approaches 50% in Western adults older than 60 years of age. The direct cost of treating diverticular disease in the United States in 1998 has been estimated at $2.4 billion.[7] The sexes tend to be affected similarly; however, males are affected more frequently under the age of 40 years, whereas females predominate over 40.[8] Epidemiologic studies suggest that fiber-deficient diets in the Western world lead to the development of smaller, firmer bowel movements, as well as higher pressures within the sigmoid colon, with areas of segmentation. In areas where high-fiber diets are common (rural Africa), diverticulosis is unusual.

Myoelectric studies of patients with symptomatic diverticular disease show an abnormal slow-wave pattern that returns to normal when they ingest bran. Asymptomatic patients with diverticulosis have unchanged motility patterns after eating bran. Dietary supplementation with fiber increases stool weight, decreases intraluminal pressure, and alters transit time. However, firm evidence is lacking that ingestion of a high-fiber diet actually slows the progression of established diverticulosis or the risk of complications.[9]

DIAGNOSTIC MODALITIES

A number of modalities are available to make the diagnosis of diverticular disease. In the noninflamed colon, diverticula are easily recognized during colonoscopy,

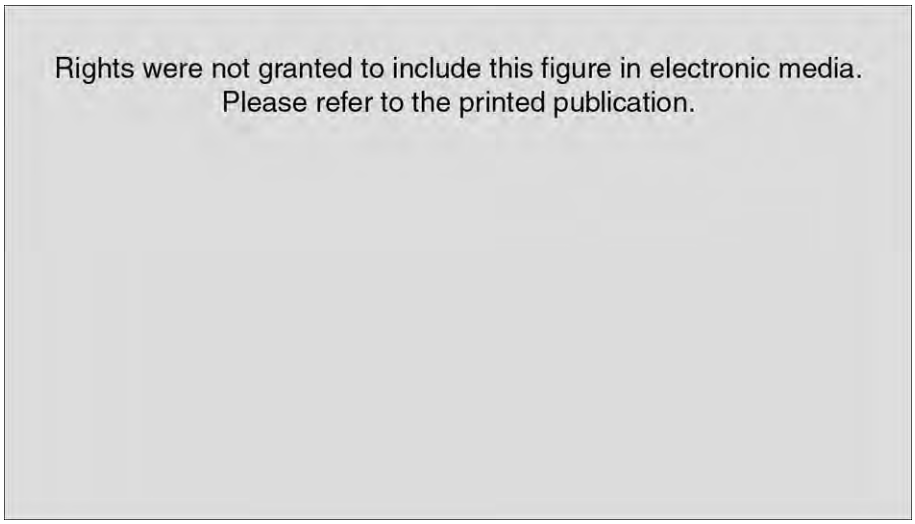

Figure 146–1. Anatomy of the colon that contains diverticula. (From Rodkey GV, Welch JP: An overview. In Welch JP, Cohen JL, Sardella WV, et al [eds]: Diverticular Disease: Management of the Difficult Surgical Case. Philadelphia, Lippincott Williams & Wilkins, 1998, p 8.)

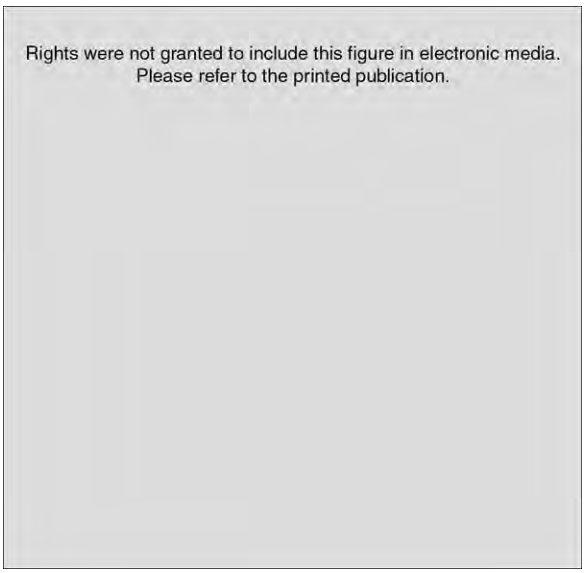

Figure 146–2. Schematic representation of the process of segmentation in the colon. (From Pemberton JH, Armstrong DN, Dietzen CD: Diverticulitis. In Yamada T [ed]: Textbook of Gastroenterology, 2nd ed. Philadelphia, Lippincott, 1995, p 1879.)

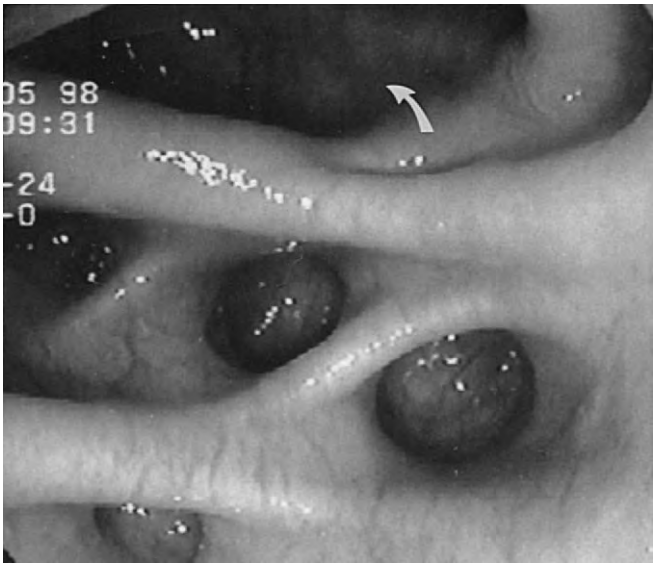

Figure 146–3. Multiple sigmoid diverticula seen with the colonoscope. The lumen is seen in the upper portion of the photograph *(arrow)*.

although numerous diverticula can make visualization of the colonic lumen more confusing (Fig. 146–3). Radiating folds enter the colonic lumen and by lessening colonic peristalsis, administration of glucagon facilitates identification of the lumen. In the case of active diverticulitis, colonoscopy is generally not indicated since there is risk of converting a minor site of intestinal perforation into a free perforation. (Table 146–1). The lumen may also be narrowed by edema and spasm, and the procedure is apt to be painful with fixation of the bowel wall. Little air should be insufflated. The value of the test is limited as well by the fact that diverticulitis is usually extraluminal. In the case of a chronic stricture, it may be quite difficult to enter the area of disease and even to differentiate it from cancer (see later).

Contrast studies provide a "road map" in the elective setting (after the acute process has subsided) in that they show mucosal details and the anatomic distribution of diverticula (Fig. 146–4). The examination is accurate and of relatively low cost, and it is widely available. Contrast studies should be used judiciously in the acute setting, however, since they can be complicated by perforation of the colon. The clinician should request that the enema be done under low pressure with visualization only of the involved sigmoid. If a localized perforation is suspected, a water-soluble agent such as Gastrografin should be used because of the deleterious effects of stool and barium in the peritoneal cavity. Water-soluble agents are less

Table 146–1 Diagnostic Tools for Acute Diverticulitis

Type of Study	Advantages	Disadvantages
Barium enema	Inexpensive, widely available	Potential for extravasation
CT scan	Extramural detail, abdominal evaluation, therapeutic potential	No mucosal detail
Endoscopy	Mucosal evaluation, ability to biopsy	Perforation, inability to completely evaluate

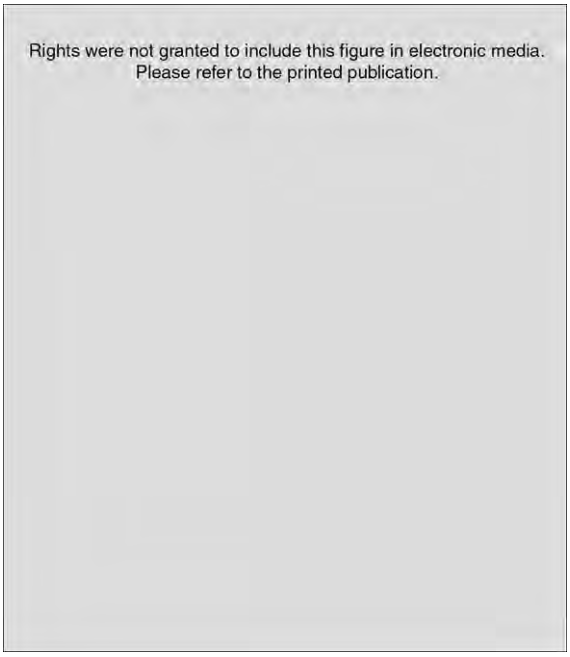

Figure 146–4. View from a barium enema showing sigmoid diverticulosis *(arrows)*. (From Oliveira L, Werner SO: Abdominal pain and diverticulosis. In Welch JP, Cohen JL, Sardella WV, et al [eds]: Diverticular Disease: Management of the Difficult Surgical Case. Philadelphia, Lippincott Williams & Wilkins, 1998, p 39.)

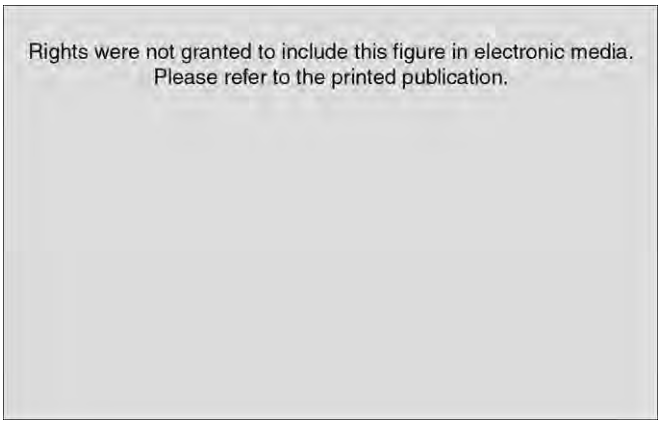

Figure 146–5. A pelvic CT view shows an inflamed sigmoid colon and adjacent tissues together with extraluminal gas confirming the diagnosis of diverticulitis. (From Markowitz SK, Kirejczyk W: Radiologic evaluation of the small and large intestines. In Welch JP, Cohen JL, Sardella WV, et al [eds]: Diverticular Disease: Management of the Difficult Surgical Case. Philadelphia, Lippincott Williams & Wilkins, 1998, p 103.)

reactive in the peritoneal cavity and will be absorbed over time; they cause few artifacts if a computed tomographic (CT) scan is done subsequently.

Although some favor a contrast enema as the initial study, CT scanning has become the most useful modality for the evaluation of acute diverticulitis in hospitalized patients.[10] It not only defines the nature of the process involving the colon (Fig. 146–5) but extracolonic changes as well, such as fluid collections, abscesses, extraluminal air, or fistulas. The sensitivity is as high as 97% (Box 146–1).[11] Diseases in other organs such as the ovaries or appendix can also be evaluated.

Good candidates for CT scans are patients with suspected abscess, with deteriorating clinical status despite appropriate medical treatment, or with suspected complicated diverticulitis. In the uncommon event that findings are unclear, a contrast enema is useful.[10] Helical CT

Box 146–1 **CT Criteria for Diagnosing Diverticulitis**

- Presence of sigmoid diverticula
- Inflammatory infiltration of pericolonic fat
- Thickened colonic wall (>4 mm)
- Fluid and/or contrast collection within thickened colonic wall
- Pelvic abscess associated with inflamed sigmoid colon
- Extrapelvic abscess and/or peritonitis associated with inflamed sigmoid
- Fistula formation (especially sigmoidovesical)

From Neff CC, van Sonnenberg E: CT of diverticulitis: Diagnosis and treatment. Radiol Clin North Am 27:744, 1989.

with colonic contrast alone has been suggested to avoid the risks, costs, and delays of oral and intravenous contrast administration. CT scanning may result in more appropriate patient care and allow cost savings. In some hands, ultrasound has also been useful, showing a thickened colon, diverticula, and sites of local tenderness. This modality is limited by patient obesity and underlying bowel gas, and the results are more subjective and operator dependent than those of CT. Transrectal sonography can increase the sensitivity of abdominal ultrasound for diverticulitis involving the lower sigmoid colon.[12]

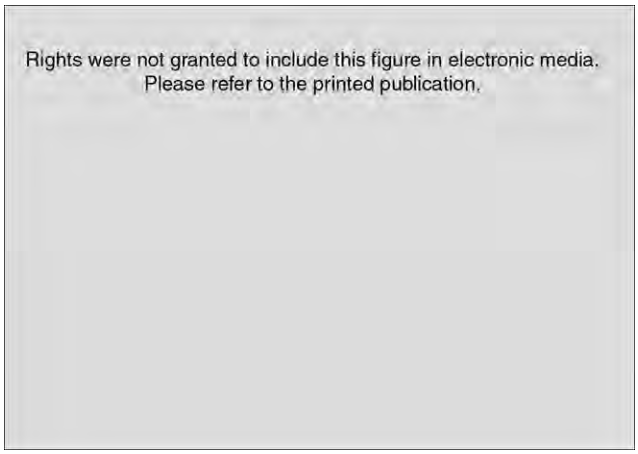

Figure 146–6. Barium enema view of a long stricture of the colon. (From Morgenstern L: "Malignant" diverticulitis. In Welch JP, Cohen JL, Sardella WV, et al [eds]: Diverticular Disease: Management of the Difficult Surgical Case. Philadelphia, Lippincott Williams & Wilkins, 1998, p 184.)

CLINICAL FEATURES

Diverticulitis

The classic signs and symptoms of uncomplicated acute diverticulitis are fever, left lower quadrant abdominal pain, irregular bowel habits, and variable urinary symptoms. Patients complain of diarrhea or of constipation with rectal urgency. The abdomen is maximally tender in the left lower quadrant with some rebound tenderness. Plain abdominal films are of limited value. The white blood cell count is frequently elevated with a left shift, and the urinalysis is normal. Usually the erythrocyte sedimentation rate is elevated. Patients with uncomplicated diverticulitis are managed either on an outpatient basis or in the hospital, depending on the severity of the attack, with antibiotics and a liquid diet or intravenous fluids. Such attacks may recur after variable time periods, and the frequency of such recurrences weighs in the decision whether to treat patients medically or surgically.

Diseases Confused with Diverticulitis

Diverticulitis and colon cancer are common disorders that may coexist. Differentiating a perforated cancer from diverticulitis or detecting a sigmoid carcinoma amidst numerous diverticula may be difficult. Since a perforated cancer will ordinarily require early operation, an effort should be made to establish the correct diagnosis.

CT scanning can be a valuable early test.[13] The patient should receive oral and rectal contrast if possible to increase sensitivity. Certain signs are suggestive of diverticulitis, including (1) localized thickening of the colonic wall; (2) the presence of diverticula; (3) inflammation of the adjacent pericolic fat; and (4) a possible associated collection. Despite these signs, making the correct diagnosis sometimes is difficult using CT alone.

If contrast studies are done, water-soluble contrast rather than barium is used because of the risk of extravasated barium. Only the left colon is examined. Several signs suggest diverticulitis rather than carcinoma, including (1) a gradual rather than abrupt transition from normal to diseased colon; (2) intact mucosa in the abnormal segment; (3) a long involved segment (≥6 cm) (Fig. 146–6); and (4) an intramural mass deforming the colon with intact mucosa. The greater the number of diverticula, the more difficult it is to detect a neoplasm lying within them; thus, most incorrect diagnoses are false negatives. Other radiologic tests such as ultrasound (endoluminal or transabdominal) or nuclear imaging are of limited value.

Does endoscopy play a role? If rectal bleeding has occurred, the risk of neoplasm is increased and the procedure should be done if possible. Unfortunately, endoscopy can be difficult because of narrowing or spasm of the colon. A risk of worsening a site of local perforation exists as well. If the diseased segment can not be completely traversed, a neoplasm cannot be ruled out and operative exploration may be necessary. Colonoscopy is facilitated if associated inflammation is allowed to subside (a useful approach if acute diverticulitis appears more likely than a neoplasm) over a period of 4 to 6 weeks.

Usually diverticulitis and Crohn's colitis can be differentiated, except in a few difficult cases. "Red flags" suggesting the possibility of Crohn's disease include rectal bleeding, perianal inflammation, unusual fistulas, extraintestinal signs, multiple operations, or postoperative complications. Patients with diverticulitis tend to be older and to have more localized pain. Ongoing diarrhea is suggestive of inflammatory bowel disease. Differential radiologic findings also exist (e.g., presence versus absence of transverse fissures, or short vs. long paracolic tracts). Histologic features suggesting a Crohn's disease type of reaction in a localized segment of diverticulitis should not be given undue weight if diverticulitis is suspected as the primary disease. However, the finding of noncaseating epithelioid granulomas along with deep-fissuring ulcers is virtually pathognomonic for Crohn's disease.

Individuals hospitalized in the intensive care unit following cardiovascular or aortic surgery occasionally develop abdominal catastrophes attributed to the colon; ischemic colitis is characteristic in this setting rather than complicated diverticulitis. Patients with ischemic colitis

and diverticulitis complain of abdominal pain, but rectal bleeding is more characteristic of ischemia. An abdominal mass suggests a diverticular phlegmon or abscess rather than ischemia. Endoscopy is the most accurate way to differentiate the two disorders.

Patients with diverticulosis may develop abdominal pain resembling that of diverticulitis. The term *painful diverticulosis* has been coined to describe episodes of abdominal pain and irregular bowel habits. This condition and another source of abdominal pain, the irritable bowel syndrome, are managed with a high-fiber diet and increased fluid intake, as well as antispasmodics. Other illnesses that can be confused with diverticulitis include appendicitis, pelvic inflammatory disease, and pyelonephritis.

Complicated Diverticular Disease

Included under this designation are a number of complications of diverticular disease that challenge the clinical acumen, judgment, and technical abilities of the surgeon. These include obstruction, abscess or fistula formation, free perforation, and bleeding.

Subacute (Persistent) Diverticulitis

Some patients develop a persistent form of inflammation following the onset of diverticulitis that fails to respond to treatment with antibiotics and bowel rest. Characteristically an abscess is not present but the patient does have persistent pain, a low-grade fever, possible urinary symptoms, and failure to thrive. An abdominal mass may be present. Some patients have few symptoms such as vague pelvic discomfort. Due to the varied clinical presentation, definitive surgical treatment is often delayed, and the irritable bowel syndrome must be ruled out.[14]

Since the inflammation is persistent rather than episodic or brief, the colon tends to thicken with development of fibrosis. Patients will often develop chronic symptoms of partial large bowel obstruction. Attempts should be made in these patients to prepare the bowel for a one-stage resection and anastomosis, as the obstruction is rarely complete.

Diverticular Hemorrhage

In a literature review, hemorrhage of colonic origin was caused by diverticular disease (40%), inflammatory bowel disease (21%), neoplasia (polyps and cancer) (14%), coagulopathy (12%), benign anorectal disease (11%), and arteriovenous malformations (2%). Disorders proximal to the ligament of Treitz caused 10% to 15% of rectal bleeds and small bowel disease accounted for 3% to 5%.

Patients with diverticular bleeding tend to be elderly males[8] with diseases such as hypertension and atherosclerosis, and hospitalizations for this complication will likely increase in the future. In half the cases bleeding originates in the right colon, despite the fact that diverticula are situated much more commonly in the sigmoid.

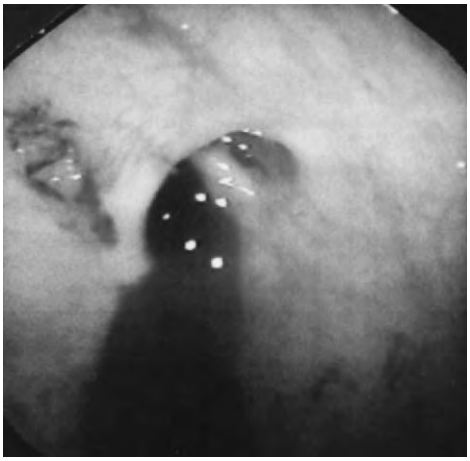

Figure 146–7. Colonoscopic view of an actively bleeding diverticulum.

Regular use of NSAIDs may potentiate bleeding from diverticula.

Most diverticular bleeds are self-limited. Monitoring is appropriate, with its intensity based on the severity of the bleeding and the patient risk. Transfusions may be needed, especially in patients with anemia or heart disease. Colonoscopy can then be performed (Fig. 146–7). There are a few reports of aggressive colonoscopy within hours of hospitalization (following an oral purge). Just as with an upper gastrointestinal bleed, endoscopists can employ epinephrine injections or coagulation at the site of the diverticular bleed, and the colon can be tattooed to facilitate surgical recognition of the bleeding site. There are also reports of endoscopic band ligation[15] and of endoclip usage[16] on the protruding vessels in bleeding diverticula.

Rarely the bleeding is massive, accompanied by hypotension. Such patients need aggressive resuscitation followed by arteriography or bleeding scan (Figs. 146–8 and 146–9). Operative exploration is the only alternative if the blood pressure cannot be controlled. The sensitivity of angiography can be improved with the use of drugs such as urokinase, heparin, and tolazoline. Contrast studies should not be done since retained contrast interferes with the ability to perform arteriography. Vasopressin and more recently embolization techniques have been used in the event of a positive arteriogram.

Pericolic Abscess

An inflammatory mass adjacent to the colon may develop into an abscess, the most common complication of acute diverticulitis, occurring in 10% to 68% of patients. It begins as a small abscess in the sigmoid mesentery and may remain localized by adherence of omentum and adjacent viscera. The collection may also enlarge and extend to more distant sites such as the pelvis. Retroperitoneal abscesses have extended into extra-abdominal areas such as the hip, flank, or leg.

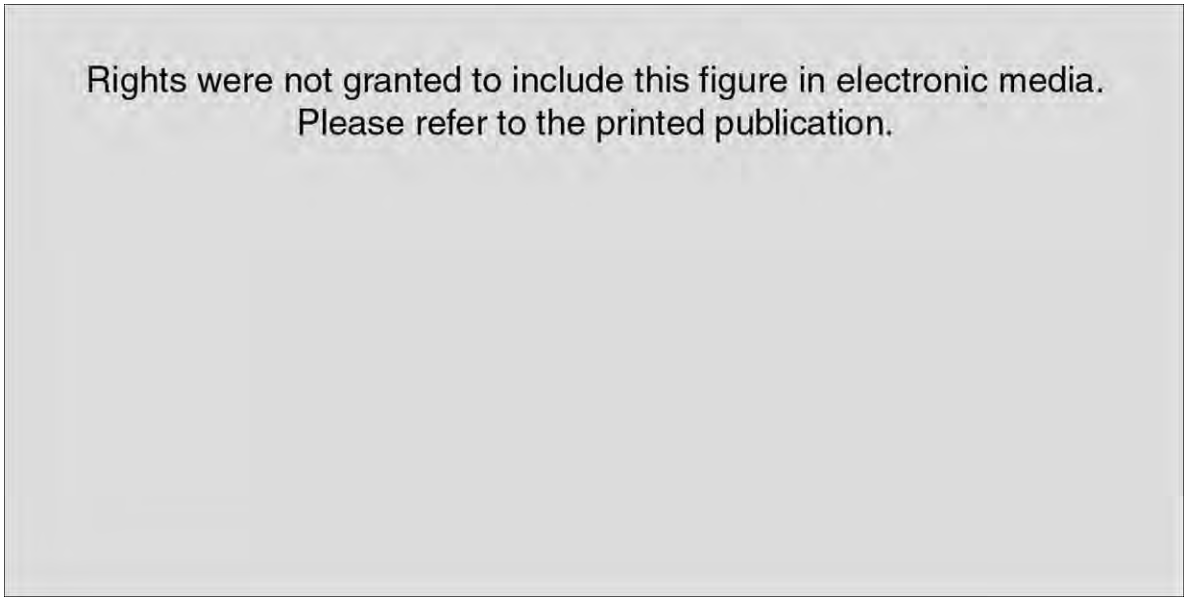

Figure 146–8. **A,** Arteriographic view shows extravasation of contrast *(arrow)* in patient with lower gastrointestinal bleed. **B,** Following embolization with coils *(arrows)*, the active bleeding has ceased. (**A** and **B,** From Pennoyer W, Cohen J: Diverticular hemorrhage. In Welch JP, Cohen JL, Sardella WV, et al [eds]: Diverticular Disease: Management of the Difficult Surgical Case. Philadelphia, Lippincott Williams & Wilkins, 1998, p 84.)

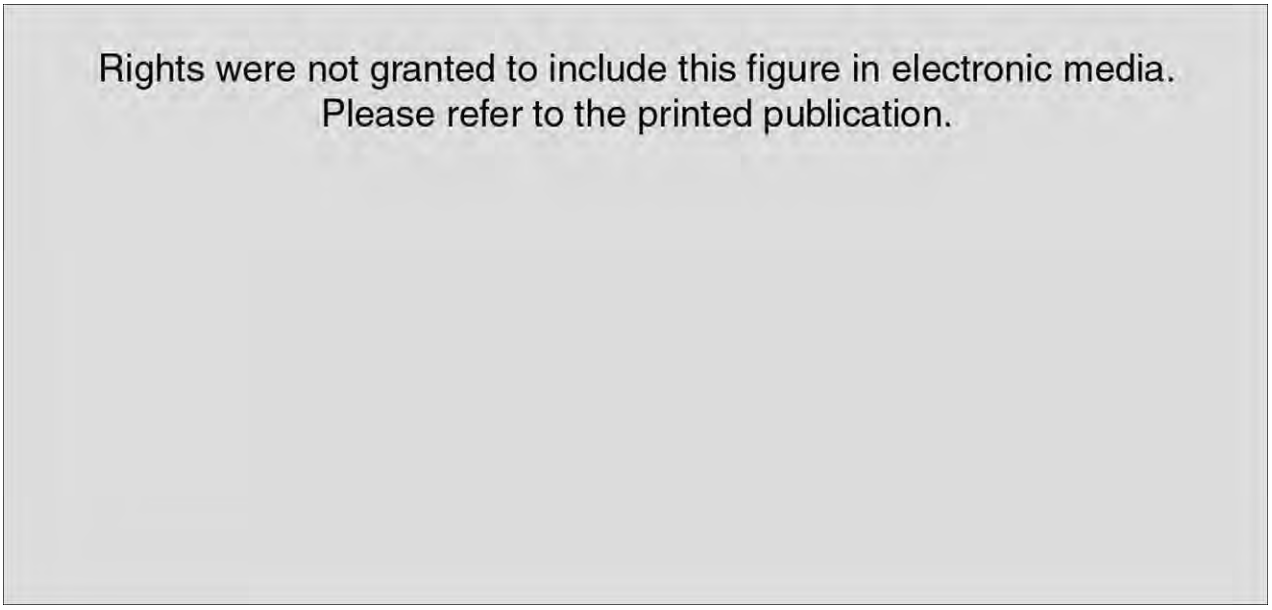

Figure 146–9. Site of bleeding *(arrow)* is detectable in this view from a nuclear scan. (From Pennoyer W, Cohen J: Diverticular hemorrhage. In Welch JP, Cohen JL, Sardella WV, et al [eds]: Diverticular Disease: Management of the Difficult Surgical Case. Philadelphia, Lippincott Williams & Wilkins, 1998, p 82.)

Abscesses cause fever and chills, and a tender mass may be felt on abdominal, rectal, or vaginal examination. Leukocytosis is characteristic.

When an abscess is suspected, a CT scan is the imaging test of choice, since the study delineates the size and the location of the collection.

Fistula

Some abscesses complicating diverticulitis lead to the formation of fistulas by rupturing into adjacent viscera. The most common (50% to 65%) are colovesical fistulas. These develop more frequently in males because of the

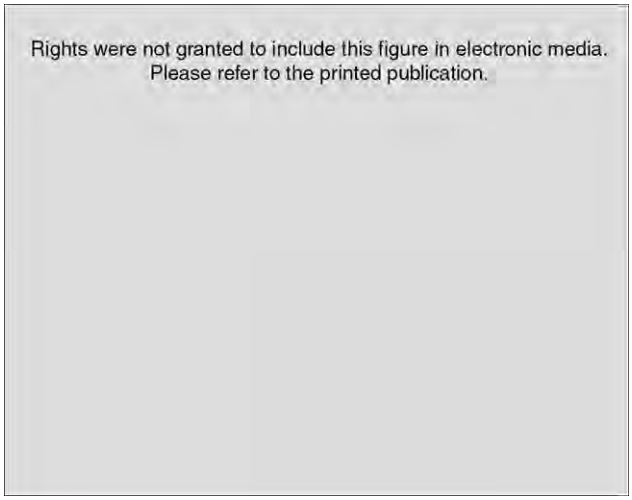

Figure 146–10. In this patient who had a sigmoidovesical fistula, rectal contrast was administered and contrast filling of the bladder is present *(arrow)*. (From Markowitz SK, Kirejczyk W: Radiologic evaluation of diverticular disease of the small and large intestines. In Welch JP, Cohen JL, Sardella WV, et al [eds]: Diverticular Disease: Management of the Difficult Surgical Case. Philadelphia, Lippincott Williams & Wilkins, 1998, p 119.)

Figure 146–11. Depiction of a colovaginal fistula caused by diverticulitis. The fistula is occurring at the site of the vaginal cuff. (From Chinn BT, Eisenstat TE: Colovaginal fistulas. In Welch JP, Cohen JL, Sardella WV, et al [eds]: Diverticular Disease: Management of the Difficult Surgical Case. Philadelphia, Lippincott Williams & Wilkins, 1998, p 168.)

protective effects of the uterus. Symptoms caused by the fistula are usually urologic, including recurrent urinary tract infections, pneumaturia, and fecaluria. The most sensitive diagnostic test is a CT scan with contrast agent that shows a thickened bladder wall, thickening of the bowel adjacent to the bladder, an abscess or extraluminal mass, an opacified fistula, and oral contrast in the bladder (Fig. 146–10). Cystoscopy may show bullous edema or erythema at the site of the fistula.

Most colovaginal fistulas occur in women with diverticular disease who have undergone a hysterectomy. The fistula occurs at the site of contact of the inflamed colon with the vaginal cuff (Fig. 146–11). Vaginal discharge is the most frequent complaint. CT scans with contrast are of significant diagnostic value. Vaginography using a Foley catheter is a highly sensitive test as well.

Colocutaneous fistulas rarely occur spontaneously and should raise the suspicion of Crohn's disease. They tend to complicate a previous operation for diverticulitis.

The diagnosis of Crohn's disease should be ruled out in all patients with fistulas.

Generalized Peritonitis

Generalized peritonitis complicates only 1% to 2% of cases of acute diverticulitis, when an abscess ruptures or when the surrounding tissues are unable to wall off an open rent in a diverticulum. Immunocompromised patients taking steroids are at particular risk to develop the latter complication. In the Hinchey classification of the pathologic stages of perforated diverticulitis, free perforation of a localized peridiverticular abscess site into the peritoneal cavity with purulent peritonitis is termed *stage III* and diffuse feculent peritonitis is *stage IV* (Fig. 146–12). Patients usually present with rather severe abdominal pain, but pain and tenderness may be limited to the left lower quadrant. Plain films may or may not show pneumoperitoneum. Early CT scanning allows visualization of small amounts of free air or fluid, suggesting free perforation. Use of a barium contrast enema for diagnosis is dangerous if free perforation is suspected.

These patients require urgent laparotomy (see later).

Intestinal Obstruction

Large bowel obstruction is caused by diverticular disease in approximately 10% of patients. The usual mechanisms include circumferential colonic thickening and fibrosis, as well as marked angulation of the pelvic colon, with adherence to the pelvic sidewall. Stricturing of the colon develops as a result of recurrent attacks of diverticulitis (symptomatic or subclinical) or of persistent inflammation.

Patients complain of chronic constipation and narrowed stools. The obstruction is typically partial in nature, although complete obstruction may occur. Since carcinoma is a much more frequent cause of obstruction,

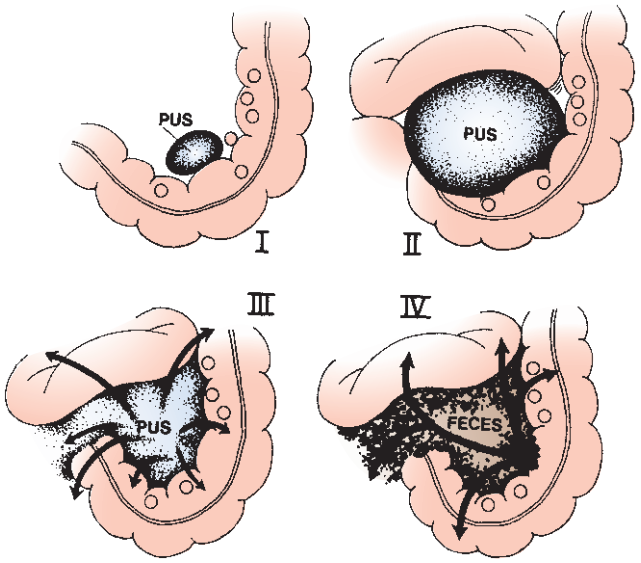

Figure 146–12. A grading system for perforated diverticulitis. I represents a localized pericolic abscess. In II, there is a larger mesenteric abscess spreading toward the pelvis. III depicts a free perforation causing purulent peritonitis. IV shows fecal peritonitis caused by free perforation. (From Hinchey EJ, Schaal PG, Richards GK: Treatment of perforated diverticulitis of the colon. Adv Surg 12:89, 1978.)

the two diseases must be differentiated. Making this distinction may be difficult and, therefore, may be an indication for surgery (see earlier). Limited barium studies (see Fig. 146–6) or flexible sigmoidoscopy are useful diagnostic adjuncts.

Although 10% of operations carried out for diverticular disease involve intestinal obstruction, the risk of acute high-grade obstruction is only in the range of 3% in patients with acute diverticulitis. In the latter group, edema of the colon contributes to the mechanical obstruction; some resolution may occur following administration of antibiotics along with bowel rest. If distention of the colon is marked, there is risk of cecal perforation, and the cecal diameter is monitored with periodic abdominal films and physical examinations.

The clinical picture may be confusing if acute small bowel obstruction complicates acute diverticulitis. Small bowel may adhere to the point of colonic inflammation or to the walls of a pericolic abscess. Fistula formation into the adherent small bowel should raise suspicion of possible Crohn's disease. The presence of one illness may be obscured by the other depending on the clinical presentation. Signs of small bowel obstruction can be obscured by symptomatic diverticulitis, or conversely, the patient may be suspected of having small bowel obstruction alone. Symptoms such as diarrhea or lower abdominal pain should alert the clinician to possible colonic disease accompanying small bowel obstruction. Small bowel obstruction is suggested by symptoms such as periumbilical crampy pain, vomiting, and abdominal distention as well as physical findings of dehydration, tachycardia, and abdominal tenderness.

Abdominal films or CT scans are particularly useful tests in making the differentiation. Contrast material can also be administered per rectum to determine if there is a stricture of the colon. Small bowel studies following oral barium are less desirable, since the colon may be obscured by contrast and any operation is complicated by considerable barium within the bowel.

Unusual Problems

Diverticulitis of the Cecum

The incidence of right-sided diverticulitis appears to be related to the number of diverticula. Thus the highest incidence comes from areas in Asia where the disorder is most common.[17] The natural history of this disease appears to be mild and self-limited in most cases,[18] as opposed to left-sided diverticulitis requiring emergent surgery.[19] Acute appendicitis is usually suspected because of similar symptoms of right lower quadrant pain and tenderness, emesis, fever, and leukocytosis. This disorder should be considered in patients who have undergone appendectomy or when cecal diverticulosis has been detected previously. The appropriate diagnosis can be made with CT scans,[20] although the differentiation from appendicitis or carcinoma may still be difficult.

A useful classification scheme has been proposed by Thorsen and Ternent[21] (Fig. 146–13), as follows:

- Grade I is a discrete, inflamed diverticulum.
- Grade II represents a simple cecal wall mass.
- Grade III refers to a localized abscess or fistula.
- Grade IV is associated with peritonitis (purulent or feculent).

Grades III or IV cecal diverticulitis are easily mistaken for a perforated adenocarcinoma.

Nonresection or diverticulectomy can be applied to grade I and possibly grade II lesions.[22] If the degree of inflammation is minimal, nonresectional treatment is favored with antibiotic therapy (and incidental appendectomy if the cecum at the base of the appendix is uninvolved). If perforated carcinoma is suspected (grades III to IV lesions), colectomy is recommended; anastomosis is reserved for the stable patient with limited contamination.

Giant Diverticula

Rarely a diverticulum can increase to a large size (as much as 40 cm), termed a *giant diverticulum,* or less commonly a giant air cyst, solitary gas cyst, or pneumocyst of the colon. Some have speculated that growth occurs because of a ball-valve mechanism that is a result of fecal material intermittently occluding the neck of the diverticulum and trapping air within it.[23]

Most patients are asymptomatic or present with chronic symptoms such as mild abdominal pain or bloating; rarely, acute complications such as perforation or torsion develop. Classically a soft, somewhat mobile mass is palpable; this is seen as a solitary gas-filled cyst in plain films of the abdomen. The cyst and its relation to the

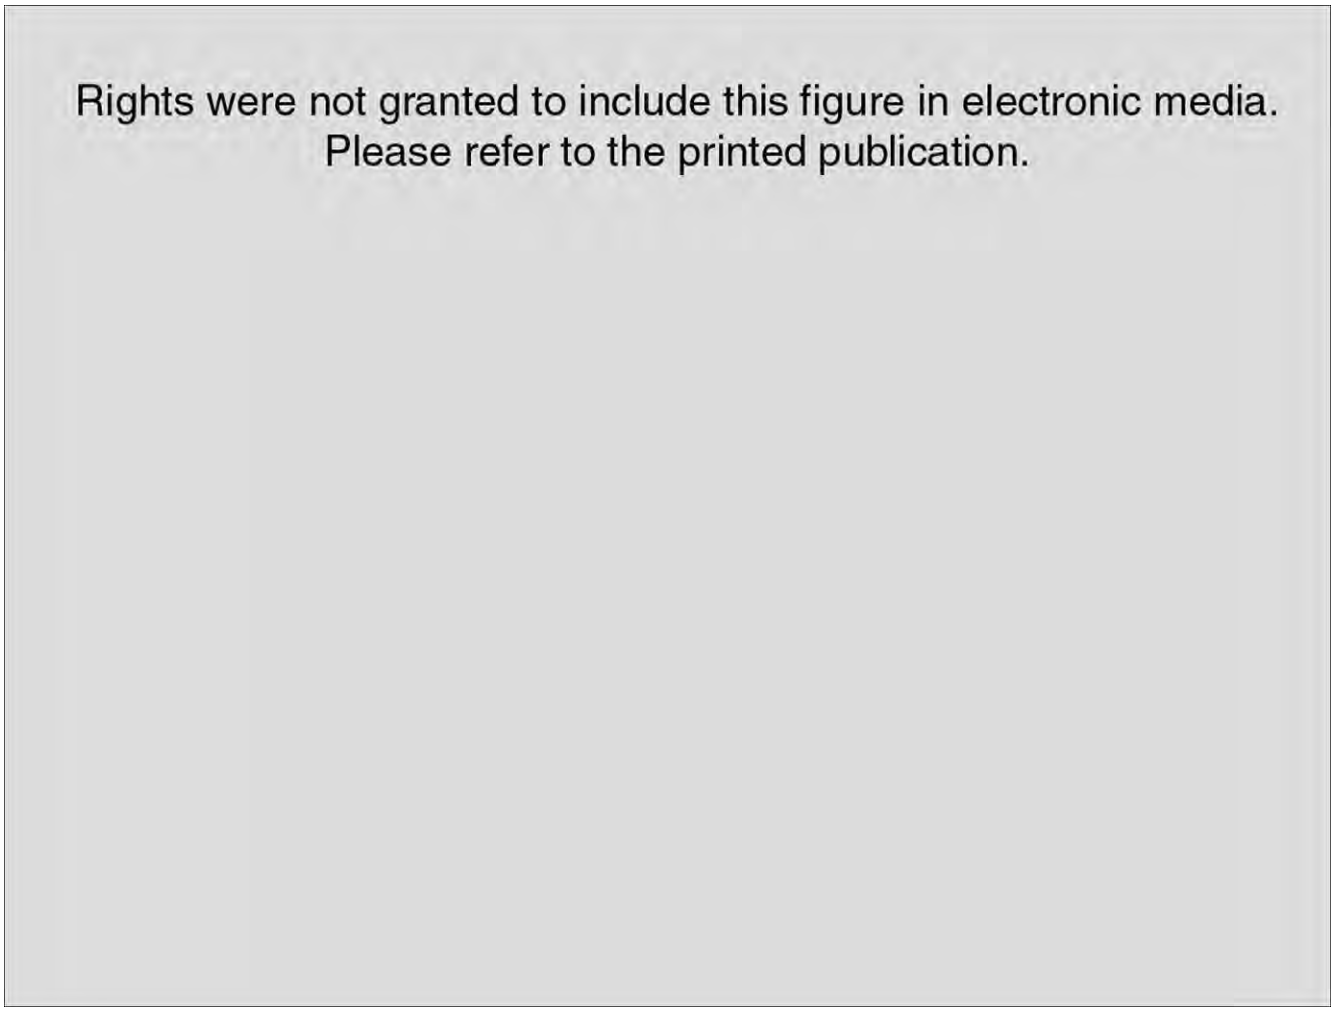

Figure 146–13. The spectrum of pathologic findings in cecal diverticulitis is depicted in these illustrations. **A,** Grade I is a well-identified projecting inflamed cecal diverticulum. **B,** Grade II is a cecal mass. **C,** In Grade III there is a localized abscess or fistula. **D,** Grade IV represents a free perforation or ruptured abscess with peritonitis. (**A-D,** From Thorsen AG, Ternent CA: Cecal diverticulitis. In Welch JP, Cohen JL, Sardella WV, et al [eds]: Diverticular Disease: Management of the Difficult Surgical Case. Philadelphia, Lippincott Williams & Wilkins, 1998, p 435.)

colon are apparent with a barium enema or CT scan (Fig. 146–14). The contrast studies are useful in differentiating other causes of gas-filled masses such as an intra-abdominal abscess or a duplication of the colon. The diverticulum tends to adhere to adjacent structures such as the bladder or small bowel. Once discovered, the diverticulum should be resected in most patients along with the adjacent sigmoid colon. Recurrence is not seen following this procedure. Diverticulectomy alone can lead to formation of a colocutaneous fistula.

The Immunocompromised Patient

Increasing numbers of immunocompromised patients (alcoholics, diabetics, transplant recipients, or patients receiving chemotherapy or steroids) are being hospitalized with diverticulitis. Patients with adult polycystic kidney disease may be at particular risk.

Of interest, immunocompromised patients do not have a higher risk of developing diverticulitis from asymptomatic diverticulosis.[24] However, once diverticulitis develops, it is more complex and severe in the immunosuppressed individual. Corticosteroids serve to mask symptoms and signs of peritonitis in these patients because of their known anti-inflammatory effects. As a consequence, definitive treatment may be delayed and the mortality increased. Surgical mortality has been in the range of 40%.

If diverticulitis is suspected, the clinician should be particularly observant. Toxic granulations are a "red flag" for a septic process. If the patient is receiving high doses of steroids, few physical findings should be expected. Contrast-enhanced CT scans provide important information about perisigmoidal inflammatory changes and possible free perforation in the presence of an "unimpressive" physical examination.

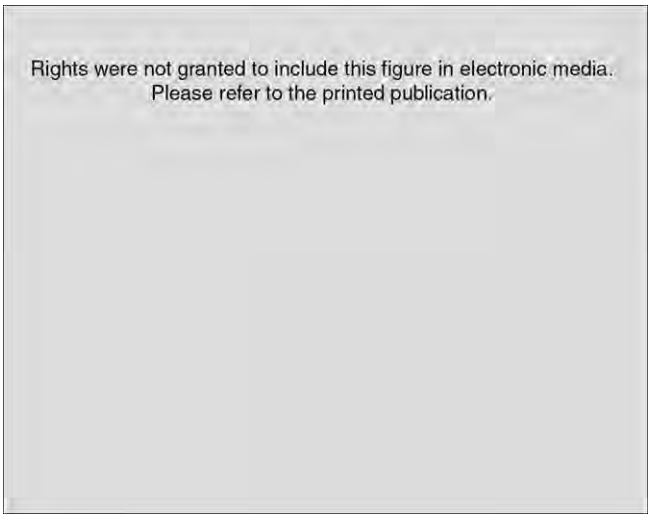

Figure 146–14. Barium enema view showing a giant diverticulum arising from the sigmoid colon. (From de Oliveira NC, Welch JP: Giant diverticula of the colon. In Welch JP, Cohen JL, Sardella WV, et al [eds]: Diverticular Disease: Management of the Difficult Surgical Case. Philadelphia, Lippincott Williams & Wilkins, 1998, p 414.)

Table 146–2 Unusual Extra-abdominal Presentations of Diverticulitis

Type of Presentation	Specific Manifestation
Dermatologic	Pyoderma gangrenosum
Urinary	Ureteral obstruction, coloureteral fistula
Soft tissue	Thigh abscess, necrotizing fasciitis
Orthopedic	Osteomyelitis
Gynecologic	Colouterine fistula, ovarian tumor/abscess
Genital	Epididymitis, pneumoscrotum
Neurologic	Coloepidural fistula
Vascular	Femoral vein thrombosis, mesenteric vein thrombosis, pylephlebitis, colovenous fistula
Perineal	Fournier's gangrene, complex anal fistula

From Polk HC, Tuckson WB, Miller FB: The atypical presentations of diverticulitis. In Welch JP, Cohen JL, Sardella WV, et al (eds): Diverticular Disease: Management of the Difficult Surgical Case. Philadelphia, Lippincott Williams & Wilkins, 1998, p 385.

Diverticulitis in the Young

Autopsy studies suggest that only 6% to 9% of patients younger than 40 years of age have colonic diverticular disease. Young patients diagnosed with diverticulitis are usually obese men, perhaps due to underdiagnosis of the disease in women of reproductive age. Diverticulitis may be missed in men as well, since it may not be suspected by the treating clinician. The theory that younger patients may have more virulent forms of diverticulitis is countered by significant numbers of undiagnosed patients who are never hospitalized. Since young patients do not tend to have comorbid illnesses (unlike elderly patients), those hospitalized have advanced diverticulitis.

An aggressive surgical approach has been advocated for diverticulitis occurring in young patients. Support for this approach is predicated on the impression that young patients experience a more aggressive variant of the disease, as well as an increased rate and severity of recurrence. The higher operative rate following the first presentation of these patients is more likely due to the mistaken diagnosis of appendicitis than to an increased virulence of the initial presentation. Furthermore, although the patients who develop a recurrence may be more likely to require surgery than the general population, there does not appear to be an increased rate of recurrence. Furthermore, young patients who develop a recurrence generally undergo an elective procedure and do not require a staged resection. For these reasons, diverticulitis in young patients does not need to be distinguished from and treated separately from the disease in the general population.[25,26]

Atypical Presentations

Inflammatory diseases originating in bowel such as diverticulitis, Crohn's disease, or appendicitis can be accompanied by unusual systemic manifestations or complications. The atypical presentations of diverticulitis are summarized in Table 146–2 and can be classified as either intra-abdominal or extra-abdominal. Immunosuppressed patients are at increased risk of developing these complications.

Intra-abdominal fistulas usually are colovesical, colocutaneous, or colovaginal but may be coloureteral, colorenal, colouterine, colovenous (involving the mesenteric veins), or colobiliary. Pylephlebitis developing as a complication of diverticulitis can lead to a pyogenic liver abscess. Adnexal masses managed surgically by a gynecologist can prove to be a diverticular phlegmon or abscess.

Pyoderma gangrenosum may complicate diverticulitis. Arthritis may also be seen. Distant abscesses have been seen in the brain. Retroperitoneal perforations can manifest in a number of ways. Anatomic communication to the thigh, genitalia, or knee can lead to cellulitis or abscesses in these locations.[27] The usual portals include the psoas muscle, the femoral canal, the obturator foramen, or the sacrosciatic notch. Escape of air into the mediastinum can lead to subcutaneous emphysema in the neck.[28]

MEDICAL MANAGEMENT

The medical therapy of diverticular disease depends greatly on the severity of the clinical presentation. In its mildest form, symptomatic diverticulosis may be manifested solely by left lower quadrant discomfort. In the absence of signs of infection, empirical therapy can be initiated and directed toward the treatment of a colonic motility problem. The initiation of a high-fiber diet has been demonstrated to have a beneficial effect on patients with symptomatic diverticulosis. Increased fecal bulk may increase bowel wall diameter, thereby lessening wall tension according to Laplace's Law. Furthermore, increased fiber probably decreases intestinal transit time, lessening the deleterious effects of constipation, including the development of diverticular complications.

Patients who present with localized abdominal pain and tenderness but without systemic signs of toxicity are usually managed successfully on an outpatient basis. A liquid or low-residue diet is initiated along with oral antibiotic therapy directed at the bacterial flora of the gut. In a prospective Italian trial, cyclic intake of a broad-spectrum antibiotic together with fiber was more effective than fiber alone in decreasing subsequent episodes of diverticulitis.[29] For mild cases of diverticulitis, we tend to prescribe trimethoprim-sulfamethoxazole or ciprofloxacin in conjunction with metronidazole. Unfortunately, it may be difficult for patients to tolerate the combination of trimethoprim-sulfamethoxazole and metronidazole when they may already be experiencing some degree of gastrointestinal upset. Within several days, the patient's symptoms usually begin to resolve and antibiotic therapy is continued for a 7- to 10-day period. If a patient has not been previously diagnosed with diverticulitis, an elective evaluation of the colon is performed once the clinical symptoms have resolved.

Patients who present with a more advanced form of acute diverticulitis generally require admission to the hospital. The disease may be manifested by high fevers, lower abdominal peritonitis, and dehydration secondary to nausea or vomiting. Bowel rest is initiated with intravenous hydration and antibiotic therapy. Although cost-effective treatment for these more serious infections may still include triple-antibiotic therapy with ampicillin, gentamicin, and metronidazole, newer combinations of third-generation cephalosporins with metronidazole or even single-drug therapy such as ampicillin/sulbactam may be preferable in certain hospitals or regions. Furthermore, if the patient improves clinically and can tolerate oral intake, intravenous antibiotic therapy can be completed on an outpatient basis. Generally, antibiotic therapy is continued for 10 to 14 days in this setting, although occasionally a prolonged course for up to 1 month may be beneficial.

For most patients presenting with acute diverticulitis severe enough to require hospitalization, early evaluation with CT imaging is extremely beneficial. Not only does CT scanning confirm the diagnosis, but it also reliably assesses the degree of surrounding inflammation. Although this information can assist in predicting the treatment course for the patient, the ability to detect diverticular abscesses can also lead to further therapeutic benefit. Percutaneous drainage of diverticular abscesses is now routinely performed in the treatment of complicated diverticular disease. The ability to drain these abscesses percutaneously, either under CT or ultrasound guidance, has led to more elective, single-stage resections.

Figure 146–15. CT view of patient with a large pelvic abscess secondary to acute diverticulitis. A drainage catheter introduced via the transgluteal approach is seen within the cavity.

Small pericolic abscesses (<5 cm) generally resolve with bowel rest and intravenous antibiotics and are amenable to resection of the diseased segment en bloc with the abscess. Larger abscesses should be drained percutaneously, provided several caveats are followed. The abscess cavity should be well defined, localized, and have a safe access route, either via an abdominal route or transgluteally (Fig. 146–15). Deep pelvic abscesses can be difficult to drain.[30] Furthermore, pneumoperitoneum and gross feculent peritonitis are contraindications to this approach.

The timing of surgery following percutaneous drainage depends on factors such as the patient's response to drainage, the degree of surrounding inflammation on CT scan, and the nutritional status. If patient improvement is rapid following drainage of a single abscess and minimal surrounding inflammation is seen on CT scan, an operation may be performed during the same admission. Alternatively, if the CT demonstrates significant surrounding inflammation or the patient is otherwise debilitated, a more prudent course is to delay surgery for 4 to 6 weeks.

SURGICAL MANAGEMENT

Elective Resection

It has been estimated that 20% of patients with acute diverticulitis ultimately require surgery. Although many of these patients develop a complication necessitating emergency operative intervention, there remain several indications for elective surgical intervention.

Following an episode of acute diverticulitis, recurrent attacks requiring readmission to the hospital occur in 20% to 40% of patients. Complication rates related to diverticulitis increase with subsequent attacks, exceeding 50% after two episodes. Because of the natural history of the disease, the most common indication for elective surgery in diverticular disease is recurrent episodes of acute diverticulitis interfering with the quality of the patient's daily living. The actual number of attacks warranting elective resection is somewhat controversial.[31] Other indications for elective sigmoid resection are fistula formation and previous percutaneous drainage of a diverticular abscess. Although some evidence exists that percutaneous drainage of an abscess does not mandate follow-up surgery, most surgeons believe that this complication is serious enough to warrant definitive surgical treatment.

Given the difficulty in distinguishing the symptoms of recurrent diverticulitis from other sources of abdominal pain, especially irritable bowel syndrome, some objective evidence of diverticulitis should be present prior to recommending surgery. This is most commonly obtained with a CT scan, although signs of acute diverticulitis, such as sinus tracts or extraluminal barium, can be seen in contrast studies. Even when operated on for proven diverticulitis, the patient should be cautioned regarding the possibility that not all of the abdominal symptoms will resolve following surgery.

Patients undergoing elective diverticular resection receive a mechanical and antibiotic bowel prep. Placing the patient in the lithotomy position allows access to the anus for performing a stapled anastomosis. Furthermore, should difficulty arise in identifying the ureter, this position allows for intraoperative urologic manipulations. For elective resections, preoperative placement of ureteral stents is unnecessary and adds cost to the procedure. Should an unexpected inflammatory mass be found and ureteral identification and preservation be difficult, stents can then be placed intraoperatively. They clearly save time during the operation, although placement of the stents may not actually prevent ureteral injury.

At the time of operation, the abnormally thickened and diseased sigmoid colon should be resected. Although this may involve only a small portion of the sigmoid colon, the distal point of resection must extend to the rectosigmoid junction. This can be identified by the loss of the taeniae coli. Failure to resect the distal sigmoid colon increases the incidence of recurrent diverticulitis from 6% to 13% to 23% (see later). The extent of proximal resection is not as important but should always be performed through soft, healthy-appearing bowel. Mobilization of the splenic flexure is performed if there is concern regarding anastomotic tension. Often mobilization of the rectum from the presacral space will obviate the need for splenic flexure mobilization.

Recent advances in laparoscopic surgery have facilitated its use in the treatment of diverticular disease. In general, laparoscopic surgery results in decreased postoperative pain and hospital length of stay, leading to an earlier return of normal patient function.[32] Once the bowel has been mobilized laparoscopically, the increasing use of the technique of hand-assisted laparoscopic surgery (HALS), or "handoscopy," has allowed for the use of minimally invasive surgery even in complicated diverticular disease (Fig. 146–16).[33] The opportunity for the surgeon to preserve tactile sense facilitates dissection of the chronically inflamed sigmoid colon and shortens operative time and the learning curve. HALS has had its greatest impact in separating the colon from the left pelvic sidewall and in resecting the thickened sigmoid mesentery (Fig. 146–17). The use of the surgeon's hand (usually nondominant) simplifies maneuvers such as control of bleeding, manipulation of staplers into position, or occlusion of the bowel during testing of a

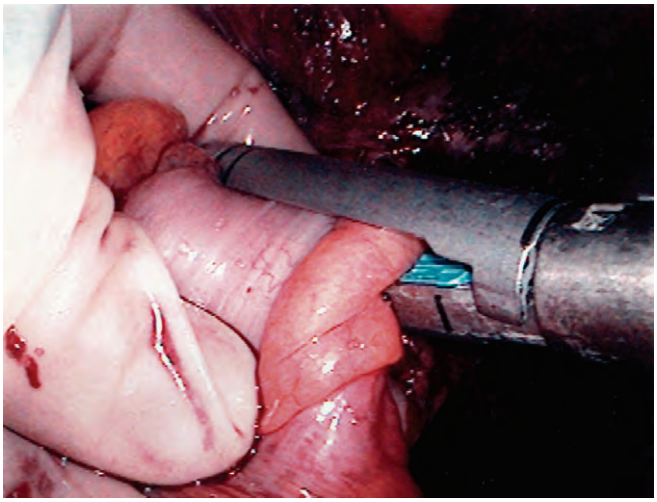

Figure 146–16. Hand-assisted laparoscopic surgery demonstrating transection of rectosigmoid colon with an endoscopic stapler.

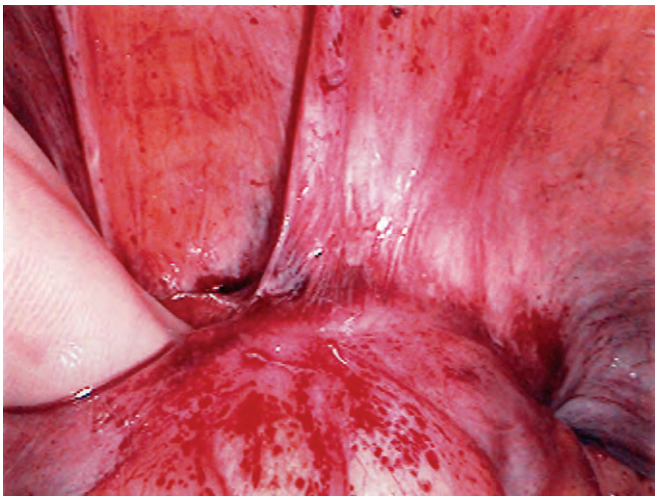

Figure 146–17. Inflamed sigmoid colon stuck to the left pelvic sidewall. Separation is facilitated using hand-assisted laparoscopic surgery.

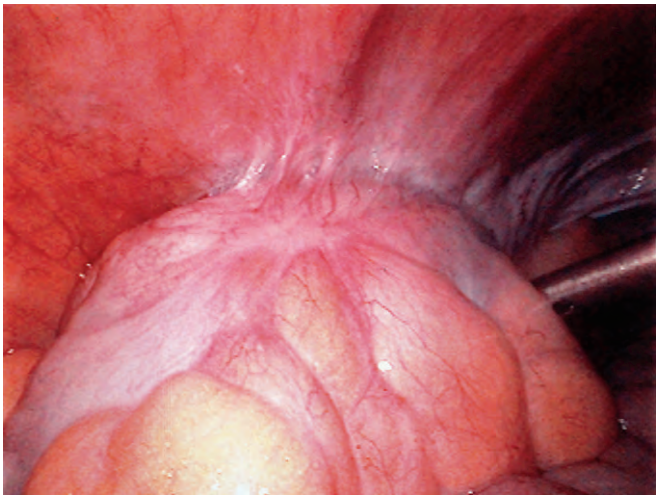

Figure 146–18. Appearance of a colovesical fistula. There is fusion of the chronically inflamed sigmoid colon to the urinary bladder.

low-stapled anastomosis. It is clear that HALS is becoming increasingly common when managing surgical disorders of the colon.[34,35]

Diverticular fistulas can usually be treated on an elective basis, since they tend to develop slowly and rarely lead to sepsis with patient instability. Most of these fistulas presumably develop from the sigmoid colon to the bladder or vagina after a diverticular abscess has developed (Fig. 146–18). Once other etiologies have been excluded, treatment essentially involves disconnection of the fistula with resection of the diseased sigmoid colon. It is not necessary to repair the defect in either the bladder or vagina, although a bladder repair is usually performed with an omental flap interposition between the colonic anastomosis and the bladder. A study of 37 patients from the Cleveland Clinic with colovesical fistulas did not demonstrate a benefit for any single type of repair.[36] Postoperatively the bladder is routinely drained for 5 to 7 days, although this time interval can be shortened if a voiding cystogram is obtained.

There are several technical aspects to division of the diverticular fistula that facilitate the dissection and increase the safety of the procedure. It is beneficial to divide the proximal bowel early in the operation and to identify the ureter at the pelvic brim. If a phlegmon is present, dissection distal to the fistula at the level of the proximal rectum can facilitate isolation of the fistulous segment.

Finally, the fistula can be "pinched" between the surgeon's fingers, allowing safe separation of the fused organs and minimizing injury to the bladder or ureter. If performed laparoscopically, this maneuver is made significantly easier by using handoscopy (Fig. 146–19). In a series of 36 HALS performed for colovesical fistulas, 75% were successfully completed without the need for conversion.[37] With increased experience over a 6-year period, the conversion rate decreased below 15%.

In most patients, primary anastomosis can be performed safely since the degree and extent of the surrounding acute inflammation are minimal. The surgeon's experience appears to be a variable in the success of this procedure, with the goal of avoiding the need for temporary diversion. In one study of surgery for diverticular fistulas, colorectal surgeons experienced a lower rate of diverting procedures and postoperative complications as compared with general surgeons.[38]

Emergency Surgery

Many patients with diverticular disease develop a surgical emergency as their first presentation.[39] Generalized peritonitis, free perforation, and high-grade obstruction all require urgent surgical intervention, and bleeding may also lead to an emergency operative procedure.

Historically, surgery for diverticular disease was performed in stages. By the 1980s, however, it had become clear that leaving the diseased colon in place while merely diverting the fecal stream (three-stage resection) was associated with unacceptably high morbidity and mortality rates. Removing the septic focus at the time of the initial operative intervention decreased mortality from 25% to 30% to less than 10%. Given these findings, as well as the decreased likelihood of ever completing all three operations and restoring intestinal continuity, a three-stage approach is rarely used today in the treatment of complicated diverticular disease.

When operating on unprepped bowel in the case of perforation, generalized peritonitis, or obstruction, the most difficult decision relates to restoration of intestinal continuity. Systemic issues such as hemodynamic instability, malnutrition, or coagulopathy are of paramount concern and may preclude any consideration of performing an intestinal anastomosis. Otherwise, the degree of peritoneal contamination at the time of surgery reliably predicts the safety of performing a primary anastomosis versus resection with diversion. The classification system devised by Hinchey et al. attempts to describe the

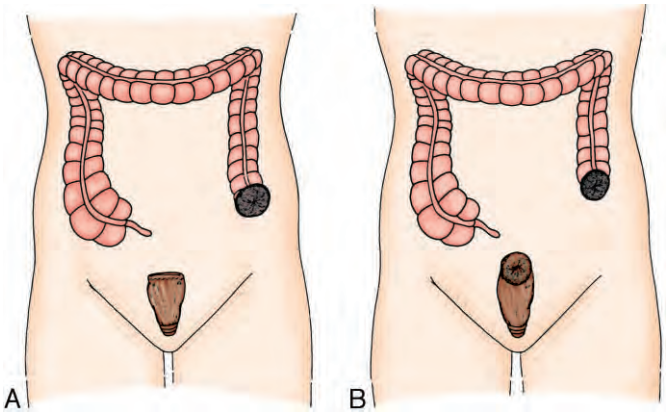

Figure 146–20. The Hartmann procedure is commonly done for patients who have perforated diverticulitis without a bowel prep **(A)**. If the distal bowel reaches the abdominal wall, a mucous fistula is constructed **(B)**. (**A** and **B,** From Gordon PH: Diverticular disease of the colon. In Gordon PN, Nivatvongs S [eds]: Principles and Practice of Surgery for the Colon, Rectum, and Anus. St. Louis, Quality Medical, 1992, p 766.)

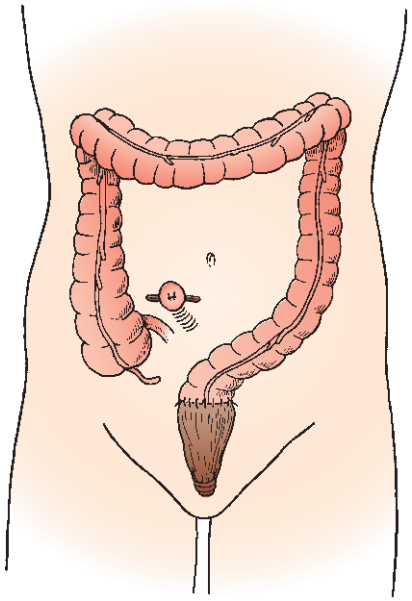

Figure 146–21. An alternative to the Hartmann procedure, including sigmoid resection, primary anastomosis, and proximal diverting loop ileostomy.

degree of inflammation associated with complicated diverticular disease (see Fig. 146–12), but it does not account for patient comorbidities. Resection with primary anastomosis (one stage) appears to be safe for Hinchey I and II stages, whereas we favor resection and diversion in cases of free purulent or feculent peritonitis (Hinchey stages III and IV).[40,41] Controversy exists, however, and there are reports of successful resection and primary anastomosis for stage III and IV cases employing extensive abdominal lavage and on-table colonic lavage.[42-46]

The Hartmann procedure is the most widely practiced two-stage operation for the treatment of diverticulitis. First described by the French surgeon, Henri Hartmann, in 1921 as an alternative for the treatment of carcinoma of the rectosigmoid, it involves resection of the sigmoid colon with proximal diversion and oversewing of the distal stump (Fig. 146–20A).[47] Alternatively, the distal segment may be exteriorized to facilitate subsequent restoration of intestinal continuity (see Fig. 146–20B). However, the latter procedure usually is not feasible for diverticulitis, since resection of the involved segment does not leave enough length to reach the anterior abdominal wall. The operative mortality of performing a Hartmann procedure for perforated diverticulitis ranges from 0 to 15%. A disadvantage of this approach is that a second major procedure with attendant risks is needed to restore intestinal continuity.

Silvis and Keeman attempted to distinguish between one- and two-stage resections when stratified for Hinchey classification. While mortality rates were similar between the two types of operations for Hinchey I and II classes, the mortality rate was more than double for one-stage operations when used for Hinchey III (17% vs. 8%) and Hinchey IV groups (64% vs. 28%).[48]

The timing of the second operation to reverse the colostomy after the Hartmann procedure is of some importance. Most surgeons recommend waiting at least 3 months to allow for postoperative inflammation to resolve. Furthermore, patients can return to complete health after having undergone emergency surgery. The second operation can be technically difficult, leading to a complication rate of 20% to 46%, including an anastomotic leakage rate of 16%. Furthermore, at least 30% of patients who undergo a Hartmann procedure will never have intestinal continuity restored.

An alternative procedure attempts to reduce the difficulties of reversing the Hartmann procedure. At the time of initial resection, a primary anastomosis is performed with creation of a proximal diverting loop ileostomy (Fig. 146–21).[49,50] This is a much easier stoma to reverse, and the procedure avoids reoperation in the pelvis.

Obstruction

Obstruction is the indication for surgery in approximately 10% of patients requiring operation for symptomatic diverticular disease. Only rarely, however, is emergency surgery required because of a high-grade obstruction placing the patient at risk for cecal perforation. Typically, patients experience repeated bouts of acute diverticulitis that heal with progressive scarring. This leads to mild obstructive symptoms including pain, bloating, and chronic constipation.

When a patient presents with complete obstruction and develops proximal colonic dilation, urgent surgery is required to prevent the life-threatening complication of perforation. In this setting it is difficult, if not impossible, to perform an adequate preoperative mechanical preparation. Since proximal fecal loading has been

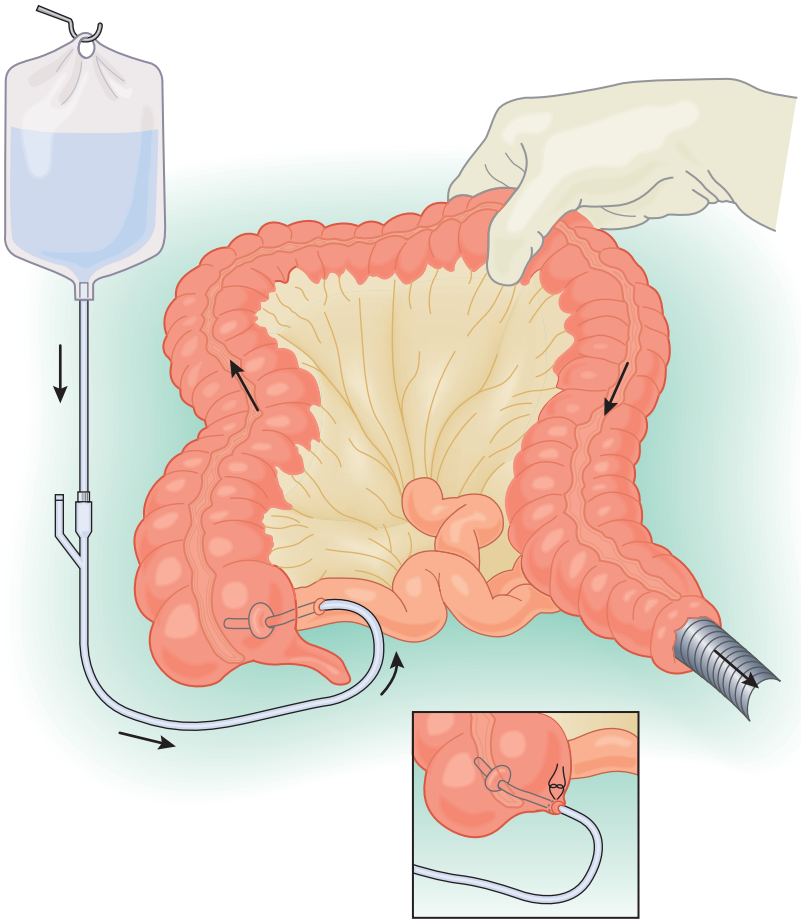

Figure 146–22. Technique of on-table lavage. The Foley catheter is introduced through the base of the appendix. If the appendix has been removed, the catheter can be placed through an enterotomy in the ileum or a cecotomy. Corrugated plastic tubing introduced into the colon is passed off the table into canisters. (From Ross HM, Roberts PL: Role of on-table lavage for complicated diverticular disease. Semin Colon Rectal Surg 11:219, 2000.)

demonstrated to impair anastomotic healing, this situation has generally mandated a staged resection such as a Hartmann procedure, with delayed restoration of bowel continuity. Alternatively, an anastomosis can be performed with proximal diversion by a loop ileostomy. If a diverticular stricture cannot be reliably diagnosed preoperatively, a wide mesenteric resection must be performed in case the obstruction is secondary to sigmoid carcinoma.

In the absence of hemodynamic instability or a perforation with feculent peritonitis, on-table colonic lavage can be used to prepare the bowel intraoperatively for a primary anastomosis. The technique was first described by Muir in 1968 and refined by Radcliffe. Following intestinal resection, both flexures are mobilized, an appendectomy is performed, and an appendicostomy tube is placed through the base of the appendix. Corrugated tubing is inserted into the end of the colon proximal to the resection and secured with a Dacron tape (Fig. 146–22). Three to six liters of saline are used to wash out any feculent material from the colon. Using this technique, Lee et al. reported a series of 33 patients undergoing on-table lavage for complicated diverticular disease.[51] One patient developed an anastomotic leak and was the only mortality reported. There was a 42% morbidity rate, but the technique appears safe for patients with obstruction who are hemodynamically stable during the operation.

Bleeding

Lower gastrointestinal bleeding occurs in approximately 20% of patients with diverticulosis, of whom 5% experience severe hemorrhage. Although bleeding spontaneously ceases in 80% to 90% of patients, the risk of rebleeding approaches 25%. For this reason, a rapid evaluation of the patient should take place even while the patient is being resuscitated in the emergency department.

Since 10% of all lower gastrointestinal bleeding ultimately arises from a gastroduodenal source, a nasogastric tube should be placed early in the evaluation. Furthermore, proctoscopy must be performed to confirm that the source of bleeding is not from the rectum or anal canal.

Every attempt should be made to localize the source of bleeding preoperatively, since the mortality rate of emergency subtotal colectomy ranges from 10% to 50%. Although nuclear imaging scans can detect bleeding at rates as low as 0.1 ml/min, surgery based solely on this evaluation misses the source of bleeding 25% of the time. Angiography has the benefit of localizing the bleeding site prior to surgery accurately, reducing the operative mortality from 50% to 10%. Furthermore, superselective embolization can be performed safely, obviating the need for surgery in more than 80% of patients in whom it is used (see Fig. 146–8).

An alternative approach for localizing a colonic source utilizes colonoscopy. Advocates of emergency colonoscopy during the initial period of presumed ongoing bleeding point to the high rate of localization (74% to 85%) while incurring low complication rates. The examination is facilitated by either rapid whole-gut lavage via a nasogastric tube or, alternatively, the use of cleansing enemas combined with frequent, aggressive pulsatile irrigations during the colonoscopy procedure. Additional arguments for this approach point to the potential therapeutic benefit of colonoscopy and its cost-effective advantage when compared with arteriography.

Admittedly, emergency colonoscopy in a patient with ongoing bleeding is a difficult technical exercise, even for the experienced endoscopist. Furthermore, hemodynamic instability limits the ability to sedate patients well for colonoscopy, thereby increasing the difficulty of the examination. Given these considerations, a more reasonable, safe approach is to stabilize the patient first and then perform early colonoscopy after a rapid gut lavage with polyethylene glycol. Only if the patient presenting with lower gastrointestinal bleeding cannot be easily stabilized should other diagnostic modalities be employed first. The diagnostic accuracy of early colonoscopy for lower gastrointestinal bleeding has been reported to be 40% to 90%. Although the varied results depend to a large degree on the timing of the procedure, the criteria for diagnosis also play a role. Findings at colonoscopy that help support a definitive source include an actively bleeding site, isolated fresh blood in one segment of the colon only, or adherent clot to a "lesion."

Should emergency surgery be necessary without the benefit of preoperative localization, intraoperative colonoscopy can be performed to assist in identifying the bleeding site. If a localized site of bleeding is not found within the colon, an emergency subtotal colectomy should be performed. The mortality rate in this setting is equal to that of a blind segmental resection but with a much lower rebleeding rate. If a localized site of bleeding is not found intraoperatively, maneuvers such as multiple colotomies or a transverse colostomy should be discouraged—they only increase the complication rate without controlling the source of bleeding.

Postresection Diverticulitis

Recurrent diverticulitis following resection is uncommon, occurring in 1% to 10% of patients. Given the unusual nature of this situation, a complete evaluation should be performed to eliminate other potential causes. Symptoms of irritable bowel syndrome frequently overlap those of diverticular disease, with the exception of fever and leukocytosis. Other conditions such as Crohn's disease, carcinoma, and ischemic colitis may be confused with acute diverticulitis. Previous pathology specimens should be reviewed with the differential diagnosis in mind.

The most likely explanation for the development of recurrent disease is an incomplete resection at the time of the initial operation. While the inflammatory process frequently involves only a small portion of the sigmoid colon, a complete sigmoidectomy needs to be performed. The distal point of resection should be through soft, pliable bowel at the rectosigmoid junction. This area is identified by the convergence of the taeniae coli into a confluent sheet of longitudinal muscle surrounding the rectum. In a series of 501 patients undergoing a resection for diverticular disease, recurrent diverticulitis developed in 12.5% in whom the sigmoid colon was used as the distal resection margin. This contrasts to a 6.7% recurrence rate when the anastomosis was performed to the rectum.[52]

Although the routine use of ureteral stents is unnecessary for diverticular resections, they can be beneficial when operating for recurrent disease. Typically the inflammatory process involves the left pelvic sidewall that has been dissected previously. The preoperative placement of a left ureteral stent may not prevent injury in this setting, but it can facilitate the dissection and allow for rapid identification of an injury should it occur.

As with the initial operation, reoperative surgery should commence by dissection through noninflamed tissue with early identification of the left ureter. Splenic flexure mobilization becomes mandatory, and often the anastomosis will be to the transverse colon. Most important, the previous anastomosis must be resected and the new anastomosis must incorporate the noninflamed rectum.[53]

Hemorrhoids

Anthony J. Senagore

There are few diseases more chronicled in human history than symptomatic hemorrhoidal disease.[1,2] References occur in ancient texts dating back to Babylonian, Egyptian, Greek, and Hebrew cultures.[1,2] Included in many of these writings are multiple recommended treatment regimens, including anal dilation, topical ointments, and the intimidating red hot poker.[3,4] Although few people have died of hemorrhoidal disease, many patients wish they had, particularly after therapy, and this fact led to the beatification of St. Fiachre, the patron saint of gardeners and hemorrhoidal sufferers.[5] Hopefully, this discussion will guide the practitioner in a more humane approach to hemorrhoidal disease, with the emphasis on cost-effectiveness with minimal morbidity and mortality.

ANATOMY AND ETIOLOGY

The hemorrhoidal cushions appear predictably in the right anterior, right posterior, and left lateral positions, although there may be intervening secondary hemorrhoidal complexes that blur this classic anatomy.[6] The blood supply is similarly constant, deriving from the superior rectal artery, a branch of the inferior mesenteric; the middle rectal arteries arising from the internal iliac arteries; and the inferior rectal arteries arising from the pudendal arteries. The venous drainage transitions from the portal venous system above the level of the dentate line to the systemic venous system below this level.[6]

It was originally reported that the vascular cushions from the termination of the vascular supply within the anal canal contributed to the maintenance of anal continence.[6] Hemorrhoidal disease occurs as the result of abnormalities within the connective tissue of these cushions, producing bleeding with or without prolapse of the hemorrhoidal tissue.[7] This can occur as the result of excessive straining, chronic constipation, or low-fiber dietary intatke.[8] A clear understanding of the pathophysiology is important when considering therapeutic interventions. At the earlier stages of disease progression, when the major manifestation is transudation of blood through thin-walled, damaged veins and/or arterioles, ablation of the vessels should be adequate. Conversely, in late stages of the disease, when there is significant disruption of the mucosal suspensory ligament, a technique requires fixation of the mucosa to the underlying muscular wall for effective therapy.[9] Internal anal sphincter dysfunction may play a role, since a number of investigators have demonstrated increased internal anal sphincter tone in patients with hemorrhoidal disease.[10-12] In reality, probably a combination of all of these factors is important for the ultimate development of large prolapsing hemorrhoidal disease.

The standard classification for hemorrhoidal diseases[13] is as follows:

- Grade I = bleeding
- Grade II = protrusion with spontaneous reduction
- Grade III = protrusion requiring manual reduction
- Grade IV = irreducible protrusion of hemorrhoidal tissue

Although this staging system tends to correlate with patient's symptoms, it is unclear that it can be completely relied on when making therapeutic decisions. As outlined later, it is important to consider the relative role of internal hemorrhoidal tissue as well as external hemorrhoidal skin tagging when choosing a modality for complete resolution of all of the patient's symptoms.[7]

CLINICAL EVALUATION

Bleeding, protrusion, and pain are among the most common symptoms associated with hemorrhoidal disease. However, Mazier reported on a series of 500 patients with anorectal complaints they associated with their hemorrhoids and ultimately only 35% of patients were found to have any significant hemorrhoidal disease.[14] Hemorrhoidal bleeding typically results in bright red blood either on the toilet paper or actually

into the commode after bowel movements, generally painless in nature. More vigorous bleeding can occur, however, as the hemorrhoids enlarge and particularly in advanced stages when a portion of the complex is fixed externally, allowing the blood to drip or spurt into the commode. Usually, prompt reduction of the protruding mass causes this symptom to abate. Acute thromboses of internal or external hemorrhoids are usually associated with severe pain in association with a palpable perianal mass. These patients are generally quite uncomfortable, and the diagnosis is immediately obvious on clinical examination.

Examination of the patient with hematochezia, although tailored by the age of the patient, should include sufficient investigations to rule out a proximal source of bleeding such as inflammatory bowel disease and neoplasia. Hemorrhoids should not be dismissed as the cause of iron deficiency anemia as this is an uncommon occurrence.

I prefer to examine the patient in the left lateral position with the knees drawn up toward the chest as high as possible. This approach allows relative patient comfort and the ability to clearly inspect the perianal skin and perform anoscopy and proctosigmoidoscopy. A careful digital examination of the anal canal and distal rectum should be performed to include the prostate in men. An anoscope is essential to clearly inspect the hemorrhoidal tissue and anal canal. The three common locations for hemorrhoids should be inspected, and the size, friability, and ease of prolapse of these areas should be recorded. Following this, the decision regarding the need for more proximal colorectal evaluation should be considered, although rigid proctoscopy would be the minimum in all patients. After the hemorrhoids are appropriately graded, a discussion can be enjoined with the patient regarding treatment options.

NONEXCISIONAL OPTIONS

Most patients evaluated for hematochezia that ultimately proves to be hemorrhoidal in origin can be managed with fiber supplementation and a variety of available anal ointments. Although it is not clearly proven that constipation is causal, it appears of practical utility to improve bowel function and thereby reduce hemorrhoidal complaints in most early-stage patients. Similarly, the ointments available, although homeopathic, may minimize ongoing trauma to the hemorrhoidal cushions and similarly reduce symptoms. The remaining nonoperative and operative interventions should be reserved for patients with advanced hemorrhoidal disease who are unresponsive to conservative medical management.

SCLEROTHERAPY

Sclerotherapy of symptomatic internal hemorrhoidal disease was first advocated by Mitchell in 1871 and has enjoyed significant experience.[15] The purpose of sclerotherapy is ultimately to scar the submucosa, resulting in atrophy of the tissue injected and scarification with fixation of the hemorrhoidal complex within its normal location in the anal canal. A variety of solutions have been advocated, although it appears that sodium morrhuate and sodium tetradecyl sulfate predominate currently. This modality is most effective in situations with minimal enlargement of hemorrhoidal complexes where the primary complaint is bright red rectal bleeding.

The procedure is performed with the patient in the left lateral decubitus position. An anoscope is inserted to clearly identify the symptomatic complex and a 25-gauge spinal needle is used to instill the sclerosant into the submucosal space (Fig. 147–1). The syringe should be

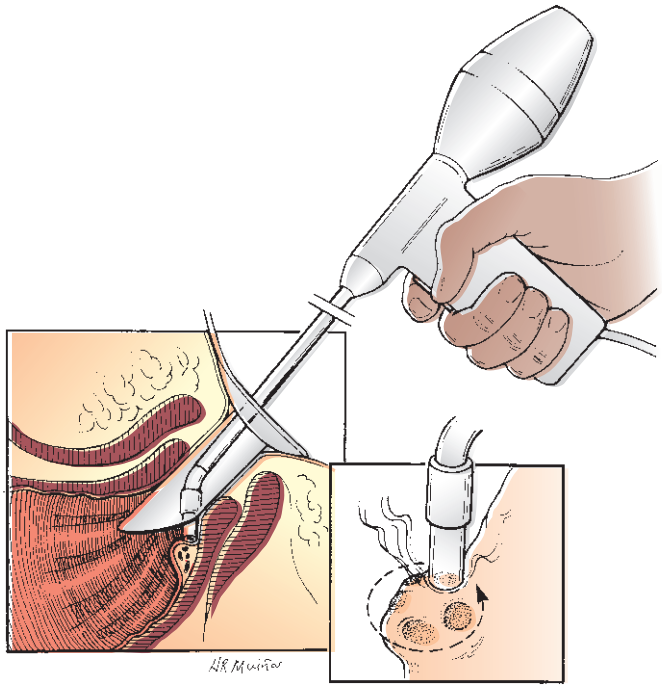

Figure 147–2. Infrared coagulation. *Left,* Coagulator inserted through a Hirschman anoscope. *Right,* Coagulation points.

aspirated prior to injection to avoid a direct intravascular injection. Typically 1 to 2 ml of sclerosant is adequate. The surgeon can inject as many locations as desired because the procedure is essentially painless. It is important, however, not to circumferentially inject the anal canal because this may induce stricture formation.

BIPOLAR DIATHERMY

Bipolar diathermy employs electrical current to coagulate the hemorrhoidal tissue, including the mucosa and submucosa.[16,17] The machine generates a 2-second pulse of energy to accomplish the treatment. Once again, this approach is applicable for small bleeding hemorrhoids and probably has no greater efficacy than does sclerosing.

Other variations on the use of energy to destroy internal hemorrhoids includes infrared coagulation and Ultroid (direct-current) therapy.[17,18] The infrared coagulation employs a tungsten halogen lamp that generates heat energy generally for a 1.5-second period resulting in destruction of the mucosa and submucosa at the application site (Fig. 147–2). The depth of penetration of this injury is usually 3 mm. Conversely the Ultroid uses electrical current that is applied for up to 10 minutes per complex treated. Ultimately, all of these new modalities are a variation on the theme of local tissue destruction and fixation of the hemorrhoidal tissue at the appropriate level. There is probably no advantage of one technique over the other; however, sclerotherapy offers an advantage to the physician since minimal instrumentation is required.

HEMORRHOIDAL LIGATION WITH RUBBER BANDS

Barron was the first to describe hemorrhoidal banding using rubber bands in 1963.[19] Since this original description there have been a number of reports that have documented the significant efficacy banding offers for the management of most patients with grades II and III internal hemorrhoids.[20-24] The procedure is generally well tolerated without the need for prescription analgesia if the band is placed above the level of the dentate line. The technique is demonstrated in Figure 147–3. It is important to ask patients if they experience any pain during placement of the bander, prior to deployment of the band. If they have pain prior to placement of the bander, it will worsen after deployment. Discomfort immediately after band placement may be reduced by the injection of a local anesthetic agent; however, this does not appear to be a long-lasting benefit.[25] Banding does carry the rare but frequently fatal complication of postbanding sepsis, which is heralded by the symptoms of increasing rectal pain, fever, and inability to void.[26-29] It is essential to treat these symptoms early and aggressively with early antibiotic treatment coupled with aggressive surgical drainage.[26]

Bayer et al. reported a series of 2934 patients with 79% of patients achieving complete relief of symptoms following a single session of banding at only one or two locations.[21] Using this approach, patients required multiple sessions for control of symptoms (2 sessions, 32%; 3 sessions, 17%; 4 sessions, 25%; and ≥5 sessions, 20%). Although the multiple sessions required are a negative aspect of this technique, only 2.1% of patients required excisional hemorrhoidectomy. It may be possible to achieve a similar outcome with a shorter duration of therapy, albeit at the expense of greater post-treatment pain, by banding all symptomatic hemorrhoidal sites at the initial visit.[30-32] Banding techniques appear to be durable after initial control of symptoms, with 69% of patients maintaining long-term relief and only 7.5% ultimately requiring excisional hemorrhoidectomy.[22]

EXCISIONAL HEMORRHOIDECTOMY

The decision to proceed to excisional hemorrhoidectomy requires a mutual decision by the physician and patient that medical and nonexcisional options have either failed or are not appropriate. The usual clinical symptoms that lead to surgical excision are frequent prolapsing of the internal hemorrhoids that results in discomfort and anal seepage. Alternatively, the thickened and prolapsing internal/external hemorrhoidal complexes may make anal hygiene difficult for the patient and may make excision preferable. The final indication for excisional hemorrhoidectomy, although debatable, is the development of acutely thrombosed and gangrenous internal hemorrhoids. Surgical excision of acutely thrombosed external hemorrhoids may also be warranted, primarily for more rapid pain relief and avoidance of a residual skin tag. These external thromboses are usually easily managed in the office setting with local

anesthesia and complete excision with or without skin closure (Fig. 147–4).

Options for excisional hemorrhoidectomy include the following techniques: Milligan-Morgan hemorrhoidectomy; Ferguson closed hemorrhoidectomy; Whitehead hemorrhoidectomy; and the more recently described stapled hemorrhoidectomy. The procedures are usually performed in the operating theater after minimal preoperative preparation of the bowel. The use of lasers for excisional hemorrhoidectomy offers no advantage and in fact causes delayed healing, increased pain, and increased cost.[33] Anesthetic selection is usually left to the anesthesiologist and patient; however, local anesthesia supplemented by the administration of intravenous narcotics and propofol is highly effective and short acting. The use of spinal anesthesia, although effective, may increase the risk of postoperative urinary retention due to a higher intraoperative administration of intravenous fluids.

The Milligan-Morgan hemorrhoidectomy, which is widely practiced in Europe, was originally described in 1937, and its efficacy has been documented in many

series subsequently.[34-36] This technique includes resection of the entire enlarged internal hemorrhoid complex, ligation of the arterial pedicle, and preservation of the intervening anoderm.[33] The distal anoderm and external skin are left open to minimize the risk of infection in the wounds. Results from this technique have shown this to be a safe and effective means for managing advanced hemorrhoidal disease.[33] However, the fact that the external wounds are left open for delayed healing can be a cause of considerable discomfort and prolonged morbidity after this procedure. The closed Ferguson hemorrhoidectomy was proposed as an alternative to the Milligan-Morgan technique and enjoys a similar large body of evidence regarding its safety and efficacy.[37-40] This technique employs an hourglass-shaped (centered at the midportion of the anoderm) excision of the entire internal/external hemorrhoidal complex, preservation of the internal and external anal sphincters, and primary closure of the entire wound. Occasionally, it is necessary to undermine flaps of anoderm and perianal skin to allow removal of intermediate hemorrhoidal tissue while preserving the bridges of anoderm between pedicles. This technical adjustment avoids postoperative strictures.

The Whitehead hemorrhoidectomy, described in 1882, was devised to eradicate the enlarged internal hemorrhoidal tissue in a circumferential fashion and to relocate the prolapsed dentate line that is often a component of prolapsing hemorrhoids.[41] Although this technique enjoyed a long period of widespread application, it was subsequently largely abandoned because of the high rates of mucosal ectropion and anal stricture.[42-45] The technique has enjoyed renewed support, with several authors documenting minimal stricture rates and no occurrences of mucosal ectropion.[46,47] Despite these promising reports, the Whitehead procedure is technically demanding because of the need to accurately identify the dentate line and relocate it to its proper location.

INSTRUMENTATION FOR EXCISIONAL HEMORRHOIDECTOMY

The specific techniques for excisional hemorrhoidectomy were reviewed earlier, and this section discusses the relative benefits of scalpel and the available energy-delivering excisional tools. Cold scalpel or scissor excision has long been the mainstay of surgical hemorrhoidectomy, and the data on outcomes are well validated. Over the past 10 to 15 years, a variety of new devices have been advocated for hemorrhoidectomy. These energy-based cutting devices have been devised to allow simultaneous tissue division and coagulation. The main advantage proposed for these devices is provision of hemostasis without need for suture ligation and therefore reduction in postoperative pain. However, these benefits must be interpreted in the context of the significant cost of acquisition of the devices compared to a disposable scalpel blade.

The first energy cutting tool applied to hemorrhoidectomy is standard monopolar electrocautery. The tool has been reported widely for the two dominant types of hemorrhoidectomy. Surgeons using this tool have also employed various degrees of wound closure by suture, ranging from pedicle ligation only to complete wound closure.[48-50]

Laser technology has been evaluated both as a means of cutting hemorrhoidal tissue and as a technique for ablation. Zahir et al. evaluated the role of the Nd-YAG laser for excision and coagulation of residual tissue and reported a reduction in postoperative pain and a greater percentage of patients returning to work at 1 week.[51] Alternatively, we found delayed wound healing, increased cost, and increased pain scores with Nd-YAG hemorrhoidectomy compared with scalpel excision.[52] Hodgson and Morgan evaluated a series of patients with second- and third-degree hemorrhoids managed by CO_2 excision, with only one patient readmitted for postoperative hemorrhage.[53] The data suggest that either Nd-YAG or CO_2 laser excision may be performed; however, it is not clear that the added expense or benefits are superior to scalpel or scissor excision.[54]

A bipolar cautery device capable of simultaneous tissue division and blood vessel coagulation is the LigaSure. This device has been compared to monopolar diathermy hemorrhoidectomy with most of the data suggesting reductions in operative time and early postoperative pain.[55,56] Chung and Wu compared a sutureless LigaSure technique to the standard closed Ferguson hemorrhoidectomy and confirmed a reduction in operative time and pain reduction during the first 48 hours.[56] However, there were no significant differences in wound complications or time to full recovery. Similarly, a comparison of LigaSure to a standard Milligan-Morgan hemorrhoidectomy confirmed reduction in operating time and early postoperative pain.[55]

A competing technology is the Harmonic scalpel, which relies on a rapidly reciprocating blade to generate heat for coagulation and tissue transection. The largest reported experience was provided by Armstrong et al. with 500 consecutive excisional hemorrhoidectomies.[57] They reported a low postoperative hemorrhage rate (0.6%). The overall postoperative complication rates were low, with urinary retention in 2%, fissure in 1%, and abscess/fistula in 0.8%. Several subsequent prospective, randomized comparisons of diathermy to Harmonic scalpel failed to confirm any advantages between the two tools.[58-60]

Probably the best guidance on this topic is the study by Chung et al., who evaluated scissor/Milligan-Morgan, Harmonic scalpel, and bipolar scissors for hemorrhoidectomy: Harmonic Scalpel™ demonstrated superior early pain scores to scissor; however, the long-term recovery was similar between the groups.[61] Therefore, the cumulative data suggest that patient benefits are modest for any of the energy-delivering techniques and the cost differential is significant.

PROCEDURE FOR PROLAPSING HEMORRHOIDS

A new management option for advanced hemorrhoidal disease is a nonexcisional hemorrhoidectomy or pexy procedure referred to as the *procedure for prolapsing hem-*

orrhoids (PPH).[62] The technique (Fig. 147–5) uses a circular, transanally placed pursestring suture placed 4 cm from the dentate line and within the enlarged internal hemorrhoids. A 31-mm stapler is then placed transanally to perform a circumferential excision of rectal mucosa just rostral to the hemorrhoidal columns. The procedure provides for a repositioning of both the anoderm and hemorrhoidal columns to the appropriate locations within the anal canal and fixation of these structures via the rectal staple line.

Since the introduction of the PPH technique there have been a large number of prospective randomized trials comparing this approach to excisional hemorrhoidectomy.[63-66] Most of the data support the concept that PPH is associated with a lesser degree of early postoperative pain and a general reduction in the duration of this pain after surgery.[63-67] A recently published multicenter trial comparing PPH to Ferguson closed hemorrhoidectomy confirmed similar benefits and reported a reduction in the need for early reoperation for complications in the PPH group.[68] Although the bulk of the data supports the safety of this new technique, there have been several reports of complications. Molloy and Kingsmore reported a case of severe pelvic sepsis, probably resulting from an inadvertent rectal injury.[69] Cheetham et al. also raised a concern over persistent severe anorectal pain as a possible sequela of PPH.[70]

POSTOPERATIVE MANAGEMENT AFTER HEMORRHOID SURGERY

Regardless of the excisional technique used for treatment of advanced hemorrhoidal disease, the key to effective patient management is avoidance of postoperative complications. Pain is the most frequent complication and is the most feared sequelae of the procedure from the patient's perspective. A variety of analgesic regimens have been recommended, usually consisting of a combination of oral and parenteral narcotics.[71-75] The use of local infiltration of bupivacaine into the wounds and perianal skin has been variably successful in long-term pain reduction.[76,77] Conversely, ketorolac has demonstrated considerable efficacy in managing posthemorrhoidectomy pain.[78] The use of alternative administration routes for narcotics either by patch or subcutaneous pump have been successful in controlling pain; however, the management of these routes of administration can be risky in the outpatient setting because of the risk of narcotic-induced respiratory depression. The most appropriate regimen following outpatient hemorrhoidectomy appears to be intraoperative use of ketorolac, sufficient doses of oral narcotic analgesics for home administration, and supplementation of the narcotics by an oral nonsteroidal medication.

Urinary retention is a frequent postoperative problem following hemorrhoidectomy, ranging in incidence from 1% to 52%.[79-82] A variety of strategies have been used to treat the problem, including parasympathomimetics, α-adrenergic blocking agents, and sitz baths.[83,84] The best approach, however, seems to be a strategy of prevention that includes limiting perioperative fluid administration to 250 ml, an anesthetic approach that avoids use of spinal anesthesia, avoidance of anal packing, and an aggressive oral analgesic regimen.[85]

Early postoperative bleeding (<24 hours) occurs in approximately 1% of cases and represents a technical error requiring return to the operating theater for resuturing of the offending wound.[86] Delayed hemorrhage occurs in 0.5% to 4% of cases of excisional hemorrhoidectomy at 5 to 10 days postoperatively.[87-89] The etiology has been held to be early separation of the ligated pedicle before adequate thrombosis in the feeding artery can occur.[90] The bleeding in this scenario is usually significant and requires some method for control of ongoing hemorrhage. Options include return to the operating theater for suture ligation or tamponade at the bedside by Foley catheter or anal packing.[90-92] The subsequent outcome after control of secondary hemorrhage is generally good with virtually no risk of recurrent bleeding. It may be helpful to irrigate out the distal colorectum with posthemorrhage enemas or at the time of intraoperative control of bleeding to avoid confusion when the residual clots pass per anum.

CONCLUSION

The management of symptomatic hemorrhoidal disease should be directed at the symptom complex of the individual patient. Most of these patients can be successfully treated by improving bowel function, correcting constipation, and using any of a variety of anal ointments. For persistent symptoms, either injection or banding of the internal hemorrhoids is predictably successful. Only a few patients should require excisional hemorrhoidectomy by any of the described techniques. Circular stapled hemorrhoidectomy may prove to be an effective, less painful technique to manage grade III hemorrhoids.

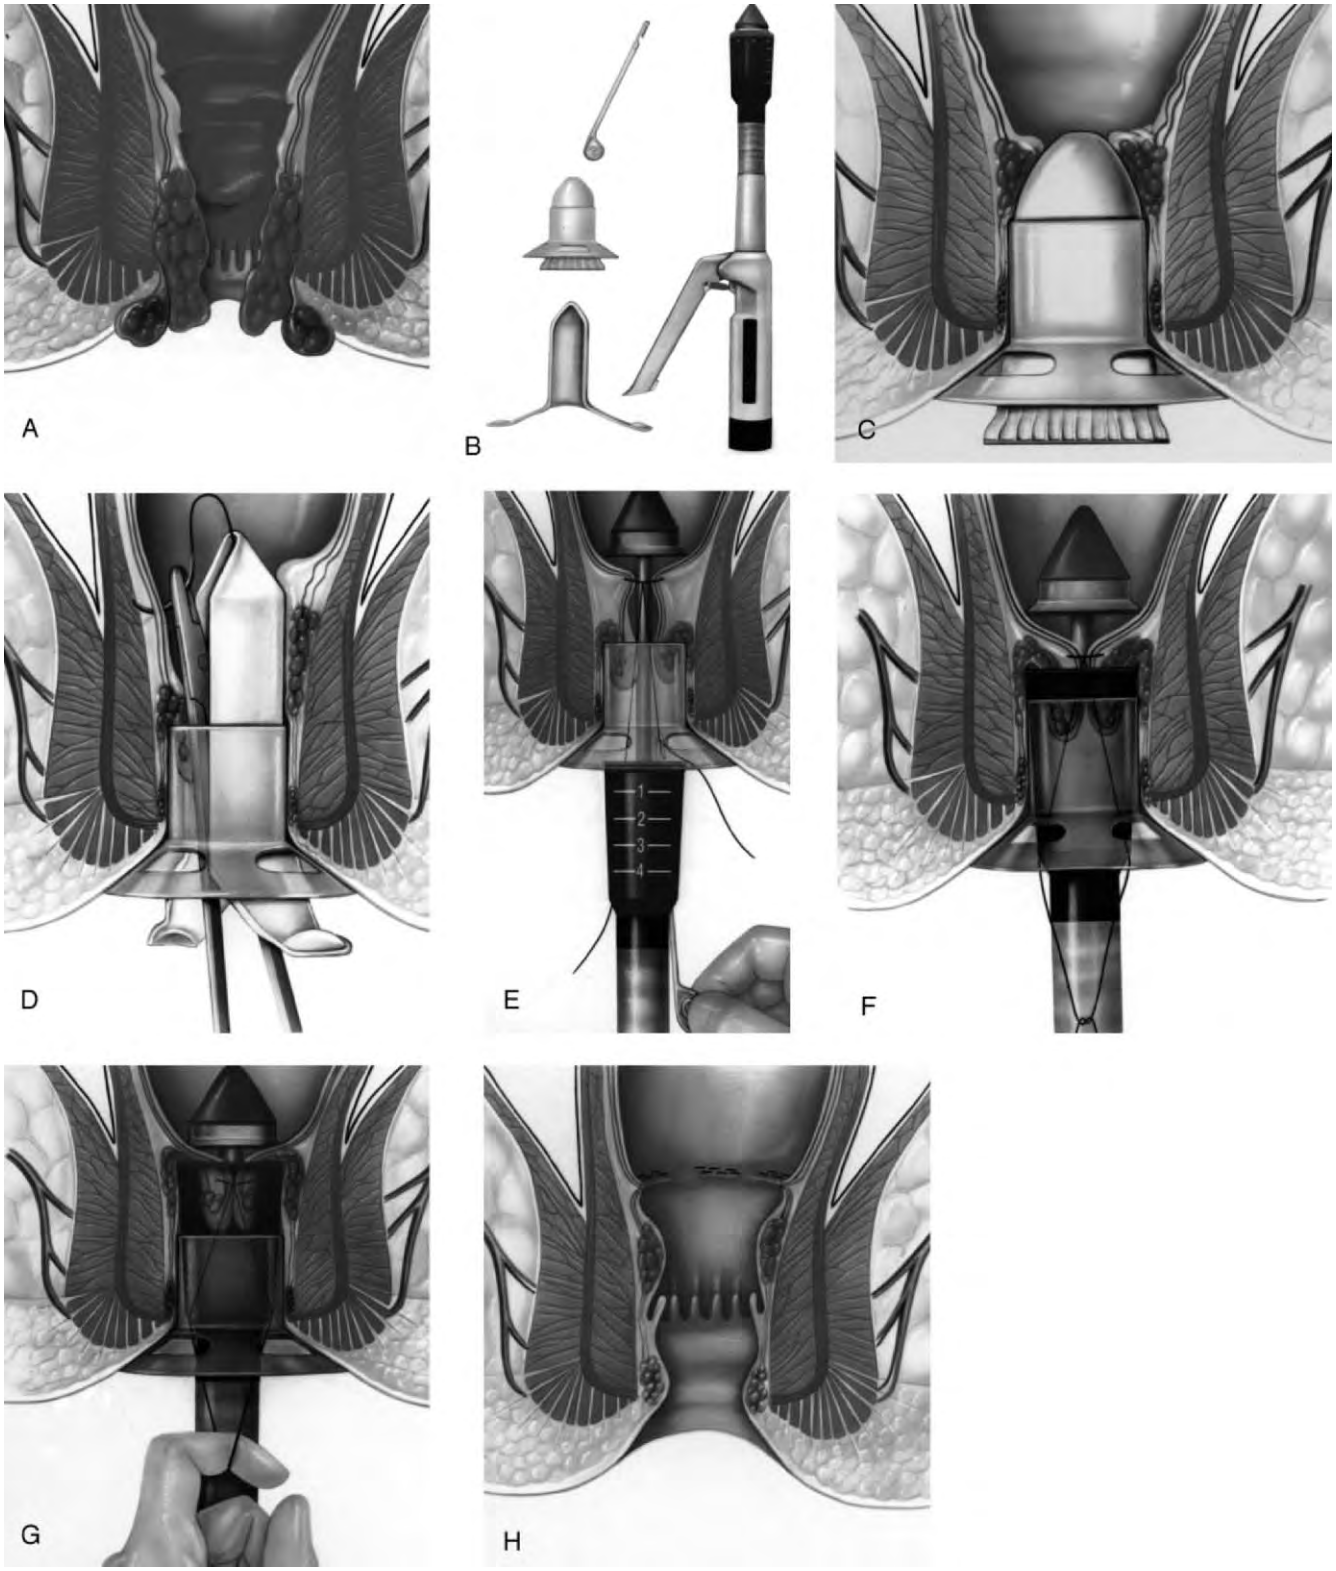

Figure 147–5. **A** and **B,** Identification of the internal hemorrhoidal complexes and the instrumentation utilized for a stapled hemorrhoidectomy are shown. **C** and **D,** A pursestring suture is accurately placed 4 cm above the dentate line by the use of an anoscope. **E** to **G,** The pursestring is tied securely around the rod of the stapling anvil, which allows the hemorrhoidal tissue to be pulled into the barrel of the stapler head. **H,** The stapler is closed, fired, and held in place for 20 to 30 seconds. The staple line should be inspected and any bleeding sites suture-ligated.

Fissure-in-Ano

Harry T. Papaconstantinou · Philip Huber, Jr. · Clifford L. Simmang

Anal fissure (fissure-in-ano) is a common condition that usually presents as anal pain on defecation. Bleeding occurs but is usually scant, bright red, and found on the tissue when cleansing after a bowel movement. Anal fissure is described as a linear defect, or laceration, in the anoderm, located between the dentate line and the anal verge. An acute fissure is a simple laceration, whereas a chronic anal fissure has exposed internal anal sphincter muscle fibers at the base and built-up edges. In addition, there may be a perianal skin tag at the external margin of the fissure and a hypertrophied papilla at the dentate line. Chronic fissure is defined by these three findings: (1) visible muscle, (2) a skin tag (sentinel tag), and (3) hypertrophied papilla (Fig. 148–1). Acute and chronic anal fissures are almost always located in the midline, with the posterior location predominating (women, 90%; men, 99%). Fissures located off the midline are usually associated with more serious systemic diseases such as Crohn's disease and immunodeficiency syndromes (Fig. 148–2).

ETIOLOGY

Trauma to the anal canal, due to passing hard stools, is probably the most frequent cause of fissure-in-ano. Loose, watery stools are also associated with the development of anal fissures. Preexisting anal canal irritation has been postulated to lead to fissure. Scarring, stricture, and stenosis from prior anal injury or surgery are recognized conditions that predispose to fissure formation.[1] Because fissures occur most often in the posterior midline, various structural theories have been proposed as causes,[2-4] the most compelling of which suggests that the vascular anatomy of the internal sphincter may be a factor.

In 1989, Klosterhalfen and associates[5] reported on anatomic dissections that detailed the blood supply of the inferior hemorrhoidal artery. In most cadaver specimens (85%), the posterior commissure of the anal canal was not directly perfused except by end arterioles. Moreover, branching from the sphincteric arterioles occurred at right angles to the parent vessels and coursed perpendicularly through the circular fibers of the internal sphincter. These anatomic findings established the possibility of decreased mucosal perfusion, particularly in the posterior midline. In addition, sphincter spasm or hypertonicity further decreases blood flow. Schouten and colleagues[6,7] have shown increased anal canal pressures correlated with decreased mucosal blood flow as measured by laser Doppler flowmetry. Reports of normal anal maximal resting pressure are highly variable, ranging from 60 to 100 cm H_2O in women and slightly higher in men; however, the measurement is defined as the maximal pressure recorded at rest.[8] The higher pressures seen in patients with anal fissures produce a sawtooth pattern on manometry tracings. This vascular-anal resting pressure hypothesis has prompted trials aimed at improving blood flow and lowering anal canal resting pressures. Whether sphincter hypertonia is a cause or effect is unknown.

The most common systemic conditions that are associated with atypical anal fissure/anal ulcer are Crohn's disease and acquired immunodeficiency syndrome. Both of these conditions lead to an immunocompromised patient. Atypical features include fissures off the true midline, shaggy large defects with undermined edges, and granulation tissue in the base. Actual cavitation of the internal sphincter is another ominous clue to the presence of systemic disease. In the immunocompromised patient, a fissure or an ulcer and a concomitant mass should raise the question of malignancy. Lymphoma, leukemic ulcer, and anal canal epithelial tumors are often associated with surface defects. There are subtle changes that distinguish these conditions from uncomplicated acute or chronic anal fissure.

Infections also cause fissure-in-ano. Although uncommon in the United States today, syphilis and tuberculosis were seen not infrequently in the last century. More commonly seen today are the viral conditions of

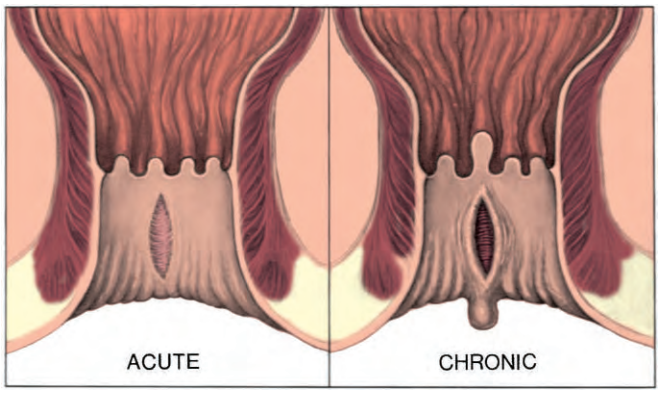

Figure 148–1. Acute and chronic fissure. (Modified from Hicks TC, Ray JE: Rectal and perianal complaints. In Polk HC Jr, Stone HH, Gardner B [eds]: Basic Surgery, 3rd ed. Norwalk, CT, Appleton-Century-Crofts, 1987, p 455.)

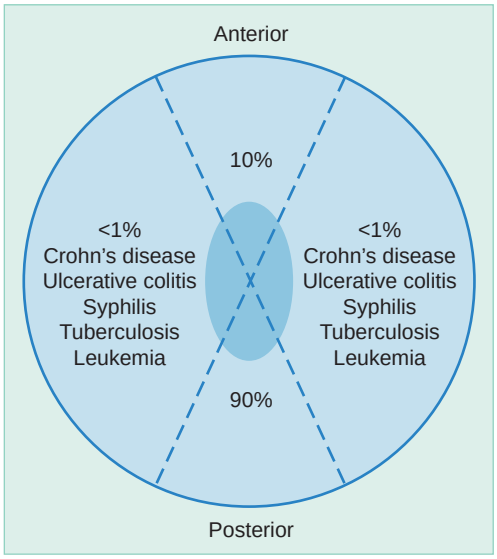

Figure 148–2. Diagram of the location of typical fissures and atypical fissures where a systemic illness should be suspected.

herpes simplex, cytomegalovirus, and chancroid associated with sexual transmitted diseases and immunocompromised conditions. Herpes simplex infection manifests multiple superficial ulcers and vesicles at presentation; syphilitic ulcers are purulent and have a granular base. It is important to understand the difference between anal canal fissures and atypical anal canal ulcers (see Fig. 148–2).

DIAGNOSIS

A tearing or burning discomfort during defecation is by far the most common symptom of anal fissure. Bleeding is usually only detected on the toilet paper. The pain associated with anal fissure lasts for minutes to hours, and in

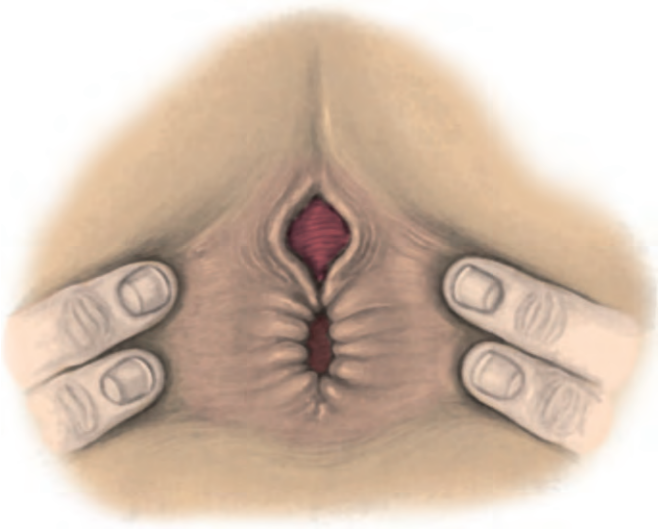

Figure 148–3. Inspection of fissure.

patients with a chronic fissure, it is most often described as profound anal "tightness" or "spasm." Examination must be carefully performed; the pain caused by an aggressive examination of an anal fissure is not easily forgotten. Simple spreading of the buttocks to gently roll open the anal verge usually demonstrates the fissure (Fig. 148–3). Endoscopy, which must be performed as part of the complete evaluation of patients with fissure, should be postponed; a more complete anorectal examination can be better accomplished when the fissure is healed. Topical anesthetics do not facilitate pain-free examinations.

Atypical-appearing fissures require more intensive inquiry. Symptoms of inflammatory bowel disease should be sought. Sexual activity and drug history should likewise be documented. High-risk behavior for human immunodeficiency viral infection necessitates screening and may explain the presence of the atypical fissure. Syphilitic ulcers can be diagnosed with dark-field, wet-prep microscopy. Tuberculous ulcer, although commonly superinfected, shows acid-fast bacilli on staining. The critical issue in patients with atypical-appearing fissures is a high index of suspicion. If an atypical fissure is treated the same way as a typical fissure, a large nonhealing wound could result.

Most diagnostic tests are not tolerated as office procedures. Examination under anesthesia permits a thorough evaluation of the anus and rectum. Cultures, biopsies, and possible therapeutic interventions can be safely and carefully performed with anesthesia. Indeed, patients embrace the opportunity to have a pain-free evaluation under anesthesia.

NONSURGICAL MANAGEMENT

General Approaches

The first-line therapy for patients with simple, acute fissure-in-ano includes warm water sitz baths and stool-

bulking agents. Warm water soaks likely relieve anal discomfort by lowering anal canal pressures, but results from prospective studies are contradictory.[9] Nevertheless, heat provides dramatic relief to most patients with acute and chronic fissure-in-ano and should be used in all patients. Stool-bulking agents, such as psyllium, bran, and fiber, draw water into the stool, changing its consistency, and therefore prevent the formation of hard, stool that causes sustained trauma to the anal canal. Furthermore, bran has been shown to be effective in preventing recurrence of acute anal fissure.[10] Topical creams and steroids are of limited utility and not routinely recommended as management options, since these modalities do not address the underlying problem. These conservative, nonsurgical measures successfully heal 90% of acute anal fissures but only 40% of chronic fissures. Chronic anal fissures are managed with medications that provide a "chemical sphincterotomy" (described later).

Topical Nitroglycerin

It has been suggested that poor posterior anal canal blood flow and generalized hypertonia of the internal anal sphincter are causes of anal fissures. Therefore, improvement in the blood supply and sphincter relaxation should facilitate healing. Nitric oxide is a potent smooth muscle relaxant and promotes vasodilation. Topical nitroglycerin is a nitric oxide donor that is absorbed transcutaneously and, when applied to the anus, has been shown to reduce anal canal pressure.[11] Indeed, nitroglycerin has become an important adjuvant treatment option in patients with fissures that do not heal with stool-bulking agents and local heat therapy.[12,13] A recent meta-analysis of randomized, controlled trials comparing nitroglycerin ointment to placebo for the treatment of anal fissures has shown that nitroglycerin is significantly more effective than placebo in primary healing of anal fissure (46% versus 33%; $P < .0001$).[14] In fact, several independent studies have demonstrated the therapeutic efficacy of nitroglycerin paste in 60% to 75% of patients with anal fissures.[15-20]

The dosage and strength of the nitroglycerin have varied from study to study, but there is some correlation between dose and degree of sphincter relaxation.[21] Application of 200 to 500 mg of 0.2% nitroglycerin paste (about the size of a pea) to the anus is performed at least twice daily. It is important to inform patients that either they should use a cotton-tipped applicator or a glove should be worn to protect against absorption of the nitroglycerin through the skin on the finger. The ointment should be protected from exposure to air and light because nitroglycerin paste is volatile and will deactivate. Pain relief is nearly immediate (5 minutes) and lasts for up to 12 hours.[12,15,16] Headache is a significant side effect and limits the amount of paste that can be applied. When nitroglycerin ointment is used specifically for the treatment of chronic anal fissures, 34% of patients can be expected to developed headaches.[14] With this therapy, healing of the fissure takes 4 to 6 weeks. Patients with fissures that fail to heal often have persistently elevated anal canal pressures despite the use of nitroglycerin. Recurrent disease after initial healing can be successfully retreated.[15,16] Other adverse effects such as orthostatic hypotension, syncopal attacks, and tachyphylaxis are well described and may limit the use of this treatment modality.[21-23]

Calcium Channel Blockers and Botulinum Toxin

Alternatives to nitroglycerin ointment that can produce a similar so-called chemical sphincterotomy effect include topical application of calcium channel blockers (nifedipine and diltiazem) and botulinum toxin A injection. Topical nifedipine has been shown to reduce resting anal sphincter pressures and heal significantly more chronic anal fissures than control (95% versus 16%; $P < .001$).[24] These positive effects were achieved with no significant side effects of this medication. Other calcium channel blockers, such as topical 2% diltiazem, have been shown to be as effective as nitroglycerin in the treatment of chronic anal fissures.[25,26] In fact, topical diltiazem heals between 48% and 75% of fissures that have failed to heal with nitroglycerin alone.[27,28] This class of drug may ultimately supersede nitroglycerin in the treatment of chronic anal fissure because it is equally effective in treating chronic anal fissures and has a superior side effect profile.

Botulinum toxin A is an exotoxin produced by the bacterium *Clostridium botulinum* that causes paralysis of skeletal muscle by preventing the presynaptic release of acetylcholine. Botulinum toxin A has been shown to be efficacious in the treatment of chronic anal fissure. In one study, 73% of anal fissures were healed at 8 weeks, with no recurrences at a mean of 16 months' follow-up.[29] Results of a randomized, double-blind, placebo-controlled trial comparing botulinum toxin A injection to topical nitroglycerin ointment showed that at 8 weeks anal fissures were healed in 96% of patients injected with neurotoxin and 60% of those treated with nitroglycerin.[30] There was no recurrence in either group at a mean follow-up of 15 months. The optimal dose and injection site of botulinum toxin A for the treatment of chronic anal fissures is unclear. Injection of up to 50 units of botulinum toxin A is well tolerated,[31] and healing of posterior anal fissures is accelerated in patients injected with neurotoxin in the anterior anus when compared to posterior injection.[32] Although initial studies reported injections into the external anal sphincter, recent studies have performed intersphincteric injections or injection into the internal sphincter with excellent results.[30,33] Complications of this form of treatment are infrequent and include transient incontinence to flatus and perianal hematoma. Although botulinum toxin A injection has been supported as a first-line therapy for the treatment of chronic anal fissures, cost and convenience issues argue for its second-line use after nitroglycerin failure. Nitroglycerin remains an ideal first-line treatment because it is cheap, convenient, and widely available; however, topical diltiazem may challenge its role in the future.

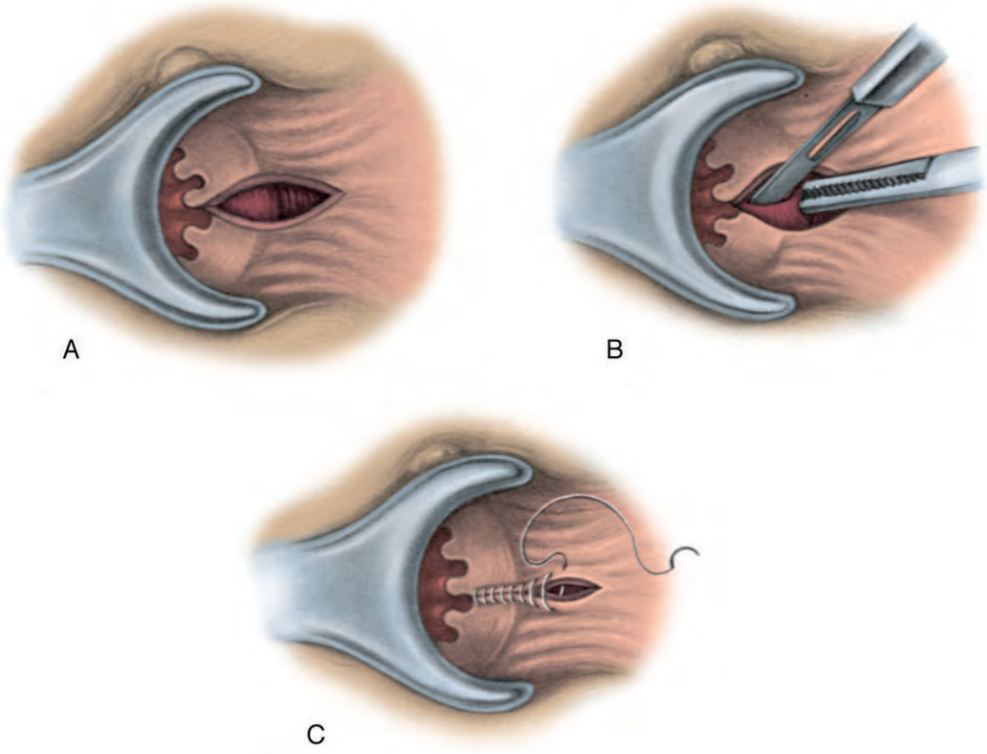

Figure 148–4. Lateral internal anal sphincterotomy. **A,** Internal anal sphincter visible through incision. **B,** Lateral division of internal anal sphincter. **C,** Wound closure. **(A-C,** Modified from Storer EH, Goldberg SM, Nivatvongs S: Colon, rectum and anus. In Schwartz SI [ed]: Principles of Surgery, 4th ed. New York, McGraw-Hill, 1984, p 1169.)

SURGICAL THERAPY

Internal anal partial sphincterotomy (Fig. 148–4) is reserved for chronic anal fissures that fail nonsurgical management, and this technique does require the surgeon to be familiar with anal canal anatomy. The strategy of operative sphincterotomy is to divide the hypertonic portion of the internal anal sphincter muscle to reduce anal canal pressure and facilitate healing of the anal fissure. This procedure was originally described by Eisenhammer in 1951 as a midline posterior incision through the fissure.[3] However, subsequent studies noted problems with wound healing and the formation of a "keyhole" deformity to the anus.[2] Keyhole deformities are a persistent groove in the midline following sphincter division that may result in a significant degree of anal seepage or incontinence. Subsequent modifications to this procedure included repositioning the incision to the right or left lateral position that has effectively eliminated the complication of this deformity.[4] Notaras is credited with introducing the "closed" sphincterotomy that is performed through a stab incision at the intersphincteric groove (Fig. 148–5) rather than an "open" exposure of the internal sphincter.[34] This closed technique can be done in the office setting with local anesthetic using either a small anoscope or a finger in the anal canal to guide division of a portion of the sphincter.

Lateral sphincterotomy has produced excellent results for the treatment of chronic anal fissure with an 85% to 100% healing rate and low incidence of persistent or early relapse (Table 148–1).[35-42] There has been a low, but persistent complication rate for soiling (1% to 22%) and incontinence to flatus (0 to 28%) and stool (0 to 11%). Comparing open versus closed techniques has not shown any differences of significance in postoperative pain, treatment success, complication of incontinence, or overall outcome. However, the length of internal sphincterotomy may influence outcome in terms of healing and incontinence, and division of the sphincter limited to the length of the fissure seems most appropriate.[40,43] Some degree of transient incontinence may be experienced by the patient in the early postoperative period, but this usually improves with time.[42] Therefore, given the low but persistent rate of incontinence with lateral internal sphincterotomy, this operation should be performed in select patients who have failed nonsurgical therapy. Absence of preoperative continence problems and meticulous surgical techniques are necessary to achieve good results.

Other surgical procedures for the management of chronic anal fissures exist but are performed less frequently and are mentioned only for completeness. Fissurectomy is the excision of the anal fissure and is still performed today. This procedure results in a defect in the anoderm that can be covered with a rotation or advancement flap to avoid a keyhole deformity and address a coincidental stricture or anal stenosis.[44] Finger dilation of the anal canal has fallen out of favor and should be discouraged because this procedure results in an uncontrolled stretching of the anal sphincters and results in unacceptable levels of postoperative incontinence. Furthermore, a recent meta-analysis showed that anal dilation resulted in significantly greater persistence of disease than sphincterotomy.[45] Retractors and balloon-tipped dilating catheters have been used for dilation in the treatment of chronic anal fissures.[46-49] These more

controlled dilation procedures have been reported to be as efficacious as lateral internal sphincterotomy; however, its use should be discouraged since there is no way to reliably standardize the procedure, and both the internal and external sphincters can be disrupted or fragmented in an irregular manner,[50,51] with reported incontinence rates ranging from 12.5% to 24.3%.[49,51]

CONCLUSION

Most acute anal fissures heal with conservative measures. Those that become chronic may respond to medical therapies or injection of botulinum toxin. Persisting fissures should be considered for lateral partial internal sphincterotomy. A reasonable approach is outlined in the algorithm (Fig. 148–6).

Anal Sepsis and Fistula

Michael A. Jobst · Alan G. Thorson

DEFINITION

Anorectal suppurative disease may manifest itself in an acute or a chronic setting. Anal sepsis (abscess) represents the acute manifestation, and anal fistula represents the chronic form of the suppurative process. In its simplest form, an anal fistula represents a communication between an internal opening in the anal canal and an external opening through which an abscess drained. A fistula and abscess may coexist or be associated with atypical internal openings and multiple tracts that result in a complex suppurative process.

ETIOLOGY

Foreign bodies, malignancy, trauma, tuberculosis, actinomycosis, leukemia, postoperative infection, inflammatory bowel disease, and simple skin infections have *long* been associated with anal sepsis. Recently, an association between anal abscess-fistula and history of concurrent or recent cigarette smoking has been demonstrated.[1] This association diminishes as the history of cigarette smoking grows more remote. Most anal sepsis, however, is related to an infection of the anal glands and ducts. Fecal bacterial plugging of the ducts leads to obstruction and subsequent abscess formation. This process represents the cryptoglandular theory of anal sepsis. Robinson,[2] Seow,[3] and their associates have suggested that the description of the anal glands by Chiari in 1878 and the subsequent histologic studies of Parks in 1961 contributed to the acceptance of the cryptoglandular theory as the most common cause for anal sepsis.

CLASSIFICATION

Anorectal Abscess

Anorectal abscesses are classified according to the perirectal space involved in the suppurative process; these include the perianal, ischiorectal, intersphincteric, submucosal, deep postanal, and supralevator spaces (Fig. 149–1). A given suppurative process may involve multiple perirectal spaces. For example, the classic "horseshoe" abscess originates in an infected gland in the posterior midline extending through the intersphincteric and deep postanal spaces to one or both of the ischiorectal spaces. A condition known as "floating anus" may occur with circumanal spread of intersphincteric, supralevator, or ischiorectal collections.

It is difficult to accurately assess the incidence of various abscesses due to the varying classifications and referral patterns reflected in large series.[4-8] However, perianal abscesses account for the largest number in most series (Table 149–1).

Anal Fistula

Historically, anal fistulas have been classified in many different ways.[9-12] However, the Parks classification introduced in 1976 is the most comprehensive and widely used. It is derived from the cryptoglandular hypothesis and has therapeutic implications.[13] Parks classified fistulas into four main subgroups according to the course taken by the main tract: intersphincteric, trans-sphincteric, suprasphincteric, or extrasphincteric.[13] Each category can be further subclassified based on associated secondary tracts and other anatomic details (Fig. 149–2).

As with abscesses, the incidence of various fistulas is difficult to quantify. Overall, however, intersphincteric fistulas seem to predominate (Table 149–2).

DIAGNOSIS

Anorectal Abscess

History

Symptoms common to all abscesses include the slow, gradual onset of pain, increasing in intensity to the sensation of pressure and fullness. This is a constant, not intermittent, sensation. These symptoms should always lead to the consideration of an abscess even in the

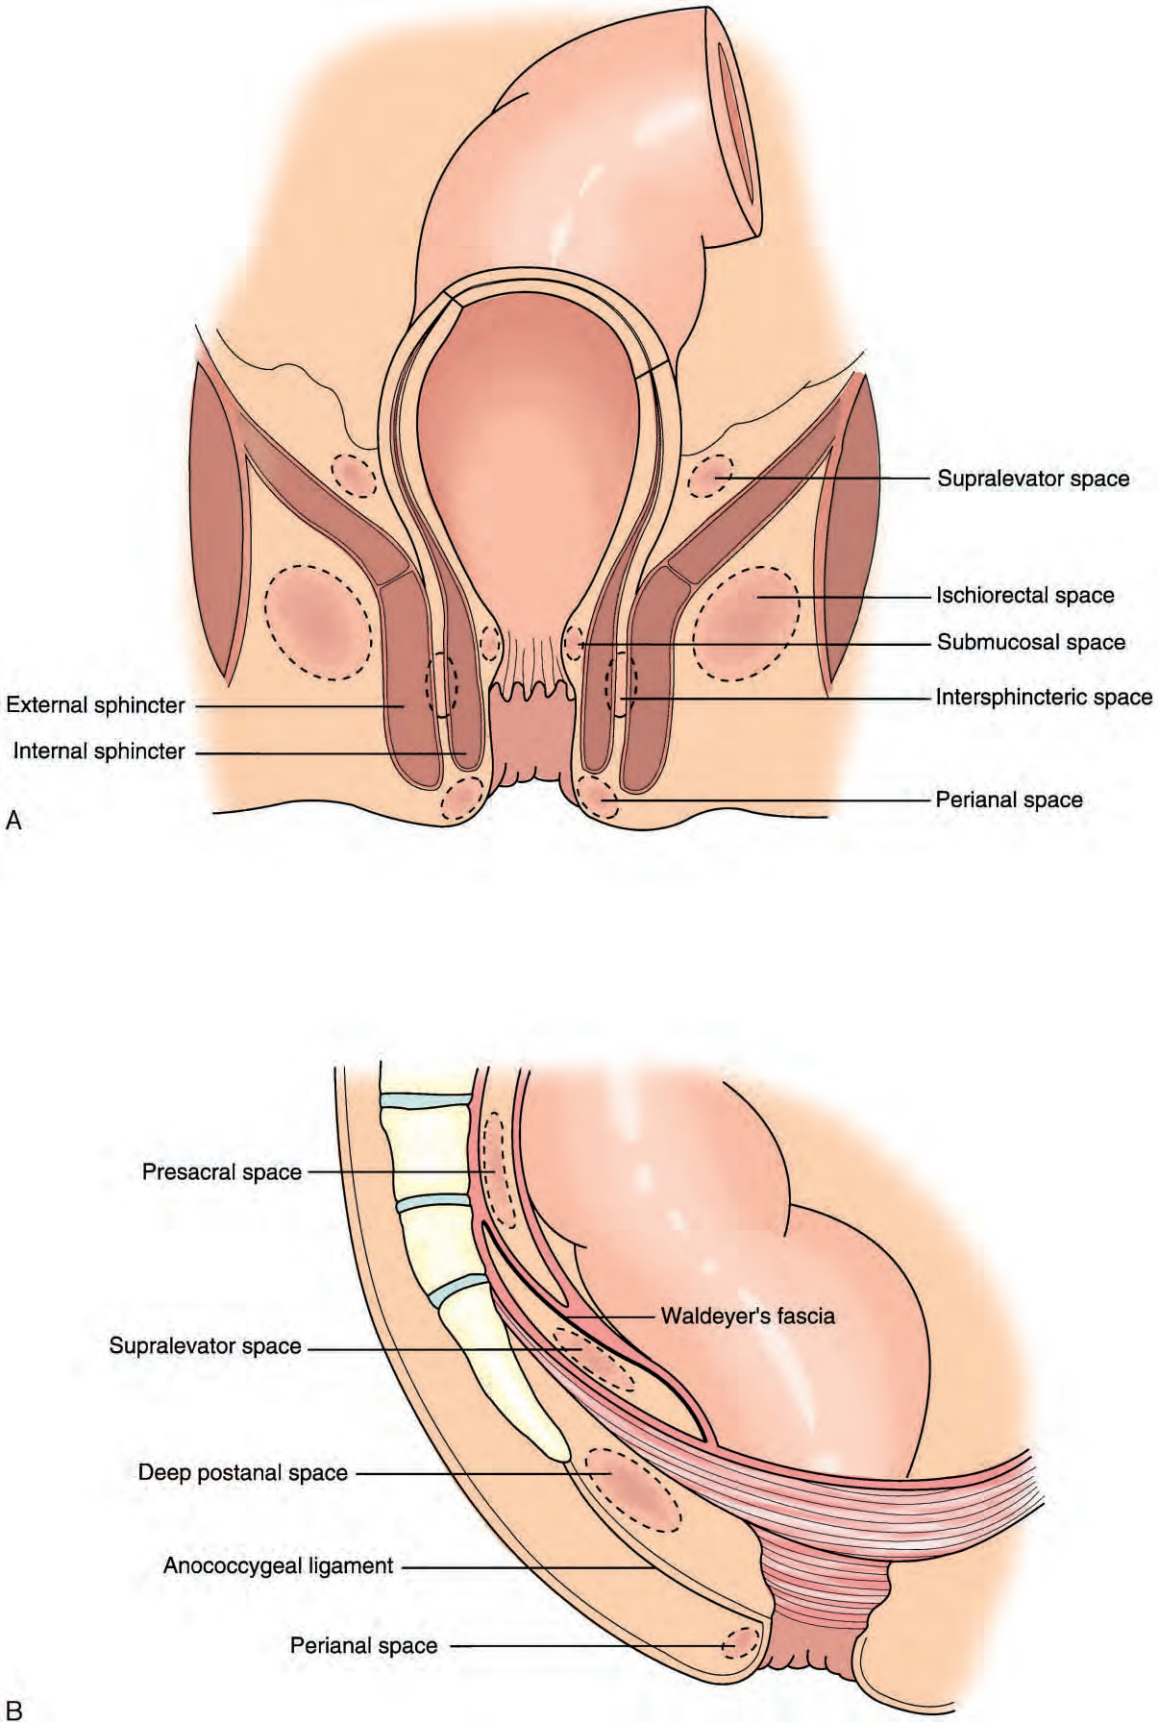

Figure 149–1. Classification of anorectal abscesses by location. **A,** Coronal view. **B,** Sagittal view.

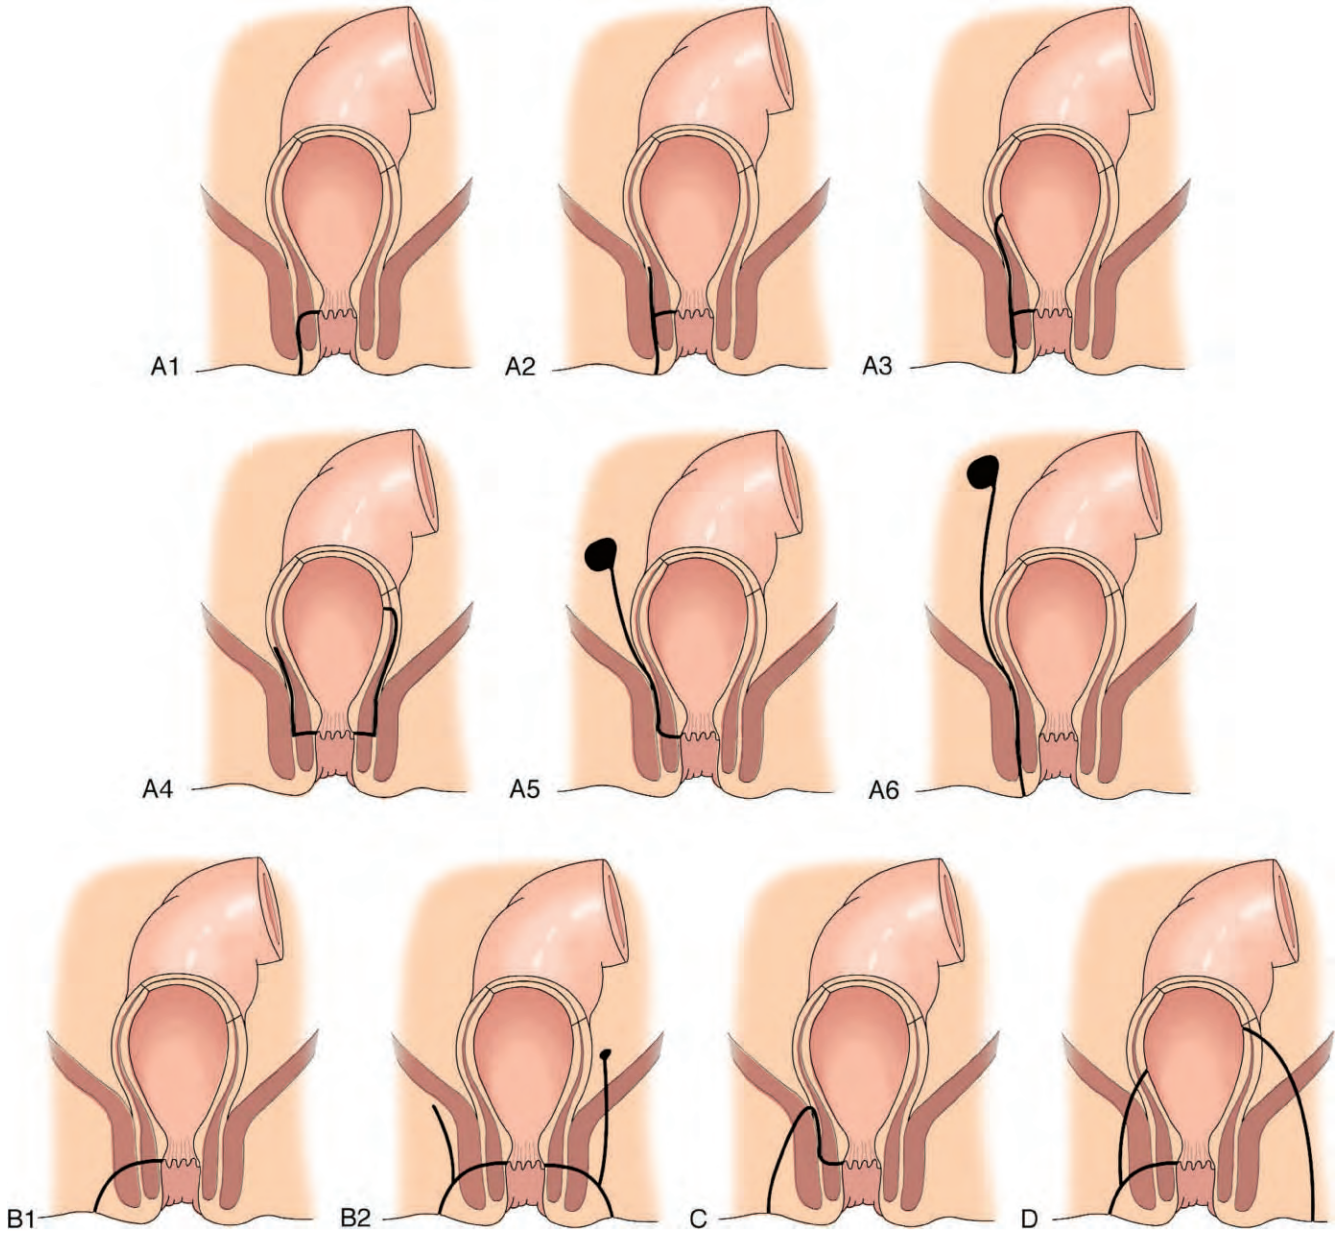

Figure 149–2. Classification of anal fistulas. **A,** Intersphincteric: The tract remains in the intersphincteric plane. *1,* Simple. *2,* High blind tract. There is a high extension of the fistula between the internal sphincter and the longitudinal muscle of the upper anal canal. *3,* High tract with rectal opening. *4,* High intersphincteric fistula without a perineal opening. There may or may not be a rectal opening. *5,* High intersphincteric fistula with a pelvic extension. The infection spreads up to reach the true pelvic cavity lying above the levator musculature. *6,* Intersphincteric fistula secondary to pelvic disease. This fistula results from the spread of pelvic collections via the intersphincteric plane. This does not represent a true anal fistula because its origin is outside the anal area. There is no opening at the dentate line. **B,** Trans-sphincteric: The fistula tract passes from the intersphincteric plane through the external sphincter muscle. *1,* Uncomplicated. *2,* High blind tract. The upper tract extension may go to the apex of the ischiorectal fossa or extend higher through the levator musculature into the pelvic cavity. **C,** Suprasphincteric: There is an upward extension of the fistula tract in the intersphincteric plane. The tract then passes above the level of the puborectalis muscle and continues downward through the ischiorectal fossa to the perianal area. **D,** Extrasphincteric: There is a tract that passes from the skin of the perineum through the ischiorectal fossa and the levator muscles before entering the rectal wall. This fistula may be a consequence of an extension of a trans-sphincteric fistula or secondary to trauma, anorectal disease, or pelvic inflammation.

absence of obvious physical findings (hidden abscesses). Approximately 20% to 33% of all patients give a history of a previous episode of anorectal sepsis.[8,17]

Physical Examination

The physical findings associated with anorectal abscesses vary depending on the anatomic location of the abscess. The presence of pus in any of the perianal and perirectal spaces may be confirmed with needle aspiration. An examination under general anesthesia may be necessary to confirm a diagnosis.

Perianal Abscess Localized swelling, hyperemia, induration or fluctuance, and tenderness are present adjacent to the anus. A purulent discharge may be present if spontaneous drainage has occurred. Although there usually are no systemic symptoms, the patient may have fever or malaise or be acutely ill.

Ischiorectal Abscess Although small collections may present with discrete localized swelling, more commonly there is a large, erythematous, and indurated mass in the buttock. Large volumes of purulent material may accumulate in the ischiorectal space. Fever and leukocytosis are common. A large ischiorectal abscess frequently represents a horseshoe extension (see later). A source in the posterior midline should be sought.

Intersphincteric and Submucous Abscess In intersphincteric and submucous abscess, there usually is no visible evidence of sepsis because these "hidden abscesses" are confined to the anal canal. Owing to the patient's discomfort, a digital rectal examination is not always possible. In this situation, an examination under general anesthesia is warranted to identify the abscess.

Supralevator Abscess Supralevator abscess may occur as an upward extension of a collection in the distal anal canal, usually an intersphincteric abscess, or as a true pelvic abscess secondary to intra-abdominal or pelvic pathology. Possibilities include appendicitis, diverticulitis, pelvic inflammatory disease, or ruptured viscus. The

patient may be systemically ill. A pelvic mass may be identified by rectal or vaginal examination.

Postanal Abscess and Horseshoe Extension Transsphincteric extension of an intersphincteric abscess in the posterior midline leads to the accumulation of purulent material in the deep postanal space. This space is difficult to evaluate clinically, making these the second type of hidden abscess. Inspection does not reveal any inflammatory skin changes because the abscess is deep. There may be tenderness posterior to the anus but anterior to the coccyx. The collection may be apparent only by needle aspiration or with an examination under general anesthesia. A horseshoe abscess is the result of a direct extension of a postanal abscess into the ischiorectal space (see Ischiorectal Abscess). It may be unilateral or bilateral.

Anorectal Fistulas

History

Most patients with a fistula-in-ano have a previous history of anorectal suppuration. The patient usually presents with complaints of intermittent or persistent purulent or serosanguineous drainage from an external opening in the perianal area. Symptoms classically consist of a build-up of pain, slight fever, and pain on defecation followed by mucopurulent drainage and abatement of the pain.[18] Pruritic symptoms may be present due to skin irritation associated with the chronic discharge.

Physical Examination

Fistula tracts are fibrous inflammatory tubes with a diameter of 3 to 7 mm. They are lined with infected granulation tissue. Many fistulas may be palpated during a careful digital rectal examination. Essential points that should be obtained from a clinical examination were described nearly 100 years ago by Goodsall and Miles[9]; they include the identification of the external and internal openings, the course of the primary and any secondary tracts, and an assessment for the presence of an underlying complicating disease.

Using an anoscope, systematic inspection and palpation can define most of these characteristics. The gentle use of a number of malleable anorectal probes and crypt hooks can help delineate the fistula by attempting to pass these instruments via the internal or external opening. It is important not to force the passage of the probe because the development of false tracts can complicate evaluation and management. Secondary tracts may be present when induration is palpated or asymmetry is noted between the right and left sides of the anorectum.[3] In only a few cases will the use of sophisticated diagnostic imaging techniques be required.

The external opening is identified as a small pit surrounded by scar or granulation tissue. Active seropurulent drainage may be present. Intersphincteric tracts usually open externally close to the anal verge; transsphincteric and other complicated tracts open farther away. Occasionally, the external opening may be localized inside the anal canal or at the distal end of a fissure. Several external openings may be present due to multiple complex fistula tracts; this condition is known as "watering-pot perineum."

The internal opening may be felt as an indurated nodule, most often at the dentate line. This is consistent with the cryptoglandular theory of anorectal sepsis. The use of saline,[19] milk,[20] dye,[21] or dilute hydrogen peroxide[22] as an injection into the external fistula opening has been made in an attempt to localize the internal opening. An enlarged papilla may be noted at this site. Because most of the anal glands are located in the posterior midline,[23] it is not surprising that 61% to 69% of internal openings can be traced to this location.[3]

Goodsall's rule may be helpful in locating the internal opening. This rule states that an external opening anterior to an imaginary transverse anal line in the coronal plane most likely communicates with an internal opening lying at the end of a radial line drawn to the nearest crypt at the dentate line. If the external opening is posterior to this line, the internal opening will most likely be located in the posterior midline with the tract following a curved route to reach its source. Exceptions to this rule include anterior openings more than 3 cm from the anal verge and the presence of multiple external openings. In these cases, the internal opening will most likely be in the posterior midline (Fig. 149–3). However, the predictive accuracy of Goodsall's rule has been challenged, especially with anterior external openings[24] or when Crohn's disease or carcinoma is present.[18]

Special Studies

Sigmoidoscopy and Colonoscopy

Sigmoidoscopy should be performed in all patients with anorectal fistulas. The presence of associated pathology such as neoplasms, inflammatory bowel disease, or associated secondary tracts in the rectum must be sought. Such findings may dictate the need for full colonoscopic evaluation.

Fistulography

Fistulography may be warranted in patients with recurrent fistulas or when a prior procedure has failed to identify the internal opening.[25] With this technique, the external opening is cannulated with a small-caliber tube and contrast material is injected under minimal pressure while films are taken in several projections. Fistulography may be useful in identifying unsuspected pathology, planning surgical management, and demonstrating anatomic relationships.[26-28] However, a study by Kuijpers and Schulpen[29] found fistulography to be unreliable compared with operative findings. They observed a prohibitively high incidence of false-positive results that could lead to unnecessary and harmful surgical exploration.

Anorectal Ultrasonography

Transanal ultrasound can delineate the muscular anatomy of the anal sphincters in relation to an abscess or a fistula. *Most commonly,* ultrasonographic examination

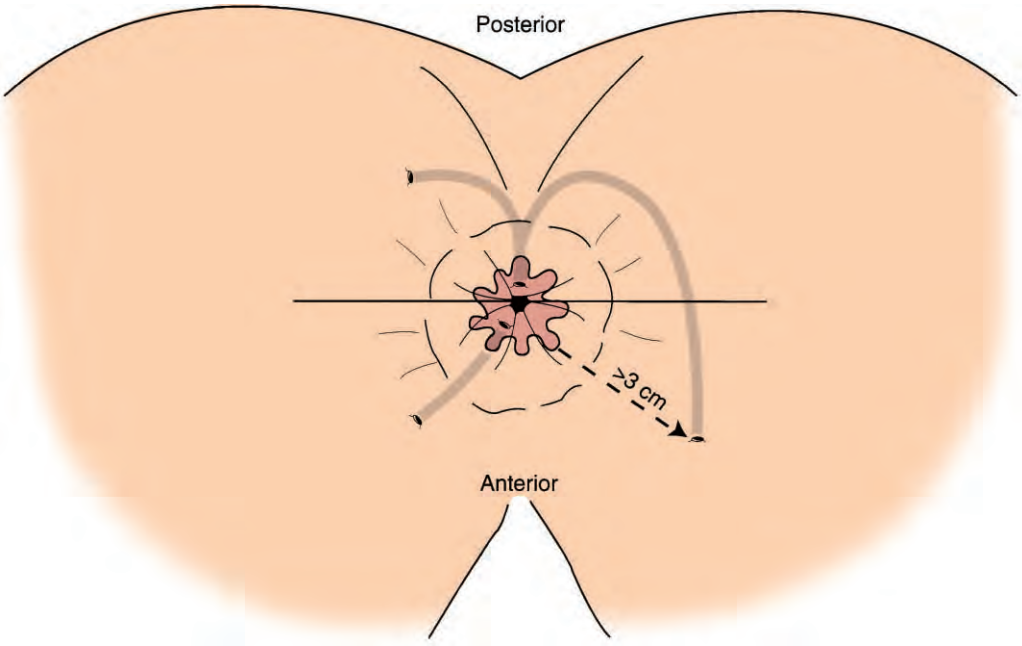

Figure 149–3. Goodsall's rule.

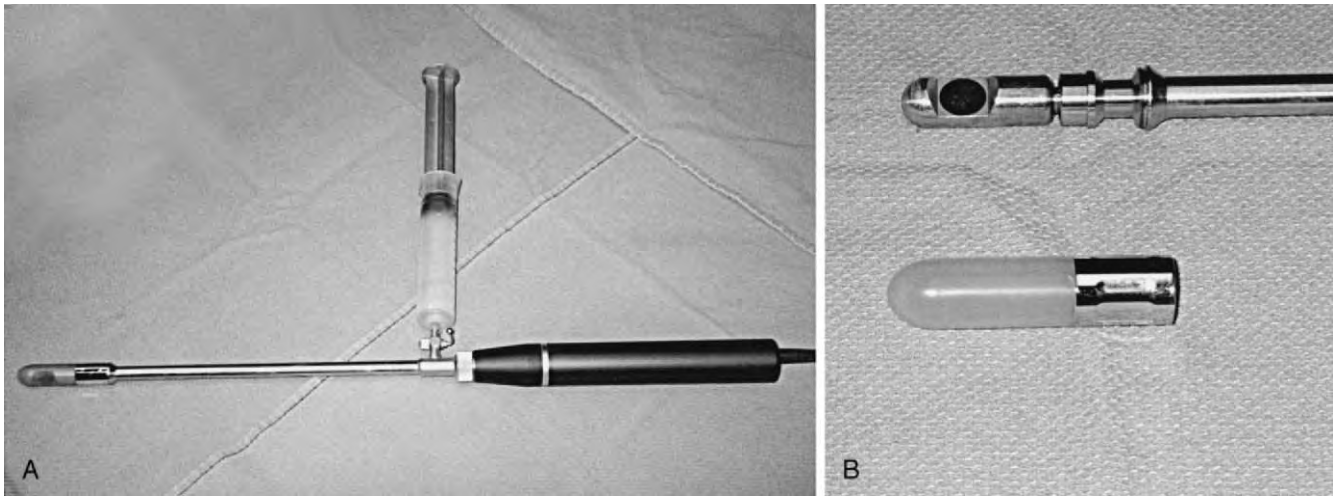

Figure 149–4. **A,** Transanal ultrasound probe (type 1850; Brüel and Kjaer, Naerum, Denmark). **B,** The rotating transducer is covered by a hard plastic sonolucent cone, which is then filled with water to provide an acoustic interphase.

of the anal canal is performed with the use of a 360-degree rotating probe using a 7- or 10-MHz transducer with a hard plastic water-filled sonolucent cone over the transducer (Fig. 149–4).[25] Fistula tracts and abscesses appear as hypoechoic defects within the muscular elements of the anal canal (Fig. 149–5). The internal opening is not distinctly identified. Although generally accurate in the localization of abscesses and fistula tracts,[30,31] primary superficial, extrasphincteric, and suprasphincteric tracts or secondary supralevator or infralevator tracts may be missed.[32] The use of hydrogen peroxide injected into fistulas as an image enhancer has been shown to be safe, effective, and more accurate than conventional transanal ultrasound in the evaluation of anal sepsis (Fig. 149–6).[33,34] However, the complication of oxygen embolization arising from hydrogen peroxide irrigation of wounds, particularly when irrigated under pressure, has been described.[35-37] This has led some to investigate alternative echo-enhancing media such as galactose particles and palmitic acid (Levovist), which has been proven safe in echocardiography.[38]

The use of a linear 7-MHz ultrasound device instead of a radial probe has been described and may carry the advantages of greater focal depth, improved ischiorectal

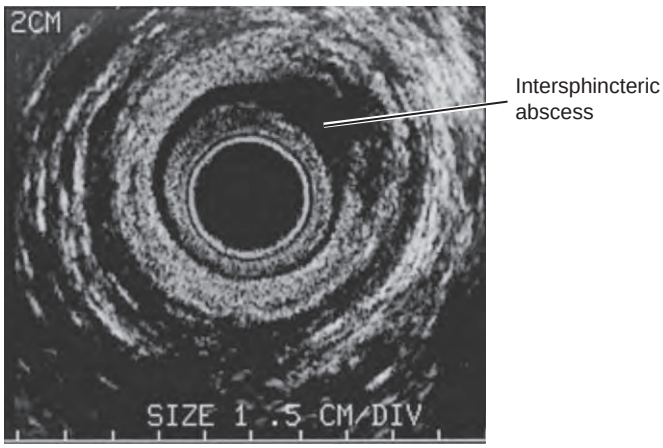

Figure 149–5. Intersphincteric abscess as seen with the use of transanal ultrasound.

and supralevator visualization, multiplanar views of complex fistulas, and less need for echo-enhancing injection.[39] Finally, it has been shown that vaginal endosonography may increase the diagnostic yield of perianal sepsis in 25% of patients and may obviate the need for uncomfortable digital or endoanal ultrasound examinations in those patients with hidden abscesses or anal stenosis.[40]

Magnetic Resonance Imaging

Using surface and body coils, Myhr et al.[41] studied the use of magnetic resonance imaging (MRI) with saline solution as a contrast agent in the evaluation of anorectal sepsis. Multiplanar MRI defined soft tissue anatomic abnormalities in 15 of 16 patients. The administration of a gadolinium enema greatly enhanced T2-weighted images and improved lesion identification, especially in cases of chronic or recurrent fistula.[42] Others have found high concordance rates between MRI and operative findings.[43,44] Lunniss et al.[45] compared MRI with anal endosonography and operative findings in the evaluation of 20 patients with anal fistula. The overall concordance for the primary tract between MRI and surgery was 85% compared with 65% for endosonography. MRI also proved to be superior for the assessment of secondary tracts (100% concordance for MRI vs. ≤50% with endosonography). The use of an MRI endoanal magnetic coil has been found to be superior to surface coil MRI and endoanal ultrasonography in fistula evaluation.[46,47] In all of these studies, however, the use of endosonic-enhancing media was not used when comparing endoanal ultrasound with MRI.

Computed Tomography

The use of computed tomography (CT) in the evaluation of anal fistulas is limited due to poor visualization of the levators and sphincter complex. The role of CT in anal sepsis and fistula is thus limited to the assessment of associated pelvic pathology in patients with supralevator abscesses and in patients with some complex anal fistulas.

Anorectal Manometry

Anorectal manometry is an objective method for studying the contribution of the anorectal sphincter to the physiologic process of defecation.[48] Normal anorectal manometric parameters in adults have been established.[49] Manometry can thus assist in identifying patients at the greatest risk for postoperative incontinence. Surgical management can be tailored accordingly, improving clinical and functional outcome.[50,51] The selective use of anorectal manometry is warranted in patients with suspected sphincter impairment; patients suspected of needing substantial portions of the external sphincter divided for fistula cure; and women with a history of multiparity, forceps delivery, third-degree perineal tear, high birthweight, or prolonged second stage of labor.[18] Patients with lower preoperative resting pressures have significantly poorer continence control following surgery for intersphincteric fistula when compared prospectively to patients with normal preoperative resting pressures.[52]

Fistuloscopy

Anorectal fistuloscopy using flexible ureteroscopes has been recently described.[53] This is a potentially useful intraoperative technique to identify primary fistula openings, multiple or complex tracts, and iatrogenic tracts. Modified flexible ureteroscopes are in the early developmental stages. We look forward to their evolution because they represent a novel diagnostic and therapeutic tool that may significantly improve the outcomes of complex fistula diagnosis and treatment.

TREATMENT

Anorectal Abscess

The treatment of anorectal abscesses should be considered a surgical emergency, with early drainage the mainstay of treatment. There is no place for conservative management. Treatment delay may result in chronic infection and tissue destruction with fibrosis and long-term impairment of function. The condition of the patient and the type of abscess usually determine whether drainage can be performed in the office or emergency department or in the operating room. Antibiotics should be used as adjunctive therapy in special circumstances only; these include patients with valvular heart disease, immunosuppression, extensive associated cellulitis, and diabetes.[25]

Anorectal abscesses associated with gut-derived organisms are more likely to be associated with an underlying fistula and have a higher incidence of recurrence than are abscesses associated with skin-derived organisms.[54-56] However, the positive predictive value for this association has been found to be quite low[57]; therefore, cultures are rarely indicated.

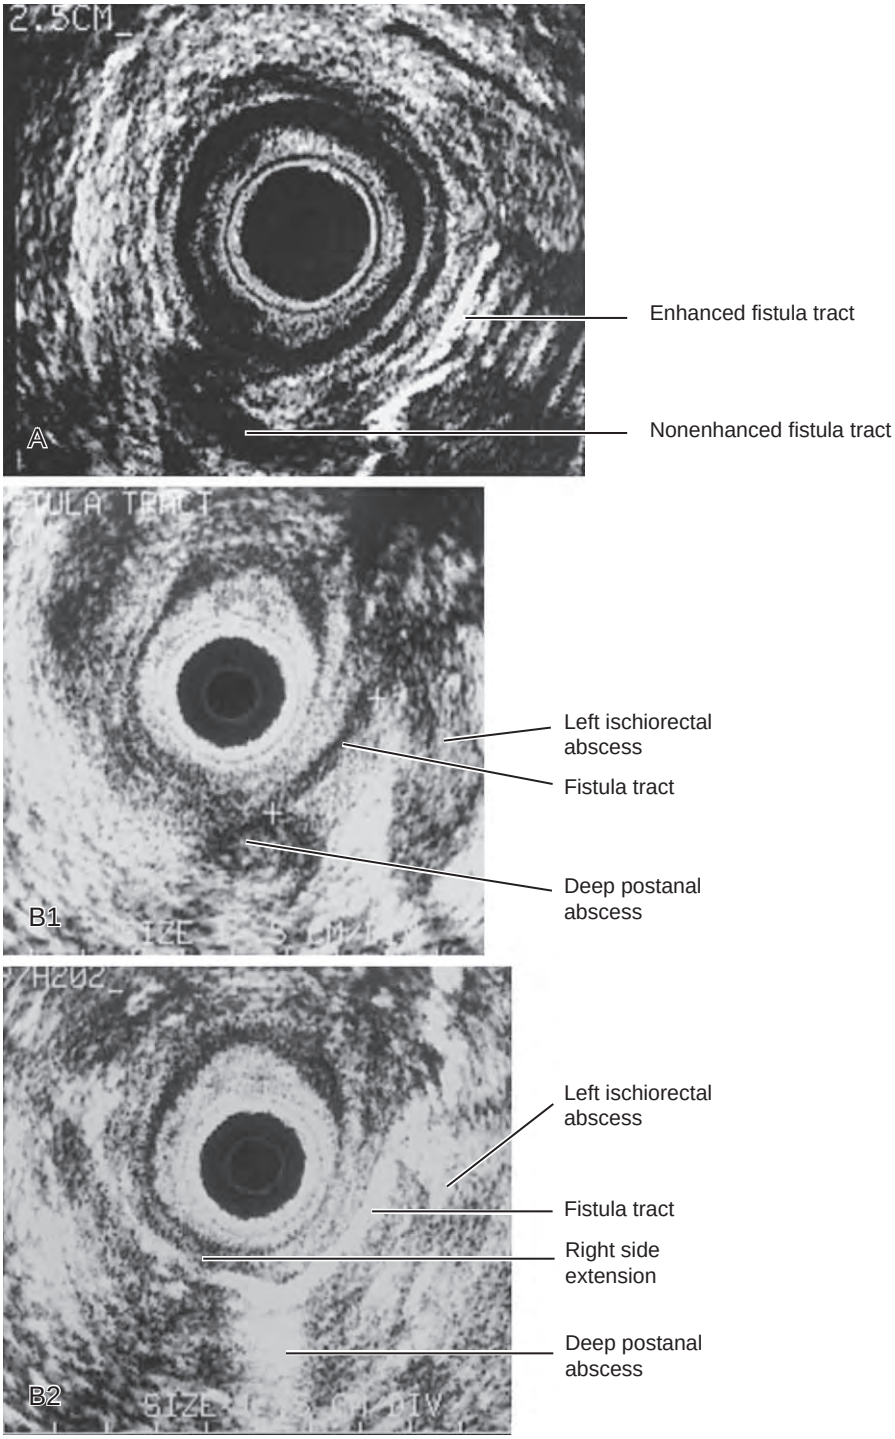

Figure 149–6. A, Trans-sphincteric hypoechogenic tract extending toward the posterior midline. The tract is enhanced as hydrogen peroxide is injected into the external opening. **B,** Complex fistula tract and collections as seen without *(1)* and with *(2)* hydrogen peroxide enhancement. Hydrogen peroxide enhancement allowed for a more precise delineation of the tracts in addition to a right-sided extension of the tract.

Perianal Abscess

Simple perianal abscesses can almost always be drained as an office or outpatient procedure, usually under local anesthesia. A cruciate incision is made over the most tender or fluctuant point as close to the anal verge as possible. If a fistula develops, the external opening will be close to the verge, so a fistulotomy would require division of the least amount of muscle. The skin edges are usually excised to avoid early coaptation, which could seal the cavity prematurely and lead to recurrence (Fig. 149–7).

After all loculations are broken, packing is not required; packing contributes to significant discomfort and does not allow for free drainage of the abscess cavity. Continued drainage of large cavities may be achieved with the use of a 3- to 5-mm de Pezzer or similar catheter left in situ until drainage subsides.[58] This technique may

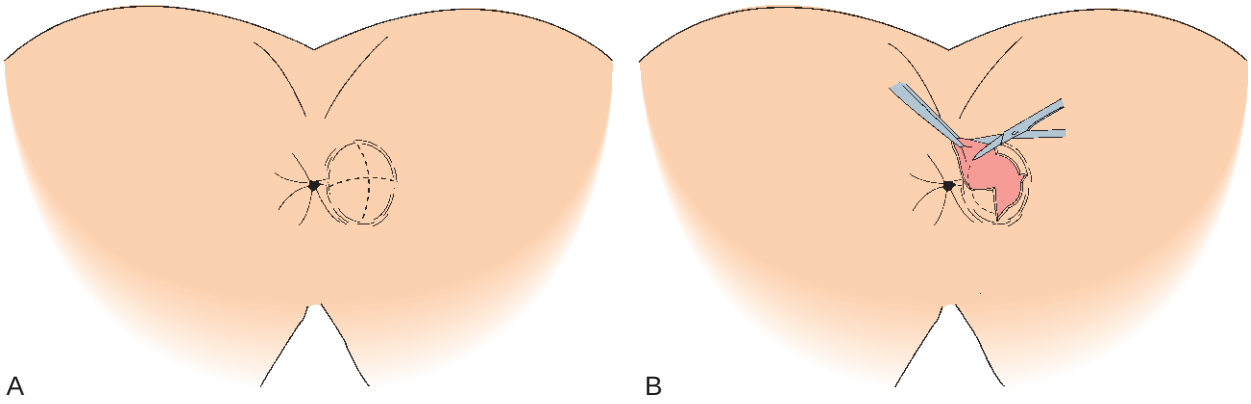

Figure 149–7. **A,** Cruciate incision made over the most tender or fluctuant area. **B,** The skin edges are excised.

be used in a number of different abscesses but is not suitable for use in cases of submucous or intersphincteric abscess.

Ischiorectal Abscess

After horseshoe extension is excluded by ensuring that the deep postanal space is not involved, unilateral ischiorectal abscesses may be drained through a single incision or several counterincisions over the area of maximal swelling, pain, and fluctuance but as close to the anal verge as possible. Here, too, a de Pezzer catheter may be used to enhance the drainage of large cavities.

Intersphincteric Abscess

An intersphincteric abscess is drained by laying open the internal sphincter (sphincterotomy) overlying the cavity. By definition, a fistulotomy is performed by destruction of the inciting anal gland. For hemostasis, adequate drainage, and faster healing, the edges of the wound may be marsupialized.

Submucosal Abscess

Submucosal abscesses are drained internally by incising the mucosa over the abscess. The edges of the wound may be marsupialized. No packing or drainage catheter is indicated.

Supralevator Abscess

Anatomic localization of the septic origin is of paramount importance in the management of supralevator collections. Collections that result from abdominopelvic disease may be drained transrectally or transabdominally. Overall management depends on the underlying pathology. Supralevator collections that result from an upward extension of an intersphincteric abscess should be drained transrectally. Transperineal drainage through the ischiorectal fossae could result in a suprasphincteric fistula. Supralevator collections that result from the cephalad extension of a trans-sphincteric fistula or an ischiorectal collection should be drained transperineally through the ischioanal fossae. If erroneously drained transrectally, the result will be an extrasphincteric fistula. Transperineal drainage of this type of collection will likely result in a trans-sphincteric fistula that is relatively easy to manage (Fig. 149–8).

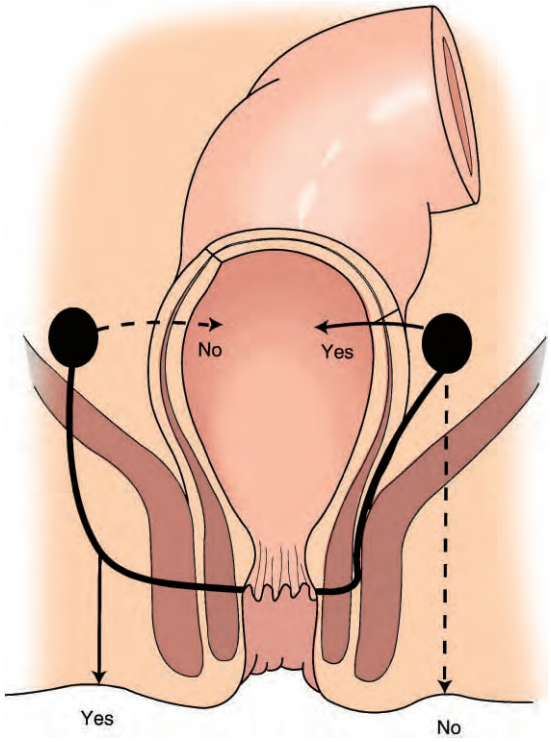

Figure 149–8. Appropriate type of drainage of supralevator abscesses depending on the course taken by the fistula tract.

Postanal Abscess and Horseshoe Extension

Patrick H. Hanley first described the conservative surgical approach to a horseshoe abscess that preserved function and anatomy.[59] The abscess in the postanal space is drained by a deep posterior midline incision. All of the muscles attached to the coccyx, the superficial external

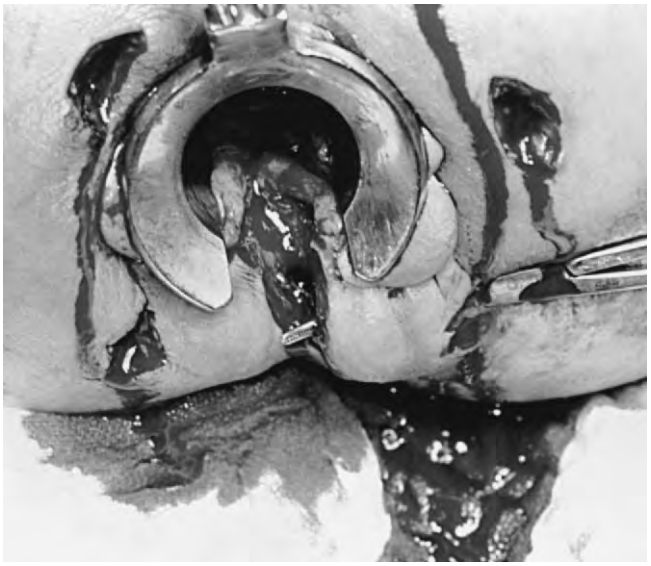

Figure 149–9. Drainage of a postanal abscess with horseshoe extension. The postanal space has been laid open as described by Hanley. Secondary incisions are placed in the skin overlying the ischiorectal space.

sphincter, and the lower edge of the internal sphincter are divided. When the suppurative process extends to the ischiorectal spaces as a horseshoe, one or multiple secondary incisions are placed in the skin overlying the ischiorectal space. These may be connected to each other with soft drains to allow for continuous drainage. We favor a modification of Hanley's technique in which the posterior midline incision consists of only a partial distal internal sphincterotomy to include a fistulotomy with destruction of the anal gland at the dentate line. The external sphincter and the muscular attachments to the coccyx are not divided. This allows for faster healing while maintaining adequate drainage (Fig. 149–9). Counterincisions and drains are used for horseshoe extensions as previously described.

Primary Versus Delayed Fistulotomy

The use of primary fistulotomy when draining an abscess remains controversial. Issues that surround this controversy include the ability to localize an internal opening at the time of an acute septic event and the effect of primary fistulotomy on recurrence and continence. Does the type of abscess affect the risk of recurrent fistula? Is it cost-effective to take a patient for whom an outpatient procedure is performed under local anesthesia to the operating room for a thorough examination under general anesthesia and a primary fistulotomy in the hope of avoiding a second procedure for a fistula that might develop if only simple drainage were performed?

A one-stage procedure theoretically destroys the cryptoglandular source of sepsis, decreasing the incidence of fistula formation. However, internal openings may not always be found. Attempts to define a primary opening in the setting of an acute infection may be a hazardous undertaking. Because not all abscesses lead to fistulas, some patients would undergo an unnecessary procedure that puts them at risk for incontinence.

The reported incidence of recurrent abscess and subsequent development of anorectal fistula varies considerably. Scoma et al.[7] found that 66% of 232 patients developed a fistula or recurrent abscess after incision and drainage alone. Vasilevsky and Gordon[8] found that 11% of 83 patients developed recurrent abscess and 37% developed a fistula after incision and drainage. They noted that the greatest risk of recurrence was in patients who had ischiorectal abscesses, an observation we have also made. The subset of patients with no previous episode of anorectal suppuration had a lower incidence of recurrence. Both authors advocated incision and drainage alone for acute abscesses, reserving fistulotomy as a secondary procedure in patients with recurrence.

In contrast, several authors favor a policy of immediate fistulotomy in the treatment of anorectal abscesses. In a series of almost 800 cases, Eisenhammer[60] described a nearly 100% cure rate obtained with a single operation. McElwain and colleagues[4] reported on the outcome of 1000 cases of primary fistulotomy for anorectal abscesses, including intersphincteric and postanal abscesses. The recurrence rate was 3.6%, and the disturbance of continence rate was 3.2%. However, this approach requires the consistent finding of an internal opening to perform fistulotomy. In two studies, the internal opening could be identified in only approximately 34% of acute abscesses.[5,61] In other series, 69% to 88% of the internal openings were identified.[62,63]

Ramanujam et al.[5] found long-term recurrence to be less in a group of 323 patients (1.8%) who had primary fistulotomy compared with a group of 668 patients with incision and drainage alone (3.7%). A small prospective, randomized study of 45 patients by Tang and colleagues[64] did not show such a difference. However, a larger prospective, randomized study by Schouten and van Vroonhoven[6] did show a difference: Of 32 patients, 10 developed a recurrent abscess and 3 developed a persistent fistula in the drainage-only group; in the primary fistulotomy group, 1 patient of 34 developed a persistent fistula. The incidence of anal functional disturbances did not differ among the groups. In a randomized, prospective trial of 200 patients, Oliver and colleagues demonstrated that drainage with fistulotomy was safe (incontinence 6% at 1 year) and effective (recurrence 5% at 1 year) when compared with drainage alone (0% incontinence and 29% recurrence).[65]

In summary, a percentage of patients who have drainage alone for the treatment of anal abscess develop a recurrent abscess or subsequent fistula. A primary fistulotomy in this setting may decrease this risk but at the expense of a small increase in the risk for disturbances of continence. Primary fistulotomy should be considered in patients who have a history of previous anorectal sepsis or who present with an ischiorectal abscess with an internal opening that is readily apparent. This controversy has no impact in dealing with postanal abscesses with horseshoe extensions or intersphincteric abscesses. In these

cases, a fistulotomy is performed when the sphincterotomy is the primary drainage technique.

Anorectal Fistulas

Once diagnosed, patients with anorectal fistulas should undergo surgical treatment. Anorectal fistulas rarely heal spontaneously. Untreated patients frequently develop chronic abscess formation and complex fistula tracts. Surgical treatment for most anorectal fistulas is best accomplished in the operating room, with good lighting and appropriate instrumentation. The patient is positioned in prone jackknife position with the buttocks taped apart. General, regional, or local anesthesia with intravenous sedation should be selected based on individual patient characteristics. The three basic surgical techniques for the treatment of anorectal fistulas are fistulotomy, use of a seton, and endorectal advancement flaps. The use of fistulectomy is not recommended except when it is necessary to provide histologic material.[25]

Fistulotomy

Most anorectal fistulas may be adequately treated by the classic laying-open technique or fistulotomy. Recurrence rates are low, and risks for continence disturbances are minimal.[3] A fistulotomy is accomplished by passing a fistula probe via the external opening, along the tract, and through the internal opening. With the probe in place, the relationship of the fistulous tract to the external sphincter muscle can be determined. If the tract lies distal to the majority of the external muscle, then cautery is used to lay it open. Secondary tracts should be drained through the fistulotomy incision after all tracts have been curetted. Marsupialization with a running continuous absorbable suture is associated with faster healing.[66]

In patients with otherwise normal continence, the perianal skin, anal epithelium, a portion of the internal anal sphincter, and a few fibers of subcutaneous external sphincter may be divided without risk to continence. However, in women with anterior fistulas, such a fistulotomy is associated with an unacceptably high risk of incontinence due to the intrinsic thin nature of the sphincter mechanism in this area. Therefore, other techniques should be used in the treatment of anterior fistulas in women.

Traditional fistulotomy has been performed with scalpel or electrocautery in the lay-open technique. Very recently, Gupta has described a lay-open fistulotomy technique using radiofreqency.[67] Also known as *radiofrequency fistulotomy,* this technique employs very high-frequency radio waves that vaporize intracellular water without utilization or generation of heat. The hand-held terminal has different attachments that can be selected by the surgeon to cut, cauterize, or shave tissue without collateral heat damage to healthy surrounding tissues. How this technology compares to traditional electrocautery in terms of fistula recurrence, incontinence, and cost remains to be studied.

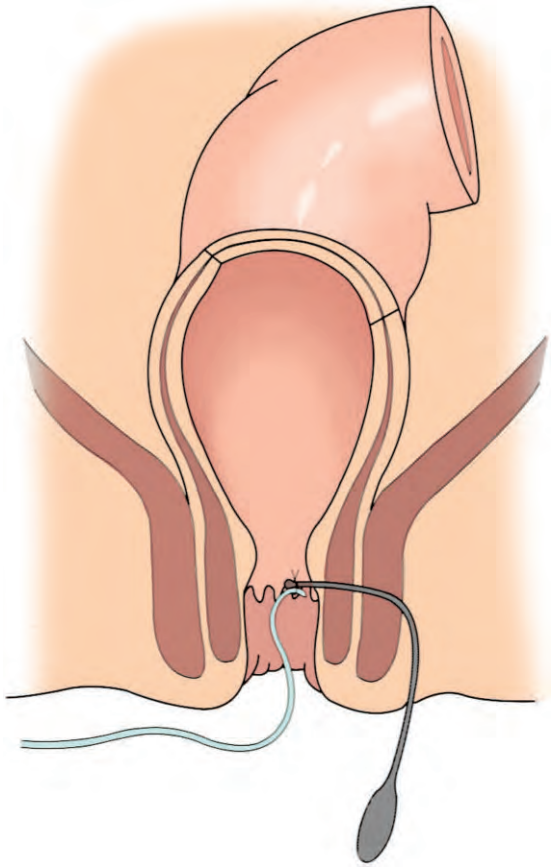

Figure 149–10. Insertion of a seton with the aid of a fistula probe.

Seton Management

The word *seton* is derived from the Latin word *seta,* meaning "bristle." It refers to any foreign material that can be inserted into the fistula tract to encircle the sphincter muscles. These materials include silk,[68,69] Penrose drains,[70,71] Silastic vessel loops, rubber bands,[72] nylon or polypropylene,[73] and braided steel wire.[74] Setons are placed by securing the selected material to the end of a fistula probe after the probe has been passed through the internal opening (Fig. 149–10).

Setons are useful in the management of complex anorectal fistulas where there is an appreciable risk of incontinence or poor healing; such cases include patients with Crohn's disease, immunocompromised and incontinent patients, patients with chronic diarrheal states, and anterior fistulas in women. Complete healing of selected anorectal fistulas has been reported solely with the use of long-term setons.[75]

Setons may be used for marking, draining, cutting, or staging.[76] A marking seton is useful when it is difficult to determine the amount of muscle the fistula tract crosses. Encircling the tract with a seton allows the surgeon to assess the amount of muscle, particularly the puborectalis, once the patient is awake. If adequate muscle is present above the fistula tract, a fistulotomy may be performed without significant risk for incontinence.

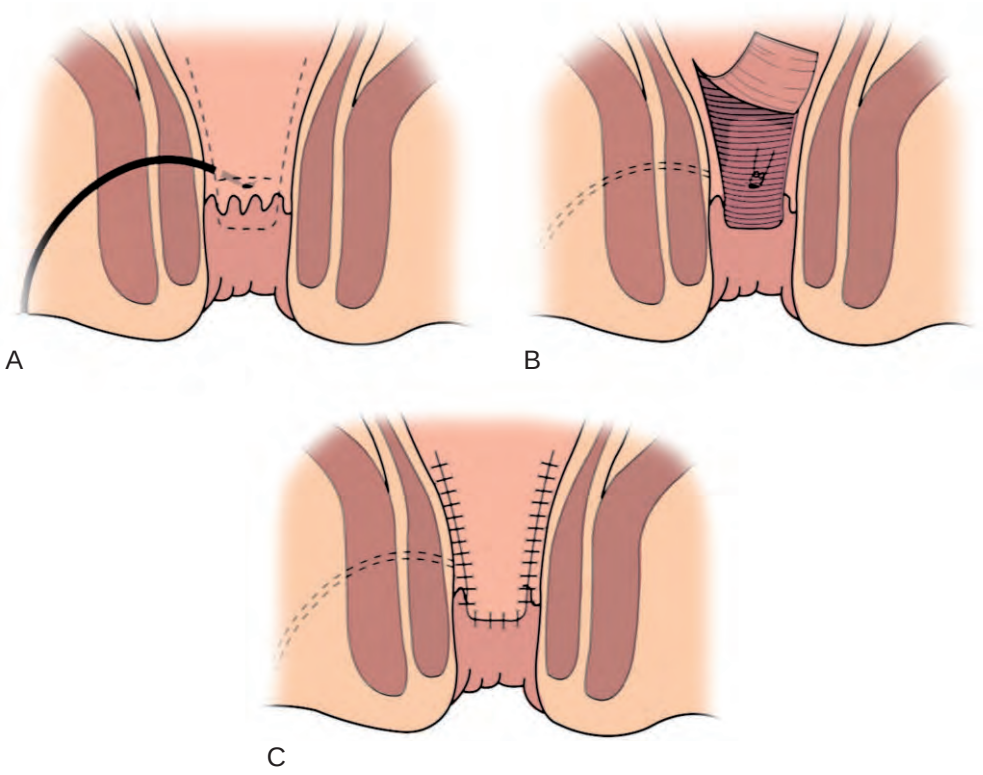

Figure 149–11. **A,** Anorectal advancement flap for closure of the internal opening in the treatment of perianal fistulas. The base of the flap should be wider than the apex. **B,** With the flap elevated, the internal opening is débrided and closed with a suture. **C,** The apex of the flap is advanced and sutured over the defect.

A draining seton traverses a fistula tract to provide long-term drainage of a septic process. It may be used as a bridge to definitive surgical therapy or be left in place for long periods. Epithelialization of the tract prevents recurring abscesses. Long-term draining setons are tied loosely. They are particularly useful in the management of complex fistulas associated with Crohn's disease.[77] The combination of draining seton and immunomodulation therapy with infliximab appears to improve outcomes while maintaining sphincter function in Crohn's patients with complex anal fistulas.[78]

A cutting seton is used to gradually transect the striated sphincter muscle. This technique promotes fibrosis in the tissue surrounding the muscle encircled by the seton. At regular intervals (2 weeks), the seton is progressively tightened, dividing the muscle by a process of ischemic necrosis. The cut edge of the divided muscle does not separate because of the fibrosis that forms during the time it takes to divide the muscle. The seton can be progressively tightened with silk ligatures. Alternatively, a hemorrhoid ligator may be used to progressively tighten the seton with rubber bands.[79]

When a staging seton is used, the fistula tract is identified and only the most superficial portion is divided. The seton is placed through that portion of the fistula tract that traverses the sphincter, thus encircling the muscle. This portion of the tract is divided as a second procedure once adequate fibrosis occurs (usually 8 weeks). A "high" fistula may be converted to a "low" fistula by dividing only the proximal portion of the tract, leaving the distal tract encircled with a seton for division at a later date.

Whether to use a cutting seton or a staging seton with second-stage fistulotomy appears to be up to surgeon preference. In a study of 59 patients with high anal fistula, Garcia-Aguilar et al.[68] showed no difference in fistula eradication, incontinence, and patient satisfaction between 12 patients treated with cutting setons and 47 treated with two-stage seton fistulotomy.

Closure of the Internal Opening: Anorectal Advancement Flaps

Advancement flaps consist of mucosa, submucosa, and part of the internal sphincter. The underlying fistula tract is débrided, and the internal opening is sutured at the level of the muscle. The edge of the elevated flap containing the internal opening is excised, and the flap is advanced and sutured over the internal defect (Fig. 149–11).

Advancement flaps offer the advantage of a one-stage procedure, quicker healing, limited damage to the underlying sphincter, and minimal risk of anal canal deformity.[3] Several studies have reported good success with few complications using anorectal advancement flaps in the treatment of both simple and complex fistulas.[80-82]

Fibrin Glue

The use of fibrin glue in the management of anorectal fistulas has been popularized.[83,84] A prepared mixture of fibrinogen and thrombin is injected into the fistula tract after it has been curetted. The resulting coagulum plugs the fistula tract. This technique represents an alternative mode of treatment in complex cases for which standard treatment has failed. The complete healing rate in one

series was 60% and included patients with Crohn's disease and human immunodeficiency virus (HIV)-associated anal disease.[83] Sentovich performed a two-stage fistulotomy with injection of fibrin glue into the external opening after seton removal at the second operation with 69% success in 48 patients.[85] Buchanan et al.[86] found only a 14% complex fistula closure rate in 22 patients. Though results have been mixed, fibrin glue remains a viable treatment option due to its safety, ease of application, and low risk of sphincter injury. A biodegradable "collagen plug" derived from porcine submucosa has been trialed against fibrin glue in a small sample of patients with promising results: 13 (87%) of 15 patients enrolled in the collagen plug arm of the study had complete fistula healing compared with 4 (40%) of 10 who were treated with fibrin glue ($P < .05$).[87]

POSTOPERATIVE CARE

In general, if surgery is performed as an outpatient procedure, patients are instructed in consuming a high-fiber diet. No bowel confinement regimen is required for the treatment of simple conditions. For complex procedures, bowel confinement has been recommended,[82] but it is of questionable value.[88] Sitz baths are recommended for perianal hygiene and comfort. More complex procedures may require inpatient status for pain management and wound care. Wound healing after fistulotomy usually takes 4 to 8 weeks. Patients with anorectal abscess should be followed closely after drainage for possible fistula development.

COMPLICATIONS

Complications after surgical intervention for anorectal suppurative disease are numerous and related to surgical technique. Urinary retention is the most common complication, occurring in up to 25% of patients.[89] Other complications include hemorrhage, acute external thrombosed hemorrhoids, cellulitis, fecal impaction, stricture, rectovaginal fistula, incontinence, and recurrence.[89] Local wound problems and complications associated with anesthesia, such as hypotension, hypertension, and seizures, have also been reported.[61] The issue of fistula recurrence after drainage of anorectal abscess has been discussed previously.

The rate of recurrent fistula after fistulotomy ranges from 0% to 18%,[90] although the true incidence is probably around 3% to 7%.[5,16] The primary causes of fistula recurrence relate to unrecognized internal openings and inadequate drainage of abscess cavities.[2] In a study of 375 patients, Garcia-Aguilar[16] found that recurrence was also associated with lateral location of internal openings and fistulas with horseshoe extension.

The rate of disorders of continence after fistulotomy ranges from 18% to 52%.[90] Factors associated with incontinence risk include the complexity of the fistula, female sex, division of a significant portion of the external sphincter, the use of two-stage seton or cutting seton fistulotomy (probably due to complexity of the fistula), and a history of prior fistula surgery.[16]

SPECIAL CONSIDERATIONS

Crohn's Disease

The incidence of perianal complications in patients with Crohn's disease (see Chapters 151 and 153) varies from 22% to 54%, with many due to anorectal sepsis and fistula.[91-93] Anorectal abscess in patients with Crohn's disease should be treated with prompt drainage. Long-term catheter drainage has been found to be safe and effective and may be of benefit in preventing or delaying recurrence and the subsequent need for proctectomy.[94,95]

The treatment of anorectal fistulas in patients with Crohn's disease should be tailored to the specific situation encountered. Consideration should be given to the complexity of the fistula and the presence of active Crohn's disease in the rectum. In general, treatment modalities should be conservative. Extensive procedures may increase the risk of incontinence and nonhealing wounds. A simple fistula in a patient with a normal rectum can be treated by primary fistulotomy with good outcome and satisfactory healing rates.[96-98] Complex fistulas in patients with active rectal Crohn's disease remain a therapeutic challenge. These cases are better served with prolonged drainage to achieve long-term palliation.[99] In selected cases, rectal advancement flaps may be used with good functional results.[82,100] Some patients with complex anorectal fistulas in the presence of anal Crohn's may require diversion of the fecal stream for symptomatic relief.[101] Ultimately, between 5% and 18% of patients require a proctectomy.[25] Shinozaki et al., in a series of 39 patients, found that simultaneously performing a bowel resection for active Crohn's disease at the time of drainage of perianal sepsis or draining seton placement led to better healing of the anal fistula.[102] It is theorized that control of the intra-abdominal Crohn's disease improves healing of perianal Crohn's fistulas.

The long-term administration of metronidazole may be beneficial in the management of patients with perianal manifestations of Crohn's disease. Symptomatic improvement has been reported in the range of 71% to 100%, although complete healing is less frequent.[103-107] Side effects associated with the chronic use of metronidazole include paresthesias, metallic taste, and pancreatitis. These complications have been reported to occur in 50% to 100% of patients.[103-105,108]

A monoclonal antibody to tumor necrosis factor (TNF)-α was approved in August 1998 by the U.S. Food and Drug Administration for the treatment of patients with fistulizing Crohn's disease. Infliximab (Remicade) is a genetically constructed murine-human chimeric immunoglobulin. It neutralizes the biologic activity of TNF-α and inhibits binding to its receptors.[109] A randomized trial in which infliximab was used in the management of patients with Crohn's fistulas (perianal and abdominal) demonstrated a 62% clinical response (defined as >50% reduction from baseline in the number of draining fistulas) and a 46% complete closure of all fistulas compared with 26% and 13%, respectively, of patients in the placebo group.[110] However, the duration of response is short lived. Repeat treatment or

chronic use may be required for a long-term beneficial effect.

The safety and efficacy of infliximab for long-term use have not been established. Severe infusion reactions have been reported.[111] The development of human antichimeric antibodies that may result in delayed hypersensitivity reactions and the possibility of attenuation of therapeutic effect with the subsequent exposure to the drug are issues under investigation. The development of a purely human TNF-α monoclonal antibody, adalimumab (Humira), may obviate these concerns. Associations between biologic disease-modifying antirheumatic drugs, such as infliximab and adalimumab, and lymphoid malignancies are anecdotal and similar to the associations seen between other immunomodulatory drugs and malignancy.

Fistula in Infancy

Anal fistula in infancy occurs almost exclusively in otherwise healthy boys younger than 2 years of age. The cause of this condition appears to be a congenital abnormality of the anal glands with abnormally deep and thick crypts of Morgagni. These factors predispose the patients to cryptitis with abscess and fistula formation.[112] Simple fistulotomy is recommended in this patient population with expected good results.[113] A concomitant cryptotomy has been recommended by some to decrease the likelihood of recurrence.[114] Nonoperative management is favored by those who believe that abscess and fistula are self-limited in this population.[115] Opponents argue that such fistula disease is seldom time limited. They argue that the process is truly characterized by frequent intermittent relapse or a prolonged silent state with late recurrence requiring subsequent intervention.[116]

Malignant Transformation in Chronic Anal Fistula

Carcinoma arising in an anorectal fistula is a rare condition. Rosser[117] established the first association between adenocarcinoma and anal fistula. There is controversy regarding the possibility of malignancy arising from a benign anorectal fistula. A slow-growing cancer may not become evident for years, and in some cases the fistula could result from the breakdown of a neoplasm. To rule out the preexistence of even the slowest growing cancer, it has been arbitrarily determined that a fistula should have been present for at least 10 years before the diagnosis of carcinoma if malignant transformation is to be considered.[118]

Carcinoma arising in anorectal fistulas in patients with Crohn's disease has been reported; the estimated incidence is 0.7%.[119] Deep biopsy samples, careful histologic examination of atypical cells obtained from ductal structures, and a high index of suspicion in cases of long-standing anorectal fistulas may provide a clue to the diagnosis of underlying carcinoma.[120] Resection with either wide local excision or abdominoperineal resection has the potential to result in cure.[121]

Anorectal Sepsis and Fistula in Human Immunodeficiency Virus Disease

Anorectal disease is a prevalent problem in the HIV-positive population, with an estimated frequency of 6% to 34%.[122] Although there is concern in performing elective anorectal surgery in this population because of the fear of poor healing, symptomatic anorectal sepsis and fistula often require surgical management. Treatment should be tailored to the patient's severity of illness. The risk for disturbed wound healing increases as the preoperative $CD4^+$ count decreases.[122] The presence of an acquired immunodeficiency syndrome–indicator condition (Kaposi's sarcoma, immunoblastic lymphoma, and so on) and a white blood cell count of less than $3000/mm^3$ are also associated with poor wound healing.[123,124] In the absence of these risk factors, fistulotomy for simple fistulas may be performed with expected good results. For complex fistulas and patients with risk factors for poor healing, the liberal use of draining setons is recommended for symptomatic relief.[25,124]

Anorectal Complications in Patients with Leukemia

Anorectal complications in patients with leukemia represent a rare but potentially life-threatening problem. The incidence of concomitant symptomatic anorectal disease has been reported to be as high as 5.8%. Acute anorectal sepsis accounts for almost half of all cases.[125] The mortality rate for patients with acute perianal sepsis in this population has been reported to be from 16% to as high as 54%.[125-127] In general, surgical treatment of anorectal sepsis in uncontrolled acute leukemia has been avoided because of the fear that the septic process would spread and wound healing would be impaired. Historically, this led to a policy of combined radiation therapy and symptomatic care as primary treatment, with surgical management reserved for the drainage of an obviously fluctuant abscess.[128] Symptomatic care consisted of sitz baths or warm compresses, stool softeners, analgesic agents, and broad-spectrum antibiotics. Additional precautionary measures included no rectal examinations, no instrumentation, and no enemas. However, reports indicate that surgical intervention in the form of incision and drainage appears to be safe in this patient population. Two studies found no difference in morbidity and mortality rates between patients who had surgical drainage versus those who did not.[125,129] Barnes et al.[130] found that when spontaneous drainage did not occur, mandatory surgical drainage of anorectal abscess contributed to a better outcome in terms of mortality rates and wound healing.

Chapter

150

Miscellaneous Disorders of the Rectum and Anus

David E. Beck

Stricture, Pruritus Ani, Pain Syndromes, Solitary Rectal Ulcer, Colitis Cystica Profunda, and Hidradenitis Suppurativa

Other chapters in this text have covered the more common anorectal conditions. A group of less common but still important conditions are discussed here. This summary of the disease process, evaluation, and management will prepare the provider to manage patients with these conditions.

STRICTURE

Nonmalignant stricture or stenosis of the anal canal is an uncommon but potentially debilitating condition. Patients with this condition have anal pain, obstipation, and frequent bleeding. The scarred anal canal may also be sufficiently noncompliant to cause incontinence. Anal stenosis is most commonly (87%) caused by excessive excision of the anoderm during hemorrhoidectomy.[1] An improperly performed hemorrhoidectomy may also produce an ectropion (rectal mucosa in the distal anal canal), also referred to as a *Whitehead deformity*. Other causes of anal stenosis include recurrent anal fissure; chronic diarrhea; recurrent abscess and fistula requiring surgical treatment; anal Crohn's disease; radiation; and excision of perianal skin lesions as in Paget's or Bowen's disease.[1,2]

The treatment of anal stenosis depends on its severity and position in the anal canal. High anal strictures that are covered entirely by mucosa are more difficult to treat than the low anal strictures at the level of the anoderm. Mild anal stenosis responds to more conservative therapy, whereas severe anal stenosis may require more extensive surgical procedures.

Medical Therapy

Medical therapy for anal stenosis combines bulking of the stool with dilation in the office or at home using the finger or calibrated rubber dilators and topical anesthetics. Dilation is an ideal treatment for patients with Crohn's disease or high-risk patients with otherwise weakened external sphincters.[3]

The combination of repeated dilation and steroid suppositories may prevent early recurrence of the stenosis, but no well-controlled trials have been reported. Anal stenosis in elderly patients has been shown to cause megarectum. These patients are usually nursing home residents who require daily enemas for constipation.

Surgical Therapy

The surgical treatment of anal stenosis includes lateral internal sphincterotomy, any one of a number of flaps, and occasionally a colostomy. Anal strictures may be associated with an *ectropion* (a distal protrusion of mucosa onto the anoderm as the scarring tissue retracts toward the perineum). A lateral internal sphincterotomy has been suggested as a means of treating anal stenosis that is mild and low in the anal canal. Although the results have been adequate, sphincterotomy does not treat the ectropion or add additional tissue to enlarge the anal canal.

Several varieties of flaps have been used to manage anal stenosis. Some, as described later, also address the problem of the ectropion. The flaps are formed with

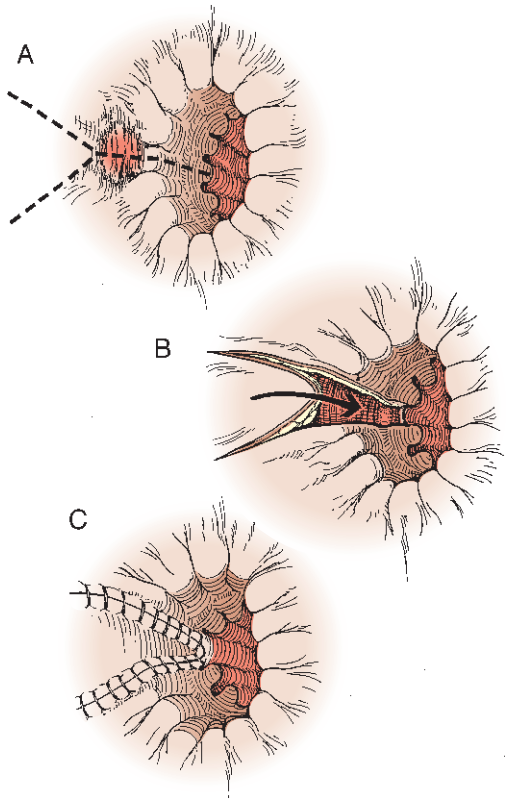

Figure 150–1. Y-V advancement flap. **A,**Y-flap inscribed outside ectropion and stenosis. **B,** Ectropion excised, Y-flap incised. **C,** Flap sutured with V closure. (**A-C,** From Fleshman JW: Fissure-in-ano and anal stenosis. In Beck DE, Wexner SD [eds]: Fundamentals of Anorectal Surgery, 2nd ed. London, WB Saunders, 1998, pp 209-224.)

V-Y advancement flap. **A,** Lateral inverted-V inscribed over ectropion or mucosal defect. **B,** Flap mobilized to preserve vasculature after stenosis is divided or ectropion is excised. **C,** Flap sutured in place with Y closure. (**A-C,** From Fleshman JW: Fissure-in-ano and anal stenosis. In Beck DE, Wexner SD [eds]: Fundamentals of Anorectal Surgery, 2nd ed. London, WB Saunders, 1998, pp 209-224.)

either mucosa or skin and include advancement, island, or rotational flaps.

Advancement Flaps

Advancement flaps advance mucosa or skin supported by muscle or subcutaneous fat.

The blood supply for this tissue comes from the adjacent intact lateral or inferior tissue. The *mucosal advancement flap* (Martin anoplasty) advances a pedicle of mucosa into the anal canal by way of an incision made through the stenotic area.[4] This posterior or lateral flap results in a mucosal ectropion that prevents repeat stricturing. This technique is simple and safe but creates an ectropion with associated mucous discharge. This type of flap is best used for proximal anal canal stenosis.

A *Y-V advancement flap* moves perianal skin into the distal anal canal.[1] The vertical limb of the Y is inscribed on the anal canal at the level of the stenosis, and the V of the Y is drawn on the lateral perianal skin (Fig. 150–1). The skin is incised, and the V-shaped flap of skin is freed laterally. The blood supply of the flap comes from the adjacent or underlying subcutaneous tissue. The V is then introduced into the stenotic anal canal to close the wound as a V-shaped incision. This can be used unilaterally or bilaterally with good results. Because the V is still attached to the buttock skin, the flap will not remain within the anal canal if the tension is too great and stenosis will recur.

Island Flaps

An island flap differs from advancement flaps in a division of all adjacent mucocutaneous edges. The blood supply is derived solely from the inferior supporting tissue. The increased mobility of these flaps makes them especially useful to treat anal stenosis.[4] Following incision of the stenotic scar at the dentate line a flap is created. The *V-Y flap* advances a triangular or V-shaped portion of skin into the anal canal. The V is drawn with the wide base at the dentate line and incised through the skin (Fig. 150–2). The subcutaneous attachments in the lateral edges of the V are released to allow mobilization of the skin into the anal canal. The blood supply to the flap relies on perforating vessels in the subcutaneous fat. The skin is then closed behind the V at the external

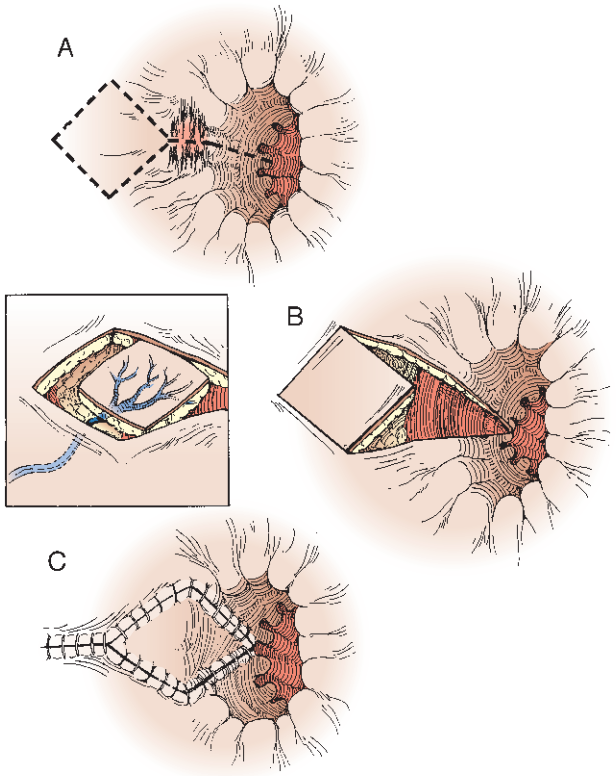

Figure 150–3. Diamond island flap. **A,** Stenosis incised in lateral midline and diamond inscribed laterally to match defect. **B,** Diamond flap incised and advanced into anal canal. **C,** Flap secured with wide point at stenosis line. (**A-C,** From Fleshman JW: Fissure-in-ano and anal stenosis. In Beck DE, Wexner SD [eds]: Fundamentals of Anorectal Surgery, 2nd ed. London, WB Saunders, 1998, pp 209-224.)

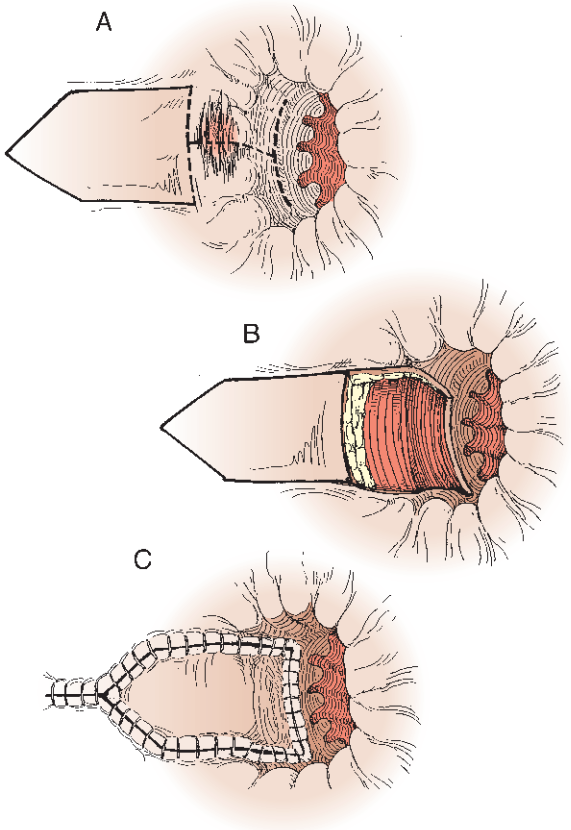

Figure 150–4. House advancement flap. **A,** House-shaped flap is created. **B,** The flap is advanced into the anal canal. **C,** The flap is sutured in place. (**A-C,** From Fleshman JW: Fissure-in-ano and anal stenosis. In Beck DE, Wexner SD [eds]: Fundamentals of Anorectal Surgery, 2nd ed. London, WB Saunders, 1998, pp 209-224.)

portion of the perineum to push the V into the anal canal and widen the stenotic area. This method may be used for the treatment of ectropion or low stenosis. However, the flap does not advance a wide portion of skin into the scar. The benefit obtained with this flap is derived from soft pliable tissue inserted into the nonpliable scar. If more tissue is needed to allow the canal to dilate, this technique may be repeated on the opposite side of the anal canal.

A *diamond-shaped island* of skin from the lateral perineum is inscribed to match the defect in the anal canal made by this incision (Fig. 150–3). The flap is then mobilized from its lateral subcutaneous attachments and advanced into the incision made in the stenotic anal canal. This flap of skin opens the stenosis widely when the lateral corners of the diamond are sutured at the level of the stenosis. This flap allows advancement of maximal skin to the point of stenosis with minimal tension. A *U-shaped flap* as described by Pearl and associates[5] is especially useful for patients with Whitehead deformity and ectropion. The U is a broader-based version of the V-Y flap but allows the ectropion to be excised across a wide base and the inverted U to be advanced into the anal canal to fill the defect.

Christensen et al.[6] proposed the "house" advancement pedicle flap. This flap is easy to construct, can cover as much as 25% of the anal circumference, and permits primary closure of the donor site (Fig. 150–4). This type of flap is the most frequent type used by the author. If additional coverage is needed, two, three, or even four flaps may be used.

Rotational Flaps

The S-plasty is a rotational flap that is used to provide a wide area of skin to cover a perineum that is entirely excised for disease such as Bowen's or Paget's disease. It does not open a stricture as well as the previously described advancement flaps. The base of the S is drawn on the lateral buttock, and the necessary tissue is excised (Fig. 150–5). The skin and subcutaneous tissue in the S are rotated down to the mucosal incision and sutured in place. The opposite curve of the S is treated similarly on the other side of the anal canal. This shape provides for adequate blood supply and avoids tension; unilateral or bilateral S-flaps can be performed.

Advancement, rotational, or island flaps can be fashioned using local or regional anesthesia. Each type of

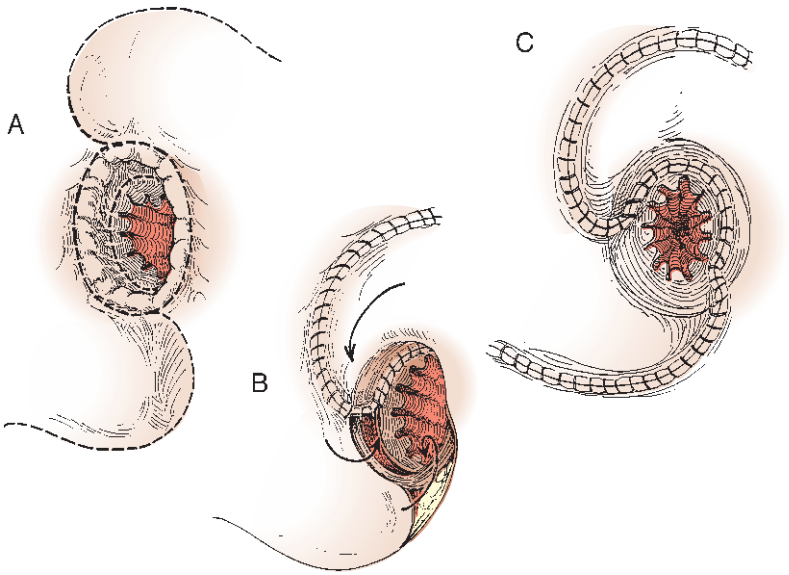

Figure 150–5. S-plasty. **A,** Perianal skin lesion requiring removal of large skin area. **B,** Area of perianal skin excised, with lateral curves incised onto buttocks. **C,** Curves of skin advanced into perianal defect and secured laterally to produce S-shaped closure of rotated flaps. (**A-C,** From Fleshman JW: Fissure-in-ano and anal stenosis. In Beck DE, Wexner SD [eds]: Fundamentals of Anorectal Surgery, 2nd ed. London, WB Saunders, 1998, pp 209-224.)

flap has advantages, and proper selection produces good results. Surgeons should therefore be experienced in all types, allowing individualized treatment. Rotation and advancement flap techniques require more mobilization of tissue, more suture lines, and a complete bowel preparation. Flap anoplasty techniques are reserved for the most severe problems after conservative measures have failed. Complications of anoplasty include infection, failure of the anoplasty to correct the stenosis, and slough of the flap. These can usually be avoided with adequate preparation and adherence to good technique. In certain settings, a diverting stoma may be considered.

Patients with strictures secondary to Crohn's disease, lymphogranuloma venereum, or syphilis usually respond best to repeated dilation.[3] Only rarely has anal stenosis secondary to inflammatory bowel disease been treated with anoplasty. The patients may require anoderm release incisions with repeated dilation. It is difficult to use anoplasty because the underlying disease process is continuous and may affect the healing.

PRURITUS ANI

Pruritus ani is a symptom complex that consists of an intense itch and burning discomfort of the perianal skin. It has a multiplicity of causes, several of which may coexist. It is frequently associated with varying degrees of skin breakdown, weeping, maceration, lichenification, and superinfection. Pruritus may be refractory until the specific cause is identified, but many symptoms can be successfully treated without determining a specific cause.[7]

History

A carefully taken history can often aid in identification of the cause of pruritus.[8] This history should include the onset of symptoms and their relationship to diet, medication, bowel evacuation, and anal hygiene practices. Pruritus may begin insidiously, with the patient complaining of the sensation of uneasiness or itching in the perianal region. As the area of involvement spreads and the intensity of itching increases, the patient reflexively begins scratching and clawing at the skin. This leads to further skin damage, excoriation, and potentially a secondary skin infection.

All medications should be identified because many can contribute to pruritus; special attention should be given to antibiotics, colchicine, quinidine, and topical medicines that contain corticosteroids, estrogens, or "-caine" drugs. Systemic illnesses, such as diabetes mellitus, chronic renal failure, or lymphoreticular diseases such as polycythemia vera or Hodgkin's disease, should be identified. The history should also elicit any symptoms of inflammatory bowel disease or acholic stools. Prior anorectal surgery may suggest deformed anorectal anatomy, which in turn can lead to poor continence. The physician should also document allergies or any generalized dermatoses such as psoriasis or seborrhea. A sexual history should include sexual orientation and specific practices, especially the practice of anal receptive intercourse. The immune status is also important, not only because of primary immunodeficient states or contracted states such as acquired immunodeficiency syndrome but also in transplant recipients who are receiving immunosuppressive medications. A careful gynecologic and obstetric history should be obtained from female patients and should include contraceptive practices and any history of inflammatory or ulcerative lesions. A history of difficult vaginal deliveries or perineal trauma should increase the suspicion for anatomic or functional sphincter compromise; manometry and rectal ultrasonography can be helpful in selected cases. A brief psychological profile may be beneficial to identify any association between symptoms and social or financial stresses with which the patient may be confronted.

Physical Examination

After completing a detailed medical history, the clinician should perform a meticulous physical examination. Initially, the general dermatologic evaluation may isolate conditions such as psoriasis, seborrheic dermatitis, or fungal or other infections. The patient should come to the examining suite without bowel preparation and with instructions not to have applied any creams or ointments to the perianal area. The examining room should be well stocked, with a bright light source and magnifying glass along with disposable enemas for bowel preparation and all clinical equipment necessary to obtain appropriate cultures, scrapings, or biopsy samples. After the patient is assisted into the prone jackknife position, the perianal region should be carefully inspected for signs of excessive moisture, soiling, excoriation, skin maceration (Fig. 150–6), or any perianal dermatoses. After giving instructions to the patient to strain (Valsalva maneuver), the clinician can evaluate the perianal region for possible prolapsing hemorrhoidal tissue. An initial digital examination should be performed without bowel preparation to evaluate the consistency of the stool. All abnormalities should be carefully documented, as should an assessment of the resting and squeeze sphincter strengths.

Next, the clinician can take any culture materials, biopsy samples, or scrapings that are thought necessary to make an appropriate clinical diagnosis. Suspicious skin lesions can be biopsied using a punch biopsy technique.[8] This technique involves the subdermal infiltration of a few milliliters of 1% lidocaine with epinephrine (1:200,000) under the biopsy site. A punch biopsy tool is driven into the area with a circular motion by swirling the punch between the thumb and index fingers. After the punch is 4 to 5 mm beneath the skin, it is gently raised and the resulting circular wedge of skin and subcutaneous tissue is excised with a fine scissors. Bleeding should be minimal, and simple pressure or treatment with a silver nitrate stick should adequately effect hemostasis. A simple gauze dressing or Band-Aid is all that is required. The punches are available in a number of sizes ranging in diameter from 1.0 mm to 1.0 cm. For convenience, I use disposable punches. Two disposable enemas should then be administered to the patient, after which a careful sigmoidoscopy and anoscopy are performed. Evaluation for hemorrhoids, polyps, cancer, fistula, mucosal prolapse, stenosis, or evidence of previous surgery is documented. Sigmoidoscopy may be helpful to identify proctitis, inflammatory bowel disease, rectal lesions, or active infections. Pruritus ani may be associated with colorectal neoplasms at a disproportionately high rate,[8] particularly when the symptom is chronic. The examiner should adhere to universal precautions when evaluating any patient and should decide on a case-by-case basis whether to perform pelvic examinations in women or to recommend pelvic examination performed by a gynecologist.

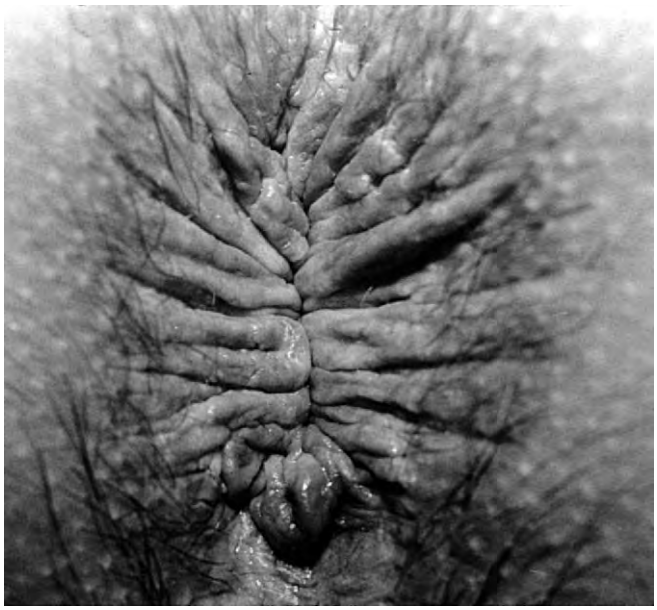

Figure 150–6. Pruritus ani. (From Hicks TC, Stamous MJ: Pruritus ani: Diagnosis and treatment. In Beck DE, Wexner SD [eds]: Fundamentals of Anorectal Surgery, 2nd ed. London, WB Saunders, 1998, p 199.)

Pathophysiology

The perianal skin is richly supplied with sensory nerve endings that mediate a variety of sensations.[9] These sensations may be elicited by local irritation from excoriation, alkaline secretions, and various chemical irritants. The receptor apparatus for both itch and pain is located at the dermo-epidermal junction of the skin and consists of a plexus of free nerve endings. Damage to cells in close proximity to these nerve endings causes a release of diffusible mediators that may stimulate the receptors. Slow-conducting neurons transmit the itch sensation to the lateral spinothalamic tracts through synapses that connect with secondary fibers and send the sensation to the thalamus. It is questionable whether tertiary neurons relay the itch sensation to the cortex. Greaves[9] pointed out that pain and itch are served by the same receptors and neural pathways, which explains the effectiveness of pain (scratching) in relieving itch.

Causes

The cause of pruritus ani is appropriately categorized under the headings of idiopathic and secondary types. The specific etiologic factors responsible for the diagnosis of secondary pruritus ani are nearly encyclopedic, yet despite comprehensive evaluations, in more than one half of patients with pruritus ani the cause is categorized as idiopathic. The major contributors to secondary pruritus ani are listed in Table 150–1.

Personal Hygiene

Clinicians have long been aware of the irritant effect of feces on the perianal area, especially in cases of prolonged contact. In patients with continued fecal contamination, the use of bulking agents and an appropriate

Table 150–1 Major Causes of Pruritus Ani

Cause	Examples
Personal hygiene	Poor cleansing habits resulting in chronic exposure to residual irritating feces; conversely, overmeticulous cleansing with excessive rubbing and soap use
Diet	Consumption of large volumes of liquids; coffee (caffeinated and decaffeinated, coffee-containing products), chocolate, citrus, spicy foods, tea, beer, and foods high in milk content; vitamin A and D deficiencies, fat substitutes
Anatomic compromise	Obesity, deep anal clefts, excessive hair, tight-fitting clothing (tight clothing or clothing that impairs adequate ventilation), fistula, fissure, skin tags, prolapsing papilla, or mucosal prolapse
Systemic disease	Jaundice, diabetes mellitus, chronic renal failure, iron deficiency, thyrotoxicosis, myxedema, Hodgkin's lymphoma, polycythemia vera
Gynecologic conditions	Pruritus vulvae, vaginal discharge (endocervicitis, vaginitis)
Neoplasms	Bowen's disease, extramammary Paget's disease, squamous cell carcinoma, cloacogenic carcinoma, anorectal polypoid lesions
Diarrheal states	Irritable bowel syndrome, Crohn's disease, chronic ulcerative colitis
Radiation	Postradiation changes
Psychogenic	Anxiety, neuroses, psychoses
Drugs	Quinidine, colchicine, antibiotics (tetracycline), intravenous hydrocortisone phosphate, ointments or creams that contain "-caine" drugs, and nonprescription medications for personal hygiene (e.g., perfumed soaps and ointments that may contain alcohol, witch hazel, or other astringents)
Dermatologic conditions	Psoriasis, seborrheic dermatitis, atropic dermatitis, lichen simplex and lichen sclerosis
Infections	Viruses: herpes simplex, cytomegalovirus, papillomavirus Bacteria: *Staphylococcus aureus,* erythrasma, mixed infections, syphilis Fungi: dermatophytosis, candidiasis Parasites: pinworms, scabies, pediculosis
Idiopathic	—

cleansing regimen often alleviates symptoms. Another group of patients, known as the "overachiever group," have pruritus secondary to their personal hygiene practice of compulsively cleaning the perianal area. Their meticulous cleansing is usually associated with abrasive rubbing and the use of irritating alkaline soaps, which can result in chronic pruritus. Physicians have categorized this maneuver as the "polishing the anus syndrome." Symptoms often resolve immediately once patients adopt a less traumatic perianal hygiene program.

Anatomic Compromise

An estimated 25% of patients with pruritus ani have causative or contributory anorectal disorders.[10] Lesions such as anal fistula, fissure, skin tags, prolapsing anal papillae, or mucosal prolapse may lead to the seepage of fluid from the anal canal onto the perianal skin, which in turn leads to inflammation, ulcerations, and, if infected, suppuration. Surgical intervention to relieve pruritus has been reported to be successful in fewer than 15% to more than 80% of patients.[8] Thus, it becomes important for the clinician to be highly selective in choosing surgical candidates, preferably only after appropriate medical therapy has failed.

Obese patients are predisposed to pruritus because their anatomy produces a persistently moist environment that may lead to difficulties in achieving appropriate personal hygiene. Patients with weak sphincter tone may have mucosal prolapse or fecal contamination of the perianal area, leading to pruritus. Wearing tight clothing (tight jeans, underwear, and girdles) or clothing that does not allow proper ventilation also predisposes to this trapped moisture syndrome.

Systemic Diseases

On occasion, systemic diseases may lead to generalized itching; perhaps the best recognized of these disorders is jaundice. Cholestatic jaundice has been associated with oral contraceptives, testosterone, and chlorpromazine. The itching associated with jaundice has long been attributed to elevated bile salt levels in the skin and blood, but this theory has not been substantiated. However, the administration of cholestyramine or colestipol hydrochloride is often helpful in reducing itching in this group of patients.[9]

Chronic renal failure is the most common systemic illness that elicits pruritus. Clinical manifestations are thought to be present in more than 90% of patients receiving hemodialysis. The cause of the itching is unclear; ultraviolet B radiation is the most successful treatment.[9] Diabetes mellitus is often associated with vulvar and anogenital pruritus because of the frequent association of the disease with candidiasis. Pruritus can

also be associated with iron deficiency, anemia, thyrotoxicosis, myxedema, Hodgkin's disease, and polycythemia vera.[9]

Diet

Dietary factors may represent the most significant cause of secondary pruritus ani. Diet may incite symptoms through three major pathways. First, it affects the consistency of the stool, which in turn can lead to fecal soiling. Second, the components of the diet may lead to direct irritation secondary to their chemical composition. Third, if an excessive volume of liquid is consumed, it could directly lead to more watery stools and pruritus as a result of frequent contact irritation. Many food groups, such as coffee (caffeinated and decaffeinated), chocolate, citrus, spicy foods, tea, beer, and foods with a high milk content, have been implicated in initiating or promoting symptoms. Patients with vitamins A and D deficiencies are also believed to be predisposed to pruritus ani.[8]

Most patients with diet-induced pruritus ani can relate the onset of their symptoms to the ingestion of coffee or dairy products. Coffee is an irritant that can elicit pruritus when it is ingested in any form (fresh, instant, decaffeinated, or when used as a flavor additive to other foods, such as ice cream). An apparent threshold for coffee drinkers usually varies between 2 and 4 cups per day. A similar threshold, noted in milk-drinking patients, arises at the ingestion of 6 to 10 oz daily.[11] Pruritus caused by chocolate, tea, and cola is believed to be related to the xanthine content of these substances. Olestra, a fat substitute, may result in pruritus ani secondary to fecal seepage induced by the nonabsorbed, oily food additive. The appearance of diet-induced pruritus is often symmetrical.[11]

Gynecologic Conditions

Pruritus ani often can be attributed specifically to diseases of gynecologic origin. Pruritus vulvae may extend posteriorly to involve the anal skin and can often be attributed to vaginal discharge or urinary incontinence. Irritation secondary to vaginal discharge may also lead to pruritus as the result of endocervicitis, trichomonal vaginitis, or candidal vaginitis, which cause a leukorrhea that irritates the perianal skin. Physicians should be prepared to perform pelvic examinations and to obtain appropriate cultures and stains in this subset of patients. Pruritus ani can be reported in women during menopause independent of any identifiable local causes, probably secondary to estrogen deficiency.

Neoplasms

Neoplasms of the perianal region can be responsible for pruritus ani. The clinician must be cognizant of these potential causes and should exclude them by performing a careful physical examination and biopsy if necessary. Polypoid tumors of the anorectum may lead to soiling, which may be secondary to changes in the normal anatomy or mucous secretions, as seen in the case of villous lesions. Bowen's disease is a unique form of squamous cell carcinoma in situ. The disease can present as pruritus or may be found incidentally in an anorectal surgical specimen. The lesion is characteristically an erythematous, hyperkeratotic plaque sharply demarcated from the surrounding skin. The size of the lesions ranges from a few millimeters to several centimeters. Because these lesions remain stable in size for long periods, they are often clinically overlooked or may be mistaken for psoriasis. If these lesions become pigmented, they can be confused with superficially spreading melanoma. Small lesions may be treated successfully with topical 5-fluorouracil, but generous local excision with an adequate margin remains the preferred therapy.[8]

Extramammary Paget's disease is an intraepidermal adenocarcinoma. Although the cell type of this lesion is still undefined, it is believed to be a pluripotential epithelial cell that borders on differentiation into sweat gland tissue. The lesions are usually red, indurated, scaling plaques often confused with eczema.[8] The treatment for the noninvasive lesion is wide local excision.

Squamous cell carcinoma of the perianal region may also present as pruritus. The lesion is usually a nodular plaque with a warty appearance often confused with condyloma acuminatum. The clinician must be cognizant of the lesion's metastatic potential and should know its pattern of nodal spread, although wide local excision is usually sufficient curative therapy. Basal cell carcinomas are rare tumors of the anorectal area. The characteristic appearance is similar to that found elsewhere on the body. This nodular growth, with its classic central depression, is usually treated by wide local excision. More radical surgery may be necessary for invasive or neglected tumors. In situ squamous carcinomas and cloacogenic carcinomas of the perianal region are being seen in increasing numbers in immunodeficient patients and male homosexuals.[12] It is imperative that the clinician take a biopsy sample of any suspicious or nonresponding lesions of the perianal region.

Anorectal melanoma, a rare tumor of ectodermal origin, is the most devastating perianal tumor. Regardless of the lesion's size, most anorectal melanomas have metastasized by the time of diagnosis. Unfortunately, these tumors usually do not respond to radiation or chemotherapy, and heroic efforts such as abdominoperineal resection yield only a 5% to 10% 5-year survival rate. Because of these dismal survival statistics, palliative therapy is often the treatment plan.

Diarrheal States

Clinical and experimental data have shown that skin trauma secondary to moisture is one of the primary contributors to pruritus ani. Such moisture is seen not only in patients with colitis (Crohn's, ulcerative, or nonspecific) but also in patients who abuse laxatives or who ingest an excessively high-fiber diet. Patients with dumping or malabsorption syndromes, such as lactose intolerance, are also predisposed to pruritus. In the diarrheal patient, not only is the stool a direct skin irritant but also the frequent hygiene it necessitates leads to abrasive trauma.

Radiation

Patients with rectal or anal canal cancers are often treated with a combination of chemotherapy and radiation. Radiation to the skin causes alterations in the normal cell cycle that induce erythema and edema, which may progress to sclerosis and fibrosis. If the injury progresses, a full-thickness radiation burn will lead to ulcerations. Patients complain of pain, burning, and itching due to perianal skin injury. In addition, radiation proctitis leads to diarrhea, which further exacerbates local perianal skin irritation. Radiation proctitis can be managed with dietary measures and bulking agents or a trial of hydrocortisone retention enemas. Radiation dermatitis is difficult to treat; initially, the physician should closely inspect the anoderm and take a biopsy sample of all suspicious areas. Controlling pruritus is often difficult; treatment should include cleansing the anoderm with a mild emollient soap substitute such as Balneol and water. If these simple maneuvers fail to control symptoms, a short trial of topical hydrocortisone (1% to 2.5%) may be helpful.

Psychological Factors

The clinician should not underestimate the significance that psychological factors play in the cause of pruritus ani. Often, the patient with pruritus can relate its onset to anxiety. The "stress years" of midlife produce the largest patient population that complains of pruritus ani, perhaps suggesting more than a casual relationship with other etiologic factors.

Drugs

Several oral medications have been implicated in eliciting pruritus ani through both contact irritation and increased leakage of fecal material from the anal opening. Quinidine and colchicine can initiate the acute onset of pruritus, although these medications may have been taken in consistent dosages for years. Pruritus is usually controlled when the medication is temporarily stopped, which may be related to a threshold phenomenon. Mineral oil (taken orally) has also been detected as an offending agent; in this instance, pruritus is believed to be secondary to the pasty stool that develops and the associated perianal seepage. The ingestion of tetracycline also may cause pruritus by irritating the gut, which leads to a loose stool. In addition, tetracycline facilitates the occurrence of secondary perianal candidal infections. The intravenous administration of hydrocortisone phosphate has also been shown to produce pruritus ani. The application of certain topical ointments, creams, or cleansing agents may also elicit pruritus. Preparations containing the "-caines" are notorious for producing intense inflammation in some susceptible patients. Many over-the-counter hygiene products, such as scented soaps, deodorants, colored toilet tissues, and laundry detergents, contain chemicals that may cause increased skin sensitivity and irritation. These chemicals include formaldehyde, alcohol, perfumes, and astringents that elicit symptomatology by depriving the skin of its natural acidity. The increased use of anal wipes that are alcohol based or that contain witch hazel may lead to excoriation if used frequently or if left in contact with the skin for a prolonged period. Because of this, many of the new personal cleansing tissues are free of alcohol and witch hazel. Patients must be assisted in their selection of appropriate nonirritating, atraumatic perianal cleansing products.

Dermatologic Conditions

A large proportion of cases of pruritus ani may be attributable to nonmalignant dermatologic lesions. *Perianal psoriasis* may be a cause of refractory pruritus ani. The clinician should carefully inspect the patient for the presence of characteristic psoriatic patches elsewhere on the body, such as the scalp, knees, elbows, or other bony prominences. A perianal lesion may be the first or the only psoriatic lesion and is usually found in the gluteal cleft spreading toward the sacrum. Although a perianal psoriatic lesion has a definitive border, it does not have the scaling of systemic psoriatic plaques. A multitude of treatment modalities exist for psoriasis, including local lubrication to prevent fissuring and to maintain flexibility of the skin, topical corticosteroids, coal tar applications, phototherapy (ultraviolet A light used in conjunction with the photosensitizing properties of psoralen compounds [PUVA]), methotrexate, and low-dose cyclosporine.[8]

Seborrheic dermatitis may also be a factor in perianal pruritus, and *contact dermatitis* may be allergic or irritant in nature. *Allergic dermatitis* is the result of a cell-mediated immune response to a specific exogenous allergen, which may be the chemical component of a plant or an animal, a fabric, or a medicinal product. The most frequent offenders are poison ivy, poison oak, nickel, rubber (latex) compounds, procaine, neomycin, and the topical anesthetics of the "-caine" family. The lesions from contact dermatitis may vary from vesicles to eczematoid plaques with ill-defined borders. Dermatologic skin testing can often identify the offending agent. Treatment is aimed at prevention of allergen exposure supplemented by topical or systemic steroids if a reaction occurs. Nonallergenic contact dermatitis, or irritant dermatitis, is caused by exposure to such substances as acids, alkalis, the salts of metals, and hydrocarbons. The treatment is avoidance of exposure to these irritants and symptomatic measures on occasions when such exposure leads to dermatitis. All soaps, laundry detergents, and fabrics should be inventoried to detect any temporal relation between the onset of pruritus and the acquisition of new clothing, soap, toilet tissue, or laundry detergent.

Lichen sclerosis et atrophicus is a rare condition most commonly referred to as *lichen sclerosis*. Its cause is unknown, and it affects women in a ratio of 5:1 over men. In women, the disease often presents around the time of menopause and in many cases is associated with a previous episode of vaginitis. The lesions are elevated, ivory white, and macular. When several lesions coalesce, they form a "cigarette-paper crinkling" of the skin surface. There is no cure for the disease, and treatment is

symptomatic, involving the use of topical steroidal creams in conjunction with estrogen-containing creams.[8]

Atopic eczema is a chronic, relapsing pruritic dermatitis that usually occurs in adults and is localized to the flexural surfaces of the face, neck, cubital or popliteal fossa, and hands. The dermatitis usually occurs in patients with a personal or family history of atopy or hay fever/asthma/urticaria; lesions may present as papular, scaly, or chronic lichenified plaques. The cause is unknown but is believed to be IgE mediated.[8] Some researchers support food allergies and proteinaceous aeroallergens as possible causes. Patients with atopic dermatitis are likely to acquire both bacterial and viral infections. Treatment is directed at skin hydration, corticosteroid administration, and antibiotics if secondary infections are present. Unfortunately, eczema is a chronic disease and relapses are common.

Infections

Infectious agents must be considered in the differential diagnosis of secondary pruritus ani. The etiologic agents may be bacterial, viral, mycotic, or parasitic. Primary bacterial infections are an unusual occurrence, and when infectious agents can be documented, they are usually superimposed on preexisting perianal skin trauma. Pruritus secondary to infectious agents often has an asymmetrical appearance around the anus.[11]

Bacteria *Hidradenitis suppurativa* (HS), as described later, may cause pruritus. *Staphylococcus aureus* can frequently be cultured from the perianal area of patients with pruritus. *Erythrasma* is an uncommon bacterial infection caused by *Corynebacterium minutissimum,*[8] producing lesions that initially present as a reddish scaly area that is well demarcated but eventually change to a tannish color during the course of the disease. The diagnosis can be confirmed by using a Wood's ultraviolet lamp, which allows the examiner to observe the characteristic red fluorescence of these lesions. A 10-day course of erythromycin usually relieves the symptoms, but the condition sometimes recurs. *Syphilitic lesions* in their primary or secondary stages may have an associated exudate. Continued local irritation secondary to moisture may lead to maceration and pruritic complaints.

Viruses Pruritus ani may be associated with three major sexually transmitted viruses: herpes simplex virus (anogenital herpes), papillomavirus (condyloma acuminatum), and cytomegalovirus (CMV). Patients with *herpes simplex virus* present with painful small vesicles surrounded by an erythematous areola. The vesicles usually rupture at approximately 48 hours and then progress over weeks to scaly eschars; the diagnosis can be confirmed by viral culture. Oral acyclovir is the current treatment of choice; studies have indicated that the prophylactic use of this medication is successful for frequent recurrences.[8] *Condylomata acuminata* are wart-like lesions found in the perianal region and the anal canal. The clinician should remember that the main reason for recurrence of these lesions is failure to eradicate anal canal lesions. Patients with *immunodeficiency states* are likely to develop CMV anal ulcerations or CMV colitis. Biopsy of these lesions can confirm the diagnosis. Unfortunately, these organisms are notoriously resistant to antiviral therapy.

Mycotics Mycotic organisms such as *Epidermophyton, Trichophyton,* and *Candida* can produce pruritus. Candidiasis of the perianal region as a primary source of pruritus is rare, identified in fewer than 1% of random skin scrapings.[8] These lesions are usually erythematous with classic well-defined borders and are usually either secondary to the overgrowth of mycotic organisms after the use of antibiotics or topical corticosteroids or associated with vaginal infections. Mycotic etiology can be confirmed by microscopic inspection or select cultures.

Parasites Parasitic infection should always be included in the differential diagnosis of patients with perianal pruritus. *Pinworms (Enterobius vermicularis)* are the most common cause of perianal itching in children. The diagnosis can be made by microscopically evaluating perianal skin samples collected on cellulose tape. It is imperative that other family members be evaluated so they can be treated and recontamination does not occur. The symptoms usually occur in the evening, when these 6-mm-long parasites migrate to the perianal skin. *Scabies,* a contagious skin infestation due to the mite *Sarcoptes scabiei,* can elicit severe pruritus. Although usually found on the finger webs or sides of the fingers, these lesions can often be identified in the perianal region. The diagnosis of scabies can be confirmed by demonstrating the mite or its products, such as ova or feces, from scrapings prepared on a slide with one drop of 10% potassium hydroxide. Lesions appear initially as vesicles as the mite burrows its way into the stratum corneum. Treatment consists of the application of an appropriate scabicide such as Kwell lotion. The parasite *Pediculosis pubis* (crab or louse) can often be found grasping the base of a hair shaft and is noted to produce macular steel-gray spots, especially on the thighs and chest. With careful examination under magnification, this parasite strikingly resembles a crab. Management requires the treatment of all infected family members; appropriate delousing of all fomites such as clothes, bedding, and upholstery; and showering with an appropriate pediculicide such as permethrin.[8]

Treatment

Once the clinician has acquired a comprehensive history, performed a thorough examination, and obtained appropriate culture samples, scrapings, and biopsy samples, the primary cause for pruritus ani may be identified and appropriate therapy instituted. Treatment may include the following:

- Conservative dietary changes to identify offending agents or their symptomatic thresholds
- Appropriate medical therapy for infections, dermatoses, or systemic disorders
- Surgical intervention for the few anatomic deformities that contribute to pruritus

- Nonspecific therapy for most cases of pruritus with no identifiable etiology

Treating idiopathic pruritus requires a focused therapeutic approach, which includes clear instructions tempered with realistic expectations for a response and a consistent follow-up pattern. Instruction should begin with appropriate perianal hygiene. These initial efforts are directed toward keeping the perianal skin dry, clean, and slightly acidic. Any nonessential antibiotics should be discontinued, as should other irritants to the perianal area such as harsh toilet paper, soaps, and any personal hygiene products being applied to the area. The use of any topical steroid agents also should be discontinued initially because of harmful thinning of the perianal skin. Trauma incurred by scratching must be stopped, and for patients with severe symptoms, wearing white cotton gloves at bedtime may be necessary. An alternative to harsh toilet paper is small nonalcoholic towelettes, with appropriate drying of the perianal region with either a soft towel or a hair dryer. Substitute soap preparations such as Balneol are useful and can be applied with the fingertips or moist cotton balls. During the day and at bedtime, it may be helpful to apply a thin cotton pledget directly into the anal crease. The pledget should be small enough that the patient is not conscious of its presence. Dusting the pledget with baby powder (nonperfumed) or cornstarch may improve moisture control.

The patient should also be counseled on dietary changes. As mentioned earlier, food products such as coffee, teas, cola, chocolate, beer, and tomatoes have been identified as offending agents, but there appears to be a threshold at which these products elicit pruritus. For this reason, the patient should discontinue ingestion of these items and then slowly reinstate them into the diet in an attempt to isolate the offending agent. Once the offending agent, such as coffee, is identified, it may be possible to find the patient's threshold so that total abstinence from the product is unnecessary. Any habit-forming cathartics should be discontinued, and a bulking agent should be taken instead to keep the stool soft, large, and nonirritating. The psyllium decreases trauma to the anal canal and helps maintain better perianal hygiene.

For continued uncontrolled leakage, rectal irrigation performed with a 4-oz bulb syringe and warm water is an acceptable adjunct.[8] Daily sitz baths in warm water may also be helpful, but no chemicals should be added. In the unfortunate patient who has intractable pruritus ani, many therapies have been tried, including injection of alcohol- or oil-soluble anesthetics, injection of methylene blue, tattooing of the perianal skin with mercuric sulfide, surgical undercutting, and radiation therapy, most of which have had unacceptable results.[8] These procedures have been associated with complications such as skin necrosis, local sepsis, and sloughing of the perianal skin. The use of sedation, tranquilizers, and biofeedback by well-trained practitioners may demonstrate some clinical benefit. Regardless of the treatment or initial success, intermittent recurrences of the disease are common. The patient should be instructed not to become despondent but to reconsult the physician so that the appropriate therapeutic corrections can be made. If symptoms continue despite aggressive therapy and if appropriate changes in therapy fail to give relief, a second opinion from a dermatologist, gynecologist, or internist should be considered.

PAIN SYNDROMES

Pain syndromes of the pelvic, rectal, and perianal region are referred to by a variety of names: *levator syndrome, levator spasm, proctalgia fugax, coccygodynia,* and *chronic idiopathic rectal pain*. These terms describe a "wastebasket" of pain syndromes that are localized to the rectal area. Each of these syndromes may describe a distinct entity or these pain syndromes may overlap.[13] Once organic causes have been excluded, the patient can present a therapeutic challenge.

Levator spasm is characterized by episodic pelvic or rectal pain caused by spasm in the levator ani muscles. Symptoms of this syndrome are variable and include complaints of pressure or discomfort and the feeling "like sitting on a ball." Left-sided involvement is more common, and the pain occasionally radiates into the gluteal region. The syndrome is more common in women and sometimes occurs after pelvic infections or surgery. The clinical finding in this group of patients is levator sling tenderness on transanal palpation.

Proctalgia fugax is described as brief and sometimes severe episodes of rectal pain similar to "having a knife inserted up the rectum." Patients are often awakened from sleep and have associated irritable bowel syndrome and constipation. The syndrome is more common in men, and there are no physical signs. It is theorized that the pain results from spasm of the rectal muscle wall. For the purpose of this discussion, proctalgia fugax is considered a variant of levator spasm.

Coccygodynia refers to a syndrome of rectal and perineal discomfort associated with coccygeal injury.[14] This is a rare cause of rectal pain. Tenderness is elicited by coccygeal motion in excess of that elicited by the levator muscle. True coccygodynia is a secondary condition of the coccyx and so is not a variant of this functional syndrome.

Multiple factors associated with these syndromes include irritable bowel syndrome, previous pelvic surgery, and disordered defecation syndromes. Occasionally, the rectal or pelvic pain does not match the classic descriptions, in which case it is labeled as *chronic idiopathic rectal pain*.

Evaluation of the patient with levator spasm, proctalgia fugax, and pelvic pain must include a methodical history and careful examination of the pelvic viscera to rule out an organic cause for the discomfort. Inspection, digital rectal examination, and sigmoidoscopy reveal most common anorectal pathology. Diagnostic imaging may be helpful and includes computed tomography (CT) scanning, magnetic resonance imaging (MRI), and endorectal ultrasonography to seek less obvious sources of rectal pain. The role for anorectal physiologic testing in these conditions is uncertain.[15] Finally, many patients with pelvic pain syndrome have a psychiatric illness.[16]

The following overview of the organic and functional perineal pain syndromes provides a framework for the evaluation and the results of treatments for this commonly encountered condition.

Anatomic Considerations

As previously stated, proctalgia fugax, levator spasm, and pelvic pain can involve overlapping presentations. Pain syndromes may involve any or all of the structures of the pelvis. Disorders of the following organs or organ systems can lead to the complaint of pelvic pain. A complete assessment should exclude each of these as potential causes. An integrated approach may be required and may necessitate orthopedic, neurosurgical, gynecologic, and urologic consultation.

Spine and Bony Pelvis

Primary and secondary diseases of the pelvic girdle and the lower axial skeleton may present as pelvic pain. Trauma, inflammatory conditions, or malignancy can affect these supporting structures. *Coccygodynia* refers to primary coccygeal injury that causes pain localized to the coccyx. Used in this specific fashion, the term denotes a coccyx that is tender to touch and movement.

Pelvic Musculature

The pelvic floor or pelvic diaphragm is composed of the levator ani muscles. The levator ani are striated muscles: the puborectalis, pubococcygeus, and iliococcygeus. Inferiorly, the external sphincter encircles both the anal canal and the internal sphincter. As is the case in all striated muscles, the levator ani are subject to sustained contractions that can produce local ischemia and pain. Most authors attribute the pain of levator spasm to spasm in this muscle group. The internal sphincter is smooth muscle and is located medial to the striated muscle of the external sphincter. Physiologic testing suggests hypertrophy of the internal anal sphincter as a possible cause of this pain syndrome.

Other Causes

Previous pelvic surgery can also produce pain in this region. Dissection of the pelvic floor during a low anterior resection of the rectum can produce mechanical trauma, which might result in pain in some patients, although the pain most likely is caused by an infection. Inflammatory conditions or malignancy of the prostate and seminal vesicles can be diagnosed in men by eliciting tenderness of these structures on digital rectal examination. In women, diseases of the vagina, uterus, fallopian tubes, or ovaries may present as pelvic pain. Careful inspection and bimanual examination of the female patient are critical to an accurate assessment of pelvic pain. Malignancy and inflammatory conditions of the lower alimentary tract may produce complaints of pain.

Nervous System

Any condition that affects the cauda equina, roots S2 through S4, and the pudendal nerve can cause pelvic pain. Degenerative disease of the spine, primary or metastatic disease of the spine, primary or metastatic tumors, cysts, and local trauma all must be considered. Other neurologic disease, such as multiple sclerosis or spastic neuropathy, can produce pain. Laxity of the pelvic floor may cause traction on the pelvic nerves, creating this type of pain syndrome. Specific physiologic testing, such as electromyography (EMG), anorectal manometry, and dynamic proctography, may be useful in the assessment of these conditions. Finally, psychiatric illness is frequently associated with the complaint of pelvic pain. When indicated, competent psychiatric evaluation may be illuminating.

Causes of Pelvic and Rectal Pain

Considering the number of anatomic structures, there are many disease processes that cause pelvic and rectal pain. In some patients, no actual disease process can be identified. Box 150–1 describes a classification system that provides the clinician with a systematic approach to the diagnosis and management of pelvic pain syndromes.

Organic: Inflammatory Diseases That Affect the Pelvis and Anorectum

Common anorectal disorders that present as perineal or pelvic pain readily lend themselves to diagnosis; these include abscesses (cryptoglandular, intramuscular), fistulas, Crohn's disease, and ulcerative proctitis. These conditions must be excluded as the source of pelvic pain.

In men, chronic or acute prostatitis may present as rectal or pelvic pain. Urinary symptoms are often present and should be elicited in questioning. Digital rectal examination in men should always include careful prostatic palpation to exclude these conditions. Transrectal ultrasound may be helpful to diagnose pelvic pain, revealing pathology of the male reproductive organs. In women, tubo-ovarian infections, ectopic pregnancy, endometritis, and endometriosis are potential sources of pelvic pain. Bimanual pelvic examination with speculum visualization of the cervix usually suffices to eliminate these concerns. Occasionally, ultrasonography or CT of the pelvic viscera is necessary to complete the evaluation.

Occasionally, complicated diverticular disease of the sigmoid colon or a pelvic appendicitis may present as pelvic pain. The history generally directs the clinician to a more specific gastrointestinal work-up. Contrast radiography, CT, and ultrasonography may assist in this determination.

Mechanical

Pelvirectal pain may be multifactorial. Causes include constipation or dyschezia, pudendal neuropathy, descending perineum syndrome, incomplete or internal rectal prolapse, rectal ulcer, and pelvic floor hernias.

Box 150–1 Classification of the Causes of Pelvic Pain

Organic

- Inflammatory diseases of the pelvis and anorectum
  - Cryptoglandular abscess
  - Fistula-in-ano
  - Crohn's disease
  - Ulcerative colitis
  - Radiation proctitis
  - Endometriosis
  - Infectious proctitis
  - Prostatitis
  - Tubo-ovarian abscess
  - Endometritis
  - Pelvic appendicitis
- Ectopic pregnancy

Mechanical

- Incomplete rectal prolapse
- Descending perineum syndrome
- Torsed ovary
- Fissure
- Pelvic surgery

Neoplastic

- Nonmalignant tumors
  - Nerve
  - Muscle
  - Bone
  - Endometrioma
- Malignant tumors: primary and recurrent
  - Rectum
  - Prostate
  - Ovary
  - Uterus
  - Bladder
  - Nerve
  - Muscle
  - Bone
  - Metastatic gastric

Neurologic

- Multiple sclerosis
- Peripheral neuritic/degenerative disease

Orthopedic

- Coccygeal trauma—coccygodynia
- Degenerative disease of the lumbosacral spine
- Osteogenic tumors

Functional/Idiopathic Causes

- Levator spasm/proctalgia fugax
- Depression
- Chronic idiopathic rectal pain

Other mechanical causes of pelvic and rectal pain are muscle spasm or inflammation of surrounding tissue. Anal fissures commonly cause perineal pain. Simple mechanical trauma due to straining can produce this condition. Pain of fissure can be exacerbated by an inflammatory response in internal sphincter spasm and secondary hypertrophy. Anorectal or pelvic surgery is a frequently associated factor in patients with this type of pelvic pain. The pain of pelvic surgery may be due to a perioperative inflammatory process, traumatic neuropathy, or fibrosis of the pelvic floor. After anorectal surgery, levator spasm and sphincter spasm frequently result in anorectal pain complaints. Fortunately, these complaints are often self-limited and resolve spontaneously in time.

Neoplastic

In a report by Oliver et al.,[17] 12 of 102 patients with the diagnosis of levator spasm were subsequently found to have organic causes of their rectal pain. Two patients had pelvic recurrence of visceral cancer, and 1 patient had prostate cancer. This highlights the importance of considering malignant recurrence in patients presenting with complaints of pelvic pain and a known history of previous malignancy.

Nonmalignant tumors rarely cause levator spasm. Symptoms are related to their mass effect on adjacent structures. Neurogenic benign tumors (rhabdomyomas and leiomyomas), cysts, and endometriosis should be sought when preliminary tests are suggestive or when an obvious cause is lacking. Endometriosis produces pain via its ectopic growth pattern and subsequent sclerotic tissue reaction. The cyclic nature of the pain and bleeding should alert the clinician to consider this diagnosis. Although endometriosis is common, it is uncommon as a cause of isolated pelvic pain.

Both primary and recurrent pelvic malignant tumors can cause pain by direct extension and by involvement of the sensory pathways in this region. Most commonly, advanced rectal, prostate, ovarian, uterine, or bladder cancer is the cause of malignant pelvic pain syndromes. Occasionally, pelvic metastases from gastric carcinoma produce this syndrome. Less commonly, malignant bone, muscle, or nerve tumors are the cause. The chronic, progressive, and persistent nature of pain due to malignant disease suggests its consideration in the evaluation of this complaint. A history of pelvic organ malignancy should

provoke a thorough search for recurrent disease in any patient who complains of pelvic or perineal pain.

Neurologic

Multiple sclerosis, peripheral neuritis, and degenerative conditions that affect the cauda equina may produce rectal pain. Degenerative disease of the lumbosacral spine not infrequently causes complaints of pain, although pain related to such disorders is more commonly noted in the buttock or thigh region. Radicular symptoms should prompt a search for a reversible neurologic process. Evaluation might necessitate CT, MRI, or EMG testing.

Orthopedic

The classic orthopedic condition associated with rectal pain is coccygodynia. Injury to the coccyx may result in degenerative joint disease, arachnoiditis, and/or secondary spasm of the muscles with insertion or origin on the coccyx. This diagnosis should be made only when direct manipulation of the coccyx results in painful complaints. Radiologic confirmation of coccygeal damage reinforces the diagnosis. Postacchini and Massobrio[18] argued that anatomic variations in coccygeal shape and configuration are responsible for a condition they term *idiopathic coccygodynia.* They advocate surgical coccygectomy, partial or complete, based on the radiologic configuration noted. Overall, the treatment of any form of coccygodynia by coccygectomy is a questionable practice. For all cases of coccygodynia not due to direct trauma, a thorough search for the precipitating cause will provide a rational approach to therapy.

Functional

Functional or idiopathic cases of rectal pain occur with disturbing frequency. A recent U.S. survey confirmed that between 8% and 19% of the population experience functional rectal pain.[19] This study also demonstrated a great deal of overlap in patients who experience functional gastrointestinal symptoms. Only 22.6% of patients with functional anorectal pain sought medical care. Although the syndrome of paroxysmal rectal pain is quite common, few patients will ever see a physician because of this complaint.

Evaluation

The evaluation of the patient with pelvic pain begins with a thorough history. This is followed by inspection, palpation, and local endoscopy, which are the first steps in excluding organic causes. On palpation of the levator ani muscle group, palpation of the right levator ani reproduces the patient's discomfort exactly. Diagnostic tests such as transrectal ultrasound, anorectal manometry, cinedefecography, and EMG all have been used in the assessment of the patient with levator spasm and its variants with varying results.[16] The problem seems to be in correlation of the findings with the symptoms.

CT scanning and MRI are useful to rule out mass lesions that may cause rectal pain. Transrectal ultrasonography further reveals tumors or abscesses of the anorectum. For patients in whom the specific pathology is elusive, however, specific anorectal physiologic testing has been performed to elucidate the cause of pain, but anorectal manometry, for example, has been found to have a low diagnostic yield for patients with levator spasm. There are studies, however, that report abnormalities in anal resting pressures in patients with rectal pain.[16]

Unlike manometry, EMG and nerve conduction study of the patient with rectal pain frequently show abnormalities. These abnormalities include paradoxical puborectalis contraction and prolonged pudendal nerve terminal motor latency on electrophysiologic testing. Unfortunately, these can also be found in patients with no symptoms.[16] Thus, it appears that this occurrence can be a cause of rectal pain in a subgroup of patients.

Cinedefecography can demonstrate dysfunction of pelvic floor musculature, although EMG is more sensitive for the diagnosis of paradoxical puborectalis contraction.[16] Cinedefecography can also show rectocele, increased perineal descent, and early rectovaginal intussusception. Because these radiologic findings can be detected in patients who are completely asymptomatic, some authors have questioned the clinical significance of these findings as far as providing clues for therapeutic intervention.

Despite the diagnostic tools available, the cause of levator spasm remains unknown or at least multifactorial. Most evidence points to actual spasm of the pelvic floor. The precise cause of the spasm is unknown, and most therapies are directed at relieving the spasm.

Treatment

When an organic cause of rectal pain is diagnosed, treatment is directed at that cause. For most patients, the cause of their discomfort remains unknown. First, these patients must be reassured that they do not have a malignancy. The next level of therapy is local massage. This entails massaging the levator sling with the examiner's index finger until the muscle feels relaxed. For patients with refractory symptoms, consideration may be given to adding a muscle relaxant or an oral analgesic. This treatment is combined with local heat provided by warm soaks in a tub, heating pads, or heat lamps.

In 1982, Sohn et al.[20] introduced electrogalvanic muscle stimulation (EGS) for the treatment of levator spasm. Low-frequency oscillating electrical current applied to a muscle induces fasciculation and fatigue. The success of EGS is quite variable in the literature.[16,21]

Biofeedback may also benefit patients with levator spasm. When conservative management fails to relieve severe pain, biofeedback, EGS, and other therapeutic alternatives are available but are investigational. Pharmacologic agents that relax smooth muscle such as β-adrenergic agonists and calcium channel blockers have been demonstrated to decrease the frequency and intensity of pain in some patients with proctalgia fugax.[16] The

results are preliminary, and more research is required to evaluate the effectiveness of these forms of therapy. Local anesthetic steroid mixtures block the nerves that may have contributed to the spasm of the muscle. Botulinum toxin type A injected into the levator muscle to cause local paralysis has also been used with some success; however, further research is needed before more patients can be offered this form of therapy for the treatment of levator spasm. Finally, short-wave diathermy (available through physicians who are interested in physical medicine and rehabilitation) is an excellent approach for patients with levator spasm.

Anxiety and depression are common in patients with levator spasm. Regardless of whether this psychiatric state is a coexisting, separate illness or secondary to the chronic painful state engendered by the most extreme forms of levator spasm, expert psychiatric help may be mandatory. The clinician who treats a patient with levator spasm must be alert to the more serious signs of psychiatric illness. With this in mind, it is ill advised to prescribe antianxiety agents or narcotic analgesics for long periods. Although most patients do well with a conservative regimen, the few with serious psychological problems will be helped only with an appropriate referral to receive competent psychiatric care. The management of patients with levator spasm is summarized in Box 150–2.

Box 150–2 Management of Levator Spasm and Its Variants

Evaluation of Underlying Cause

- History and physical examination
- Radiologic investigation where appropriate
- Physiologic testing when indicated by associated symptoms

Conservative Measures

- Local heat (tub soaks, diathermy)
- Stool softeners
- Short-term muscle relaxants, analgesics, antidepressants

Refractory Cases

- Levator massage
- Electrogalvanic stimulation
- Nerve blocks, steroid injection, local anesthetic, botulinum toxin type A injection (investigational)

SOLITARY RECTAL ULCER SYNDROME AND COLITIS CYSTICA PROFUNDA

Solitary rectal ulcer syndrome (SRUS) is an uncommon benign condition characterized by rectal bleeding, copious mucous discharge, anorectal pain, tenesmus, and feelings of obstructed defecation or incomplete evacuation that results in intense, prolonged straining to defecate. This straining to defecate results in trauma and possibly ischemic ulceration of the anterior rectal wall. Occasionally, the straining results in anterior mucosal prolapse, rectal intussusception, or rectal procidentia. SRUS has its peak incidence in the 20s and 30s, with the female predominance emerging after the age of 30.[22] These symptoms lead to numerous daily trips to the toilet, many of which produce nothing more than frustration. Self-digitation to facilitate evacuation is a not uncommon practice.

SRUS is actually a misnomer because in many patients, no ulceration is present and occasionally multiple ulcerations are evident. When present, the typical solitary rectal ulcer ranges from 1 to 5 cm in size and is located on the anterior rectal wall 5 to 8 cm from the anal verge. These traumatic ulcers can be distinguished from malignant ulceration because they are punched out and shallow with a gray-white base and have a surrounding zone of edema or hyperemia without a thickened margin. A biopsy is performed to rule out rectal cancer because an SRUS can mimic rectal cancer in appearance. Often, there is granularity, friability, and localized proctitis. In general, up to 70% of solitary rectal ulcer lesions are located in the anterior rectum.[23,24] Some patients exhibit circumferential ulceration, particularly those with associated rectal prolapse or internal intussusception. The ulceration can also present as a fungating polypoid mass or nodules or as an area of serpiginous ulceration with intervening pseudopolyps. These lesions are far more difficult to differentiate from carcinoma or inflammatory bowel disease, and a biopsy is almost always necessary.

Diagnosis

The diagnosis is almost invariably established by endoscopy and biopsy. This procedure also excludes benign and malignant neoplasms, localized areas of inflammatory bowel disease, radiation proctitis, and pseudomembranous colitis. Contrast enemas are occasionally useful in confirming other abnormalities, but the actual ulcer is identified in fewer than half.[25] A cinedefecogram is best used to document the presence of associated rectal intussusception and anterior rectal mucosal prolapse. It is occasionally necessary to document complete rectal prolapse in cases where the patient is unable to reproduce the prolapse in the office. The cinedefecogram can suggest the presence of nonrelaxing puborectalis syndrome if the anorectal angle remains acute during straining, but as was stated earlier, this finding can occur in asymptomatic subjects. Defecography can also demonstrate the extent of rectal emptying and perineal descent. The goal of physiologic studies of patients with SRUS has been to explain its cause and prominent symptoms of disordered evacuation. Paradoxical puborectalis and overt or internal rectal intussusception have been described. Internal intussusception is neither a necessary

Figure 150–7. Photomicrograph of colitis cystica profunda (Hematoxylin-eosin, ×100). (From Timmcke AE: Functional anorectal disorders. In Beck DE, Wexner SD [eds]: Fundamentals of Anorectal Surgery, 2nd ed. London, WB Saunders, 1998, pp 90-98.)

nor a sufficient condition for the development of SRUS, because patients can develop the syndrome without intussusception and not all patients with rectal intussusception develop SRUS. Despite these criticisms, it appears likely that in many cases, a causal relationship does exist between internal rectal intussusception and SRUS. Supporting this notion is the fact that surgical approaches designed to correct rectal intussusception are often beneficial in the treatment of the rectal ulceration.

The histologic features of solitary rectal ulcer and colitis cystica profunda are essentially the same and pathognomonic. Muscle fibers are seen streaming out into the lamina propria below and between glands (Fig. 150–7). There is thickening of the muscularis mucosae with intense fibrosis of the lamina propria. The epithelium is hyperplastic with a preponderance of sialomucins, as opposed to the usual sulfomucins. And most important, mucous glands are displaced deep within the submucosa and muscularis mucosae—hence, the name *colitis cystica profunda.* Rutter and Riddell[26] believed that the displaced glands represented the healing phase of a rectal ulcer. These displaced mucinous glands associated with ulceration make it imperative to differentiate this lesion from well-differentiated mucinous adenocarcinoma lest an unwarrantably radical operation be performed. Cellular atypia, multilayering of the cystic glandular mucosa, intraglandular budding, and papillation, as well as a desmoplastic host stromal response, are features characteristic of carcinoma.

Treatment

Medical management should be attempted in all cases except for those patients with complete full-thickness rectal prolapse. Such treatment consists primarily of avoidance of straining and the use of bulk agents, stimulating suppositories, and enemas or laxatives to retrain the patient to achieve a regular bowel habit. With this approach, as many as 70% of patients were improved and showed healing of the ulcer.[27] Those patients with concomitant nonrelaxing puborectalis syndrome may benefit from biofeedback, as discussed earlier.

Local excision of the rectal ulcer is not recommended because this procedure does not address the responsible pathophysiology and because the lesions tend to recur. Surgery should be considered only in those patients refractory to persistent attempts at medical management. Surgery that is attempted to correct the results of a behavioral disorder is seldom successful, as evidenced by the large number of surgical procedures that have been used to treat SRUS (e.g., local excision, DeLorme procedure, Gant-Miwa procedure, and excision of anterior rectal mucosal prolapse).[28] A DeLorme procedure can be difficult to perform secondary to fibrosis. Furthermore, any surgery performed for rectoanal intussusception is fraught with the potential for resolution of the anatomic problem without any symptomatic improvement. Abdominal rectopexy and anterior resection have been successful in the treatment of patients with concomitant complete rectal prolapse, and these procedures have also had some success in treating patients with rectal intussusception and anterior mucosal prolapse.[23,29]

HIDRADENITIS SUPPURATIVA

HS is a chronic and often debilitating inflammatory disorder of the skin that involves apocrine gland–bearing tissue, notably in the axilla, groin, perineum, and perianal regions. The disease usually exhibits a chronic course marked by recurrent suppurative events that result in chronic draining wounds. Recurrence after surgical treatment is common and reflects the aggressive nature of the disease.[30]

Pathophysiology

Fundamentally, HS occurs secondary to a mechanical plugging or obstruction of the apocrine gland unit with keratotic debris, which leads to infection in the gland. Glandular obstruction leads to apocrine sweat retention, followed by suppuration secondary to bacterial proliferation. As the gland ruptures into the surrounding subcutaneous tissues, multiple small epithelial tracks develop. Ultimately, these tracks emerge on the epidermis as tiny pits. Left untreated, apocrine infections and

the associated inflammatory responses result in thickening and fibrosis of the involved skin. In support of this proposed pathogenesis, HS has been experimentally induced by the application of occlusive tape to apocrine gland–bearing areas.[31]

HS presents clinically in a distribution strictly related to the distribution of apocrine glands in the inguinal, axillary, and perianal regions. Because apocrine glands typically become activated with the onset of puberty, HS usually presents after puberty, with the highest incidence in the teens, 20s, and 30s.[32] Although HS most commonly occurs in the axillary region, the second most frequently affected area is the perianal region. Approximately 16% of all patients with HS have perianal involvement.[24] Overall, HS is more common in women and blacks; however, perianal HS has been reported to be twice as common in men than in women.[33]

The exact cause of HS remains unknown.[34] Histologic studies have not convincingly demonstrated significant differences in apocrine gland size or density between normal control subjects and patients with HS.[35] Because anatomic glandular differences do not account for susceptibility to HS, presumably HS occurs in patients with an increased propensity to apocrine duct occlusion. Factors predisposing to duct occlusion that have been implicated in HS include close shaving, poor personal hygiene, tight-fitting clothes, and the use of antiperspirants and depilatories.[36] Many different bacteria identified in association with HS include *Staphylococcus aureus, Streptococcus milleri,* and *Chlamydia trachomatis.*[37,38]

Figure 150–8. Hidradenitis suppurativa. (From Timmcke AE: Functional anorectal disorders. In Beck DE, Wexner SD [eds]: Fundamentals of Anorectal Surgery, 2nd ed. London, WB Saunders, 1998, pp 90-98.)

Clinical Presentation

Patients with perianal HS typically present with complaints of pain and swelling. Early in the course of the disease, they will be found to have localized disease with tender, subcutaneous nodules in the perianal region or buttocks. Patients with a previous history of HS demonstrate chronic inflammatory changes in the skin with findings of diffuse induration and multiple pits (Fig. 150–8). Evidence of the disease should be sought in other body regions, including the axilla, groin, and perineum, to confirm the diagnosis and to ensure complete treatment of all disease.

Although frequently simple, the clinical presentation and management of perianal HS may be complicated by two factors. First, the presenting signs and symptoms are often nonspecific. Second, perianal HS may coexist with other diseases, specifically Crohn's disease and squamous cell carcinoma.

The clinical presentation of perianal HS can be readily confused other perianal disorders, including lymphogranuloma venereum (diagnosed by positive titers for *C. trachomatis*), granuloma inguinale (diagnosed by staining of biopsy for Donovan bodies), tuberculosis of perianal skin (diagnosed by demonstration of acid-fast bacillus in biopsy specimens), and actinomycosis (diagnosed by culture of tissues or exudates or by the demonstration of sulfur granules). Finally, the suppurative disease and resulting fistula tracks from HS may be difficult to distinguish from those of complex cryptoglandular disease or isolated perianal Crohn's disease.[36,38,39] In the absence of a clear history or physical evidence in support of cryptoglandular abscesses leading to fistula formation or other gastrointestinal manifestations of Crohn's disease, HS can be differentiated from these diseases by examination for the origin of the fistula tracks. Although cryptoglandular fistulas arise at the level of the dentate line, Crohn's disease typically originates cephalad and HS originates caudad to the dentate line.[40]

As well as confounding the diagnosis of perianal HS, Crohn's disease can coexist with perianal HS. A series of 61 patients with perianal HS revealed that 38% also had Crohn's disease.[41] Although this series comprised selected patients and probably overestimated the true coexistence of HS and Crohn's disease, the two diseases should be considered when perianal HS is coupled with gastrointestinal symptoms or when tracks originate proximal to the dentate line.[40]

Squamous cell carcinoma has also been identified in association with perianal and perineal HS. Of 27 cases reported in the literature since 1958, all have involved perineal, perianal, or buttocks skin.[39,42-44] The incidence of squamous cell carcinoma in patients with perianal HS is not known, but these reported cases underscore the importance of early intervention to prevent chronic wounds and close observation to ensure early detection.

Treatment

Perianal HS presents a spectrum of disease, with regard to both severity and chronicity, ranging from single acute episodes of mild disease that require simple surgical

drainage to recurrent aggressive disease that requires extensive excision and tissue coverage.

In its simplest form, perianal HS may present as a single painful inflamed nodule with or without a draining sinus track. The treatment of uncomplicated disease should be directed toward symptomatic relief with heat, improved hygiene, and drainage of any collections of purulence. Many systemic remedies have been prescribed, including antibiotics, isotretinoin,[45] and steroids; however, none of these have proved to be beneficial over drainage. Although antibiotics do not play a major role in the management of HS, associated cellulitis may at times indicate the use of antibiotics, with target organisms being those of skin flora, as discussed earlier. Oral erythromycin (500 mg four times daily) is recommended to treat the most commonly encountered organisms. In addition to drainage, emphasis should be placed on the prevention of recurrence. Specifically, patients should be counseled on factors that may predispose to apocrine gland occlusion, such as poor hygiene and the wearing of tight-fitting garments such as synthetic support stockings.

Chronic perianal HS often requires more aggressive treatment. Approaches include unroofing of tracks, incision and drainage, or limited excision and/or wide local excision. Unroofing of all sinus tracks with secondary healing has been reported as a successful treatment option for perianal HS.[40,46] This approach involves the opening and exposure of all involved tracks with preservation of the floor of the track to aid in closure by secondary intent. Because the floor of the track is an epithelialized surface, preservation of this surface allows quick and complete healing through rapid re-epithelialization. With this approach, healing rates without recurrence have been reported as high as 100%.[40]

For extensive perianal disease, wide excision appears to be the most frequently used surgical approach.[47] Anderson and Dockerty reported on 117 cases of perianal HS, of which 64 were treated with wide local excision.[32] Two thirds of the patients were successfully treated with a one-stage excision; the remaining third required multiple-staged excisions. Of all patients available for follow-up, 21% had no further symptoms, 32% had mild symptoms but did not require further surgery, and 45% required further treatment, usually surgery. Another report included 43 patients with perianal HS treated in large part (72%) by wide local excision.[48] This aggressive treatment was considered more effective than unroofing or incision and drainage; however, 9 (21%) of 43 patients had a recurrence at the surgical site and 12 (28%) of 43 had a flare of disease at another perianal site, for a combined perianal recurrence rate of 49%. These studies have established that even with wide surgical excision, recurrence can be expected.

Due to the pathophysiology of HS, the most appropriate therapy for severe disease should achieve ablation of involved and surrounding apocrine glands, removal of infected tissue, and establishment of a clean wound bed for optimal healing. Because aggressive wide local excision achieves all of these objectives, it should be considered the procedure of choice for severe chronic cases of perianal HS.

Just as the extent of resection remains controversial, so does the best strategy for wound management. For small and moderate wounds, primary closure (sometimes with flaps) can often be performed. For large wounds, options include split-thickness skin grafting and closure by delayed healing or secondary intent. Skin grafting offers the advantages of early wound coverage, rapid healing, and reduction in the pain and inconvenience of chronic open wounds.[39,49] This technique requires that the patient be motivated and able to comply with early postoperative wound care and avoid behavior detrimental to graft healing, including smoking, poor perianal hygiene, and direct pressure or trauma to the new graft. Healing by secondary intent eliminates the early risks of the grafting procedure and has been reported as satisfactory to patients. Wound healing can take 2 to 3 months, and the care of these large wounds is cumbersome.[19] For patients who cannot comply with early postoperative wound care, secondary healing may be the best option. However, because of more rapid wound healing and avoidance of chronic dressing changes, split-thickness skin grafting is the preferred method of coverage of these large wounds in most patients.

The possibility of coexisting cancer must be considered, especially in cases where there is a mass lesion or chronic, nonhealing component. Biopsies are indicated for all suspicious lesions. In cases complicated by squamous cell carcinoma, excision must provide margins wide enough for oncologic clearance. Because these are principally skin cancers, as such they will rarely if ever require abdominoperineal resection. In cases associated with severe perianal Crohn's disease or in association with severe rectal Crohn's involvement, wide excision may be combined with proctocolectomy. In general, standard guidelines for treatment of associated disorders should principally be followed, with complementary management of HS as indicated.

In summary, perianal HS is a chronic inflammatory condition of the skin that involves the infection of apocrine glands in the perianal region.[46] The disease causes chronic scarring with persistent sinus tracks. It can be confused with other inflammatory and infectious disorders and in rare cases can occur in association with other benign and malignant conditions such as Crohn's disease and squamous cell carcinoma. Treatment should be tailored to the severity and chronicity of the presenting disease. Acute localized infections can be drained, and preventive measures are stressed. For intermediate lesions that are chronic but not severe, unroofing is preferred, yet for severe chronic disease, wide excision with grafting or delayed healing may be required. Despite aggressive surgical therapy, high recurrence rates can be anticipated.

Inflammatory Bowel Disease

Edward V. Loftus, Jr. ▪ Robert R. Cima

ULCERATIVE COLITIS

Epidemiology and Etiopathogenesis

Ulcerative colitis (UC) is an idiopathic inflammatory condition involving the mucosa of the colon and rectum. The adjusted incidence of UC in Olmsted County, Minnesota, in the 1990s was 8.8 cases per 100,000 person-years, and the adjusted prevalence in the same location on January 1, 2001, was 246 cases per 100,000 persons.[1] If these figures are extrapolated to the estimated national population of 297 million persons in 2005, then approximately 26,000 new cases of UC are diagnosed annually in the United States, and overall there are approximately 730,000 people with UC.[2]

UC is most likely caused by a complex interplay of genetic factors, immune dysregulation, and environmental factors. Genetic susceptibility is likely, given the 5% to 15% prevalence of the disease occurring in families,[3-5] compared with a 0.25% occurrence in the general population.[1] Twin studies also suggest a genetic basis for UC (albeit weaker than what has been observed in Crohn's disease)—the concordance for UC in monozygotic twins is 15% to 20% compared with a concordance of 0% to 5% in dizygotic twins.[6-8] The incidence of UC may be higher among Jews in a given geographic region compared to non-Jews[9]; furthermore, the familial risk of UC in Jews appears to be higher than in non-Jews.[10]

Well-established environmental influences on the risk of UC include cigarette smoking and a history of appendectomy.[2] Current cigarette smokers are significantly less likely than never smokers to develop UC, while former smokers are at increased risk.[11] The "protective effect" of smoking may be explained by nicotine, which exerts important changes in rectal blood flow, colonic mucus, and cytokine and eicosanoid production.[12] Appendectomy in childhood for appendicitis also appears to diminish the risk of UC, suggesting that removing the appendix might influence the mucosal immune system.[13] The role of dietary factors in UC remains controversial, but increased carbohydrate and animal fat intake may be deleterious.[14,15] An infectious cause of UC has been suggested, but no specific bacterial or viral agent has been isolated. However, specific pathogens such as cytomegalovirus or *Clostridium difficile* that result in acute colitis may trigger UC in susceptible hosts.[16] Historically, psychosomatic factors were thought to play a major role in the etiology of UC, but this hypothesis has been discarded for the most part. In certain patients with established UC, increased stress may result in disease exacerbation, but studies are conflicting in this regard.[17,18]

Since immune dysregulation is suspected to play a major role in inflammatory bowel disease (IBD) etiopathogenesis, much effort is being made to understand the role of cytokines in IBD. Cytokines modulate the intestinal immune system. It is hypothesized that regulation of the immune response is a result of the balance between proinflammatory cytokines such as interleukin (IL)-1, tumor necrosis factor (TNF)-α, interferon (IFN)-γ, IL-6, IL-8, and IL-12, and anti-inflammatory cytokines such as IL-1 receptor antagonist (IL-1RA), IL-4, IL-10, IL-11, and transforming growth factor (TGF)-β. Perturbations in this balance may result in a loss of gut homeostasis and uncontrolled bowel inflammation.[19]

Table 151–1 Characteristics of Crohn's Colitis and Ulcerative Colitis

Features	Crohn's Colitis*	Ulcerative Colitis*
Macroscopic		
Thickened bowel wall	+++	+
Narrowing of bowel lumen	+++	+
Discontinuous disease	++	⊕
Rectal involvement	⊕	+++
Deep fissures and fistulas	++	⊕
Confluent linear ulcers	++	⊕
Perianal disease	++	⊕
Microscopic		
Transmural inflammation	+++	+
Submucosal infiltration	+++	+
Submucosal thickening, fibrosis	+++	⊕
Ulceration through mucosa	+++	++
Fissures	+++	+
Granulomas	++	⊕

*Features are characterized as being present consistently (+++), frequently (++), infrequently (+), or rarely (⊕).

Figure 151–1. Nonspecific ulcerative colitis. The colonic lumen is greatly narrowed throughout, particularly in the upper left (proximal transverse colon). Even more striking is the degree of thickening of the wall and total lack of any semblance of normal mucosa. (From Roth JA: Ulcerative colitis. In Bockus HL [ed]: Gastroenterology, 3rd ed. Philadelphia, WB Saunders, 1974.)

Pathologic Features

In general, UC is present in the rectum and extends proximally to involve the remainder of the colon in a diffuse, continuous manner (Table 151–1). The disease process may end gradually or abruptly at any level within the colon. Approximately 10% to 20% of patients with extensive UC have mild mucosal inflammation of the terminal ileum, or "backwash ileitis." The extent of the disease may vary from proctitis (i.e., involvement of the rectum alone, 25% of patients in most population-based cohorts) to left-sided colonic involvement (distal to splenic flexure, 25%) to extensive colonic involvement (proximal to splenic flexure, 50%).[20]

On gross examination, the lesions of UC begin with erythema, granularity, mucosal edema, and loss of the normal vascular pattern (see Table 151–1).[21] Mucosal friability increases with activity, and this produces the bleeding that is seen with the disease. Ulcerations occur with moderate and severe UC. These may be superficial and smooth or ragged and undermined. Eventually, ulcers may replace the entire colonic mucosa. With ongoing chronic inflammation, marked narrowing, thickening, and rigidity of the bowel occur as the muscular coats are replaced by scar tissue (Fig. 151–1). Polypoid masses or pseudopolyps, caused by hyperplasia of remaining small islands of mucosa and by the margins of ulcerations, may be present and may persist or recede as the inflammatory process becomes quiescent.

Microscopic examination of the inflamed colon shows distortion of crypt architecture and infiltration of the lamina propria not only with polymorphonuclear leukocytes but also basal plasma cells (see Table 151–1).[21] Distortion of the crypt architecture is a hallmark feature of chronic colitis. Microscopic crypt abscesses are common and penetrate just into the submucosa with the production of wide areas of ulceration of the overlying mucosa. Depletion of goblet cell mucin and superficial erosions are also commonly seen. There usually is an increase in the number of Paneth cells in the colonic crypts distal to the hepatic flexure. Granulomas, which are often seen in Crohn's disease, are extremely uncommon in UC.

Clinical Course

Like many chronic inflammatory conditions, UC is highly variable in severity, clinical course, and ultimate prognosis. In general, the severity of the disease correlates with the extent and severity of the changes in the bowel wall. UC has a peak incidence in the 3rd and 4th decades of life—the median age at diagnosis in most series is in the early 30s.[2] The condition may be slightly more common among males, but data are conflicting.[2] After its onset, the disease may take one of several courses. In a few patients (<10%), UC may be fulminant, typically becoming its most severe in the first few months

after diagnosis, often requiring surgery.[22] In most cases, UC becomes a chronic condition characterized by remissions and exacerbations.[23] Approximately 75% of patients have intermittent attacks of symptoms with complete symptomatic remissions between attacks. Disease activity in the preceding year and the presence of systemic symptoms such as fever and weight loss appear to be the strongest predictors of UC relapse.[23] A few patients (<5%) are troubled by continuous symptoms without any remission. Up to 20% of patients have only one attack with no subsequent symptoms.[23]

The most common symptoms of active UC are diarrhea and the passage of blood and mucus.[24] Unlike Crohn's colitis, in which hematochezia may be absent, bloody diarrhea is the hallmark of UC. The amount of blood may vary from a small amount of bright red blood, which is mistaken for hemorrhoidal bleeding, to massive bleeding. The diarrhea may be minimal, or patients may have 10 to 20 bowel movements per day. Patients who complain of constipation usually have proctitis or left-sided inflammation. These patients often have tenesmus and urgency but pass only a bloody mucous discharge, so it is important to inquire not only about the number of stools per day but also the number of trips to the bathroom.

In patients with acute severe colitis, abdominal pain is a frequent manifestation. It tends to be colicky. On examination of the abdomen, there may be tenderness over the colon, especially in the left lower quadrant. Large doses of corticosteroids may mask clinical signs in acute disease.

With milder forms of distal colitis, there may be only slight impairment of general health. In severe UC, systemic symptoms can be profound, and the patient may become rapidly debilitated and emaciated. Associated with these effects is fever; however, a temperature of more than 38° C is unusual, except in the rare fulminating type of colitis or in cases in which there is an intra-abdominal perforation. Weight loss and anemia tend to occur in proportion to the severity of symptoms.

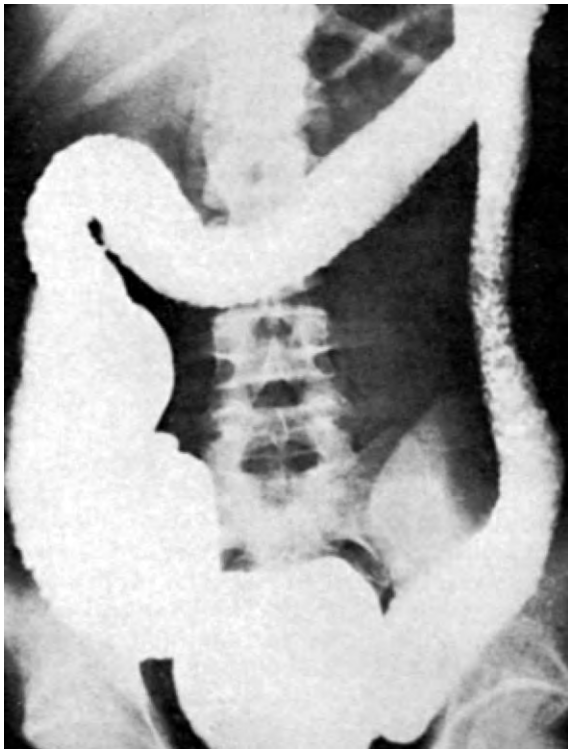

Figure 151–2. Barium enema film taken during the course of a recurrent chronic type of ulcerative colitis of 6 years' duration. The entire colon is involved with an extensive polypoid change, giving a honeycombed effect, which is more marked in the descending colon. (From Bockus HL [ed]: Gastroenterology, Vol. 2. Philadelphia, WB Saunders, 1946.)

Diagnosis

The diagnosis of UC should be suspected in patients with a history of bloody diarrhea in whom an infectious cause has been eliminated.[24] Flexible sigmoidoscopy and colonoscopy are the cornerstones of diagnosis. Colonoscopy with biopsies is more accurate than barium radiography, particularly for detecting mild colitis and determining extent. Colonoscopy with intubation of the ileocecal valve and examination of the terminal ileum allows an assessment for backwash ileitis or Crohn's ileitis. Sigmoidoscopy or colonoscopy reveals the typical gross features already described. Frequently, there also is a purulent exudate with bloody mucus, an adherent membrane, or both. With chronic inflammation, one can expect to find loss of haustral markings associated with narrowing of the lumen and shortening of the colon (Fig. 151–2). Colonoscopy is generally the preferred endoscopic test, but sigmoidoscopy is useful as an office procedure requiring little preparation or in the case of a severely ill UC patient. To complete the gastrointestinal investigation, a small bowel imaging study (i.e., small bowel follow-through, enteroclysis, or computed tomographic enterography) should be performed to exclude the possibility of Crohn's disease of the small bowel.

Colorectal Cancer and Dysplasia

Patients with UC are at increased risk of colorectal cancer (CRC).[25,26] In well-designed studies of population-based cohorts, the relative risk of CRC in UC is two to eight times higher than that in the general population.[27] The two most important risk factors for cancer are the duration of the colitis and the extent of colonic involvement.

The incidence of CRC increases with the duration of the disease.[28] The incidence rate varies widely, and, in general, population-based studies yield lower cancer incidence rates than referral center–based or hospital-based studies. A recent meta-analysis pooled the results of 116 observational studies of CRC risk in UC, involving more than 54,000 patients, and concluded that annual cancer incidence was 0.2% in the 1st decade of disease, 0.7% in the 2nd decade, and 1.2% in the 3rd decade.[29] Altogether, the cumulative risk of CRC was estimated to be 18% after 30 years of disease. Since the pooled analysis included referral center–based studies, the "real"

absolute risk of CRC in UC may actually be lower than 18%.[29] Indeed, in some population-based cohorts, the risk of CRC is no higher than expected in the general population.[30,31] Whether variations in cancer incidence among population-based cohorts can be explained by differences in treatment policies (e.g., higher rates of 5-aminosalicylate use or higher colectomy rates) remains unclear.

The extent of the colitis is an important determinant of CRC risk in UC.[28] Patients with proctitis alone do not have a significantly increased risk of developing carcinoma relative to the background population.[27] Patients with pancolitis have the highest relative risk, and patients with left-sided colitis carry an intermediate risk.[27] Significant differences in CRC risk according to UC extent have been demonstrated both in referral center–based[25,26] and population-based studies.[27,32-34]

Whether age at onset of UC is a risk factor for CRC independent of duration of disease remains controversial.[25,27,35,36] Although some studies have suggested that childhood-onset UC has a higher risk of CRC, independent of duration,[25,27,35] at least one study has suggested that patients diagnosed in the 6th and 7th decades of life have a higher relative risk of CRC.[36]

Another controversial point is whether disease activity is a risk factor for colorectal neoplasia in UC.[37] Studies focusing on clinical activity (i.e., symptoms) could not demonstrate a relationship between disease activity and CRC.[38] Indeed, a common clinical scenario is the UC patient with clinically quiescent disease who is lost to follow-up and returns years later with a symptomatic malignancy. A recent study from St. Mark's Hospital, focusing on endoscopic and histologic activity (rather than symptoms), suggested that increased endoscopic activity was associated with a twofold increase in the risk of colorectal neoplasia, while increased histologic activity increased the risk by a factor of five.[37] Confirmatory studies on this point are needed.

Two additional risk factors warrant comment. The presence of concomitant primary sclerosing cholangitis (PSC) appears to be another important cancer risk factor.[39-41] It can be debated whether PSC is an independent risk factor or whether it is a marker for long-standing pancolitis. One study of newly diagnosed PSC patients with no history or symptoms of UC showed that the vast majority had subclinical pancolitis, and one patient already had low-grade dysplasia present.[42] Regardless of the mechanism for increased cancer risk, PSC-IBD patients are at high risk for CRC.[43] Family history of CRC (regardless of the family history of IBD) is another independent indicator of cancer risk in several studies, increasing the risk by a factor of at least two.[44,45]

Unlike sporadic CRC, which tends to occur more frequently within the left colon, cancers in UC patients are more evenly distributed throughout the colon.[46] There is a higher likelihood of synchronous tumors in UC-related CRC. These lesions are more likely to be mucinous and poorly differentiated. For these reasons, they may escape detection via colonoscopy or even at surgery. As a result, they tend to be discovered at a later stage. Another reason for the late detection of UC-related CRC is that the common symptoms of abdominal pain, change of bowel habit, bleeding, and mucous discharge are often attributed by both patient and physician to the underlying UC rather than to CRC.

Despite these differences in tumor characteristics, most recent studies show no significant differences between sporadic and UC-related CRC with respect to prognosis. The most recent study compared the prognosis of 241 UC patients with CRC diagnosed at Mayo Clinic between 1976 and 1996 with the prognosis of a group of sporadic CRC patients matched on age at cancer diagnosis, gender, and cancer stage.[46] The 5-year survival in the UC-CRC group was 55%, compared to 53% in the sporadic CRC group.

In the past, prophylactic proctocolectomy was recommended for patients with long-standing disease, regardless of their disease activity, because of the risk of the development of cancer. However, with the availability of colonoscopy for surveillance of the entire colon and the recognition that premalignant changes on rectal biopsy were associated with CRC, the standard practice in the gastroenterology community is to recommend periodic colonoscopic surveillance in a search for premalignant lesions ("dysplasia") in the colonic epithelium. The objective of this course of action is to recognize dysplastic changes before the onset of carcinoma.

More than 20 years ago, the Inflammatory Bowel Disease-Dysplasia Morphology Study Group published a consensus report on the classification of colorectal dysplasia.[47] Histologic changes were classified as positive, negative, or indefinite for dysplasia. Definite dysplasia was further classified into low grade and high grade. There is reasonably good evidence that dysplastic change precedes frank carcinoma in most cases. Unfortunately, however, carcinoma may already be present when dysplastic changes are detected. It is also recognized that the pathologist may have difficulty deciding whether microscopic changes are due to the normal regenerative changes seen in UC or represent true dysplastic changes. Despite the availability of a standardized classification system for colorectal dysplasia for more than 2 decades, there remains considerable interobserver variability among pathologists for the finding of dysplasia.

Numerous professional societies have issued practice guidelines or consensus statements regarding the practice of surveillance colonoscopy in UC. The most recent recommendations, issued by a task force of the Crohn's and Colitis Foundation of America (CCFA), recommend surveillance colonoscopy every 1 to 2 years in patients with left-sided or extensive colitis with approximately 8 to 10 years of disease duration.[48] Patients with proctitis alone do not require surveillance, whereas patients with concomitant PSC should enter a surveillance program immediately regardless of UC duration.

The patient must be properly prepared for colonoscopy so that all of the mucosa can be visualized. The colonoscopy must be complete to the cecum, and the endoscopist must search for any suspicious plaque-like or nodular lesions. The CCFA consensus statement recommends that at least 33 random biopsies of the colon be obtained, typically in a four-quadrant fashion every 10 cm in the proximal colon and every 5 cm in the rectosigmoid.[48] At our institution we obtain a total of 32

biopsies divided into four bottles (eight pieces from the cecum and ascending colon, eight pieces from the transverse colon, eight pieces from the descending colon and proximal sigmoid colon, and eight pieces from the rectosigmoid). Visible lesions should be biopsied separately. Dysplasia may be present in grossly flat mucosa or may have a villous or nodular appearance. With accurate endoscopic and pathologic assessment of the mucosa, a reasonable course of management can be recommended to the patient.

Although there is broad consensus that patients with high-grade dysplasia should undergo immediate colectomy, there is no consensus on how to manage a finding of low-grade dysplasia.[48] Some recommend attempting to manage the disease medically and repeating colonoscopy and biopsy in 3 months. If there is no further dysplasia, the patient will undergo colonoscopy in 1 year. If low-grade dysplasia is again present, the patient will undergo repeat colonoscopy in 3 months, and if dysplasia is still present, serious consideration will be given to surgical intervention. However, others (including us) recommend colectomy for a finding of low-grade dysplasia, since several studies of patients with low-grade dysplasia have suggested that the actuarial rate of progression to high-grade dysplasia or cancer may be higher than 50% after 5 years.[49,50]

As the optical capabilities of endoscopes improve and our diagnostic awareness of dysplasia increases, we are beginning to understand that not all colorectal dysplasia in IBD is flat. Indeed, recent studies suggest that polypoid dysplasia is more common than flat dysplasia.[51] Patients with "dysplasia-associated lesion or mass (DALM)" were once thought to be at a particularly high risk for synchronous or metachronous CRC. Blackstone and colleagues reported that invasive carcinomas were present in 7 (28%) of 25 patients in whom mild dysplastic changes were found in so-called villous lesions.[52] However, more recent studies suggest that certain polypoid dysplastic lesions can be managed via endoscopic polypectomy.[53-55] If the lesion is well defined and amenable to endoscopic polypectomy, and if biopsies of the flat mucosa immediately surrounding the polypectomy site do not demonstrate dysplastic change, then these patients can be managed with close colonoscopic follow-up. For lesions that are not amenable to endoscopic polypectomy or have surrounding dysplasia, colectomy is recommended.

Acute, Severe Colitis

Although acute severe colitis is an uncommon form of UC, affecting approximately 15% of all patients with the disease, it can be life-threatening.[56] Fortunately, the mortality of acute severe colitis has dropped at referral centers over the past half-century from 30% to much less than 5% with increased recognition of the more toxic forms of the condition and with more intensive therapy.[57] Nevertheless, among those requiring hospitalization for acute severe colitis, approximately 30% to 40% require colectomy.[57] *Toxic megacolon,* the most fulminant form of acute colitis, is defined as a severe attack of colitis with total or segmental dilation of the colon (usually defined as a colonic diameter >5.5 cm on plain films). In a case series of 55 UC patients with toxic dilation, Jalan and colleagues defined toxicity as the presence of any three of the following conditions: fever higher than 38.5° C, tachycardia (>120 beats/min), leukocytosis (>10,500 cells), and anemia (hemoglobin <60% of normal).[58] In addition, one of the following conditions must have been present: dehydration, mental changes, electrolyte disturbances, or hypotension. This degree of toxicity, coupled with clinical or radiographic evidence of colonic distention, completes the presentation of toxic megacolon.

Toxic megacolon can complicate long-standing UC or can occur in patients presenting with their first attack. Various precipitating factors for toxic megacolon have been identified, including antidiarrheal agents, opioid analgesics, barium enema, and electrolyte abnormalities (including hypokalemia). The cause is unknown but is thought to be due to a paralysis of the myenteric plexus, perhaps resulting from transmural inflammation occurring acutely.

Toxic dilation of the colon is generally considered the most serious complication of UC. The colon loses its ability to contract and becomes widely distended, resulting in a thinned wall in danger of perforation. The most common sites of perforation are around the peritoneal attachments of the splenic flexure and at the cecum.

The clinical presentation of toxic megacolon is dramatic. Patients may suddenly become acutely ill with rapid progression of symptoms that include fever, mental aberrations, tachycardia, tachypnea, and bloody diarrhea. Abdominal pain may be diffuse and severe but may be lacking, particularly in patients who are taking high-dose corticosteroids. Sigmoidoscopy may reveal changes typical of UC. Biopsies should be obtained, and the pathologist should be instructed to exclude the possibility of cytomegalovirus superinfection as a cause of the exacerbation.[59] A stool sample for *C. difficile* toxin should be obtained, as *C. difficile* toxin can be recovered from approximately 20% of patients with UC exacerbations, and treatment with metronidazole or vancomycin frequently results in improvement.[60] The diagnosis of toxic megacolon can usually be made on a plain radiograph of the abdomen, which shows dilation of the large bowel (Fig. 151–3). Although colonoscopy appears to be surprisingly safe in "garden variety" acute severe colitis, it remains contraindicated in the patient with toxic megacolon.[61]

Patients who present with signs of localized or generalized peritonitis, radiographic evidence of perforation, or systemic instability should undergo immediate surgery. Otherwise, intensive medical management, consisting of high-dose parenteral steroids and intravenous (IV) fluids, should be initiated immediately. Patients tend to be dehydrated and may have electrolyte imbalances because of losses from vomiting and diarrhea. These imbalances must be corrected, and the patients who are anemic should undergo transfusion. Restriction of oral intake is initiated along with nasogastric suction to avoid further intestinal distention. Although randomized trials have not shown convincing benefit, broad-spectrum antibiotics are frequently administered in this

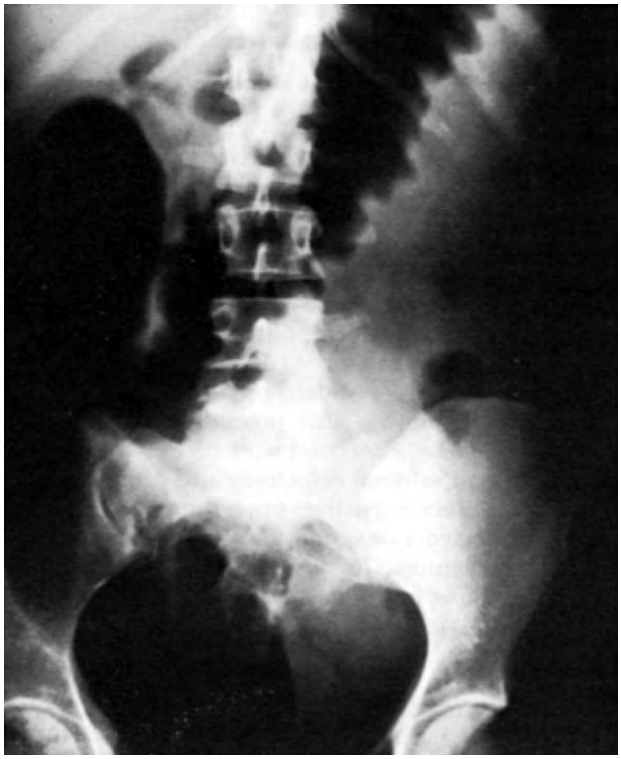

Figure 151–3. Toxic dilation of the colon. Note the gross enlargement, particularly of the transverse colon and cecum.

setting because of the potential for bacteremia or microperforation.

The patient with toxic megacolon must be observed very closely with serial physical examinations every 2 to 4 hours and serial plain films of the abdomen daily. The timing of surgery in toxic megacolon remains controversial, with some authors advocating early colectomy (i.e., shortly after recognition of toxic megacolon) and others noting little or no mortality by treating with IV corticosteroids and antibiotics for up to 7 days in patients who appear to be improving. Most authors agree that patients who are not improving or are deteriorating need surgery urgently. Several studies indicate that the presence of more than eight stools daily, or a combination of elevated C-reactive protein (>4.5 mg/dl) and more than three stools daily, on the 3rd hospital day predict colectomy in about 85%.[57,62] Close follow-up by both the medical and surgical teams, with open lines of communication between the two, is required.

Massive Hemorrhage

Although rectal bleeding is a common symptom of UC, massive hemorrhage that necessitates rapid blood transfusion and emergency treatment is unusual, occurring in fewer than 5% of patients. Most frequently, it occurs in patients with acute severe colitis. The treatment of these patients is usually twofold. First, treatment of the UC necessitates the use of high-dose steroids and other supportive measures. Second, the bleeding must be treated expeditiously and any coagulation abnormality corrected. In most patients, hemorrhage subsides spontaneously. It is unusual that the bleeding originates from a discrete site. The indication for surgery is not arbitrary but must be individualized for each patient. Once the decision is made to operate, the standard procedure has been proctocolectomy. However, this procedure, as previously mentioned, can be associated with higher mortality and morbidity rates than subtotal colectomy and it obviates the possibility of a reconstructive procedure in the future. Thus, in selected cases, one might consider a total abdominal colectomy, leaving a short rectal stump, sufficient to allow future reconstructive surgery. In most instances, this type of surgery controls the bleeding, although continuing massive hemorrhage can still occur in approximately 10% to 12% of patients.

CROHN'S (GRANULOMATOUS) COLITIS

Epidemiology and Etiopathogenesis

Crohn's disease is the other major subtype of idiopathic IBD. Crohn's disease results in transmural, often granulomatous, inflammation that can occur anywhere in the gastrointestinal tract, and it has a propensity to cause intestinal fistulas and/or strictures. It is now well accepted that Crohn's disease of the large and small intestine is one disease, but it is separate and distinct from UC. The incidence and prevalence of Crohn's disease are similar to that of UC. In the 1990s, the adjusted incidence of Crohn's disease was approximately 6 cases per 100,000 person-years, and the adjusted prevalence on January 1, 2001, was 162 cases per 100,000 persons.[1] Extrapolating these figures to a U.S. population suggests that about 19,000 patients are diagnosed annually and that there are approximately 480,000 people with Crohn's disease.[2] As is the case with UC, Crohn's disease appears to be more common in whites, especially Jews, less common in African Americans, and more frequent in populations of westernized cultures than those of Africans and Asians.[63] However, a number of studies suggest that these differences are narrowing over time. For example, one pediatric study from Atlanta suggested that Crohn's disease was as common among African American children as among whites. Studies from Japan, South Korea, Singapore, and now India suggest that IBD is becoming more common in these areas, too.[63]

In contrast to UC, cigarette smoking is a risk factor for Crohn's disease, and patients with Crohn's disease who smoke have a more severe clinical course (i.e., requiring more corticosteroids, immunosuppressive agents, and surgery) than those who do not.[12] Similar to UC, a family history of IBD is one of the strongest risk factors for Crohn's disease identified. Studies of twin registries suggest a strong genetic component in the pathogenesis of Crohn's disease—approximately 50% of monozygotic twin pairs are concordant for the disease versus only 20% concordance among dizygotic twins.[6-8] The identification in 2001 of the *CARD15/NOD2* mutations provided the first definitive genetic link to the condition.[64-66] Up to

40% of Crohn's disease patients carry at least one of three mutations in this gene, which appears to encode a protein important in the innate immune system.

Crohn's disease primarily affects young individuals, with the median age at diagnosis being in the late 20s. There may be a slight female predominance in Crohn's disease, in contrast to the slight male predominance seen in UC. Approximately 40% to 50% of Crohn's disease patients have both small bowel and colonic involvement, 20% have isolated small bowel (usually ileal) involvement, and one third have colonic disease alone. Disease in which the colon is primarily involved may occur more frequently in patients diagnosed at a somewhat older age.

The colon may be involved with Crohn's disease in one of several ways. First, the colon alone may be the site of Crohn's disease. The large bowel may be involved in its entirety, but more often there is segmental disease with sparing of the rectum and part of the sigmoid. In addition to Crohn's colitis, there may be involvement of the small bowel. This form of ileocolitis is the most common type of Crohn's disease. The colon may become involved with Crohn's disease only after surgery for ileitis, but this is not particularly common, because most recurrences appear proximal to the ileocolonic anastomosis. Finally, the colon may be involved indirectly via fistula formation from a loop of small bowel that is the site of the primary disease. In this case, most commonly there is no primary disease in the colon but only secondary inflammation from the disease in the small intestine.

Figure 151–4. Crohn's disease of the colon. Transmural involvement is present with mucosal ulceration (U), edema of the entire bowel wall, and serosal noncaseating granulomas *(arrows)* (hematoxylin-eosin, ×25). (Courtesy of Stanley Hamilton, MD, Department of Pathology, School of Medicine, Johns Hopkins University, Baltimore, Maryland.)

Pathologic Features

Crohn's colitis typically involves all layers of the bowel wall as a transmural reaction (Fig. 151–4). This transmural reaction may be noted grossly but is present in the early phases of the disease when only microscopic changes are noted.[21] Although the gross and microscopic features of Crohn's disease are well established, there is no pathognomonic feature. The features of UC and Crohn's disease are listed in Table 151–1. In approximately 10% to 15% of patients, it may be difficult to unequivocally differentiate Crohn's disease from UC. The term *indeterminate colitis* has been used in these cases in which a definitive pathologic diagnosis cannot be made.[67]

On macroscopic examination, the bowel wall appears to be thickened, particularly in the submucosal layer (see Table 151–1).[21] There is a corresponding narrowing of the lumen. Edema, thickening, and overgrowth of the mesenteric fat encroaching on the serosal aspect of the bowel wall are extremely common in Crohn's disease of both the small and large intestine (Fig. 151–5). The serosa tends to be hyperemic, and there are chronic subserosal inflammatory changes with exudate production. Mesenteric lymphadenopathy may be present. The gross appearance of the mucosal surface varies depending on the extent and severity of the disease. The mucosa may appear to be normal except for hyperemia and edema, or there may be longitudinal ulcers that cause the mucosal surface to have a cobblestone appearance. The ulcers vary in depth but usually extend at least to the

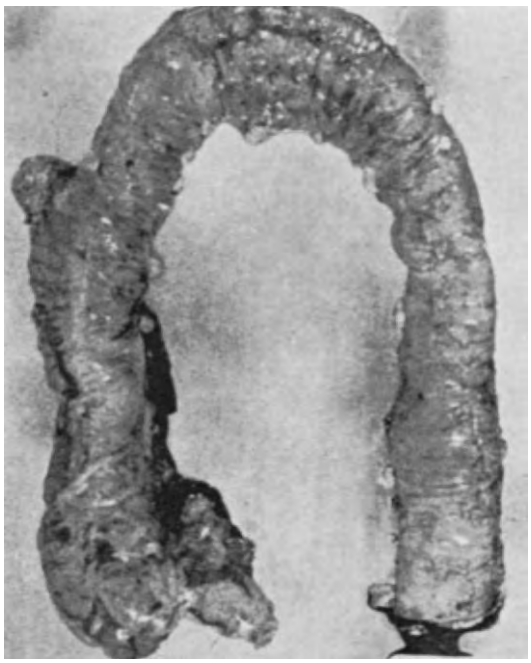

Figure 151–5. Serosal surface of colon resected for granulomatous colitis. (From Barnett WO, Mora LO, Varner JE: Granulomatous colitis. South Med J 62:373, 1969.)

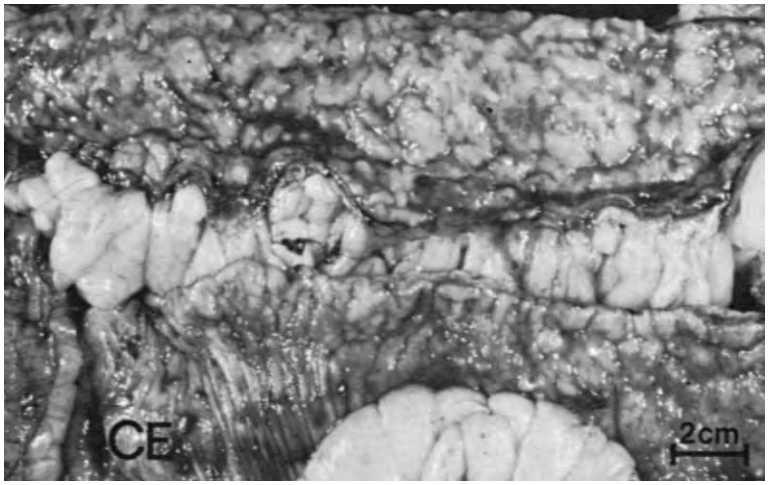

Figure 151–6. Crohn's disease of the colon. The mucosal surface shows serpiginous ulceration and has a cobblestone appearance. The cecum (CE) is less severely involved than is the remainder of the colon. submucosa and often to the serosa (Fig. 151–6). Because of this, frequently other loops of intestine adhere to the involved segment, and fistulas may occur. In addition, skip areas may be seen.

Microscopic changes include infiltration of inflammatory cells in all layers and marked submucosal and subserosal thickening and intramural fissures that can extend through to the mesenteric fat (see Table 151–1). Giant cells or epithelioid granulomas may occur either intramurally or within regional lymph nodes (Fig. 151–7). Other histologic findings include transmural fibrosis, submucosal lymphangiectasia, chronic serositis when there has been no prior surgery, muscle wall thickening (more than twice that of normal), and segmental involvement.

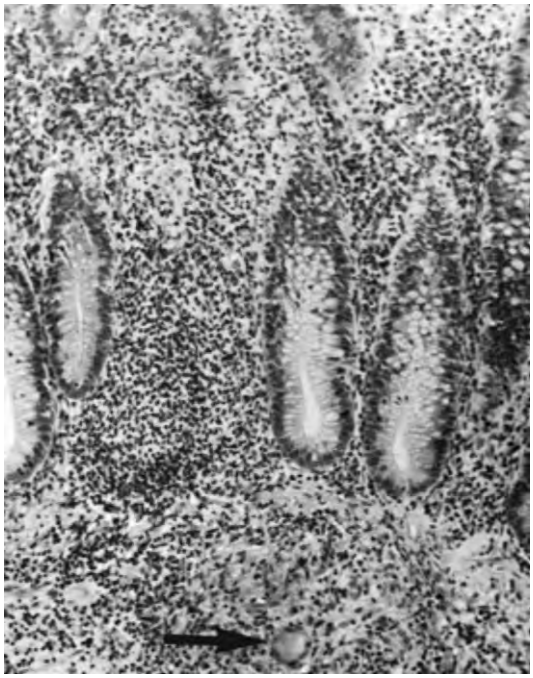

Figure 151–7. Crohn's disease of the colon. A noncaseating granuloma with epithelioid macrophages and a multinucleated giant cell *(arrow)* is present in the submucosa (hematoxylin-eosin, ×160). Clinical Features

Symptoms of Crohn's colitis include diarrhea, midabdominal and lower abdominal crampy pain, malaise, and weight loss.[24] Other symptoms and clinical findings include fever, rectal bleeding, anemia, nausea, and vomiting. Occasionally, patients may present with symptoms suggestive of an acute abdomen. It is now recognized that toxic megacolon can complicate Crohn's colitis as well as other forms of colitis. Extraintestinal manifestations are common, with musculoskeletal manifestations being the most frequent.

Clinically, Crohn's colitis often has an extremely variable onset and course. Although diarrhea is a dominant feature of both UC and Crohn's colitis, colonic bleeding is less common with Crohn's disease.[24] However, massive bleeding from acute Crohn's colitis can occur on occasion. Colonic sinuses, fistulas, and strictures are characteristic of Crohn's colitis. However, these internal complications do not occur as frequently in colon disease as they do in terminal ileum disease.

Perianal Crohn's disease is a frequent complication. It is an extremely troublesome problem and difficult to treat successfully. Population-based studies suggest that up to 40% of Crohn's disease patients develop perianal involvement at some point during their clinical course.[68] The perianal lesions can precede the clinical appearance of the colitis by a variable number of years. Perianal Crohn's disease has been classified into the following categories: skin lesions, anal canal lesions, fistulas, and hemorrhoids.[69] *Skin lesions* include maceration, erosion, ulceration, abscess formation, and skin tags. Because of the frequency of diarrhea in this disease, the skin around the anus may become macerated, leading to ulceration

and subcutaneous abscess formation. Skin tags are frequent manifestations. They tend to be edematous and larger, thicker, and harder than those seen in patients without Crohn's disease. *Anal canal lesions* include fissures, ulcers, and stenosis of the anal canal. The fissures tend to be deep and wide, with undermined edges. The fissures may be eccentrically placed in any position around the anus, in contrast to uncomplicated midline fissures in patients who do not have Crohn's disease. *Fistulas* and *abscesses* are perhaps the most difficult of the perianal lesions to treat. They may arise from an infected anal gland, as in patients without Crohn's disease. More commonly, however, they result from penetration by anal canal or rectal fissures or ulcers. The most superficial fistulas can be treated in a conventional manner, but more complex fistulas may have a high internal opening with multiple indirect tracts opening on the buttocks or scrotum. Fistulas tend to be chronic, indurated, and cyanotic, but despite their appearance, they are often painless. If the patient does complain of pain, one should suspect an abscess.

Rectovaginal fistulas can also complicate Crohn's disease and tend to result from direct penetration of rectal wall fistulas into the vagina. They are a relatively frequent complication of severe perianal disease, with rates varying from 3.5% to 20%.[70-72] Quite frequently, these fistulas are asymptomatic, and no surgical intervention should be attempted. However, if the patient is symptomatic, surgery is indicated. Various local procedures have been described, but none are extremely successful. Some patients require proctectomy (see Chapter 153).

Diagnosis of Crohn's Colitis

Endoscopic evaluation of the colon and rectum is essential. Colonoscopy is particularly important to determine the extent of the disease and is more sensitive than radiographic examination. The often discontinuous nature of Crohn's colitis can be seen better with the colonoscope than on barium enema. All patients who undergo surgery for Crohn's disease, including those with presumed ileitis, should undergo a preoperative colonoscopy to fully determine the extent of the disease. The endoscopic appearance of Crohn's colitis is usually quite different from that of UC. The rectum is spared in approximately 50% of patients with large bowel involvement. Depending on the extent and severity of the disease, there may be isolated aphthous ulcers with normal intervening mucosa, or there may be irregular mucosal thickening, congestion, edema, and a cobblestone appearance with deep linear ulcerations and fistulas. Pathognomonic histologic features of Crohn's disease (i.e., granulomas) are present only infrequently.

Radiographic features characteristic of Crohn's colitis are similar to those seen in terminal ileum disease. The radiographic features that substantiate the diagnosis of Crohn's colitis include skip areas, longitudinal ulcerations, transverse fissures, eccentric involvement, pseudodiverticula, narrowing, strictures, pseudopolypoid changes, a cobblestone pattern, internal fistulas, sinus tracts, and intramural fistulas that extend parallel to the lumen of the thickened bowel (Fig. 151–8). Any portion of the colon may be involved with Crohn's colitis. The segment least frequently involved is the rectum. Skip

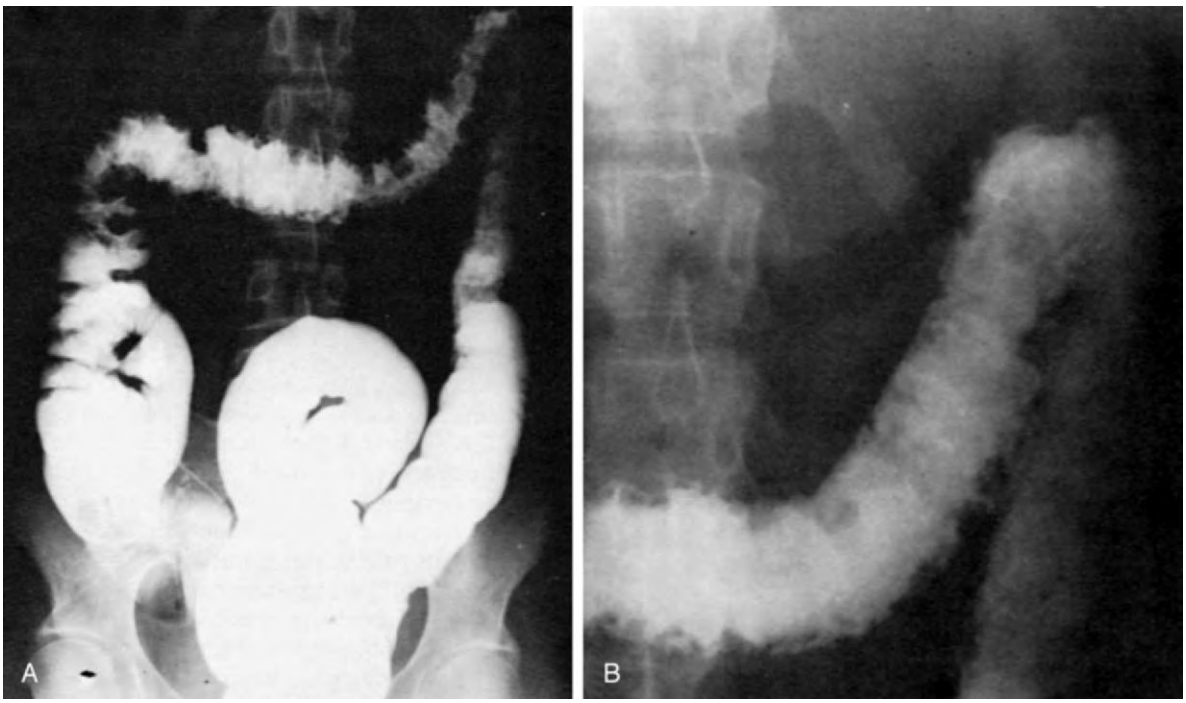

Figure 151–8. Granulomatous colitis. **A,** Barium enema showing segmented colonic narrowing and mucosal ulceration, especially of the proximal descending colon. **B,** Barium enema showing intramural fistulous tract of medial aspect of distal transverse colon.

areas must be sought carefully, because discontinuous involvement may be limited to one wall, may appear as a nodular filling defect, or may involve straightening and rigidity of a short segment of the colon. The combination of longitudinal ulcers, edematous mucosa, and transverse linear ulcers produces the cobblestone pattern previously described. Transverse linear ulcers may penetrate so deeply into the wall of the colon that they appear in contour as numerous long, thin spicules perpendicular to the long axis of the bowel or as a sinus tract. They may ultimately lead to small intramural abscesses or fistulas. A small bowel enema or enteroclysis should be included as part of the work-up in patients with Crohn's colitis to document the total extent of the disease.

Crohn's Colitis and Colorectal Cancer

Crohn's colitis has been recognized as a condition predisposing to the development of CRC. The risk of developing carcinoma in Crohn's disease is not as well defined as in UC, with relative risks in well-designed population-based studies ranging from no increased risk[73-76] to a sixfold elevation.[77] Carcinoma may also occur in chronic perianal fistulas. Although the incidence of cancer in Crohn's colitis is increased, it is still unclear how frequently these patients should be followed with surveillance colonoscopy and biopsies. Our recommendations for patients with Crohn's colitis are similar to those for patients with chronic UC of similar extent (see earlier).

THERAPY OF ULCERATIVE COLITIS AND CROHN'S DISEASE

Although traditional drugs such as corticosteroids, sulfasalazine (Azulfidine), and 5-aminosalicylic acid (5-ASA) compounds are the mainstays of the medical management of IBD (especially UC), many other modalities and drugs are used, including antibiotics, the purine analogues azathioprine and 6-mercaptopurine, methotrexate, cyclosporine, and infliximab.

Sulfasalazine and 5-Aminosalicylic Acid Compounds

Sulfasalazine is composed of sulfapyridine linked to 5-ASA by an azo bond. It is poorly absorbed in the upper gastrointestinal tract and is degraded into its two components by colonic bacteria containing azoreductase. The 5-ASA moiety is the active anti-inflammatory compound of sulfasalazine, whereas sulfapyridine acts only as the carrier for 5-ASA.[78] It is the sulfapyridine moiety to which many patients have side effects and allergic reactions. Various 5-ASA compounds have been developed and have been shown to be as effective as sulfasalazine but with reduced side effects. Olsalazine (Dipentum) is a 5-ASA dimer joined by an azo bond. Mesalamine, or 5-ASA alone, is commercially available in two delivery systems in the United States. Asacol is mesalamine coated with an acrylic-based resin, Eudragit S, which does not dissolve until the luminal pH rises to 7.0 or higher. In general, this agent is released in the terminal ileum and colon. Pentasa is an ethylcellulose-coated, controlled-release formulation of mesalamine. Approximately 20% to 30% of this agent is released and absorbed in the small bowel, with the remainder delivered to the colon. Finally, balsalazide (Colazal) is a nonsulfa 5-ASA prodrug, containing 5-ASA and 4-aminobenzoyl-β-alanine joined by an azo bond. Free active 5-ASA is released in the colon similar to sulfasalazine and olsalazine. Mesalamine in enema formulation (Rowasa) is efficacious in mildly to moderately active left-sided UC and proctitis. Mesalamine suppositories (Canasa) are efficacious for active ulcerative proctitis.

Sulfasalazine and the 5-ASA compounds inhibit various products of the metabolism of arachidonic acid (e.g., prostaglandin G_2, leukotriene B_4, and thromboxane A_2)—all known to play a major role in the inflammatory process in the intestinal mucosa.[79] They also decrease the synthesis of other inflammatory cytokines (IL-1 and TNF-β) and inhibit the action of IFN.

Sulfasalazine

Sulfasalazine is the oldest and the least expensive 5-ASA compound in use. In a low dosage (1 to 2 g/day), it is used to maintain remission in patients with UC, whereas in a higher dosage (4 to 6 g/day), it can be used to treat active UC.[80,81] In Crohn's disease, the efficacy of sulfasalazine is less clear and depends on the site of the disease. Because sulfasalazine is cleaved into its active compounds in the colon, its use is limited to Crohn's disease with ileocolonic or colonic involvement.[82,83] It is of little known benefit in isolated small bowel disease.

Adverse events following sulfasalazine therapy are common and include nausea, headaches, malaise, and vomiting.[84] These side effects can be minimized or prevented by initiation of therapy with a low starting dose (500 mg every 6 to 12 hours) and gradual increase in the dosage. Hypersensitivity reaction to sulfasalazine can cause rash, fever, hemolytic anemia, and hepatotoxicity. We typically coadminister folic acid 1 mg daily to prevent folate deficiency. The drug may cause a reversible but clinically significant azoospermia in men, so discontinuation of the drug should be considered in the family planning stage. This particular effect is not seen with the nonsulfa 5-ASA compounds.

Olsalazine

Olsalazine delivers intact 5-ASA to the terminal ileum, which is then cleaved by the colonic bacteria to free 5-ASA. Olsalazine has been shown to be of benefit in the maintenance of remission of patients with UC.[80] At higher doses it may result in a watery secretory diarrhea.[84] No therapeutic benefit has been shown in patients with mild to moderate attacks of Crohn's disease.[85]

Mesalamine

At a dosage of 2.4 to 4.8 g/day (usually given in three to four divided doses), mesalamine has been shown to be efficacious in patients for both induction and maintenance of remission of mildly to moderately active UC.[80,81] It was found in a recent meta-analysis to be nearly as effective as sulfasalazine in maintaining remission in patients with UC.[80] Mesalamine enemas at dosages of 1 to 4 g/day are effective in treating patients with distal UC, whereas patients with limited ulcerative proctitis can benefit from mesalamine suppositories at a dosage of 500 mg twice a day.[86]

The role of mesalamine for treatment of mildly to moderately active Crohn's disease remains controversial. Although mesalamine at dosages between 3.2 and 4 g/day has been associated with clinical improvement or remission in mildly to moderately active Crohn's disease,[87,88] other studies have failed to demonstrate a benefit.[89,90] A pooled analysis of three trials using the Pentasa formulation of mesalamine (including two unpublished trials that were negative) suggested that Pentasa resulted in a net decrease of 18 points on the Crohn's Disease Activity Index (CDAI), which, although statistically significant, may not represent a clinically meaningful response.[90] The role of mesalamine and other 5-ASA therapies to maintain remission and prevent relapse in Crohn's disease remains controversial, too. A 1997 meta-analysis of all available trials suggested that the net incremental benefit of mesalamine compared to placebo in maintaining medically induced remission was only 4.7%.[91] The number needed to treat (NNT) to prevent one additional relapse would therefore be more than 20 patients. In contrast, the net incremental benefit of mesalamine in maintaining surgically induced remission was slightly better at 13.1% (NNT, 7). A more recent meta-analysis, incorporating additional studies, suggested that mesalamine provided no benefit whatsoever in maintaining medically induced remission in Crohn's disease.[85] Mesalamine does not carry an indication approved by the U.S. Food and Drug Administration (FDA) for the treatment of Crohn's disease.

Potential adverse events from mesalamine therapy include headache, abdominal pain, nausea, and diarrhea.[84] Mesalamine can less commonly cause hypersensitivity colitis, pancreatitis, pleuritis, interstitial pneumonitis, interstitial nephritis, and hepatotoxicity.

Balsalazide

Balsalazide at a dosage of 6.75 g/day (in three divided doses) has been shown to be effective for the treatment of mildly to moderately active UC.[92] It is equivalent to mesalamine in efficacy.[92] Adverse events include headache, abdominal pain, nausea, and diarrhea.[84] Rare reports of aggravation of colitis, pancreatitis, and hepatotoxicity have been described.

Corticosteroids

The benefit of corticosteroid therapy for UC was first reported by Truelove and Witts.[93] Corticosteroids still remain the cornerstone of medical treatment of moderately to severely active IBD. Their broad mechanism of action occurs through modification of gene expression, ultimately resulting in inhibition of proinflammatory cytokines; repression of phospholipase A, cyclooxygenase-2, and nitric oxide synthase; and inhibition of adhesion molecules.[79] The end result is reduction in leukocyte migration and inhibition of multiple inflammatory mediators.[79]

The initial treatment in patients with moderate to severe UC is prednisone at 40 to 60 mg daily. In severely ill, hospitalized patients, initial therapy consists of 100 mg IV hydrocortisone three times daily or its equivalent. Corticosteroids are also effective in the treatment of moderate to severe Crohn's disease. In the National Cooperative Crohn's Disease Study, prednisone administered at dosages of 0.25 to 0.75 mg/kg/day to 85 patients with active Crohn's disease resulted in remission in 60% of patients compared with a rate of only 30% in a placebo group.[82] Although corticosteroids are highly effective in the short term for inducing remission, only a few patients remain in remission off corticosteroids over the longer term.[94,95] Studies of population-based cohorts in the preimmunosuppressive era suggest that approximately one third of patients receiving corticosteroids will be steroid dependent and about one third will have required surgical resection at the end of 1 year.[94,95] These studies highlight the need for early and aggressive use of steroid-sparing medications in IBD patients whose disease is active enough to require corticosteroids.

The systemic side effects of conventional corticosteroids have led to the development of modified formulations that are more potent and more rapidly metabolized. Modified corticosteroids offer the promise of being as effective as traditional corticosteroids with fewer systemic side effects. Similar to 5-ASA preparations, different packaging of these agents is available, which offers the possibility of drug delivery to the small bowel and the colon with minimum side effects. Oral delayed-release budesonide (Entocort EC) is the most notable of these new corticosteroids.[96] This controlled ileal release formulation is indicated for induction of remission in mildly to moderately active Crohn's disease involving the ileum or right colon. In one head-to-head study, budesonide at 9 mg/day was more efficacious than mesalamine 4 g/day for this indication.[97] In a pooled analysis of four maintenance trials (each individually negative), budesonide was associated with a significantly longer median time to relapse (268 days) than placebo (154 days).[98]

Topical corticosteroids may be of benefit in patients with either limited distal disease or with rectal involvement along with more proximal disease.[86] Corticosteroid enemas or foams can be used for the treatment of active disease, but no role in maintenance therapy has been proved.

Antibiotics

Multiple lines of evidence suggest that bacteria may play a role in the pathogenesis of IBD, perhaps due to an unusual response of the mucosal immune system to

normal intestinal flora, or a breakdown in the intestinal defenses allowing microorganisms to invade the intestinal mucosa. Some have even hypothesized that a specific bacteria such as *Mycobacterium avium* subspecies *paratuberculosis* may be responsible for Crohn's disease, but this remains extremely controversial.[2]

In patients with UC, both IV and oral antibiotics have been studied in placebo-controlled trials. No statistically significant results have been reported in IV studies involving patients with severe UC.[99] Two studies of oral antibiotics in patients with mild to severe UC have reported statistically significant results: one with tobramycin 120 mg orally three times a day (78% improvement at 4 weeks versus 43% with placebo; $P = .008$)[100] and one with ciprofloxacin 500 to 750 mg orally twice a day (79% response at 6 months versus 56% with placebo; $P = .02$).[101] However, the difference in the latter study was of borderline significance after 12 months of follow-up (55% response in the ciprofloxacin group versus 40% in the placebo group; $P = .07$). Furthermore, another randomized, placebo-controlled trial of oral ciprofloxacin in mildly to moderately active UC was negative.[102] A small placebo-controlled trial of rifaximin showed numerical but not statistical superiority against placebo in active UC (response rates 64% versus 42%; P = NS).[103] At the present time, oral antibiotics are not routinely prescribed for UC; however, the conflicting trial results suggest that additional studies need to be performed to definitively prove or disprove the role of oral antibiotics in mildly to moderately active UC.

Evidence for antibiotic use in Crohn's disease from randomized, controlled trials is limited. Sutherland et al. performed a study comparing metronidazole to placebo in patients with active Crohn's disease.[104] According to the CDAI scores, the metronidazole group showed significantly greater improvement in disease ($P = .001$). This improvement was greatest in patients with colonic involvement ($P = .05$) but less remarkable in those with ileitis (P = NS). This finding appears to be common in Crohn's disease; patients with colonic involvement seem to benefit the most from antibiotic treatment. The adverse effects of metronidazole, however, are substantial. They include nausea, anorexia, metallic taste in the mouth, furry tongue, candidiasis, and dose-dependent peripheral neuropathy.

Ciprofloxacin has also been evaluated in Crohn's disease. Although somewhat safer than metronidazole, ciprofloxacin is associated with notable adverse events, including nausea, the potential for drug interactions (and possibly prolongation of the QT interval), and the risk of tendonitis or tendon rupture, particularly when combined with corticosteroids. In one study, investigators compared ciprofloxacin and high-dose mesalamine.[105] In this study, comparable proportions of patients had improvement (17% ciprofloxacin, 5% mesalamine) and achieved remission (56% ciprofloxacin, 55% mesalamine) with either ciprofloxacin (1000 mg/day) or mesalamine (4 g/day). Although fewer patients failed treatment with ciprofloxacin (17% versus 36%), there were no significant differences between groups.[105] Another study compared the combination of ciprofloxacin and metronidazole with methylprednisolone.[106] After 12 weeks of treatment, 46% of the antibiotic group and 63% of the steroid group obtained clinical remission. This difference was not significant. The results of this study suggest that combinations of antibiotics may be worthwhile in patients prior to initiating steroid therapy.[106] A small open-label study evaluated rifaximin 200 mg three times a day for 16 weeks in patients with mildly to moderately active Crohn's disease.[107] The average decline in CDAI score after 1 month of treatment was 100 points. Most patients also achieved and maintained remission through the 4-month study.[107]

Immunosuppressive Agents

Immunosuppressive agents such as azathioprine/6-mercaptopurine and methotrexate are being increasingly used to treat IBD patients who do not respond to first-line therapies or who are steroid dependent or steroid refractory. In general, the threshold to use these agents is lower in Crohn's disease than in UC, likely a reflection of the relatively poor efficacy of first-line agents in maintaining remission in Crohn's disease. These drugs are thought to act by blocking the proliferation and activation of the T-helper lymphocytes, which play a major role in the inflammatory cascade through the production of various cytokines such as IL-1, IL-2, IL-6, IL-8, TNF-β, and IFN-γ.[79]

Azathioprine and 6-Mercaptopurine

Azathioprine (Imuran, Azasan) and 6-mercaptopurine (Purinethol) are thiopurine compounds used in the management of steroid-dependent IBD, steroid-refractory IBD, and fistulizing Crohn's disease. They act either via inhibition of purine RNA synthesis and cell proliferation or via inhibition of natural killer cells and suppression of cytotoxic T-cell functions.[79] Azathioprine is a prodrug of 6-mercaptopurine, and both drugs are converted via several enzymatic steps to the 6-thioguanine nucleotides, which are thought to be the active metabolites. These mechanisms of action likely explain the 3- to 4-month delay in the onset of their clinical effectiveness. One of the inactivating enzymes in the metabolism of these agents, thiopurine methyltransferase (TPMT), has a trimodal distribution of activity in the population.[108] About 89% of patients have normal TPMT activity, 11% have intermediate activity, and 1 in 300 persons have minimal or no enzyme activity, such that normal doses of purine analogues can result in prolonged bone marrow suppression and fatal infectious complications. Many physicians routinely obtain a TPMT genotype or enzyme activity level prior to initiation of these agents to better predict a dosage that will not result in early leukopenia.

Azathioprine and 6-mercaptopurine are both used in the management of patients with active Crohn's disease and UC who have not responded to systemic steroids.[109,110] In addition, both drugs have been successfully used as steroid-sparing agents in patients with IBD who are unable to be weaned from steroid therapy.[109,110] Furthermore, both drugs have been shown to be

effective for maintenance of remission in both conditions. For IBD patients with normal TPMT levels, the typical dose of azathioprine is 2 to 2.5 mg/kg body weight daily and the dose of 6-mercaptopurine is 1 to 1.5 mg/kg body weight daily. The typical dose of these agents in those with intermediate TPMT levels is half that of patients with normal enzyme activity.

Unfortunately, observational studies suggest that 20% to 25% of IBD patients taking these agents need to discontinue them due to adverse events.[111] Among the side effects of azathioprine and 6-mercaptopurine are pancreatitis, which occurs in approximately 3% of patients, usually presents within the first 6 weeks of therapy, and resolves promptly when the drug is withdrawn.[112] Other adverse events include nausea, fatigue, and hepatotoxicity, all of which seem to be dose related. Other idiosyncratic reactions that can occur include fever, influenza-like symptoms, and abdominal pain. Patients on these agents should undergo monthly complete blood counts to monitor for leukopenia, and quarterly hepatic biochemistries to monitor for hepatotoxicity. Like all immunosuppressive agents, these drugs seem to be associated with an increased risk of non-Hodgkin's lymphoma. A recently published meta-analysis of observational studies suggested a threefold to fourfold increased relative risk[113]; however, the absolute risk of lymphoma remains low (probably <1 case per 1000 person-years), and decision analysis models suggest that the benefit far outweighs the risk in properly selected patients.[114]

Methotrexate

Methotrexate acts via inhibition of dihydrofolate reductase to impair DNA synthesis and reduce production of IL-1, IL-6, and TNF-α.[79] A multicenter, placebo-controlled trial with 141 patients with active Crohn's disease confirmed that methotrexate at a dosage of 25 mg administered intramuscularly or subcutaneously once a week, over 16 weeks, allowed steroid tapering and maintenance of remission in 39% of patients treated compared with 19% in those receiving placebo.[115] A subsequent trial randomized Crohn's disease patients with methotrexate-induced remission to continued methotrexate at 15 mg weekly or placebo.[116] Patients receiving methotrexate were significantly less likely to experience relapse (35%) compared to those receiving placebo (61%). Although several open-label uncontrolled studies have suggested efficacy for methotrexate in UC,[117-120] a randomized trial of this agent failed to demonstrate efficacy[121]; therefore, its routine use in steroid-dependent or steroid-refractory UC is not recommended.

Potential side effects of methotrexate include leukopenia, requiring monthly monitoring of the blood count, and hepatic fibrosis, necessitating monthly hepatic biochemistries. Patients with risk factors for fatty liver disease (e.g., obesity, diabetes mellitus, ethanol use) and those with persistent elevations in hepatic biochemistries should undergo percutaneous liver biopsy. Methotrexate-induced pneumonitis is occasionally encountered, so patients who develop cough or fever while on this agent should be investigated thoroughly.

Cyclosporine and Tacrolimus

Cyclosporine is a potent immunosuppressive drug that is used in organ transplantation as well as "rescue therapy" in patients with acute severe UC.[122] It blocks transcription of cytokines that activate T-helper lymphocytes, thus inhibiting the production and liberation of proinflammatory cytokines.[79] IV cyclosporine has been shown to be effective in the short term in patients with acute severe colitis.[123] The major problem with the drug is that although short-term improvement may be achieved, long-term maintenance with the oral form of the drug produces excessive side effects.[123] Side effects and toxicity of treatment with cyclosporine include electrolyte abnormalities, seizures, paresthesias, hypertrichosis, nephrotoxicity, hypertension, tremors, and headaches, which can occur in up to 60% of patients treated.[79] Fatal opportunistic infections have been reported with the use of this agent; therefore, the risks of cyclosporine therapy must be weighed against the benefits on a case-by-case basis.

Infliximab and Other Biological Therapies

It would not be an exaggeration to state that the availability of infliximab (Remicade), a chimeric monoclonal antibody to TNF-α, has significantly altered the way gastroenterologists treat steroid-dependent, steroid-refractory, and fistulizing Crohn's disease. Randomized trials have established that infliximab is effective for inducing and maintaining remission of Crohn's disease in patients who failed to respond to conventional therapy[124,125] and that the antibody significantly reduces the number of open, draining perianal and enterocutaneous fistulas and maintains this response.[126,127] Endoscopic studies suggest that infliximab is associated with a significant reduction in endoscopic activity of Crohn's disease and in some cases is associated with complete mucosal healing.[128] Patients receiving infliximab on a regularly scheduled basis appear significantly less likely to require hospitalization and surgery.[129,130] Recent trials in patients with moderate to severe UC also demonstrated efficacy,[131,132] and infliximab was recently approved by the FDA for reducing signs and symptoms, achieving clinical remission and mucosal healing, and eliminating corticosteroid use in those with moderately to severely active UC who have not responded to conventional therapy.

The typical starting dose of infliximab is an infusion of 5 mg/kg body weight over a 2- to 4-hour period. A three-dose induction is administered at 0, 2, and 6 weeks, and maintenance doses are administered every 8 weeks thereafter. The chimeric nature of the molecule results in significant immunogenicity, and improper administration of the drug may result in the formation of antibodies to infliximab, which are associated with infusion reactions and, more important, a loss of response to the drug over time.[133] For this reason, maintenance use (and

not episodic use) of the drug is strongly recommended. Many physicians routinely coadminister a concomitant immunosuppressive such as azathioprine, 6-mercaptopurine, or methotrexate because there is considerable evidence that this will further reduce the risk of antibody formation.[133] Some physicians also administer corticosteroids as IV premedication to reduce antibody formation on the basis of a randomized trial.[134]

Adverse events following infliximab therapy have included serious (and sometimes fatal) infections including tuberculosis, histoplasmosis, coccidiomycosis, listeriosis, and *Pneumocystis carinii* pneumonia.[79] Hepatotoxicity, worsening of congestive heart failure, serious hematologic events, demyelinating disorders (e.g., multiple sclerosis and optic neuritis), and malignancies (lymphoma, lung malignancies) have been reported following the use of the drug. As with all immunosuppressive agents, the potential benefits of infliximab need to be weighed against the possible risks, but with proper selection of patients the risks appear manageable.[135]

Other anti-TNF agents have been studied in IBD. Etanercept (Enbrel) did not demonstrate efficacy in Crohn's disease.[136] Adalimumab (Humira) is a fully human antibody to TNF that has demonstrated efficacy in Crohn's disease in several randomized and open-label trials.[137-141] This drug is administered subcutaneously every 1 to 2 weeks and is already commercially available in the United States for treatment of rheumatoid arthritis. Certolizumab pegol (formerly known as CDP870) is a humanized Fab TNF antibody fragment that has been "PEG-ylated" (i.e., attached to a polyethylene glycol [PEG] molecule) to improve the half-life of the drug. Randomized trials have also demonstrated efficacy for this agent in Crohn's disease with once-monthly subcutaneous dosing.[142]

Other biological therapies that are being actively investigated for IBD include natalizumab (Tysabri), a monoclonal antibody to the adhesion molecule α_4 integrin[143]; MLN-02, an antibody to α_4/β_7 integrin, which may have more gut specificity[144]; antibodies to IL-12[145]; visilizumab, a non–Fc receptor-binding anti-CD3 antibody[146]; and fontolizumab, an antibody to INF-γ.[147]

SURGICAL CONSIDERATIONS IN INFLAMMATORY BOWEL DISEASE

Surgical intervention in IBD patients is primarily reserved for patients with disease complications or for those who have failed to respond to medical therapy to control symptoms of the disease. Depending on the underlying disease process, surgery may be curative for the intestinal manifestations of the disease, as is seen with UC, or as an adjunct to medical therapy in controlling symptoms or as treatment of disease complications, as is often the case in Crohn's disease. No matter the surgical indication, good communication between the treating gastroenterologist and surgeon is extremely important. The surgeon must be aware of the history of the patient's medical therapy, the current specific treatment objective, and possible future therapies that might influence the surgical decision making. In the following section, we briefly discuss the indications, surgical approaches, and reported outcomes of surgical intervention in UC and Crohn's disease. We also discuss the role of laparoscopy in the surgical management of both diseases.

Surgical Management of Ulcerative Colitis

The surgical approach to patients with UC can be divided into two broad categories: emergent and elective surgical intervention. Indications for emergent intervention in UC include fulminant colitis, toxic megacolon, colonic perforation, and massive hemorrhage. Fortunately, with better understanding of the disease and improved medical treatments, these situations arise less frequently, but even today approximately 10% of newly diagnosed UC patients present with fulminant colitis. In these emergent situations, the goal of the surgical procedure is to address a life-threatening clinical situation without precluding a future restorative procedure. In nearly all emergent situations, there is no role for proceeding with a rectal dissection because this is time-consuming, increases the complexity of the surgery, and makes possible future ileal pouch reconstruction extremely difficult. In a patient with known UC or indeterminate colitis who requires emergent operation for a complication related to their colonic disease, the procedure of choice is the subtotal colectomy with end ileostomy. This procedure removes most of the diseased organ but leaves the rectum in situ and avoids any disturbance to the important dissection planes in the pelvis. This approach addresses the complication that prompted surgical intervention and also allows the patient to improve their overall health and nutritional status and to transition off medications such as corticosteroids. The patient can then proceed at a later date to a restorative or definitive operation without any deleterious impact on the functional outcomes. If the rectal disease does become troublesome, it can usually be managed with topical corticosteroids or mesalamine. Until recently, emergent subtotal colectomies were considered a contraindication to a laparoscopic approach. However, it has recently been shown to be equally effective and safe in an experienced surgeon's hands and to provide some patient benefits related to recovery.[148] The more common situation in the UC patient is to address electively the failure of medical therapy to control disease symptoms, long-term deleterious side effects of medications, or the development of intestinal dysplasia or cancer.

As discussed more fully in Chapter 152, the currently accepted surgical approaches to treating UC are total proctocolectomy with end ileostomy or total proctocolectomy with ileal pouch–anal anastomosis (IPAA). Both operations cure the patient of the intestinal manifestations of the disease. However, the IPAA avoids the requirement for a permanent ileostomy. Parks and Nicholls first described the IPAA procedure in 1978.[149] IPAA is an ideal operation for the treatment of UC because it removes the entire diseased organ while simultaneously preserving the normal anatomic route for

defecation.[150] Construction of the ileal pouch is the key to the success of this operation, since it provides an adequate fecal reservoir to allow voluntary defecation, albeit at a higher but manageable daily frequency than patients with a normal rectum. The decision to proceed with an operation other than IPAA for UC is based on individual patient circumstances or preexisting medical or physiologic conditions that are considered contraindications for this type of restorative procedure. Previously, "advanced age" (i.e., age >50 years) was considered a contraindication; however, a recent publication suggested that chronologic age itself should not be considered a contraindication because many older patients seem to have quite comparable surgical and functional outcomes relative to younger patients.[151]

Details of the IPAA procedure are beyond the scope of this chapter and are discussed more fully in Chapter 152. Although each surgeon might have slightly different ways of performing the operation, the operation basically involves the following four steps:

1. Removal of the intra-abdominal colon
2. Dissection and removal of the rectum, sparing the pelvic nerves and the anal sphincter mechanism
3. Construction of an ileal reservoir
4. Anastomosis of the ileal reservoir to the anal canal

Even though a large number of surgeons and institutions have reported their experience with IPAA procedure, the functional results are quite similar.[152-157] Most patients report good to excellent function with their ileal pouch. In a Mayo Clinic series of more than 1300 IPAAs, the average number of daytime bowel movements at the time of discharge after closure of the ileostomy was six per day, and the average number of nocturnal bowel movements was one per night.[152,153] During the day, 79% of patients reported complete continence, 19% had occasional incontinence and 2% had frequent episodes of incontinence. During the night, 59% of patients had no incontinence whatsoever, whereas 49% reported occasional nocturnal incontinence. A recent report of patients from this cohort who were followed for more than 15 years showed that pouch function is relatively stable over time, with no real significant decline in functional parameters, except for an increase in episodes for both day and nocturnal incontinence.[158] Although it would appear at first glance that these functional changes might result in a decline in satisfaction with the outcome of the surgery, the patients reported no such decline.

Although the functional results of the surgery are fairly well described and are consistent among the many reported series, it is unclear if patient quality of life (QoL) is consistently improved by the IPAA.[159] Most patients report a high degree of satisfaction with the functional result from their IPAA. Fazio and colleagues have shown that the QoL after IPAA is comparable to the norms for the general healthy U.S. population.[160] Most QoL assessments of these patients are confounded by the differential impact on QoL of the removal of the diseased bowel with respect to overall health, the ability to discontinue medications, and the ability to voluntarily control stools. The literature contains conflicting reports on this point. Some authors report improved QoL after IPAA compared to end or continent ileostomy,[161-163] whereas others have shown that QoL improves no matter what procedure is performed and is probably due to eradication of the disease.[164-166] In a recent report using specific and generic QoL questionnaires and a survey instrument that estimated the monetary value for continuing disability related to the surgical procedure, they found that the patients with an IPAA had much better body image compared to patients with a Brooke or Kock ileostomy.[167] However, all patients assigned an equal monetary value to the disability associated with each operation. The IPAA patients actually reported altered bowel emptying function as more disabling than patients with stomas. The findings in the literature would suggest that the currently available instruments to measure QoL might not be sensitive or specific enough to detect the many facets of a patient's QoL after a period of prolonged illness and possibly multiple surgeries.

Although there are a few technical issues related to the IPAA procedure that are still debated, such as hand-sewn versus double-stapled anastomosis, or the role of a temporary ileostomy, the most recent advance related to the procedure is the role of laparoscopic surgery. As surgeons have become more familiar with laparoscopic colorectal surgery, and newer instrumentation has been developed specifically for complex laparoscopic colorectal surgery, an increasing number of institutions have reported their results with laparoscopic IPAA.[168,169] A number of different laparoscopic techniques have been described, including purely laparoscopic, a combined laparoscopic mini-laparotomy, or a hand-assisted laparoscopic technique. These reports have presented small series of patients and have demonstrated fairly similar perioperative complication rates and short-term functional outcomes as compared to traditional open techniques. Although laparoscopic IPAA surgeries usually have longer operative times compared to open procedures, they usually result in shorter postoperative lengths of stay, decreased postoperative narcotic use, and improved cosmesis. In the only reported long-term matched case-control study of laparoscopic versus open IPAA, there were no long-term functional or QoL differences between the two surgical modalities.[170] Aside from the technical challenge associated with performing this complex procedure laparoscopically, there is no reason to believe that it is not equivalent to the traditional open surgery and that it might provide some substantial benefits to the patient.

Surgical Management of Crohn's Disease

Unlike UC, where surgery can be considered curative for the intestinal manifestations of the disease, surgery in Crohn's disease is directed at relieving symptoms or complications of the disease. Surgery should only be considered once maximal medical therapy has failed in controlling symptoms of Crohn's disease, to treat complications of the disease that prevent the initiation of medical therapy, or to treat emergent conditions. Because Crohn's disease can manifest itself anywhere along the intestinal tract, the location of disease and the

indications requiring surgery are numerous. However, in the most general terms, surgical intervention for abdominal Crohn's disease is directed at three areas: relief of obstruction, treatment of intestinal fistulas, or treatment of medically refractory disease. Less frequent indications for surgery include addressing free perforations and cancer. An essential component of treating Crohn's disease patients is a close collaboration between the treating gastroenterologist and the surgeon. A thorough review of the patient's medical options and planned postoperative medical follow-up and treatment schedule needs to be considered during the surgical planning. Finally, surgical planning should always be directed at performing the minimal amount of surgery to resolve the problem. Given the recurring nature of Crohn's disease, surgical resection of the intestine, especially the small intestine, needs to be minimized to avoid the possible complications related to short bowel syndrome.

As previously noted, the main indications for surgical intervention in the treatment of abdominal Crohn's disease are relief of obstruction, treatment of intestinal fistulas, or treatment of medically refractory disease. These different indications seem to be influenced by the site of primary disease activity. In a review of patients who underwent surgery at Cleveland Clinic, bowel obstruction and internal fistula or an abscess tended to be the most common reasons for surgery in patients with small bowel disease. The indications for surgery in 127 patients with colonic disease were poor response to medical care (25%), internal fistula and abscess (23%), toxic megacolon (20%), perianal disease (19%), and intestinal obstruction (12%).[171] A detailed discussion of the specific indications and surgical treatment options for Crohn's disease patients is presented in Chapter 153. Important to the discussion of the surgical treatment of abdominal Crohn's disease is a consideration of the natural history after surgery. Surgery is rarely curative, with nearly 60% to 80% of patients with Crohn's disease developing endoscopic recurrence by 1 year after surgery, 10% to 20% experiencing clinical relapse, and 5% developing recurrence that requires repeat surgical intervention.[172,173] The impact of the standard use of immunosuppressives (azathioprine and 6-mercaptopurine) to reduce the need for surgery or recurrence after surgery in Crohn's disease patients is not clearly understood. A recent French report could not demonstrate a significant decline in the risk of intestinal complications or the need for surgery in patients who had been treated with immunosuppressive agents.[174] The role of the new biological agents, such as infliximab, in slowing the progression of disease to the point that it would not require surgery, or reducing the incidence of recurrence after surgery, is not clear at this time. Large well-designed and well-powered clinical trials need to be performed to test the efficacy of these novel but expensive agents before they become routinely recommended as agents that can change the need for or prevent a clinical recurrence of the disease that requires surgery.[175]

Although abdominal complications of Crohn's disease can be challenging to treat, the surgical decision making is often fairly straightforward; however, treatment of perianal Crohn's disease can be quite difficult for both the patient and treating physician. The dreaded end result of unsuccessful treatment can lead to removal of the entire rectum and anus and the need for a permanent ostomy. As in treatment strategies for proximal intestinal Crohn's disease, judicious surgery combined with maximal medical therapy with an eye toward symptomatic disease control as opposed to disease eradication needs to be the therapeutic goal. The incidence of perianal involvement has been reported to range from 13% to 43% of patients with Crohn's disease.[68,176,177] Although the manifestations of perianal Crohn's disease are numerous, encompassing enlarged anal tags to complex abscesses and fistulas, the most difficult problem to manage is fistulas. Before embarking on treatment of perianal Crohn's disease fistulas, it is important to ensure that any abscess that might be perpetuating the fistula is adequately drained. It is not uncommon to have both abscess and fistula occurring either simultaneously or close in time. As the complexity of the fistula tract increases, the higher the likelihood of a persistent abscess.[178]

The most important component of treatment is evaluating the perineum and determining the anatomy of the fistula. Traditionally, an examination under anesthesia has been the mainstay of determining the perianal anatomy. However, advanced radiographic imaging modalities have demonstrated good success in determining the path of anal fistulas. In a study in which each patient had anal endoscopic ultrasound, pelvic magnetic resonance imaging (MRI), and surgical examination under anesthesia, the anal ultrasound was found to be more sensitive in determining the extent and course of anal fistulas than MRI and equivalent to surgical evaluation.[179]

Once the fistula tract is identified, primary surgical management should be directed at controlling any septic process associated with the fistula. Once any local sepsis is drained, a minimalist approach to further surgery should be considered. As discussed in greater detail in Chapter 153, liberal use of draining setons to maintain adequate drainage of the tract should be encouraged for all but the most superficial fistulas. Surgical drainage combined with maximal medical therapy including infliximab has dramatically improved treatment outcomes for this difficult problem. In a recent report by Talbot and colleagues, combined infliximab and surgery for complex perianal Crohn's fistula disease resulted in complete resolution of the disease in 47% of patients and marked improvement in all of the remaining patients.[180] Essential to the successful treatment of perianal Crohn's disease is bringing under control rectal and more proximal disease. Failure to control the rectal disease leads to a much higher rate of proctectomy and permanent ileostomy than in patients whose proximal and rectal disease is improved. If perianal disease continues and is symptomatic, proctectomy may be necessary. Before a proctectomy is performed, it is important that the patient be in optimal medical condition, because this operation is associated with relatively high morbidity rates. Preoperative measures to decrease local sepsis and improve healing should be undertaken, including improved control of local sepsis, maximal nutritional supplemen-

tation, and decreasing corticosteroid use if possible. To decrease local sepsis and improve the patient's overall medical condition, a staged procedure may be planned by performing an initial subtotal colectomy and ileostomy or ileostomy alone. Overall, the successful management of perianal Crohn's disease, just as treatment of Crohn's disease elsewhere in the intestine, requires close collaboration with the treating gastroenterologist to ensure that appropriate maximal medical therapy is being administered. Furthermore, a conservative surgical approach, to improve the patient's symptoms and not with the goal of eradicating the disease, should be employed.

QUALITY OF LIFE IN INFLAMMATORY BOWEL DISEASE

IBD is a chronic disease that profoundly impacts the patient's daily QoL. Many of patients are diagnosed in their early adulthood, which means that they will require chronic medical attention, medication use, frequent surgeries, or live with the after-effects of surgical treatment for the remainder of their lives. A patient's health-related QoL (HR-QoL) comprises three general domains: physical, social, and psychological.[181] Although many generic HR-QoL instruments exist that are useful for measurements across all diseases and medical intervention, they evaluate the three health domains in general terms. The most commonly used validated disease-specific QoL instrument for IBD patients is the Inflammatory Bowel Disease Questionnaire (IBDQ) developed by Guyatt,[182] Irvine,[183] and their associates.

Chronic medical conditions have been linked to increased psychological distress in numerous community and clinical studies.[184,185] Overall, patients with IBD demonstrate a higher degree of psychological distress compared to healthy controls.[186] Not surprisingly, the level of distress correlates with the level of disease activity.[186,187] Also, nearly all studies have shown that patients with Crohn's disease have more psychological distress and, in general, worse QoL than patients with UC.[187] In a large population-based study in Sweden using both a generic HR-QoL instrument (the SF-36) and the IBDQ, the authors found that UC patients reported superior QoL in all dimensions of health-related and disease-specific QoL than did patients with Crohn's disease.[188] The latter reported more anxiety and depression, which was directly related to the severity of their symptoms. Having an ileostomy in either the Crohn's disease or UC patient groups was not associated with a negative impact on QoL. However, among UC patients with either an ileostomy or an IPAA, there was overall better QoL in those patients with an ileostomy, due to better physical function, emotional function, and fewer bowel-related symptoms. This finding differs from many other studies that have shown that patients with a properly functioning IPAA reported a HR-QoL comparable to the general public.[189]

An important issue to consider when discussing QoL measurement in patients with IBD is the difficulty in comparing how the interaction of medical and surgical therapy affects QoL. For example, in Crohn's disease surgical therapy often is reserved for patients who have progressive symptoms or complications in spite of medical therapy. In this setting a comparison of patients with medically controlled disease to those who undergo surgery might demonstrate a negative impact on QoL due to surgery. However, the confounder is that those patients that underwent surgery were in general sicker or had a more chronic course of their disease. Similarly, it is difficult to compare UC patients on chronic medical management for UC to those that underwent surgery. Patients who are on chronic medical therapy even with good symptom control perceive themselves as having a chronic disease, whereas patients who have undergone surgery are cured of the intestinal manifestations of the disease but now have altered bowel function. In general, QoL assessments in both Crohn's disease and UC patients have shown that the most important predictor of good or improved QoL is directly related to the severity of symptoms and the success of interventions that control patient symptoms.

SUMMARY

IBDs, which are broadly divided into Crohn's disease and chronic UC, are notable for relapsing disease activity. In most cases, initial management is directed at symptom control using medical management. Current medical therapy includes a broad array of options including agents directed at local control of the inflammatory process, immunosuppressive agents, and monoclonal antibodies directed at specific inflammatory mediators. Surgical interventions in Crohn's disease should be directed at controlling complications from the disease that are unresponsive to maximal medical therapy. Although surgery for UC can cure the intestinal manifestations of the disease, it often requires a staged approach associated with significant morbidity and change in lifestyle. For IBD patients, the most important contributor to a patient's QoL is controlling the disease symptoms. To achieve this goal, there needs to be a coordinated treatment approach between gastroenterologists and surgeons to ensure that complementary medical and surgical interventions are instituted directed at achieving long-term control of disease symptoms.

Surgery for Inflammatory Bowel Disease: Chronic Ulcerative Colitis

Peter M. Sagar ▪ John H. Pemberton

The optimal surgical procedure for most patients with chronic ulcerative colitis (CUC) is ileal pouch–anal anastomosis (IPAA).[1] Patients with CUC need no longer live with the fear that their ultimate surgical fate is to be a permanent ileostomy with its attendant psychological, social, physical, and sexual problems. Indeed, IPAA confers a good quality of life. The principal aim of this chapter is to review the technical details of IPAA and the available choices of ileal pouch and ileoanal anastomosis, as well as the complications and their sequelae. Alternative procedures will also be discussed.

INDICATIONS FOR SURGERY

Indications for surgery can be divided into two major types: elective and emergency.

Indications for Elective Surgery

Failure of Medical Therapy

Patients with CUC may require surgery either because they have failed to respond to medical therapy or because the complications of the medical therapy outweigh its benefits. CUC can cause debilitating symptoms and lead to a poor quality of life despite appropriate medical treatment. Persistent anemia, undernutrition, and protein-losing enteropathy should prompt consideration of surgical intervention. Close consultation between the patient, gastroenterologist, and surgeon is important. Careful explanations of the long-term side effects and implications of medical therapy and the risks, benefits, goals, and alternatives of the surgical options need to be given.

Presence of Cancer and Dysplasia

Cancer complicating long-standing colitis is an obvious indication for surgery. Patients with ulcerative colitis for more than 10 to 15 years have a well-recognized increased risk for cancer. Those with sclerosing cholangitis as a complication of ulcerative colitis seem to have a particularly high incidence.[2] Colonoscopic surveillance is recommended in patients with long-standing ulcerative colitis. The development of an obstructing lesion, dysplasia, or a dysplasia-associated lesion of the mucosa is an indication for surgery.

Indications for Emergency Surgery

Fulminant Colitis

Patients with a severe attack of ulcerative colitis should be resuscitated and treated medically. Deterioration of the patient's condition or failure to improve within 5 days is an indication for surgical intervention. In an ill patient, intervention should take the form of emergency total colectomy with preservation of the rectum and an end ileostomy. The rectal stump may be oversewn or brought up to the abdominal wall as a mucus fistula.

Toxic Megacolon

Toxic megacolon is a life-threatening condition. Although it may occur as an acute exacerbation of the disease, it is an initial manifestation in most patients. There is segmental or total dilatation of the colon. Patients are very ill with high fever, abdominal pain and tenderness, tachycardia, and leukocytosis. Prompt resuscitation and medical therapy are essential, along with early recourse to resection.

Hemorrhage, Perforation, and Obstruction

Massive hemorrhage is uncommon and accounts for up to 10% of emergency colectomies in patients with CUC.[3] Perforation of the colon is a clear indication for surgery. If it occurs in the absence of megacolon, the possibility of Crohn's disease should be raised. High doses of steroids mask the symptoms and signs. Strictures in patients with CUC are rare unless a carcinoma has developed.

ILEAL POUCH–ANAL ANASTOMOSIS

Overview of the Operation

The operation is usually performed in two stages.[4] First, the cecum, colon, and rectum are mobilized and removed. Care is taken to preserve the pelvic nerves. The ileum is preserved in its entirety. A reservoir (ileal pouch) is constructed from 30 to 44 cm of distal ileum and anastomosed to the anal canal at or just above the dentate line. IPAA can be performed with sutures or stapling instruments and with or without transanal rectal mucosectomy. A temporary ileostomy is used to protect the pouch and anastomosis. The ileostomy is closed 8 to 12 weeks later. IPAA removes all diseased tissue and yet maintains normal bowel function and fecal continence. As experience has been acquired with the procedure, the technique has been simplified, which has led to improved outcomes. Quality of life in patients with a pelvic ileal reservoir is better than that of patients with Brooke ileostomies, continent Kock ileostomies, and medically treated colitis.[5,6]

Laparoscopic Ileal Pouch–Anal Anastomosis

Techniques for laparoscopic colectomy have been developed and now provide an adjunct to traditional operative modalities for colonic surgery. The use of these techniques has expanded, and they have been applied to the performance of IPAA. Laparoscopic surgery appeals to patients undergoing IPAA because they are generally young and hope to gain the potential benefit of reduced disability, more rapid recovery, and a better body image as a result of more cosmetic incisions. Most reports have consisted of relatively small series and have tended to avoid patients with a body mass index greater than 30, toxic megacolon, or treatment with high-dose steroids. The best laparoscopic technique to use, be it laparoscopically assisted[7-10] or hand assisted,[11,12] is presently the subject of intense debate.

Operative Technique

The patient is placed in the dorsolithotomy position with Allen stirrups and minimal hip flexion (Fig. 152–1). A 12-mm port is placed at the umbilicus, and pneumoperitoneum is initiated at 15 mm Hg. A 10-mm, 30-degree laparoscope is used throughout. Additional ports are placed at the lateral edge of the rectus sheath: a 12-mm port at the site of the temporary ileostomy, a 5-mm port at the lateral edge of the future Pfannenstiel incision, a 5-mm suprapubic port, and a 5-mm left upper quadrant port. With the patient in a steep reverse Trendelenburg position and rotated to the right, the dissection begins at the left lower quadrant. The colon is retracted with atraumatic graspers and mobilized with a harmonic scalpel up to the splenic flexure. The patient is then rotated to the left and the ascending colon is mobilized similarly. The omentum is retracted in a cephalad direction and mobilized from the colon, again with the harmonic scalpel. The transverse mesocolon is approached from either side and divided with the harmonic scalpel, and the major mesenteric vessels are ligated with clips. With the patient then in a steep Trendelenburg position, the presacral space is entered and the dissection continued to the pelvic floor while avoiding damage to the autonomic nerves and ureters. A 6-cm Pfannenstiel incision is used to complete the mobilization of the lower portion of the rectum, and the rectum is transected at the anorectal junction with a linear stapler. The ileal pouch is then constructed through the Pfannenstiel incision after securing the anvil of a circular stapler within the pouch with interrupted sutures. The IPAA is then constructed with a double-staple technique. A suitable loop of ileum is identified for the diverting loop ileostomy at the right midquadrant trocar site.[13]

Alternatively, laparoscopic proctocolectomy can be accomplished with a hand-assisted technique. Here, a 7- to 8-cm Pfannenstiel or low midline incision is made at

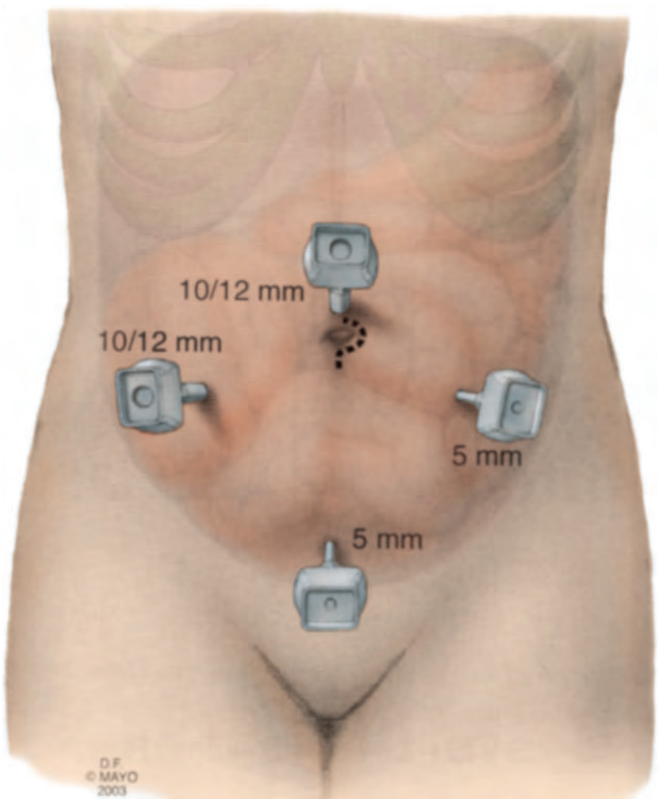

Figure 152–1. Laparoscopic ileal pouch–anal anastomosis.

the start of the operation through which the hand port is placed. Two or three additional trocars are used, one 5 or 10 mm above the umbilicus (laparoscope), a 5-mm port in the epigastrium (for dissection), and a 12-mm trocar in the lower left quadrant (for dissection, stapling, and clipping). A randomized trial that compared 30 patients after hand-assisted laparoscopic IPAA with 30 patients after open IPAA by measuring postoperative recovery and quality of life in the 3 months after surgery found no difference between the two procedures in quality of life at 3 months after surgery. Operative times were longer in the laparoscopic group than in the open group (210 versus 133 minutes, $P < .001$). No significant differences were found in morphine requirements, morbidity, or postoperative hospital stay between the two groups. However, postoperative stays were quite long in both groups, and 10% of patients required a reoperation. The median overall cost was 16,728 Euros for the hand-assisted laparoscopic procedure and 13,406 Euros for the open procedure.[14]

Laparoscopic IPAA is technically feasible and can be carried out within a reasonable time frame. It is safe. The operative technique will undoubtedly undergo modification, and operating times will decrease as laparoscopic surgeons become more experienced with the technique. Concern about operative cost needs to be balanced with earlier return to work and economic benefit to the community. Furthermore, maintenance of the integrity of the abdominal wall may also benefit patients by reducing long-term disability, including the development of incisional hernias and late interventions for adhesions. Operative cost analysis alone should not condemn laparoscopic surgery.

The functional outcome after laparoscopically assisted IPAA is no different from that after conventional IPAA. In a case-control study of 16 patients after laparoscopic IPAA, questionnaires were completed to assess functional outcome, quality of life, body image, and cosmesis. No differences were found in functional outcome and quality of life. Satisfaction with the cosmetic result was significantly higher in the laparoscopic group than in the conventional group.[15] Similarly, a case-control study of 20 patients who had undergone laparoscopic IPAA versus 20 open cases found significantly longer operative times, quicker return of bowel function, and shorter length of stay in laparoscopic versus open cases.[10] A case-matched series of 33 laparoscopically assisted and 33 open IPAA procedures reported a postoperative morbidity rate of 6% in the laparoscopic group versus 12% in the open group.[8] No differences were observed in functional outcome between the two groups, and quality of life was similar.

DESIGN OF THE ILEAL POUCH

The pelvic ileal reservoir may be constructed from two, three, or four limbs of distal ileum anastomosed in side-to-side fashion (Fig. 152–2).[16] There is no agreement regarding the ideal configuration, and there is little difference in functional outcome among the available designs of pouch. However, some pouches are easier to

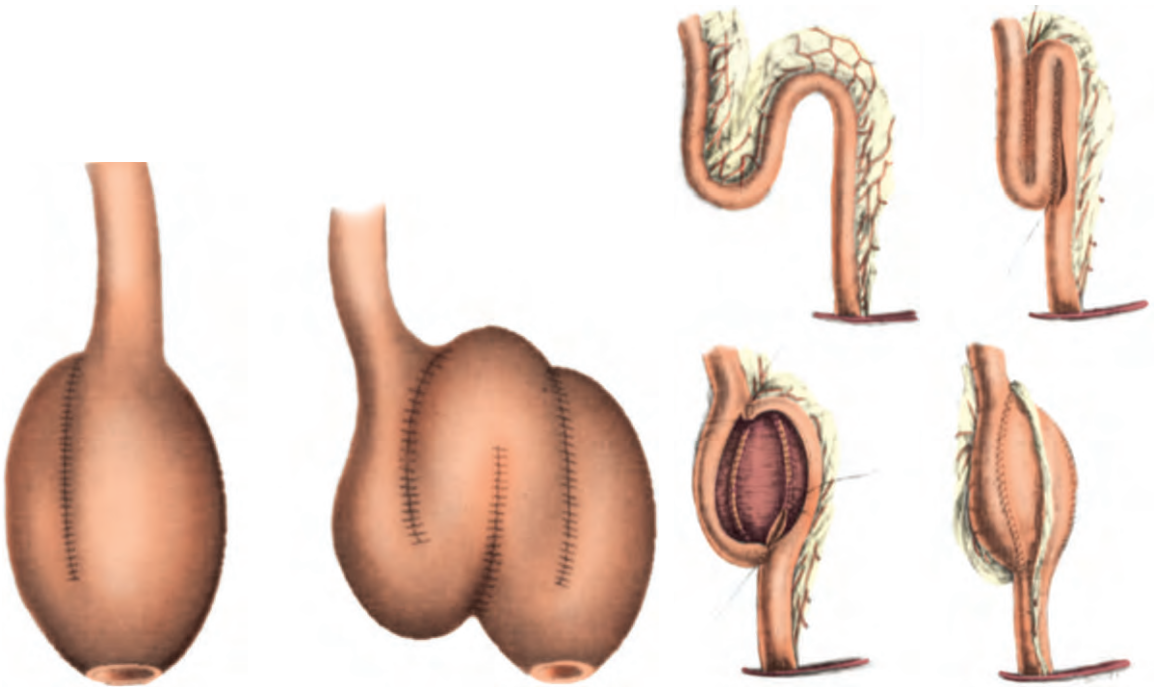

Figure 152–2. **A** and **B,** The pelvic ileal reservoir.

construct than others, and the patient's body habitus may influence the choice of pouch.

Three-Limbed Pelvic Ileal Reservoir—S Pouch

The S pouch was the first pelvic ileal reservoir to be described (see Fig. 152–2).[17] It was a modification of the reservoir originally described by Kock for use as a continent ileostomy[18] and was constructed from 30 cm of distal ileum. A 25-cm segment was opened along the antimesenteric border and folded three times, and the adjacent edges were sutured together. The most distal 5 cm was not incorporated into the reservoir but rather acted as an efferent conduit or spout. Unlike the Kock reservoir, there was no inverted nipple valve. Self-catheterization was needed to empty the pouch in four of the original five patients,[19] but this problem was largely overcome by reducing the length of the efferent spout and avoiding a long rectal muscular cuff. A long efferent limb (4 to 6 cm) would tend to impede evacuation because of acute angulation between the pouch and the efferent spout. The longer the limb, the more likely it was to angulate and hence obstruct.[20]

Although it is not widely used, the S pouch is of value in a patient in whom it is difficult to mobilize the ileum sufficiently to allow the apex of a conventional two-limbed pelvic ileal reservoir to reach the anal canal without tension. In this situation, the most distal part of the ileum can usually be made to reach low enough in the pelvis to allow construction of a tension-free anastomosis.

There is no firm rule with regard to the length of ileum used to construct the S pouch or, indeed, any pouch. After the initial descriptions, most S pouches have been constructed from three limbs of 15 cm of ileum. If too large a pouch is made, however, there is a tendency for it to become distended and atonic. Although such pouches may be both capacious and compliant, the tone of the muscular wall may be low, which can lead to stasis and incomplete evacuation. Furthermore, the efferent spout possesses peristaltic activity that is independent of the body of the ileal reservoir, and this may further impede emptying.[21] The S pouch can be constructed with no efferent spout. The distal end of the ileum is oversewn and an enterotomy made at the apex of the first and second loops at the most dependent part. The IPAA is constructed in side-to-end fashion between the most dependent part of the reservoir and the anal canal. Such construction permits spontaneous evacuation. Although the S pouch is usually hand-sutured, linear stapling instruments can be used with no increase in morbidity.[22]

The efficiency of evacuation of S pouches is less than that of J- and W-pouches, and a small minority of patients still need to self-catheterize.[23] Self-catheterization is not popular with patients because it is messy, time-consuming, and unpleasant.[24] Such pouches can be revised, particularly if the efferent limb is too long either because of the original construction or because the spout has lengthened with time after surgery. A small group of patients who have an efferent spout of only 1 cm at the time of surgery return with a 4- or 5-cm spout. Revision of the segment, without changing the configuration of the pouch, can restore satisfactory function.[25] Long efferent limbs may be shortened or excised, or the S pouch may be converted to a J pouch.[25] Resection of a long efferent limb and reanastomosis may be performed by means of a transanal approach, but the success rate is low.[26] Revision usually requires complete mobilization of the reservoir and its efferent conduit by a transabdominal approach, which can be a challenge. The ileoanal anastomosis is taken down and the entire efferent spout excised. The IPAA is then re-established. Most of the small number of patients who have undergone such revision surgery have been able to evacuate their reservoir spontaneously.[27] Alternatively, the septum between the pouch and the efferent limb may be divided transanally with the linear stapler,[28] or the efferent spout may be shortened by inserting a circular staple gun into the pouch and positioning it such that when the gun is closed, part of the efferent spout is trapped. When the gun is subsequently fired, the spout is shortened and the IPAA simultaneously re-created. Nevertheless, the difficulties of revision surgery on the IPAA must not be underestimated, and only about 50% of these patients will eventually have good function.[25]

Two-Limbed Pelvic Ileal Reservoir—J Pouch

The two-limbed J-shaped reservoir was introduced by Utsunomiya and colleagues[4] in 1980 (see Fig. 152–2) and is now by far the most popular pouch. The J pouch is constructed from a long side-to-side anastomosis along the antimesenteric border of the ileum with the limbs arranged in an iso-antiperistaltic fashion. The apex of the ileal loop that reaches to the level of the anal canal without tension is chosen to form the most dependent part of the reservoir. Transillumination of the mesentery helps identify the vessel arcades. The ileocecal artery may be divided to increase the mobility of the ileal mesentery. Reach may be increased by making windows in the ileal mesentery and scoring the peritoneum over the mesentery, although this may predispose to the development of hematomas. The length of the two limbs is variable and depends partly on the amount of fat in the ileal mesentery and the distribution of the ileal arcades. There is no difference in functional outcome between J pouches constructed from two 10-cm limbs or two 20-cm limbs.[29] The J-shaped reservoir is simple and quick to construct, particularly if linear stapling devices are used.

Despite the aforementioned maneuvers, difficulty may be experienced in allowing the apex of the ileal loop to reach down to the anal canal without tension. In this event, two further tactics are useful. First, an efferent limb may be constructed by division of the apex of the ileal loop. The two ileal limbs are then anastomosed in the usual iso-antiperistaltic fashion, with a 2-cm efferent spout emerging from the isoperistaltic limb (see Fig. 152–2). This design facilitates greater length of the reservoir and reduces the possibility of tension on the IPAA. Alternatively, the ileal loop may be divided at a point

proximal to the apex. An efferent spout is fashioned such that the ileal spout is positioned in an antiperistaltic manner, which may result in improved continence and reduced fecal leakage, although this might be outweighed by a tendency for the antiperistaltic efferent limb to impede evacuation. In practice, careful division of the ileocolic vessels will usually permit a tension-free anastomosis. Division of the visceral peritoneum on either side of the ileal mesentery allows the mesentery to stretch, but this can be risky because tension on the pouch as it is brought down to the anal canal may tear the terminal branches of the superior mesenteric arcades at the apex of the J, which are now unsupported by their protective mesentery. Generally, if the most dependent part of the pouch will reach to a level 5 to 6 cm below the upper border of the symphysis pubis, there is sufficient length to allow a tension-free anastomosis.

Quadruplicated Pelvic Ileal Reservoir—W Pouch

The quadruplicated or W pouch was introduced in 1985 in an attempt to answer the problems of incomplete evacuation of the S pouch and to improve the functional results obtained with the J pouch.[30,31] It was constructed from four 12-cm lengths of ileum that were sutured in a W arrangement.[32] The IPAA was created in side-to-end fashion between the most dependent part of the reservoir and the top of the anal canal.

The spheroidal design gives the greatest volume for a given length of ileum,[33] the pouch sits well within the confines of the pelvis, and the horizontal diameter of the W pouch is similar to that of the normal rectal ampulla.[34] One drawback, however, is that the bulky nature of this pouch can cause difficulty, especially in an obese male patient with a narrow pelvis. The design of the reservoir may be modified such that the distal two limbs are each 11 to 12 cm in length whereas the more proximal two limbs are 9 to 10 cm long (see Fig. 152–2). The reservoir is then effectively two J-shaped reservoirs anastomosed together but slightly offset. This arrangement allows the reservoir to sit more comfortably within the bony confines of the pelvis while maintaining its large capacity.

Comparative Studies of Pouch Design

There is an inverse relationship between the frequency of bowel movements and the volume of the reservoir. The volume of expansion, however, may be less in J pouches and W pouches than in S-shaped pouches, where outflow obstruction may lead to dilation of the reservoir.

A 2 × 2 prospective randomized trial that compared J and W pouches, as well as large and small pouches (2 × 20 versus 2 × 10 cm and 4 × 10 versus 4 × 15 cm), showed no statistically significant difference between the pouch designs; indeed, the smaller reservoirs in the study paradoxically seemed to offer slightly better functional outcome.[35] Improved results for the W pouch may be related to both the volume and the shape of the configuration. Studies of the influence of pouch design on function during the so-called maturation period after closure of the ileostomy have been conducted in a randomized setting in which 24 patients randomly assigned to J-pouch or W-pouch construction were studied at regular intervals in the 12 months after closure of the ileostomy. During the maturation period, the frequency of defecation decreased in both groups, but patients with a W reservoir had significantly lower values than did patients with a J reservoir. Similarly, both nighttime defecation and the use of antidiarrheal medication were significantly lower for patients with a W reservoir.[36]

Comparative studies have suggested that W pouches have some benefits over other designs of pouch in terms of capacity, compliance, and evacuation characteristics,[23,32] but prospective randomized studies have not shown a significant benefit in functional outcome.[37] Essentially, the few published prospective randomized studies that have compared the design of the ileal reservoir have failed to provide a convincing argument for surgeons to abandon the relatively quick and easy J pouch in favor of the W pouch, which tends to be hand-sutured and take much longer to construct than the stapled J pouch.

The J pouch has therefore become established as the most popular design of ileal reservoir.

FUNCTION OF THE ILEAL POUCH

Pouch Compliance and Capacity

The maximum tolerated capacity of the rectum is 300 to 400 ml.[38] At these volumes, intrarectal pressure rarely exceeds 15 to 20 cm H_2O, and compliance (rate of increase in pressure per unit increase in volume) is about 18 ml/cm H_2O. Compliance of the distal ileum is considerably lower, however, at 2 ml/cm H_2O.[39]

In contrast to the ileum, the capacity and compliance of ileal pouches differ little from those of a normal rectum. One study of 23 patients found the maximum capacity to be 320 ± 36 ml with a compliance of 14.7 ± 1.4 ml/cm H_2O.[38]

Ileal Motility

In terms of motor function, the principal difference between normal rectum and ileum is the response to distention. The rectum relaxes, whereas the ileum responds by contraction and forceful peristalsis. The rectum acts as a reservoir, whereas the ileum acts as a conduit.

Two types of motor waves are generated by the ileum—a low-amplitude (<10 mm Hg) phasic contraction of short duration (3 to 6 seconds) and a tonic contraction of longer duration (40 to 60 seconds) and large amplitude (>25 mm Hg). The frequency and amplitude of high-pressure waves increase after feeding[40] and are abolished by evacuation.[41] Tonic waves occur in response to ileal distention, and patients feel the need to evacuate. Both phasic and tonic waves are also seen in patients with Kock continent reservoirs, straight ileoanal anastomoses,[39] and pelvic ileal reservoirs.[42] Tonic waves are

generated in response to distention, and the volume required to provoke these high-pressure contractions is significantly less in a single-lumen ileum (30 ml) than in three-limbed pouches (322 ml). The ileal reservoir therefore acts more like a capacitance organ with the ability to distend without contraction before a significant volume has amassed, whereas a single-lumen ileum constantly attempts to clear its contents.

Propulsive peristaltic waves are seen in a single-lumen ileum even when not distended.[43] Although ileal reservoirs develop similar propulsive peristaltic waves, they occur only during distention of the reservoir when the filling pressure exceeds 20 cm H_2O. The frequency and amplitude of the peristaltic waves are proportional to the degree of distention. Measurement of myoelectrical activity confirms the motor findings, with uncoordinated activity being present in the ileal reservoir at rest. Myoelectrical spike activity becomes coordinated in the reservoir only in response to distention and produces coordinated propulsion.

As the pouch fills with effluent, high-pressure waves are produced. They are recognized by the patient as a desire to evacuate the pouch or as lower abdominal discomfort. They occur more frequently after meals and are largely abolished by evacuation of the pouch. The interval between onset of the high-pressure waves is directly related to the frequency of bowel action.[41] Therefore, the volume of distention at which high-pressure waves occur is a major determinant of stool frequency. The *threshold volume* at which high-pressure waves occur is related to stool frequency: the larger the threshold volume, the lower the frequency of bowel movements.[38] An increase in pressure within the lumen of the pouch is associated with increased resting anal canal pressure and rate of contraction.[44] The pressure gradient between the anal canal and pouch is less in incontinent patients, who have lower resting anal pressure, higher nocturnal pouch pressure, and larger-amplitude high-pressure waves in the pouch than continent pouch patients do.[45] The pressure gradient in the neorectal canal is frequently reversed in incontinent patients. These patients have lower resting anal pressure during sleep, and this lower pressure, together with marked variations in mean anal canal pressure, leads to incontinence. In a small minority of patients, high-pressure waves may be generated within the ileal wall at low volumes of distention. The amplitude of these waves may exceed that of resting anal pressure and thus may lead to seepage or soilage of the perineum.

Continuous manometric recordings at spaced intervals throughout the jejunoileum have demonstrated the presence of large-amplitude waves that propagate rapidly throughout the jejunum of patients who have undergone IPAA. Such waves are normally confined to the distal ileum of healthy individuals.[46] They have been shown to propel intestinal contents through canine ileum.[47] These waves may be a manifestation of increased storage and distention of the distal ileum.

The presence of a pouch influences proximal gut transit. Although gastric emptying is similar in patients with pouches, patients with Brooke ileostomies, and controls, small bowel transit of radiolabeled material was significantly longer in patients with pouches than in controls or those with Brooke ileostomies.[48]

The use of radiolabeled artificial stool has shown that as the ileal reservoir fills to its threshold volume and defecation is postponed, the pouch does not continue to distend, but rather there is retrograde reflux of up to 40% of the stool into the ileum immediately proximal to the reservoir. As this more proximal part of the ileum distends, high-pressure waves are generated that tend to propel the ileal contents back into the pouch. As the volume of distal ileal and pouch contents increases, the frequency and intensity of the high-pressure waves increase and will eventually produce abdominal discomfort and urgency of defecation.[38] Reflux of stool into the proximal ileum at the time of defecation does not appear to occur.[49]

Efficiency of Evacuation

The desire to evacuate the pouch occurs as it distends to the threshold volume. The time between one evacuation and the desire to evacuate again is influenced by a number of factors, such as capacity and compliance, the rate at which fecal contents reach the reservoir, and the completeness of evacuation. Most ileal reservoirs fail to empty as completely as normal rectum.[50,51] Nevertheless, studies with radiolabeled gel have shown that two-limbed pouches generally evacuated 60% to 70% of their contents.[41] The rate of evacuation of ileal pouches is about 11 ml of stool per second. In the absence of pouch dysfunction, the intrinsic motility of the pouch is not directly responsible for evacuation. The frequency of bowel action is directly correlated with the efficiency of evacuation. Thus, pouches that evacuate most efficiently result in the lowest frequency of bowel action.[38] Similarly, the slower the reservoir fills to its threshold volume, the lower the frequency of bowel movements and the volume of stool produced each day. This is one of the most important determinants of the frequency of bowel action.[38] Therefore, factors that either hasten filling of the reservoir or impede emptying promote earlier onset of reservoir contractions and lead to a greater frequency of defecation.

Postprandial Pouch Tone

Small intestinal motility is propagated into the ileal pouch, and this may influence pouch function. Both the tone of the pouch and motility have been shown to increase after a meal.[52] The extent to which pouch function is influenced by changes in pouch tone and motility induced by a meal has been studied with the electronic barostat. The electronic barostat is an ideal instrument to characterize not only the compliance and sensory characteristics of the pouch but also postprandial changes in pouch tone and motility. The electronic barostat used to distend the ileoanal pouch involves the use of a polyethylene bag tied to the end of a 19-French multilumen tube, and this catheter in turn is connected to the barostat. The barostat is able to induce distention at constant pressure (isobaric distention), and the

pressure is kept constant by electronic feedback regulation of the air volume within the bag.[53] A functional study of 19 patients with ileal pouches and either high stool frequency ($n = 8$) or adequate stool frequency ($n = 11$) were studied in this way. This comparative study found similar pouch compliance and sensitivity between the two groups of patients but demonstrated that postprandial pouch tone was increased significantly in patients with high stool frequency.[54] Many patients report the urge to defecate directly after a meal. Not only is pouch tone increased after a meal, but the increase in pouch tone also appears to be related to pouch function—the postprandial increase in pouch tone is greater in patients with poor pouch function than in patients with adequate pouch function. Therefore, in the absence of differences in pouch compliance, sensitivity, and 24-hour stool volume, the postprandial meal response may have an important influence on pouch function. The increase in pouch tone depends on the state of filling of the pouch. When the pouch is full, an increase in tone will increase pouch pressure. This results in urgency. If the pouch is empty, an increase in tone will reduce pouch volume. Therefore, it will be full earlier and the frequency of stool evacuation will increase.[54] Although there is a significant correlation between postprandial pouch tone and pouch function, the correlation between pouch compliance and pouch function is less strong, thus implying that the clinical significance of postprandial pouch tone may be greater than that of pouch compliance in patients with ileal reservoirs. Reports of rupture of J reservoirs after the rapid consumption of high-calorie, high-fiber meals support this hypothesis and suggest that the meal response can lead to serious complications.[55]

Ecology of the Pouch

The bacterial flora of pouches, together with their products of metabolism, especially volatile fatty acids, may have an important influence on the function of pouches. Major differences have been observed between the ecology of three- and four-limbed pouches.[23] Significantly greater numbers of bacteroides and concentrations of acetic, propionic, butyric, and valeric acid are seen in the effluent from three-limbed pouches than in the effluent from four-limbed pouches. The absolute numbers of bacteroides and bifidobacteria, the ratio of anaerobes to aerobes, and the concentrations of volatile fatty acids are also greater in the effluent from patients with pouches than in the effluent from patients who have undergone conventional panproctocolectomy with ileostomy. The flora of ileal reservoirs therefore more closely resembles that of the colon than normal ileum. There appears to be no correlation between the proportion of stool retained after defecation and the number of anaerobic bacteria.[56]

Volatile fatty acids may be beneficial to pouches. Within the colon they are the major substrate, and butyrate promotes sodium and hence water absorption.[57,58] Indeed, increased production of volatile fatty acids in experimental animals is associated with suppression of enteropathic bacteria.[59]

Functional Outcome

The choice of reservoir design is largely a question of personal preference and occasionally operative restraints. The decision is usually a compromise between the smaller-capacity, but easily constructed duplicated (J) pouch and the larger-capacity, but more time-consuming three-limbed or four-limbed pouches.[37]

Frequency of bowel action correlates inversely with the capacity of the reservoir.[38] The best results should therefore be obtained in patients with the largest reservoirs. However, huge reservoirs are associated with impaired contractility and poor evacuation, and several authors have noticed an improvement in bowel frequency with a decrease in size of the reservoir.[24,60]

Patients with a pouch pass about 600 to 700 ml of semiformed stool each day, which is about four times that of healthy controls with intact anorectums. Loperamide reduces intestinal motility and thus may improve intestinal absorption and reduce the volume of stool and the frequency of bowel action. Although dietary discretion and stool-bulking agents may decrease the urgency of defecation and perianal irritation by increasing stool consistency, these measures seem to have minimal effect on stool volume. Studies have shown little difference in the efficiency of evacuation of pouches according to the consistency of stool, which implies that measures to alter the consistency of stool will have no influence on pouch function.[61]

The frequency of bowel action has been shown to be significantly less in patients with three-limbed pouches than in those with two-limbed pouches[62,63] and significantly less in patients with four-limbed pouches than in those with either two- or three-limbed pouches.[30] However, the only prospective randomized trial that compared the functional results of duplicated (J) with quadruplicated (W) pouches failed to show any significant difference in the frequency of bowel action.[37] Compliance of the pouch is closely related to capacity: the larger the pouch, the greater the compliance. The correlation between frequency of bowel action and compliance of the reservoir is not, however, as strong as the correlation with capacity of the pouch. Larger reservoirs have lower contractility, which may lead to stasis and progressive dilation, particularly in the presence of a long efferent limb with its potential to impede evacuation.[21,50]

The perfect pouch has not been described. The choice of pouch design depends on the characteristics of the patient and the surgeon's preference. The functional outcome varies little between the basic options, and most patients will find that they will have bowel action between four and seven times per 24 hours with perhaps one nocturnal evacuation. They will experience a normal urge to defecate and will be able to defer defecation and to discriminate between flatus and feces.

THE ILEOANAL ANASTOMOSIS

The method used to construct the IPAA is debatable, and there are two options:

1. Transanal mucosal resection with a hand-sutured anastomosis between the pouch and the internal anal sphincter fashioned at the level of the dentate line[64]
2. Single- or double-stapled technique with construction of the IPAA at a slightly higher level[65]

An advantage of transanal mucosectomy is that all diseased mucosa is removed with no possibility of symptoms from residual diseased mucosa. The risk of cancer developing in the persistent rectal mucosa is eliminated. Resting anal pressure falls after IPAA, irrespective of the surgical technique used.[66] However, significant recovery of anal sphincter function, with a rise in resting anal pressure, return of the recto-anal inhibitory reflex, and improvement in clinical outcome, is seen to occur for at least 12 months after stapled IPAA.[67] Similar recovery may or may not occur after transanal mucosectomy.[64,68] Surgeons in favor of the double-stapled technique suggest that it is an easier operation with improved functional outcome. This latter point is debatable, however, because most reports of studies in which comparisons have been made between the two operative techniques have not been randomized and have included historical controls, which have invariably been taken from the learning curve of the surgeon's experience. The few randomized trials[69] and case-control studies[70] published to date, though small in numbers, show no functional differences.

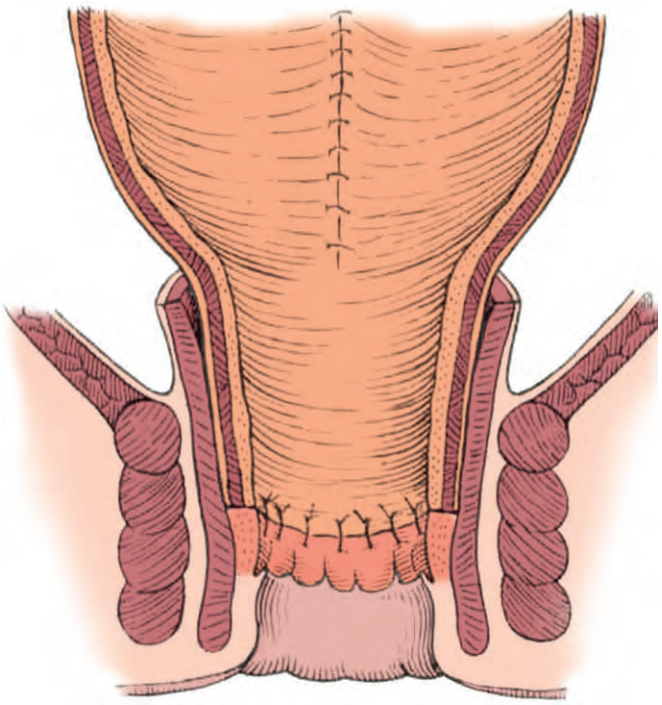

Figure 152–3. Ileal pouch–anal anastomosis with mucosal resection.

Transanal Mucosectomy

To preserve normal rectal sensation, it was long thought necessary to preserve a long muscular cuff of rectum. Preservation of a 10- to 12-cm rectal cuff denuded of its mucosa was very tedious and difficult, especially in the presence of severe disease, and it often required a combination of both abdominal and transanal dissection. Transanal mucosal resection required a long period of anal retraction, which was associated with significant functional impairment of the anal sphincter,[66] although this problem was minimized if the amount of anal retraction was reduced.[71] Extensive rectal mucosectomy was also associated with a high incidence of postoperative pelvic sepsis in the form of cuff abscesses despite meticulous hemostasis and drainage of the cuff space.[27] The realization that the sensation of rectal fullness and the need to evacuate were preserved in the absence of a rectum allowed the length of mucosal resection to be shortened significantly. Transanal mucosal resection is now carried out for a distance of only 3 to 4 cm and can be completed with minimal retraction on the anal sphincter, especially if a specifically designed ring retractor is used.

After the rectum has been fully mobilized to the pelvic floor, the surgeon moves to the perineum. With the patient in the modified Lloyd-Davies position, retraction hooks are placed circumferentially into the dentate line to splay the mucosa of the anal canal (Lone Star retractor, Lone Star Company, Texas). The submucosal plane is infiltrated with a solution of 1:100,000 epinephrine, and the mucosa is dissected off the underlying rectal wall with either scissors or diathermy. Dissection is continued to the level of the pelvic floor, at which point the muscularis is incised and the presacral space is entered. The rectum is fully divided at this level and the mucosectomy specimen retrieved through the anus. The pouch is then delivered into the pelvis and its apex brought down to the pelvic floor. An abdominal operator may insert four-quadrant sutures into the incised apex of the pouch, which are then passed in turn to the perineal operator to complete the IPAA (Fig. 152–3).

Single- or Double-Stapled Technique

This technique, in which either a purse-string suture is inserted into the anal stump or the anal stump is cross-stapled about 2 cm above the dentate line and a circular stapling device is inserted into the anal stump to perform the IPAA, has acquired wide popularity. The technical difficulties of transanal mucosal resection and hand-sutured IPAA are eliminated.

An early stimulus to the development of this procedure was the high incidence of nocturnal incontinence after mucosectomy and hand-sutured anastomosis. The anal transitional zone (ATZ) is richly innervated and seems to be important in the discrimination between flatus and feces.[72,73] Preservation of the ATZ improves anal sensation,[74] and several authors have demonstrated recovery of motor function of the anal sphincter.

The cecum, colon, and rectum are mobilized in the usual manner, with care taken to preserve the pelvic nerves. The rectum is mobilized fully to the pelvic floor

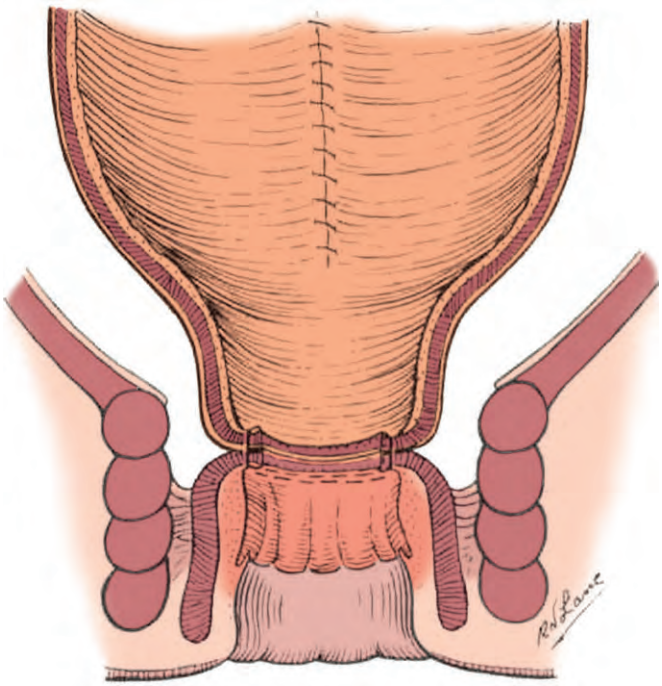

Figure 152–4. Double-stapled ileal pouch–anal anastomosis.

and a small (35-mm) linear cross-stapler is maneuvered into the lower portion of the pelvis. When the surgeon is confident that the stapler is in the correct position, which is confirmed by measuring the distance above the dentate line by insertion of a digit, the linear stapler is closed and fired. This leaves a stapled anal stump with the ATZ intact. A circular stapling device is then inserted into the anal stump and the central trocar advanced through the cross-staple line. The detached head of the gun, positioned within the ileal pouch, is manipulated into line with the shaft of the circular gun. The gun is closed and fired, and the double-stapled IPAA is complete (Fig. 152–4). Concern about the possibility of an anastomotic leak after stapling across a staple line (double-stapled technique) has led some surgeons to use a purse-string suture to close the anal stump around the shaft of the circular stapler (single-stapled technique).

The exact distance between the level of the ileoanal anastomosis and the dentate line may be critical in terms of functional outcome. A comparison of ileoanal anastomoses made at the dentate line, at the top of the anal columns of Morgagni, and at a level 1 cm above the columns showed the importance of this region in terms of fecal continence and fine control of defecation.[75] Construction of the ileoanal anastomosis at the dentate line was associated with a higher incidence of seepage and soilage than when the anastomosis was made at the top of the anal columns. If the anastomosis was made too far proximal, however, recurrence of disease was noted. It can be very difficult to accurately place the linear stapler, particularly if the patient is a thick-set male with a narrow pelvis. However, it remains surprising just how low the stapler can be placed, even in such large patients. Conversely, in a thin female with an accessible pelvis, the linear stapler may be positioned too low on the rectum such that the doughnuts of the stapling device may include part of the internal sphincter. To permit direct inspection of the upper border of the ATZ, the anorectum can be everted by fully mobilizing the rectum to the level of the upper anal canal. The rectum is then transected at midbody. Stay sutures are inserted into the lateral walls of the rectal stump and passed transanally to the perineal operator. Strong distal traction on the anorectum everts it through the anal canal and allows direct visualization of the ATZ and accurate placement of the cross-stapler. The residual rectal sleeve is then removed and the blind anal stump allowed back into the pelvis. The IPAA is then stapled into position in the usual manner.[76] This technique is more likely to result in a true IPAA than in an ileal pouch–rectostomy.

Despite full rectal mobilization, quite firm traction is required by the perineal operator to achieve complete eversion. Early reports of this technique suggested that the functional results of everted and noneverted ileoanal anastomoses were similar.[77] However, measurements of anal sphincter function have shown increased pudendal nerve latency times and blunted electrosensation after double-stapled IPAA with anorectal eversion.[78] This appears to result in some impairment in anal sensation and a greater tendency of patients to experience seepage than after conventional IPAA.

The Critical Level of the Ileal Pouch–Anal Anastomosis

The precise relationship between the level of the ileoanal anastomosis and the dentate line may be critical in terms of recurrence of disease and objective measurements of pouch and anal function. Preservation of the ATZ may be associated with a potential for the development of proctitis, dysplasia, and cancer. The upper border of the ATZ is irregular, with fingers of ATZ interdigitating with true rectal columnar mucosa. The rectal tongues may extend all the way down to the dentate line. Ulcerative colitis has been shown to be present within the transitional area in 90% of specimens resected by conventional proctocolectomy.[79] Mucosal columnar epithelial cells may remain within the ATZ in up to 20% of patients after mucosectomy.[80] However, mucosectomy does not guarantee elimination of the disease.[81] Indeed, the only reports to date of rectal cancer after restorative proctocolectomy have been in patients who had undergone mucosectomy with hand-sutured anastomoses and preservation of a rectal cuff.[82] Most patients with a stapled IPAA will have inflammation at the margin of the staple line.[83] The incidence of dysplasia in mucosal strippings from the anal stump was 2.5% in a series of 118 patients with ulcerative colitis.[84] A retrospective study of 254 patients who underwent restorative proctocolectomy for ulcerative colitis with a stapled IPAA revealed low-grade dysplasia in 8 patients (3.1%).[85] Neither high-grade dysplasia nor cancer was identified in the ATZ. However, biopsies of the ATZ taken 6 months later revealed dysplasia in two patients, in one of whom the

initial diagnosis was chronic ulcerative colitis with concurrent colon cancer (T3, N0, M0), whereas the other patient had CUC with concurrent high-grade dysplasia. Both subsequently underwent completion mucosal resection. Although the incidence of low-grade dysplasia in the ATZ is low after restorative proctocolectomy with stapled IPAA[85] and it remains to be determined whether low-grade dysplasia always progresses to high-grade dysplasia and cancer, it is probably wiser to perform total mucosectomy with a hand-sutured IPAA in patients with a preoperative diagnosis of concurrent colon carcinoma or dysplasia.

Resting anal pressure falls after restorative proctocolectomy irrespective of surgical technique. Factors other than simple traction on the sphincter have been implicated. Submucosal dissection may result in inadvertent dissection of the inner circular muscle fibers with consequent fibrosis.[86] Similarly, the submucosal neurologic plexus may be partially disrupted and the autonomic nervous supply to the anal sphincter may be injured. Extrinsic sympathetic nerves reach the anorectum from two sources: the presacral nerves, which form two nerve trunks and run along the lateral pelvic walls, and the inferior mesenteric nerves, which form a periarterial plexus around the inferior mesenteric and later the superior rectal arteries.[87] Although the presacral nerves can be easily identified at the pelvic brim and swept out of the operative field, their direct connections to the internal sphincter are at risk in the later stages of mobilization and division of the rectum. Division of the superior rectal artery and therefore the periarterial mesenteric nerves results in an immediate drop in resting anal pressure of about 20%.[88] Complete mobilization of the rectum and division at the anorectal junction also contribute to the fall in resting anal pressure. However, significant recovery in anal sphincter function, with a rise in resting anal pressure and improvement in clinical outcome, is seen to occur for at least 12 months after stapled restorative proctocolectomy.[67] Similar recovery has not been reported in patients after mucosectomy. Therefore, avoiding significant anal manipulation with the stapled technique provides better manometric results than transanal mucosectomy does.[89]

Any potential benefit in terms of functional outcome achieved by preservation of the ATZ must be balanced against the potential need for intervention if symptomatic inflammation or malignancy develops. The majority of patients who undergo restorative proctocolectomy are young adults. They are likely to require good anal sphincter function for many years, but conversely, any residual rectal mucosa will potentially have that long to undergo malignant degeneration. This may be dealt with by reoperation consisting of transanal dissection of the residual mucosa, disconnection of the IPAA, resection of any rectal cuff, and reanastomosis.[90]

Two Stage or One Stage: Use of a Diverting Ileostomy

Pelvic sepsis is the bête noire of IPAA. Postoperative leakage from either the pouch or the pouch-anal anastomosis leads to a high rate of eventual failure and excision of the pouch.[25,91] Concern about sepsis has meant that most surgeons use a temporary diverting ileostomy as a matter of routine to divert the intestinal contents away from the pouch and anastomosis until they have healed.

The temporary ileostomy is itself a potential source of morbidity.[92] Intestinal obstruction, before and after closure of the stoma, is more common in patients with a temporary ileostomy than in patients whose IPAA is completed as a one-stage procedure. Inevitably, the stoma is located more proximal than with a conventional ileostomy and is therefore more commonly associated with dehydration secondary to high stomal losses. The stoma may also be associated with peristomal skin breakdown, retraction, stenosis, and prolapse.

Several centers have presented the outcome of one-stage IPAA.[83,93-96] These studies suggest that a one-stage procedure is safe. Selection of patients is critical, however. An acutely unwell malnourished colitic patient taking high-dose steroids is not a candidate for a one-stage procedure. If a surgeon opts for a one-stage operation, even when all factors are favorable, a heavy burden is assumed. The surgeon must have a low threshold to reoperate if signs suggestive of pelvic peritonitis develop. Patients who undergo this one-stage procedure should (1) not be taking high-dose steroids, (2) undergo an uneventful operation, and (3) be in good general health. The postoperative course is more difficult for patients because they must adapt to the ileal reservoir at the same time as recovering from their operation.

A number of precautions can be taken to minimize the risk for complications after one-stage IPAA. The distal ileum should be irrigated with a solution of antibiotics before construction of the pouch. Likewise, the anorectum should be irrigated before division of the rectum, and a 24-French urinary catheter should be placed in the pouch and brought out through the anal canal to allow drainage of accumulated blood, mucus, and other secretions in the postoperative period.

There have been no randomized trials of sufficient power to adequately address the question of the advantages and disadvantages of one-stage versus two-stage IPAA.

Most centers perform the ileal pouch–anal anastomosis procedure with the use of a protective ileostomy, although reports continue to emerge of large series of patients operated on by one surgeon with relatively low complication rates.[97] It is, however, important to remember that reports of a single surgeon's experience may not always be extrapolated beyond that surgeon's practice. Most surgeons in institutions where randomized controlled trials are being carried out to compare the ileal pouch procedure with and without a diverting stoma continue to believe that they would rather deal with the complications associated with the ileostomy and its subsequent closure rather than deal with the potentially catastrophic complications of pelvic sepsis and failure of the pouch that may occur in patients without a diverting stoma.

MANAGEMENT OF POUCH-SPECIFIC POSTOPERATIVE COMPLICATIONS

Postoperative Hemorrhage

The linear stapling devices used to construct J pouches are not hemostatic. If marked bleeding is noted at the time of construction of the pouch, the pouch should be inverted and the bleeding points under-run. A large Foley catheter can be passed into the pouch for irrigation. Most bleeding will promptly stop. Sometimes the anal sphincter will retain blood in the pouch and obscure hemorrhage. Persistent bleeding warrants examination under anesthesia. Frequently, a single point of bleeding may be identified and controlled with diathermy coagulation or under-running with a suture, but more often bleeding of this extent is secondary to a disrupted suture line either in the pouch or at the ileoanal anastomosis. If the bleeding is uncontrollable by the transanal approach, laparotomy is indicated. Intra-abdominal bleeding that is not pouch related may be from one of three sites: the colonic bed, the lateral pelvic walls, particularly in the region of the lateral ligaments, and slipped ligatures from the mesenteric vessels.

If a defect in the ileoanal anastomosis is seen and no sepsis has occurred, the problem may be corrected by interrupted sutures. A significant hematoma developing within the walls of the pouch does not augur well and may be a prelude to a leak from the pouch. The patient should be treated with broad-spectrum antibiotics, careful observation, and laparotomy if indicated.

Small Bowel Obstruction

Small bowel obstruction is the most common complication seen after IPAA. Most large studies report a combined incidence of between 15% and 40% after IPAA and closure of ileostomy.[64] This rate is higher than that reported after construction of a Brooke ileostomy. A previous colectomy with avoidance of the use of a temporary ileostomy reduces but does not eliminate the problem.[25,95] Most episodes respond to conservative management such as intestinal rest, nasogastric suction, and intravenous fluids. Failure to respond necessitates laparotomy. Most cases are due to adhesions. If adhesiolysis is indicated, care must be taken to prevent damage to the pouch that may otherwise go unrecognized and lead to pelvic sepsis. If laparotomy is undertaken in the interval before closure of the ileostomy, reversal of the stoma is appropriate as long as contrast studies have demonstrated satisfactory healing of the pouch and ileoanal anastomosis. Occasionally, the afferent limb to the pouch may be identified as the site of obstruction either by becoming stuck in the pelvis and creating a flap valve or by herniating behind the pouch. Once mobilized, it is wise to tack the limb to the abdominal wall to prevent recurrence.

Intra-abdominal Abscess

An intra-abdominal abscess is usually the result of a defect in the pouch or a leak from the site of closure of the ileostomy. Patients have abdominal pain, diarrhea, localized or generalized peritonitis, and fever. A computed tomography (CT) scan will confirm the presence of an abscess. Pelvic sepsis develops in up to 25% of patients[98] and is likely to be secondary to pouch dehiscence or a defect in the ileoanal anastomosis. The risk for sepsis decreases as surgical experience increases.[25]

Intra-abdominal abscesses require drainage either percutaneously or surgically, together with broad-spectrum antibiotics. Immediate management of a pelvic abscess includes examination under anesthesia, catheterization of the pouch, and drainage of any collection of pus. Drainage of pus from above or even removal of the pouch may be required.

A pouchogram and examination under anesthesia will reveal whether a pelvic abscess is due to dehiscence of the ileoanal anastomosis or disruption of the pouch itself. A collection associated with dehiscence of the ileoanal anastomosis is best drained through the suture line because the incidence of pouch-vaginal fistula and fistula-in-ano is high if the collection is drained through the perineum or vaginal vault. A pelvic collection may discharge spontaneously through the IPAA with subsequent formation of a fistula or stricture. Fifty percent of patients with pelvic sepsis require laparotomy, and a secondary ileostomy may need to be created. Prompt treatment is essential if the pouch is to be saved. Pelvic sepsis results in a stiff, noncompliant reservoir. The ultimate functional result is likely to be poor, and these patients have a high rate (40%) of excision of the pouch.[91] In contrast, more than 90% of patients in whom no reoperation is required may expect a satisfactory outcome.[91]

Anastomotic Cuff Abscess

Sepsis in the space between the residual rectal muscle and the pouch, often accompanied by partial separation of the anastomosis, is associated with persistent anal pain, diarrhea, and fecal leakage.[99] The clinical findings can be subtle, so a high index of suspicion is essential. Predisposing factors are a difficult mucosectomy with troublesome hemostasis and a long rectal cuff. The incidence of cuff abscess has decreased with the use of shorter rectal cuffs.[99] A cuff abscess may be the result of an ascending infection from anastomotic disruption or a descending infection as a result of intraoperative contamination or a pelvic hematoma. A cuff abscess may drain through the IPAA and create a sinus or a fistula. A pouchogram with water-soluble contrast medium and examination under anesthesia should establish the diagnosis, and a CT scan will identify any associated collections in the pelvis. A sinus should be treated by curettage, whereas a fistula should be managed by fistulotomy, curettage of the fistula, insertion of a seton, or mucosal flap advancement.[25] The fecal stream should be diverted or reversal of the stoma delayed. Late manifestation of anastomotic sinuses or fistulas months or years after the original operation are often subsequently found to be associated with Crohn's disease.

Stricture at the Ileal Pouch–Anal Anastomosis

Stricture at the site of the IPAA has been reported in up to 38% of patients. It is persistent and severe in 16%.[100] Tension and ischemia are predisposing factors. Stricture is more likely to develop if there was dehiscence of the IPAA, with or without pelvic sepsis, or if a small-diameter (25 mm) stapling gun was used. If the pouch is placed under tension or if the sutures between the pouch and anus are placed haphazardly or break such that the anastomosis separates, the denuded anal sphincter is left exposed. Heavy scarring and a dense stricture result. A pouch that has been brought down under some tension is more likely to be associated with anastomotic stricture, probably because of ischemia or partial disruption of the anastomosis with healing by secondary intention and stenosis. Patients with an IPAA stricture usually have frequent watery stools and urgency of defecation associated with straining and a sensation of incomplete evacuation. The stricture generally responds to dilatation with a digit in the clinic or Hegar's dilators under a brief general anesthetic. A lumen that allows insertion of an index finger to the level of the distal interphalangeal joint is adequate.[28] Self-dilatation with a St. Marks' dilator is useful. In the absence of pelvic sepsis, the anastomotic stricture is usually web-like after a stapled IPAA but long and narrow after mucosectomy and a hand-sewn anastomosis.[100] Pelvic sepsis leads to longer strictures that are less likely to yield to simple dilatation. Refractory strictures are best treated by pouch advancement and a new ileoanal anastomosis.[101] The functional outcome of patients who have undergone successful treatment of their strictures is no different from that of other patients with pouches.[25]

A study of 1884 pouch-anal anastomoses constructed at the Mayo Clinic between 1981 and 1996 was carried out to identify and define different types of strictures and the factors that influence their occurrence.[102] Strictures developed in 213 patients, 86% of which were nonfibrotic and 14% were fibrotic. A greater number of strictures were seen in patients who had undergone a hand-sewn anastomosis than in those with a stapled anastomosis. Intraoperative technical difficulties were noted in 13% of patients, with anastomotic tension being the most commonly described problem. Postoperative complications such as abscess, fistula, and pouch retraction occurred in 13% of cases and were primary associated with fibrotic strictures. The time between construction of the IPAA and the appearance of nonfibrotic and fibrotic strictures was 9 and 6.2 months, respectively. Anal canal anastomotic dilatation was successful in 95% of the nonfibrotic strictures but in only 45% of the fibrotic strictures, and the average number of dilatations was 1.5 (range, 1 to 7). In the Mayo series, surgical procedures were necessary in 12% of all strictures (mainly fibrotic). The surgical procedures included (1) excision of the strictured segment with advance of a flap of ileal mucosa over the excised area; this technique was used for segmental and short strictures that appeared as a fibrous ring with the rest of the pouch remaining supple; (2) excision of the pouch and permanent ileostomy; almost all of these patients had other perianastomotic complications—abscess, fistula, pouch retraction; (3) disconnection with segmental excision of the fibrotic segment and reanastomosis of the pouch to the anus; and (4) repeated anal dilatation with drainage of abscess, division of an obstructing bridge, or débridement and curettage of a fistula.[102]

Symptomatic Proctitis or Dysplasia in Residual Rectal Mucosa

Symptomatic proctitis may develop after double-stapled IPAA, especially if an excessively long anorectal stump has been left in situ. Foci of high-grade dysplasia may also be seen in surveillance biopsies of retained ATZ.[90] Although proctitis may respond to topical or oral steroids, some patients prove resistant.

The troublesome mucosa is mobilized via a perineal approach with submucosal infiltration of a solution of 1:100,000 epinephrine. Mucosal resection is performed from the level of the dentate line to the level of the stapled IPAA. The anastomosis is then dissected radially and circumferentially mobilized to allow delivery of the pouch to the level of the anal verge. A new IPAA is made with interrupted sutures.[90] Although this technique may seem to be an attractive option, the mucosal resection and mobilization of the IPAA are actually quite difficult because of extensive fibrosis and adhesions between the pouch and the sphincter. The lack of mobility of the pouch may prevent the construction of a tension-free anastomosis. In practice, it may be necessary to perform transabdominal mobilization of the pouch or sacrifice the anal canal altogether and create a permanent ileostomy.

Enterocutaneous Fistulas

Enterocutaneous fistulas typically occur after unrecognized injury to the small bowel, often at the time of closure of the abdominal wound or after closure of the ileostomy. Usually, they can be managed conservatively with total parenteral nutrition as long as there is no distal obstruction. If the fistula arises from the pouch itself, a prolonged period of diversion of the intestinal stream, excision of the fistula, or closure of the defect in the pouch will generally be successful. Persistence of a fistula suggests unresolved sepsis or Crohn's disease.

Pouch-Vaginal Fistulas

Fistulas from the pouch to the vagina may be the result of sepsis and anastomotic dehiscence or may represent technical error. The use of stapling instruments places the posterior vaginal wall at risk. Fistulas may develop in patients with transmural inflammation, and deep ulceration of the pouch may occur in those with unsuspected Crohn's disease. Fistulas related to technical error occur early, whereas disease-related fistulas tend to occur late.

Investigation involves pouchoscopy and a vaginal speculum examination with the instillation of either methylene blue or 1% hydrogen peroxide solution.

Water-soluble contrast studies via the pouch or vagina may delineate the fistulous tract. Pouch biopsy and small bowel contrast studies are needed when Crohn's disease is suspected. Fecal diversion should be established. A small low fistula may be managed by means of mucosal flap advancement via a transanal or transvaginal approach if no significant sepsis is present. Large high tracts, especially if stapled, require reconstruction or abandonment of the IPAA.

A retrospective review of 60 females with pouch-vaginal fistulas managed at the Cleveland Clinic found that the average time to pouch-vaginal fistula formation after IPAA was 21 months (range, 1 to 132 months).[103] Postoperative pelvic sepsis had occurred in 17 patients (28%). The primary treatment modality was local repair (77%), the majority of which took the form of an ileal advancement flap, redo restorative proctocolectomy (10%), and excision of the pouch (8%). Initial healing was achieved in 20 of 52 evaluable patients, and an additional 11 patients had a successful outcome, albeit with repeat procedures. The overall healing rate was 52% at a mean 50 months' follow-up. A delayed diagnosis of Crohn's disease was eventually made in 24 patients, and the chance of success after an ileal advancement flap was significantly lower in patients with Crohn's disease than in those without Crohn's disease (25% versus 48%, respectively).

The reported experience in the Cleveland Clinic mirrors that of other major centers—about half the patients with a pouch-vaginal fistula will eventually achieve a successful outcome, with a quarter of the patients having persistence of a fistula but with the pouch in situ and a further quarter of patients undergoing long-term diversion or pouch excision. The majority of patients with pouch-vaginal fistulas can be managed by local methods, and several key technical points should be stressed. Adequate drainage of any septal sepsis must be achieved preoperatively—usually with draining setons with or without antibiotics. Careful and thorough hemostasis must be achieved. Any concurrent stricture should be débrided or excised, and the repair should be free of any tension.

A transvaginal approach to a pouch-vaginal fistula allows direct access to the internal opening and permits closure without damage to the anal sphincter[104] (Fig. 152–5). With the patient in the lithotomy position and the bladder catheterized, an inverted T-shaped incision is made along the midline longitudinal access of the posterior vaginal wall. With the horizontal limb located at the junction of the perineal skin and the posterior vaginal wall, the vagina is then dissected from the anal canal and ileal pouch, and two lateral flaps are created to expose the anterior wall of the pouch and the pouch-anal anastomosis. The internal opening of the fistula (pouch end) is then excised and the defect closed transversely with dissolvable sutures. The vaginal flaps are replaced and closed with dissolvable suture, and a vaginal pack is inserted to reduce the formation of hematoma by opposing the vaginal wall to the pouch and therefore reducing the dead space. Because the vagina has an excellent blood supply, creation of a full-thickness flap is technically straightforward. This technique avoids trauma to the anal sphincters and therefore reduces the risk for sphincter injury and subsequent fecal incontinence. Although there is no definite evidence that a diverting stoma reduces recurrence of a pouch-vaginal fistula, an argument can be made for its use in this situation first to give the patient some relief from symptoms and second to maximize the chance for success of the repair. This technique achieved success in 11 of 14 patients at St. Marks Hospital, London.[104]

Functional Results After Perineal Complications

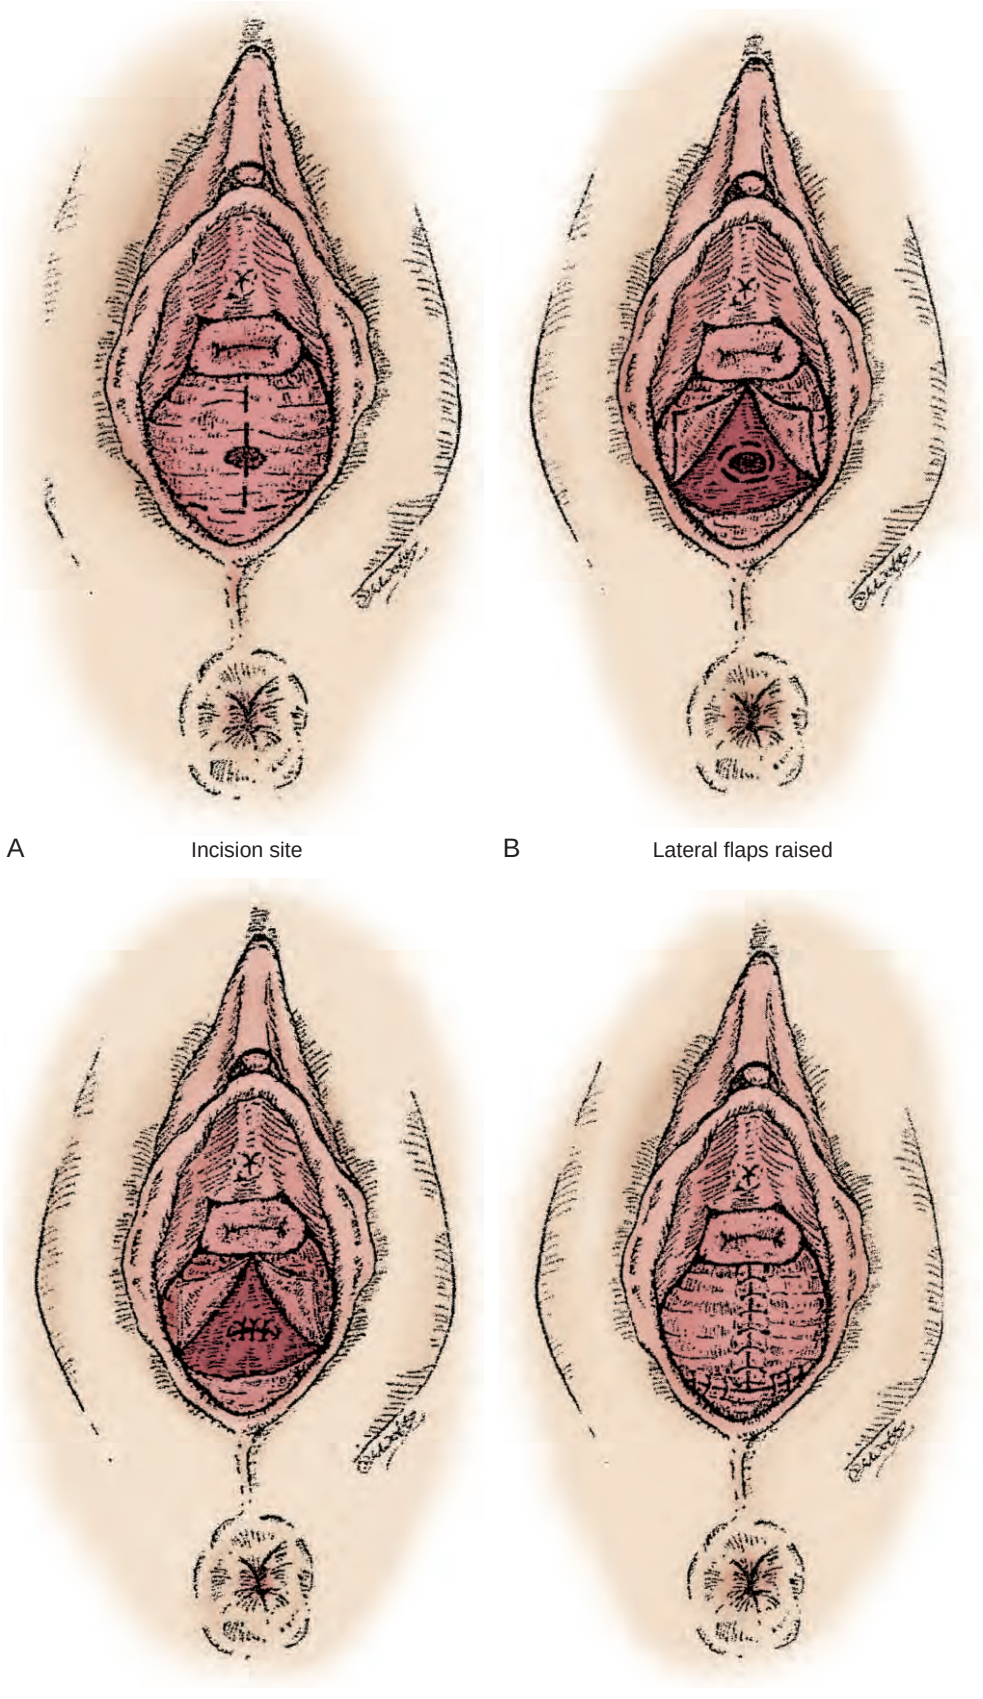
As noted earlier, there are a significant number of complications that involve the perineum after IPAA. Although the various complications can be minor, some lead to poor functional results or even loss of the pouch. A review of a registry of 628 patients from the Lahey Clinic identified 24.4% of patients in whom perineal complications had developed—anastomotic strictures, anastomotic separation, pouch fistulas, and pelvic sepsis. If the complications were addressed, the pouch failure rate was low (10%). Indeed, most of the pouch failures that occurred were the result of pouch fistulas, and in turn, most of these fistulas occurred in patients in whom the ultimate diagnosis was Crohn's disease. The functional result in patients in whom the perineal complications were successfully dealt with were no different from those of control patients in whom no such complications developed.[105]

Pouchitis

The pelvic ileal reservoir may become nonspecifically inflamed—pouchitis. The incidence of pouchitis varies from 11% to 34%, depending on the diagnostic criteria used,[106,107] and it increases with time after surgery. The cause is unknown.

Pouchitis is associated with episodes of increased frequency of bowel action along with the passage of loose, blood-stained stools usually accompanied by malaise, low-grade fever, and lower abdominal discomfort. Extraintestinal manifestations similar to those seen in colitis, such as erythema nodosum, uveitis, and arthritis, may occur at the same time as relapse of pouchitis.[108] The mucosa is inflamed and extensively ulcerated, produces a copious exudate, and bleeds on contact. Biopsies reveal a marked acute inflammatory infiltrate with villous atrophy and crypt abscesses. Neutrophils migrate from the circulation to an inflamed pouch. A positive indium-labeled granulocyte scan together with increased 4-day fecal indium granulocyte excretion may help identify patients with pouchitis and allow assessment of response to treatment.[109] A subgroup of patients are eventually found to have Crohn's disease or an indeterminate form of colitis.[100]

The use of these descriptive diagnostic criteria is open to misinterpretation. There has been a tendency to set the threshold for each of the three components too high such that only patients with severe pouchitis are included. Therefore, more objective quantification of pouchitis is neded. A Pouchitis Disease Activity Index (PDAI) has been developed that quantitates clinical



A Incision site

B Lateral flaps raised

C Lateral opening excised and closed

D Flaps replaced

Table 152–1 Pouchitis Disease Activity Index

Criteria	Score
Clinical	
Stool frequency	
Usual postoperative BM	0
1-2 BM more than usual	1
3+ more than usual	2
Rectal bleeding	
None	0
Present daily	1
Fecal urgency or cramps	
None	0
Occasional	1
Usual	2
Fever	
Absent	0
Present	1
Endoscopic Inflammation	
Edema	1
Granularity	1
Friability	1
Loss of vascular pattern	1
Mucous exudate	1
Ulceration	1
Acute Histologic Inflammation	
Leukocyte infiltration	
Mild	1
Moderate with crypt abscess	2
Severe with crypt abscess	3
Ulceration per low-power field (mean)	
<25%	1
25%-50%	2
>50%	3

Pouchitis is defined as a total score greater than 7 points.
BM, bowel movement.
From Sandborn WJ, Tremaine WJ, Batts KP, et al: Pouchitis after ileal pouch–anal anastomosis: A Pouchitis Disease Activity Index. Mayo Clin Proc 69:409-415, 1994.

findings and the endoscopic and histologic features[110] (Table 152–1). It includes several clinical symptoms, not simply diarrhea, and expresses the endoscopic and histologic findings on a continuous scale rather than requiring minimum scores. Patients with pouchitis of mild or moderate severity can therefore be included in the diagnosis. The PDAI is significantly greater in patients with pouchitis than in patients without pouchitis, and it provides a simple, objective, and reproducible scoring system for pouchitis

Pathogenesis of Pouchitis

The causes of pouchitis are not well understood. Previous expectations that the knowledge of inflammatory bowel diseases in general would be expanded by means of studies of pouchitis have not been achieved. A number of etiologic factors involved in the development of pouchitis have been suggested, such as mucosal ischemia, immune deficiency, stasis of pouch contents, bacterial imbalance, or a recurrent form of ulcerative colitis or a variation of Crohn's disease. Certainly, the incidence of pouchitis is higher in patients with ulcerative colitis associated with primary sclerosing cholangitis and is very low in patients with familial adenomatous polyposis. Therefore, there may be a persistent predisposition to inflammation in patients with ulcerative colitis after IPAA, and this predisposition, with or without other factors, may result in pouchitis. Patients with extraintestinal manifestations of ulcerative colitis before IPAA had a 10-fold increased risk for the development of pouchitis (48% versus 4.6%, $P = .01$).[111] There is some evidence that dietary factors may play a role by modification of the ecology of the ileal pouch. A study that looked at interactions between nutritional factors, fecal and mucosal bacterial flora, and mucosal morphology in 21 patients with pouchitis versus 11 patients with healthy ileal pouches found no difference in mean nutrient intake, fecal bile acids, or microbial tissue biopsy cultures between the two groups, but there was a significantly higher concentration of anaerobes and aerobes in the feces of patients with pouchitis. Differences in the composition of the pouch microbial flora may be of key importance in the interaction with epithelial cells within the pouch mucosa and thus in the subsequent development of pouchitis.[112] Sulfate-reducing bacteria (a species of strict anaerobes) appear to exclusively colonize ileal pouches in patients with ulcerative colitis. There appears to be an increase in the ratio of strict to facultative anaerobes in ileal pouch patients with pouchitis as compared with those who have normal ileal pouches.[113]

Because pouchitis has been suggested to be a recurrence of ulcerative colitis in colonic-type mucosa, topical steroids have been used as a therapeutic alternative. A randomized trial of 26 patients randomized to receive either budesonide enema plus placebo tablets or oral metronidazole plus placebo enema found similar efficacy but improved tolerability of budesonide enemas in comparison to oral metronidazole.[114]

Anti–Tumor Necrosis Factor

Monoclonal antibodies have been successfully used in the treatment of fistulating perianal Crohn's disease. The efficacy of one such monoclonal antibody (infliximab) has been studied in the treatment of chronic refractory pouchitis complicated by perianal fistulas after IPAA. An open study of seven patients with pouchitis complicated by fistulas in whom Crohn's disease had been carefully excluded were treated with infliximab, 5 mg/kg at 0, 2, and 6 weeks. At 10-week follow-up, six of the seven patients had a complete clinical response.[115]

Severe Pouchitis

Severe refractory pouchitis is rare, and when it occurs, other causes such as infection with cytomegalovirus or *Clostridium difficile* needs to be considered. Pouchitis induced by cytomegalovirus requires treatment with

antiviral therapy such as ganciclovir. *C. difficile*–associated infection requires treatment with oral metronidazole or vancomycin.[116]

Morphologic Changes in Ileal Pouch Mucosa

A number of studies have demonstrated morphologic changes in the ileal pouch mucosa, including villous atrophy and crypt hyperplasia. The changes are classified as colonic metaplasia. It is not clear whether such changes represent long-term adaptation or response to inflammation. A study of 24 patients with no history of pouchitis, 31 patients with a history of pouchitis, and 8 patients in whom IPAA was carried out because of familial adenomatous polyposis found that the colonic metaplasia score was higher in patients with inflammation. The greater the colonic metaplasia score, the greater the inflammation score, and the authors concluded that colonic metaplasia is found primarily on a background of inflammation and therefore probably represents a reparative response.[117]

Treatment of Acute Pouchitis

Patients with pouchitis generally respond to metronidazole either orally or applied topically. The usual oral dose is 750 to 1500 mg/day for 7 to 14 days, and clinical improvement is generally prompt (within 3 days). A randomized, double-blind, placebo-controlled crossover trial in 13 patients has confirmed the long-held view of the efficacy of this form of treatment. The side effects of oral therapy are avoided by topical therapy, in which serum concentrations of metronidazole are very low. Patients who are unresponsive to metronidazole may respond to cyclic courses of three or four antibiotics given at weekly intervals, corticosteroids, ciprofloxacin, amoxicillin/clavulanic acid, erythromycin, tetracycline, allopurinol, Salazopyrin, or 5-aminosalicylic acid. Budesonide suppositories (1.5 mg/day) have also been shown to be efficacious. Frequent relapses of pouchitis require treatment with long-term, low-dose suppressive metronidazole therapy.

The fecal concentration of lactobacilli and bifidobacteria is significantly decreased in patients with pouchitis. A randomized, double-blind, placebo-controlled trial evaluated use of the probiotic VSL#3, which consists of eight bacterial strains, in the prevention of recurrence of pouchitis. In the treatment group, 17 of 20 patients were still in remission at 9 months, as compared with 0 of 20 patients treated with placebo. All patients who received VSL#3 relapsed within 4 months of concluding the treatment. The fecal concentrations of lactobacilli and bifidobacteria were significantly increased in the treatment group during the study but returned to baseline 1 month after completion of the study.[118] It remains unclear whether multiple bacterial strains are required to induce remission.

Other Complications

Polyps may develop within a pouch as in the rest of the small bowel. Inflammatory polyps may occur in up to 20% of patients with ulcerative colitis.[119] Inflammatory fibroid polyps, though rare, may cause bleeding or obstruction. Such polyps may occasionally grow sufficiently to fill the lumen of the pouch and require resection[120] with conversion to a permanent ileostomy.

There have been occasional reports of alopecia after IPAA. Indeed, one series reported a somewhat surprising incidence of 38% (in a series of 24 patients).[121] Fortunately, it is a temporary phenomenon, but female patients in particular should be warned. Treatment, if it occurs, is reassurance.

Lateral popliteal nerve palsy has been reported and is related to compression damage from pressure exerted by the leg supports after particularly long procedures. Anterior compartment syndrome of the lower limbs has similarly been reported after lengthy operations and may result in myonecrosis and footdrop unless fasciotomy is carried out. Careful positioning and adequate padding should eliminate these complications.

Risk for Neoplasia

There are suggestions that the mucosa of ileal pouches may be at risk for the development of neoplasia. If true, the likelihood is that the incidence of such events is very low. In a series of 160 patients undergoing routine pouch surveillance with multiple biopsies and a mean length of follow-up of 8.4 years, only one patient was found to have low-grade dysplasia, but even this was not confirmed on further routine follow-up. The incidence of cancer after IPAA is very low, with only 19 reported cases of adenocarcinoma of the pouch or anal canal after this operation in the literature.[122] The majority of these cases have occurred either in the rectal stump or around the anastomosis, and in all but two cases the original pathologic specimen demonstrated either dysplasia or cancer.

The widespread adoption of the use of stapled IPAA with preservation of the ATZ has raised questions about the need for long-term surveillance. The Cleveland Clinic group carried out a prospective evaluation with a minimum 10-year follow-up on 289 patients who were studied by serial ATZ biopsy. ATZ dysplasia developed in only eight patients between 4 and 123 (median, 9) months after surgery. The dysplasia was high grade in two patients and low grade in six patients. No cancers developed in the ATZ during the study period. This group recommended that in patients in whom there had been no dysplasia in the original proctocolectomy specimen and no other risk factors such as primary sclerosing cholangitis or a strong family history of colorectal cancer, a biopsy specimen should be taken from the ATZ at 1 year and then every 2 to 3 years thereafter. In patients in whom there was dysplasia in the original proctocolectomy specimen but no involvement of the lower two thirds of the rectum, biopsy of the ATZ should be performed every year. In patients in whom there was either a carcinoma complicating ulcerative colitis or dysplasia in the lower two thirds of the rectum at the time of proctocolectomy, a stapled IPAA was not performed but rather transanal mucosectomy and a hand-sewn anastomosis. Even within this group the option of a stapled IPAA would be offered to obese or elderly patients or

those with low sphincter pressure, in whom mucosectomy and a hand-sewn anastomosis might not be easily feasible because of reach or concerns about poor pouch function. In patients in whom low-grade dysplasia is found on biopsy, repeat biopsy should be performed every 6 months for up to 3 years. If no further dysplasia is detected, annual biopsies would be required thereafter, but if persistent low-grade or, indeed, high-grade dysplasia is found on three consecutive samples, the patient should undergo mucosectomy and pouch advancement.[123]

Male Sexual Function

Most patients who undergo the IPAA procedure are young, sexually active, and concerned about their sexual function after pelvic surgery. Pelvic surgery may cause male sexual problems such as erectile dysfunction, absence of ejaculation, or retrograde ejaculation. Only a small percentage (2% to 4%) of male patients have severe sexual problems after surgery.[124,125] Sexual function of males has been examined in a systematic manner by means of a validated scoring system, the International Index of Erectile Function (IIEF). The IIEF was used to study 122 males who underwent IPAA between 1995 and 2000, with comparison of results before and after IPAA. There was a statistically significant improvement in erectile function, sexual desire, intercourse satisfaction, and overall satisfaction, with patients having improved scores after surgery versus before surgery. The mean erectile function score was higher after surgery than before surgery. Overall psychometric sexual satisfaction and sexual quality of life were increased, most likely because of enhanced general health. This study would suggest that male patients undergoing IPAA may be counseled that their sexual function is likely to be retained after surgery.[126]

Female Reproductive Health

IPAA does not seem to affect menstrual function or gynecologic symptoms. Overall sexual satisfaction may be improved with surgery, although the ability to experience orgasm and the frequency of coitus are unchanged. There is an increase in dyspareunia after IPAA, and fertility is adversely affected, most likely because of pelvic adhesions. During pregnancy there is a transient increase in the frequency of stools both by day and by night. Nocturnal incontinence increases, but this resolves after delivery. The ideal route of delivery has yet to be determined, but vaginal delivery is safe and does not appear to directly influence pouch function.[127]

Ileal Pouch–Anal Anastomosis and the Menstrual Cycle The majority of women report no change in their menstrual cycle after IPAA. Any noted change in menses or related symptoms seem to be infrequent. A study of 46 women who had undergone IPAA with a follow-up of 28 months showed no change in menses in 68%, increased regularity in 26%, and dysmenorrhea in 15%.[128] A similar study of 21 women a mean of 38 months after IPAA noted dysmenorrhea in 10%; no patients identified changes in their cycle.[129]

Ileal Pouch–Anal Anastomosis and Female Sexual Function Although most women report no change in overall sexual satisfaction, 16% to 50% reported an increase in satisfaction after IPAA.[130] Nine percent to 26% of women reported decreased overall satisfaction. IPAA does not seem to affect the ability to experience orgasm, with a similar frequency of orgasm before and after surgery (range, 67% to 86%).[128-130] An increase in the ability to attain orgasm was noted in 9% to 18% of patients, whereas 0% to 15% of patients reported decreased ability. Although the frequency of coitus remains unchanged or is increased after IPAA, 3% to 18% of women fear leakage of stool at the time of sexual intercourse. This concern is alleviated by emptying the pouch before intercourse. Preexistent dyspareunia may be exacerbated by surgery. In studies that included preoperative baseline data, the incidence of dyspareunia rose from 5% to 10% to as high as 15% to 22% after surgery.[124,131] This may be due to alterations in pelvic anatomy or the formation of adhesions after IPAA.

Ileal Pouch–Anal Anastomosis and Fertility A number of studies (mostly characterized by small number of subjects attempting conception after surgery) suggest reduced fertility in women after IPAA. Two large studies that were methodologically sound have shown decreased postoperative fertility. A postal questionnaire of 300 women of reproductive age who underwent IPAA between 1983 and 2001 found that before IPAA, 48 (38%) of 127 patients were unsuccessful in their attempt to conceive after 1 year of unprotected intercourse whereas after IPAA, 76 (56%) of 135 patients were unsuccessful. The infertility rate was higher after surgery than before ($P < .001$). In a subgroup of 56 women who tried to get pregnant both before and after surgery, the infertility rate was higher after surgery than before (69% versus 46%, $P = .005$). The use of an intraoperative blood transfusion was associated with a higher rate of infertility than in patients who did not have an intraoperative blood transfusion (54% versus 21%, $P = .023$).[132] A Scandinavian study of 237 women compared the rate of preoperative fertility from the age of 15 until colectomy and the rate of postoperative fertility from 12 months after closure of ileostomy until data collection or menopause. There was a mild decrease in observed preoperative births (87% of expected, $P < .05$), whereas the incidence of postoperative births was only 35% of expected after IPAA ($P < .001$) Successful in vitro fertilization was excluded from the study.[133] This decrease in postoperative fertility has been attributed to probable tubal occlusion from adhesions, although the possibility that physicians and surgeons have recommended against conception after IPAA and the possibility of patient concerns about having children affected with ulcerative colitis may well play a role.

Mode of Delivery After Ileal Pouch–Anal Anastomosis In theory, a vaginal delivery may increase the risk for pudendal nerve damage, injury to the anal sphincter complex, and loss of fecal continence in patients after

IPAA as compared with cesarean section before the onset of labor. However, a postal questionnaire study that addressed this issue in 29 subjects who had undergone 49 deliveries found that there were 25 vaginal deliveries and 24 cesarean sections. A third of the subjects had disturbances in pouch function during pregnancy, almost exclusively during the third trimester, with an increase in stool frequency by day and by night and transient loss of nighttime control. There was no correlation between the mode of delivery and pouch complications or functional impairment. In particular, vaginal delivery was not shown to adversely affect pouch or anal function. Vaginal delivery after IPAA would appear to be safe, and the method of delivery should be dictated by obstetric or specific local perineal conditions.[134]

Age-Related Surgical Results and Functional Outcome

Although no age cutoff for patients undergoing IPAA has been defined, many surgeons would anecdotally suggest an upper age limit of 60 or 65 years. There is little evidence to support such a recommendation, and the relative infrequency of IPAA in older patients has made it difficult to assess outcomes of surgery according to age. The Cleveland Clinic carried out a prospective evaluation of the functional outcome and quality of life in 1895 patients who had undergone IPAA, with stratification of patients by age at the time of surgery into younger than 45 years, between 46 and 55 years, between 56 and 65 years, and older than 65 years. Functional outcome and quality of life were assessed at 1, 3, 5, and 10 years of follow up. The study reported incontinence and nighttime seepage to be more common in older patients, and there were minor differences in quality of life, health, energy, and happiness, with a slight benefit for those younger than 45 years. There were no differences in the level of happiness with surgery at 1, 3, 5, or 10 years of follow-up. At all times in the study, at least 95% of patients in each group would undergo their surgery again and would recommend IPAA to someone else with the same diagnosis.[135]

The effect of the aging process itself on functional outcome and the quality of life of patients with an ileal pouch was studied by the Mayo Clinic group, with the functional and quality-of-life outcomes of 409 patients being assessed at 5, 10, and 15 years. Over this time frame there was little change in daytime stool frequency, whereas nighttime frequency increased from one stool to two stools per night. Incontinence to gas and stool increased from 1% to 10% during the day and from 2% to 24% at night over the 15-year period. After 15 years, more than 90% of patients were in the same job, and social activities, recreational sports, long-distance travel, and sexual activity all improved after surgery and did not show deterioration over time.[136]

Revision Pouch Surgery

In a small subset of patients the long-term functional result is poor. Although in many of these cases the problem may be related to recurrent episodes of pouchitis or postoperative pelvic sepsis, some patients may benefit from surgical intervention.

Patients who are being evaluated for pouch dysfunction months or years after the original operation should undergo a series of investigations, including inspection and palpation of the anastomosis, stool culture, pouchoscopy and multiple biopsies, water-soluble contrast enema, manometry of the anal sphincter and pouch, and a small bowel contrast study if Crohn's disease is suspected. Mechanical causes of dysfunction may be identified, such as an excessively long efferent spout, a small pouch, a long mobile blind limb capable of obstructing outflow from the pouch, twisted pouches, or intussusception of bowel proximal to the pouch within the pouch. Problems specific to the IPAA included partial separation, residual disease after a double-stapled anastomosis, and a long stenosis.

Surgical Technique

With the patient in the synchronous (combined) position, the abdomen is opened through the previous laparotomy incision. Adhesiolysis is performed and the ileal pouch identified and dissected out with a combination of electrocautery and sharp dissection. In most cases, mobilization of the pouch can be achieved without major difficulty and without entering the lumen. Once the IPAA has been identified from above, attention is turned to the perineal dissection. Again, a combination of electrocautery and scissors dissection is used to dissect out the IPAA. Further transanal mucosectomy is performed if residual mucosa is identified. Great care is taken to identify and preserve the sphincter musculature. The IPAA is then disconnected and the pouch delivered out of the abdomen. The pouch is revised according to the nature of the problem, which may involve excision of a long efferent spout with or without sacrifice of the original pouch, excision of the original pouch with construction of a new pouch, excision of a long blind end, rotation of the pouch on its longitudinal axis, and excision of fistulous tracts with repair of the pouch. The new pouch is then anastomosed to the anal canal with four anchoring sutures placed into the walls of the pouch and the levator muscles and then a series of interrupted absorbable sutures placed between the pouch and the anal mucosa. The procedure should be covered with a diverting ileostomy in all cases. Intestinal continuity is restored 2 to 3 months later after a water-soluble contrast study has demonstrated satisfactory healing.

A series of 23 patients in whom disconnection, pouch revision, and reanastomosis were carried out has been reported.[137] Functional problems included impaired evacuation ($n = 15$), excessive frequency ($n = 4$), and fistulas ($n = 4$). At surgery, the functional problems were found to be due to a long efferent spout ($n = 9$), a redundant or perforated blind limb ($n = 6$), a twisted pouch ($n = 3$), or other causes ($n = 5$). The pouch was salvaged in 14 patients and a new pouch was constructed in 9. The pouch-anal anastomosis was resutured in 22 patients and stapled in 1. Postoperative complications (all minor) occurred in 5 of 23 patients. Two patients underwent

Table 152–2 Disconnection, Pouch Revision, and Redo Ileal Pouch–Anal Anastomosis

Author	*N*	Problem	Outcome
Liljeqvist[138]	7	Long spout	Good function in 5 patients, 2 failures
Pogglioli[139]	6	Twisted pouch (1) Afferent limb stricture (1) Pouch-urethral fistula (1) Pelvic sepsis (1) Ischemic pouch (1) Outflow obstruction (1)	Good function in 4 patients, pouch excised in 1, and stoma not closed in 1
Nicholls[30]	6	Long spout	Good function in 4 patients, 2 self-catheterize
Fazio[90]	2	Residual disease, dysplasia	Good function in both patients
Sagar[137]	23	Long spout (9) Sepsis (4) Blind limb (3) Twisted pouch (3) Revision of IPAA (3) No pouch (1)	Success in 17 patients
Herbst[140]	16	Pouch outlet obstruction	Improved function in 12 patients
Fonkalsrud[141]	58	Elongated IPAA spout	Improved function in 93%
Baixauli[142]	100	Chronic leak (27) PV fistula (47) Stricture (22) Long spout (36) Previous pouch excision (6)	5-year survival rate of pouch = 74%
MacLean[143]	57	PV fistula (21) Pelvic sepsis (14) Long spout (14) Stricture (5) Perineal fistula (2) Pouchitis (1)	Success in 89%

IPPA, ileal pouch–anal anastomosis; PV, pouch-vaginal.

revision IPAA twice. At a median follow-up of 5 years (range, 1 to 10), 11 patients reported good to excellent function, 5 patients reported fair function, and 1 patient reported recurrent pouchitis. Revision surgery was unsuccessful in 6 of 23 patients (gross incontinence in 3, excessive bowel movements in 2, Crohn's disease in 1), and they subsequently underwent pouch excision. Table 152–2 shows the results of studies of redo IPAA.[30,90,137-143]

A series of 63 reconstructive procedures were performed in 57 patients. The primary indication for reconstruction was a pouch-vaginal fistula in 21 patients, a long outlet in 14, pelvic sepsis in 14, IPAA stricture in 5, pouch-perineal fistula in 2, and chronic pouchitis in 1 patient.[143] All patients received a covering loop ileostomy. Forty-two patients (73.7%) have a functioning pouch, whereas 7 (12.3%) have had their pouch excised and an ileostomy has not been closed in the other 8 (14.0%) patients. The functional results in the patients with a pouch in use were categorized as good, and this group of patients rated their physical and psychological health as good to excellent.

Good results can be obtained by experienced surgeons after abdominoperineal reconstruction for a failed IPAA. Selection of patients is important. The original pathology and current pouch biopsies should be reviewed by an experienced gastrointestinal pathologist and every effort made to rule out Crohn's disease. Active sepsis must be controlled, and on occasion it may be necessary for the pouch to be made nonfunctional for a period before reconstructive surgery is attempted. A major commitment is required by both the patient and surgeon, but the effort is worthwhile when satisfactory function and quality of life are obtained.

Alternative Techniques for Pouch Salvage

A technique to treat and salvage an ileal pouch affected by chronic fistulating disease on a background of ulcerative colitis has been described and involves an abdominoperineal approach with transabdominal mobilization of the pouch to the level of the anastomosis and then perineal dissection to disconnect the anastomosis transanally (Fig. 152–6). The pouch is delivered out of the abdomen and the pouch fistulous connections are excised. This part of the pouch is then closed and the pouch inverted through the cone formed by the J pouch

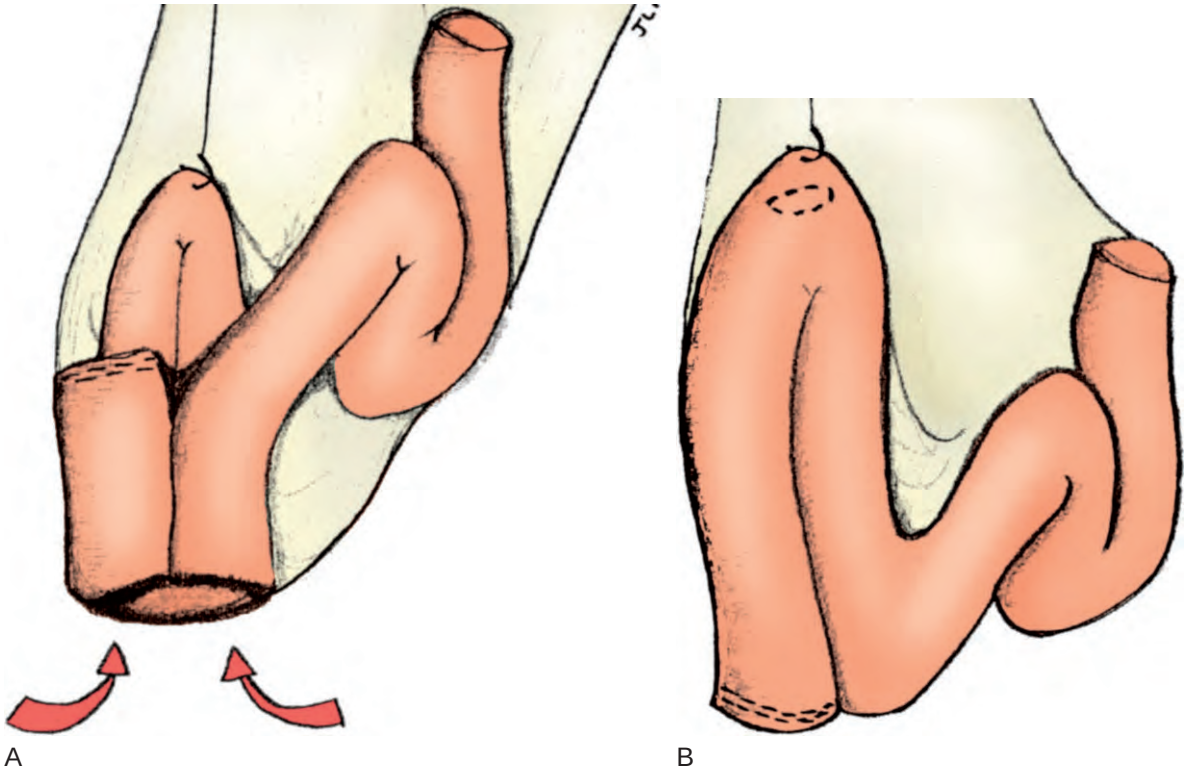

Figure 152–6. **A** and **B,** Inversion, 180-degree forward rotation, and then 180-degree axial rotation.

anteriorly and the mesentery posteriorly. The formerly hidden part of the pouch then becomes the apparent one and vice versa. A 180-degree forward rotation with 180-degree axial rotation permits enough length to bring a new healthy part of the same pouch to the anus. The pouch-anal anastomosis is constructed after any granulation and fibrotic tissue has been fully curetted and a mucosectomy has been performed to remove any residual mucosa distal to the previous anastomotic site. The anastomosis and pouch are protected with a temporary diverting ileostomy. This is a useful technique to perform before admitting defeat and excising the pouch so that the patient is left with a permanent ileostomy, although difficulties may result if there is insufficient mesenteric length remaining after pouch inversion and double rotation. Usually, however, the mesentery has elongated several months after the original IPAA has been formed, so length is not generally a problem. The technique permits excision of all inflamed tissue related to the fistulating disease, it permits diagnosis and closure of all fistula tracts, the anastomosis is constructed with a new healthy part of the pouch, and the inflamed bowel specimen excised from the pouch can be examined histologically and Crohn's disease excluded.[144]

A short small bowel mesentery can create difficulty with reach of the pouch to the pelvic floor at the time of the original IPAA. Indeed, this may account for a number of postoperative problems and pouch dysfunction. If such patients come to revision or redo surgery, it may prove technically impossible for the new pouch to reach down to the pelvic floor if the original pouch has had to be sacrificed because of sepsis or other problems. A technique to overcome this problem has been described in which a new 18-cm J pouch is formed with a jejunal segment (Fig. 152–7). Selective division of axial vessels allows adequate length to form a jejunal pouch anal anastomosis, and the small bowel distal to the pouch is then interposed between the proximal jejunum and the J pouch. This technique of jejunal J-pouch formation and small bowel interposition offers a useful alternative to definitive ileostomy or Kock pouch in patients undergoing salvage surgery after failed IPAA.[145]

Quantification of the Risk for Pouch Failure

Although IPAA is an effective and safe surgical option for patients with ulcerative colitis and is associated with low perioperative mortality and acceptable functional results, there are marked variations in the characteristics of patients in whom the pouch procedure is ultimately shown to fail. For instance, a study from Birmingham, England, reported a failure rate of 12.7% as a result of pouch ischemia (19.3%), pelvic sepsis or fistula (35.5%), Crohn's disease (12.9%), anastomotic stricture (16.1%), or pouchitis (16.1%),[146] whereas a series from Rochester, Minnesota, reported a failure rate of only 3.8% with the principal causes being anastomotic stricture (19%), pelvic sepsis or fistula (73%), and poor function (8%).[25] These and similar discrepancies together with the move

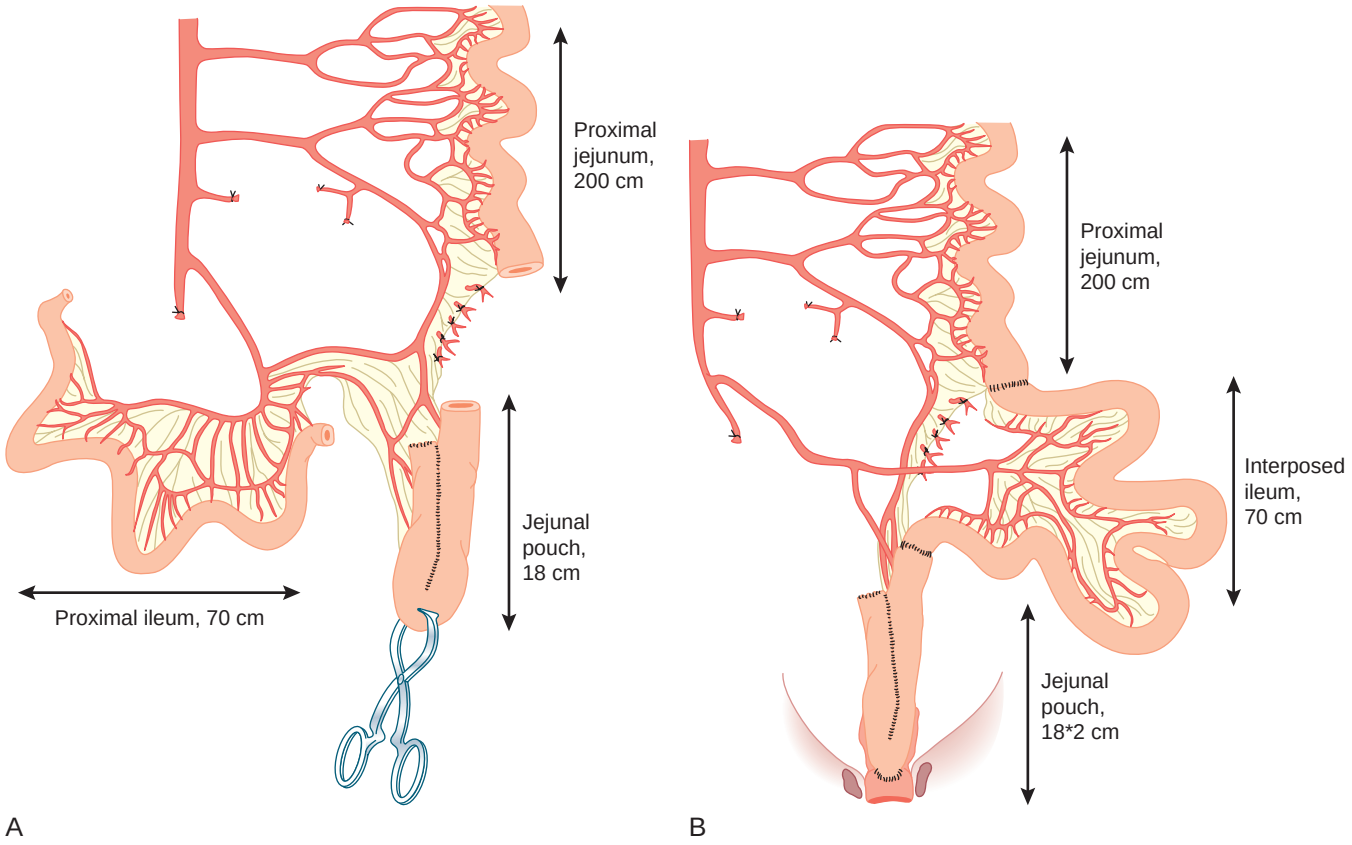

Figure 152–7. Salvage ileal pouch–anal anastomosis with a jejunal pouch and ileal interposition.

into an era of public and professional accountability for clinical outcomes have led to a need for predictive indices to allow quantification of operative risk after IPAA that is based on the comorbid condition of the patient and the complexity of the procedure. The Cleveland Clinic Foundation (CCF) ileal pouch failure model is one such index.[147] Data on 23 preoperative, 7 intraoperative, and 10 postoperative risk factors were recorded from 1965 patients between 1983 and 2001. With ileal pouch failure as the primary end point, the CCF ileal pouch failure model was developed by means of parametric survival analysis and a 70%-30% split-sample validation technique for model training and testing. This split-sample validation procedure was repeated 10,000 times to calculate standard errors and correct bias. Independent predictors of pouch survival were patient diagnosis, previous anal pathology, abnormal anal manometry, comorbidity, pouch-vaginal or pouch-perineal fistula, pelvic sepsis, anastomotic stricture, and anastomotic separation. The CCF ileal pouch failure model is to be commended because it was based on extensive preoperative, intraoperative, and postoperative data with good follow-up (median 4.1 years). It is a simple additive scoring system with eight risk factors used to calculate the risk for pouch failure at a particular time interval after IPAA. It can be readily applied to surgical practice.

Crohn's Disease

A recently completed meta-analysis of more than 8500 patients who have undergone IPAA over the last 20 years in 20 major centers around the United States suggested an overall failure rate of 6%. If only reports from the last 5 years are considered, however, the failure rate appears to have fallen to around 2%, probably as a result of selection of patients, more experience and better surgical techniques, and improved postoperative care. Today, the main contributor to failure appears to be Crohn's disease or suspected Crohn's disease–related complications. Crohn's disease is an independent predictor of pouch failure.

Patients with Crohn's disease have generally been excluded as candidates for IPAA. Clinical and histopathologic distinction between ulcerative colitis and Crohn's disease can be difficult. The pouch failure rate in patients in whom IPAA has been carried out inadvertently and Crohn's disease proved to be the ultimate diagnosis is about 50%.

Somewhat controversially, a number of authors have suggested that IPAA can indeed be used in selected patients with colorectal Crohn's disease in whom proctocolectomy with permanent end ileostomy would be the only alternative. Rather than compare the results of IPAA in patients with Crohn's disease against IPAA for other

conditions such as ulcerative colitis and familial adenomatous polyposis, perhaps we should consider IPAA in Crohn's disease just as a restorative operation in its own right. A French group reported the results of IPAA in 41 patients with Crohn's disease limited to the large bowel, that is, with no past or present history of small bowel involvement or anal manifestations. At a median follow-up of about 2 years, 27% of patients had experienced Crohn's disease–related complications—seven with pouch-perineal fistulas treated surgically, two with extrasphincteric abscesses, and two with persistent anal ulceration with pouchitis and granulomas on pouch biopsy.[148] In a subset of 20 patients with follow-up greater than 10 years, 35% had experienced Crohn's disease–related complications and in 2 patients the pouch was eventually excised. The authors concluded that such good long-term results justified the results of IPAA in selected patients.

The disparity in outcome between previous studies of patients undergoing inadvertent IPAA for Crohn's disease and the French group raised the question of whether the latter study population had suffered from indeterminate or even ulcerative colitis rather than Crohn's disease. There were questions over the exact pathologic criteria used. It is well recognized that patients with indeterminate colitis, although it has a lower success rate than ulcerative colitis does, do much better than those suffering from Crohn's disease. The situation may of course change with the advent of the era of monoclonal antibodies raised against tumor necrosis factor-α. The selection of future patients for IPAA may well change as we gain longer patient follow-up and are able to correlate clinical, endoscopic, and histologic features with outcome. Ultimately, it is for the patient to decide with appropriate and thorough counseling from the surgeon and physician.[148]

ALTERNATIVES TO ILEAL POUCH–ANAL ANASTOMOSIS

Panproctocolectomy with Ileostomy

This procedure removes all diseased tissue and thus "cures" the disease. Gastrointestinal output is effectively managed by an ileostomy appliance. All patients are suitable candidates for the operation irrespective of age, size, and body shape. However, the fatter the patient, the more difficult it is to construct a stoma and the more likely the patient is to run into problems with the stoma. Rectal mobilization is carried out close to the rectum, the sympathetic nerves are protected at the sacral promontory, and the hypogastric plexus is protected in the pelvis. The perineal phase completes the dissection, and the intersphincteric plane is used to afford protection to the external anal sphincter and the puborectalis and levator muscles. Bladder paralysis and sexual dysfunction occur rarely with this approach.[149] The perineal wound is small and can be closed relatively easily.

The downside of the operation is obvious. Patients are incontinent of gas and stool and must always wear an appliance. Some patients consider life with a stoma to be worse than the disease itself. The quality of life of patients with ileostomies seems to have improved little since the original description of Brooke ileostomy in 1952.[150]

Colectomy with Ileorectal Anastomosis

Ileorectostomy removes most of the diseased colon but leaves the diseased rectum in situ. The operation avoids the need for a stoma and reduces the risk of damage to the pelvic nerves. The functional results are variable and depend largely on the capacity and compliance of the residual rectum. Interval proctectomy may be required in up to 40%, and the risk for rectal cancer is about 15% after 30 years.[151-153] The operation is, however, a viable alternative in patients with good rectal compliance and minimal quiescent rectal disease if they are willing to undergo regular screening for rectal cancer. Although quality of life is generally good, patients do not feel as though they have been cured because they are still at risk for relapse from their rectal disease and must undergo regular surveillance.

Kock Continent Ileostomy

The Kock pouch consists of an ileal pouch with a valve, created by intussuscepting the terminal ileum into the pouch, and an exit spout (see Fig. 152–7). The pouch is emptied intermittently by intubation.[18] This option has the advantage that although a stoma is constructed, the effluent can be controlled. An external appliance is not needed. The main problem, however, is a *high* complication rate. Reoperation is common, particularly for prolapse and intussusception of the valve. The role of the Kock pouch is minor and it is probably restricted to patients who have undergone panproctocolectomy and wish to have control over their ileostomy effluent and those undergoing restorative proctocolectomy in whom the ileal reservoir cannot be safely brought down to the anal canal because of a short mesentery. Other patients should be discouraged.

CONCLUSION

The development of IPAA has led to significant advances in the surgical treatment of CUC. IPAA is safe and successful in about 95% to 98% of patients. The procedure may be performed laparoscopically. The vast majority of patients, if carefully selected, can expect a good outcome after IPAA. Two factors are critical: an anal sphincter capable of providing an adequate high-pressure zone to act as a barrier to pouch contents and the construction of a pouch with adequate capacity to act as a reservoir. The duplicated J pouch with a stapled IPAA is the most widely practiced variant of the procedure. The operation is undoubtedly complicated, as illustrated by the relatively high rates of associated morbidity. The specific choice of the type of IPAA performed continues to be the subject of debate, and the cause of pouchitis remains a challenge. Nevertheless, IPAA is now an established procedure that offers cure of disease and good quality of life.

Surgery for Inflammatory Bowel Disease: Crohn's Disease

David W. Larson ▪ Bruce G. Wolff

Crohn's disease presents multiple surgical challenges and has done so since the first description of the disease by Penner and Crohn.[1] Although new medications such as FK-506 (tacrolimus) and infliximab (Remicade) have changed the way Crohn's disease is managed medically, underlying surgical principles remained unchanged.

The philosophy of bowel and sphincter preservation, along with a combined approach to the treatment of Crohn's disease, is central to the management of this disease. The historical concern that surgery is futile and leads to further complications has largely disappeared. With changes in preoperative care, improved medical therapy, and new and more noninvasive surgical techniques, the gastroenterologist and surgeon, working in concert, now offer more options to Crohn's patients. From a technical perspective, one of the most important changes in the surgical management of Crohn's disease has been the widespread adoption of laparoscopic resection techniques.

INDICATIONS FOR SURGERY

Between 70% and 90% of patients with Crohn's disease undergo an operation for the disease at some time during their life.[2] It is an unpredictable and insidious disease that affects patients in the prime of their lives. There is a bimodal distribution of incidence, with patients developing Crohn's in their 20s and 30s and others in their 60s and 70s. By far the leading indication for operation is the failure of medical management. The most common complication leading to surgery is intestinal obstruction, which is rarely complete. Other surgical indications include fistula or abscess, gastrointestinal bleeding, and the rare cases of spontaneous perforation with peritonitis.[3] Unique indications for operative intervention include children who experience growth failure; these patients often benefit dramatically and rapidly from surgery, experiencing accelerated growth after resection. Toxic megacolon and fulminant colitis are fortunately unusual presentations. The ultimate choice to intervene surgically is one that is based on the informed discussion among the patient, surgeon, and gastroenterologist.

MEDICAL TREATMENT OF CROHN'S DISEASE

Crohn's disease may present as one of three different subtypes: fibrotic, fistulizing, or inflammatory. Many patients present to the surgeon with the diagnosis of Crohn's already made and on medical therapy. The current options for medical therapy of Crohn's are extensive and complex. Many patients have been treated with 5-aminosalicylate (ASA) products including sulfasalazine, oral mesalamine (Pentasa, Asacol), and rectal mesalamine (Rowasa). Controlled trials of sulfasalazine, 3 to 5 g/day, in patients with mildly to moderately active Crohn's disease have not demonstrated efficacy for inducing remission.[4,5] In a subset of patients with Crohn's colitis there were trends toward a benefit, but this was not statistically significant.[3,4] Likewise, doses of 2.5 to 3 g/day were not effective for maintaining remission in patients with Crohn's disease.[3,4] The data for oral mesalamine in the treatment of Crohn's disease are also unclear. Data from controlled trials[4,5] of oral mesalamine, 1 to 4 g/day, for maintenance of medically induced remission or postoperative remission in patients with Crohn's disease are conflicting.[6] Overall, sulfasalazine or mesalamine appears to provide minimal benefit for inducing remission, and both are less effective than oral corticosteroids for active Crohn's disease.

The data for use of antibiotics in Crohn's disease are conflicting. A placebo-controlled trial of metronidazole, 750 mg/day or 1500 mg/day, did not demonstrate efficacy in patients with active Crohn's disease.[4,5] A single controlled trial demonstrated that metronidazole, 1500 mg/day, was effective for maintaining postoperative remission.[4,5] Studies of patients with fistulizing disease include only uncontrolled series that have reported that metronidazole, 750 to 1500 mg/day, and ciprofloxacin, 1000 mg/day, may be effective in patients with fistulizing Crohn's disease, particularly with perianal fistulas. Based on these results, the role of antibiotic therapy in patients with Crohn's disease is controversial.

The uses of steroids, azathioprine, and methotrexate have evolved to become the mainstay of medical treatment of Crohn's disease. Controlled trials have demonstrated that oral prednisone administered at a dose of 60 mg/day is effective for inducing remission in mildly to moderately active Crohn's disease. In contrast, low-dose corticosteroids are not effective for maintaining remission. Controlled trials have also demonstrated that azathioprine (Imuran) at doses of 2 to 3 mg/kg/day and 6-mercaptopurine at a dose of 1.5 mg/kg/day is effective for inducing remission and closing fistulas in patients with active Crohn's disease.[4,5] Further study has demonstrated that azathioprine at 2 to 3 mg/kg/day and 6-mercaptopurine, 1.5 mg/kg/day, is effective for maintenance of remission and steroid sparing in Crohn's disease.[4,5] Controlled trials have demonstrated that higher dose methotrexate (25 mg/week intramuscularly and 15 mg/week orally) is effective for inducing remission in patients with steroid-dependent and steroid-refractory active Crohn's disease. Methotrexate at doses of 15 to 25 mg/week intramuscularly is effective for maintenance of remission and steroid sparing in patients with Crohn's disease.[4,5]

The newest agents in the treatment of Crohn's include infliximab, which is a chimeric monoclonal antibody directed at tumor necrosis factor-α. Controlled trials have demonstrated that infliximab, 5 mg/kg, administered one to three times over 6 weeks as an intravenous infusion is effective for inducing remission and closing fistulas.[7] A preliminary maintenance of remission study showed that infliximab, 10 mg/kg, administered intravenously every 8 weeks is effective in maintaining remission in patients with Crohn's disease.

In summary, initial treatment of mild to moderately active Crohn's disease should consist of budesonide or oral corticosteroids (alternatively, many clinicians would use 5-ASA and/or antibiotics prior to beginning corticosteroids). Patients with persistent symptoms may require oral corticosteroids, azathioprine or 6-mercaptopurine, methotrexate, infliximab, or surgical resection. Treatment of fistulizing Crohn's disease should initially consist of antibiotics and surgical incision and drainage of abscesses and/or fistulotomy if necessary. Patients with more refractory fistulizing disease may require treatment with azathioprine or 6-mercaptopurine and/or infliximab. Remission in patients with Crohn's disease should be maintained with oral mesalamine (minimal benefit), azathioprine or 6-mercaptopurine (these medications are also steroid sparing), methotrexate (also steroid sparing), and infliximab.

PREOPERATIVE PREPARATION

Once the decision to operate has been made, it is important to categorize the patient's preoperative comorbidities. Evaluating the nutritional status of patients is important because it is often compromised by severe disease and long-standing poor nutrition. If needed, total parenteral nutrition (TPN) is occasionally indicated in patients who are chronically ill. In a study of 395 malnourished patients, those who received 1 week of TPN had fewer noninfectious complications[8] than did those who did not receive TPN (43%).[9] Issues such as anemia can also be addressed prior to operative intervention.

Standard bowel preparation is provided to the patient and typically consists of laxatives and enemas, or 2 L of a lavage solution such as GoLYTELY. Metronidazole and neomycin are administered after completion of the mechanical preparation.[10] Alternatively, broad-spectrum intravenous antibiotics can be administered before and during the operation. We do not believe it is necessary to administer both preoperative and intraoperative broad-spectrum antibiotics unless an infectious complication is present at the time of surgery. Patients who have been treated with steroids are administered dexamethasone intravenously intraoperatively and postoperatively to avoid adrenal crisis induced by the stress of surgery. In addition to these measures, preoperative urethral stent placement can be an important adjunct to surgical therapy in situations such as a large abdominal abscess or phlegmon.

OPERATIVE CONCERNS

Intraoperative assessment of remaining bowel length is an important part of any surgical exploration in patients with Crohn's disease. Not only does this allow assessment of nutritional viability but it provides needed information for future discussions about additional surgical resections. The dreaded fear of short bowel syndrome, although real, has been significantly reduced with the addition of newer medications and a more conservative operative approach. In general, the mean length of small bowel in healthy people is approximately 640 cm.[11] Important anatomic markers of resection such as the terminal 80 cm of ileum are important because resection of this leads to disruption of the enterohepatic circulation and subsequent diarrhea, as well as hyperoxaluria and vitamin B_{12} malabsorption. In addition, surgeons must keep in mind that with greater resection length, a greater degree of malabsorption of fat-soluble vitamins and lactose may occur. It is well known that resection of more than 50% of the small bowel almost always produces malabsorption, and if 70% of the small bowel is resected, supplemental parenteral nutrition is nearly always required.

Recurrence

Possible predisposing factors for recurrence of disease are age and onset of disease; sex; site of disease (ileocolic having the highest risk); number of resections; symptomatic status at the time of surgery; length of small bowel resection; fistulizing versus obstructing forms of disease; proximal margin length; microscopic margin histology; strictureplasty; number of sites of disease; and the presence of colonic-only disease, granulomas, blood transfusions, family history, and prophylactic treatment.[12] Several authors have reported that there may indeed be cofactors or stimulants in the luminal contents that may induce early recurrence of Crohn's disease at a preanastomotic site.[13,14] Cameron et al.[13] have shown that patients who have a side-to-end ileocolonic anastomosis have recurrent involvement of the portion of ileum adjacent to the colon but not of the blind pouch distal to the anastomosis. Rutgeerts et al.[15] have shown that proximal diversion above an ileocolonic anastomosis prevents recurrence at that anastomotic site but that with closure of the proximal ileostomy, any possible recurrence will present promptly.

Anastomotic Technique

As with all bowel anastomosis, the principles of a successful anastomosis (no tension, good blood flow, and no contaminants) are followed in surgery for Crohn's disease. Options include the hand-sewn and the stapled anastomosis. It is helpful for surgeons to remember that when choosing a stapling device, there are 3.6- and 4.8-mm staple sizes. The largest staple length may be more appropriate for very thickened bowel. However, hemostasis may not be as good as that obtained with the 3.6-mm-length staple. Although resectional procedures can be performed in either manner, we have found that stapling strictureplasties can be difficult in fibrotic bowel.

The technical question of whether a wide side-to-side anastomosis as opposed to an end-end would reduce recurrence rates, perhaps by reducing stasis, is one which is currently being evaluated. Clearly patients undergoing an ileocolonic anastomosis face high rates of recurrence—42% by 15 years.[16-18] Whether a wide (90- to 100-mm) stapled anastomosis would result in a lower recurrence rate is the subject of the prospective Canadian-American Surgical Trial (CAST). The technique of a large side-to-side anastomosis is illustrated in Figure 153–1.

However, controversy exists, in that Cameron et al.[13] found no differences in recurrence for either anastomotic technique. Several retrospective studies have found that a stapled anastomosis achieved longer intervals of time between recurrences. Trials by Hashemi,[19] Yamamoto,[20] and Munoz-Juarez[21] and their colleagues have documented that stapled anastomoses are superior to hand-sewn ones in this regard. Specifically, Hashemi et al.[19] reported a reoperative rate of 2% in the stapled anastomotic group compared with 43% in the sutured end-to-end anastomotic group. Munoz-Juarez et al.,[21] in a bi-institutional retrospective study of 138 patients, found that 46 developed symptoms of recurrent Crohn's disease, of whom 33 were in the sutured conventional end-to-end group (48%) and 13 (19%) were in the wide-lumen stapled anastomotic group. The current CAST group study has completed enrollment of 173 patients in a prospective, randomized, controlled trial on this issue and is in the follow-up period.

Resection Margin

The role that margins play in recurrence of Crohn's disease is controversial as well. A long-term retrospective study by Krause et al.[22] compared two groups of patients: one with a "radical" resection of more than 10 cm of disease-free margins incorporated into the resection versus one with less than 10 cm of uninvolved bowel. They found, after a 14-year follow-up, that patients with longer margins have a lower recurrence rate (31%) and a better quality of life than patients with a shorter margin (83%). A similar retrospective review[23] reported similar results: A margin of normal tissue of less than 4 cm was associated with a 10-fold higher recurrence. In contrast, a study by Raab et al.[24] showed that the length of disease-free resection margins did not influence the risk of recurrence in a univariate and multivariate analysis in 353 patients undergoing a "curative" resection between 1969 and 1986. The only prospective study to address this issue compared patients undergoing ileocolic resection who were randomly assigned to one of two groups: (1) proximal margin of 2 cm or (2) proximal margin of 12 cm from the macroscopically involved disease.[25] There was no significant difference in recurrence rate in the 56 patients undergoing extended resection in contrast with the 75 patients undergoing limited resection, although the recurrence rate in the extended group was lower (18% vs. 25%).[25] These studies, along with several retrospective ones, have small numbers of patients and may harbor type II errors. This includes our own study, which did not show a significant difference between a proximal margin length of less than 5 cm versus a margin of 5 cm or more.[6]

How to proceed if all gross disease is resected, but microscopic changes remain at the margin of the resection, is controversial. Retrospective studies have yielded opposite results, with several reports showing a benefit of microscopically disease-free margins.[26-28] Other studies[25,29-34] have shown no difference in recurrence rates based on microscopic changes at the resection margin. The proximal histology at the margin of resection was examined in our prospective, randomized trial in which we compared nonspecific changes versus normal features on light microscopy and found no difference in recurrence rate.[6] Again, as in many other studies, there is a possibility of not detecting a true difference due to the small numbers in each group. Most recently we looked at 140 primary Crohn's resections and found that microscopic disease at the margin did indeed increase the risk for recurrence even in the setting of prophylactic medical therapy.[35]

In hopes of preserving bowel length, most surgeons accept an observed grossly negative margin of 1 or 2 cm. Few surgeons rely on frozen section margins. Although

a study of such a phenomenon in a large number of patients might show some difference (i.e., a lower recurrence rate) with negative margins or increasing length of resection, the theoretical benefit of a lower recurrence rate is outweighed by the inherent disadvantage of losing small bowel length. In addition, the widespread use of prophylactic medical therapy may have rendered this issue moot.

SITE-SPECIFIC CROHN'S DISEASE

Colonic Crohn's Disease

Crohn's disease involving only the colon occurs in 10% of patients. Most present with ileocolonic (40%) or small bowel only (30%) disease. The issue of retaining intestinal continuity is one that has been debated for years. Goligher[36] reported on 207 patients who underwent resection for colonic Crohn's disease. He found that there was a significantly higher recurrence rate in those undergoing subtotal colectomy and ileorectal anastomosis than in those undergoing proctocolectomy and ileostomy. These observations have also occurred in other series.[3,37] In our series of patients[6] with colonic Crohn's disease there was a significantly lower risk of recurrence in the group of patients who underwent a total proctocolectomy versus any other procedure. Having said this, our own follow-up series on the use of segmental resection clearly showed that long-term intestinal continuity can be maintained with a conservative surgical approach.[38] Given these observations, segmental resection should be the primary surgical procedure when appropriate, with an ostomy reserved for patients when extensive disease prompts proctocolectomy.[38]

Ileal Pouch–Anal Anastomosis in Patients with Crohn's Disease

Can surgeons successfully perform ileal pouch–anal anastomosis (IPAA) in patients with Crohn's disease?

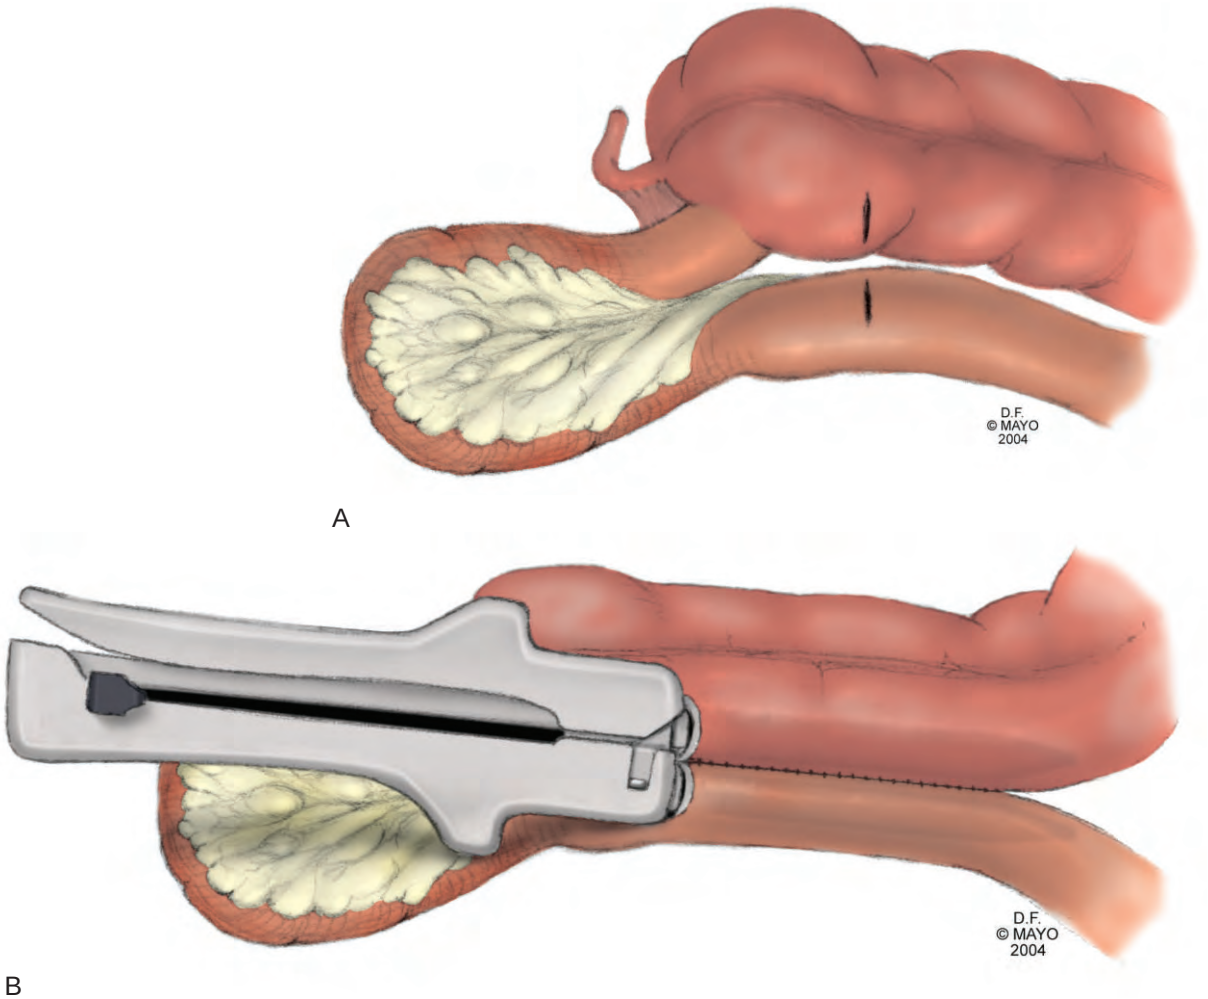

Figure 153–1. Line of resection for a right hemicolectomy done for cancer. **A,** One-centimeter transverse incisions are made on the antimesenteric borders of the ileum and colon to begin a stapled anastomosis. **B,** The first of two staple firings needed to create an anastomosis.

Although it is certainly technically possible, complication rates have been high.[39-41] In our series[42] of 37 patients who developed Crohn's disease subsequent to IPAA, 34 had manifestations of Crohn's in the pouch and/or anal canal; 45% of these patients required diversion or pouch excision. A series from Lahey Clinic[39] found that among their 32 patients with IPAA and Crohn's disease, 93% had complications and 29% experienced pouch failure within 5 years of surgery. Recently, our group reported pouch salvage rates with infliximab of 67% in patients with Crohn's disease.[43]

IPAA may be indicated for patients with Crohn's disease limited to the colon without evidence of anal canal involvement or small bowel disease. In a series by Regimbeau et al.,[44] only 35% of such highly selected patients experienced morbidity, with 10% experiencing failure. Although we believe that Crohn's disease remains a contraindication for IPAA, aggressive preoperative management with azathioprine and infliximab may facilitate IPAA in patients with Crohn's disease in the near future.

Laparoscope-Assisted Surgery for Crohn's Disease

Minimally invasive techniques are ideally suited for patients with Crohn's disease and have been shown in both randomized and nonrandomized studies to demonstrate similar or improved morbidity and mortality when compared with open resection.[45-60] Although the technique is less successful in patients with Crohn's disease who have large fixed masses, multiple complex fistulas, or recurrent disease, it may be still technically possible. Duepree et al.[51] reported that patients who underwent laparoscopic ileocolic resection for Crohn's disease had a shorter time to resumption of diet, time to bowel function, and length of stay. Others such as Milsom et al.[46] found that recovery of pulmonary function returned earlier in the laparoscopic group but time to first bowel movement and hospital stay were not significantly different. Bergamaschi et al.[49] found not only shorter hospital stay but a decreased rate of small bowel obstruction (35% in the open group, 11% in the laparoscopic group). In our own case-matched series of 70 laparoscopic versus 70 open resections for Crohn's disease, we found shorter operative times, decreased narcotic use, shorter length of stay, and a similar quality of life.[35]

SPECIFIC OPERATIONS

With improvements in medical therapy and acute care, emergency procedures for Crohn's disease are uncommon. If one is faced with acutely perforated Crohn's, depending on the degree of peritonitis,[61] one can either resect with a primary anastomosis or perform a diverting ileostomy or colostomy. Even though hemorrhagic episodes, especially life-threatening ones, are rare, this can occasionally occur, and all of the usual methods to localize bleeding points, including mesenteric arteriography, should be used. With localization of the disease and surgical resection, results should be excellent.[62]

Small Bowel

The three operative options that have been widely used for small bowel Crohn's disease are bypass, resection, and strictureplasty. Bypass was commonly used in the decades of the 1950s and 1960s but is rarely used now because a severely diseased segment of bowel left in place may cause continued symptoms, require treatment with steroids, and perhaps harbor a malignancy.[63] Small bowel bypass might be useful in patients with an already shortened small bowel or in patients with extensive strictures throughout the small bowel. Gastrojejunal bypass is useful in gastroduodenal Crohn's disease as an alternative to duodenal strictureplasty.

Resection

Resection and primary anastomosis are used in patients with fistulous disease of the small bowel, contained abscess, and isolated stenotic lesions in patients in whom there is adequate bowel remaining. During exploration—whether it be open or laparoscopic—bowel length is measured. Careful assessment of the extent of the disease is made. Typically, ileal Crohn's disease affects the distal 25 to 30 cm of terminal ileum and may continue into the cecum (Fig. 153–2). This type of resection for isolated Crohn's disease accounts for 80% to 90% of operations for Crohn's disease. An end-to-end ileoascending colostomy can be sutured, or a wide-stapled side-to-side, functional end-to-end anastomosis can be made with the linear stapler (see Fig. 153–1).

Strictureplasty

If the patient has the stenosing form of Crohn's disease, with skip areas present in the more proximal ileum and jejunum, strictureplasty is useful. Frequently, a combination of resection and strictureplasty is the optimal choice and has become widely accepted. Strictureplasty plays a prominent role in the surgical management of small bowel Crohn's disease. Isolated strictures under 10 cm in length are often considered best for strictureplasty (Fig. 153–3). Our original experience with 35 patients, in whom 71 strictureplasties were performed, and who were followed for more than 3 years, found no significant increase in postoperative morbidity and symptomatic recurrence rates of 20%.[64] Two more recent reports of more than 1400 strictureplasties, followed for more than 7 years, found reoperation rates of between 34% to 44% and symptomatic relief in more than 95% of patients.[65,66] The technique of strictureplasty is shown in Figure 153–3. It may be helpful to use a Baker tube, after making the initial transverse incision for strictureplasty, to define proximal and distal strictures that may be subtle or undetected. This also provides a method to further decompress the small bowel. Biopsy of the wall of each strictureplasty occasionally reveals an unsuspected adenocarcinoma.

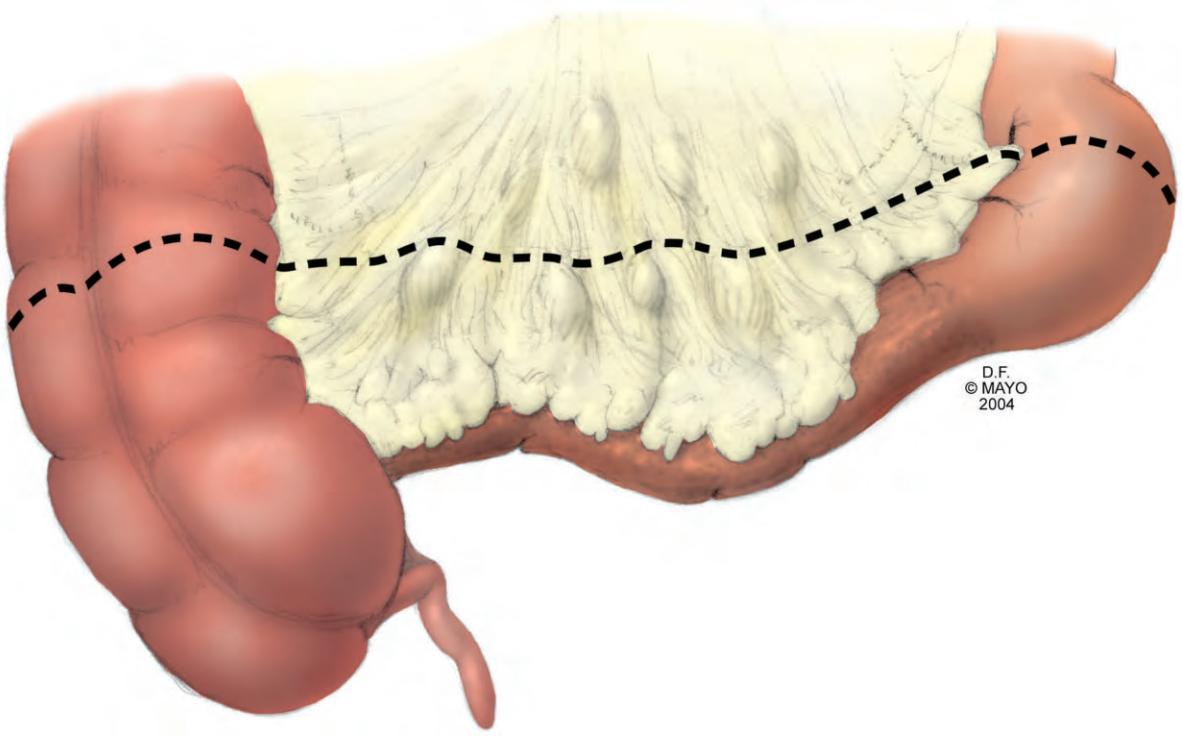

Figure 153–2. Ileocolonic Crohn's disease with line of transection. (©Mayo, 2004.)

Colonic Crohn's Disease

Preservation of bowel length and intestinal continuity remains the primary goal in patients with Crohn's disease of the colon. For those patients with severe disease scattered throughout the colon, subtotal colectomy and an ileorectostomy can be safely performed. Of the 42 patients who had this operation at the Mayo Clinic, 91% had improved health and quality of life after surgery, and 66% maintained an acceptable, functioning ileorectal anastomosis for at least 10 years.[67] Some patients may have more limited colonic involvement, and in this situation a segmental resection with anastomosis is indicated; 86% of these patients will remain stoma-free over a 14-year follow-up.[38]

Long colonic strictures may harbor an adenocarcinoma.[68] Strictureplasty has been occasionally used for colonic Crohn's disease, but one must question its use because strictures often represent carcinomas and recurrent Crohn's disease is common. Given the success of medical therapy, recently some would argue that if the patient has mild rectal disease and minimal perianal involvement, it would be reasonable to leave a short segment of rectum and anal canal in place but excluded from the fecal stream. In this way, the patient with anorectal Crohn's disease may respond to diversion and local treatment, with an opportunity for future reanastomosis.[19] In one study,[69] the long-term chances for closure of a temporary stoma were 75% when used for anastomotic protection or avoidance, 79% after postoperative complications, but only 40% for perianal or genital fistulas or for rectal inflammation or stenosis. Rectal disease and perianal fistula were independent predictors of a low possibility of stoma closure during follow-up. Unfortunately, many patients have not only severe colonic disease but mild to severe rectal disease with anorectal complications. These patients are best served with proctocolectomy and Brooke ileostomy.[70]

On those rare occasions that a patient presents with toxic megacolon from Crohn's disease, colectomy with closure of the proximal rectum and end-ileostomy is the procedure of choice. This operation can be done expeditiously and leaves no anastomosis in the abdomen. A common concern remains the treatment of the distal rectal stump.[71] It is our practice to oversew the stump or, in severe cases, to exteriorize it as a mucus fistula. In extreme cases, when both the colon and the rectum are severely involved, proctocolectomy with permanent end-ileostomy (Brooke ileostomy) may be required.[72] Occasional decompression of the stapled rectal remnant may decrease the incidence of stump "blowout."

It is well known that Crohn's patient are at high risk for perianal wound complications. Among 32 patients with Crohn's disease treated with complete proctectomy and primary closure at the Mayo Clinic, 50% had a healed perineum by 1 month after surgery, and 90% had healed by 1 year.[73] Persistent nonhealing of perineal wounds requires excision of the wound surface and secondary closure, skin grafts, a musculocutaneous flap, or some combination thereof.[74] To avoid the problem of a nonhealing wound, endorectal and sphincter-saving excisions rather than wide excision of the entire anorectum are useful. By using the well-vascularized muscles of the

anal canal, more rapid and complete healing can be expected.

The practice of proximal diversion is controversial. This operation may have its greatest role in patients who are extremely ill with Crohn's colitis. Proponents have reported improvement from fecal diversion.[75,76] In light of medical therapy such as the use of infliximab, the future treatment of diseased segments and the ability to close existing stomas may indeed be improved. Future studies in this area will be needed. In the past, it has been commonly noted that once the stoma is reversed, the disease flares again, requiring surgical treatment.[75]

Anorectal Crohn's Disease

The surgical treatment of perianal Crohn's disease is evolving. Today management is customarily a combined approach, encompassing both aggressive medical and conservative surgical management.[77] Anorectal Crohn's disease typically presents in three ways: ulceration, fistula, and stricture.[78-80] Michelassi et al.[81] observed that 23% of patients with Crohn's disease manifested perineal fistulas, 18% stenoses, 16% abscesses, 9% rectovaginal fistulas, 5% incontinence, and 29% a combination of problems. The cumulative incidence of perianal fistulas in Crohn's disease has been estimated by two population-based studies. Hellers et al.[82] reported a cumulative incidence of perianal fistulas of 23%. In a Mayo series, Schwartz et al.[83] showed that the cumulative incidence of fistulizing Crohn's disease in Olmsted County, Minnesota, between 1970 and 1993 was 38%. The lifetime risk for developing a fistula is 20% to 40%.[83-87] The key concept when operating on patients with anorectal Crohn's disease is to be conservative. Wide excisions of large amounts of tissue should not be performed. With conservative medical and surgical therapy, symptoms are often improved.

Perianal Abscess

The treatment of perianal abscess is prompt and adequate surgical drainage. Superficial abscesses require simple incision and drainage. Abscesses that are deep (supralevator or ischiorectal) should be drained using a mushroom catheter and/or a noncutting seton to provide adequate drainage with as little tissue trauma as possible (Fig. 153–4).[88]

Fistulas

Fistula disease is common among Crohn's patients. The surgical treatment of Crohn's fistula most commonly involves using a noncutting seton.[89-93] A seton is a nonabsorbable suture (or vessel loop) that is placed through the fistula tract (Fig. 153–5). The purpose of the seton is to promote drainage; thus, it decreases the risk of recurrent abscess while aggressive medical therapy is being

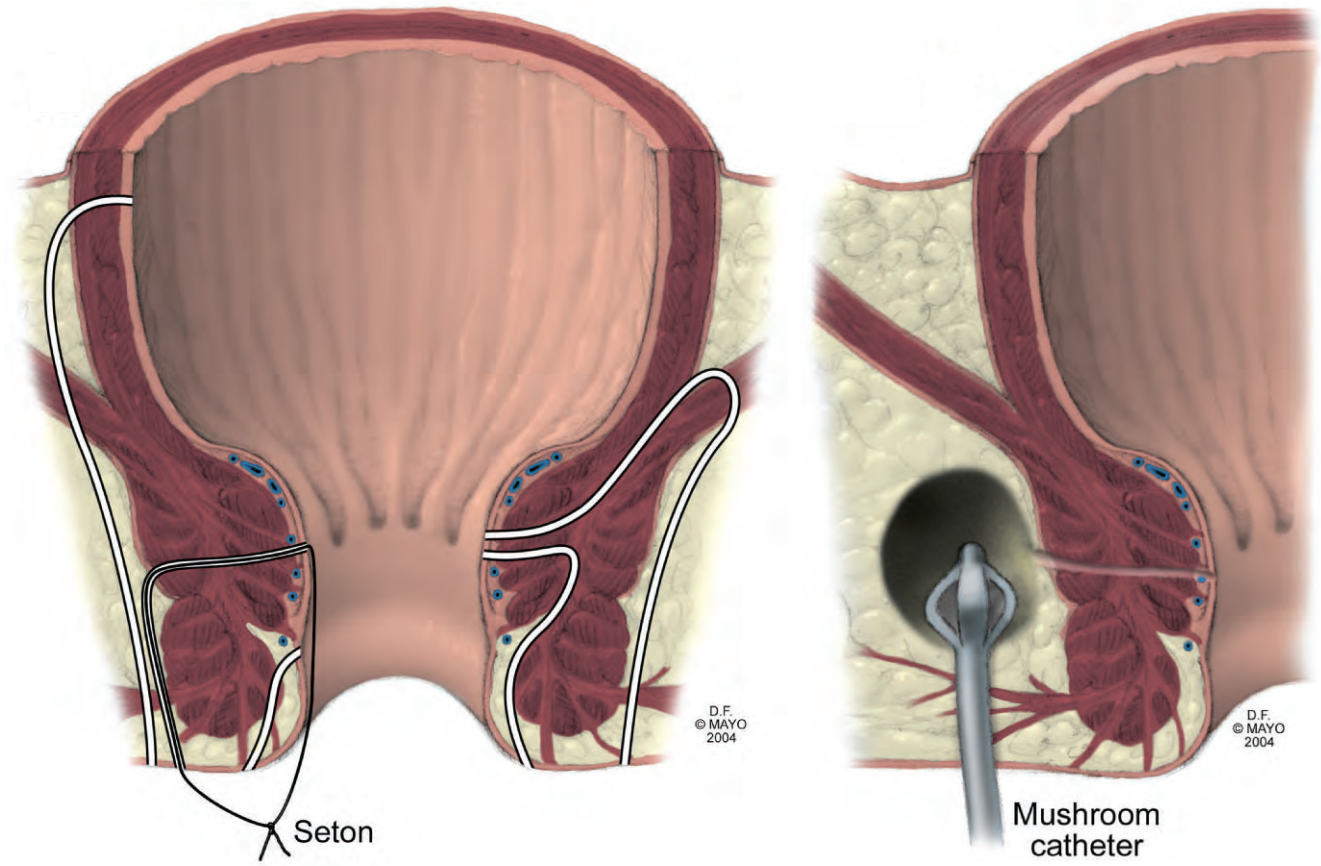

Figure 153–4. **A,** Draining seton in place, through a trans-sphincteric fistula. **B,** Perianal abscess treated with a Malecot catheter. (**A** and **B,** ©Mayo, 2004.)

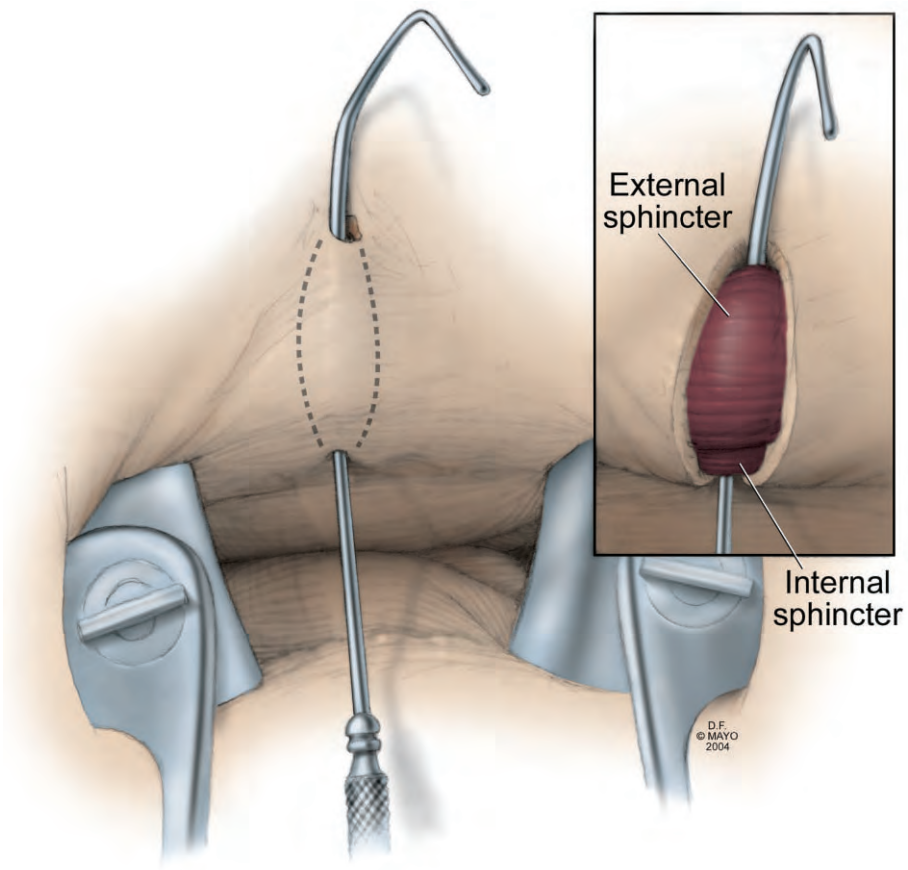
instituted. At the Mayo Clinic, 110 patients were surgically treated for perianal Crohn's fistula with either seton or superficial fistulotomy and aggressive medical therapy. After a median follow-up of 3 years, 86% of patients had complete healing or were asymptomatic.[94]

Others have studied similar patients. Among 27 patients with fistulizing Crohn's disease, Scott and Northover[92] reported that 85% of patients treated with noncutting setons experienced fistula closure. A high recurrence rate, which may be as much as 40% after removing the seton,[89,95] lends legitimacy to our use of concomitant antibiotics, azathioprine, or 6-mercaptopurine and infliximab.[77,95] With the use of medications such as infliximab, long-term and initial healing rates may be improved. The Mayo Clinic gastroenterology group recently reported that infliximab along with seton led to the complete resolution of perianal fistulas in 68% of patients.[96] We found that the addition of seton placement with infliximab reduced the rate of recurrent abscess. In a comparative study by Regueiro and Mardini,[97] perianal fistulas were treated with infliximab alone versus combination infliximab plus seton placement. They found that the initial response was improved with seton placement (100% versus 82.6%), lower recurrence rates (44% versus 79%), and longer time to recurrence (13.5 versus 3.6 months).

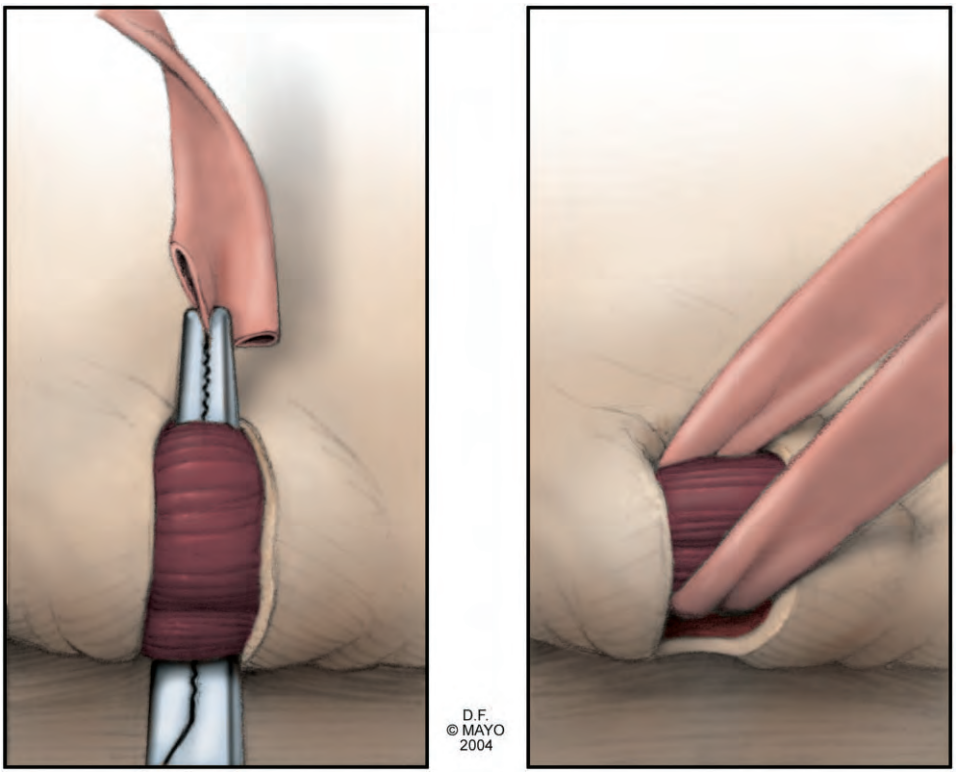
Although improvements in medical therapy and conservative surgical management of perianal Crohn's may lead to healing, some patients go on to proctectomy. In our own long-term series of patients with anorectal Crohn's,[98] two groups emerged. The first suffered severe rectal involvement and proceeded to proctectomy quite early in the disease process. The second group had more limited rectal disease and has been managed well with conservative treatment. Within this series, the cumulative probability of avoiding proctectomy was 92% at 10 years and 83% at 20 years.[99] In our more recent surgical study of 110 patients treated surgically for perianal disease, the severity of proctitis, the extent of fistulas and abscesses, and the presence of recurrent abscess all lead to a higher incidence of failure.[94]

Rectovaginal Fistula

Rectovaginal fistula is a particularly distressing complication of Crohn's disease. About 2% of women with Crohn's disease develop a rectovaginal fistula.

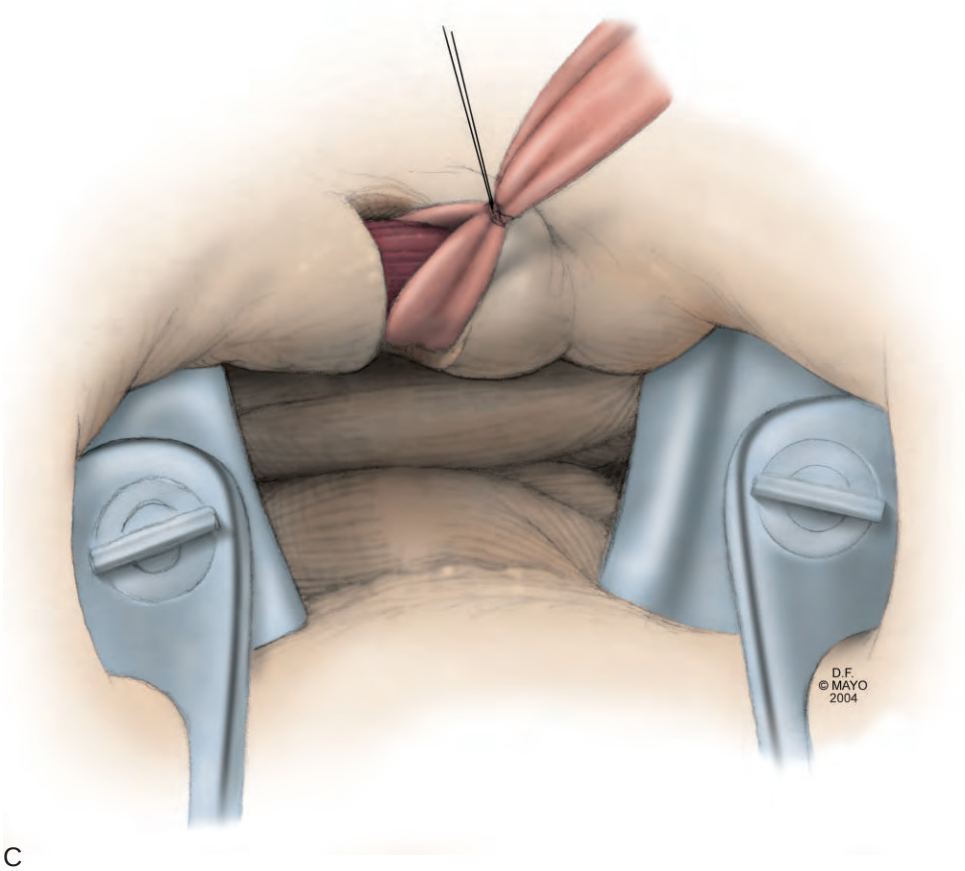


A



B

Figure 153–5. **A,** Probe through a perianal fistula with the internal sphincter exposed. **B,** Placement of a seton. *Continued*



C

Figure 153–5, cont'd. **C,** Securing a seton in place. (**A-C,** ©Mayo, 2004.)

Fortunately, most fistulas are very low and have no associated symptoms. Surgical treatment is reserved for those patients with an unacceptable quality of life in whom medical treatment has failed. The development of a rectovaginal fistula is a poor prognostic sign and may require proximal diversion to decrease local sepsis and/or eventual proctectomy. In patients undergoing rectovaginal fistula repair, the disease should be quiescent and the rectum distensible. In general, for very low rectovaginal fistula (<15% of the sphincter involved) and normal sphincter function, simple fistulotomy is a viable option. However, some surgeons advocate use of an endorectal advancement flap as an alternative to fistulotomy or noncutting setons in patients with a simple fistula who do not have active rectal inflammation.[99,100] An advancement flap involves creating a flap of tissue around the internal opening of a fistula and then moving healthy tissue over the excised area.[99,101] Joo et al.[99] reported sustained closure in 74% of 26 patients with fistulizing Crohn's disease treated with endorectal advancement flap. Hull and Fazio[102] reported that among 35 patients with an advancement flap for low anovaginal fistulas, the initial healing rate was 54% and an ultimate healing rate with repeat procedure was 68%, but few others have reported such good outcomes. Although these reported successes exist, in our experience this approach yields unpredictable results at best.

SUMMARY

In summary, surgery for Crohn's disease can be both extremely frustrating and highly rewarding. Surgeons must be familiar with a variety of techniques and options to adapt to the multitude of possible presentations in this disease. Innovation, research, and a combined medical-surgical approach will aid surgeons in conserving bowel length, preserving intestinal continuity, restoring patients to active lives, and improving their quality of life.

ACUTE APPENDICITIS

Acute appendicitis is one of the most common causes of an abdominal emergency and accounts for approximately 1% of all surgical operations.[1] Although rare in infants, appendicitis becomes increasingly common throughout childhood and reaches its maximal incidence between the ages of 10 and 30 years. After 30 years of age, the incidence declines, but appendicitis can occur in individuals of any age. Among teenagers and young adults, the male-to-female ratio is about 3:2. After age 25 years, the ratio gradually declines until the sex ratio is equal by the mid-30s.

Pathophysiology

The most commonly accepted theory of the pathogenesis of appendicitis is that it results from obstruction followed by infection.[2] The lumen of the appendix becomes obstructed by hyperplasia of submucosal lymphoid follicles, a fecalith, tumor, or other pathologic condition. Once the lumen of the appendix is obstructed, the sequence of events leading to acute appendicitis is probably as follows: Mucus accumulates within the lumen of the appendix, and pressure within the organ increases. Virulent bacteria convert the accumulated mucus into pus. Continued secretion combined with the relative inelasticity of the serosa leads to a further rise in pressure within the lumen. This results in obstruction of the lymphatic drainage, leading to edema of the appendix, diapedesis of bacteria, and the appearance of mucosal ulcers. At this stage, the disease is still localized to the appendix; therefore, the pain perceived by the patient is visceral and is localized to the epigastrium or periumbilical area.

Continued secretion into the lumen and increasing edema bring about a further rise in intraluminal and tissue pressure, resulting in venous obstruction and ischemia of the appendix. Bacteria spread into and through the wall of the appendix, and acute suppurative appendicitis ensues. Somatic pain occurs when the inflamed serosa of the appendix comes in contact with the parietal peritoneum and results in the classic shift of pain to the right lower quadrant.

As this pathologic process continues, venous and arterial thromboses occur in the wall of the appendix, resulting in gangrenous appendicitis. At this stage, small infarcts occur, permitting escape of bacteria and contamination of the peritoneal cavity. The final stage in the progression of acute appendicitis is perforation through a gangrenous infarct and the spilling of accumulated pus. Perforating appendicitis is now present, and morbidity and mortality increase.

Symptoms

The symptomatic history in acute appendicitis may vary, but cardinal symptoms are usually present.[1,3] The history usually begins with abdominal pain often localized to the epigastrium or the periumbilical area, followed by anorexia and nausea. Vomiting, if it occurs, appears next. After a variable period, usually about 8 hours, the pain shifts to the right side and usually into the right lower quadrant. At the time of presentation, the duration of pain is less than 24 hours in 75% of patients.

Pain

The typical pain of acute appendicitis initially consists of diffuse, central, minimally severe visceral pain, which is followed by somatic pain that is more severe and usually well localized to the right lower quadrant. Failure to follow the classic visceral-somatic sequence is common in acute appendicitis, occurring in up to 45% of patients who are proved subsequently to have appendicitis. Atypical pain may be somatic and localized to the right lower quadrant from its initiation. Conversely, the pain may remain diffuse and may never become localized. In older patients, atypical pain patterns occur more frequently.

Patients with high retrocecal appendicitis may present with only diffuse pain in the right flank. Similarly, patients in whom the entire appendix is within the true

pelvis may never experience somatic pain and, instead, may have tenesmus and vague discomfort in the suprapubic area.

Anorexia, Nausea, and Vomiting

Anorexia and nausea are present in almost all patients with acute appendicitis, but vomiting occurs in less than 50% of patients. The presence or absence of vomiting is not a criterion for the diagnosis of appendicitis. When vomiting does occur, it is usually not persistent, and most patients vomit only once or twice. If vomiting occurs, it occurs *after* the onset of pain with such regularity that if it precedes pain, the diagnosis of appendicitis should be questioned.

Constipation and Diarrhea

A history of the recent onset of constipation or diarrhea is not helpful in the diagnosis of appendicitis. A greater percentage of patients with appendicitis complain of constipation, but some give a history that defecation relieves the pain.

Physical Examination

Typical physical signs of acute appendicitis include localized tenderness in the right lower quadrant, muscle guarding, and rebound tenderness. Cutaneous hyperesthesia, right-sided pelvic tenderness on rectal examination, and the presence of a psoas or obturator sign occur less frequently and tend to be highly dependent on the examiner. Although often temperature is normal, fever up to 38° C occurs. In the usual case of acute, nonperforated appendicitis, higher fever occurs infrequently.

Tenderness and Muscle Guarding

On routine abdominal examination, an area of maximal tenderness often is elicited in the area of McBurney's point, which is located two thirds of the distance along a line from the umbilicus to the right anterior superior iliac spine. If the appendix is in a high retrocecal position or is entirely within the true pelvis, point tenderness and muscle rigidity might not be elicited. In high retrocecal appendicitis, tenderness may occur over a large area, and there may be no signs of muscle rigidity. In pelvic appendicitis, neither tenderness nor muscle guarding may be present. Both signs are often lacking or only minimally expressed in the aged population.

Signs of peritoneal inflammation or irritation in the right lower quadrant are also helpful in the diagnosis of acute appendicitis and can be demonstrated by many methods. Asking the patient to cough or bounce on the heels elicits this type of pain in 85% of patients. Rebound tenderness is elicited by the sudden release of abdominal palpation pressure. Rovsing's sign—pain elicited in the right lower quadrant with palpation pressure in the left lower quadrant—is a sign of acute appendicitis. Muscle guarding, manifested as resistance to palpation, increases as the severity of inflammation of the parietal peritoneum increases. Initially, there is only voluntary guarding, but this is replaced by reflex involuntary rigidity.

Abdominal Mass

As the disease process progresses, it may be possible to palpate a tender mass in the right lower quadrant. Although the mass may be caused by an abscess, it can also result from adherence of the omentum and loops of intestine to an inflamed appendix. When appendicitis becomes advanced enough that there is a large, inflamed mass and the anterior abdominal wall is involved, the patient often avoids sudden movements that can cause pain.

Psoas Sign

The right hip is often kept in slight flexion to keep the iliopsoas muscle relaxed. Stretching the muscle by extension of the hip or further flexion against resistance can initiate a positive psoas sign, indicating irritation of the muscle by an inflamed appendix. A psoas sign is seldom seen in early appendicitis and can be elicited in patients without any pathologic condition.

Rectal Examination

Rectal examination, although essential in all patients with suspected appendicitis, is helpful in only a few of them. In patients with an uncomplicated appendicitis, the finger of the examiner cannot reach high enough to elicit pain on rectal examination.

If the appendix ruptures, the physical examination will change. If the infection is contained, a tender mass will often develop in the right lower quadrant, and the area of tenderness will now encompass the entire right lower quadrant. Involuntary guarding becomes evident and rebound tenderness more marked. The patient's temperature will be more like that seen with abscess formation and may rise to 39° C with a corresponding tachycardia.

If appendiceal rupture fails to localize, signs and symptoms of diffuse peritonitis will develop. Tenderness and guarding become generalized, the temperature remains higher than 38° C with spikes to 40° C, and the pulse rate increases to more than 100 beats/min.

Laboratory Tests

In the early diagnosis of acute appendicitis, laboratory tests are of little value. Up to one third of patients, particularly older patients,[4] have a normal total leukocyte count with acute appendicitis,[1,5] and more than half have, at most, a mild elevation. Even when the total leukocyte count and the differential white blood cell (WBC) count are abnormal, the degree of abnormality does not correlate well with the degree of appendiceal

inflammation.[6] Even when the total WBC count is normal, the differential WBC count often reveals a shift to the left with an increase in the percentage of polymorphonuclear neutrophils.[5] Less than 4% of patients have both a normal total WBC count and a normal differential count. The most important fact to remember when considering the diagnosis of appendicitis is that the clinical findings take precedence over the WBC count when they are at variance.

Urinalysis is helpful in the differential diagnosis of patients with lower abdominal pain only when it reveals significant numbers of red blood cells, WBCs, or bacteria. Minimal numbers of red blood cells, WBCs, and bacteria are seen in normal patients as well as in patients with appendicitis.

Patients with advanced appendicitis and abscess formation or generalized peritonitis may have abnormalities in liver function tests that mimic obstructive jaundice, biliary stasis, or other primary liver problems.

Radiographic Examination

With rare exceptions, plain roentgenologic examination of the abdomen is of little help in the differential diagnosis of acute appendicitis. The exceptions are when a fecalith is demonstrated and when other diagnoses such as acute cholecystitis, perforating duodenal ulcer, perforating colon cancer, acute diverticulitis, and pyelonephritis are being excluded.

It is not unusual to see cecal distention or a sentinel loop of distended small intestine in the right lower quadrant in patients with acute appendicitis. In late appendicitis with perforation and abscess formation, a mass can often be demonstrated that is extrinsic to the cecum. There may be scoliosis to the right, lack of the right psoas shadow, lack of small bowel gas in the right lower quadrant with abundant gas elsewhere in the small bowel, and signs of edema of the abdominal wall. With late appendicitis and generalized peritonitis, there is an ileus pattern with generalized gas throughout the small and large intestine.

Barium enema (BE) examination was recommended in the past in young women in whom the diagnosis was still in question after hours of observation and in patients with a debilitating systemic disease, such as leukemia, in whom the operative risk is markedly increased.[7] The findings of significance on BE include lack of filling or partial filling of the appendix and an extrinsic pressure defect on the cecum (the "reverse 3" sign).[8] Computed tomography (CT) and ultrasonography (US) are now preferred to BE in these circumstances.

As demonstrated in many studies, an experienced radiologist is able to diagnose acute appendicitis using US with an accuracy of greater than 90%.[9-11] Appendicitis is diagnosed if the maximal cross-sectional diameter of appendix exceeds 6 mm, if it is noncompressible, if an appendolith is present, or if a complex mass is demonstrated.[12] There are other criteria that are not universally agreed on, such as rigidity and nonmobility. Nonvisualization of the appendix is not a criterion for appendicitis. US can also be helpful in the diagnosis of perforated appendicitis with abscess formation. Studies that compared US and CT have demonstrated CT to be more accurate than US in the diagnosis of appendicitis in clinically equivocal cases.[3] Therefore, US should be used only when an experienced radiologist with an interest in appendicitis is available.

Although more expensive, CT has also been demonstrated to be of benefit in the diagnosis of acute appendicitis and has an accuracy of greater than 94%.[13,14] The cost can be reduced with no significant loss in diagnostic accuracy by performing a limited, unenhanced CT.[15] Appendicitis is diagnosed when the appendix is thickened with a diameter greater than 6 mm; a phlegmon, fluid, or abscess is present; there is an appendolith; and there are inflammatory changes in the periappendiceal fat (streaking and poorly defined increased attenuation).[13,14] The presence of pericecal inflammation without the presence of an inflamed appendix or an appendolith without the presence of periappendiceal inflammation are both insufficient to diagnose acute appendicitis.

An important consideration for CT in the diagnosis of acute appendicitis is when to use it. In one study, CT scanning excluded appendicitis in almost half of the patients in the study and identified an alternative diagnosis in 51% of those patients. The authors stated that the routine use of CT in patients with suspected appendicitis avoids unnecessary appendectomies and unnecessary delays before surgical treatment and saves money.[16] CT is not indicated in patients with an unequivocal diagnosis of appendicitis or in patients with a low risk of the diagnosis. In menstruating women and any patient with an equivocal diagnosis, a CT scan is probably indicated. An added benefit of the use of CT is that an identified abscess can be percutaneously drained during the same procedure.[17]

Acute Appendicitis in Infants and Young Children

The diagnosis of acute appendicitis is difficult in infants and young children for many reasons. The patient is unable to give an accurate history, and although appendicitis is infrequent, acute nonspecific abdominal pain is common in infants and children. Because of such factors, the diagnosis and treatment are often delayed, and complications develop.[18,19]

The clinical presentation of appendicitis in children can be quite similar to nonspecific gastroenteritis; thus, the suspicion of appendicitis often is not entertained until the appendix has ruptured and the child is obviously ill.[20] Two thirds of young children with appendicitis have had symptoms for more than 3 days before appendectomy.[19] Because children often cannot give an accurate history of their pain, the physical examination and other aspects of the history must be relied on to make the diagnosis. Vomiting, fever, irritability, flexing of the thighs, and diarrhea are likely early complaints. Abdominal distention is the most consistent physical finding. As in adults, the total leukocyte count is not a reliable test.

The incidence of perforation in infants younger than 1 year of age is almost 100%, and although it decreases with age, it is still 50% at 5 years of age. The mortality rate in this age group remains as high as 5%. In one series, nearly 40% of children with complicated appendicitis had been seen previously by a physician who failed to make the diagnosis of appendicitis.[19]

Appendicitis in Young Women

Although the overall incidence of negative laparotomy in patients suspected of having appendicitis is as high as 20%, the incidence in women younger than 30 years of age is as high as 45%. Pain associated with ovulation; diseases of the ovaries, fallopian tubes, and uterus; and urinary tract infections (cystitis) account for most of the misdiagnoses. If a young woman has atypical pain; no muscular guarding in the right lower quadrant; and no fever, leukocytosis, or leftward shift in the differential WBC count, it is best to observe the patient with frequent re-examinations. If after several hours the patient's signs and symptoms remain stable, it is appropriate to perform a CT scan.

Appendicitis During Pregnancy

The risk of appendicitis during pregnancy is the same as it is in nonpregnant women of the same age; the incidence is 1 in 2000 pregnancies. Appendicitis occurs more frequently during the first two trimesters, and during this period the symptoms of appendicitis are similar to those seen in nonpregnant women.[21] Surgery should be performed during pregnancy when appendicitis is suspected, just as it would be in a nonpregnant woman. As in the nonpregnant patient, the effects of a laparotomy that produces no findings are minor, whereas the effects of ruptured appendicitis can be catastrophic. Recent studies indicate that there is no increase in morbidity and mortality with laparoscopic appendectomy versus open appendectomy for the patient or the fetus.

During the third trimester of pregnancy, the cecum and appendix are displaced laterally and are rotated by the enlarged uterus. This results in localization of pain either more cephalad or laterally in the flank, leading to delay in diagnosis and an increased incidence of perforation. Factors such as displacement of the omentum by the uterus also impair localization of the inflamed appendix and result in diffuse peritonitis. In cases of uncomplicated appendicitis, the prognosis for the infant following appendectomy is directly related to the infant's birth weight. If peritonitis and sepsis ensue, infant mortality increases because of prematurity and the effects of sepsis.

Acute appendicitis can be confused with pyelitis and torsion of an ovarian cyst. However, death from appendicitis during pregnancy is mainly caused by a delay in diagnosis. In the final analysis, early appendectomy is the appropriate therapy in suspected appendicitis during all stages of pregnancy.[21]

Appendicitis in the Elderly Population

Appendicitis has a much greater mortality rate among elderly persons when compared with young adults. The increased risk of mortality appears to result from both delay in seeking medical care and delay in making the diagnosis.[22] The presence of other diseases associated with aging contributes to mortality, but the major reason for the increased mortality of appendicitis in the aged is delay in treatment. Classic symptoms are present in elderly persons but are often less pronounced. Right lower quadrant pain localizes later and may be milder in elderly persons. On initial physical examination, the findings are often minimal, although right lower quadrant tenderness will eventually be present in most patients.[23] Distention of the abdomen and a clinical picture suggesting small bowel obstruction are commonly seen.

More than 30% of elderly patients will have a ruptured appendix at the time of operation.[23] Although other factors play a role, delay in seeking care and in making the diagnosis are the major reasons for perforation. It is imperative, therefore, that once the diagnosis of acute appendicitis is made, an urgent operation must be advised.

Differential Diagnosis

The differential diagnosis of abdominal pain is a stimulating exercise. When the classic symptoms of appendicitis are present, the diagnosis of appendicitis is usually easily made and is seldom missed. When the diagnosis is not obvious, knowledge of the differential diagnosis becomes important. Most of the entities in the differential diagnosis of appendicitis also require operative therapy or are usually not made worse by an exploratory laparotomy. Therefore, it is essential that one eliminate those diseases that do not require operative therapy and can be made worse by operation, such as pancreatitis, myocardial infarction, and basilar pneumonia.

The diseases in young children that are most frequently mistaken for acute appendicitis are gastroenteritis, mesenteric lymphadenitis, Meckel's diverticulum, pyelitis, small intestinal intussusception, enteric duplication, and basilar pneumonia. In mesenteric lymphadenitis, an upper respiratory infection is often present or has recently subsided. Acute gastroenteritis is usually associated with crampy abdominal pain and watery diarrhea. Intestinal intussusception occurs most frequently in children younger than 2 years of age, an age at which appendicitis is uncommon. With intussusception, a sausage-shaped mass is frequently palpable in the right lower quadrant. The preferred diagnostic procedure is a gentle BE, which, in addition to making the diagnosis, usually reduces the intussusception.

In teenagers and young adults, the differential diagnosis is different in men and women. In young women, the differential diagnosis includes ruptured ectopic pregnancy, mittelschmerz, endometriosis, and salpingitis.[24] Chronic constipation also needs to be considered in young women. The symptoms that accompany the acute

onset of regional enteritis can mimic acute appendicitis, but a history of cramps and diarrhea and the lack of an appropriate history for appendicitis are hints that the diagnosis is regional enteritis.

In young men, the potential list of differential diagnoses is smaller and includes the acute onset of regional enteritis, right-sided renal or ureteral calculus, torsion of the testes, and acute epididymitis.

In older patients, the differential diagnosis of acute appendicitis includes diverticulitis, a perforated peptic ulcer, acute cholecystitis, acute pancreatitis, intestinal obstruction, perforated cecal carcinoma, mesenteric vascular occlusion, rupturing aortic aneurysm, and the disease entities already mentioned for young adults.

Treatment

Preoperative Preparation

It is not necessary to rush a patient with a presumed diagnosis of acute appendicitis directly to the operating room. All patients, especially those with a presumed diagnosis of peritonitis, should be adequately prepared before being taken to the operating room. Selected patients with a palpable right lower quadrant mass may be initially managed without operation.[25]

Intravenous fluid replacement should be initiated and the patient resuscitated as rapidly as possible, especially when peritonitis is suspected. Once the patient has a good urinary output, it can be assumed that resuscitation is complete. Nasogastric suction is especially helpful in patients with peritonitis and profound ileus. If the patient's body temperature is higher than 39° C, appropriate measures should be taken to reduce fever prior to beginning an operation.

A broad-spectrum antibiotic, such as cefoxitin, should be administered preoperatively to help control sepsis and to reduce the incidence of postoperative wound infections. If, at the time of operation, the patient has early appendicitis, antibiotic administration can be stopped after one postoperative dose. Antibiotics should be continued as clinically indicated in patients who have gangrenous or ruptured appendicitis with localized or generalized peritonitis.

Examination Under Anesthesia

After the induction of anesthesia, the patient's abdomen should be systematically palpated. Such an examination may, on occasion, demonstrate another pathologic condition to be the cause of the patient's symptoms, such as acute cholecystitis. It also may be possible to palpate an appendiceal mass that will confirm the suspected diagnosis.

Uncomplicated Appendicitis Without a Palpable Mass

In this circumstance, when the diagnosis of acute appendicitis has been made and there is no reason to suspect that the appendix has ruptured, an appendectomy should be performed. The earlier the diagnosis is made and the sooner the appendectomy is performed, the better the prognosis. As stated earlier, if there is any doubt about whether the appendix has ruptured, the operation should be performed at once, because the morbidity of a perforated appendix is 100-fold greater than that of an uncomplicated appendectomy. The latter procedure should have a surgical mortality rate of less than 0.1%, whereas in contrast, the mortality rate of a ruptured appendix can be as high as 10%.

One recommended incision for a routine appendectomy is a transverse one (i.e., Rockey-Davis, Fowler-Weir-Mitchell incisions). The incision is made in a transverse direction, 1 to 3 cm below the umbilicus, and is centered on the midclavicular line. The length of the incision should be approximately 1 cm longer than the breadth of the surgeon's hand. The aponeurosis and muscles of the abdominal wall are split or incised in the direction of their fibers (Fig. 154–1). Exposure of the appendix through this incision is better when compared with that obtained through the classic McBurney incision, particularly in patients with a retrocecal appendix and in those who are obese.

The other recommended incision, the gridiron, or muscle-splitting one (McBurney incision), can be used. This is the most widely used incision in uncomplicated appendicitis. The skin incision is made through a point one third of the way along a line from the anterosuperior spine of the ileum to the umbilicus. The incision is made obliquely, beginning inferiorly and medially, and extending laterally and superiorly. It should be 8 to 10 cm in length, with its most medial extent being the lateral edge of the rectus muscle. The aponeurosis and muscles of the abdominal wall are split or incised in the direction of their fibers in such a manner that the entire skin incision can be used for exposure. After entering the peritoneum, the appendix is found as described for the transverse incision. The exposure through a McBurney incision, especially for a retrocecal appendix, can be awkward unless the appendix lies immediately below the incision. If necessary, the incision can be extended medially, partially transecting the rectus sheath, but this maneuver is usually helpful only in a pelvic appendicitis.

If there is doubt about the diagnosis of acute appendicitis and an exploratory laparotomy is indicated, a vertical midline incision is more appropriate. An appendectomy can be performed with little difficulty through such an incision.

After the peritoneum is opened, the appendix is identified by following the anterior cecal taenia to the base of the appendix. The inflamed appendix is coaxed into the wound by gentle traction and the transection of adhesions, if present. If the appendix is retrocecal or retroperitoneal, or if the local inflammation and edema are intense, exposure is improved by dividing the lateral peritoneal reflection of the cecum. At the end of this maneuver, the cecum should lie within the wound and the appendix should be at the level of the anterior abdominal wall so that continuing vigorous retraction is unnecessary while removing the appendix (see Fig. 154–1).

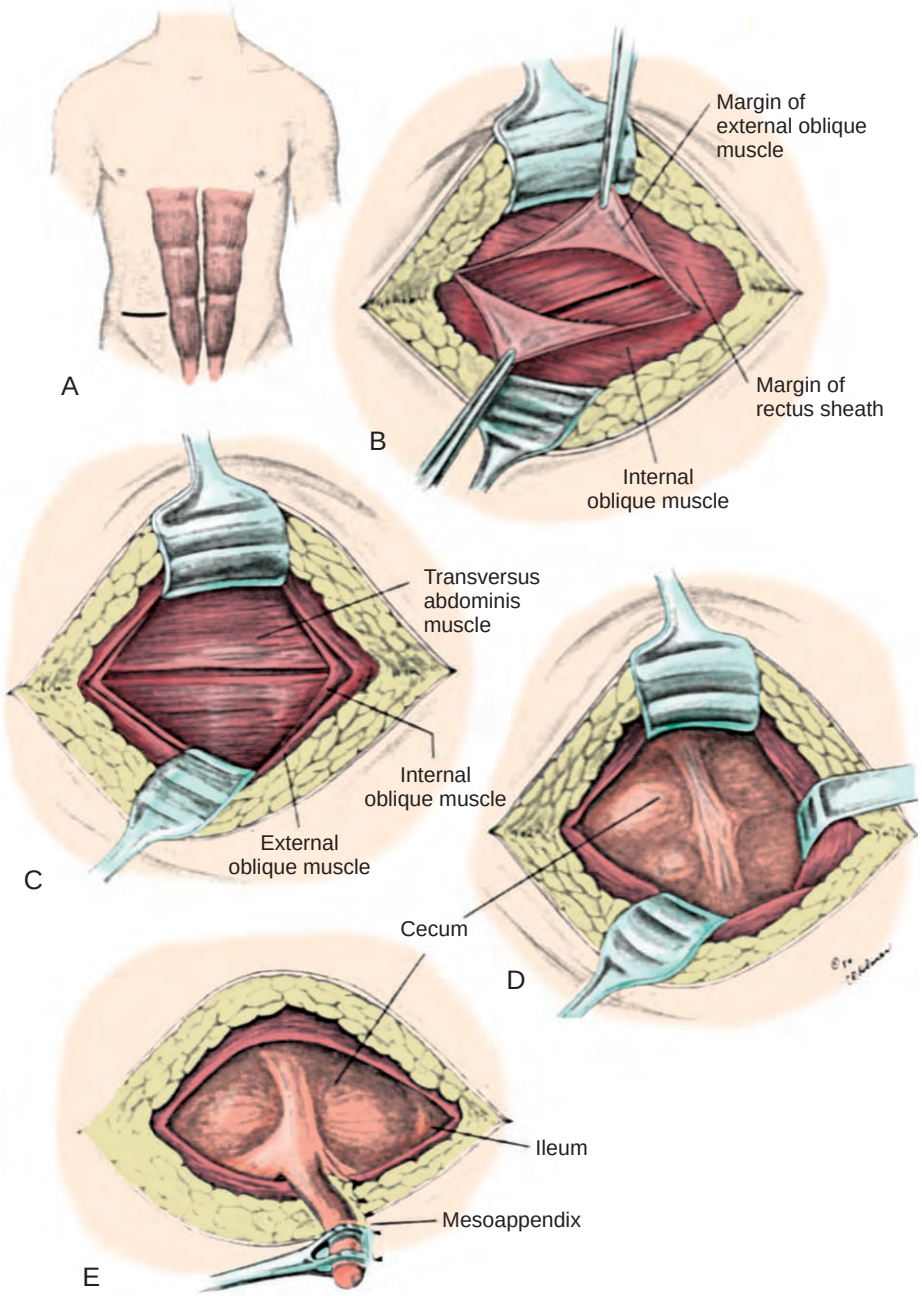

Figure 154–1. Steps in exposing the appendix for an appendectomy through a transverse incision. **A,** Placement of the skin incision. **B** and **C,** External and internal oblique and transversus abdominis muscles are divided in the direction of their fibers. **D,** After incision of the peritoneum, the cecum is exposed and the appendix is located by following the anterior cecal taenia inferiorly. **E,** The cecum is mobilized into the wound through incision of its lateral peritoneal reflections. (**A-E,** From Moody FG, Carey L, Jones RS, et al: Surgical Treatment of Digestive Diseases. Chicago, Year Book, 1986.)

If the appendix is not adherent, its base can be easily identified because the entire appendix often pops into the operative field. If the appendix is adherent, however, its base may be difficult to recognize. Aids in recognition include the following:

1. All three taeniae lead to and end at the base of the appendix.
2. The ileocecal junction can usually be identified, just below which is the base of the appendix.

If the appendix does not come into the wound but the base has been identified, an Allis clamp can be placed around but not on the appendix for traction. An effort is made to deliver the tip of the appendix into the operative field. If the appendix is not adherent to surrounding tissues, traction on the Allis clamp is usually successful in delivering the appendix.

Once the appendix has been freed up, the mesoappendix is transected beginning at its free border, taking small bites of the mesoappendix between pairs of hemostats placed approximately 1 cm from and parallel to the appendix. This process should be repeated until the base of the appendix is reached. If exposure of a long, adherent appendix is difficult, the mesoappendix can be transected in a retrograde manner beginning at the base of the appendix.

There are three ways to handle the appendiceal stump: simple ligation, inversion, and a combination of ligation and inversion. Either simple ligation or inversion

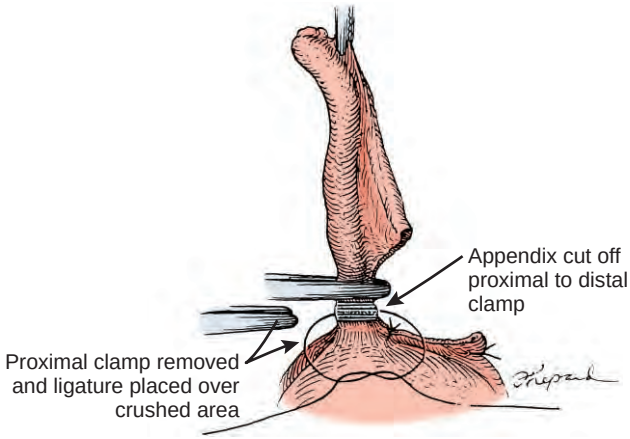

Figure 154–2. Ligation of the stump of the appendix in the groove formed by a crushing clamp. (From Partipilo AV: Surgical Technique and Principles of Operative Surgery, 4th ed. Philadelphia, Lea & Febiger, 1949.)

is acceptable and has a comparable incidence of complications. The combination of ligation and inversion is not recommended, because it does not reduce the risk of septic complications, but it does create conditions conducive to the development of an intramural abscess or mucocele. Also, the ligated and inverted appendiceal stump may later appear on a subsequent BE as a cecal "tumor" and be a source of diagnostic difficulties.[26]

Simple ligature of the appendiceal stump is accomplished by crushing the appendix at its base with a hemostat, then moving the hemostat and replacing it on the appendix just distal to the crushed line. A ligature of monofilament suture is placed in the groove caused by the crushing clamp and is tied tightly (Fig. 154–2). The appendix is transected just proximal to the hemostat and removed. Inversion of an unligated stump using a Z-stitch (Fig. 154–3), rather than the more conventional pursestring suture, is preferred. The upper level of the Z-stitch is placed as a Lembert suture in the cecum, just distal to the base of the appendix. The suture is then brought around the base of the appendix and continued as a second Lembert suture beneath the base of the appendix. The appendix is then transected between clamps, the stump is inverted into the cecum, the proximal clamp is removed, and the ends of the Z-stitch are tied over the stump of the appendix. The appendiceal stump is not ligated. If the appendiceal stump is unsuitable for inversion because of edema, it should simply be ligated and not inverted.

Laparoscopic Appendectomy

Laparoscopic and minimal access surgery continues to expand in the field of general surgery, and diagnostic laparoscopy and laparoscopic appendectomy have become accepted procedures in many surgeons' practices. The early use of diagnostic laparoscopy in patients with right lower quadrant abdominal pain and suspected appendicitis reduces the risk of appendiceal perforation and the negative appendectomy rate to less than 10%.[27] Diagnostic laparoscopy is particularly useful in women of reproductive age and in the obese. In the former, frequently confounding gynecologic disorders can be well visualized to provide the diagnosis, and in the latter, laparoscopy can eliminate the morbidity risks of a large incision. In addition, it is safe to not proceed with appendectomy if the appendix appears normal.[28,29]

Conversion of diagnostic laparoscopy to therapeutic laparoscopy is easily accomplished by the addition of other ports. Trocar placement for laparoscopic appendectomy is a matter of surgeon choice with consideration of the triangle rule for port placement. Diagnostic laparoscopy is usually performed through a periumbilical port, with a 10/11-mm port added midway between the umbilicus and pubis and a 5-mm port placed over the appendix or the right midlateral abdomen if appendectomy is performed (Fig. 154–4). Once the diagnosis is confirmed, the mesoappendix can be taken down with either hemoclips or the harmonic scalpel. The appendix is amputated from the cecum between endoloops or with an endo-GIA stapler (Fig. 154–5). The appendix can then be removed from the abdomen with a specimen pouch or withdrawn into the 10/11-mm port. Care should be taken to prevent contact of the appendix or its contents with the wound edges.

There is general agreement that patients undergoing laparoscopic appendectomy have less postoperative pain, a lower rate of wound infection, a lower overall complication rate, a more rapid return to diet, a shorter hospital stay, a longer operative time, and more equipment charges in the operating room.[30-33] In contrast, a more rapid return to work and a lower complication rate are more controversial claims because prospective studies show differing results.[34,35] Laparoscopic appendectomy results in a lower wound infection rate compared with an open procedure but has a higher intra-abdominal abscess rate if the appendix is perforated. Appendicitis with abscess should not be addressed laparoscopically because the pneumoperitoneum can disrupt the abscess cavity with soilage of the abdomen. Dissection of the abscess laparoscopically carries an undue risk of injury to the bowel and mesentery. Other relative contraindications to laparoscopic appendectomy include previous abdominal surgery precluding safe trocar placement, uncontrolled coagulopathy, and significant portal hypertension.

Laparoscopic appendectomy appears to be safe and efficacious. It provides a rapid diagnosis and a significant reduction in negative appendectomy rate in females of child-bearing age with suspected appendicitis. Minimal access surgery reduces the morbidly risk in obese patients who require an appendectomy.

Perforated or Gangrenous Appendicitis with a Periappendiceal Mass

When a mass is detected by examination under anesthesia, a transverse incision is made over the most prominent portion of the mass. The muscles and aponeuroses are split along their lines of cleavage in gridiron fashion.

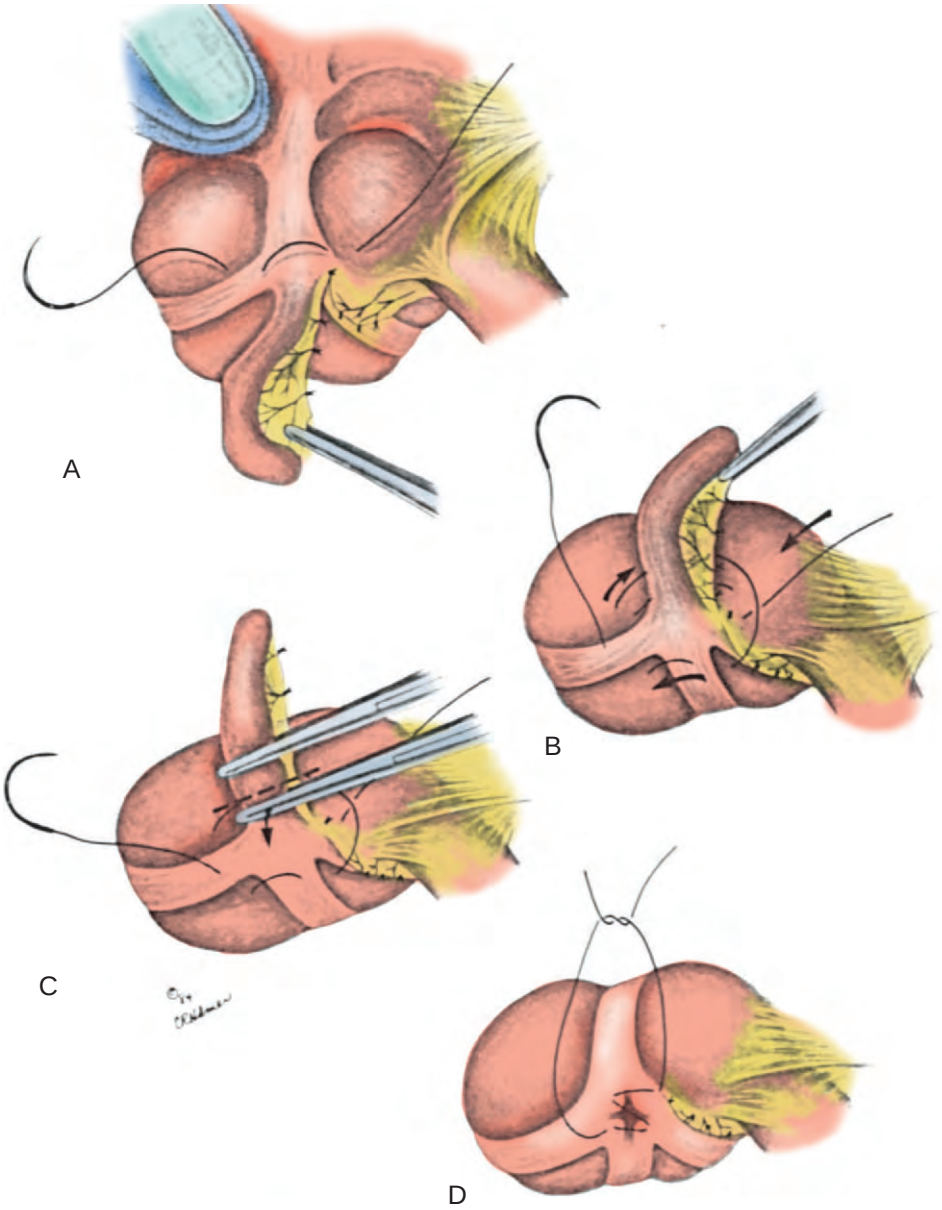

Figure 154–3. Use of a Z-stitch to invert the unligated appendiceal stump. **A,** Two bites of the suture are placed in the cecum 1 cm distal to the base of the appendix. **B,** The suture is then brought around the appendix medially and two additional bites are placed beneath the base of the appendix. **C,** The appendix is then transected. **D,** The stump of the appendix is inverted into the cecum and the clamp is removed as the suture is tightened. (**A-D,** From Adams JT: Z-stitch suture for inversion of the appendiceal stump. Surg Gynecol Obstet 127:1321, 1968.)

After entering the peritoneal cavity, the wound should be packed immediately to prevent contamination of the abdominal cavity. As mentioned earlier, the mass may be made up of omentum and loops of small intestine adherent to the inflamed appendix, and an abscess may not be present. If feasible, an appendectomy is then performed; usually it will not be possible to invert the stump, so simple ligation is preferred.

It is not necessary to place a subfascial drain in a patient with a gangrenous appendix and minimal or no periappendiceal pus. If there is a periappendiceal abscess and the tissues are fixed so as to create a dead space, the cavity should be drained with one or more closed-suction drains brought out through a separate stab incision.

Before fascial closure, the right iliac fossa and the wound should be liberally irrigated. Muscles and aponeuroses should be closed with interrupted nonabsorbable sutures. The skin should be left open, to be closed with adhesive paper tapes on the 5th or 6th postoperative day. Parenteral antibiotics should be continued for 5 days after operation or until clinical signs indicate no infection.

Perforated Appendicitis with Localized Abscess Formation

If, at the time of initial physical examination, a well-localized periappendiceal mass is found and the patient's symptoms are improving, it is acceptable in healthy adults to initiate parenteral antibiotic treatment and to follow the patient expectantly.[36] This form of therapy is not appropriate in children, pregnant women, or elderly patients. In these groups, an emergency operation is indi-

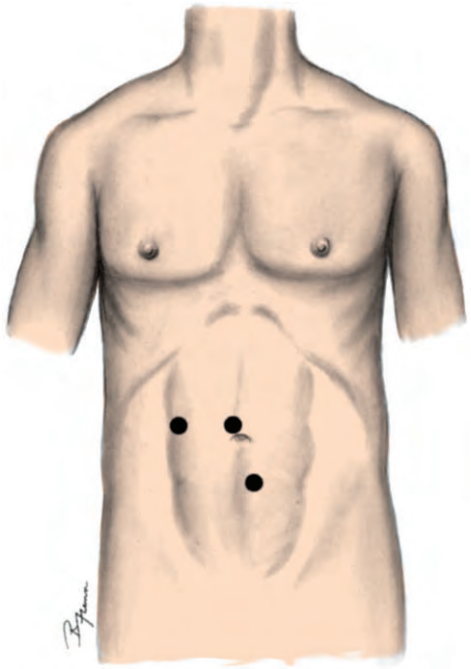

Figure 154–4. Trocar placement for laparoscopic appendectomy. Additional trocars can be placed in the right upper or left lower quadrants. (From Frantzides CT: Laparoscopic and Thoracoscopic Surgery. St. Louis, Mosby–Year Book, 1994, p 66.)

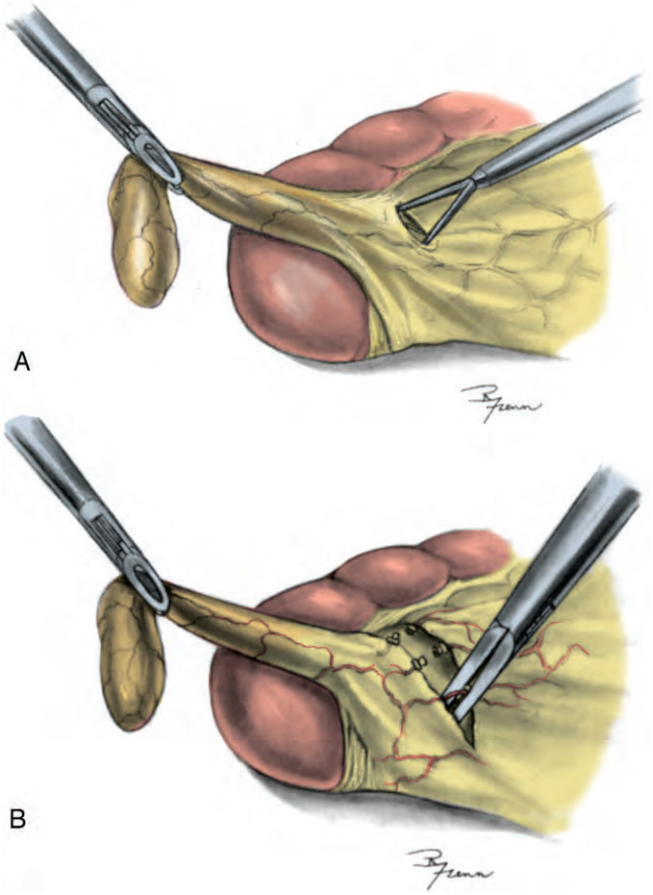

Figure 154–5. Technique for laparoscopic appendectomy. **A,** The appendix is grasped and retracted toward the pelvis, thus exposing the mesoappendix. **B,** The mesoappendix is divided using individually placed clips. (**A** and **B,** From Frantzides CT: Laparoscopic and Thoracoscopic Surgery. St. Louis, Mosby–Year Book, 1994, p 67.)

cated. In two thirds of patients, expectant treatment of an appendiceal mass succeeds, and an interval appendectomy can be performed at a later date. In one third of patients, symptoms do not subside and an emergency CT scan should be performed. If an abscess is identified on CT scan an attempt should be made to drain the abscess percutaneously under CT or US guidance.[17] If not successful, the abscess should be drained surgically.

The skin incision for drainage of a periappendiceal abscess is made just medial to the crest of the ilium at the level of the abscess. Using a muscle-splitting technique, the lateral edge of the peritoneum is exposed and pushed medially so that the abscess is approached from its lateral aspect. Once the abscess is entered, a finger should be used to break up the loculations. If the appendix can be freed up without breaking down adhesions, an appendectomy should be performed. If an appendectomy is not performed, an interval appendectomy can be done 3 to 6 months after drainage from the abscess has ceased and the wound has completely healed.

After the wound has been thoroughly irrigated with normal saline, a closed-suction drain should be inserted into the abscess cavity and brought out through a separate stab wound in the flank. The muscles and aponeuroses are closed with interrupted nonabsorbable sutures, and the skin and subcutaneous tissues are packed open with saline-soaked gauze. The drain should be left in place until it is draining less than 50 ml/day and then advanced progressively until removed.

Systemic antibiotics should be continued for 5 days postoperatively or until signs of sepsis have cleared. A daily rectal examination should be done to detect pelvic abscess. The patient may be discharged from the hospital when there is no fever 48 hours after the discontinuation of antibiotic therapy.

Perforated Appendicitis with Diffuse Peritonitis

The major cause of mortality from appendicitis is generalized peritonitis. Therefore, immediate exploration is indicated in a patient with a diagnosis of acute appendicitis in whom the physical findings are consistent with diffuse peritonitis. If a perforated appendix and diffuse peritonitis are documented at operation, an appendectomy should be performed and the abdomen thoroughly irrigated. The use of drains in diffuse peritonitis is not recommended unless there are localized abscesses requiring drainage.[37] The wound and postoperative care should be handled as described in a patient with a periappendiceal abscess.

Normal Appendix When Appendicitis Is Suspected

If a patient undergoes exploratory laparotomy (especially through a right lower quadrant incision) for suspected acute appendicitis, and a normal appendix is subsequently found, a careful search for another pathologic condition should be made and an appendectomy performed. The abdomen should not be closed until the cause of the symptoms has been identified and treated or the surgeon is sure that no lesion requiring treatment is present. The normal appendix is *removed* to obviate diagnostic confusion in the future.

If the history and physical examination were appropriate for the diagnosis of acute appendicitis, it is not an error to perform an exploratory laparotomy and remove what appears to be a normal appendix. A policy of early surgical intervention on the basis of clinical suspicion has been demonstrated overall to reduce both the morbidity and mortality of acute appendicitis.

In the past, a negative appendectomy rate of 20% was acceptable.[38] Studies have suggested that rates of 10% to 15% and lower are feasible without an unacceptably high rate of perforated appendicitis.[39-41]

Complications

Postoperative complications occur in 5% of patients with an unperforated appendix but in more than 30% of patients with a gangrenous or perforated appendix. The most frequent complications after appendectomy are wound infection, intra-abdominal abscess, fecal fistula, pylephlebitis, and intestinal obstruction.

Subcutaneous tissue infection is the most common complication after appendectomy. The organisms most frequently cultured are anaerobic *Bacteroides* species and the aerobes *Klebsiella, Enterobacter,* and *Escherichia coli.*[42] When early signs of wound infection (undue pain and edema) are present, the skin and subcutaneous tissue should be opened. The wound should be packed with saline-soaked gauze and reclosed with Steri-Strips in 4 to 5 days.

Pelvic, subphrenic, or other intra-abdominal abscesses occur in up to 20% of patients with a gangrenous or perforated appendicitis. They are accompanied by recurrent fever, malaise, and anorexia of insidious onset. CT scanning is of great help in making the diagnosis of intra-abdominal abscess. When an abscess is diagnosed, it should be drained either operatively or percutaneously.

Some fecal fistulas close spontaneously, provided that there is no anatomic reason for the fistula remaining open. Those that do not close spontaneously obviously require operation. Pylephlebitis, or portal pyemia, is characterized by jaundice, chills, and high fever. It is a serious illness that frequently leads to multiple liver abscesses. The infecting organism is usually *E. coli.* This complication has become rare with the routine use of antibiotics in complicated appendicitis. Although not frequent, true mechanical bowel obstruction may occur as a complication of acute appendicitis. As with any other mechanical small bowel obstruction, operative therapy is indicated.

CHRONIC AND RECURRENT APPENDICITIS

There are occasional patients who have had one or more attacks of what appears to be acute appendicitis. Between attacks, these patients are free of symptoms and the physical examination is normal. In such patients, if a fecalith is present on abdominal radiograph, if a BE demonstrates no filling of the appendix, or if repeated examinations during an attack provide evidence of recurrent appendicitis, elective appendectomy should be undertaken.[43] To sustain a diagnosis of chronic appendicitis, the resected appendix must demonstrate fibrosis in the appendiceal wall, partial to complete obstruction of the lumen, evidence of old mucosal ulceration and scarring, and infiltration of the wall of the appendix with chronic inflammatory cells.

MUCINOUS CYSTADENOMA AND CYSTADENOCARCINOMA

Distention of the lumen of the appendix by the mucus secreted by proliferating tumor cells can occur with both mucinous cystadenoma and cystadenocarcinoma. Because it is difficult to distinguish between benign and malignant tumors, a right hemicolectomy should be performed, since appendectomy is not curative in the usual circumstance. When there are numerous peritoneal implants of a mucinous-like substance, a diagnosis of pseudomyxoma peritonei is appropriate. Within these gelatinous masses are nests of tumor cells attached to the peritoneum.

TUMORS OF THE APPENDIX

Neoplasms of the appendix are rare. The two most frequently observed are carcinoid tumor and adenocarcinoma. The appendix is the most common site of carcinoid tumor, and carcinoid is the most common neoplasm of the appendix. It is found in approximately 0.1% of all surgically removed appendices. The only setting in which the diagnosis is suspected preoperatively is in the rare patient with symptoms of the carcinoid syndrome. This syndrome is characterized by flushing, diarrhea, and asthma-like symptoms. If a carcinoid tumor is in the mid or distal appendix and is less than 1 cm in diameter, a simple appendectomy is adequate therapy. If the tumor is greater than 1 cm in diameter or is in the base of the appendix or if there is evidence of nodal metastases, a right hemicolectomy is recommended.[44]

Adenocarcinoma of the appendix may appear as either a well-differentiated mucus-producing tumor or as a poorly differentiated adenocarcinoma that appears as a solid mass. Both types of adenocarcinoma of the appendix have been reported to metastasize to regional lymph nodes, although malignant mucocele has been considered clinically to be less virulent. If an adenocarcinoma of the appendix is confined to the mucosa (carcinoma in situ), there is no difference in survival between simple appendectomy and appendectomy com-

bined with right hemicolectomy. If the tumor is invasive, however, the prognosis is improved by right hemicolectomy, so the more extensive operation is recommended for most cases.[45]

Colorectal Polyps, Polyposis Syndromes, and Hereditary Nonpolyposis Colorectal Cancer

David B. Chessin · José G. Guillem

POLYPS OF THE COLON AND RECTUM

Definitions and Classification

The word *polyp* derives from Latin and Greek root words meaning "many feet" and is defined as a mass that protrudes into the lumen of the bowel.[1] It is believed that most polyps originate as *sessile* lesions, defined grossly by their broad base without a stalk. Traction on the polyp can lead to a *pedunculated* polyp with a stalk.

Several histologic types of colorectal polyps have been described and can be broadly classified into neoplastic polyps and non-neoplastic polyps based on their malignant potential (Table 155–1). The most common neoplastic polyp is the adenoma, which harbors malignant potential. Other, less common neoplastic polypoid lesions include carcinoid tumor, melanoma, lymphoma, and rare mesenchymal tumors such as gastrointestinal stromal tumor and Kaposi's sarcoma.

The most common non-neoplastic polyp of the colorectum is the hyperplastic polyp. Other non-neoplastic polyps include hamartomatous polyps (such as those seen in juvenile polyposis syndrome [JPS] and Peutz-Jeghers syndrome [PJS]) and inflammatory polyps. Submucosal lesions that resemble polyps include lymphoid polyps, lipomas, leiomyomas, neuromas, and angiomas.

Adenomatous Polyps

Up to 66% of adenomatous polyps are asymptomatic and are discovered during screening or surveillance.[2] However, when symptoms do occur, they are most commonly rectal bleeding, a change in bowel habits, mucus discharge, and nonspecific abdominal pain. In addition, large distal rectal adenomas have been reported to produce watery diarrhea or form the lead point for a colocolonic intussusception. Colorectal adenomas are uncommon prior to age 50 years and may be more frequent in men.

Adenomas vary from 1 mm up to several centimeters. They arise as a result of epithelial proliferative dysplasia. The nuclei of adenomatous cells appear hyperchromatic and cigar-shaped in a palisading pattern.[1,3] Grossly, they may appear sessile or pedunculated. Most small adenomas have a smooth surface but develop nodularity and superficial clefts as they increase in size.

Table 155–1 Histologic Classification of Colorectal Polyps

Neoplastic	Non-neoplastic
Adenoma	Hyperplastic
Tubular	Hamartoma
Tubulovillous	Juvenile
Villous	Peutz-Jeghers
Rare malignant lesions	Inflammatory
Carcinoid tumor	Submucosal lesions
Melanoma	Lymphoid
Lymphoma	Lipoma
Mesenchymal tumors	Leiomyoma
	Neuroma
	Angioma

Histologically, adenomas are classified as tubular (85% to 90%), tubulovillous (5% to 10%), or villous (1%) (Fig. 155–1).[1] Tubular adenomas are characterized by closely packed straight or branching tubules extending into a normal-appearing lamina propria. Villous adenomas are characterized by finger-like processes made up of a core of lamina propria enveloped by adenomatous epithelium. The tall columnar cells become mucin depleted with basally located oval nuclei. As the adenoma develops dysplasia, nuclear atypia, mitotic figures, and loss of polarity become evident.

Adenoma to Carcinoma Sequence

The major clinical importance an adenomatous polyp is its malignant potential because most, if not all, colorectal cancer (CRC) arises from an adenomatous polyp. The risk of malignancy in an adenomatous polyp is related to its size, histologic appearance, and severity of dysplasia. The interval between formation of a colorectal adenoma and development of CRC varies, but the average is from 8 to 10 years. However, most colorectal adenomas do not progress to cancer.[4,5] In fact, the cumulative risk of CRC at the site of an adenomatous polyp is approximately 2.5% at 5 years, 8% at 10 years, and 24% at 20 years.[6]

Several lines of evidence support the adenoma to carcinoma concept, including the observation that up to one third of resected CRC specimens contain synchronous adenomas,[5,7] the parallel increase in risk of CRC with increasing number of adenomas,[8] the inevitable development of CRC in patients with familial adenomatous polyposis (FAP),[9] and the high rate of development of CRC in patients who refuse removal of adenomas.[6] In addition, molecular and genetic evidence has emerged to further support the adenoma-to-carcinoma sequence.[10-13]

Screening for Adenomatous Polyps

CRC is the second most common cause of cancer mortality in the United States.[14] However, colonoscopic

Table 155–2 Guidelines for Screening of Colorectal Neoplasms Based on AGA, ACS, and ASCRS Recommendations

Risk Category	Recommendations	Age to Begin, yr	Interval
Average Risk			
Patients ≥ 50 yr who do not meet criteria for moderate or high risk	One of the following:		
	FOBT or FIT	50	Every yr
	Flexible sigmoidoscopy	50	Every 5 yr
	FOBT or FIT plus flexible sigmoidoscopy	50	Every 5 yr
	DCBE	50	Every 5 yr
	Colonoscopy	50	Every 10 yr
Moderate Risk			
Personal history of colorectal adenoma	Colonoscopy	At polyp diagnosis	Within 3 yr (5 yr for patients with complete removal of 1 or 2 small adenomas)
Personal history of resected CRC	TCE	At CRC resection	Within 1 yr (then every 3 to 5 yr if normal)
CRC or adenoma in first-degree relative <60 yr of age at diagnosis	TCE	40, or 10 yr before the youngest familial CRC	Every 5 yr
CRC in ≥ 2 first-degree relatives	TCE	40, or 10 yr before the youngest familial CRC	Every 5 yr
High Risk			
Family history of FAP	Flexible sigmoidoscopy	10-12	Every 1 to 2 yr
Family history of HNPCC	Colonoscopy	20-25, or 10 yr earlier than youngest familial CRC	Every 2 yr until age 40, then every yr
Personal history of IBD	Colonoscopy with biopsies	8-10 yr after onset of colitis	Every 1 to 2 yr

ACS, American Cancer Society; AGA, American Gastroenterological Association; ASCRS, American Society of Colon and Rectal Surgeons; FAP, familial adenomatous polyposis; FOBT, fecal occult blood test; FIT, fecal immunochemical test; DCBE, double-contrast barium enema; HNPCC, hereditary nonpolyposis colorectal cancer; IBD, inflammatory bowel disease (ulcerative colitis and Crohn's disease); TCE, total colorectal examination (colonoscopy or DCBE and flexible sigmoidoscopy).

detection and treatment of adenomatous polyps, prior to the development of invasive cancer, has led to a decrease in the incidence of CRC.[15] The relative lack of signs and symptoms of colorectal adenomas and the potential benefit of their early diagnosis and treatment provide the rationale for screening of the general population. Regardless of the screening regimen chosen, a positive screening test should be followed by a diagnostic colonoscopy with surgical resection when clinically appropriate and follow-up surveillance for adenomas treated with polypectomy alone.[16]

The American Cancer Society recommends an average risk individual begin CRC screening at 50 years of age with one of the following five options: (1) annual fecal occult blood test or fecal immunochemical test; (2) flexible sigmoidoscopy every 5 years; (3) annual fecal occult blood test or fecal immunochemical test plus flexible sigmoidoscopy every 5 years; (4) double-contrast barium enema (DCBE) every 5 years; or (5) colonoscopy every 10 years (Table 155–2).[17] These recommendations are similar to those of the American Gastroenterological Association, American Society of Colon and Rectal Surgeons (ASCRS), and the U.S. Preventive Services Task Force (USPSTF).[16,18,19]

It is important to stratify patients into moderate- or high-risk categories for colorectal adenomas or CRC, as these patients are screened with colonoscopy or a combination of flexible sigmoidoscopy and DCBE (see Table 155–2). Moderate-risk patients include those with a personal history of a colorectal adenoma or resected CRC, a CRC or adenoma diagnosed in a first-degree relative before 60 years of age, or CRC in two or more first-degree relatives. High-risk patients include those with a family history of FAP or HNPCC or a personal history of inflammatory bowel disease (ulcerative colitis or Crohn's disease). The presence of a rectosigmoid polyp is an indication for colonoscopy, because 30% to 50% of patients have at least one synchronous colon lesion.[7,20,21] Others have reported that patients with distal rectal adenomas have a twofold to threefold increased risk of advanced

adenomas of the proximal colon.[22] For patients with untreated polyps of the proximal colon, the risk of CRC doubles.[23]

The standard flexible colonoscope, which is 160 cm long, is the most accurate method of detecting colorectal polyps less than 1 cm in diameter. It can be used to visualize the mucosa of the entire colon and rectum as well as the terminal ileum. When colorectal lesions are detected, polypectomy, biopsies, and brushings for tissue diagnosis can be achieved through the colonoscope. The diagnostic accuracy of colonoscopy is as high as 94% for polyps of 1 cm or greater but falls to 73% for polyps less than 6 mm.[24] Complications from colonoscopy occur in 0.4% of cases, the most common being bleeding and perforation.[25] Colonoscopic visualization of polyps is more challenging in areas of acute angulation (i.e., sigmoid colon and hepatic flexure), behind the ileocecal valve, in regions with colonic spasm or acute inflammation (i.e., diverticulitis), or when the bowel preparation is poor. Good bowel preparation and patient compliance are essential for a complete colonoscopic examination. In addition, endoscopy units should be properly equipped and staffed for the administration of monitored sedation. Despite optimal conditions, in approximately 5% of cases the endoscopist cannot reach the cecum.[26] In these cases, a DCBE is recommended to evaluate the unexamined colon. In addition, virtual colonoscopy may be used to complete the colonic evaluation, although we await more data before its role in this setting can be completely defined.

Current recommendations state that flexible sigmoidoscopy combined with a high-quality DCBE is an acceptable alternative to colonoscopy in average risk patients.[17] It is estimated that 35% of colonic adenomas are proximal to the reach of the flexible sigmoidoscope. In addition, although DCBE is less sensitive than colonoscopy for polyps less than 1 cm and exposes the patient to 0.03 Gy of radiation, it has the advantages that it is less expensive, does not require sedation, and is associated with fewer complications. However, if a lesion is diagnosed by DCBE, a colonoscopy is required for tissue diagnosis.

Practice parameters for antibiotic prophylaxis to prevent endocarditis or infection of prosthetic material during colorectal endoscopy have been developed by the ASCRS in conjunction with the American Heart Association.[27] The ASCRS parameters state that antibiotic prophylaxis be used only for patients at high risk for bacterial endocarditis. These patients include those with prosthetic cardiac valves, a history of endocarditis, surgically constructed systemic pulmonary shunts, complex cyanotic congenital heart disease, and vascular grafts that have been implanted in the prior 6 months.[27] Antibiotic regimens for these patients include (1) ampicillin, gentamicin, and amoxicillin, (2) vancomycin and gentamicin, or (3) amoxicillin or ampicillin alone, but these regimens are not all inclusive and must be tailored to the individual patient.[27] Bacterial endocarditis is a moderate risk in patients with most congenital cardiac malformations, rheumatic and other acquired valvular dysfunction, idiopathic subaortic stenosis, and mitral valve prolapse with insufficiency. Antibiotic prophylaxis is currently not recommended for patients with these moderate-risk conditions.[27]

Initial Management of Adenomatous Polyps

All polyps detected by endoscopy should be removed because it is not possible to accurately determine whether a polyp is premalignant or malignant by visual inspection and size criteria. It is important to record polyp size, morphology, and location in the colon. The endoscopist should make all efforts to completely excise the polyp and properly orient it to allow the pathologist to provide a precise histologic evaluation. Pathologic evaluation should include determination of tubular or villous architecture, low-grade or high-grade dysplasia, and if invasive cancer is present. In the case of invasive cancer (malignant polyp), the pathology report should include whether the resection margins are involved with malignant or adenomatous cells, grade (differentiation), and the presence of lymphovascular or perineural invasion. Randomized, controlled studies have documented a significant reduction in subsequent colorectal adenoma formation in patients treated with aspirin who have a personal history of resected CRC[28] or colorectal adenomas.[29] Its use may be recommended in these cases, but the risks of aspirin require individualized use based on each patient's overall medical condition.

Small Polyps The management of colorectal polyps less than 6 mm in diameter is not well established. The clinical significance and management of these lesions are controversial, because they may confer a low risk of malignant degeneration.[30] In addition, it is uncertain whether biopsy alone is adequate therapy for these lesions. A study of 5137 adenomas less than 5 mm in diameter reported no invasive carcinoma.[30] However, another review of 2064 colorectal adenomas less than 6 mm in diameter determined that 4% contained high-risk features (>25% villous architecture or severe dysplasia) and 0.1% contained invasive cancer.[31] Therefore, colorectal polyps less than 6 mm should be endoscopically treated when clinically appropriate, given their potential for high-risk features and malignancy.

Techniques available for the management of small colorectal polyps include biopsy, ablation (using hot biopsy forceps, bipolar forceps, heater probe, or laser), and removal with a snare (cold snare). The complication rate for colonoscopic treatment of colorectal polyps less than 6 mm has been reported to be as low as 0.15%.[31] The risk of bleeding and perforation using the hot biopsy forceps technique, particularly in the thin-walled right colon, and the associated tissue damage from coagulation necrosis suggest this technique may be suboptimal for the management of small colorectal polyps.[32] The cold-snare technique appears to safely remove these lesions while preserving the architecture of the specimen for pathologic examination.[33]

Pedunculated Polyps Colonoscopic polypectomy is the best treatment for most pedunculated polyps. The cautery snare is placed around the polyp stalk at a point to adequately remove the polyp with a margin of normal

tissue while avoiding thermal injury to the bowel wall at the base of the stalk. Caution should be taken to avoid transmission of electric current through the head of the polyp to the opposite wall.

Sessile Polyps Sessile polyps less than 2 cm in diameter can often be treated endoscopically. However, barring medical contraindications, a bowel resection is indicated for polyps that cannot be completely excised endoscopically or any polyp containing invasive cancer. Large sessile polyps (>2 cm) often require surgical excision or resection, due to their increased incidence of malignancy (5% to 15%),[34-36] increased incidence of complications following endoscopic treatment, and requirement for piecemeal excision in many cases. In select benign-appearing cases, piecemeal excision may be an appropriate initial therapy. Small bites of 0.5 to 1.5 cm are taken with the cautery snare, using a lower current to avoid injury to the bowel wall. The goal is to achieve subtotal resection of the polyp head until the base is reached. Injection of saline in the submucosa below the polyp to elevate the adenomatous tissue has been used successfully to facilitate piecemeal excision.[35] All excised tissue should be retrieved for pathologic analysis, and extraction baskets and bags are commercially available for this purpose. For incomplete piecemeal excision, fulguration of the polypectomy site with the argon plasma coagulator may decrease adenoma recurrence.[34,36] It is important to mark the area with a 0.1-ml submucosal injection of India ink or other agent for colorectal wall "tattooing." This mark may be used for localization of the polypectomy site if subsequent surgery is indicated, such as for positive margins or detection of invasive cancer. Follow-up colonoscopy 3 to 6 months after treatment is necessary to determine if excision was complete and to treat any retained or recurrent adenomatous tissue. Disadvantages of piecemeal excision include lack of pathologic orientation of the specimen and difficulty determining margin status when the polyp is treated with fulguration.

Malignant Polyps A malignant polyp is defined as a polyp containing invasive cancer that has invaded across the muscularis mucosa.[37] They are diagnosed in 2% to 12% of polyps removed endoscopically.[37-39] Colonoscopic polypectomy may be appropriate for small pedunculated invasive cancers with favorable criteria because the risk of residual cancer or lymph node metastases is minimal (0.3% to 1.5%). However, the decision for further treatment with surgical resection is based on the risk of lymph node metastases and the general medical condition of the patient.[37] The finding of lymphovascular invasion, poor differentiation, cancer within 2 mm of the resection margin, flat or ulcerated lesion, or cancer invasion into the lower third of the submucosa indicate the need for colonic resection.[40-42] Follow-up colonoscopy and surveillance of the polypectomy site are recommended 3 to 6 months following therapeutic endoscopy to assess for retained or recurrent neoplastic tissue.

The most significant risk factor for lymph node invasion in patients with a malignant polyp is depth of invasion in the bowel wall. In 1985, Haggitt et al. introduced an anatomic classification system for malignant polyps that helps guide subsequent therapy. Pedunculated polyps with carcinoma in situ or those with invasive cancer limited to the polyp head, neck, or stalk may be treated with endoscopic polypectomy and close surveillance (Fig. 155–2).[43] The risk of lymph node metastases

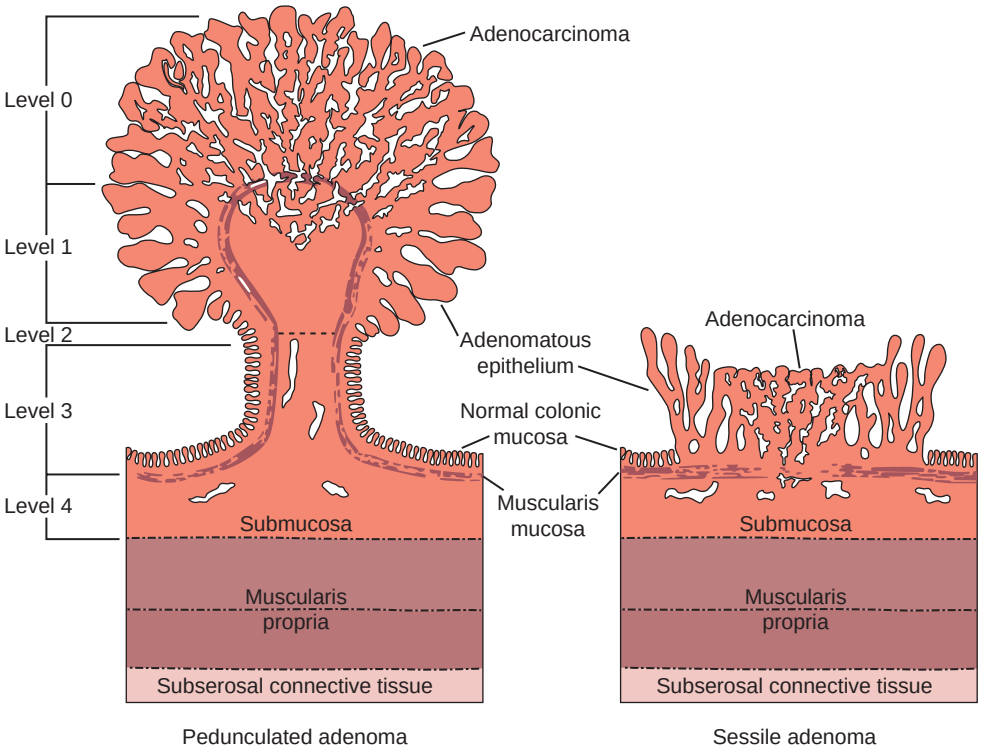

Figure 155–2. Haggitt's classification for anatomic landmarks to guide the management of malignant colorectal polyps.[43]

from these lesions is less than 1%.[43-45] However, once carcinoma invades the submucosa of the bowel wall, surgical resection is recommended for patients who are medically appropriate. The risk of lymph node metastases for these lesions has been reported from 12% to 25%.[40,46,47] By definition, a sessile polyp has no stalk, and the submucosa is immediately adjacent to the muscularis mucosa. Therefore, a sessile polyp containing invasive cancer is optimally treated with formal bowel resection. The decision to proceed with colectomy is based on the risk of residual cancer and lymph node metastases as predicted by pathologic determinants balanced against operative morbidity and mortality risks and the life expectancy of the patient. Prior to radical resection, it is important to clearly inform the patient that there is a potential for no viable cancer to be detected in the bowel wall or lymph nodes on pathologic analysis.

Complications of Therapeutic Colonoscopy The overall rate of serious complications following colonoscopy is 0.6%.[25] The most common complications associated with the procedure are perforation and bleeding. Perforation has been reported in 0 to 2% of cases, and is seen more commonly following a cautery burn or full-thickness snare of the bowel wall and after treatment of a villous lesion.[25,48-50] A small perforation in a patient with a complete bowel preparation and minimal contamination may be treated conservatively with intravenous antibiotics and close observation. However, if signs of sepsis or peritonitis develop, operative intervention is indicated.

The most frequent site of bleeding is the stalk after polypectomy. Bleeding can be divided into two categories: (1) early bleeding, which is diagnosed at the time of endoscopy; and (2) late bleeding, which becomes clinically apparent following completion of endoscopy. Early bleeding has been reported as high as 13% to 22% of cases, the majority of which are self-limited or controlled endoscopically.[48,51] Late bleeding, which may require intervention, has been reported in 0.4% to 3% of cases.[25,48,51] Recauterization by colonoscopy may be required, but uncontrolled hemorrhage may require colectomy to remove the site of bleeding.

Follow-up Surveillance

The basis for surveillance colonoscopy is the increased risk of metachronous neoplasms, which occur at a rate of 29% to 60% following polypectomy of an adenoma, depending on the interval of follow-up.[20,52,53] The risk is higher for patients older than 60 years of age and those with multiple or large adenomas.[21] Other risk factors for metachronous neoplasia may include increasing dysplasia and villous architecture. Due to the finding that colonoscopic polypectomy and subsequent surveillance reduces CRC incidence,[15,54] patients with a personal history of adenomatous colorectal polyps should be offered follow-up surveillance with colonoscopy.[16] Flexible sigmoidoscopy with DCBE may be an acceptable alternative if colonoscopy is not available.[16]

The recommended surveillance interval following removal of an adenomatous colorectal polyp varies depending on the findings of the index colonoscopy. In patients with an incomplete index examination, a repeat colonoscopy should be performed within 3 months. Patients with advanced or multiple (≥3) adenomas should have follow-up colonoscopy within 3 years because there is evidence from a randomized trial that a follow-up interval of 3 years is comparable to an interval of 1 year at detecting advanced adenomas.[15,16] Patients with one or two tubular adenomas less than 1 cm in diameter may wait 5 years for follow-up colonoscopy, because these patients are at low risk for developing advanced adenomas.[16,55] However, as with all screening and surveillance recommendations, management should be individualized with consideration given to comorbid illnesses and the concerns of the patient.

Hamartomatous Polyps

A *hamartomatous polyp* is a localized overgrowth of normal, mature intestinal epithelial cells.[1] They are usually lined with normal epithelium over a submucosal core. Juvenile polyps are the most common type of colorectal hamartomas and occur most commonly in children younger than 5 years of age 5. Up to 80% of juvenile polyps occur as a single lesion of the rectum, but they have been described throughout the colon.[1] Typical symptoms are rectal bleeding, mucus discharge, diarrhea, and abdominal pain. Intussusception through the rectum has also been described. Grossly, a juvenile polyp is a pedunculated, bright red to brown, spherical polyp 1 to 3 cm in diameter that has a friable, granular surface (Fig. 155–3). Microscopically, they contain abundant stroma, most of which is lamina propria, separating tubules of cystically dilated glands (Fig. 155–4).[1] Juvenile polyps are also called *retention polyps* due to the inflammatory obstruction of the crypt necks that leads to cystic dilation of the mucus-filled glands. In general, they do not carry an increased risk of cancer; however, the autosomal dominant JPS, characterized by 50 to 100 juvenile polyps in the gastrointestinal tract, is associated with an increased risk of CRC.[1]

The autosomal dominant–inherited PJS is also characterized by hamartomatous polyps. These lesions are

hemispheric or finger-like protrusions ranging in size from 0.1 to 10 mm, although they may grow to 4 cm. PJS hamartomas are characterized by hypertrophy or hyperplasia of the smooth muscle of the intestinal wall, which can extend into the superficial epithelial layer in a "tree-like" manner, a process that has been termed *arborization* (Fig. 155–5). As the smooth muscle extends upward and invaginates the superficial layers of the bowel wall, epithelial cells can become trapped within the muscle layer, which may be confused with malignant transformation.[56] Mucus-filled cysts in the mucosa are commonly present. Normal columnar epithelium usually covers the polyps, but a small proportion of polyps contain mixed adenomatous/hamartomatous elements.

Hyperplastic Polyps

Hyperplastic polyps account for more than 90% of all colorectal polyps.[1] They are found in the rectosigmoid in more than 50% of cases and are diagnosed most commonly after age 50 years. They are usually less than 5 mm in diameter at diagnosis and appear grossly as pale, broadly based, flat, smooth nodules. Hyperplastic polyps arise from faulty epithelial maturation, characterized microscopically as elongated nonbranching mucosal crypts and hyperplasia without atypia (Fig. 155–6). It is generally accepted that hyperplastic polyps have no premalignant potential, but adenomatous change has been described on histologic examination of otherwise typical hyperplastic polyps.[57] These "serrated" or mixed polyps have been associated with the development of carcinoma.[58,59] In addition, recent evidence suggests that patients with hyperplastic polyposis (>20 hyperplastic polyps) may be at increased risk of developing CRC.[60]

Inflammatory Polyps

Inflammatory polyps, also known as *pseudopolyps,* arise from mucosal ulceration and repair. They occur most frequently in the setting of chronic ulcerative colitis but are also seen in Crohn's disease. Inflammatory polyps are uniform in width from the base to the head and consist of islands of inflamed regenerating mucosa surrounded by ulceration (Fig. 155–7).[1] Patients with inflammatory polyps usually require no treatment other than that for the underlying colitis, but the possibility of neoplastic disease should be excluded.

POLYPOSIS SYNDROMES

Gastrointestinal polyposis syndromes include a variety of entities characterized by the number and histologic type of colorectal polyps, as well as polyposis of the upper

Table 155–3 Summary of Gastrointestinal Polyposis Syndromes

Polyp Histology	Syndrome	Genetic Basis	Gene Locus
Adenomatous	FAP*	Germline *APC* mutations	5q21
	aFAP*	Germline *APC* mutations	5q21
	MYH polyposis	Biallelic germline *MYH* mutations	1p34.3-p32.1
	HNPCC*	Germline *MMR* mutations (*hMLH1, hMSH2, hMSH6, hPMS1, hPMS2*)	*hMLH1*: 3p21 *hMSH2*: 2p16 *hMSH6*: 2p16 *hPMS1*: 7p22 *hPMS2*: 7p22 *hMLH3*: 14q24
	Muir-Torre syndrome*	Germline *MMR* mutation (*BTP1*)	
	Turcot's syndrome*	Germline APC mutations (*BTP2*)	
Hamartomatous	JPS*	Germline *SMAD4* mutations	*SMAD4*: 18q21.1
		Germline *BMPR1A* mutations?	*BMPR1A*: 10q21-22
	PJS*	Germline *LKB1/STK11* mutations	19p13.3
	Cronkhite-Canada syndrome*	N/A	N/A
	Cowden's disease	Germline *PTEN* mutations	10q23.3
	Ruvalcaba-Myhre-Smith syndrome	Germline *PTEN* mutations	10q23.3
	Neurofibromatosis		
Other	Hereditary mixed polyposis syndrome	Germline *CRAC1* mutation?	15q13-14
	Hyperplastic polyposis syndrome*	MSI pathway?	
	Inflammatory polyposis	N/A	N/A
	Lipomatous polyposis	N/A	N/A

*Increased risk of CRC.
CRC, colorectal cancer; FAP, familial adenomatous polyposis; aFAP, attenuated FAP; HNPCC, hereditary nonpolyposis CRC; N/A, not applicable.

gastrointestinal tract and specific extraintestinal manifestations (Table 155–3). Adenomatous polyposis syndromes are characterized by adenomas of the gastrointestinal tract and include FAP and hereditary nonpolyposis CRC (HNPCC). Hamartomatous polyposis syndromes are characterized by gastrointestinal hamartomas, or an overgrowth of cells native to the area in which they normally grow, and include JPS, PJS, Cowden's disease, Ruvalcaba-Myhre-Smith syndrome, and Cronkhite-Canada syndrome.[61] Hereditary mixed polyposis syndrome is a variant of JPS that is characterized by both hamartomatous and adenomatous polyps of the gastrointestinal tract.[61]

Familial Adenomatous Polyposis

Clinical Considerations

FAP is an autosomal dominant disease with nearly 100% penetrance characterized by the development of many (usually >100) adenomatous polyps of the colon and rectum.[62] The genetic etiology of the disease is a germline mutation of the APC gene, located on chromosome 5q21.[63] Up to 80% of patients have a family history of FAP, but 10% to 30% of cases represent new mutations. The disease has an incidence of 1 in 5000 to 10,000 live births and accounts for less than 1% of all cases of CRC.[62,64] Almost all patients develop CRC by 40 years of age if colectomy is not performed, usually within 10 to 15 years of diagnosis. Extraintestinal manifestations are common in FAP and include desmoid tumors,

duodenal and periampullary adenomas, gastric fundic gland polyps, thyroid and brain tumors, and congenital hypertrophy of the retinal pigmented epithelium (CHRPE). The combination of FAP with desmoid tumors, osteomas, and sebaceous cysts is known as *Gardner's syndrome.*[65] FAP in association with brain tumors (particularly glioblastoma) is known as *Turcot's syndrome.*

The average age of adenoma development in FAP is 15 years, with approximately 15% manifesting polyps by 10 years, 75% by 20 years, and 90% by 30 years of age.[66] At-risk individuals participating in a screening program are usually diagnosed with FAP by the age of 22 years, whereas the average age at diagnosis in patients presenting with symptoms ranges from 34.5 to 43 years.[67] The average age of development of CRC is 35 to 39 years.[67] The relatively long interval between polyp and cancer development reflects the relatively slow process of FAP CRC tumorigenesis. This slow progression is further substantiated by the observation that only a small number of adenomatous polyps, among the hundreds to thousands in patients with FAP, ultimately develop into invasive cancer.

The polyps in FAP may carpet the entire surface of the colorectal epithelium or spare portions of the epithelial lining (Figs. 155–8 and 155–9). The adenomas may be pedunculated or sessile and have tubular, tubulovillous, or villous histology.[1,67] Most grossly visible adenomas are 5 to 10 mm in diameter. In addition, innumerable microadenomas, which may be limited to one crypt on grossly normal mucosa, are often identified on microscopy. The finding of at least one polyp more than 1 cm is associated with a 47% risk of CRC, whereas polyps greater than 2 to 3 cm usually contain invasive cancer.[68] Most patients with FAP present with distal, left-sided CRC that is similar in anatomic distribution to sporadic CRC. Patients with FAP are at substantial risk for synchronous and metachronous CRC, which emphasizes the need for treatment with total colectomy.

Extracolonic Manifestations

Extracolonic manifestations reflect the systemic growth regulation disorder that afflicts patients with FAP. They usually become clinically evident after colorectal polyposis, but there are reports of FAP presenting with extracolonic manifestations.[68] Benign extracolonic manifestations include CHRPE,[69] osteomas,[70] dental odontomas,[71] and epidermoid cysts.[72] The incidence of these lesions is unclear because they are not a part of routine screening and often require special studies to identify. The value of these benign lesions lies in their ability to screen family members or identify patients with de novo mutations as most are not of major clinical consequence. For example, CHRPEs are asymptomatic and have no malignant potential but may be useful in determining carrier status in asymptomatic individuals. CHRPE in patients with FAP are significantly larger, multiple, bilateral, and with mixed pigment than sporadic CHRPE.[69] Osteomas are benign, slow growing neoplasms of the bone. They occur in more than 50% of patients with FAP, are typically found in the skull and mandible, and are a constituent of Gardner's syndrome, where their presence may precede that of gastrointestinal polyposis.[70] Benign dental abnormalities, diagnosed in up to 70% of patients with FAP, include supernumerary or missing teeth and fused roots of molar teeth and are diagnosed by physical examination and panoramic dental radiographs.[73] Epidermoid cysts are commonly diagnosed in the mid to late teenage years, are often multiple, and occur in atypical locations (face, scalp, and extremities).[74]

After CRC, the most common malignancy diagnosed in patients with FAP is periampullary adenocarcinoma of the duodenum.[75,76] Other malignancies associated with FAP include tumors of the thyroid, brain, pancreas, biliary tree, stomach, small intestine, and adrenal gland. Hepatoblastoma, a rare embryonal tumor of the liver, affects children with FAP at a much higher rate than expected in the general population.[77] Because desmoids

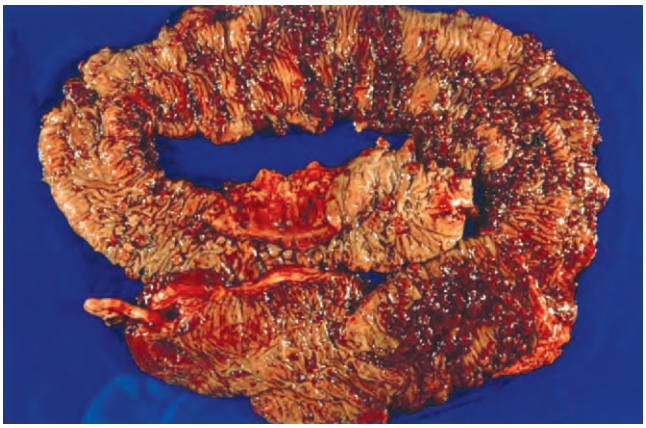

Figure 155–8. Gross appearance of the colon of a patient with familial adenomatous polyposis. (Courtesy of Jinru Shia, MD, Department of Pathology, Memorial Sloan-Kettering Cancer Center, New York.)

and upper gastrointestinal tract neoplasia represent major management issues in patients with FAP, they are discussed individually.

Desmoids Desmoids are slow-growing, benign mesenchymal tumors characterized by mature, highly differentiated fibroblasts and myofibroblasts with abundant collagen matrix.[78] It has been estimated that between 8% and 17% of patients with FAP develop desmoids, and they are diagnosed at a rate of almost 1000 times that in the general population.[79] Although sporadic desmoids are more common in women,[80] this gender difference is less apparent in patients with FAP and may even be reversed.[81] They do not metastasize, but are locally aggressive, tend to infiltrate surrounding tissues, and have a high recurrence rate following surgical therapy. Desmoids can be fatal, related in large part to their aggressive local growth with compression of surrounding organs (intestine, ureter, and vessels), erosion of adjacent structures, and interference with surgical therapy. In patients with FAP, up to 80% of desmoids are observed in the small intestinal mesentery and 20% to 30% are diagnosed in the abdominal wall or extremities.[67,82] Early desmoids, which have been termed *desmoid precursor lesion* or *desmoid reaction,* appear as flat, white plaques.[83] Larger lesions tend to form nonencapsulated, lobulated masses. Desmoids can become massive and occupy a large portion of the abdomen or pelvis. Clinical presentation ranges from asymptomatic plaques or masses discovered incidentally on imaging or during prophylactic surgery to many nonspecific symptoms. Symptomatic desmoids may cause abdominal pain, bowel obstruction or ischemia, deep venous thrombosis from venous compression, sensory and motor deficits from nerve compression, ureteric obstruction, sepsis from enteric fistula, upper gastrointestinal hemorrhage, and pouch failure.[67,84]

Surgical trauma is a major risk factor for the development of intra-abdominal and abdominal wall desmoid tumors.[85] The interval between surgery and the diagnosis of desmoid tumors is usually less than 5 years but may extend well beyond this interval.[85,86] Estrogens have been implicated in the stimulation of desmoid growth, because they often develop in women of reproductive age and growth is often temporally related to pregnancy or the use of oral contraceptives.[87] In addition, regression has been reported following natural or surgical menopause. Genotype-phenotype correlations have been suggested, as mutations toward the 3′ end of the APC gene may be more likely to be identified in FAP kindreds that have a high incidence of desmoids.[88,89] A genetic predisposition to the development of desmoids, independent of the APC gene, has also been suggested.[90]

Currently, the most useful imaging modality for the preoperative evaluation of desmoids in patients with FAP is contrast-enhanced computed tomography (CT). Mesenteric fibrosis and desmoid precursor lesions have been identified on preoperative CT in up to 20% of patients with FAP.[91] Although CT findings correlate poorly with symptoms, poor prognostic features include size greater than 10 cm, multiple lesions, bilateral hydronephrosis, and extensive small bowel involvement. In addition, a CT scoring system has been introduced that may predict the clinical course of desmoid precursor lesions.[92] Magnetic resonance imaging is most useful for extremity and abdominal wall desmoids but can also be used to evaluate intra-abdominal lesions. High signal intensity on T2-weighted images has been suggested to correlate with active growth.[93] Radionuclide scans may have some use in differentiating scar from recurrent desmoid tumor during postresection follow-up examination.

Treatment of desmoids may be broadly categorized into nonsurgical and surgical approaches, although there is no singularly affective therapy. Because failure with one treatment does not preclude successful therapy with a different approach, clinicians should explore all options in resistant or recurrent cases. Both cytotoxic and noncytotoxic pharmacologic agents have been used, with variable success, in the treatment of desmoid tumors.[94] Nonsteroidal anti-inflammatory drugs (NSAIDs) and antiestrogens are frequently used agents.[87,94,95] In addition, modifiers of cyclic adenosine monophosphate metabolism (ascorbic acid, theophylline, testolactone, and chlorothiazide), corticosteroids, colchicine, interferon-alpha, and warfarin have all been used. NSAIDs (sulindac and indomethacin) are considered first line therapy for desmoids, resulting in response rates of up to 57%.[96] Most patients respond to NSAIDs within 3 months, but delayed response over 24 months has been reported.[94] Antiestrogens, primarily tamoxifen,[95] raloxifene,[87] and toremifene,[97] have been reported to produce response rates comparable to those of NSAIDs, but there are no randomized studies documenting their efficacy. Recently, combination regimens containing both NSAIDs and tamoxifen have been reported to result in improved response rates, a finding that awaits confirmation by larger trials.[95] There are limited data on the use of interferons in the treatment of desmoids, and currently their use is most appropriate in clinical trials.

The most commonly used and successful cytotoxic chemotherapy regimens in the treatment of desmoids are combinations of antisarcoma agents, usually doxorubicin with dacarbazine or cyclophosphamide and vincristine.[98] Reported response rates range from 17% to 100%, with a median of 50%.[94] However, severe early and late toxicity are major concerns with cytotoxic therapy, which limits its use to extensive life-threatening disease that is resistant to other therapy or when alternative approaches are contraindicated. Regional chemotherapy with isolated limb perfusion for extremity desmoids has been reported with encouraging results from small series, but larger studies are required before definitive recommendations can be made.[99] In addition, radiation therapy in doses of 36 to 65 Gy may provide acceptable local control following surgical resection (80%) and as primary therapy for unresectable tumors (81%).[100] Although early in its development, preclinical research with gene transfer to treat patients with FAP and desmoids has been reported.[101]

Surgery for intra-abdominal desmoids should be reserved for select cases of symptomatic disease given their often unresectable nature due to their common

location in the root of the mesentery and their high recurrence rates following resection. Often, their characteristic infiltrating growth pattern makes complete resection impossible without extensive small bowel resection. Local control rates following resection with positive and negative margins are reported as 41% and 72%, respectively.[102] The addition of postoperative radiation therapy, when clinically feasible, can improve local control to as high as 94% when negative pathologic margins are achieved.[102] Bypass procedures are controversial but may be required to treat select cases of nonresolving bowel obstruction. Major complications have been reported in up to 50% of patients with intra-abdominal desmoids treated with surgical resection. In addition, extensive resection may lead to short bowel syndrome and its associated difficult management. Another difficult issue associated with the surgical treatment of intra-abdominal desmoids is the high recurrence rate (up to 85% in some series). Given these limitations, surgery should be reserved for symptomatic patients or those with complications. Abdominal wall desmoids may be treated with surgical resection, with margins of 2 cm. Reconstruction with prosthetic mesh or a myocutaneous flap may be required when large lesions are treated. Extra-abdominal desmoids may be treated with surgical resection, with reported 10-year disease-free rates of 76% for primary tumors and 59% for recurrent tumors.[103]

A reasonable approach to desmoids may be to begin with NSAIDs such as sulindac (150 mg twice per day) as first-line therapy. If the tumor does not respond or progresses following 6 or more months of therapy, an antiestrogen such as tamoxifen (starting at 30 mg per day, with a slow increase up to 120 mg per day) or raloxifene (60 mg twice a day) may be added. If the tumor responds, therapy can be gradually withdrawn over 6 months. Cytotoxic chemotherapy with a doxorubicin-based regimen should be reserved for extensive or life-threatening tumors that do not respond to noncytotoxic pharmacologic regimens and are not amenable to surgery. Surgery should be reserved for localized desmoids of the limbs or abdominal wall or intra-abdominal desmoids causing symptoms or complications.

Upper Gastrointestinal Neoplasia Upper gastrointestinal polyps in patients with FAP may be non-neoplastic, as is the case for most gastric polyps, or neoplastic, which is typical of duodenal or periampullary polyps. Gastric polyps, which are also called *fundic gland polyps,* are benign hamartomas, are diagnosed in 13% to 84% of cases of FAP, and were believed to have a very low malignant potential.[104] However, recent data suggest that fundic gland polyps may be associated with an increased risk for adenomas[105] and high-grade dysplasia.[106] In patients with FAP, duodenal and periampullary polyps usually harbor dysplasia and are premalignant. Duodenal polyps are observed in 65% of patients at first endoscopy and eventually develop in 90% to 100% of patients with FAP, although they usually appear 10 to 20 years after colorectal polyp formation.[76] In contrast with the near-ubiquitous finding of duodenal adenomatosis, the reported incidence of duodenal cancer ranges from 0 to 5%.[75,76,107] Upper gastrointestinal polyps are usually asymptomatic, with symptoms suggesting invasive cancer.

Table 155–4 Modified Spigelman Classification for Staging Duodenal Polyposis in Patients with FAP*

	Grade of Duodenal Disease (points)		
Variable	*1*	*2*	*3*
Polyp number	1-4	5-20	>20
Polyp size (mm)	1-4	5-10	>10
Histology	Tubular	Tubulovillous	Villous
Dysplasia	Low grade	—	High grade

*Stage 0 (no polyps) = 0 points; Stage I = 1-4 points; Stage II = 5 or 6 points; Stage III = 7 or 8 points; Stage IV = 9-12 points. Data from Spigelman AD, Williams CB, Talbot IC, et al: Upper gastrointestinal cancer in patients with familial adenomatous polyposis. Lancet 2:783-785, 1989.

Upper gastrointestinal surveillance is recommended with the goal of early detection and treatment of suspicious, premalignant polyps.[75,76,107] Spigelman's criteria have been developed to predict the malignant risk of duodenal polyposis in patients with FAP and guide surveillance and management. Spigelman's criteria is determined by duodenal polyp number, size, histology, and dysplasia (Table 155–4).[108] Using these features, patients are stratified into a low-risk group (stages 0, I, and II) in whom screening endoscopy is recommended every 2 to 3 years and a high-risk group (stages III and IV) in whom endoscopy with biopsy is recommended every 6 to 12 months. In addition, surgical intervention is justified in advanced duodenal polyposis (Spigelman stage IV and select stage III). The cumulative risk of developing stage IV duodenal polyposis has been estimated at 40% by age 60 years and 50% by age 70 years.[107]

Because clinically significant issues from upper gastrointestinal polyposis are rare before the diagnosis of colorectal disease, upper gastrointestinal screening is initiated at the time of FAP diagnosis. Symptoms of unexplained epigastric pain, weight loss, jaundice, anemia, melena, or vomiting should prompt evaluation with endoscopy, abdominal ultrasound, and CT scan. Imaging findings are used to plan subsequent therapy, including surgical resection when indicated.

Management of duodenal polyps in patients with FAP includes medical intervention (with NSAIDs such as sulindac), endoscopic polyp ablation, and surgical resection. Sulindac has been used because of its potential to stabilize, and in some cases reverse, the development of gastrointestinal neoplasia, especially colorectal adenomas. Sulindac is most successful in the treatment of small (<1 cm) duodenal polyps, whereas large polyps do not respond well and progression to adenocarcinoma has been reported in patients during sulindac treatment. In addition, data to support its benefit are largely derived

from retrospective case series.[109] Endoscopic techniques to treat duodenal polyps include polypectomy; snare ampullectomy; and laser, thermal, and photodynamic ablation. Endoscopic approaches are limited because they cannot definitively treat duodenal polyposis despite multiple interventions and morbidity is a major concern for procedures performed near the duodenal ampulla.

Surgical therapy is reserved for patients at a high risk for cancer, including those with extensive duodenal polyposis, rapid polyp growth, villous lesions with high-grade dysplasia, and suspicious endoscopic features (i.e., induration). In addition, patients with Spigelman IV polyposis have a high risk of harboring or developing duodenal cancer (reported as up to 36%), and surgical resection should be strongly considered in these patients.[75] Operative intervention should be individualized and alternatives include local resection, ampullectomy, pancreas-sparing duodenectomy, and pancreaticoduodenectomy. Local resection is a less attractive option because it has a high failure rate owing to difficulty in complete eradication of duodenal polyps, it makes subsequent surgical resection difficult, and it is associated with a significant morbidity from postoperative duodenal leaks.[110] Pancreaticoduodenectomy is indicated for cancer and large, rapidly growing adenomas with severe dysplasia and may be performed with acceptable morbidity and limited mortality.[111]

Genetics

Adenomatous Polyposis Coli Gene Mutations in the adenomatous polyposis coli *(APC)* gene, located on chromosome 5q21, are responsible for FAP.[63] The *APC* gene consists of 15 exons and 2843 codons and functions as a tumor suppressor gene via its 300-kD protein product. Individuals affected with FAP have a germline mutation in one of their two copies (alleles) of the *APC* gene. When a somatic mutation in the second APC allele occurs, the FAP phenotype develops. Germline mutations have been reported throughout the *APC* gene, with more than 90% resulting in a premature stop codon and a truncated protein product.[12,62] More than 300 different mutations in the *APC* gene have been reported, including insertions, deletions, and nonsense mutations that lead to a truncated protein.[112] The truncated protein may have impaired function, as well as interact with the wild-type protein product of the normal APC allele to cause its inactivation through a dominant negative mechanism.[62,113]

The normal APC protein product is involved in inhibition of the Wnt signaling pathway.[114] The APC protein functions by binding to β-catenin, a cytoskeletal protein and activator of growth regulatory genes. When normal APC is bound, β-catenin is targeted for degradation and cell growth is down-regulated. When APC is mutated, its interaction with β-catenin is impaired, and β-catenin accumulates in the nucleus where it simulates cell growth in an unregulated manner, ultimately leading to polyp and cancer development.[62]

APC Genotype-FAP Phenotype Correlation Correlations have been made between the site of mutation on the *APC* gene and the phenotypic expression of FAP, although these genotype-phenotype correlations are complex and their clinical utility is uncertain (Fig. 155–10).[89] Mutations in the *mutation cluster region* on exon 15 of the *APC* gene (codons 1250 to 1400) have been associated with classic FAP and severe, diffuse polyposis.[115] In addition, patients with a mutation at codon 1309 have been reported to have early-onset, severe polyposis, and death 10 years younger than untreated patients with FAP caused by mutations at other loci on the *APC* gene.[89,115,116] Mutations at the 3′ or 5′ ends of the *APC* gene may be associated with late-onset, mild polyposis and the syndrome of attenuated FAP.[117-119]

Several mutations in the *APC* gene have been correlated with an increased incidence of extracolonic manifestations of FAP. Gardner's syndrome most commonly occurs in patients with mutations distal to codon 1403.[112] In addition, desmoid tumors have been reported in higher incidence in patients with a mutation between codons 1445 and 1580.[120] CHRPE has been reported most commonly when the mutation is between codons

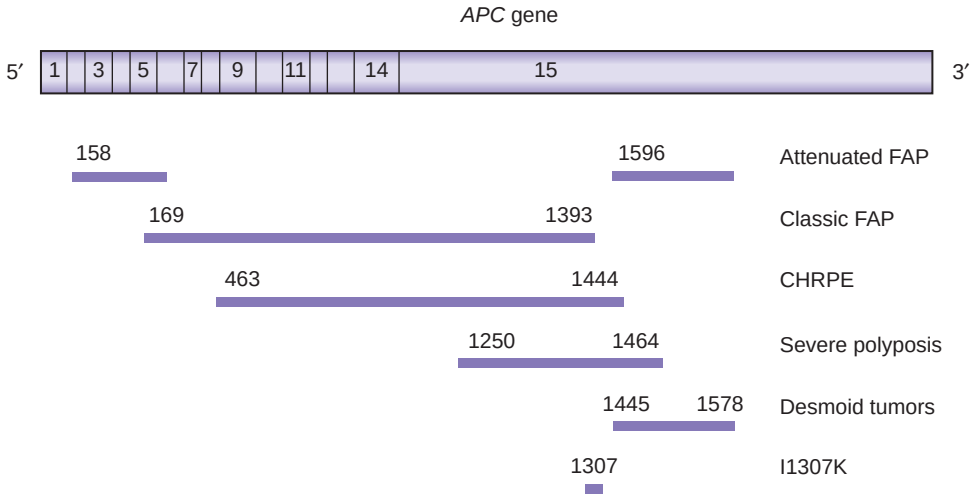

Figure 155–10. Genotype-phenotype correlations between the *APC* gene and familial adenomatous polyposis (FAP). CHRPE, congenital hypertrophy of the retinal pigmented epithelium. (From Jo WS, Chung DC: Genetics of hereditary colorectal cancer. Semin Oncol 32:11-23, 2005.)

457 and 1444.[121] Genotype-phenotype correlations for other extracolonic manifestations are less clearly defined.[89] In addition, it must be emphasized that genotype-phenotype correlations are variable within and between families with identical mutations, likely due to the complex interaction of the type of mutation, impact of the mutation on wild-type APC protein expression, modifying genes (e.g., secretory phospholipase A_2 and DNA methyltransferase), and environmental factors.[122] Currently, the clinical impact of genotype-phenotype correlations in FAP is limited to predictive genetic testing for early diagnosis and the research setting.[89]

Diagnosis

Clinical Diagnosis FAP should be suspected when hundreds to thousands of adenomatous colorectal polyps are diagnosed. Current criteria for the clinical diagnosis of FAP include more than 100 colorectal adenomas or multiple adenomas in a patient with a first-degree relative with FAP. However, the attenuated FAP phenotype presents with less than 100 proximal, flat colorectal polyps and a spared rectum, although the risk of CRC remains high.[119]

Molecular Diagnosis Individuals with a documented mutation in the *APC* gene almost certainly develop FAP, whereas the absence of a mutation in an asymptomatic individual from a family with a known *APC* mutation excludes disease.[123] The identification of gene carriers in presymptomatic at-risk members of an FAP kindred may be achieved using clinically available tests, including linkage analysis, protein truncation testing, confirmation strand gel electrophoresis, and sequencing of the entire gene.[124] Accuracy of linkage analysis has been reported as high as 80% but is limited in some individuals because markers associated with the APC allele may not be informative.[125] Also, DNA is required from family members, and this may be cumbersome to obtain. Finally, gene recombination, although rare, may segregate the linkage marker away from the disease-causing APC allele.

The most common method used to screen for *APC* mutations is the protein truncation test (also known as the *in vitro synthesized protein assay*), which recognizes the smaller protein transcribed from a disease-causing APC allele secondary to a premature stop codon. The protein truncation test alone detects up to 80% of disease-causing APC mutations but does not detect missense mutations.[126] However, the combination of the protein truncation test and strand gel electrophoresis is commercially available and has a mutation detection rate of up to 90%.[124,125] Other screening tests that recognize a premature stop codon include polymerase chain reaction (PCR), single-stranded conformation polymorphism, and denaturing gradient gel electrophoresis.

Direct DNA sequencing is the most accurate method of detecting *APC* mutations, with detection rates reported as high as 95%, and overcomes many of the limitations of linkage analysis.[125] If a disease-causing mutation is documented in a family, the accuracy of the test for other at-risk family members is almost 100%.[124] However, some difficulty with this method is derived from the large APC coding region and the fact that most APC mutations are small insertions, deletions, or substitutions. Also, interpretation of direct DNA sequencing is complicated by the detection of amino acid alterations of uncertain significance.[124]

A positive screening test should be confirmed with a diagnostic modality able to identify the abnormal nucleotide sequence in the disease-causing APC allele. These confirmatory tests include direct DNA sequencing, allele-specific oligonucleotide hybridization (ASO hybridization), ASO amplification (ASO-PCR), restriction fragment length polymorphisms, and ligase chain reaction.

Genetic Testing and Counseling—Implications for Screening and Surveillance

The surveillance of patients at-risk for FAP includes a detailed personal and family history, thorough physical examination, and biannual flexible sigmoidoscopy beginning at age 10 to 12 years.[123-125,127] Once the diagnosis of FAP is made, a full colonoscopy should be performed to evaluate disease severity (CRC, polyp burden, large polyps, or atypia) and to decide appropriate timing for prophylactic colectomy.

Clinical criteria for offering genetic testing to an individual include a newly recognized FAP phenotype (>100 adenomas), clinical suspicion of attenuated FAP (onset of CRC in the 50s to 60s with <100 adenomas or >20 cumulative colorectal adenomas), FAP-associated extracolonic manifestations with any number of colorectal adenomas, first-degree relative with documented FAP or attenuated FAP, or any relative with documented FAP and any number of colorectal adenomas.[123,124] The protein truncation test is the most commonly used initial genetic test. However, this test does not detect missense mutations, and false-negative tests result when there is a previously unrecognized truncating mutation. Therefore, in families in which the protein truncation test does not provide informative results, individuals should be evaluated with linkage analysis or undergo the recommended clinical surveillance regimen. In families with an informative protein truncation test, at-risk relatives should have genetic testing at age 10 to 12 years, and family members with a negative test can be discharged from further screening with almost 100% certainty.[128] However, these patients should resume screening for CRC at 50 years of age, as currently recommended for average-risk individuals.[16-19] In the setting of a positive protein truncation test, patients require genetic counseling and intensive endoscopic surveillance for early recognition of colorectal polyposis.[129] Surveillance should include annual sigmoidoscopy until adenomas are diagnosed, even beyond the age of 40 years, when the probability of developing classic FAP is low. Guidelines for testing, interpretation of results, and management of related psychosocial issues have been established by several medical societies.[123-125]

Genetic counseling is imperative prior to and after genetic testing for FAP. Pretest counseling should include discussion of the test being offered (cost, proce-

dure, risks and benefits) and the implications of a positive, negative, and uninformative result. Other important issues to be discussed include the risk of passing a mutation to children, privacy issues, and emotional distress associated with genetic testing. Post-test counseling should include interpretation of test results, concerns about decreased life expectancy, stigmatization, discrimination by insurance companies and employers, and options for future surveillance and surgery. In patients with a negative genetic test for FAP, emotional relief is common, but survivor guilt may arise due to the identification of an *APC* mutation in family members.[123-125]

Surgical Management

Prophylactic proctocolectomy is recommended for patients with FAP, given the near 100% risk of early-onset CRC. Patients with FAP who present for surgical management may be stratified into two major groups: (1) asymptomatic members of a known FAP kindred with an *APC* mutation detected by screening and (2) symptomatic patients, of whom approximately 30% have no family history of FAP.[123,130] Symptoms from FAP are attributed to CRC in up to 66% of cases. In asymptomatic patients, surveillance endoscopy may be continued when polyps are small (<6 mm) and there is no evidence of dysplasia or cancer.[128] Proctocolectomy is commonly deferred in these patients until after the high school years, due to patient and parental wishes. However, it should not be deferred after the early 20s because the risk of CRC is substantial in untreated patients.[128]

Surgical Options The ideal operative management of the colon and rectum in patients with FAP should satisfy the following three criteria:

1. Removal of all at-risk colorectal mucosa
2. Maintenance of continence with transanal evacuation and low frequency of bowel movement
3. Association with minimal operative complications

Surgical options for patients with FAP include total proctocolectomy with end ileostomy, colectomy with ileorectal anastomosis (IRA), and total proctocolectomy with ileal pouch–anal anastomosis (IPAA). Another alternative, although rarely used, is total proctocolectomy with continent ileostomy (Kock pouch) (Tables 155–5 and 155–6). The anastomosis in IPAA may be performed hand-sewn, where a mucosectomy is done to remove all at-risk rectal mucosa or stapled, where the mucosectomy is deferred and some at-risk mucosa may be left in situ. The most important consideration in choosing an operation for FAP is its effectiveness for prophylaxis against the development of CRC. However, these procedures are often performed in asymptomatic, young patients who perceive the operation as preventive rather than as therapeutic, so issues such as operative morbidity, functional results, and patient acceptability are important variables. Although IPAA meets the goals of surgical therapy in most patients, there remains a defined role for IRA[131] and total proctocolectomy with end ileostomy in specific clinical scenarios.

A total proctocolectomy with either a continent ileostomy (Kock pouch) or end ileostomy eliminates the

Table 155–5 Surgical Options for Management of Colorectal Polyposis in Patients with FAP

Procedure	Indications	Advantages	Disadvantages
TPC	Cancer of lower rectum at diagnosis	Eradicates all at-risk mucosa	Pelvic and perineal dissection (nerve injury, wound healing issues) Permanent ileostomy
IRA	Spared rectum Metastatic cancer	Improved function and continence Simpler operation (one stage, no pelvic dissection, no stoma)	Risk of rectal cancer requires lifelong surveillance
IPAA with mucosectomy	Uncontrollable rectal adenomas Poor compliance to follow-up	Eradicates all at-risk mucosa Acceptable function and continence May be performed in one stage	Pelvic dissection (nerve injury) Mucosectomy may impair continence
IPAA without mucosectomy	Spared rectum	Acceptable function Near-normal continence May be performed in one stage	Retained at-risk mucosa requires surveillance Pelvic dissection (nerve injury)

Table 155–6 Surgical Options for Management of Colorectal Disease in the Colorectal Polyposis Syndromes and HNPCC

Syndrome	Surgical Options
FAP	Total proctocolectomy with end ileostomy
	Colectomy with ileorectal anastomosis (IRA)*
	Total proctocolectomy with ileal pouch–anal anastomosis (IPAA)
	Hand-sewn (with mucosectomy)
	Stapled (without mucosectomy)
aFAP	Colectomy with IRA*
MYH polyposis‡	Colectomy with IRA*
	Total proctocolectomy with IPAA
HNPCC	Colectomy with IRA*
	Total proctocolectomy with IPAA†
JPS‡	Colectomy with IRA*
	Total proctocolectomy with IPAA
PJS‡	Intraoperative endoscopy with polypectomy
	Segmental colectomy
Cronkhite-Canada syndrome‡	Segmental colectomy
Cowden's Disease‡	Segmental colectomy
Ruvalcaba-Myhre-Smith syndrome‡	Segmental colectomy
Hereditary mixed polyposis syndrome‡	Colectomy with IRA*

*IRA may be used when there is relative rectal sparing and close endoscopic surveillance of the rectal remnant is possible.
†IPAA may be used when there is rectal cancer or when close postoperative endoscopic surveillance of the rectal remnant is not possible.
‡Surgical intervention is indicated for CRC, large polyp burden, or complications of polyposis.
See Table 155–5 for more details concerning the surgical options for FAP.

risk of subsequent development of CRC by removing all at-risk mucosa. However, the permanent ileostomy associated with these procedures is often unacceptable to young patients with FAP because of its perceived restriction on social, athletic, and sexual activities. In addition, creation of a Kock pouch is technically difficult and is associated with an early postoperative complication rate of 15%, a mortality rate of 2.2%, and continent valve-related complications that require reoperative intervention in more than 20% of patients.[132] Because the postoperative functional results in a patient with FAP are likely to be observed by family members in need of prophylactic surgery, poor functional outcome and patient dissatisfaction may deter at-risk family members from undergoing appropriate screening, surveillance, and surgical management. Total proctocolectomy is appropriate for patients with an established distal rectal cancer in whom a sphincter-preserving resection would be oncologically suboptimal. In the absence of rectal cancer, the perineal dissection can be performed in the intersphincteric plane to reduce perineal wound healing problems.

IRA with close postoperative follow-up and endoscopic ablation of rectal polyps is an option for patients with rectal sparing and acceptable rectal compliance who are reliable and willing to undergo regular endoscopic surveillance and accept the 8% to 37% risk of subsequent development of rectal cancer.[133-137] Postoperative morbidity following IRA occurs in approximately 25% of patients, with small bowel obstruction being the most common complication.[138] In addition, recent evidence suggests the risk of rectal cancer may be lower than reported in historical series, as more stringent criteria have been developed for selecting patients for IRA following the introduction of IPAA.[136] Advantages of this approach include improved postoperative bowel function, less complexity in performing the procedure, and avoidance of a permanent ileostomy.[137] However, following IRA in patients with FAP, endoscopic follow-up and ablation of residual and new rectal polyps should be performed in 6-month intervals.[128,131]

A combination of IRA and endoscopic rectal surveillance with ablation of polyps may delay the development of rectal cancer by as much as 10 years. If rectal polyps cannot be adequately managed endoscopically, a trial of sulindac can be considered. However, strong consideration should be given to converting the IRA to an IPAA. Significant rectal polyposis (>100 polyps), a long retained rectal segment, inadequate or unreliable follow-up, specific mutation loci on the *APC* gene, and the presence of colon cancer at the time of colectomy have been associated with an increased risk of developing rectal cancer following IRA.[139,140] Historical data, much of which was collected prior to the availability of IPAA as a surgical option, suggest that 16% to 32% of patients with FAP treated with IRA ultimately require proctec-

tomy.[136,141] However, when data are limited to the IPAA era, the rate of proctectomy is reported as low as 2% following IRA, likely due to limitation of IRA to patients with rectal sparing and patients with severe disease undergoing rectal excision at their initial surgery.[136] Reasons for proctectomy following IRA include metachronous rectal cancer, large adenomas, severe dysplasia, rectal strictures, incontinence, or high polyp density that prohibits adequate endoscopic surveillance. Although an IRA improves survival by 30 years in patients with FAP, overall survival remains 10 years less than that for the general population.[142]

IPAA for FAP is commonly performed in two stages. Resection of the entire colon and rectum followed by an IPAA with or without a protecting loop ileostomy is the first operation. When the anastomosis is performed hand-sewn, a mucosectomy is performed, involving the distal anorectal mucosa from the dentate line cephalad approximately 5 cm. During the mucosectomy, care is taken to preserve the internal and external anal sphincters. A reservoir is constructed from the terminal ileum, which requires mobilization of the small bowel mesentery up to the level of the duodenum and uncinate process of the pancreas as well as mesenteric-lengthening maneuvers. The second operation, performed 2 to 3 months later, consists of reversal of the ileostomy. Closure of the ileostomy is preceded by a water-soluble contrast enema to exclude pouch leaks and confirm sacralization of the pouch. Some perform IPAA as a one-stage operation, without a protective ileostomy. However, this approach is controversial because of the potential for an increase in clinically significant anastomotic leaks and pouch failure. The morbidity of the single-stage approach must be balanced against ileostomy-related complications from the two-stage procedure, which may lead to pouch failure and permanent ileostomy. Recently, small series have reported the feasibility of laparoscopic IPAA in patients with FAP.[143]

IPAA should eliminate any future risk of CRC. However, it is unclear whether an IPAA, by virtue of removal of all at-risk mucosa, can push the survival curve of patients with FAP closer to that of the general population. A stapled IPAA without mucosectomy leaves a small ring of rectal mucosa, even when performed close to the dentate line. Similarly, a hand-sewn IPAA with mucosectomy can leave small areas of rectal mucosa between the rectal cuff and serosa of the pouch, a location that is difficult to palpate and visualize endoscopically. There are reports of adenomatous polyps (up to 57% of patients) and adenocarcinomas of the ileal pouch or distal to the anastomosis, a finding that was associated with increasing length of time from IPAA surgery but not with severity of colorectal polyposis.[144] These findings emphasize the need for endoscopic surveillance of the pouch, with biopsy of suspicious lesions.

Mortality following IPAA for FAP is less than 1% and complications occur in 20% to 28% of patients, with small bowel obstruction being most common.[145,146] Postoperative fecal frequency and incontinence are important considerations in patients undergoing IPAA. Patients average between four and six bowel movements per day, with 53% to 78% with perfect continence during the day and 50% to 69% continent at night.[147] Although functional results after IPAA for FAP continue to improve with surgeon experience, the results after IRA may be better.[148] In addition, postoperative recovery, rehabilitation, and complication rates may be better when patients treated with IRA are compared to those treated with IPAA.[146,149] However, with experience, a hand-sewn or stapled IPAA can be performed with low mortality rates, acceptable morbidity rates, and long-term functional results approximating that of IRA.[150]

Issues That Modify Surgical Therapy When CRC is present, stage and location, presence of symptoms, overall patient status, and the extent and location of benign polyp disease are important considerations in planning the extent of surgical resection. If incurable metastatic disease is diagnosed, surgery should be palliative. However, if metastatic disease is resectable, a curative total colectomy with IRA should be performed in patients with colon cancer and limited rectal polyposis. Some suggest that patients with FAP and colon cancer can safely undergo IPAA, but it may be prudent to perform a colectomy and delay IPAA until after definitive pathologic and radiographic staging of the colon cancer, adjuvant treatment is completed, and a period of recovery and observation. In addition, when unsuspected colon cancer is discovered on pathologic examination following IPAA, a period of observation may be warranted before ileostomy closure because adjuvant chemotherapy may worsen anal incontinence and frequency of bowel movements. For upper rectal cancer in the setting of FAP, a staged rectal resection and subsequent IPAA may be considered. However, when the rectal cancer involves the anal sphincters, a total proctocolectomy with ileostomy is required.

A preoperative CT is helpful in the identification of desmoids, as they may influence the surgical approach. Patients with a personal or family history of desmoids are at particular risk and should have an IPAA as an initial procedure because future attempts at proctectomy may be impossible due to dense desmoid fibrosis. However, patients with extensive mesenteric desmoids at initial operation may be poor candidates for IPAA because a shortened mesentery may prohibit the terminal ileal pouch from reaching the anal canal. In addition, desmoids may cause subsequent pouch-related complications such as ulceration, bleeding, or dysfunction from pressure effects.

In women of childbearing age, postoperative fecundity is an issue to consider when planning surgical therapy for FAP. Some data suggest that women treated with IPAA may have a significantly higher infertility rate following surgery.[151,152] It has been hypothesized that pelvic adhesions, which may be significant following IPAA, contribute to postoperative infertility. Suturing the ovaries to the pelvic brim and use of antiadhesion barriers has been suggested following IPAA in women of childbearing age, but there are limited data to conclude that these measures improve postoperative fertility. Therefore, it is important to discuss the potential for impaired postoperative fertility with women of childbearing age considering an IPAA.

An alternative option for women of childbearing age who desire to become pregnant following surgery for FAP may be colectomy with IRA. Some data suggest that the postoperative fecundity of women with FAP who have an IRA is similar to that of the general population.[152] However, in most cases IRA is reserved for those with relative rectal sparing and who are willing to undergo close postoperative endoscopic surveillance of the rectal remnant.

Conclusions When deciding the colorectal operation to offer a patient with FAP, two important points should be considered: (1) colorectal surgery is usually prophylactic and performed in asymptomatic, young patients who are concerned about postoperative restrictions on social, athletic, and sexual activities; and (2) regardless of the type of surgery performed, patients with FAP will likely not have a normal life expectancy because of the morbidity and mortality associated with other manifestations of the syndrome, especially duodenal periampullary neoplasia and desmoid disease.[145] Nevertheless, IPAA is the operation of choice for most patients with FAP because it nearly eliminates the risk of CRC while maintaining transanal fecal evacuation. In a carefully selected subset of patients, IRA with close postoperative endoscopic surveillance and excision or ablation of rectal polyps is an option, recognizing that IRA is associated with somewhat better functional results and lower morbidity. Given the substantial risk of cancer developing in the rectal remnant, IRA is contraindicated in patients who are unable to comply with intensive endoscopic surveillance.

Attenuated Familial Adenomatous Polyposis

Attenuated FAP is diagnosed in a subset of patients with germline APC mutations who present with fewer colorectal polyps (<100), later age of onset of polyps (mean at age 44 years) and cancer (mean at age 56 years), and increased rate of proximal colon involvement.[119] It is inherited in an autosomal dominant fashion, and genotype-phenotype correlations between the mutated *APC* gene locus and clinical presentation of attenuated FAP have been reported.[153] In some cases it is difficult to distinguish attenuated FAP from HNPCC and sporadic colorectal adenomas or carcinomas, with further complexity added by variable patient presentation within the same kindred.[118,154] Extracolonic manifestations of FAP, such as gastric and duodenal polyps, are commonly observed in patients with attenuated FAP. However, patients with attenuated FAP rarely are diagnosed with CHRPE, desmoids, and osteomas.[119]

In asymptomatic patients belonging to an FAP or attenuated FAP kindred, the syndrome is commonly diagnosed using genetic testing. Endoscopic screening and surveillance in these patients must include colonoscopy, given the proximal location of most colonic neoplasia in patients with attenuated FAP. The diagnosis should be considered in patients with multiple colorectal polyps or characteristic extracolonic manifestations, even without a positive family history. Prophylactic surgery in these patients may be guided by the extent of colorectal polyposis. Surgical resection can be deferred in reliable patients willing to undergo close endoscopic surveillance when there are few adenomas that are adequately treated with colonoscopic polypectomy.[119] However, when there are multiple polyps or if the patient is unreliable or unwilling to undergo surveillance, prophylactic colectomy may be prudent (see Table 155–6).

MYH Polyposis

Recently, an autosomal recessive syndrome called *MYH polyposis,* characterized by multiple colorectal adenomas and CRC, has been described that has phenotypic similarities to attenuated FAP or FAP. The initial description of MYH polyposis was in a kindred with an excess of oxidative damage to the *APC* gene resulting in the substitution of thymine-adenine for guanine-cytosine.[155] Later work determined that the oxidative damage was due to missense mutations in the base excision repair gene MYH, most commonly at the loci Y165C and G382D.[156] It is this unrepaired oxidative damage to the *APC* gene that is believed to result in the increased incidence of colorectal adenomas and CRC in these patients.[155,157]

Patients with biallelic mutations in the *MYH* gene usually present with multiple (3 to 100) colorectal adenomas at a median age of 47 to 56 years.[156-158] Patients with hundreds of polyps have been described, although homozygous MYH mutations are rare in those with more than 1000 colorectal polyps.[157-159] The polyps are most commonly tubular or tubulovillous adenomas, with some displaying dysplasia.[157] In addition, these patients have microadenomas similar to those observed in patients with FAP.[158] Although not completely characterized, there have been reports of extraintestinal manifestations such as duodenal polyposis and CHRPE associated with MYH polyposis.[157]

Diagnosis of MYH polyposis requires clinical suspicion in patients with multiple colorectal adenomas, those with suspected FAP and no mutation in the *APC* gene, and those with CRC diagnosed prior to age 50.[156] Furthermore, the syndrome should be considered in patients with a family history consistent with an autosomal recessive inheritance pattern of colorectal adenomas or CRC. Homozygous *MYH* mutations are rare in patients with less than 3 colorectal adenomas, although up to 33% of patients with more than 15 adenomas may have biallelic mutations in the *MYH* gene.[156,157] In addition, in patients with a classic FAP phenotype and no mutation in the *APC* gene, up to 8% with have biallelic mutations in the *MYH* gene. It has been estimated that homozygous mutations in the *MYH* gene are responsible for 1% to 3% of cases of CRC.[160,161] Genetic testing for a known *MYH* mutation may be performed using probe-based PCR.[156] Alternatively, the entire *MYH* gene may be sequenced.[162] As for all genetic testing, pretest and post-test genetic counseling are required.

Although there are no large studies to guide the treatment approach, given the increased risk of CRC throughout the colon it is reasonable to offer patients with MYH polyposis total proctocolectomy with IPAA. Alternatively, patients with relative rectal sparing may be treated with total abdominal colectomy and IRA with close post-

operative surveillance of the remaining rectum to diagnose and treat metachronous adenomas (see Table 155–6). In select cases of MYH polyposis, colorectal adenomas may be controlled with endoscopic polypectomy and colectomy may be avoided.[156,157] The interval of colonoscopic surveillance in patients homozygous for *MYH* mutations remains to be determined, although current recommendations are similar to those for classic FAP.[156] In addition, upper gastrointestinal endoscopy is recommended for patients with homozygous *MYH* mutations.[156,157]

Hereditary Nonpolyposis Colorectal Cancer

Clinical Considerations

HNPCC is an autosomal dominant familial CRC syndrome characterized by familial clustering of early age-of-onset CRC (average age, 40 to 48 years). It is estimated to be responsible for 3% to 5% of all cases of CRC. Other prominent features of HNPCC include a predominance of right-sided colon cancer (60% to 80% proximal to the splenic flexure), an increased incidence of synchronous and metachronous CRC (up to 45% of patients), and an increased incidence of specific extracolonic cancers (endometrial, ovarian, renal pelvis, ureteral, small bowel, and gastric).[163] The first description of this syndrome was by Aldred Warthin in 1913, who reported a kindred known as "Family G" with an increased incidence of colon, gastric, and endometrial cancer.[164] However, the significance of the familial clustering of these malignancies was not fully appreciated until 1966, when Henry Lynch and colleagues reported two large families with the "cancer family syndrome."[165] In 1984, further observation led to the description of two patterns of disease presentation, termed *Lynch syndrome I* (CRC only) and *Lynch syndrome II* (CRC and associated malignancies).[166] Due to the subsequent difficulty in differentiating these two patterns of disease, the term *HNPCC* was given to this syndrome. In 1991, the International Collaborative Group on HNPCC (ICG-HNPCC) published clinical guidelines to standardize diagnosis and facilitate performance of large, cooperative studies. These studies ultimately contributed to the definition of surveillance and treatment protocols and identification of the genetic basis for the syndrome.[167]

The term *nonpolyposis* is often confusing, because patients with HNPCC do have colorectal polyps, although they do not have florid polyposis as is observed in patients with FAP. The incidence of adenomas in patients with HNPCC and CRC is similar to that of the general population with sporadic CRC. However, adenomas in patients with HNPCC have a higher incidence of high-grade dysplasia and villous architecture. In addition, polyps in patients with HNPCC develop at a younger age, tend to be larger than those in the general population, and are distributed equally throughout the colon. Adenomas in HNPCC are thought to be precancerous lesions, similar to the adenoma-to-carcinoma sequence seen in the development of sporadic CRC. However, an accelerated transition from adenoma to carcinoma has been reported in patients with HNPCC.[168]

HNPCC is inherited in an autosomal dominant fashion with 80% penetrance. Therefore, the lifetime risk of CRC is 80%, 60% of which will be diagnosed by age 60 years. CRC in these patients is more likely to be poorly differentiated and mucinous and have signet ring histology.[169] In addition, colorectal neoplasia in patients with HNPCC is more likely to demonstrate medullary growth with cribriform patterns, and a "Crohn's like" pattern of tumor-infiltrating lymphocytes.[169] Despite these normally poor prognostic features, patients with HNPCC have survival that is equivalent, if not better, than patients with sporadic CRC of similar stage.[170]

Extracolonic Cancers

Although CRC is the most common malignancy in HNPCC, several other cancers occur with increased frequency in these patients. The most common extracolonic malignancy is endometrial cancer, diagnosed in 39% to 60% of women with HNPCC by age 70 years.[125,171] Women with HNPCC also have an increased risk of ovarian cancer. Other malignancies that have been associated with HNPCC include cancers of the stomach, transitional cell epithelium of the urinary tract (renal pelvic, ureter, bladder), small bowel, and hepatobiliary system.[172] The estimated cumulative lifetime risk of developing cancers of the stomach is 13% to 19%, urinary tract is up to 4% to 7%, and hepatobiliary system is 2% to 4%.[62,171] HNPCC associated with tumors of the central nervous system (primarily glioblastoma) has been termed *Turcot's syndrome,* whereas association with benign and malignant tumors of the sebaceous glands and keratoacanthomas has been termed *Muir-Torre syndrome.*

Genetics

The genetic etiology of cancer predisposition in patients with HNPCC is a germline mutation in a mismatch repair *(MMR)* gene, which recognizes and repairs mismatched nucleotides during DNA replication.[62] When the *MMR* genes function properly, DNA nucleotides that are mismatched during replication are excised and replaced with the correct bases. Patients with mutations in an *MMR* gene lack appropriate repair of mismatched DNA and express the "mutator phenotype." Cancer develops in these patients due to failure of repair of replication errors and the ultimate dysfunction of tumor suppressor genes and oncogenes involved in tumorigenesis.

When there is a mutated *MMR* gene, the number of base pairs in known microsatellites can increase or decrease. This phenomenon, known as *microsatellite instability* (MSI), is an expression and marker of a mutated *MMR* gene. A germline mutation in one allele of an *MMR* gene along with a somatic mutation of the second allele of the same gene is required to produce MSI. MSI was initially described in unicellular organisms, such as the bacteria *Escherichia coli,* where the role of MMR genes was defined. The detection of MSI in HNPCC tumors led to the hypothesis that HNPCC was due to the mutations in human homologues of the bacterial MMR genes *MutS* and *MutL.* This led to the description of the human MMR genes human MutL homologue *(hMLH)* and

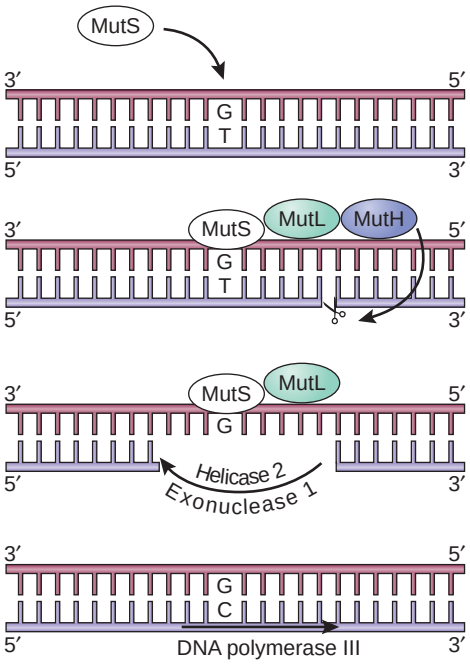

Figure 155–11. Enzymes involved in the recognition, excision, and repair of mismatched nucleotides during DNA replication. (From Service RF: Stalking the start of colon cancer. Science 263:1559-1560, 1994.)

human MutS homologue *(hMSH)* as the genetic etiology of HNPCC (Fig. 155–11).

Mismatch Repair Genes Seven mismatch repair genes have been associated with HNPCC, including four from the mutL family *(hMLH1, hMLH3, hPMS1, hPMS2)* and three from the mutS family *(hMSH2, hMSH3, hMSH6).*[62,173] However, more than 90% of cases of HNPCC are due to mutations in *hMLH1* or *hMSH2.*[174] *hMSH6* mutations are associated with atypical HNPCC, characterized by later onset of CRC, low-level MSI, and increased incidence of endometrial cancer.[175] HNPCC caused by germline mutations in *hMLH3, hPMS1,* and *hPMS2* is rare, and routine evaluation of these genes is not currently recommended.[176] A number of different types of mutations have been described, including truncating, missense, and frameshift mutations.[62] The incidence of *MMR* gene mutations in the general population ranges from 1 in 200 to 1 in 2000, with a penetrance of 80%. In kindreds with a clinical diagnosis of HNPCC, the incidence of a documented germline mutation in an *MMR* gene ranges from 15% to 86%.[177,178]

Microsatellite Instability Phenotype In 1993, DNA replication errors were described in both sporadic[179] and familial[180] CRC. Linkage of the germline etiology of HNPCC to chromosome 2, without increased *K-ras, p53,* and *APC* mutations, led to the hypothesis that CRC in HNPCC develops via a mechanism distinct from the classic pathways of loss of heterozygosity in tumor suppressor genes and oncogenes. The genetic lesions responsible for CRC via tumor suppressor genes and oncogenes are characterized by gross chromosomal abnormalities, whereas mutations in *MMR* genes are characterized by a more subtle genetic alteration, namely MSI.

There are more than 100,000 microsatellites observed throughout the human genome. In HNPCC-associated CRC, the most commonly affected microsatellites are those containing mononucleotide repeats (particularly $[A]_n$. Dinucleotide (particularly $[CA]_n$), trinucleotide, tetranucleotide, and pentanucleotide repeats are less frequently affected by MSI, demonstrating that the simpler the microsatellite sequence, the higher probability of developing instability at that locus when an *MMR* gene is mutated.[181] Most MSI-positive tumors accumulate mutations in short mononucleotide sequence near or within the coding regions of growth regulatory genes. These genes include growth factor receptors (transforming growth factor-β receptor II, insulin-like growth factor receptor II), regulators of the cell cycle, regulators of apoptosis, immune surveillance, and the MMR genes *hMSH6* and *hMSH3.*[62,173]

In 1996, the National Cancer Institute sponsored a workshop on MSI in hereditary CRC and recommended that a series of five microsatellite markers be tested to determine the MSI status of a tumor. DNA is amplified using PCR followed by microdissection, and the lengths of specific microsatellites are compared between tumor and normal tissue of the same individual.[182] When a microsatellite locus of tumor and normal tissue are of different length, that marker is considered to have MSI at that locus. When two or more loci display MSI, the tumor has high-level MSI (MSI-H). When one loci displays MSI, the tumor has low level MSI (MSI-L), and when none of the markers display MSI, the tumor is microsatellite stable (MSS).[181] In patients with MSI-L tumors, an additional panel of five MSI markers is recommended to confirm the MSI status. The MSI-H phenotype is observed in more than 90% of CRCs in patients with HNPCC, whereas it is observed in only 10% to 15% of sporadic CRCs.[173] However, it must be emphasized that MSI in HNPCC is caused by a germline mutation in an *MMR* gene, whereas MSI in sporadic CRC is most commonly due to hypermethylation (and silencing) of the *hMLH1* promoter.[183]

Despite the different mechanism underlying MSI in HNPCC and sporadic CRC, it appears that they have similar pathologic and clinical features. Sporadic MSI-H CRC of the proximal colon have an increased incidence of poorly differentiated, mucinous histology, solid cribriform growth pattern, fewer lymph node metastases, DNA diploidy, and Crohn's-like lymphoid infiltration when compared with sporadic MSS tumors.[173,184] Because these features are typical of HNPCC-associated CRC, it appears that MSI-H CRC may be characterized by distinct clinicopathologic features, regardless of family cancer history. Similar to adenocarcinoma, colorectal adenomas in patients with HNPCC have a significantly increased incidence of MSI than sporadic adenomas (57% to 90% versus 3%).[185-188] MSI-H and MSS adenomas can coexist in the same patient with a germline MMR gene mutation.[187]

Genotype-Phenotype Correlations MMR gene mutations have been evaluated for correlation with a specific clinical presentation of HNPCC. Patients with HNPCC due to a mutation in *hMSH2* may develop CRC at a later age (>40 years) and have a higher incidence of extracolonic cancer, whereas those with a mutation in *hMLH1* present with CRC at an earlier age (<35 years), have relatively fewer extracolonic cancers, and have a higher incidence of rectal cancer.[189] In addition, patients with *hMSH6* mutations may have "atypical" HNPCC, with MSI-L status, lower incidence and later onset (55 years versus 44 years) of CRC, and higher incidence of endometrial cancer and transitional cell cancer of the urinary tract.[175] Gender may affect phenotypic expression among patients with *hMSH2* mutations, because men may have a higher incidence of CRC and death from cancer, whereas women may have more extracolonic malignancies, primarily due to the increased risk of endometrial and ovarian cancer.[190,191] Others have reported a correlation between mutation of *hMSH2* and Muir-Torre syndrome.[192] Although these potential relationships may have implications for screening, surveillance, and treatment, large-scale studies with precise clinical and molecular data are still needed to establish more accurate genotype-phenotype correlations.

Diagnosis

The gold standard for diagnosis of HNPCC is the detection of a germline mutation in an *MMR* gene. In the absence of distinct phenotypic features, the clinical diagnosis of HNPCC is based on family history. The diagnosis should be considered in patients with early age-of-onset CRC, because up to 20% of patients younger than 40 to 45 years at diagnosis of CRC will have HNPCC.[193] However, a family cancer history during the initial consultation of patients with early age-of-onset CRC may be limited in its ability to detect hereditary CRC syndromes, and more extensive follow-up interviews are recommended.[194]

In 1991, the ICG-HNPCC established the Amsterdam Criteria to standardize the clinical diagnostic criteria for HNPCC (Box 155–1).[167] The Amsterdam Criteria are sensitive for the detection of HNPCC but are limited in small families, kindreds where extracolonic cancers are prominent, and in de novo cases of germline *MMR* gene mutations. In response to these concerns, less strict criteria were suggested to include other well-recognized clinical features of HNPCC, such as right-sided CRC, synchronous and metachronous CRC, associated extracolonic cancers, colorectal polyps, and familial aggregation of early age-of-onset CRC. In 1998, the ICG-HNPCC developed a revised set of clinical criteria (Amsterdam Criteria II) that includes many of these associated clinical features (Box 155–2).[195] Furthermore, in 1996 the Bethesda Guidelines were established to direct patient selection for MSI testing (Box 155–3).[182] These guidelines were revised in 2002 (Box 155–4).[196]

Box 155–1 Amsterdam Criteria for the Clinical Diagnosis of HNPCC

- CRC in three relatives, one a first-degree relative of the other two
- At least two successive generations affected
- At least one CRC diagnosed before age 50 years
- FAP is excluded

CRC, colorectal cancer; FAP, familial adenomatous polyposis; HNPCC, hereditary nonpolyposis colorectal cancer.
Data from Vasen HF, Mecklin JP, Khan PM, Lynch HT: The International Collaborative Group on Hereditary Non-Polyposis Colorectal Cancer (ICG-HNPCC). Dis Colon Rectum 34:424-425, 1991.

Genetic Testing and Counseling—Implications for Screening and Surveillance

Genetic testing provides the potential for the identification of *MMR* gene mutation carriers prior to the development of cancer. At-risk family members may benefit from detection of a recognized, specific *MMR* gene mutation in their kindred. An optimal strategy to enhance detection of HNPCC should incorporate clinical evaluation, including the Amsterdam II Criteria and Revised Bethesda Guidelines. Prior to genetic testing, individuals should be referred for pretest genetic counseling. The molecular genetic studies available include MSI testing, immunohistochemistry for expression of MMR proteins, and germline sequencing. Initial genetic testing may include MSI or immunohistochemistry for *hMLH1* and *hMSH2,* since these genes are responsible for more than 90% of HNPCC cases. However, if the genetic locus responsible for HNPCC in a particular kindred is known, targeted testing may be performed.

Recommendations for genetic testing and surveillance of patients with a known *MMR* gene mutation have been developed by various expert societies. These recom-

Box 155–2 Amsterdam Criteria II for the Clinical Diagnosis of HNPCC

- HNPCC-associated cancer (colorectal, endometrial, small bowel, ureter, or renal pelvis) in three relatives, one a first-degree relative of the other two
- At least two successive generations affected
- At least one HNPCC-associated cancer diagnosed before age 50 years
- FAP is excluded (in cases of CRC)

CRC, colorectal cancer; FAP, familial adenomatous polyposis; HNPCC, hereditary nonpolyposis colorectal cancer.
Data from Vasen HF, Watson P, Mecklin JP, Lynch HT: New clinical criteria for hereditary nonpolyposis colorectal cancer (HNPCC, Lynch syndrome) proposed by the International Collaborative Group on HNPCC. Gastroenterology 116:1453-1456, 1999.

Box 155–3 **Bethesda Guidelines for Selecting Patients with CRC for MSI Testing**

Tumors from individuals should be tested for MSI in the following situations:

1. Individuals with cancer in families that meet the Amsterdam Criteria
2. Individuals with two HNPCC-related cancers, including synchronous and metachronous CRC or associated extracolonic cancers
3. Individuals with CRC and a first-degree relative with CRC and/or and HNPCC-related extracolonic cancer* and/or a colorectal adenoma; one of the cancers diagnosed before age 45 years or the adenoma diagnosed before age 40 years
4. Individuals with CRC or endometrial cancer diagnosed before age 45 years
5. Individuals with right-sided colon cancer with an undifferentiated pattern (solid/cribriform) on histopathology diagnosed before age 45 years
6. Individuals with signet ring cell–type CRC diagnosed before age 45 years
7. Individuals with colorectal adenomas diagnosed before age 40 years

*HNPCC-related extracolonic cancer = endometrial, ovarian, gastric, hepatobiliary, small bowel, or transitional cell (renal pelvis or ureteral) cancer.
CRC, colorectal cancer; HNPCC, hereditary nonpolyposis colorectal cancer; MSI, microsatellite instability.
Data from Rodriguez-Bigas MA, Boland CR, Hamilton SR, et al: A National Cancer Institute workshop on hereditary nonpolyposis colorectal cancer syndrome: Meeting highlights and Bethesda Guidelines. J Natl Cancer Inst 89:1758-1762, 1997.

Box 155–4 **Revised Bethesda Guidelines for Selecting Patients with CRC for MSI Testing**

Tumors from individuals should be tested for MSI in the following situations:

1. CRC diagnosed in an individual who is younger than age 50 years
2. Presence of synchronous or metachronous colorectal or other HNPCC-associated cancers,* regardless of age
3. CRC with the MSI-H histology† diagnosed in an individual who is younger than age 60 years
4. CRC diagnosed in one or more first-degree relatives with an HNPCC-associated cancer, with one of the cancers being diagnosed before age 50 years
5. CRC diagnosed in two or more first- or second-degree relatives with HNPCC-related tumors, regardless of age

*Colorectal, endometrial, stomach, ovarian, pancreas, ureter and renal pelvis, biliary tract, brain cancers and sebaceous gland adenomas and keratoacanthomas.
†Tumor-infiltrating lymphocytes, Crohn's-like lymphocytic reaction, mucinous or signet ring differentiation, or medullary growth pattern. Microsatellite instability–high (MSI-H) in tumors refers to changes in ≥ 2 of the panel of five National Cancer Institute-recommended microsatellite markers.
CRC, colorectal cancer; HNPCC, hereditary nonpolyposis colorectal cancer.
Data from Umar A, Boland CR, Terdiman JP, et al: Revised Bethesda Guidelines for hereditary nonpolyposis colorectal cancer (Lynch syndrome) and microsatellite instability. J Natl Cancer Inst 96:261-268, 2004.

mendations may also be appropriate for nontested individuals in a mutation-positive kindred, as well as for individuals who belong to a family with a suspected autosomal dominant predisposition to CRC. Full colonoscopy to the cecum with the removal of adenomatous polyps is recommended to commence at the age of 20 to 25 years and be repeated every 1 to 2 years thereafter for the remainder of the patient's life.[16,17] Although there are no randomized, controlled trials to fully quantify the benefit of colonoscopic polypectomy in *MMR* gene mutation carriers, colonoscopic polypectomies of adenomas have reduced the incidence of CRC in at-risk individuals.[197] Screening for endometrial cancer is recommended to begin at 25 to 35 years of age and be repeated every 1 to 2 years. Options for screening for endometrial cancer include endometrial aspirate/biopsy and transvaginal ultrasound.[198] There is insufficient evidence to make definitive recommendations for the other HNPCC-associated cancers, namely stomach, renal pelvis, ureter, hepatobiliary tract, and ovaries. However, screening is recommended when these cancers occur in an affected individual's family. Methods for ovarian cancer screening include serum CA-125 and transvaginal ultrasound, for gastric cancer include upper gastrointestinal endoscopy, and for genitourinary cancer include abdominopelvic ultrasound and urine cytology.

Surgical Treatment

A total abdominal colectomy with IRA is recommended for individuals with an *MMR* gene mutation who develop CRC, because of the high lifetime risk of metachronous CRC and predilection for developing proximal colon cancer (see Table 155–6). However, there is up to a 12% risk of rectal cancer 10 to 12 years after total abdominal colectomy, so aggressive lifelong surveillance of the remaining rectum should be pursued.[199] In patients who present with rectal cancer, total proctocolectomy with IPAA may be offered, given the 17% to 45% rate of metachronous colon cancer in the remnant colon following segmental resection of rectal cancer in these patients.[198,200] A prophylactic total abdominal colectomy

is also recommended as an alternative to lifelong endoscopic surveillance for selected patients with an *MMR* gene mutation and colorectal adenomas. Prophylactic colectomy should be considered on an individual basis, with special consideration given to patients in whom colonoscopy is technically difficult, patients with lesions not amenable to endoscopic polypectomy, and patients who are not likely to be compliant with aggressive endoscopic surveillance. Prophylactic colectomy for individuals with an *MMR* gene mutation but no evidence of colonic neoplasia remains controversial, because as many as 20% will not manifest the disease and therefore will not benefit from the operation.[129]

Although there are no definitive data to support prophylactic hysterectomy or bilateral salpingo-oophorectomy in *MMR* gene mutation carriers, patients may be offered the procedure. In general, female patients with HNPCC who undergo CRC surgery may be advised to consider resection of the uterus and ovaries, particularly if they are postmenopausal.[198] In premenopausal women, counseling should focus on childbearing plans, the long-term effects of prolonged estrogen replacement therapy, and the risk of metachronous endometrial and ovarian cancers. The patient should be advised of the alternatives of annual gynecologic surveillance and prophylactic surgery in the future.

Other Polyposis Syndromes

Juvenile Polyposis Syndrome

Juvenile polyps, the most common gastrointestinal polyp in children, are often encountered as a single colonic lesion in children younger than 10 years of age and are likely not inherited. However, JPS is a rare autosomal dominantly inherited genetic disorder that must be considered in patients with (1) three or more juvenile polyps, (2) any number of juvenile polyps in a patient with a family history of JPS, or (3) any patient with a first-degree relative with JPS.[124] Three clinical variants of this syndrome have been described. *JPS of infancy* is an autosomal recessive disease characterized by failure to thrive, susceptibility to infection, protein-losing enteropathy, gastrointestinal bleeding, diarrhea, intussusception, rectal prolapse, and death by 2 years of age in severe cases. *Generalized JPS* presents in the 1st decade of life and is characterized by juvenile polyps throughout the gastrointestinal tract. *JPS of the colon* is the most common presentation of the syndrome and is characterized by juvenile polyps limited to the large intestine. The most common presentation is chronic anemia, followed by acute gastrointestinal bleeding, per-anal prolapse of the polyp, protein-losing enteropathy, and intussusception with or without obstruction.[127]

The most common site of polyps in JPS is the colon and rectum, although they have been described throughout the gastrointestinal tract.[127,201] Juvenile polyps appear grossly as smooth, reddish brown, pedunculated lesions with lobulated or spherical heads, and superficial ulceration. Histologically, they are characterized by an inflammatory stroma with abundant lamina propria and cystically dilated, mucus-filled glands lined with columnar epithelium. Notably, the polyps do not contain smooth muscle. In addition, foci of adenomatous tissue within a juvenile polyp have been described and may provide the basis for progression of the polyp to invasive cancer.[202]

Patients with JPS have a 10% to 38% lifetime risk of developing CRC and 68% of patients who reach age 60 years develop the malignancy.[203] CRC in patients with JPS is more likely to be distally located, poorly differentiated, have a mucinous histology, and carry a poor prognosis.[203] In addition, 15% to 21% of patients develop gastroduodenal cancer.[202] Gastric cancer is believed to progress from adenomatous foci in hamartomatous polyps, analogous to that in the colon. In addition to gastrointestinal cancers, pancreatic cancer in association with JPS has been reported.[202]

Congenital anomalies of multiple organ systems have been associated with 15% of patients with JPS.[204] Malformations of the gastrointestinal system (malrotation, mesenteric lymphangiomas, vitellointestinal duct abnormalities), genitourinary system (renal structural abnormalities, glomerulonephritis, cryptorchidism, bifid uterus and vagina), heart and vascular system (ventricular septal defect, patent ductus arteriosus, arteriovenous malformation), nervous system (hydrocephalus), and the soft tissue all have been described in these patients.[205] Other associated extraintestinal abnormalities include nail clubbing, hypertrophic pulmonary osteoarthropathy, macrocephaly, alopecia, bony swellings, and cleft lip and palate. Juvenile polyposis is also a feature of Cowden's syndrome, Cronkhite-Canada syndrome, Ruvalcaba-Myhre-Smith syndrome, and Gorlin's syndrome (nevoid basal cell carcinomas, odontogenic keratocysts, skeletal abnormalities, and intracranial calcification).

A family history of JPS is present in 20% to 50% of patients.[206] The syndrome is inherited in an autosomal dominant manner and a germline mutation of the *SMAD4* gene on chromosome 18q21.1 and the *BMPR1A* gene of chromosome 10q21-22 have been linked to the disease.[207] *SMAD4* mutations have been associated with some cases of sporadic CRC and may be a major factor in the increased risk of CRC in patients with JPS.[208] Commercial genetic testing for JPS is available and may be offered to patients meeting the clinical criteria for the syndrome and their family members.[124] As with all genetic testing, counseling is required before the test is performed.

Patients with clinically severe disease who present with gastrointestinal bleeding, anemia, diarrhea, or protein-losing enteropathy should initially be treated with fluid and electrolyte replacement, transfusion, and nutritional supplementation. These patients may be candidates for surgical treatment with total abdominal colectomy and IRA or total proctocolectomy and IPAA (see Table 155–6).[127,201] Surgical resection is also an option for patients with a large polyp burden or suspicion of CRC. Following surgical treatment of colonic disease, surveillance endoscopy of the remaining rectum or pouch and upper gastrointestinal tract is mandatory.[201] Gastric resection is indicated for patients with symptomatic polyps,

dysplasia, or cancer.[201,209] In addition, investigators have evaluated the role of cyclooxygenase inhibitors (i.e., sulindac, celecoxib) to control polyps in this syndrome.[201,210] However, given the limited experience with the use of these medications for JPS and lack of any clinical trial, it is not possible to make definitive recommendations regarding their clinical utility.

Patients who present with less severe disease should be followed with surveillance colonoscopy, esophagogastroduodenoscopy, and small bowel series. Colonoscopy is recommended every 2 years, with excision of polyps and random biopsies to detect adenomatous change and dysplasia.[127] The interval for upper gastrointestinal tract surveillance is less well defined.

Screening of family members involves a careful history, colonoscopy of potentially affected family members, and surveillance colonoscopy in patients in whom polyps have been identified and removed. Surveillance colonoscopy and esophagogastroduodenoscopy are recommended for first-degree relatives of patients with JPS starting at 12 years of age, with repeated examination every 3 years.[127] Evaluation by small bowel contrast studies is of limited value in asymptomatic patients because cancer is rare in this portion of the intestine.[68]

Peutz-Jeghers Syndrome

PJS is a rare syndrome characterized by gastrointestinal tract hamartomatous polyps (usually <100) and mucocutaneous melanin pigmentation. It is the second most common hereditary gastrointestinal hamartoma syndrome, with an incidence of approximately 1 in 120,000 to 1 in 200,000.[211,212] The hypermelanotic macules most commonly involve the perioral region, buccal mucosa, digits of the hands and feet, and perianal and genital regions. In addition to the gastrointestinal tract, hamartomas have been described in the upper respiratory tract, biliary tract, and urinary tract. Patients may present with symptoms of obstruction from large hamartomatous polyps, as well as intussusception and rectal bleeding (acute and chronic). Biliary obstruction and gastric outlet obstruction are unusual presentations of PJS.

Gastrointestinal hamartomas can occur throughout the gastrointestinal tract and range in size from less than 1 mm to more than 4 cm in diameter.[213] They are most commonly seen in the small intestine, where they appear in up to 90% of cases.[214] In the small bowel, the most common location is the jejunum. The next most common gastrointestinal site is the colon, appearing in 50% of cases, followed by the stomach. Histologically, the polyps in PJS are hamartomas, characterized by hypertrophy or hyperplasia of the smooth muscle of the intestinal wall. The smooth muscle can extend into the superficial epithelial layer in a "treelike" manner, a process that has been termed *arborization.* The histologic term for epithelial cell trapping is *pseudoinvasion,* which has been noted in up to 10% of polyps greater than 3 cm. Given the pathologic phenomena of arborization and pseudoinvasion, the diagnosis of malignancy in a Peutz-Jeghers polyp must include documentation of cellular atypia or an elevated mitotic rate. Normal columnar epithelium usually covers the polyps and mucus-filled cysts in the mucosa are common. However, instances of mixed adenomatous/hamartomatous elements and pure adenomas have been described.

Mucocutaneous pigmentation usually appears during infancy and is most commonly noted in the perioral and buccal regions, where it is seen in up to 95% of cases.[213,215,216] Melanin pigmentation may also be seen in the periorbital and facial areas, as well as the acral areas of the body, such as the hands and feet. The genital region may also be affected. Macules are most commonly 1 to 12 mm in diameter, but the size of the lesions can vary.[213,217]

Pigment spots usually appear in the first few years of life, reach a maximal level in early adolescence, and can fade in adulthood.[218] However, since pigmentation on the buccal mucosa usually remains throughout the life of the patient, buccal examinations are imperative in an adult patient suspected of having PJS.[215,216] It is important to distinguish melanin deposits from common freckles, which are absent at birth, scarce near the lips, and absent on the buccal mucosa. Histologically, the areas of cutaneous pigmentation reveal increased melanocytes at the dermal-epidermal junction, with increased melanin in the basal cells.[219] Of note, the pigmented macules of PJS do not appear to have a malignant potential.[220,221]

Although hamartomas are considered benign lesions, patients with PJS have a substantially increased risk of intestinal and extraintestinal malignancy.[221-224] In addition, malignancy developing in a hamartomatous polyp in PJS has been reported.[225] Patients with PJS have up to a 15.2 relative risk of developing at least one malignancy compared to the general population.[221] In addition, the cumulative risk for developing any cancer between 15 and 64 years of age is estimated at 93%, with the first malignancy detected at an average age of 42.9 years.[221]

The syndrome has been linked to an increased risk of developing adenocarcinoma of the esophagus, stomach, small intestine, and large intestine. There is also an increased risk for extraintestinal cancer of the thyroid, breast (which can be bilateral), lung, pancreas, gallbladder, and biliary tree (cholangiocarcinoma). Women with PJS have an increased risk of gynecologic malignancies of the ovary (bilateral sex cord tumors with annular features) and uterus (well-differentiated adenocarcinoma of the cervix, known as *adenoma malignum* [minimal deviation adenocarcinoma]). In men, there is an increased risk of feminizing Sertoli cell tumors of the testis.

PJS exhibits autosomal dominant inheritance with variable penetrance. Currently, about 50% of cases appear to have a familial component, whereas 50% appear to be due to new sporadic genetic mutations.[226] The putative genetic locus was mapped to a multifunctional serine-threonine kinase named *LKB1* (also known as *STK11*) on 19p13.3.[227,228] Although the exact function of the LKB1/STK11 protein kinase product is unknown, the gene is believed to be a tumor suppressor gene involved in the early stages of tumorigenesis by inducing G_1 cell-cycle arrest.[229-232] It has been hypothesized that an initial germline mutation of the *LKB1/STK11* gene

followed by a somatic mutation of the normal allele leads to the development of the disease.

Genetic testing can be used to screen at-risk individuals and confirm the diagnosis of PJS in patients with a characteristic clinical presentation.[130] Determination of a specific mutation may be possible in as few as 60% of families.[233] However, if a specific mutation can be found, genetic testing of other family members is accurate in up to 95% of cases.[130] If a mutation is not known in a particular patient or family, genetic testing is carried out using gene sequencing for the known mutations in PJS.

Patients typically enter a screening and surveillance program following discovery of the characteristic mucocutaneous melanin pigmentation, a known family history, or the development of symptoms from the disease. An annual serum hemoglobin level and esophagogastroduodenoscopy with removal of polyps every 2 to 3 years beginning at age 10 to 25 years has been recommended.[128,130,212,218,226,234] Routine screening of the remainder of the small bowel is generally accomplished by contrast radiographic techniques, beginning at age 10 years and repeated every 2 to 3 years.[226] Recent advances in capsule endoscopy may provide an additional modality for small bowel screening in the future. Colonoscopic screening with polypectomy is recommended to begin in the late teenage years to age 25 years, with repeat examinations every 2 to 3 years.[218,226,234,235] These recommendations are subject to change based on individual patient preference, symptoms, and clinical presentation.

In females with PJS, annual physician-based breast examination and biannual mammography should commence at 25 years of age.[130,218,226,234] Gynecologic screening should begin by age 20 years and should include annual pelvic examination and pelvic ultrasound and a Papanicolaou smear every 1 to 3 years.[235] Some authors suggest endometrial biopsy on a yearly basis starting at 20 years of age, to screen for endometrial malignancy.[130,218,226,235] In male patients, annual clinical testicular examination starting at age 10 years is recommended.[130,234,235] A testicular ultrasound can be performed if the patient has symptoms of precocious puberty or feminization or if a mass is palpated.[211,218,226,234]

Surgical intervention in patients with PJS is indicated for symptomatic lesions, complications related to polyposis, or cancer (see Table 155–6). Aggressive endoscopic polypectomy may limit the need for operative intervention or increase the interval between surgical interventions. When endoscopic techniques are unable to adequately resect a lesion, intraoperative endoscopy and polypectomy may be indicated.[236] Removal of polyps greater than 1.5 cm in diameter is attempted because these are most likely to produce symptoms or complications. The introduction of laparoscopic-assisted endoscopic polyp clearance in PJS may further reduce morbidity and improve management of these patients. Indications for bowel resection include the detection of adenomatous changes in an incompletely removed polyp, as well as patients presenting with intussusception, obstruction, or gastrointestinal bleeding. Prophylactic colectomy cannot be recommended because of the relatively low incidence of CRC.

Cowden's Disease

Cowden's disease is a rare condition characterized by multiple benign hamartomas and malignant tumors of the breast, thyroid, uterus, brain, and mucocutaneous tissue (including the gastrointestinal tract). It has also been called the *multiple hamartoma syndrome* and has been estimated to occur in 1 in 200,000 individuals.[237] The lesions arise from all germ cell layers, including the endoderm, ectoderm, and mesoderm. Diagnostic criteria for Cowden's disease were established by the International Cowden Syndrome Consortium in 1995 and revised in 2000.[237]

Gastrointestinal polyposis is not as prominent a clinical feature as mucocutaneous lesions, developmental anomalies, and breast and thyroid neoplasia. Eighty percent to 100% of patients present with dermatologic manifestations of this disease, the most common being trichilemmoma, a benign tumor of the hair shaft.[68,238] Other dermatologic signs include multiple smooth facial and oral mucosal papules and acral keratoses.[238] The second most commonly involved organ site is the central nervous system. Cowden's disease associated with cerebellar gangliocytomatosis, megalocephaly, ataxia, and epilepsy is known by the eponym *Lhermitte-Duclos syndrome*.[239] Nonspecific clinical findings include lipomas, hemangiomas, neuromas, and pigmentary disorders. Facial developmental disorders described in patients with Cowden's disease include a high arched palate, adenoid faces, prominent forehead, and hypoplastic mandible.[234] Gastrointestinal polyps are diagnosed in 35% of patients. The polyps are most commonly hamartomas (resembling juvenile polyps), but lipomas, ganglioneuromas, and inflammatory polyps have been described. Polyps are typically small and occur in the gastrointestinal tract from mouth to anus but are observed most commonly in the colon.

Benign thyroid and breast disease are prominent features of Cowden's disease. Thyroid pathology includes benign goiter, adenoma, and follicular thyroid carcinoma. Breast disease may be bilateral and includes fibrocystic disease and adenocarcinoma (both ductal and lobular).[240] The estimated lifetime risk of thyroid cancer is 10%, and that for breast cancer is 30% to 50%.[68] Other malignant diseases described in these patients include carcinomas of the endometrium, cervix, kidney, bladder, lung, and colon. In addition, there have been reports of liposarcoma, malignant melanoma, and squamous cell carcinoma of the skin.[234]

Cowden's disease is transmitted in an autosomal dominant fashion, with near-complete penetrance by the age of 20 years.[241,242] Eighty percent of patient have an identifiable germline mutation in the *PTEN* gene located at 10q23.3.[243] The *PTEN* gene is a lipid phosphatase that acts as a tumor suppressor gene via its impact on gastrointestinal cell cycle arrest and apoptosis.[244] It has been implicated in related gastrointestinal hamartomatous polyposis syndromes (Lhermitte-Duclos and Ruvalcaba-Myhre-Smith syndromes), as well as in familial thyroid cancer,[245,246] inherited breast cancer,[247] prostate cancer,[247] and malignant melanoma.[248] Recent data suggest that the etiology of Cowden's disease in patients without a

germline mutation in *PTEN* may have a mutation in the promoter region of the gene.[234,249] A genotype-phenotype correlation between germline *PTEN* mutations and breast disease has been suggested.[247]

Management of Cowden's disease is based on its accurate diagnosis and careful search for associated malignancy. The dermatologist most commonly makes the diagnosis, as the prominent clinical presentation of Cowden's disease is related to its distinct cutaneous manifestations. Gastrointestinal polyposis is treated with endoscopic surveillance and removal of polyps. Bowel resection is unnecessary because the malignant potential in the polyps is negligible. Given the relatively rare nature of the disease, there are no randomized trials evaluating appropriate screening and surveillance examinations and intervals. However, it is reasonable to recommend monthly self–breast examination and annual clinical breast examination beginning in the teenage years.[234,249] Mammography is recommended to begin at age 25 years and be repeated at least every 3 years.[238,249] Annual clinical thyroid examination is recommended, beginning in the teenage years, supplemented by thyroid ultrasound every 1 to 2 years after 18 years of age.[68] Clinical gynecologic examination and urinalysis have been suggested to screen for uterine and renal disease, respectively.[243]

Ruvalcaba-Myhre-Smith Syndrome

The features of Ruvalcaba-Myhre-Smith syndrome (also referred to as *Bannayan-Zonana syndrome, Ruvalcaba-Riley-Smith syndrome,* and *Bannayan-Riley-Ruvalcaba syndrome*) include gastrointestinal hamartomatous polyposis, developmental abnormalities (mental retardation, delayed psychomotor development), macrocephaly, ocular abnormalities, lipomas, vascular malformations, Hashimoto's thyroiditis, and hyperpigmentation of the penis.[250] It is a rare autosomal dominantly inherited disorder.[61] Ruvalcaba-Myhre-Smith syndrome is believed to be related to Cowden's disease, given that up to 60% of patients have an identifiable germline mutation in the *PTEN* gene.[243] This finding has led some to suggest reclassifying patients with Cowden's disease and Ruvalcaba-Myhre-Smith syndrome into a single entity termed the *PTEN hamartoma syndrome*. It is unclear whether the 40% of patients with Ruvalcaba-Myhre-Smith syndrome without an identifiable germline mutation of the *PTEN* gene have inactivation of the gene by other mechanisms or if other genes are involved in the phenotypic expression of the syndrome. As with Cowden's disease, the increased risk of gastrointestinal cancer is believed to be small. The treatment considerations for Ruvalcaba-Myhre-Smith syndrome are the same as Cowden's disease, with endoscopic removal of symptomatic polyps and screening of family members important considerations.

Cronkhite-Canada Syndrome

Cronkhite-Canada syndrome is a rare acquired gastrointestinal polyposis syndrome characterized by hamartomatous polyps (similar to juvenile polyps) and other epidermal changes. It involves tissues arising from the ectodermal germ cell layer but does not appear to be an inherited disorder. Most cases have been reported from Japan,[251,252] and its similarity to Ménétrier's disease have led some to conclude that the two conditions are related. The etiology of Cronkhite-Canada syndrome is unclear, although infection, toxins, nutritional deficiency, and mental and physical stress all have been suspected as risk factors.

Patients typically present in the 6th decade of life with cutaneous or gastrointestinal manifestations. In addition, watery diarrhea associated with dysgeusia (loss of taste or metallic taste), anorexia, weight loss, peripheral edema, and hypoproteinemia are characteristically observed in patients with Cronkhite-Canada syndrome.[251] Cutaneous manifestations include alopecia, macular pigmentation, patchy vitiligo and onychodystrophy and other nail changes, and skin hyperpigmentation.[253] Polyps are found throughout the gastrointestinal tract, with characteristic sparing of the esophagus.[254,255] The most common site of gastrointestinal involvement is the stomach, although the small and large bowel are also affected.[251,256]

Complications of Cronkhite-Canada syndrome are often severe and include mucosal ulceration, gastrointestinal bleeding, infection, and malnutrition. Severe intestinal polyposis can cause profound metabolic and electrolyte disturbances. In addition, intussusception and rectal prolapse has been described in these patients. There is a marginally increased risk of cancer of the stomach and colorectum.[68,256] However, the mortality from the syndrome, estimated as high as 60%, is due in large part to the associated nonmalignant complications.[256]

Management of patients with Cronkhite-Canada syndrome is multifocal. Given the increased risk of cancer of the stomach, colon, and rectum, endoscopic surveillance has been recommended, as often as on a yearly basis. Supportive care, with management of fluids, electrolytes, nutrition, and anemia, is an important consideration. Corticosteroids, antibiotics, anabolic steroids, cromolyn sodium, histamine receptor antagonists, and proton pump inhibitors have been used for therapy with variable success.[256] Medical management is usually required for 6 to 12 months, and corticosteroids have been used with success for disease recurrence.[257] Surgical management may be indicated if the stomach, colon, or rectum is the source of excessive bleeding, bowel obstruction, or cancer (see Table 155–6). However, case reports suggest that surgical management of Cronkhite-Canada syndrome may be associated with a high perioperative morbidity.[251]

Hereditary Mixed Polyposis Syndrome

Hereditary mixed polyposis syndrome is an autosomal dominant inherited polyposis syndrome characterized by colon polyps of varied histology, increased risk of CRC, and no extraintestinal manifestations.[258] The colon lesions include hamartomas, adenomas, and hyperplastic polyps. The hamartomas are similar to those seen in juvenile polyposis, and the adenomas may be tubular, villous, or flat.[259] Hyperplastic polyps with areas of

dysplasia (serrated adenomas) have also been described in patients with this syndrome.[260,261] Hereditary mixed polyposis syndrome is associated with early age-of-onset CRC, believed to develop through a hyperplastic/juvenile polyp to a mixed/serrated adenoma to carcinoma pathway.[260] There is no evidence that patients with this syndrome are at increased risk of any other type of cancer.

The number of polyps in hereditary mixed polyposis syndrome are spread evenly throughout the colon and usually number less than 15. The colon appears to be the only affected organ system, with no extraintestinal manifestations yet described.[260] Although the putative genetic locus was initially linked to 6q16-21, later data demonstrated this to be incorrect.[258] Evaluation of a large kindred with hereditary mixed polyposis syndrome allowed mapping of the etiologic gene to 15q13-14.[258] Subsequent analysis has suggested that the colorectal adenoma and carcinoma *(CRAC1)* gene may be the gene responsible for this syndrome.[258]

Because phenotypic heterogeneity is common among the gastrointestinal polyposis syndromes, clinical distinction of the hereditary mixed polyposis syndrome from FAP, HNPCC, juvenile polyposis, and PJS may initially be difficult. However, patients with hereditary mixed polyposis syndrome do not display the characteristic extracolonic features of FAP and PJS, and patients with HNPCC do not have juvenile polyps. It is more difficult to distinguish hereditary mixed polyposis syndrome from juvenile polyposis. However, pure adenomas are rare in juvenile polyposis. In addition, patients with juvenile polyposis usually have more extensive polyposis and tend to be diagnosed with polyps and cancer at an earlier age than patients with hereditary mixed polyposis syndrome.

Due to the rarity of this syndrome, definitive management recommendations have yet to be established. However, because polyps have been detected as early as 18 years of age and can develop within a 2-year interval, screening colonoscopy should begin at age 18 to 20 years and be repeated every 1 to 2 years. Total abdominal colectomy with ileorectal anastomosis is an option for selected individuals and should be the treatment of choice for patients who develop CRC (see Table 155–6). In these circumstances, close postoperative surveillance following surgery is mandatory because cancer may develop in the rectal remnant.

Adenocarcinoma of the Colon and Rectum

Martin R. Weiser · Mitchell C. Posner · Leonard B. Saltz

Colorectal cancer remains one of the most dynamic fields in oncology, both in the laboratory and in the clinic. The molecular events associated with cellular transformation were reported more than 15 years ago, and mechanisms of carcinogenesis and tumor progression continue to be intensely studied. Recently, molecularly based therapies directed against the epidermal growth factor receptor (EGFR) and against vascular endothelial growth factor (VEGF) have proven useful, and may be the harbingers of more elegant, tumor-specific colorectal cancer therapy. Clinically colorectal cancer is a diverse disease, requiring individually based treatment strategies. This chapter reviews the most current data available regarding epidemiology, screening, diagnosis, staging, and multimodal treatment of colorectal cancer.

INCIDENCE AND EPIDEMIOLOGIC ASSOCIATIONS

Colorectal cancer ranks third (behind prostate and lung cancer in men, and behind breast and lung cancer in women) as the most common malignancy in the United States and represents the second leading cause of cancer-related mortality. Approximately 147,000 patients are diagnosed with colorectal cancer each year, and 57,000 deaths are attributed to this disease.[1] The probability of colorectal cancer developing during a lifetime is approximately 6%. In contrast to the three previous decades, however, the overall incidence and mortality rate for colorectal cancer has declined for both men and women (Fig. 156–1). Age-adjusted incidence and mortality rates are associated with race and ethnicity. For example, blacks have an overall worse outcome; however, this may represent a comparative lack of access to care rather than differences in biologic aggressiveness of the individual cancers.[2]

Worldwide, an estimated 1,023,152 patients were diagnosed with colorectal cancer in 2002, with 528,978 associated deaths.[3] The highest rates of colorectal carcinoma predominate in the more industrialized countries. Lower rates are found in Eastern Europe, Asia, Africa, and South America.[4] Studies of Japanese migration to the United States, Asiatic Jewish migration to Israel, and eastern European migration to Australia have shown that migrants acquire the high rates of colorectal cancers prevalent in their adopted countries. There is little question that environmental factors, most likely dietary, account for the rise in cancer rates.

Colon cancer is three times more common than rectal cancer. Epidemiologic studies indicate a rising proportion of right-sided colon lesions. The proximal migration of colon cancer may relate to changing environmental factors; however, there is no doubt that increased colon screening results in detection of early lesions in an aging population.[5]

GENETIC PATHWAYS TO COLORECTAL CANCER

Cancer cells are characterized by uncontrolled growth, a capacity to avoid normal senescence and death, and the ability to invade and metastasize. Alterations in genes, oncogenes, and the tumor suppressor genes that normally control these functions result in cellular transformation. This is referred to as the *adenoma-carcinoma cascade* and was first described in relation to colorectal cancer by Fearon and Vogelstein[6] more than 15 years ago.

There are at least two well-described genetic pathways leading to the development of colorectal adenocarcinoma. The chromosomal instability (CIN) pathway is the result of an accumulation of inactivated tumor suppressor genes and overactive protooncogenes. Tumors developing along this pathway are characterized by mutations of the *APC, p53,* and K-*ras* genes, allelic loss of 18q, and aneuploidy. The *APC* gene plays a pivotal role in tumorigenesis, as 100% of familial adenomatous polyposis

(FAP) patients, who carry this mutation, develop colorectal cancer if prophylactic surgery is not performed. Up to 80% of tumors develop along the CIN pathway.

The microsatellite instability (MIN) pathway is the other well-described genetic cascade implicated in the development of colorectal cancer. These tumors have aberrant DNA mismatch repair, a near-diploid karyotype, and lower levels of *p53, SMAD4,* and K-*ras* mutations but higher frequencies of *BAX, TGF-BIIR,* and *BRAF* mutation. These tumors generally develop proximal to the splenic flexure and carry a better prognosis than those developing by the CIN pathway. Patients with heredity nonpolyposis colon cancer develop malignancy along the MIN pathway, with loss of genes involved in DNA-mismatch repair. This pathway is also referred to as the *replication error* (RER) pathway and is responsible for approximately 20% of carcinomas.

Some tumors do not fall into either category, indicating that other genetic pathways exist.[7] Further study of molecular events will undoubtedly lead to a better understanding of multistep carcinogenesis, molecular staging, and tumor-specific therapy. Figure 156–2 outlines the genetic pathway of colorectal cancer and the potential prophylactic role for chemopreventive agents.

COLORECTAL CANCER RISK FACTORS

Clearly, the development of colorectal malignancy involves interplay between genetic and environmental influences. The most easily identified risk factors include age older than 50 years, a personal or family history of colorectal cancer or adenoma, and a personal history of long-standing inflammatory bowel disease (IBD). Colorectal cancers that develop in individuals without hereditary links are referred to as "sporadic" and account for 75% of all such cancers. A potential genetic influence is identified in the remaining 25% of patients, including family history (15% to 20%); hereditary nonpolyposis colon cancer (HNPCC) (5%); and FAP (<1%).

Age

Age is the most common risk factor. The incidence of colorectal cancer increases from the 4th decade to 8th decade of life.[8] Most individuals present with disease after age 60 years, and only 10% of cancers occur in individuals younger than 40 years. A personal history of colorectal polyps is also a significant risk factor, and cancer can present within the polyp or at another site in the colon. The risk of a polyp harboring invasive disease is related to the size, morphology, and histology of the lesion. Polyps can be classified as tubular, villous, or tubulovillous. Large villous lesions are most likely to harbor malignancy, with about 50% of villous polyps larger than 2 cm containing cancer. Approximately 40% of patients are noted to have multiple adenomatous polyps, and these individual are at highest risk for having or developing subsequent invasive cancer.[9] Individuals previously diagnosed and treated for colorectal cancer are at significant risk for developing metachronous

disease. Approximately 40% of patients treated for sporadic colorectal cancer develop metachronous polyps, and at least 6% develop a second colorectal cancer while under surveillance.[10,11]

Inflammatory Bowel Disease

Patients with the medical condition IBD are at significantly increased risk for developing colorectal cancer; the risk is proportional to the extent and duration of disease. This has been extensively studied in ulcerative colitis patients, where the risk of cancer appears to begin after 8 to 10 years of disease and increases at a rate of about 0.5% to 1% per year. Institutional and population-based studies report the absolute risk to be 2% to 5% at 10 years, 8% to 10% at 20 years, and 20% to 30% at 30 years.[12] The risk is highest in patients with pancolitis (disease extending proximal to the splenic flexure), disease diagnosed at a young age (see Fig. 156–2),[13] and colitis-associated sclerosing cholangitis. Cancer that occurs in patients with ulcerative colitis can arise in any portion of the large bowel, usually presents in the 4th decade of life, and appears to carry the same prognosis as colon cancer in general.[14] However, disease in these patients often presents at a late stage, since endoscopic identification of a malignancy in the setting of active colitis is quite difficult. Since all currently available screening tests (including repetitive biopsies linking dysplasia and bowel mucosa transformation to cancer) are problematic,[15] most patients with long-standing colitis will probably benefit at some point from prophylactic proctocolectomy. The risk of colorectal cancer is also increased in long-standing Crohn's colitis, which until recently has been underappreciated. Currently it is believed that the cancer risk is equivalent for both Crohn's and ulcerative colitis patients who have disease of similar duration and extent.[16]

Familial Colorectal Cancer

Familial factors are associated with 25% of colorectal cancer cases. Individuals with a first-degree relative affected by colorectal cancer have twice the risk of developing the disease themselves. This risk is nearly threefold for individuals with two or more affected first-degree relatives. Not surprisingly, a positive family history is associated with younger age of diagnosis, and this finding implies a genetic predisposition.[17] Currently, the highest risk patients are those that carry the genetic mutations associated with FAP and HNPCC (Fig. 156–3). Nearly

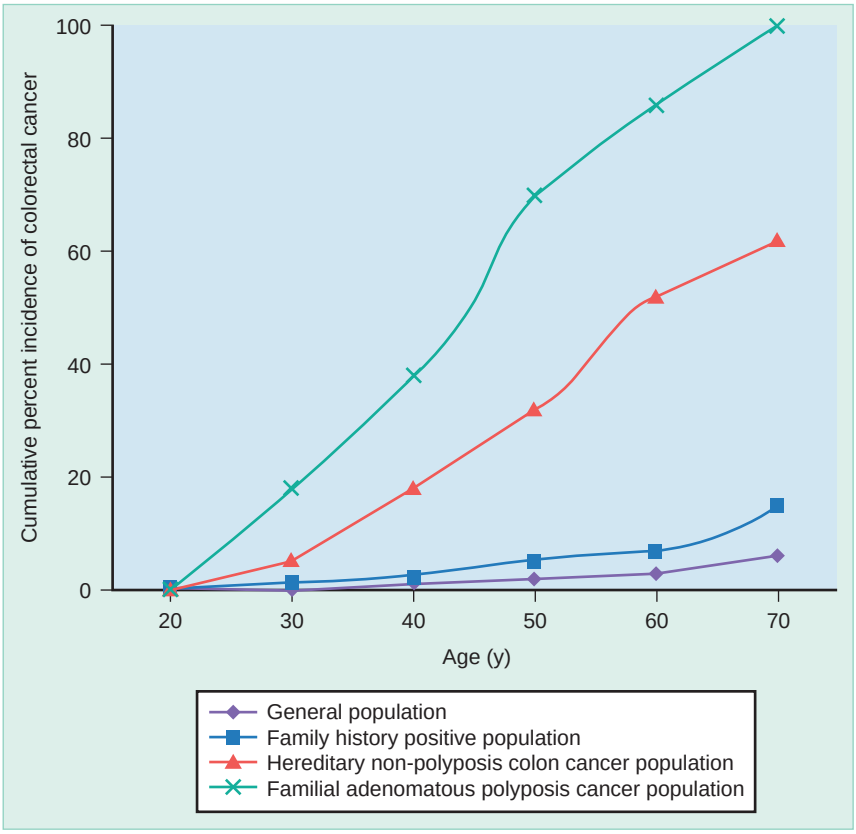

Figure 156–3. Colorectal cancer risk.

100% of patients with FAP and 80% of HNPCC patients develop colorectal cancer in their lifetime.

Familial Adenomatous Polyposis

The FAP syndromes account for 1% of all colorectal cancers and are characterized by early onset of hundreds to thousands of polyps throughout the colon. Adenomas typically begin to present early in the 2nd decade of life, with cancer inevitably developing by the 4th to 5th decade if colectomy is not performed. These syndromes affect approximately 1:8,000 to 10,000 persons; 10% to 20% of cases represent de novo mutations with no apparent family history.[18,19] The disease is inherited as an autosomal dominant trait; therefore, 50% of offspring from an affected individual develop polyposis coli. The gene that causes FAP (*APC* gene) resides on chromosome 5 (5q21). The most common genetic abnormality results in the generation of a premature stop codon, resulting in a truncated and nonfunctional protein.[20] This finding is the basis for a commonly used screening procedure in which the truncated protein is identified in vitro, thereby confirming the diagnosis.

In addition to colonic polyps, FAP patients commonly develop periampullary cancers, gastric fundic gland polyps, and intra-abdominal desmoid tumors. After the colorectal cancer is eliminated by surgery, periampullary tumors are the most frequent cause of death among individuals with FAP.[21] A variant of FAP includes Gardner's syndrome, characterized by colorectal adenomas and extraintestinal manifestations, including osteomas (mainly of the mandible and skull), soft tissue tumors (e.g., lipomas, fibromas, and epidermoid and sebaceous cysts), supernumerary teeth, desmoid tumors, mesenteric fibromatosis, and congenital hypertrophy of the retinal pigmentation epithelium. Turcot's syndrome is another variant of FAP in which colorectal adenomas are associated with brain tumors. Attenuated FAP syndrome is characterized by the development of fewer polyps, more likely in the right colon and later in life.[22] This can make clinical diagnosis of attenuated FAP versus HNPCC quite difficult. The various FAP phenotypes appear to be related to the site of mutation on the *APC* gene.[22] For example, gene mutation in attenuated FAP is usually located more proximal or distal in the *APC* gene than it is in the more common FAP syndrome.

Hereditary Nonpolyposis Colon Cancer

HNPCC is a familial disorder characterized by a high incidence of colon cancer without the excessive polyps identified in classic FAP and accounts for 5% to 6% of colorectal cancers.[23,24] Its phenotypic features include early-onset colorectal cancer with a mean age of 46 years; synchronous or metachronous colorectal cancers (noted in 35% of cases); and a proclivity for right-sided tumors.[25] There is an association with early onset of adenocarcinoma of the ovary, pancreas, breast, bile duct, endometrium, stomach, genitourinary tract, and small bowel.[26] *Lynch II* refers to the cohort of patients with colorectal cancer and an associated other adenocarcinoma, whereas *Lynch I* refers to the cohort with colorectal cancer only. Muir-Torre syndrome is a HNPCC variant associated with sebaceous gland adenomas and carcinoma.[27]

Box 156–1 Amsterdam II Criteria

- At least three relatives with an HNPCC-associated cancer (colorectal, endometrium, small bowel, ureter, or renal pelvis). One affected relative should be a first-degree relative of the other two.
- At least two successive generations should be affected.
- At least one relative should have been diagnosed before age 50 years.
- Familial adenomatous polyposis should be excluded.

Tumors should be verified by pathologic examination.
HNPCC, hereditary nonpolyposis colon cancer.

The molecular genetic marker reflective of HNPCC is MIN, which is a consequence of mutations in DNA mismatch repair genes (*hMSH2, hMLH1, hPMS1,* and *hPMS2*). Diagnostic criteria for identifying individuals with HNPCC have been established. In 1991, at a consensus conference in Amsterdam, criteria were developed to help identify and categorize patients with familial history of colorectal cancer.[25] The initial criteria, referred to as *Amsterdam Criteria I,* requires (1) three relatives with colorectal cancer, one being a first-degree relative of the other two; (2) two successive generations afflicted with colorectal cancer; or (3) one family member who developed colorectal cancer younger than 50 years of age. Furthermore, FAP must be excluded and all cancers verified pathologically. However, these criteria tend to underestimate HNPCC in some family pedigrees.[23] Therefore, *Amsterdam Criteria II* was developed to include extracolonic tumors. The accepted HNPCC-associated cancers include colorectal, endometrial, small bowel, ureteral, or renal pelvic cancers (Box 156–1).

HNPCC cancers have a characteristic histologic appearance. Adenomas tend to have a villous component with more dysplasia than typically seen in sporadic cases. Cancers commonly have signet-ring histology with poor differentiation and inflammatory cell infiltrate.[23,28] In spite of the aggressive histologic appearance, stage-for-stage survival for colorectal cancer patients with HNPCC is better than that for patients with sporadic cancers.[26] Colorectal neoplasms appear to develop more rapidly in patients with HNPCC,[24] which affects their follow-up regimen.

Genetic Syndromes

Peutz-Jeghers and familial juvenile polyposis are genetic syndromes associated with an increased incidence of colorectal cancer. These are autosomal dominant syndromes characterized by hamartomatous polyposis. The

histology of intestinal hamartomas consists of an overgrowth of cells or tissues native to the area in which they normally occur.[29] The molecular mechanisms of these syndromes are currently under study, and specific mutations have been described.[30]

Peutz-Jeghers syndrome is characterized by multiple gastrointestinal hamartomatous polyps associated with mucocutaneous melanin pigmentation. Patients can present with impending obstruction, with polyp intussusception or anemia from gastrointestinal blood loss. The polyps are generally non-neoplastic with a characteristic branching muscular framework, but they can contain carcinoma. Peutz-Jeghers patients are at increased risk for developing both gastrointestinal and extraintestinal carcinomas (e.g., pancreatic, breast, ovarian, testicular and uterine); therefore, prophylactic colectomy is usually not indicated.[31] Polyps are usually managed endoscopically, whereas surgery is reserved for large and symptomatic lesions or those with neoplastic appearance.

Familial juvenile polyposis syndrome is characterized by multiple (often 50 to 200) juvenile polyps throughout the gastrointestinal tract, often associated with other congential anomalies including cardiac and genitourinary. Patients can present in childhood with anemia caused by chronic gastrointestinal blood loss, crampy abdominal pain associated with intussusception, a protein-losing enteropathy, or frank rectal bleeding. (Patients who present with the often self-limited, solitary juvenile polyp are not included within this definition.) Individuals with this syndrome are at an increased risk for developing both upper and lower gastrointestinal cancers.[32] These polyps are generally controlled endoscopically, and total abdominal colectomy with ileal pouch-anal anastomosis is reserved for patients with large and numerous polyps or invasive malignancy.[33]

Additional Risk Factors

Recent research has identified additional genetic risk factors associated with colorectal cancer. A polymorphism in the *APC* gene has been associated with development of colorectal neoplasms in decedents of Eastern European (Ashkenazi) Jews. This population is noted to have the highest colorectal cancer incidence of any Israeli ethnic group. Studies have reported that 6% of unselected Ashkenazi Jews and 28% of those with a family history of colorectal cancer carry an *APC* missense mutation (referred to as I 1307 K). These patients do not have the typical phenotype seen with FAP, but rather the polymorphism creates a hypermutable region of the *APC* gene, which causes a predisposition to colorectal cancer.[34] This translates into a high frequency of synchronous cancer in patients with polyps: 13% of individuals carrying this polymorphism and identified adenomatous polyps harbor an invasive cancer.[35,36] Another relatively new syndrome has been described, involving mutation in the exon-excision-repair gene *MYH*. Individuals carrying this mutation can present with either the FAP or HNPCC phenotype.[37] Finally, an association between hyperplastic polyposis, defined as greater than 20 hyperplastic polyps (of at least 1 cm in size) in sites other than the rectosigmoid, and colorectal adenomas and carcinomas, has recently been described.[38] These cancers are associated with methylation silencing of mismatch repair genes and HPP1 and are referred to as *sporadic MIS tumors*. Ultimately, further identification and characterization of the various molecular pathways of carcinogenesis may lead to tumor-specific therapy.

There is no doubt that environmental factors play a critical role in the development of colorectal cancer. However, the association between dietary and lifestyle factors and development of colorectal neoplasms is extraordinarily complex. The largest body of epidemiologic data is based on case-controlled studies limited by significant recall bias. Prospective cohort studies avoid limitations in patient recollection but may be inadequate, since the food frequency questionnaires are rarely validated. Clinical trials in which nutrient supplementations are given as interventions are similarly limited, because colorectal carcinogenesis has a relatively long latency. Given the limitations of current studies, Table 156–1[39] delineates our current best knowledge regarding dietary and lifestyle risk factors for colorectal cancer.

Table 156–1 Dietary and Lifestyle Risk Factors for Colon and Rectal Cancer

Likelihood of Association	Decreased Risk	Increased Risk
Probable	Physical activity, folate, vegetables	Obesity, smoking, red meat
Possible	Fruit, calcium, vitamin D, methionine	Alcohol, processed meat, heavily cooked meat, iron
Unknown	Fiber supplement	—

COLORECTAL CANCER SCREENING

Goals

The goals of screening asymptomatic patients are to find and remove premalignant adenomatous polyps and identify early malignancies. Polyps most likely to contain invasive disease include those that are sessile rather than pedunculated, villous rather than tubular, and large (>1.5 cm) rather than small. The National Polyp Study confirmed that colonoscopic polypectomy reduces colon cancer mortality. In this study, patients whose adenomas were removed endoscopically had lower probability of developing colorectal cancer, compared with a reference group of individuals whose polyps had not been removed and individuals in a population-based registry (Surveillance, Epidemiology, and End Results [SEER]), most of whom did not have polyps.[40] In essence, this study validated the colorectal adenoma-to-adenocarcinoma

Table 156–2 Screening Guidelines for Average-Risk Individuals

Test	Internal (beginning at age 50 yr)	Comment
FOBT and flexible sigmoidoscopy	FOBT annually and flexible sigmoidoscopy every 5 yr	Flexible sigmoidoscopy together with FOBT is preferred compared with FOBT or flexible sigmoidoscopy alone All positive tests should be followed up with colonoscopy
Flexible sigmoidoscopy	Every 5 yr	All positive tests should be followed up with colonoscopy
FOBTs	Annually	The recommended take-home multiple-sample method should be used All positive tests should be followed up with colonoscopy
Colonoscopy	Every 10 yr	Colonoscopy provides an opportunity to visualize, sample, and/or remove significant lesions
Double-contrast barium enema	Every 5 yr	All positive tests should be followed by colonoscopy

FOBT, fecal occult blood test.

sequence and reinforced the importance of screening. When an adenomatous polyp is detected, the entire large bowel should be visualized endoscopically because synchronous lesions are found 35% to 40% of the time.

The specifics of colorectal cancer screening rely on an understanding of patient risk (Tables 156–2 and 156–3). Asymptomatic, average-risk individuals are candidates for routine screening, whereas those at increased risk as a result of a personal or family history of colorectal cancer or adenoma, IBD, or a hereditary colon cancer syndrome require more individualized screening and surveillance programs.[10]

Low and Average Risk

Average-risk men and women should begin routine colorectal cancer screening at age 50 years (see Table 156–2). Several options exist. The first approach includes stool occult blood test annually and flexible sigmoidoscopy every 5 years. If a positive stool blood test is detected, the patient should undergo a complete colonoscopy to evaluate the entire colon mucosa. On screening sigmoidoscopy, single small lesions should be biopsied and additional treatment predicated on histology. If the lesion is an adenomatous polyp, a colonoscopy should be performed for complete polypectomy and assessment of the proximal colon for synchronous lesions. If the polyp is a benign hyperplastic polyp, no additional test is necessary. If, however, screening sigmoidoscopy reveals either a large polyp or multiple polyps, then initial biopsy is not necessary and the patient should undergo complete colonoscopy with biopsy. The second approach to screening the average-risk individual is complete colonoscopy, repeated at 10-year intervals if negative for neoplasia. This is the preferred screening method. The third and least common screening option includes double-contrast barium enema plus flexible sigmoidoscopy every 5 to 10 years. Any positive test should be followed up by a colonoscopy.

High Risk

High-risk individuals include those with a personal history of adenomas or cancers, family history or genetic syndrome, or predisposing medical condition such as IBD (see Table 156–3). Patients with a history of colorectal adenoma require increased surveillance for metachronous polyps or missed small synchronous polyps that can occur in 15% of cases.[41] Based on the findings of the National Polyp Study, a repeat examination can be performed 3 years after polypectomy.[40] A shorter follow-up interval may be necessary after removal of multiple adenomas, excision of an adenoma with invasive cancer, incomplete or piecemeal removal of a large sessile adenoma, or suboptimal examination because of poor colonic preparation. On the other hand, if the 3-year follow-up colonoscopy is clear, the surveillance interval can be increased to every 5 years.[42]

Previous Colorectal Cancer and Family History of Colorectal Cancer

Patients with a personal history of colorectal cancer required increased surveillance for metachronous disease. In general, the first surveillance colonoscopy should be performed 1 year following cancer resection. If the colon was not fully evaluated prior to surgery, the first examination should be performed within 3 months of surgery. If the first postresection colonoscopy is normal, the interval can be increased to 3 years. However, if additional disease is noted on postoperative colonoscopy, more frequent examinations are warranted.

Patients with a family history of colorectal cancer or adenoma, including affected first-degree relatives, also

Table 156–3 Screening Guidelines for High-Risk Individuals

Risk Category	Age to Begin	Recommendation	Comment
Increased Risk			
Patient with a single small (<1 cm) adenoma	3-6 yr after the initial polypectomy	Colonoscopy	If examination is normal, they can thereafter be screened as per average-risk guidelines
Patient with a large (>1 cm) adenoma, multiple adenomas, or adenomas with high-grade dysplasia or villous change	Within 3 yr after the initial polypectomy	Colonoscopy	If normal, repeat examination in 3 yr; if normal then, the patient can thereafter be screened as per average-risk guidelines
Personal history of curative-intent resection of colorectal cancer	Within 1 yr after cancer resection	Colonoscopy	If normal, repeat examination in 3 yr; if normal then, repeat examination every 5 yr
Either colorectal cancer or adenomatous polyps, in any first-degree relative before age 60 yr, or in ≥2 first-degree relatives at any age (if not a hereditary syndrome)	Age 40 yr, or 10 yr before the youngest case in the immediate family	Colonoscopy	Every 5-10 yr Colorectal cancer in relatives more distant than first-degree does not increase risk substantially above the average-risk group
High Risk			
Family history of familial adenomatous polyposis (FAP)	Puberty	Early surveillance with endoscopy, and counseling to consider genetic testing	If the genetic test is positive, colectomy is indicated These patients are best referred to a center with experience in the management of FAP
Family history of hereditary nonpolyposis colon cancer (HNPCC)	Age 21 yr	Colonoscopy and counseling to consider genetic testing	If the genetic test is positive or if the patient has not had genetic testing, every 1-2 yr until 40 yr of age, then annually These patients are best referred to a center with experience in the management of HNPCC
Inflammatory bowel disease Chronic ulcerative colitis Crohn's disease	Cancer risks begin to be significant 8 yr after the onset of pancolitis or 12-15 yr after the onset of left-sided colitis	Colonoscopy with biopsies for dysplasia	Every 1-2 yr These patients are best referred to a center with experience in the surveillance and management of inflammatory bowel disease

require more aggressive surveillance. These individuals should undergo screening with colonoscopy beginning at 40 years of age or earlier, when they are 10 years younger than their affected family member(s) were at age of initial diagnosis.

Patients with long-standing IBD are at increased risk of colorectal cancer and should undergo routine surveillance examinations. The cancer risk in chronic Crohn's disease appears to be the same as that in ulcerative colitis; therefore, these patients should be approached similarly. In patients with pancolitis, typically defined as disease extending proximal to the splenic flexure, surveillance colonoscopy should begin after 8 years of symptoms. Surveillance can start later in those patients with left-sided colitis, generally after 12 to 15 years of disease. Colonoscopy should be performed every 1 to 2 years. During each examination, biopsies should be routinely taken at 10- to 12-cm intervals throughout the colon, from grossly normal and diseased-appearing mucosa. Colectomy is indicated for low- or high-grade dysplasia, for patients with difficult-to-control colitis, and for those patients who cannot comply with routine surveillance.

Patients from FAP families who have not been tested for an *APC* mutation should begin routine screening at puberty with annual flexible sigmoidoscopy. If polyps are

not identified by age 40 years, then the frequency of examinations can be decreased to every 3 years. On the other hand, individuals who express the phenotype require upper endoscopy to examine the periampullary region. Patients with a known genetic mutation or members of an FAP kindred should undergo colectomy when they develop polyps, because stage-specific survival of colorectal cancer appears to be the same for polyposis patients as for those who have sporadic bowel cancers.

Colorectal screening for patients with HNPCC should be performed with full colonoscopy, since these individuals have a propensity for developing proximal colon lesions. The adenoma-to-carcinoma sequence appears to be more rapid in this patient cohort, and endoscopy should thus be performed every 1 to 2 years. For individuals with known mutations or family history consistent with the Amsterdam Criteria, screening should begin at 21 years of age.[1,10] Screening for extracolonic disease should be performed as well, including urine cytology, pelvic ultrasound, and periodic endometrial biopsy.

COLORECTAL CANCER STAGING

The prognosis for patients with colorectal cancer is related to the stage of disease at diagnosis and tumor histology, including differentiation, lymphatic invasion, and extent of tumor-free surgical resection margins. Molecular genetic markers may, in the future, define subsets of patients either more or less likely to develop tumor recurrence and so lead to more rational application of adjuvant multimodality treatment.[43,44] However, at the time of this writing use of such molecular markers remains investigational.

The tumor, node, and metastasis (TNM) staging system of the American Joint Committee on Cancer (AJCC) and International Union Against Cancer (UICC) is the standard colorectal cancer staging system. The sixth edition was published in 2002 and is outlined in Box 156–2 and Table 156–4. The symbols "c" and "p" are used as prescripts to denote clinical and pathologic staging, respectively. The prescript "y" is used to denote post-treatment staging of a tumor (e.g., ypT2N1M0 represents a pathologically staged tumor extending into the muscularis propria, with metastases noted in one to three regional lymph nodes, in a patient who received preoperative treatment).

For colorectal carcinomas, the staging category pTis (carcinoma in situ) denotes either malignant cells confined by glandular basement membrane (intraepithelial carcinoma) or those invading beyond the basement membrane into the mucosal lamina propria (intramucosal carcinoma). The terms *high-grade dysplasia* and *intraepithelial carcinoma* are often used synonymously. The definition of invasive colorectal cancer (i.e., pT1) includes tumor cell invasion through the muscularis mucosa and into the submucosa, where abundant lymphatics are located. This is in contrast to the definition of other gastrointestinal and solid tumors, in which invasion below the lamina propria constitutes malignancy.

There are a few other nuances and subtle aspects to the TNM staging system. Extramural tumor nodules discontinuous from the primary tumor mass, that are irregular in shape, are included in the T category as pT3. If such nodules have smooth contours, they are classified by convention as replaced lymph nodes. *pT4* refers to extension into adjacent organs or structures, penetration of the parietal peritoneum with or without involvement of an adjacent structure, or free perforation into the peritoneal cavity.

As is true for most epithelial cancers, the presence of metastases in regional lymph nodes has a significant impact on survival. Proper staging and treatment of colorectal cancer require adequate lymphadenectomy. Goldstein et al.[45] illustrated the relationship between staging accuracy and lymphadenectomy. In this study of T3 tumors, lymph node metastases were noted in 85% of cases when 15 or more nodes were recovered but in only 22% of cases when fewer than 15 were identified in the specimen. Furthermore, within the cohort of patients who did not show nodal metastases, survival was greatest in the subgroup with high lymph node recovery.

Box 156–2 **American Joint Committee on Cancer–Union Internationale Contre le Cancer Tumor, Node, Metastasis Stage Grouping**

Primary Tumor (T)

TX:	Primary tumor cannot be assessed
T0:	No evidence of primary tumor
Tis:	Carcinoma in situ intraepithelial or invasion of lamina propria
T1:	Tumor invades submucosa
T2:	Tumor invades muscularis propria
T3:	Tumor invades into through muscularis propria into submucosa, or into nonperitonealized pericolic or perirectal tissues
T4:	Tumor directly invades other organs or structures, and/or perforates visceral peritoneum

Regional Lymph Nodes (N)

NX:	Regional lymph nodes cannot be assessed
N0:	No regional lymph nodes metastasis
N1:	Metastasis in 1 to 3 regional lymph nodes
N2:	Metastasis in 4 or more regional lymph nodes

Distant Metastasis (M)

MX:	Distant metastasis cannot be assessed
M0:	No distant metastasis
M1:	Distant metastasis

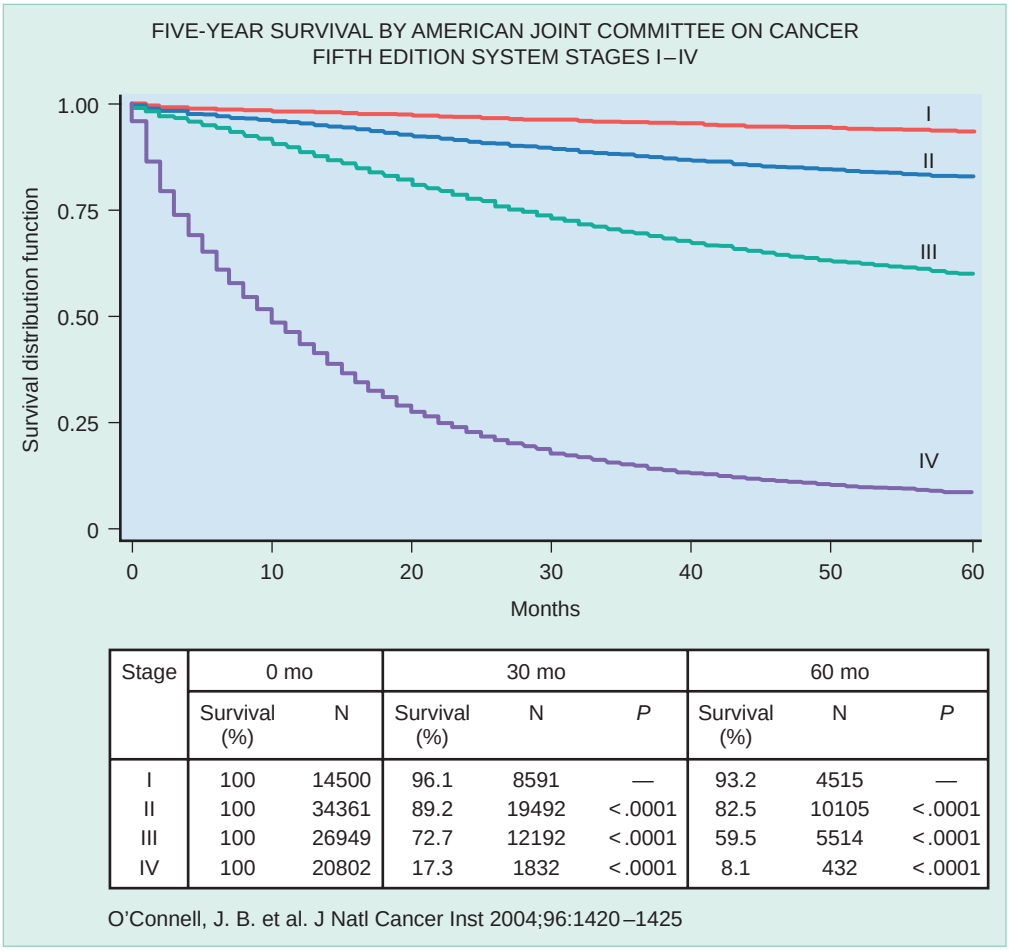
Although there are many factors related to the number of nodes examined, including extent of resection and diligence of the pathologist, these data support the concept that proper oncologic resection is associated with improved outcome. Based on this study and others, it has been recommended that at least 12 lymph nodes be examined to accurately stage colorectal cancer patients.[46]

Alternative methods for detecting very small amounts of metastatic disease have been developed, including molecular biology–based techniques and immunohistochemistry. The biologic significance and clinical impact of minute amounts of tumor detected in metastatic sites are currently unclear, and the sixth edition of the AJCC/UICC TNM staging guide does not classify such disease as N1. Further studies are needed for us to fully understand the significance of micrometastatic nodal disease in colorectal cancer. The use of sentinel node biopsy for intestinal malignancy[47] remains controversial, with at least one large prospective, randomized study showing that this technique may not be valid for colorectal cancer.[48]

The relationship between pathologic stage of disease and outcome is depicted in Figure 156–4.[49] Other pathologic features that have been demonstrated to predict



Stage	0 mo		30 mo			60 mo

Box 156–3 Selected Pathologic Prognostic Factors in Colorectal Cancer

- Adjacent organ involvement (colon)
- Radial margin (rectum)
- Degree of differentiation
- Blood vessel invasion
- Lymphatic vessel invasion
- Perineural invasion
- Immune response
- DNA content
- Proliferative index
- Allelic loss of chromosome 18q (DCC)

outcome, in addition to bowel wall penetration and lymph node status, are listed in Box 156–3. Lymphovascular invasion is associated with nodal and distant disease as well as independent predictors of survival.[50,51] In contrast to many other solid tumors, if data are corrected for nodal involvement and histologic differentiation, prognosis in patients with colorectal cancer is not influenced by the size of the primary lesion.

TREATMENT OF PRIMARY COLON AND RECTAL CARCINOMA

The mainstay of therapy for locoregional colon and rectal carcinoma is surgery. In colon cancer adjuvant chemotherapy is administered to reduce the risk of recurrence, which is usually distant failure. In rectal cancer neoadjuvant combined-modality therapy, including chemotherapy and radiation, is administered to improve resectability, aid in sphincter preservation, and reduce local as well as distant recurrence. Adjuvant chemotherapy is administered primarily to reduce the risk of distant recurrence.

Critical in the treatment of colorectal cancer is the understanding that the role of surgery for the primary tumor is limited to those patients for whom cure is realistically possible or to those patients with symptomatic lesions resulting in acute obstruction or clinically significant bleeding. For patients who present with synchronous primary and incurable metastatic disease, resection of the primary is not routinely indicated. Advances in systemic chemotherapy (outlined later) have greatly increased the likelihood of tumor control via medical management, and chemotherapy can be routinely started with an asymptomatic or minimally symptomatic primary in place. There is no need to "prepare such a patient for chemotherapy" by performing palliative resection of a primary that does not actively require palliation. In fact, resection of the primary lesion in the setting of metastatic disease has a significant associated morbidity and mortality. In a large review of Medicare/SEER data for patients 65 years of age and older, resection of a synchronous primary tumor was associated with a 10% 30-day postoperative mortality.[52]

Surgery

The basic tenet of colorectal cancer surgery with curative intent is removal of the primary lesion with adequate margins and removal of regional lymph nodes. Determining the extent of lymphadenectomy is one of the most challenging aspects of cancer surgery and is based on a thorough understanding of anatomy and lymphatic spread of intestinal cancer.

The regional lymphatics of the colon have been well described.[53] Abundant lymphatic capillaries are found in the submucosa, and efferent vessels proceed peripherally through the circular and longitudinal layers of the muscularis propria and communicate with a clearly defined subserosal plexus. Lymphatic flow in the subserosal network is principally circumferential. Longitudinal intramural lymphatic spread is generally limited to 2 cm, which explains the general rule of obtaining a 5-cm proximal and distal intestinal margin at time of surgery. Most subserosal lymphatics pass into the mesentery to reach the paracolic lymph nodes. Under normal circumstances, lymph flow within the colon mesentery proceeds centrally, in an orderly fashion, from smaller to larger collecting lymphatics and eventually leads to the root of the mesentery. Lymphatic vessels are in close association with the blood vascular pedicles, and the centrally directed flow proceeds along the nearest or most immediately accessible route to the apex of the mesentery. Thus we can conveniently describe the pathways of lymphatic flow by the appropriate vascular pedicle, including the ileocolic, right colic, and mid colic routes of the superior mesenteric system and the left colic, sigmoidal and superior rectal routes of the inferior mesenteric system.

Although there are many variations in the arrangement of lymph nodes along the pathways of flow, the following three roughly separable groups can be identified:

- First-echelon lymph nodes are paracolic, associated with the marginal vessel of Drummond. These nodes are the most numerous and have the greatest importance in surgical therapy.
- Second-echelon, or intermediate, lymph nodes are located in the mesentery at the level of division of mainstem blood vessels into peripheral branches.
- Third-echelon nodes, represented by the central or principal nodes, are closest to the root of the mesentery and associated with takeoff of the major vascular pedicles.

Cancer emboli generally take the most direct route to regional lymph nodes, and there is a stepwise progression centrally from the paracolic nodes adjacent to tumor, to the intermediate nodes along the most contiguous mesenteric vascular pedicle, and finally to the main or principal lymph nodes at the apex of the mesentery. However, variations and "skip metastases" exist. These unusually situated metastases represent retrograde lymphatic flow secondary to tumor blockage of the main

efferent lymphatic channels. Common atypical sites of lymph node metastases include the gastrocolic omentum, related to transverse colon lesions and paracolic lymph nodes noted at a distance from the primary tumor. In general, skip metastases are associated with a poor prognosis, due to the extensive nature of nodal disease.[53]

In the rectum, at about 7 to 8 cm above the anal verge and at the approximate level of the middle valve of Houston, a so-called lymphatic watershed exists: all lymph from the rectum above this point drains upward along the superior hemorrhoidal vessels, but below this level there is a dual drainage. Although flow remains predominately superior in direction, there may be independent or association drainage laterally along the middle hemorrhoid vessels to the internal iliac chain of lymph nodes, and from there by retroperitoneal vessels to the para-aortic nodes. Very distal lesions can drain along the superficial perineal lymphatics, with flow directed toward the superficial inguinal lymph nodes.

Regardless of the geographic location of the primary tumor, the goal of surgery is removal of the primary lesion with adequate intestinal margin en bloc with regional lymph nodes. As noted, longitudinal spread along the colon rarely extends beyond 2 cm; this has been the rationale for resecting 5 cm of normal intestine proximal and distal to the lesion. In practicality, however, the length of intestinal resection is generally determined by devascularization from lymphadenectomy. The lymph nodes at risk for metastases include those along the primary vascular pedicle, closest to the tumor as well as adjacent vessels. These secondary routes have been well described[53] and are summarized in Figure 156–5. There is a tendency to extrapolate from these studies and perform radical or extended lymph node resections, with hopes of improving patient outcome; however, this is not borne out in practice. For example, "high ligation" of the inferior mesenteric artery at its takeoff from the aorta has not been shown to improve outcome[54,55] but is instead associated with increased perioperative morbidity, including autonomic nerve injury and associated sexual and bladder dysfunction. Operative strategies and lymphadenectomy for colorectal cancer are outlined in Figure 156–6.

The widespread application of sphincter-sparing techniques, including low anterior resection with coloanal anastomosis, especially in combination with combined-modality therapy (chemoradiation), allows most patients to avoid abdominoperineal resection and permanent colostomy. Intersphincteric dissection is a technique increasingly used to gain distal margin and avoid a permanent colostomy. The internal sphincter (which is a continuation of the rectal muscularis propria) is resected with the rectum, allowing for an additional 1 cm of distal margin (Fig. 156–7). Following this procedure, patients rely on the external sphincter for continence. These technical advances allow sphincter preservation for the majority of rectal cancer patients, reserving abdominoperineal resection for those patients with poor preoperative function and those with tumors extending into the external sphincter complex.[56] The functional sequelae and quality of life associated with ultralow coloanal anastomosis has become the center of research.[57] Creation of a reservoir such as a colonic J-pouch or coloplasty is advocated, when technically feasible, as it appears to improve short-term and possibly long-term function.[58]

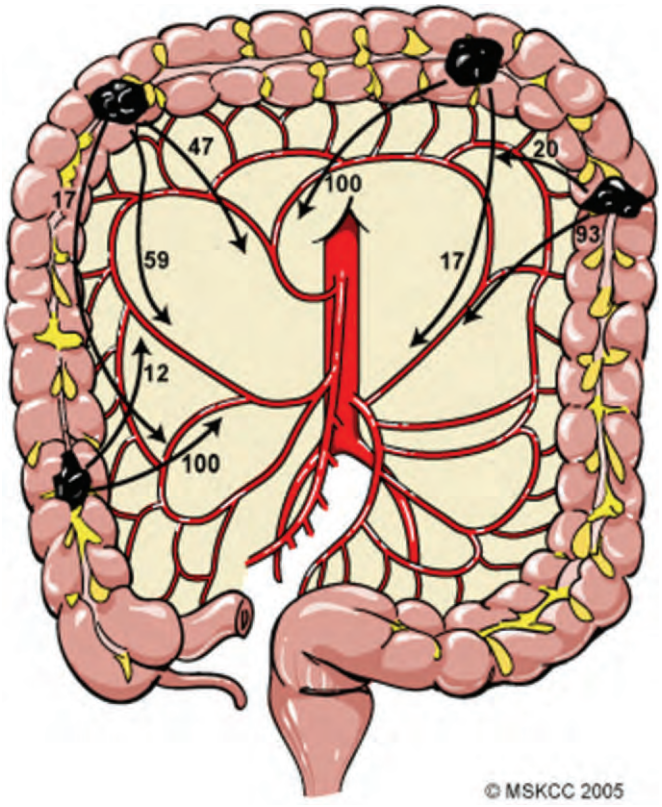

Figure 156–5. Lymphatic drainage for colon cancer. The numbers signify the percentage of metastasizing carcinoma with nodal disease along the outlined vascular pedicle. For example, node-positive tumors lying between the ileocolic and right colic arcades metastasize along the ileocolic pedicle in 100% of cases and along the right colon pedicle in 12% of cases. (© 2005, Memorial Sloan-Kettering Cancer Center, New York.)

The increasing application of these sphincter-saving techniques has renewed interest in defining the necessary length of distal bowel margin. Although 5 cm of distal rectum was originally thought to be necessary,[59] it is now widely accepted that 2 cm is sufficient.[60] More recent studies have indicated that shorter margins may be adequate, especially in the setting of significant tumor regression in response to combined-modality therapy.[61] Possibly more important than length of distal intestine removed beyond tumor is the status of the lateral and circumferential resection margin. Clearly these margins have been overlooked in the past and are as critical as distal margin with regard to tumor recurrence.[62]

It is not surprising that studies have shown a relationship between quality of surgical technique and outcome. Blunt pelvic dissection can result in local recurrence rates as high as 25%. Conversely, appropriate mesorectal

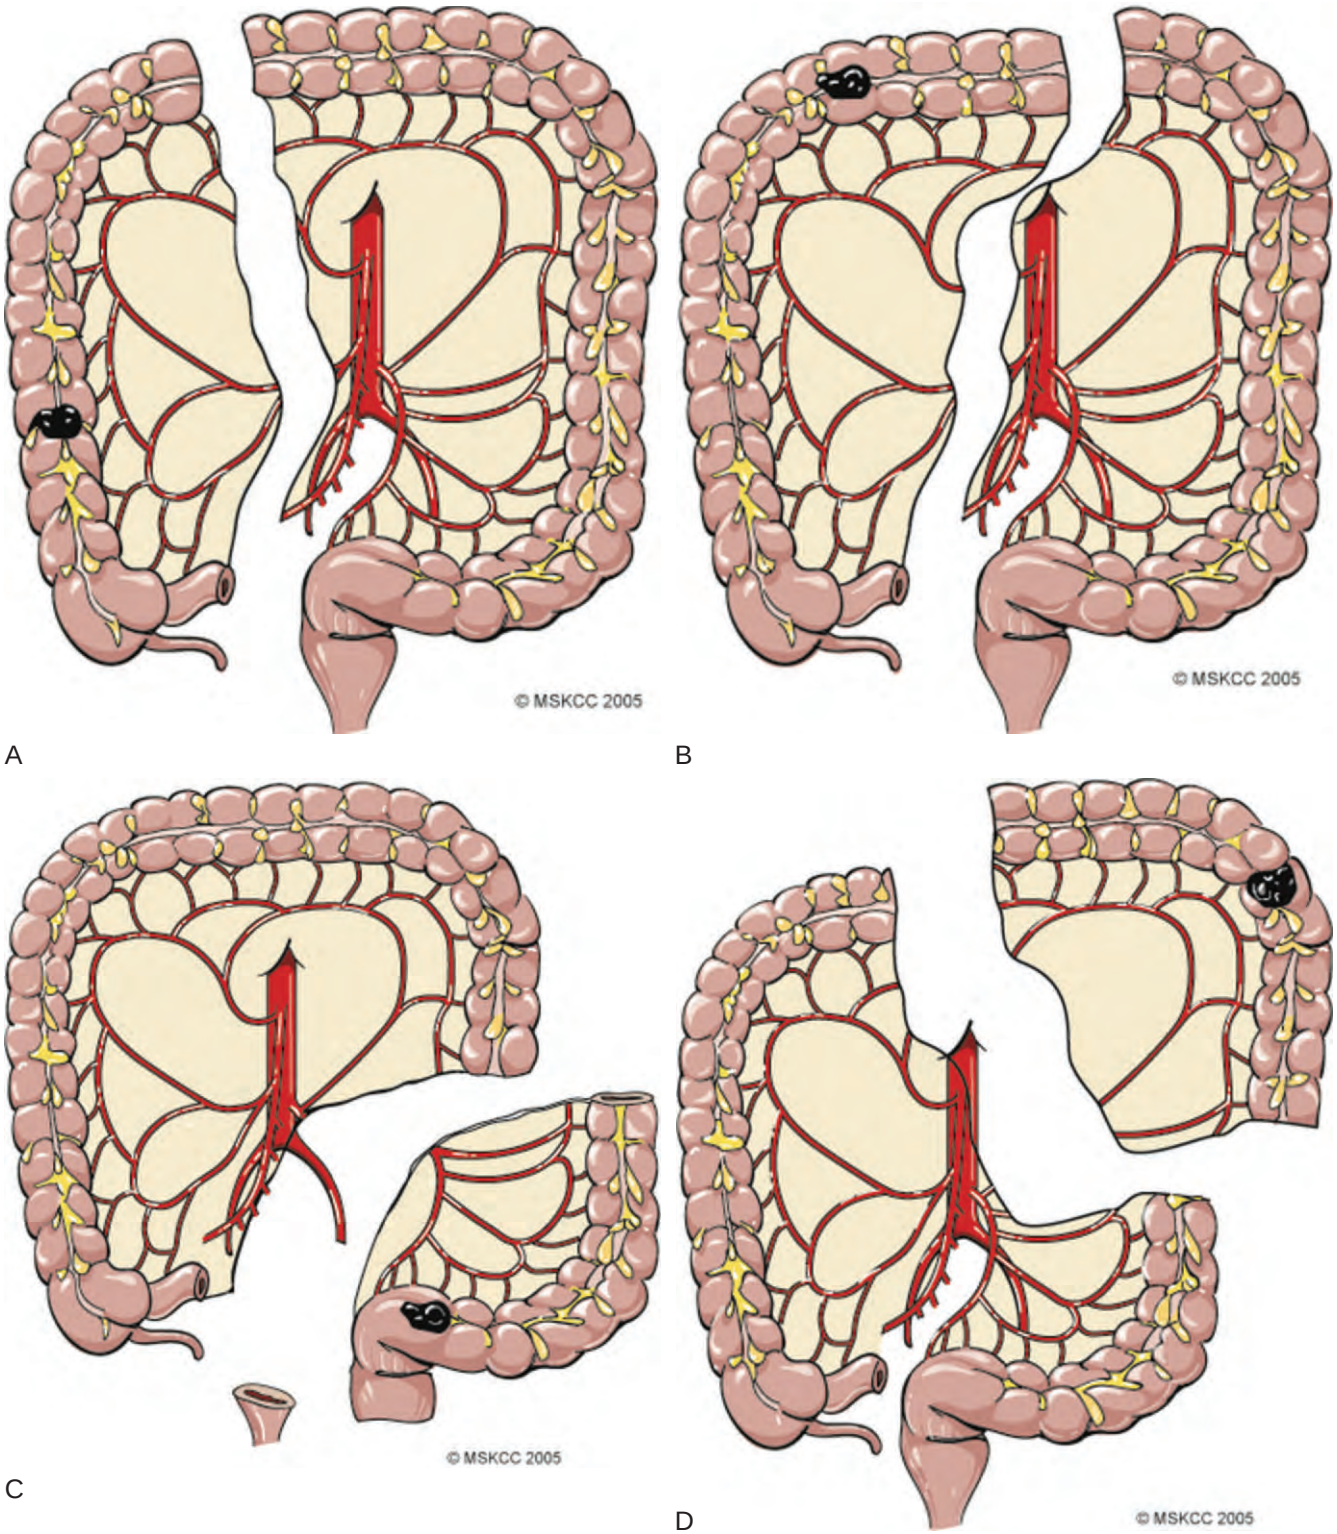

Figure 156–6. **A** to **D,** Operative strategies for colorectal cancer. (**A-D,** © 2005, Memorial Sloan-Kettering Cancer Center, New York.)

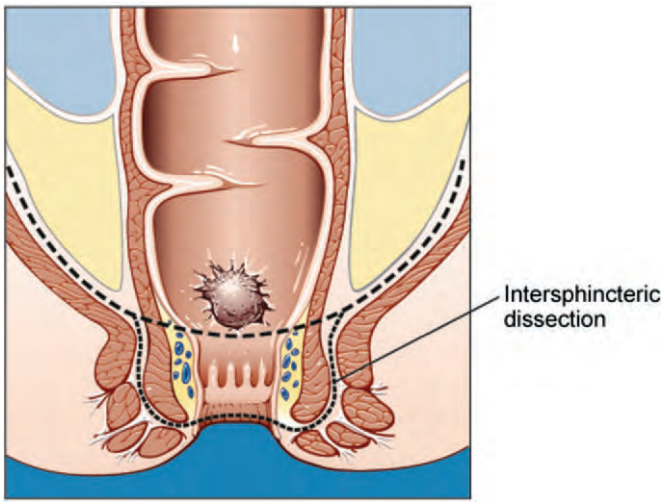

Figure 156–7. The technique of intersphincteric resection allows for additional distal margin for tumors located at the anorectal ring. (From Rullier E, Laurent C, Bretagnol F, et al: Sphincter-saving resection for all rectal carcinomas: The end of the 2-cm rule. Ann Surg 241:465-469, 2005.)

excision (mesorectal excision at least 4 cm to 5 cm below the tumor for high rectal lesions, and total mesorectal excision for middle-to-low rectal cancers) is associated with local failure rates in the 5% to 10% range.[63,64] Appropriate attention must be given to all margins, including the circumferential resection margin.[62] As might be expected, surgeon and hospital volume appear to influence outcome of colorectal cancer surgery.[65,66]

SPECIAL CIRCUMSTANCES

Surgical Treatment of Hereditary Bowel Cancer

Surgical options for patients with hereditary colorectal cancer syndromes include both therapeutic and prophylactic procedures. In patients with FAP, the most common procedures include total abdominal colectomy with ileorectal anastomosis, and total proctocolectomy with either ileal pouch-anal anastomosis or end ileostomy. Total abdominal colectomy with ileorectal anastomosis is reserved for those individuals with minimal disease in the rectum that can be controlled endoscopically. The advantage of ileorectal anastomosis includes relatively normal bowel function, less complex surgical procedure, and preserved bladder and sexual function. However, the remaining rectum requires frequent surveillance, as the risk of developing rectal cancer ranges from 10% to 50%,[67] with 40% to 75% of patients eventually requiring rectal resection. The advantages of total proctocolectomy with ileopouch anal anastomosis include elimination of the colorectal mucosa at risk. However, this is a more complex procedure, with an associated risk for bladder and sexual dysfunction as well as worse (but generally acceptable) bowel function. Total proctocolectomy with end ileostomy is usually reserved for patients who present with advanced rectal cancer or individuals unwilling and unable to undergo an ileopouch-anal anastomosis.

The surgical management of HNPCC patients depends on initial presentation. HNPCC patients who present with cancer or polyps not amenable to endoscopic removal should be considered for total abdominal colectomy with ileorectal anastomosis. Other options include segmental resection with frequent endoscopic surveillance, and enrollment in chemoprevention trial. Women, especially those who have completed childbearing, should be considered for total abdominal hysterectomy and bilateral salpingo-oophorectomy. HNPCC patients who present with rectal cancer should be considered for total proctocolectomy with ileopouch-anal anastomosis. Less preferred options that may be appropriate for select patients include segmental rectal resection with frequent endoscopic surveillance. At-risk individuals showing no colonic manifestations should be monitored with close endoscopic surveillance, since penetrance is only 80%, and up to 20% of individuals will not develop the phenotype. In select circumstances, prophylactic total abdominal colectomy may be reasonable.

Surgery for Malignant Polyps

The treatment of superficial carcinomas or malignant polyps depends on tumor location, depth of bowel invasion if a focus of carcinoma is found, and amenability of the entire tumor to endoscopic removal. Patients whose pedunculated polyps are completely removed for whom histologic examination reveals superficial carcinoma with clear margins and no high-risk pathologic features can often be closely observed, without formal colectomy. On the other hand, medically fit patients with completely resected superficial tumors or polyps that have positive margins or evidence of high-grade pathologic features such as lymphovascular/perineural invasion, poor differentiation, or single cell infiltrate are at increased risk for regional nodal metastases, and formal intestinal resection is warranted.

Local Excision of Rectal Cancer

The use of local excision of rectal cancers has recently gained popularity, although more recent data suggest that extreme caution, careful patient selection, and a full discussion of potential risks and benefits are warranted before embarking on this approach. The appeal is considerable, including rapid surgical recovery, minimal morbidity, and preservation of bowel function. Generally this is reserved for patients who have superficial rectal adenocarcinoma (T1 and T2) occupying less than one third of the bowel circumference, no palpable or radiologically documented perirectal nodes, and located within 10 cm of the anal verge. Although early results of local excision were encouraging, more recent studies with long-term follow-up data consistently show high recurrence rates and lower survival than would be expected in the setting of early rectal cancer.[68] This is

exemplified in a report of 125 patients treated with local excision. Local recurrence rates were 17% and 28% for T1 and T2 rectal lesions, respectively; much higher than reported for radical resection of stage I rectal cancer.[69] The explanation for high relapse rates following local excision is multifactorial but is clearly related to the issue of unaddressed regional lymph nodes: Local excision does not remove, pathologically assess, or treat these potential lymph nodes metastases. Although patients are screened prior to local excision with endorectal ultrasound or magnetic resonance imaging (MRI) with rectal coil, a recent report has demonstrated that nodal metastases from superficial rectal lesions (T1 and T2) are generally small and difficult to detect preoperatively.[70] Of even more concern are recent reports noting that local recurrence is not uniformly amenable to salvage surgery.[71] In fact, the two largest series of salvage surgery for recurrent rectal cancer following local excision show that relapse is generally diagnosed when disease is advanced, at which time extended multiorgan resection is usually required. Overall, postsalvage survival is disappointingly low, considering the early stage of the initial lesion.[71] Improved staging modalities are clearly needed to identify those patients who are optimal candidates for local excision. Until then, patients should be fully informed of the current limitations of local excision.

Minimally Invasive Surgery for Colorectal Cancer

Minimally invasive techniques have been successfully used in the treatment of colorectal cancer. In prospective, randomized series, laparoscopic colectomy for cancer has proven oncologically equivalent to open surgery, with the advantages of smaller incisions, less discomfort, and quicker recovery. Milsom et al.[72] reported the first randomized study of 109 laparoscopic versus conventional colectomies, noting that the minimally invasive procedure was safe, not different from conventional colectomy with regard to lymph nodes or length of intestine resected, and associated with quicker recovery. Lacy et al.[73] reported the first series of 219 randomized patients in whom recurrence and survival were the primary endpoints. Once again, recovery was quicker and morbidity lower in the laparoscopic colectomy group. Unexpectedly, cancer-related survival was higher in the laparoscopy group, without a clear explanation. In addition, the improved outcome was largely due to differences in patients with stage III tumors. Leung et al.[74] reported a randomized trial of 403 patients with rectosigmoid cancer, indicating that laparoscopic colectomy was equivalent to open colectomy. The first multiinstitutional prospective, randomized trial was recently reported by the Clinical Outcomes of Surgery Therapy (COST) Study Group. In an evaluation of 872 randomized colon cancer patients,[75] this study confirmed the oncologic equivalence of conventional and laparoscopic resection as measured by recurrence and survival. Similar to all other laparoscopy studies, laparoscopy for colorectal cancer is associated with a longer operation. Overall, these studies support the use of minimally invasive surgery for colon cancer. However, it should be stressed that all reports include surgeons with extensive experience with laparoscopic colectomy. There are some data available regarding the "learning curve" for laparoscopic colectomy, indicating that a surgeon needs to perform 30 to 50 cases to achieve proficiency with regard to complications, conversion, and operating time.[76,77] These data stress the importance of a mentored learning relationship or use of laparoscopic-assisted procedures, such as hand-assisted surgery, to gain the experience necessary to perform these procedures.

There are considerably less data available regarding laparoscopic rectal resection for cancer. Laparoscopic total mesorectal excision has been described; however, this is a technically more demanding procedure, due to the confines of the bony pelvis and limitations of current stapling technology when considering sphincter preservation.[78,79] As the field advances, the potential for minimally invasive rectal resection should be realized.

CHEMOTHERAPY

Adjuvant Chemotherapy for Stages II and III Disease

Adjuvant chemotherapy for stage III colon carcinoma is considered standard treatment, based on the results of numerous large, multi-institution, prospective, randomized trials demonstrating a disease-free and overall survival benefit for patients who receive 5-fluorouracil (FU)-based chemotherapy (5-FU and levamisole or 5-FU and leucovorin [also known as folinic acid]), compared with concurrent controls who receive no adjuvant therapy.[80-85] Initial studies used 5-FU plus levamisole. It is now widely accepted that levamisole is essentially inactive, and this drug therefore has no role in the management of colorectal cancer or any other human cancer at this time. Until recently, the standard of care has been to treat with 6 to 8 months of a 5-FU plus leucovorin (folinic acid) regimen, with chemotherapy optimally beginning between 3 and 6 weeks after operation (depending on the patient's postoperative recovery).

Recently the role of more aggressive therapies, such as irinotecan (Camptosar)- or oxaliplatin (Eloxatin)-containing regimens, has been addressed. A National Cancer Institute intergroup trial reported by Saltz et al.[86] showed the combination of irinotecan and weekly bolus 5-FU to have no therapeutic benefit over weekly 5-FU/leucovorin, with the irinotecan-containing regimen showing higher toxicity. Subsequent reports of the use of irinotecan with infusional 5-FU have also been disappointing, with the Action to Control Cardiovascular Risk in Diabetes (ACCORD) II trial being overtly negative, and the Pan-European Trial in Adjuvant Colon Cancer (PETACC) IIII trial showing some suggestion of benefit for the addition of irinotecan, but being negative for its prespecified primary endpoint.[87,88]

The Xeloda in Adjuvant Colon Cancer Trial (X-ACT), reported in abstract form, randomized patients with stage III disease to 6 months of 5-FU/leucovorin versus 6 months of oral capecitabine (Xeloda). The

capecitabine had a lower toxicity profile with at least as good efficacy parameters.[89] Thus, capecitabine can be considered as a standard adjuvant treatment option for locoregionally advanced colon cancer. It should be recalled that the trial demonstrating safety and efficacy of capecitabine in this setting was done in Europe, and that European patients appear to tolerate capecitabine better than American patients (possibly due to supplementation of folic acid in American grain products). As such, more toxicity and a greater need for dose attenuations may be expected in the United States.

A large randomized trial known as the Multicenter International Study of Oxaliplatin/5-Fluorouracil/Leucovorin in the Adjuvant Treatment of Colon Cancer (MOSAIC) trial investigated a biweekly (every other week) 2-day infusion of 5-FU and leucovorin ± a 2-hour infusion of oxaliplatin.[90] This trial included more than 2000 patients, of whom 60% were stage III and 40% were stage II. The oxaliplatin plus infusional 5-FU/leucovorin regimen, known as *FOLFOX,* was shown to be superior in terms of disease-free survival at 3 years and at 4 years. Overall survival at 4 years did not show a significant difference[91]; however, given advances in the management of recurrent disease, it is likely that the overall advantage will take longer to become apparent. Based on the compelling disease-free survival advantage, the FOLFOX combination (for 12 treatments over 24 weeks) is now widely viewed as an appropriate treatment option for most stage III colon cancer patients.

Data from the National Surgical Adjuvant Breast and Bowel Project protocol C-07 trial assessing the usefulness of oxaliplatin plus weekly bolus 5-FU (the FLOX regimen) have recently been reported in abstract form. The 3-year disease-free survival improvement seen with FLOX appears similar to that seen with FOLFOX, suggesting that either FLOX or FOLFOX could be considered acceptable for routine adjuvant treatment; however, the serious diarrhea rate with FLOX (38% grade 3 to 4) could be of significant concern.[92]

The newer agents cetuximab (Erbitux) and bevacizumab (Avastin) (see later) are currently being studied in the adjuvant setting; however, their safety and efficacy in stage II or III colorectal cancer have not been established at this time, and their use should be restricted to the investigational setting.

The usefulness of adjuvant chemotherapy in patients with stage II colon cancer remains controversial (see Fig. 156–7).[93-95] Definitive trials of adjuvant therapy for stage II colon cancer patients are difficult to accomplish due to the very large numbers of patients that would be needed to show a benefit in this population with a relatively good prognosis. The preponderance of data suggests that if there is a survival advantage in stage II patients overall, it is in the 2% to 4% range. It is a matter of some subjectivity as to whether treatment of stage II patients is warranted. Although routine treatment of all medically fit stage II patients has not been widely recommended, it is the general consensus of the academic chemotherapy community that all stage II patients deserve a medical oncology discussion of the relative pros and cons of postsurgical chemotherapy. Those patients with higher risk tumors, such as those with perforated or obstructing primaries, perivascular invasion, or poorly differentiated histology, appear to be at higher risk for recurrence and would logically be more appropriate candidates for consideration of chemotherapy using one of the regimens outlined as an option for stage III patients.

Combined Chemoradiation Therapy

Several well-done prospective, randomized, multiinstitution trials have shown that patients with rectal adenocarcinoma (stage II or III) at high risk for local and systemic failure will benefit from external-beam irradiation and chemotherapy either before or after curative surgery. Adjuvant 5-FU–based chemotherapy plus radiation therapy should be considered the conventional therapy for patients with high-risk rectal carcinoma.[96-99]

In patients with bulky or fixed rectal carcinoma, defined on digital examination under anesthesia, preoperative external-beam radiation therapy with or without chemotherapy has proved to be beneficial.[100-102] If such patients respond to 45 to 50.4 Gy and are found on subsequent digital examination to have mobile tumors, they should undergo resection (either low anterior resection with coloanal anastomosis, or abdominoperineal resection). Barring strong contraindications, it is recommended that patients receive four to six additional cycles of systemic 5-FU–based chemotherapy in the adjuvant (postoperative) setting.

Most preoperative and postoperative trials of radiation therapy alone have demonstrated a reduction in the rate of local relapse.[103] Although many single-institution studies of preoperative radiation therapy have implied increased survival in irradiated versus nonirradiated rectal cancer patients, only one prospective, randomized trial has shown survival benefit with preoperative radiation therapy compared with surgery alone.[104] The radiation doses and techniques (short, intensive course) used in the Swedish trial are associated with significant morbidity rates and are not commonly used by radiation oncologists in the United States. Preoperative irradiation is, therefore, applicable only for patients who are diagnosed as having bulky or fixed rectal carcinomas. Preoperative combined chemotherapy and radiation is being applied with ever-increasing frequency and is touted as resulting in improved bowel function and sphincter preservation compared with postoperative adjuvant therapy,[105,106] More recently, a large (>800-patient) German trial has demonstrated superior results with a preoperative radiation approach in terms of superior local control and a more favorable toxicity profile, albeit with no overall survival difference.[107]

Modern management of rectal carcinoma should include preoperative staging with an endorectal ultrasound or endorectal MRI. Those tumors found by this preoperative assessment to be T3 or T4 lesions are most appropriately treated with preoperative radiation therapy plus 5-FU–based chemotherapy.

A treatment plan that includes preoperative pelvic radiation therapy plus chemotherapy includes a plan for postoperative chemotherapy, beginning 4 to 6 weeks

after surgery and lasting approximately 4 months. It is imperative to note, and to discuss in advance with the patient, that there is absolutely no finding at operation that will lead to a lack of need for follow-up chemotherapy. Even if a pathologic complete response is noted at operation, postoperative chemotherapy must be given as initially planned. The pathologic complete response is an indication of the results of radiation plus chemotherapy. It says nothing about the effect of chemotherapy on micrometastatic disease. To fully minimize the chance of death from distant metastatic disease, the full planned course of postoperative chemotherapy must be given, regardless of the effectiveness of preoperative chemotherapy plus radiation therapy.

Survival

With conventional surgery as described for resectable colon and rectal carcinoma, approximately 50% of all patients with colon cancer and approximately 45% of all patients with rectal cancer will be alive after 5 years.[108] This expected survival rate has not changed in 4 decades. Recurrence patterns have not changed either. In cases of rectal cancer, trials have shown the possibility of increasing the patient's disease-free and overall survival rates when both external-beam irradiation and combination chemotherapy are administered, after adequate surgery, to patients with the highest-risk cancers. Initial publication by the Gastrointestinal Tumor Study Group of disease-free survival benefit in patients treated with adjuvant radiation and chemotherapy after either low anterior resection or abdominoperineal resection of Dukes-Kirklin B2, C1, and C2 rectal cancers was subsequently extended to demonstrate overall survival benefit in those same patients. Completed adjuvant therapy trials demonstrated the synergistic benefit of external-beam irradiation and chemotherapy. An Intergroup trial confirmed that continuous infusion of 5-FU is superior to bolus infusion[99]; however, a subsequent trial failed to confirm this observation.[109]

COLORECTAL CANCER POSTRESECTION FOLLOW-UP

Of patients who have recurrences after curative resection of colon and rectal carcinomas, 80% do so within 3 years. Therefore, any post-treatment plan should include a higher frequency of follow-up during these 3 years, with decreasing frequency thereafter, although data supporting intense follow-up are limited. A prospective, randomized trial conducted in Australia randomly assigned patients after curative resection of colorectal cancer to routine follow-up (history and physical examination every 3 months for 2 years and then every 6 months for a total of 5 years) and to intense follow-up consisting of yearly colonoscopy, computed tomography (CT) scan of the liver, and chest radiography in addition to the standard follow-up. No improvement in survival was noted with the intense follow-up regimen.[110] The American Society of Clinical Oncology (ASCO) has recommended a postoperative monitoring strategy for the detection of recurrent colon and rectal cancer.[111] In general, if a patient would be a candidate for resection of recurrent disease (e.g., hepatic resection), serum carcinoembryonic antigen (CEA) testing should be performed every 3 to 4 months for 2 to 3 years after resection of the primary tumor. Routine liver function tests, fecal occult blood tests, CT scanning, and chest radiography are not recommended in these ASCO guidelines for surveillance of colorectal cancer recurrence.

The rationale for colonoscopy as part of perioperative staging and follow-up is not to define recurrent cancer. The yield in the diagnosis of isolated suture line recurrence by either endoscopy or guaiac testing of the stool is low. The major rationale for colonoscopy is to define synchronous or metachronous bowel tumors, usually polyps. As patients are exposed more uniformly to follow-up endoscopy subsequent to primary colorectal cancer resection, the incidence of metachronous lesions seems to be increasing.[112-114] Whatever the ultimate incidence of metachronous bowel lesions, there is no question that patients with sentinel colorectal carcinomas are at a significant risk for the development of metachronous polyps. If these polyps are discovered and removed, the risk of subsequent development of colon and rectal cancer decreases. Adequate screening at the time of primary surgery or later, to rule out synchronous lesions, and serial follow-up every 3 to 5 years to ensure a cancer- and polyp-free colon, should be a mandatory part of any good postoperative surveillance program for colorectal cancer patients.

TUMOR MARKERS AND SURVEILLANCE

CEA remains the prototypical solid tumor marker. Despite its lack of specificity, if used correctly CEA determination is a valuable addition to clinical decision-making in patients who have been diagnosed with colon or rectal carcinoma. CEA is not an appropriate screening test. Whether sampled once or serially, CEA cannot be used to help in the differential diagnosis of an unknown suspected bowel problem or malignancy. When CEA concentrations are determined before primary tumor resection, they may provide additional prognostic value, particularly for patients who have stage II disease, in whom the poor prognostic marker of an elevated preoperative CEA may influence the choice of whether or not to administer adjuvant chemotherapy.

Serial CEA values obtained postoperatively offer a potentially effective means of monitoring response to therapy. A postoperative CEA titer serves as a measure of the completeness of tumor resection. It should be recalled, however, that the half-life of CEA is 7 to 14 days, so postoperative baselines are best established several weeks after resection. If a preoperative elevated CEA value does not fall to normal within 2 to 3 weeks after surgery, the resection was most likely incomplete or occult metastases are present. A rising trend in serial CEA values from a normal postoperative baseline

(<5 ng/ml) may predate any other clinical or laboratory evidence of recurrent disease by 6 to 9 months.

Serial CEA values tend to roughly parallel either tumor regression or tumor progression during treatment for metastatic disease.[115] However, the actual utility of these measurements is extremely limited, as decisions to continue or discontinue a chemotherapy regimen should rarely, if ever, be made on the basis of a rising CEA alone. Most patients who respond to treatment demonstrate a decline in CEA levels. Rising CEA values are usually incompatible with tumor regression.[116]

There are no data to outline an optimal schedule of CEA monitoring after potentially curative resection. A reasonable strategy is to obtain CEA levels every 3 to 4 months and then every 6 months for the next 3 years. Data do not suggest that continued oncologic monitoring with CEA screening after 5 years is of significant benefit. Colonoscopy is recommended at 1 year after resection, and every 3 years thereafter. Routine CT scans and chest radiographs have not been shown to contribute to survival, so formal, evidence-based recommendations cannot be made.

A newly elevated CEA should first be repeated to confirm the finding and rule out a laboratory error. A confirmed new elevation should be evaluated with a full-body CT scan and, if this is negative, a colonoscopy.

In considering work-up of an elevated CEA, it is important to keep in mind that the goals of this screening are to identify *potentially curable* patients, that is, patients who have surgically resectable metastatic disease. Isolated liver, lung, or ovarian metastases are potentially curable with surgery, as are some local anastomotic recurrences. Identification of asymptomatic but incurable disease, such as peritoneal metastases or retroperitoneal lymph nodes, is of essentially no benefit and does not contribute to the patient's overall well-being. There is no evidence that early initiation of systemic chemotherapy for incurable metastatic disease will yield a better outcome. Thus, the role of CEA monitoring and postoperative imaging is to attempt to identify those patients with resectable, and therefore curable, disease.

"Second-look" surgery in the absence of an identified curable lesion on imaging studies is no longer recommended, since this is extremely unlikely to identify curable disease.[117] In later applications of radioimmunologic scanning techniques using either external or intraoperative gamma scanning,[118] the weak link will still be lack of an effective systemic therapy, even when diffuse disease recurrence is found early.

When liver or lung is the first or only site of recurrence, serial CEA rise will show the steepest slope. Specific diagnostic tests to confirm recurrence in the liver or lung are now preferable to so-called blind CEA-directed second-look procedures.[119] At present, only patients who have recurrence of colorectal carcinoma with defined isolated liver, lung, ovarian, or anastomotic metastases should undergo surgery. Therefore, it is recommended that postoperative monitoring of CEA be reserved for patients who would be candidates for resection of these potentially curable metastases if they occur. As with other follow-up testing, the optimal frequency of serial CEA monitoring has not been established.[111]

Positron emission tomography (PET) scanning has been recommended by some as a tool for work-up of an elevated CEA. However, identification of asymptomatic, unresectable disease is unlikely to be of benefit to the patient in terms of long-term outcome and may actually increase anxiety. Most surgeons would be reluctant to operate on the basis of a positive PET with negative good-quality, current CT and/or MRI scans. As such, the true contribution of PET to the management of an elevated postresection CEA is questionable.

TREATMENT OF SYSTEMIC METASTATIC (STAGE IV) DISEASE

There have been substantial and dramatic changes in chemotherapy for metastatic colorectal cancer over the past decade. Whereas only one drug, fluorouracil (5-FU), was approved for the treatment of colorectal cancer through 1995, in 2005 no fewer than six drugs have received U.S. Food and Drug Administration approval for treatment of this disease. With the greater number of active drugs comes substantially more options and more effective treatments but also far greater complexity (Fig. 156–8).

Although 5-FU remains an important part of many treatment regimens, single-agent fluorouracil (with or without the biomodulation agent leucovorin) is rarely the regimen of choice for first-line management of metastatic colorectal cancer. Irinotecan[120-122] and oxaliplatin[123] are two newer cytotoxic agents that are now routinely combined with fluorouracil and leucovorin to create more active regimens. Two studies combining irinotecan plus either bolus[124] or infusional[125] 5-FU/leucovorin demonstrated a survival advantage over fluorouracil/leucovorin alone. Infusional 5-FU demonstrated advantages over bolus administration, both in terms of both efficacy and safety.[126] Subsequently, a randomized intergroup trial (N9741) of irinotecan plus bolus 5-FU/leucovorin (IFL), versus oxaliplatin plus infusional 5-FU (FOLFOX), showed a higher response rate and longer time to tumor progression for FOLFOX.[127] Survival on the FOLFOX arm was superior; however, the meaning of these survival data is difficult to interpret, since second-line irinotecan was widely available to the FOLFOX patients, whereas second-line oxaliplatin was not widely available to the IFL patients because oxaliplatin was not available in the United States at that time. Second-line irinotecan has been shown to confer a survival advantage,[121] and survival has been correlated with availability of all active drugs.[128] Another randomized study comparing first-line FOLFOX versus FOLFIRI suggested that response rate, time to tumor progression, and overall survival were virtually the same regardless of which regimen was used first (Fig. 156–9).[129] As an aggregate result of these aggregate trials, the most commonly used cytotoxic regimens in the United States and in much of Europe are the combination of leucovorin

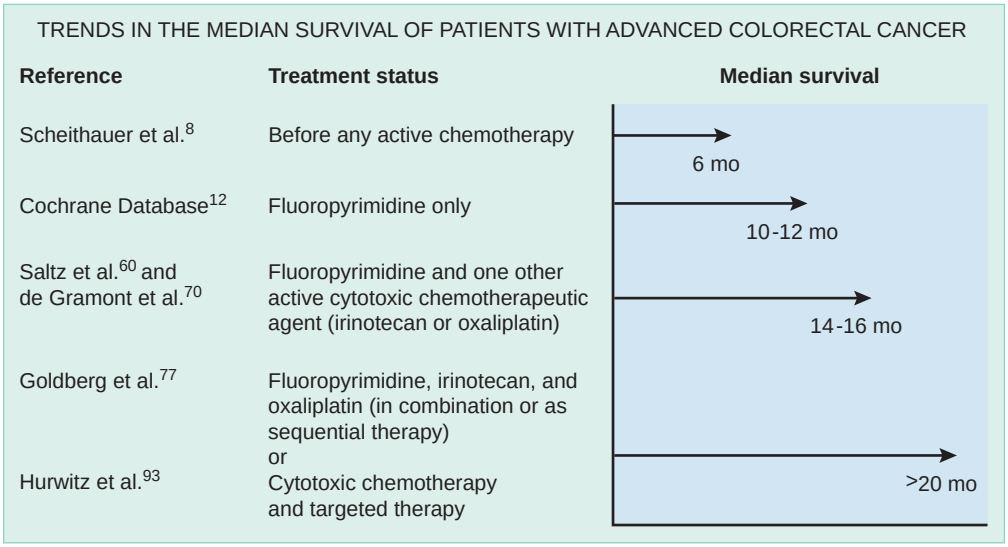

Figure 156–8. Trends in improved survival in stage IV colorectal cancer with more effective systemic chemotherapy. The references cited appear in the original source article. (From Meyerhardt JA, Mayer RJ: Systemic therapy for colorectal cancer. N Engl J Med 352:476-487, 2005.)

Figure 156–9. Survival following treatment with FOLFOX versus FOLFIRI. (From Tournigand C, Andre T, Achille E, et al: FOLFIRI followed by FOLFOX6 or the reverse sequence in advanced colorectal cancer: A randomized GERCOR study. J Clin Oncol 22:229-237, 2004.)

(FOLinic acid), a two-day infusion of Fluorouracil, and Oxaliplatin, known colloquially as FOLFOX), and the same schedule with IRInotecan substituted for oxaliplatin known as FOLFIRI.

The oral fluorouracil prodrug capecitabine has also been approved for colorectal cancer management.[83] As a single agent, this drug is getting little play. However, there is considerable interest in the possibility of replacing infusional 5-FU with capecitabine in combination regimens, thereby eliminating the need for infusion pumps. Phase II data have suggested that efficacy will be similar between capecitabine/oxaliplatin and FOLFOX regimens,[130] but randomized data have not yet been presented. A randomized phase III study of FOLFOX versus capecitabine/oxaliplatin has been accrued, and data are maturing. At present, pending availability of randomized data, routine use of capecitabine combinations would appear to be premature. Also, as mentioned previously, tolerability of capecitabine is better in European patients than in North American patients, so published toxicity and dosing data from European trials will have to be applied to American patients with caution.

Perhaps the most important changes in chemotherapy for colorectal cancer have been brought about by the recent availability of two monoclonal antibodies, bevacizumab and cetuximab. Unlike the cytotoxic chemotherapy agents discussed earlier, these agents are targeted biologic agents that exploit recent advances in the understanding of tumor biology. Bevacizumab is a monoclonal antibody that targets VEGF, a pivotal growth factor in the process of angiogenesis, or new blood vessel formation.[131] Cetuximab is a monoclonal antibody that targets and blocks the binding site of the EGFR, thereby blocking activation of this important signaling pathway.[132]

In a double-blind randomized trial of more than 800 colorectal patients treated first-line with the IFL chemotherapy regimen plus either bevacizumab or placebo, the group receiving bevacizumab had a superior response rate, longer time to tumor progression, and a substantial median survival advantage of almost 5 months (Fig. 156–10).[133] A study of FOLFOX versus FOLFOX plus bevacizumab in second-line treatment of patients who had not received previous bevacizumab also showed a survival advantage for the FOLFOX plus bevacizumab group.[134] These data have been widely extrapolated, such that in the absence of a significant contraindication it is now general practice to include bevacizumab with all front-line chemotherapy regimens.

The most common complication of bevacizumab is hypertension, requiring treatment (with routine oral antihypertensives) in approximately 10% of patients. Of more serious concern are two rare but serious complica-

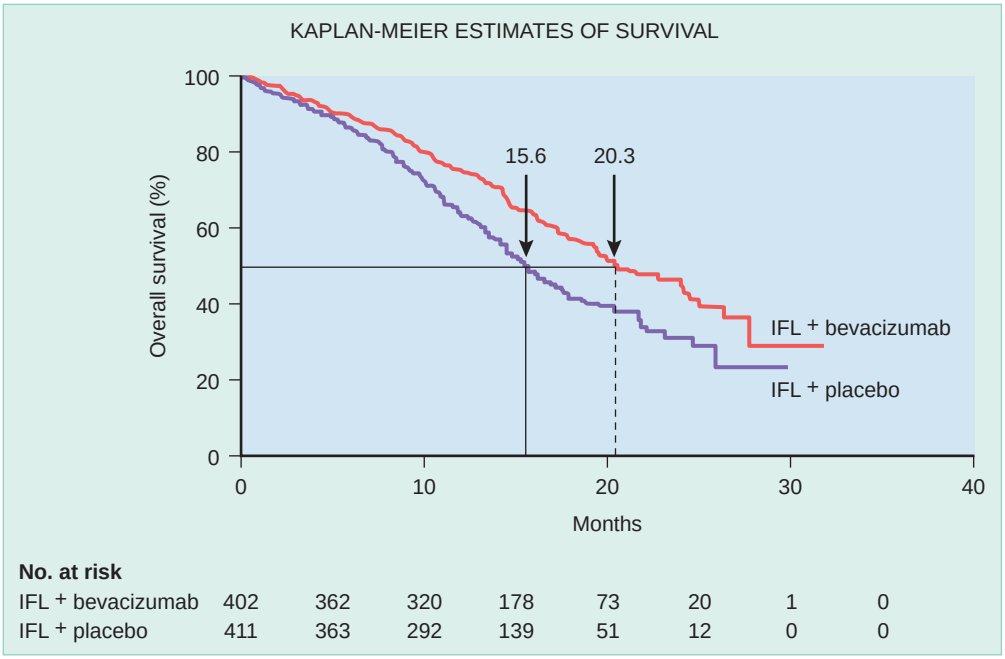

Figure 156–10. Survival advantage of irinotecan plus bolus 5-FU/leucovorin (IFL) + bevacizumab versus IFL + placebo. (From Hurwitz H, Fehrenbacher L, Novotny W, et al: Bevacizumab plus irinotecan, fluorouracil, and leucovorin for metastatic colorectal cancer. N Engl J Med 350:2335-2342, 2004.)

tions: gastrointestinal perforation and arterial thromboses. Overall, 1.5% of patients receiving bevacizumab experienced a perforation in the gastrointestinal tract. There was no consistency to the nature of the perforation, with gastric ulcers, small bowel, and large bowel perforations being reported. At present the primary site, whether resected or not, does not appear to be at increased risk for perforation. The nature of these perforations is not well understood, although they presumably represent some sort of ischemic event.

In terms of arterial thrombotic events, four events combined to obtain this statistic: myocardial infarctions, cerebral vascular accidents, transient ischemic attacks, and angina. Altogether there was a 2.5% combined incidence of these events in the control (chemotherapy only) group and 5% in the chemotherapy plus bevacizumab group. Bevacizumab would be expected to potentially interfere with wound healing, and its long half-life of approximately 3 weeks should be respected in planning preoperative or postoperative chemotherapy treatments.

Cetuximab has demonstrated a high degree of antitumor activity in colorectal cancer patients whose tumors have progressed despite standard chemotherapy. Two studies confirmed a 23% response rate when cetuximab plus irinotecan is given to patients whose tumors have grown despite irinotecan.[135,136] No randomized studies have been done to evaluate the effect of cetuximab on survival, so we simply do not know at this time whether or not a survival advantage is conferred by this drug. The major side effects of cetuximab are an acneiform rash, occurring to some degree in the majority of patients treated, and an approximately 3% risk of serious allergic reaction which, if present, usually occurs with the first dose and is managed with standard supportive measures as with other chemotherapy-induced allergic reactions. No randomized data are available on the benefit, or lack thereof, of cetuximab in front-line chemotherapy combinations, and at present clinical use of cetuximab in first-line treatment of metastatic disease should be regarded as investigational. A common misperception exists regarding the need for immunohistochemical testing of a tissue sample for use of cetuximab. Although the registered indication for cetuximab currently is for EGFR-positive colorectal cancer, the assumption that EGFR-negative tumors could not respond has been solidly disproved.[137,138] At present, it appears that currently available EGFR immunohistochemical testing has no predictive significance in terms of cetuximab activity, and EGFR testing by currently available techniques should not be used to select either for or against cetuximab therapy.

Surgery for Metastatic Disease

In numerous single-institution studies, as well as in a retrospective registry, it becomes clear that only 2000 to 4000 patients each year will have resectable, isolated liver metastases. These patients should undergo resection. The expected 5- and 10-year disease-free survival rates in these patients will be 20% to 30%, exceeding that for any other form of treatment.[139-147] No adequately powered trials of adjuvant therapy after liver resection have been or will ever be done. It is therefore not correct to say that chemotherapy after such a resection is of no use. In this situation, it is reasonable to extrapolate from the experience with stage III patients. It should be noted that

patients with so-called stage III disease who ultimately die of colorectal cancer do not die of the disease that was resected. Rather, they had unsuspected or undetected microscopic stage IV disease all along, and it is these occult micrometastases that are either cured or not cured by systemic adjuvant chemotherapy. Assuming that adjuvant therapy can cure the microscopic metastatic disease of some presumed stage III patients (which it can, otherwise all adjuvant therapy trials would be negative), then it is quite reasonable to assume, in the absence of data to the contrary (and there are none), that adjuvant chemotherapy could be expected to confer similar benefits, for similar reasons, in resected stage IV patients. It is therefore de facto routine practice to administer chemotherapy, if a potentially active regimen remains available, after resection of stage IV disease. Extrapolating from stage III data, such treatments usually start approximately 6 weeks after liver resection and continue for 6 months.

Local Excision of Rectal Cancer

Jacob A. Greenberg · Ronald Bleday

Despite recent improvements in patient awareness and compliance with screening modalities, rectal cancer continues to be a significant medical and social problem worldwide. In 2003, approximately 42,000 new cases of rectal cancer were diagnosed, and 57,000 deaths were attributed to the disease in the United States alone. Abdominoperineal resection (APR) has been the traditional treatment for *distal* rectal adenocarcinomas and continues to be the standard to which all other operations for the treatment of rectal cancer must be compared. This procedure involves the en bloc removal of the tumor, rectum, sphincter complex, and surrounding lymph nodes, leaving the patient with a permanent colostomy. The 5-year survival rates after an APR by stage range from 78% to 100% for stage I, 45% to 73% for stage II, and 22% to 66% for stage III.[1-4] Despite radical resection of both the tumor and surrounding tissue, local recurrence rates remain roughly 20%, ranging from 8.5% for stage I disease to 28.6% for stage III disease with surgery alone.[5] These variations in recurrence rates can be attributed to such variables as tumor location within the rectum, surgical technique, and the addition of adjuvant therapy.

While APR is the mainstay of therapy for distal rectal cancer, it is associated with significant morbidity and mortality. A recent review of the literature showed that mortality rates for APR range from 0% to 6.3%,[6,7] with some studies having a 61% incidence of postoperative complications.[3] The majority of these complications are urinary and perineal wound infections with rates as high as 50% and 16% respectively.[8] APR also leads to a significant change in body image and social habits. In a patient survey performed in 1983 by Williams and Johnston,[9] 66% of patients complained of significant leaks from their stoma appliances, 67% experienced sexual dysfunction, and only 40% of patients who were working pre-operatively returned to their jobs following their operation. These complications, coupled with improvements in patient selection secondary to innovations in pre-operative imaging modalities such as endorectal MRI and ultrasound, have led to a renewed interest in local treatment of rectal cancers with the hope of achieving similar survival rates with less morbidity and mortality when compared to APR.

PREOPERATIVE EVALUATION

Proper patient selection remains the key to successful local excision of rectal cancers. The retrospective literature shows that there is a direct correlation between local recurrence and specific pathologic tumor features including depth of invasion, lymphatic invasion, histologic grade, and most importantly negative margins at the time of resection. In the past, preoperative evaluation relied solely on a digital rectal examination, which was found to demonstrate depth of invasion with some degree of accuracy.[10,11] More recent studies have refuted this evidence.[12] Today imaging studies can more accurately predict preoperative stage of rectal cancers and these techniques include endorectal ultrasound (ERUS) and endorectal magnetic resonance imaging (eMRI).

Preoperative evaluation begins with a thorough history and physical, taking care to note sphincter function, as local excision in the setting of poor preoperative sphincter function may be inappropriate. A digital rectal exam should be performed in order to assess the distance of the tumor from the anal verge, as well as its size and mobility. Tumors amenable to local excision should be less than 4 cm in diameter and occupy less than 40% of the bowel circumference (Box 157–1). The distance of the tumor from the dentate line is crucially important to judge resectability: tumors less than 5 cm from the dentate are amenable to tranansal resection, while tumors in the middle third of the rectum may require a transcoccygeal approach or transanal endoscopic microsurgery (TEM). Immobile tumors are likely transmural, and thus, not amenable to local excision. The overall health of the patient must be taken into account, as patients who are considered medically unfit for a major resection are often good candidates for local excision.

Box 157–1 Properties of Distal Rectal Adenocarcinoma Amenable to Local Excision for Curative Intent

- Physical features
  - Tumors <4 cm in diameter
  - Tumor <40% of bowel circumference
  - Tumor within 10 cm of dentate line
  - Tumor freely mobile on digital rectal exam
- Endorectal US
  - T1, T2 lesions
  - No regional lymph node involvement

ERUS AND eMRI

ERUS was introduced as a means of preoperatively staging small rectal cancers during the 1990s. ERUS remains very operator dependent, and there is a significant learning curve, but in experienced hands ERUS can determine depth of tumor invasion reliably. In 1993, Solomon reported a sensitivity of 97% and a specificity of 87% in determining the depth of invasion with ERUS.[13] Garcia-Aguilar et al. found that ERUS was not as useful for determining exact stage, with an overall accuracy of only 59%. However, ERUS was very useful for differentiating tumors localized within the rectal wall, which are amenable to local excision, from those that extend into the peri-rectal fat, which require radical resection and adjuvant chemoradiation.[14] Garcia-Aguilar et al. also found that the accuracy of ERUS in detecting lymph node metastases ranged from 60% to 80%.[14]

Endorectal MRI is also being used to determine the depth of invasion of the primary rectal tumor and is the preferred preoperative evaluation method at our institution. As with ERUS, there is a significant learning curve in performing and reading eMRI.[15] Kim et al. found that the overall accuracy of eMRI for staging depth of invasion and nodal metastases was 81% and 63% respectively.[16] They also found eMRI to have a sensitivity of 78.5% and a specificity of 41.9% making it more sensitive but less specific than ERUS in their study.[16]

Computed tomography (CT) has also been used to evaluate small rectal cancers, however, it is not as accurate as ERUS or eMRI in evaluating the depth of invasion. Thus, the use of CT is not recommended for the evaluation of the primary tumor. CT is still valuable in the initial evaluation of the patient with low rectal cancer due to its ability to detect evidence of distant metastases. Posteroanterior and lateral chest radiographs are useful for the same reason.

It is our recommendation that each institution select a modality that they prefer and concentrate the experience into one person's or one team's hands so as to maximize accuracy and consistency of results. Proper decision-making and patient selection for the use of local excision or local excision with adjuvant therapy is dependent on reliable and reproducible imaging. We prefer endorectal MRI. In our hands it is less operator dependent than endorectal US and provides us significantly more information on the mesorectal tissues than endorectal US.

TECHNIQUE

Historically, there are three approaches to local excision of rectal cancer: transanal, transcoccygeal, and transsphincteric. The transsphincteric approach has been associated with fecal incontinence secondary to sphincter dysfunction, and thus has fallen out of favor. Recently a newer technique, Transanal Endoscopic Microsurgery (TEM), has provided a minimally invasive option for local excision which also allows the operator to reach lesions that are located more proximally and would have required a transcoccygeal or transsphincteric approach in the past.

Transanal Excision

Local excision is accomplished via a transanal approach in the majority of patients with low rectal cancers. In our prospective study of 48 local excisions for rectal cancer, 33 were performed using a transanal approach.[17] Prior to local excision, all patients receive a full mechanical and antibiotic bowel preparation. After induction of anesthesia, the patient is placed in the prone-jacknife position, with the buttocks taped apart. A pudendal nerve block should then be administered, which aids in the control of post-operative discomfort and more importantly relaxes the sphincter complex. A Pratt bivalve retractor is then used to dilate the anus and expose the lesion. Once adequate visualization has been obtained, traction sutures are placed 1 to 2 cm distal to the tumor, and the limits of dissection are marked on the mucosa using electrocautery. This line of dissection should be approximately 1 to 2 cm from the border of the tumor circumferentially. If visualization is not initially adequate, serial traction sutures are used to prolapse the lesion into the field of view. Next, the electrocautery is used to make a full-thickness incision along the previously marked mucosa (Fig. 157–1). Upon completion of this incision, the peri-rectal fat should be visible beneath the lesion to confirm a full-thickness excision. In anterior lesions, care must be taken not to injure the back wall of the vagina in women, or the prostate in men. The lesion is then excised leaving visible peri-rectal fat at the base of the lesion. The defect in the bowel wall is then closed transversely using interrupted 3-0 Vicryl sutures.

Complications after transanal excisions include urinary retention, urinary tract infections, delayed hemorrhage, infections of the perirectal and ischiorectal space, and fecal impactions. However, the overall incidence of these complications is quite low.[17]

Transcoccygeal Excision

The transcoccygeal approach is used preferentially over the transanal approach for larger more proximal lesions.

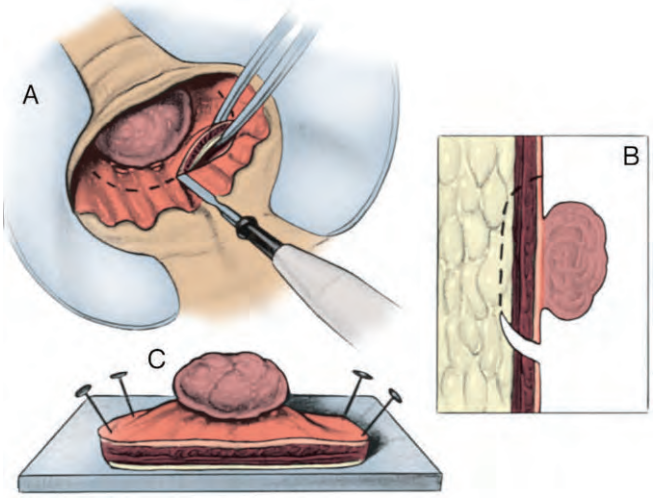

Figure 157–1. **A,** A 1-2 cm margin is marked out circumferentially on the rectal mucosa. **B,** A full thickness excision is carried out with dissection into the perirectal fat. **C,** The specimen is oriented for the pathologist in order to accurately identify all margins.

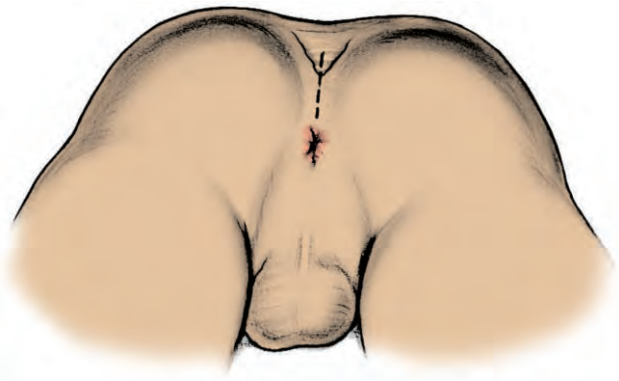

Figure 157–2. Incision line for the transcoccygeal approach.

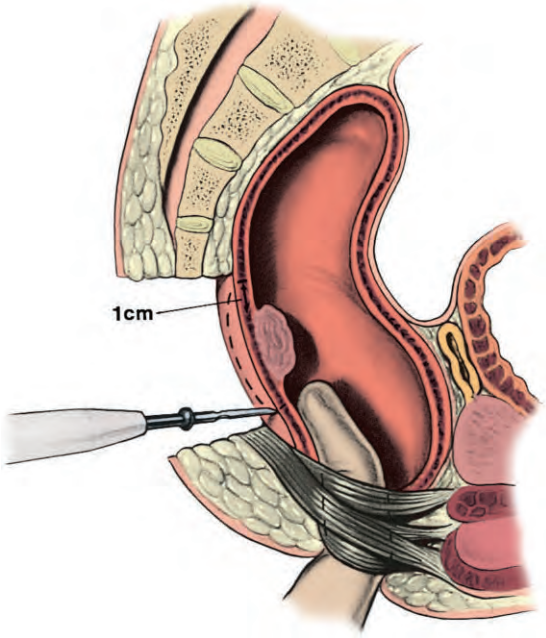

Figure 157–3. For posteriorly based lesions, after the rectum has been exposed, the surgeon can palpate the distal margin of the tumor then choose the dissection margin greater than one centimeter away from the margin for the initial proctotomy. The dissection is then completed under direct vision.

It was originally popularized by Kraske who found it beneficial when operating on lesions within the middle or distal third of the rectum. This approach is especially useful for lesions on the posterior wall of the rectum, but can certainly be used for anterior or lateral lesions as well. In our series, the transcoccygeal approach was used where the distal margin was approximately 4.8 cm from the dentate line as compared to 3.0 cm for the transanal approach.[17]

All patients undergo a full antibiotic and mechanical bowel preparation the day prior to surgery. The patient is placed in the prone-jacknife position with the buttocks taped apart after the induction of general anesthesia. The tape will be released for closure in order to facilitate the approximation of the subcutaneous tissues and skin. An incision is made in the posterior midline adjacent to the sacrum and coccyx down to the upper border of the posterior aspect of the external sphincter (Fig. 157–2). The coccyx, which along with the anal coccygeal ligament lies immediately deep to the skin and subcutaneous tissue, is removed to improve exposure. The levator ani muscles will now be visible at the base of the wound and should separated in the midline, exposing a membrane that resides just outside of the perirectal fat. Division of this membrane allows for complete mobilization of the rectum within the intraperitoneal pelvis.

For posteriorly based lesions, the distal margin of the tumor can be palpated via a rectal examination, and then the mesorectum and rectum are transected at a point 1 to 1.5 cm distal to the tumor (Fig. 157–3). The excision is then completed with a 1 cm margin surrounding the lesion. For posterior lesions, the transcoccygeal approach allows for the removal of perirectal nodes that lie in the surrounding mesorectal tissue. For anterior lesions, a posterior proctotomy is made, and then the lesion is approached under direct vision, again excising the lesion down to the perirectal fat with a 1 cm margin (Figs. 157–4 and 157–5). Following removal, the specimen is re-oriented for the pathologist and all the rectal incisions are closed in a either a longitudinal or transverse manner in order to avoid narrowing of the rectum, using an absorbable suture (Fig. 157–6). An air test should be performed, filling the operative field with sterile saline, and insufflating air in the rectum in order to check for air leaks in the suture line. Once these air leaks are controlled, the levator ani is reapproximated in the midline, and the anal coccygeal ligament is re-attached to the sacrum.

An uncommon but severe complication of this procedure is the development of a fecal fistula that extends
