Motility Disorders of the Stomach and Small Intestine

John E. Meilahn

GASTRIC MOTILITY

Normal gastric emptying reflects a coordinated function of the gastric fundus, corpus, antrum, pylorus, and duodenum. Proper gastric emptying thus involves a sequence of events involving all of these structures. Eating a meal causes receptive relaxation of the fundus for gastric storage. Subsequent fundic contraction is important for emptying liquids from the stomach. The gastric pacemaker is located in the body along the greater curvature and stimulates filling and mixing of food in the corpus and antrum. Food is sequentially mixed to and fro in the antrum against pyloric resistance in the process of trituration until food particles are ground down. Subsequent antral peristalsis, at the rate of three per minute, with associated pyloric relaxation allows small particles and liquids to pass to the duodenum. Therefore, the stomach may be thought of as three regions of motility that must act in a coordinated fashion to produce acceptable emptying of the stomach: the fundus, with relaxation and subsequent contraction; the body, with filling and mixing; and the antropyloroduodenal complex, with trituration and emptying into the duodenum as the pyloric sphincter opens.

Symptoms of abnormal gastric motility are nonspecific and generally include nausea, vomiting, epigastric fullness, postprandial bloating, and heartburn. The list of differential diagnoses includes gastroparesis, rapid gastric emptying as in dumping syndrome, functional dyspepsia with impaired fundic distention, ulcer, cancer, gastroesophageal reflux disease, rumination syndrome, cyclic vomiting syndrome, bulimia, and superior mesenteric artery (SMA) syndrome. Organic causes may be diagnosed with a combination of upper endoscopy, enteroscopy and enteroclysis, upper gastrointestinal (GI) series, or upper GI series with small bowel follow-through. If these studies are inconclusive, further testing along with gastroenterologic consultation is necessary to differentiate between nonorganic causes.

Gastroparesis

Gastroparesis is delayed gastric emptying in the absence of specific organic causes, such as stricture, ulcer, tumor, SMA syndrome, or mechanical obstruction, or of nonorganic causes, such as functional dyspepsia, rumination syndrome, cyclic vomiting syndrome, or bulimia/anorexia nervosa. Abnormal peristaltic contractile activity and abnormal electrical slow waves are usually present. Females are most often affected (about 80% female, 20% male), with the average age at onset of symptoms being about 34 years. Causes are evenly divided between diabetes and idiopathic (about 28% each), with other causes including postviral, postsurgical (especially with intended or inadvertent vagotomy), Parkinson's disease, scleroderma, and pseudo-obstruction. The predominant symptoms are nausea and vomiting with abdominal bloating and early satiety. Epigastric abdominal pain may be present in about half the patients, and some of them have become dependent on narcotics. Abdominal pain, in general, is not well treated by gastric electrical stimulation or by prokinetic drugs.[1]

The diagnosis of gastroparesis is usually made by the gastroenterologist after extensive testing to rule out other causes. Evaluation of gastric emptying by scintigraphy may be diagnostic of gastroparesis, with more than 50% of a solid meal being retained 2 hours after ingestion or more than 10% of a solid meal being retained at 4 hours. Liquid emptying, although quantifiable, is less accurate in the diagnosis of gastroparesis because liquids may empty normally even with an abnormal solid emptying scan. Either a ^{99m}Tc–sulfur colloid–labeled egg sandwich or an Eggbeaters meal is used as a test meal for the solid emptying scan. Though not commonly used in clinical settings, breath testing for gastroparesis can be performed with ^{13}C-labeled octanoate in a solid meal, which is absorbed in the small bowel after gastric emptying, metabolized there to $^{13}CO_2$, and then removed by respiration.[1]

General principles for the treatment of gastroparesis are to correct fluid and electrolyte abnormalities, as well as nutritional deficiencies, identify and treat any underlying causes, and suppress or eliminate symptoms such as nausea or vomiting. Diets may be changed toward softer solid foods and more toward liquid supplements, with smaller, more frequent meals. Total parenteral nutrition (TPN) may be necessary to provide the daily caloric intake for maintenance of body weight. In a diabetic patient, tight glucose control should be achieved because hyperglycemia may worsen gastroparetic symptoms. Hyperglycemia can impair both antral contractions and antropyloric coordination. The mainstay of medical treatment is the use of both antiemetic and prokinetic medications.[1]

Antiemetic agents useful in treating gastroparesis include prokinetic agents with antiemetic properties, such as metoclopramide (Reglan) or domperidone (Motilium). Phenothiazine derivatives, which antagonize dopamine receptors in the area postrema, include prochlorperazine (Compazine) and trimethobenzamide (Tigan). Antihistamines with H_1–receptor antagonist properties include diphenhydramine (Benadryl), promethazine, and meclizine (Antivert). Antiserotoninergics, which antagonize 5-hydroxytryptamine ($5\text{-}HT_3$) receptors, include ondansetron (Zofran), granisetron (Kytril), and dolasetron (Anzemet). Other agents include scopolamine, an anticholinergic, and aprepitant (Emend), a substance P/neurokinin-1 receptor antagonist.[1]

Not many effective prokinetic agents are currently available. Metoclopramide (Reglan) is the only Food and Drug Administration (FDA)-approved agent for gastroparesis, but it produces central nervous system side effects in 10% to 20% of patients. Cisapride (Propulsid) was approved only for the treatment of heartburn and was taken off the market in 2000 because of prolongation of the QT interval. Although domperidone (Motilium) has both prokinetic and antiemetic properties, it has not been approved by the FDA and is available only outside the United States. Erythromycin is useful as a motilin agonist, but it may have GI side effects of nausea, vomiting, and abdominal pain and is known to have decreasing effect as a result of tachyphylaxis.

Botulinum Toxin Injection

Because pyloric sphincter opening is the final step in gastric emptying, pyloric relaxation via injection of botulinum toxin A (Botox) into the pyloric sphincter may improve symptoms in those with idiopathic or diabetic gastroparesis. Botulinum toxin inhibits cholinergic neuromuscular transmission and has been used in multiple areas of the GI tract, including the lower esophageal sphincter to treat achalasia[2] and the anal sphincter to treat anal fissures. Multiple injections of botulinum toxin are placed circumferentially at endoscopy into the prepyloric area (within 2 cm of the pyloric channel). If there is a beneficial effect from injection, the process may be repeated at several-month intervals.

In a retrospective study at Temple University Hospital, 63 patients (53 females and 10 males with a mean age of 42 years) with gastroparesis were injected with botulinum toxin A.[3] Major symptoms were vomiting, nausea, and abdominal pain. Less than 10% had early satiety, decreased appetite, bloating, or weight loss as their major symptoms. None had a previous injection, and all had at least a 4-week follow-up after treatment (mean length of 9.3 months with a range of 1 to 37 months). Treatment consisted of five circumferential injections into the prepyloric area with a total of 100 to 200 U of botulinum toxin. There were no complications from endoscopy or the injection of toxin. Antiemetic and prokinetic agents were generally continued after injection, but gastric emptying studies were not usually performed. A positive symptomatic response was observed in 27 (42.9%) of the 63 patients, with a mean duration of response of 4.0 ± 2.7 months. Nine of the 27 responders had improvement for more than 6 months, all of whom were female. Fourteen of the 27 responders experienced complete resolution of all of their symptoms, with a duration of response of 5.1 ± 2.8 months. Females and patients older than 50 years had a better response rate than males and younger patients did.

Gastric Electrical Stimulation

Several different approaches have been used in gastric electrical stimulation in an effort to improve either gastric emptying or symptoms of gastroparesis. Because the intrinsic gastric pacemaker located along the greater curvature produces antral stimulation at 3 cycles per minute (cpm), low-frequency stimulation was used in an attempt to entrain and pace the gastric slow waves at 3.3 cpm to accelerate gastric emptying through possible activation of motor efferent nerves. Although the concept seems promising and has been reported in a small series of nine patients,[4] with improvement in both gastric emptying and symptoms of gastroparesis, this approach is not currently being used. *Sequential circumferential muscle stimulation* involves the use of bursts of suprahigh-frequency electrical stimulation to produce propagated antral contractions and to accelerate gastric emptying; however, this technology has not made the transition to actual clinical practice. In contrast, high-frequency stimulation is now being used in clinical practice for the treatment of both idiopathic and diabetic gastroparesis. With electrical stimulation at 12 cpm, symptoms improve in up to 60% of patients. It is thought that such stimulation activates sensory afferent nerves rather than increasing antral contractions. In addition, gastric emptying studies after stimulation may show little change in actual gastric emptying even though the gastroparetic symptoms may have improved.[5]

Medtronic (Enterra) Gastric Electric Stimulation Using high-frequency, low-energy, short-pulse electrical stimulation at 12 cpm, the Enterra stimulator with two electrical leads has been approved by the FDA for the treatment of patients with chronic, intractable (drug refractory) nausea and vomiting secondary to gastroparesis of diabetic or idiopathic origin. Ideally placed in patients who have previously undergone gastric surgery, the stimulator has also been used in those with an existing

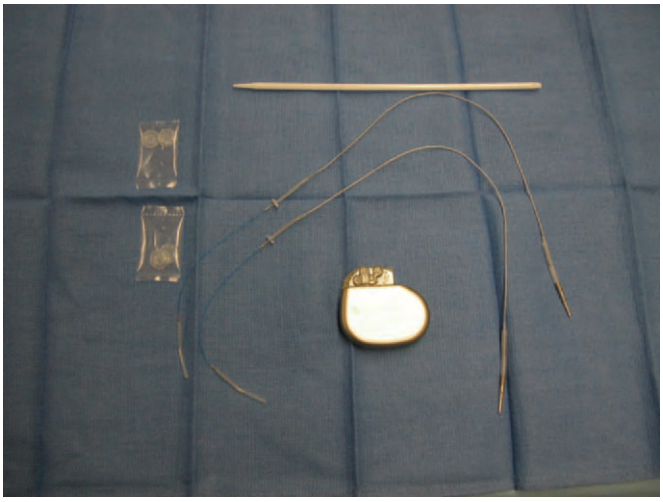

Figure 62–1. Enterra gastric electric stimulator system, with two Enterra leads, an introducer rod, plastic disks, and Enterra stimulator.

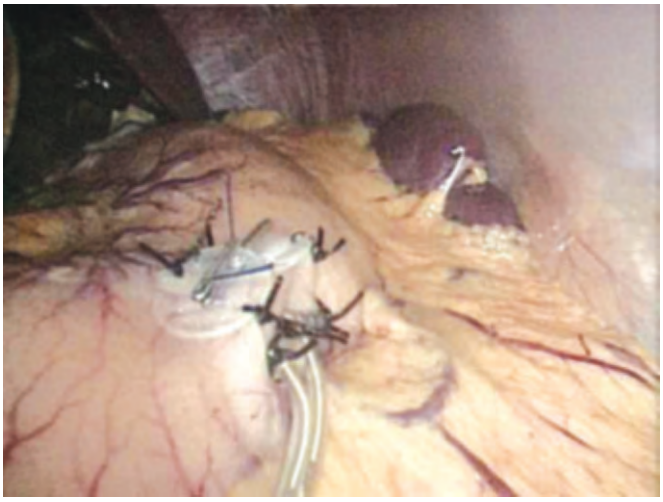

Figure 62–2. The Enterra leads are placed in the gastric wall 10 and 11 cm proximal to the pylorus and secured with plastic disks.

venting gastrostomy and feeding jejunostomy tubes. The beneficial effect of the stimulator may not be clinically apparent for several months, although some patients do report early improvement in well-being.

The stimulator package consists of a Medtronic Enterra stimulator (sized much like a cardiac pacemaker) and two insulated wire electrodes with an uninsulated metal tip connected to a monofilament suture with a straightened needle (Fig. 62–1). The two electrodes are positioned along the anterior greater curvature of the stomach, separated by about 1 cm. The most distal electrode is located about 10 cm proximal to the pylorus.[5] Both electrodes are placed parallel to each other, with partial-thickness penetration into the muscularis. The attached plastic flange of each electrode is sutured to the serosa to prevent dislodgement. Electrode placement may be done laparoscopically,[6] although needle and electrode passage in partial-thickness fashion is more difficult laparoscopically than with an open procedure, which can be performed through a small upper midline incision. In either case, upper endoscopy is recommended at the time of electrode placement to exclude full-thickness gastric wall penetration. If noted, the electrode can be repositioned and sutured (Fig. 62–2).

The stimulator itself is placed in a subcutaneous pocket on the abdominal wall in a location consistent with the patient's wishes, previous surgical procedures, and the potential need for future feeding tubes. The right side of the abdomen is preferred over the left for at least two reasons. First, space may need to be preserved for placement of a future venting gastrostomy tube or a feeding jejunostomy tube in the event that the stimulator does not reduce nausea, vomiting, or malnutrition. Second, if there are current venting/feeding tubes on the left, positioning the stimulator also on the left may increase the risk for contiguous spread of infection to the

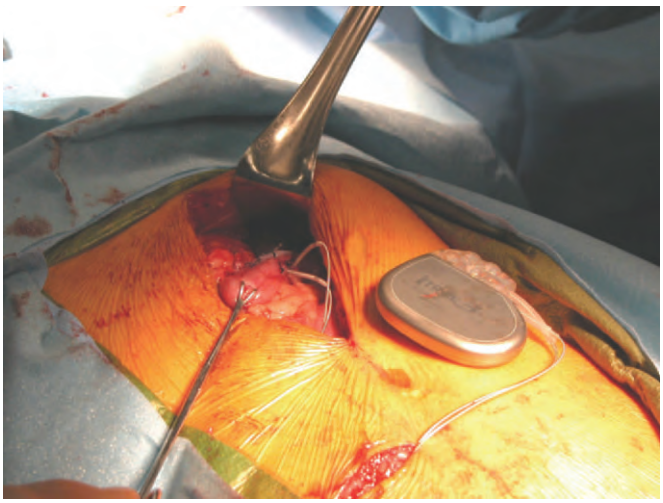

Figure 62–3. Open placement of the Enterra stimulator in a right lower quadrant pocket. Leads may be placed laparoscopically as well.

stimulator pocket if an infection or cellulitis develops at the tube site. A right upper quadrant location is easily facilitated unless the patient is short and thin, in which case the device may impinge on the costal margin when sitting. If a lower abdominal location is chosen, the stimulator should not be placed so low that it is forced upward when the patient sits. Both electrodes are brought through the abdominal wall with a trocar or provided tunneler and then connected to the stimulator (Fig. 62–3).

Next, the electrical resistance of the circuit through the gastric wall is determined before closure of the incisions. Transcutaneous interrogation of the stimulator

is performed with a sterile plastic drape–wrapped transducer connected to the Enterra computer. A typical impedance value of less than 800 ohms is satisfactory. If the impedance is greater, the electrodes could be too far apart and may need to be positioned more closely together. After closure of the incisions, the stimulator may be left in the *off* position for the first day. Nausea and vomiting are common after surgery and anesthesia, and because the stimulator is unlikely to diminish these early symptoms, it may be psychologically better to delay activation for a day until the immediate postoperative symptoms subside.

Risks associated with the gastric electrical stimulator include full-thickness penetration of the gastric wall at the time of placement or erosion into the gastric lumen with subsequent infection or abscess. Dislodgement of the leads from the stomach is possible in the early postoperative period if the plastic flanges have been inadequately sutured. Moderate fibrosis subsequently covers the lead implant sites on the stomach, thus making dislodgement a remote possibility. The presence of two looping wire electrodes within the abdomen can lead to small bowel obstruction. This possibility is quite small with the omentum in its normal configuration because the electrodes are positioned in the upper part of the abdomen and on top of the omentum. However, previous major abdominal surgery such as colectomy or partial small bowel resection may predispose to small bowel obstruction unless the electrodes are sutured loosely to the upper abdominal wall at the time of placement. It is unusual for the electrodes to become adherent to the abdominal viscera, but if it does occur, subsequent dissection of the electrodes from surrounding attachments does risk cutting the insulating layer and negating the effect of the stimulator. Hematoma may develop in the subcutaneous pocket for the stimulator in the postoperative period, either from vessels within the pocket or from the abdominal wall as a result of passage of an electrode through it. Subsequent infection or abscess at the stimulator site mandates removal of it. Erosion of the stimulator through the skin, even without cellulitis, is also treated by removal. Placement of the stimulator in the lower portion of the abdomen is sometimes complicated by local pain when sitting, either from displacement of the stimulator upward in the sitting position or from pressure on local nerves. This problem is treated by relocation of the stimulator to a more cephalad position, with care taken to not position it under a skin fold of the abdomen. Magnetic resonance imaging (MRI) is not possible after stimulator placement. If there has been no therapeutic effect from placement of the stimulator and MRI is needed to evaluate another body area, the electrodes and stimulator are removed. Laparoscopy allows evaluation and dissection of the electrodes up to the gastric wall; traction alone usually allows removal of the leads with mechanical cutting of the wires at the stomach if necessary.

At Temple University Hospital, 28 patients with a mean age of 40 years underwent Enterra implantation over an 18-month study period, with an average follow-up of 148 days.[7] Of these 28 patients, 14 felt improved, 8 remained the same, and 6 worsened according to the validated Gastroparesis Cardinal Symptom Index (GCSI) questionnaire scoring. The overall GCSI score significantly decreased by 12% ± 7%, with improvement in nausea and vomiting but no improvement in bloating or abdominal pain. The decrease in GCSI score was greater for the 12 diabetic patients (18% ± 11%; $P < .05$) than for the 16 idiopathic patients (7% ± 9%; P = NS). The subgroup of 22 patients with a chief complaint of nausea/vomiting had greater improvement (16% ± 9%; $P < .05$) than did the 6 patients with a chief complaint of abdominal pain (3% ± 11%; P = NS). The 13 patients taking narcotic analgesics at the time of Enterra implantation had a poorer GSCI response (increasing by 9% ± 10%; P = NS) than did the 15 who were not. As a result, three clinical parameters associated with a favorable clinical response to implantation were identified: diabetic rather than idiopathic gastroparesis, nausea/vomiting rather than abdominal pain as the primary symptom, and independence from narcotic analgesics before stimulator implantation.

Gastric Electrical Stimulation for Postsurgical Gastroparesis Gastric electrical stimulation is most commonly used on an intact stomach, without previous resection or surgery, except for prior gastrostomy tube placement. Postsurgical gastroparesis may develop in up to 10% of patients who have undergone vagotomy, in the absence of mechanical obstruction, and in up to 50% of those with chronic gastric outlet obstruction before surgery. Gastroparesis has been associated with partial gastrectomy, fundoplication, esophagectomy with colon interposition, and pylorus-preserving Whipple procedures. Gastric electrical stimulation is not usually thought to be suitable in these cases. However, McCallum et al. reported the application of electrical stimulation for postsurgical gastroparesis, including gastroparesis after Nissen fundoplication, vagotomy and pyloroplasty, Billroth I and vagotomy, Billroth II and vagotomy, spinal surgery, esophagectomy with colonic interposition, and cholecystectomy.[8] Sixteen patients (15 female, 1 male) with a diagnosis of gastroparesis for more than 1 year and refractoriness to antiemetics and prokinetics underwent implantation of the Enterra stimulator. In cases of antrectomy, the two electrodes were positioned within the muscularis propria 2 and 3 cm proximal to the gastric anastomosis. In those with an intact stomach, the electrodes were positioned in the usual manner at 10 and 11 cm proximal to the pylorus. Gastrostomy tubes were removed; however, feeding jejunostomy tubes were placed in 7 patients because of existing malnutrition. All patients were then monitored for at least 12 months. At 6 months after implantation, the severity and frequency of upper GI symptoms (vomiting, nausea, early satiety, bloating, postprandial fullness, and epigastric pain) were significantly reduced, and the improvement over the initial baseline state was sustained at 12 months ($P < .05$). Hospitalization for gastroparesis symptoms, which averaged 31 ± 13 days for the year preceding stimulator implantation, was reduced to 6 ± 2 days ($P < .05$) during the first year after implantation.

Gastric electrical stimulation in an intact stomach is not thought to generally improve symptoms by improve-

ment in gastric emptying, verifiable by scintigraphy. However, some patients may demonstrate improvement or normalization of gastric emptying rates by scintigraphy.[6] Retrograde stimulation of the vagal nerves has been thought to be a possible mode of symptom improvement, and therefore it may be questioned whether improvement should be expected after placement of a stimulator in those in whom vagotomy or inadvertent vagal injury has already occurred. Although vagal nerve damage or disruption was thought to be part of the underlying pathophysiology of these 16 postsurgical patients, electrical stimulation was still effective in improving symptoms. Moreover, our experience at Temple is that in an intact stomach (with no divided vagus nerves), diabetic patients improve more than idiopathic gastroparetic patients. Some neuropathy is characteristic of diabetes, which implies that vagal dysfunction was present before stimulator implantation; it also implies that gastric electrical stimulation can be effective without normal vagal function.

Surgical Procedures

When prokinetic and antiemetic medications alone are not sufficient to maintain body weight, venting and feeding tubes are used. A percutaneous gastrostomy tube alone may reduce the incidence of vomiting through intermittent venting or by setting the tube at continuous external drainage. Previous upper abdominal surgical procedures may indicate the need for laparoscopic or open gastrostomy tube placement instead of the endoscopic approach. A combination transgastric gastrojejunal tube can vent the stomach and also provide proximal jejunal tube feeding. Although the concept is attractive, it is more difficult to place the tube properly and maintain correct placement in the proximal jejunum. In addition, this combination tube design is subject to proximal displacement of the jejunal tube, with repeated bouts of emesis. The jejunal end of the tube may be forced back into the duodenum or even back into the stomach with repeated vomiting.

Placement of a feeding jejunostomy tube allows the provision of both adequate nutrition and fluids and can help reduce the need for hospitalization for intravenous repletion of fluids. Placement of both a gastrostomy tube for gastric venting and a jejunostomy tube for fluids and nutrition allows many patients with gastroparesis to manage their symptoms and improve their quality of life. Enteral feeding is preferred over parenteral nutrition because of lower overall cost and avoidance of more severe complications from central intravenous access. Enteral feeding via the jejunostomy tube may be maintained for months or years. Potential complications of a feeding jejunostomy include tube dislodgement with closure of the opening, infection and cellulitis at the site, and leakage from the site if the tract enlarges, which would require the insertion of a larger-diameter feeding tube. If small bowel dysmotility accompanies the gastroparesis, tube feed rates may need to be limited because of the nausea, pain, or bloating that may occur with normal rates of feeding. If ongoing weight loss then occurs, TPN is mandated via a PICC (percutaneous indwelling central venous catheter) line or tunneled central venous catheter. More aggressive surgical procedures have not been found to reliably reduce gastroparetic symptoms. Such procedures include pyloroplasty, gastrojejunostomy, and partial gastric resection. If gastric resection is chosen, a near-total gastrectomy with creation of a small proximal gastric pouch via a vertical staple line, as performed for a gastric bypass procedure, should be considered if blood supply is adequate. Additionally, a Roux gastrojejunostomy with at least a 15-mm opening, a short Roux limb, and a feeding jejunostomy should be performed.

Postsurgical Gastroparesis

After previous gastric procedures, complete evaluation of the gastric remnant and any anastomosis should be performed. An upper GI series will evaluate the overall morphology and may help assess for possible partial obstruction. Gastric emptying studies may be performed to evaluate the existing stomach if obstruction is not noted on the upper GI study. Endoscopic examination should be performed to examine the stomach for gastritis, the presence of *Helicobacter pylori,* ulcers, and the diameter and state of the anastomosis, as well as the possible presence of a marginal ulcer. If ulceration or friability is noted, medical treatment with proton pump inhibitors and sucralfate suspension and avoidance of nonsteroidal anti-inflammatory drugs may permit healing. A stricture may be balloon-dilated endoscopically if it is not overly fibrotic and if active inflammation is not present.[9] A perforation may occur if the dilation is overly aggressive, so limited dilation at one setting is advised. The dilation may be repeated one or more times for sequential enlargement of the anastomosis, up to 15 to 20 mm in diameter with current balloons. A wire-guided balloon catheter is safer for an initial dilation if the gastroscope cannot be passed through the anastomosis because the wire guide helps prevent perforation of the nonvisualized bowel distal to the stricture when the balloon is inflated. A gastroscope with a large working channel will be necessary if a wire-guided balloon is used.

If persistent marginal ulceration remains at the anastomosis after medical therapy (including treatment of *H. pylori* if present) or if an anastomotic stricture cannot be suitably dilated, surgical revision of the anastomosis should be considered. Revision should include completion vagotomy if there is a persistent ulcer, along with additional gastric resection. Before performing a larger operation, thoracoscopic truncal vagotomy should always be considered. If vagotomy and antrectomy have previously been performed, consider a subtotal (75%) gastrectomy. If subtotal gastrectomy has previously been performed, consider a near-total gastrectomy. If a recurrent ulcer is present after previous Roux gastroenterostomy, consider re-resection to a 95% gastrectomy with Roux gastrojejunostomy.[9,10]

In those with chronic postvagotomy, postgastrectomy gastric stasis, even aggressive resection with Roux recon-

struction may not produce satisfactory outcomes. The results of near-total completion gastrectomy for severe postvagotomy gastric stasis in 62 patients (51 female, 11 male) at the Mayo Clinic were followed for more than 5 years.[11] In these patients the gastric remnant was largely resected, with a 1- to 2-cm remnant of gastric cardia left for the gastrojejunostomy. Despite a median of four previous gastric operations and symptoms of nausea, vomiting, postprandial pain, chronic abdominal pain, and chronic narcotic use, all or most symptoms were relieved in 43% of those operated on (Visick grade I or II). However, the rest remained in Visick grade III or IV. Although nausea, vomiting, and postprandial pain were improved, chronic pain, diarrhea, and dumping syndrome were not significantly improved.

Roux Stasis Syndrome

Roux stasis syndrome is a term that has been applied to symptoms of early satiety, vomiting, and postprandial pain occurring after distal gastrectomy with Roux gastrojejunostomy; it affects up to 30% to 50% of such patients.[9] It was postulated that ectopic pacemakers occur in the Roux limb and cause orally directed Roux limb contractions, as well as aboral contractions, thereby resulting in functional obstruction to gastric emptying. Most of these patients underwent vagotomy as part of their initial surgical procedure. Although Roux limb motility may be affected by division of its mesentery, it is also likely that gastric stasis plays a significant role in producing symptoms. Endoscopy may show gastric bezoar formation or dilation of the gastric remnant, as well as possible dilation of the Roux limb. Improvement after near-total gastrectomy in patients with previous vagotomy suggests that the gastric stasis component was more significant than the effect in the Roux limb itself.[9] Moreover, current experience with Roux gastric bypass procedures for morbid obesity tends to support this concept. In most gastric bypasses, vagotomy is not performed and a small gastric pouch not based on the fundus is retained. Postprandial pain and vomiting do not usually occur in these patients. Early satiety seems to be a function of the small pouch and the controlled size of the gastrojejunostomy. In patients with a dilated gastrojejunostomy in which food more rapidly enters the Roux limb from the pouch, early satiety and vomiting do not generally occur. Instead, more food can be ingested, and feelings of hunger usually return more quickly as a result. The Roux syndrome is therefore more likely to primarily be postoperative gastric atony.

INTESTINAL MOTILITY

In the fasting state, small intestinal motility is controlled by the migrating motor complex (MMC), which exhibits three phases. Phase I is a quiescent period and represents 20% to 30% of the total cycle length. Phase II accounts for 40% to 60% of the total cycle length and is characterized by intermittent and irregular contractions. In phase III, intense, rhythmic contractions develop and propagate from the proximal to the distal portion of the intestine over a 5- to 10-minute period. The MMC cycle occurs about every 90 minutes during the interdigestive period. However, after a meal, this fasting pattern of intestinal motility is changed to a postprandial pattern, with intermittent phasic contractions of irregular amplitude that are similar to the phase II contractions of the MMC.[12] Peristalsis occurs when a segment of circular muscle contracts as a result of excitatory motor neurons while the intestinal segment aboral to the contracted segment is simultaneously relaxed by inhibitory neurons.[13]

The interstitial cells of Cajal (ICCs) are known to be essential regulators of GI motility and seem to serve as pacemaker cells in the GI tract and mediators of neural regulation in GI motility. They lie in close proximity to smooth muscle cells and elements of the enteric nervous system. The generation of slow waves occurs within Auerbach's plexus and is an intrinsic property of ICCs; both circumferential intestinal contractions and longitudinal contractions are produced.[13] ICC abnormalities are increasingly being recognized in a number of GI tract disorders, such as chronic intestinal pseudo-obstruction, with findings of decreased ICCs or an abnormal ICC network.[14,15] Surgical procedures involving the small intestine produce disruption of ICC networks at the level of the myenteric and deep muscular plexuses, with resultant loss of slow waves and phasic contractions. This loss of intestinal motility, however, partially recovers within 24 hours after surgery.[16]

Because intestinal motility is controlled by interactions between smooth muscle, enteric nerves, extrinsic nerves, and humoral factors, abnormalities in each of these areas may result in intestinal dysmotility. Small intestinal dysmotility symptoms include abdominal bloating, distention, pain, nausea, and vomiting. Primary disorders of small intestinal dysmotility include inherited familial visceral myopathies, characterized by smooth muscle degeneration, and familial visceral neuropathies, characterized by the degeneration of enteric nerves. Secondary causes of small intestinal dysmotility include myopathic processes (scleroderma, muscular dystrophies, amyloidosis), neurologic diseases (Parkinson's disease, neurofibromatosis, Chagas' disease), endocrine disorders (diabetes mellitus, hyperthyroidism, hypothyroidism, hypoparathyroidism), celiac disease, and pharmacologic agents (anti-Parkinson medications, phenothiazines, tricyclic antidepressants, narcotics).[17]

Smooth muscle disease such as scleroderma frequently affects the GI tract, and small intestinal dysmotility develops in about 40% of such patients. Proximal involvement leads to megaduodenum or wide-mouth diverticula of the small bowel, with delayed transit, bacterial overgrowth, and malabsorption. Octreotide has been useful in treating stasis and the resultant bacterial overgrowth. Muscular dystrophies affect motility of the entire gut; although barium studies may be normal, small intestinal manometry may reveal a myopathic pattern. Amyloidosis produces infiltration of both smooth muscle and the autonomic nerves and affects the motility of the entire GI tract.[17]

Neurologic disease is most commonly seen with Parkinson's disease, with degeneration of the enteric nervous system and inhibition of intestinal motility by anti-Parkinson medications. Neurofibromatosis may produce dysmotility as a result of mechanical obstruction with GI tract tumor formation, but it is also associated with neuronal dysplasia of the enteric nervous system. Chagas' disease (infection with *Trypanosoma cruzi*) results in neuronal injury and is manifested as megaduodenum, megajejunum, or pseudo-obstruction.[17] Hirschsprung's disease or its allied disorders hypoganglionosis and intestinal neuronal dysplasia may produce small intestinal dysmotility.[18]

Endocrine disorders may give rise to intestinal dysmotility that may be treated. Hypothyroidism produces delayed transit, constipation, and pseudo-obstruction, which is reversible with thyroid hormone replacement. Hypoparathyroidism may be associated with small intestinal dysmotility and pseudo-obstruction, which improve with calcium repletion. Small intestinal complications of diabetes with autonomic neuropathy include delayed transit with bacterial overgrowth and diarrhea. Celiac sprue produces abdominal pain, distention, and malabsorption, with delayed intestinal transit, bacterial overgrowth, and pseudo-obstruction.[19] Both villous damage and small intestinal dysmotility improve with a gluten-free diet.[17]

GI motility is enhanced by the stimulation of distinct serotonin (5-HT) receptors on intestinal sensory nerves. 5-HT is released from mucosal enterochromaffin cells in response to mechanical and chemical stimuli within the intestine. 5-HT activates 5-HT_4 receptors on nerves synapsing in the myenteric plexus, which then results in motor responses and increased peristalsis and intestinal transit.[16] Tegaserod, a selective 5-HT_4 partial agonist, has been shown to significantly accelerate small bowel transit time, as well as gastric emptying.[20]

Diagnosis of Intestinal Dysmotility

After the history, physical examination, and conventional radiographic studies suggest the possibility of intestinal dysmotility, an upper GI study with small bowel follow-through should be performed. This study should suggest the possibility of obstructing lesions such as tumor, stricture, diverticula, or adhesions and, in their absence, may identify general small bowel dysmotility. Evaluation of small intestinal transit may be then done by small bowel scintigraphy, with imaging up to 6 hours after ingestion of a radiolabeled meal. Scintigraphy has a specificity of up to 75% for the diagnosis of dysmotility, but it does not differentiate between myopathic and neuropathic causes.

Small bowel manometry is then performed if abnormal small bowel transit is found to be present. In the interdigestive period the MMC is monitored to examine the cycle duration (interval between phase III events), the duration of each phase, including the amplitude and propagation velocity of phase III, and the rate of contraction of phase III. A motility disorder is present with abnormal bursts of phasic activity, low-amplitude contractions, poorly coordinated activity, or absent, incomplete, or retrograde phase III activity. With eating, a change to typical postprandial activity is expected, with irregular, phasic contractions of variable amplitude as the intestinal contents are mixed and propelled distally. This postprandial period lasts for about 4 hours, and then a return to the interdigestive pattern should be noted. Whereas short-duration (2-hour) manometry studies may diagnose abnormalities while a patient is in the fed or postprandial state, longer study periods facilitate study in the interdigestive period as well. This concept has been extended to ambulatory study systems in an attempt to improve diagnostic accuracy. Manometry may also help distinguish myopathic causes of dysmotility from neuropathic causes.

Pharmacologic Treatment

Octreotide has been used to treat the chronic pseudo-obstruction and bacterial overgrowth seen with dysmotility from connective tissue diseases such as scleroderma. It induces phase III–like activity in the small intestine; however, it also decreases antral activity.[17] The addition of erythromycin, a motilin agonist, stimulates gastric emptying and also intestinal contractions at low doses. Tegaserod, a 5-HT_4 partial agonist, has been shown to accelerate small bowel transit time, as well as increase both gastric emptying and colonic transit.[17,20]

Surgical Treatment

Surgical options for the treatment of nonmechanical small intestinal dysmotility are limited. Mechanical causes of slow bowel transit, abdominal pain, or small intestinal dilation should first be investigated. The differential diagnosis includes luminal webs, polyps, carcinoid, duplication, internal hernias, intussusception, adhesions, malrotation, SMA syndrome, chronic gut ischemia, inflammatory bowel disease, radiation enteritis, and neoplasm. Radiographic modalities available for evaluation include upper GI series with small bowel follow-through and computed tomography with both oral and intravenous contrast. Transit studies with radiopaque markers may assess small intestinal motility. Upper endoscopy with enteroscopy allows evaluation of the proximal jejunum and also permits mucosal biopsy. Small intestinal manometry allows assessment of the MMC.

If radiologic and gastroenterologic studies have not enabled a diagnosis to be made, the surgeon may be requested to perform diagnostic laparoscopy. In a patient without extensive previous surgery, laparoscopy affords an adequate examination of the small intestine from the ligament of Treitz to the terminal ileum. Conversion to exploratory laparotomy may be indicated with previous surgery or with questionable findings at laparoscopy. If requested, a feeding jejunostomy tube may be placed and a full-thickness jejunal biopsy performed to evaluate for visceral myopathy or neurogenic causes of small bowel dysmotility and chronic intestinal pseudo-obstruction.[21]

Small bowel resection is uncommonly performed, although localized findings may justify segmental resection. Isolated megaduodenum (type I familial visceral myopathy) has been treated by either drainage or subtotal duodenal resection, with the posterior biliopancreatic duodenal wall left intact and the proximal jejunum used as an onlay patch.[17,22] Primary amyloidosis confined to the small intestine has been reported in the setting of persistent pseudo-obstruction and has been treated by partial jejunectomy.[23]

Chronic intestinal pseudo-obstruction in the pediatric population may occur as a result of short-gut syndrome after resection for intestinal aganglionosis or as a result of neuropathic or myopathic causes. When intestinal failure leads to permanent dependence on parenteral nutrition, patients are at risk for liver failure, eventual loss of central venous access, and catheter sepsis.[24] Small bowel transplantation with immunosuppressive treatment may be indicated for a subset of these patients and has resulted in improved outcomes. Early referral for transplantation should be considered once permanent TPN has become necessary. Multivisceral transplantation in children has also been reported, with 88.9% and 77.8% survival rates at 1 and 2 years, respectively, and all long-term survivors tolerating enteral feeding and off parenteral nutrition.[25] Intestinal and multivisceral (stomach, duodenum, pancreas, and intestine, with or without liver) transplantation has been extended to the adult population as well for short-bowel syndrome caused by intestinal infarction and for intestinal failure caused by chronic intestinal pseudo-obstruction.[26] With a mean age of 34.8 years and a mean TPN duration of 5.8 years, the 1-year graft survival rate was 88.4% for an isolated small bowel transplant and 42.8% for multivisceral transplants; the overall mortality rate was 18.5%.

Operations for Morbid Obesity

Robert E. Brolin ▪ Christopher Kowalski

THE OBESITY EPIDEMIC

Prevalence

The term *epidemic* has frequently been used to describe the dramatic increase in the prevalence of both overweight and obesity in the United States. It was recently estimated that approximately two thirds of adults in the United States are overweight, with a body mass index (BMI) greater than 25 kg/m^2, and that nearly half are obese, with a BMI greater than 30 kg/m^2.[1] Other reports suggest that the most rapid increases in prevalence are seen in the most severely obese subgroups.[2] It is estimated that nearly 24 million Americans are severely obese, with a BMI greater than 35 kg/m^2, and that more than 8 million are morbidly obese, with a BMI greater than 40 kg/m^2.[3] The rate of obesity is increasing even more rapidly in children. It was recently estimated that more than 25% of children 17 years or younger are obese.[4] This percentage had more than doubled during the past decade. The prevalence of morbid obesity, a BMI greater than 40 kg/m^2, may be increasing at a more rapid rate. There are a number of recent reports of severe obesity-related comorbid conditions in children, including type 2 diabetes, hypertension, hyperlipidemia, and sleep apnea syndrome.

Health Risk, Mortality

Entering the new millennium, it was estimated that obesity is the second leading cause of preventable deaths in the United States and that it accounts for approximately 300,000 deaths annually.[5] Moreover, it was projected that because of rapidly increasing prevalence, obesity would soon overtake cigarette smoking as the foremost cause of preventable deaths. The prevalence of complications related to severe obesity increases sharply at a level corresponding to approximately 60% above desirable weight. At that level there is a twofold increase in morbidity and mortality. However, the slope of the "risk curve" rises almost exponentially above the 60% overweight level such that the complication rate corresponding to 100% above ideal weight is in the range of 13 to 14 times normal. Unfortunately, there is a paucity of actuarial statistics for adults who are more than 45 kg overweight. These data are particularly lacking in women, who are the most frequent subjects of obesity operations.

The mortality rate associated with *morbid* obesity, or a BMI greater than 40 kg/mg^2, has not been accurately estimated. Until recently, only one study was focused on mortality differences between morbidly obese subjects and normal-weight individuals of similar age and gender. In 1980, Drenick et al. reported a markedly increased mortality rate in morbidly obese males versus age-matched normal-weight men (Fig. 63–1).[6] The most common causes of death in the overweight men in this study were myocardial infarction and stroke. More recently, there have been three published reports in which mortality was compared in surgically treated, morbidly obese patients and a similar age/gender group who did not have surgery. In 1997, MacDonald et al. reported a greater than sixfold increase in mortality among morbidly obese diabetics who for a variety of reasons did not undergo gastric bypass surgery after preoperative evaluation versus a similar age/gender mix of patients who underwent Roux-en-Y gastric bypass (RYGB).[7] In 2004, Flum and Dellinger reported a 1.5 times higher mortality rate over a 15-year period in 62,781 subjects who did not have surgery versus 3328 who had surgical treatment in Washington State.[8] The 1.9% operative mortality rate in the Washington report is at least twice as high as in most published series of bariatric surgical patients.[7,9,10] During the same year, Christou et al. reported 0.68% mortality in surgical patients versus

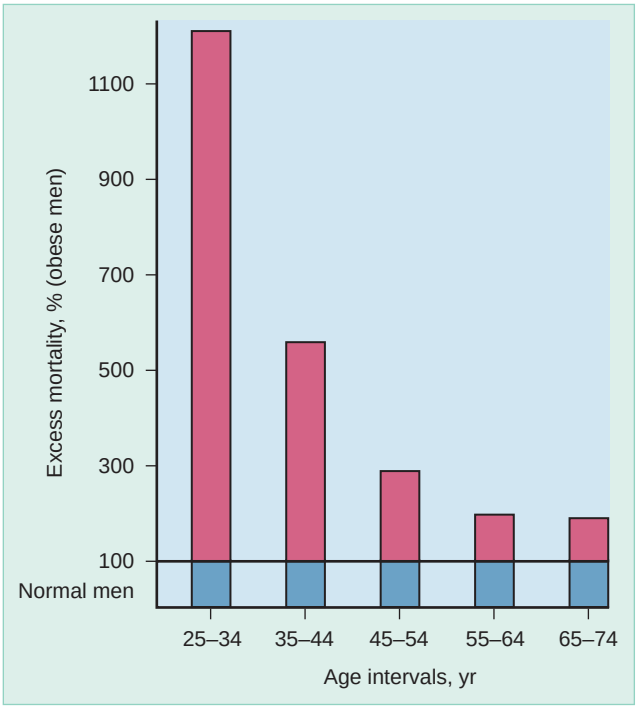

Figure 63–1. Comparison of excess mortality in men with morbid obesity *(red bars)* versus normal-weight men *(blue bars)* by age interval. (From Drenick EJ, Bale GS, Seltzer F, Johnson DG: Excessive mortality and causes of death in morbidly obese men. JAMA 243:443-335, 1980.)

Table 63–1 Diseases Associated with Severe Obesity

Comorbidity	Incidence (%)
Hypertension	20-55
Obesity-hypoventilation/sleep apnea syndrome	20-50
Cholelithiasis	25-45
Degenerative osteoarthritis	20-50
Psychological depression	15-35
Hyperlipidemia	15-25
Diabetes mellitus	10-25
Asthmatic bronchitis	10-15
Coronary artery disease	5-15
Heart failure (right sided and/or left sided)	5-15
Stasis ulcers/venous insufficiency	5-15
Gastroesophageal reflux	5-15
Stress overflow urinary incontinence	5-15
Pseudomotor cerebri	1-2
Sexual hormone imbalance/infertility	—*
Malignancy (uterine, colon, gallbladder)	—*
Pulmonary embolism/thrombophlebitis	—*
Necrotizing subcutaneous infections	—*

Comorbid conditions are listed in the approximate order of reported frequency.
*Lack of specific numerical data in diseases known to be more common in obese patients.

a 6.17% death rate in a similar mix of nonoperative subjects monitored over a 16.5-year period, which represents a greater than 80% reduction in mortality risk in the surgical group.[11]

The health risk associated with severe obesity is intimately related to obesity-related illnesses. Table 63–1 shows a list of diseases associated with severe obesity. Although cardiovascular disease is reported as the leading cause of death in obese patients, the prevalence of cardiovascular symptoms in bariatric surgical cohorts is relatively low. Many obesity-related comorbid condition, such as degenerative arthritis, sleep apnea, and venous stasis, have a profoundly negative impact on *quality of life.*

Obesity-Related Cost

In 2000, the combined estimated direct and indirect costs associated with treatment of obesity and related comorbid conditions approached $117 billion.[1] At the same time, the annual expenditure in weight loss–related endeavors in the United States was conservatively estimated at $30 billion. Medicare is currently re-evaluating its policy on reimbursement for treatment of obesity because of the rapidly rising cost of obesity-related disability and medications used for the treatment of various comorbid diseases.

INDICATIONS FOR SURGERY

The primary premise as well as justification for surgical treatment of morbid obesity has been the compelling evidence that severe obesity is associated with a shortened life span and a variety of other serious medical problems. Severe obesity has been notoriously refractory to virtually every method of nonoperative treatment. The 2-year failure rate of diet and behavior modification in the morbidly obese approaches 100%. Many morbidly obese patients gain substantial weight after unsuccessful attempts at dieting. This so-called yo-yo syndrome is characterized by transient weight loss, followed by greater weight gain, and probably contributes to the refractoriness of nonsurgical treatment of severe obesity. A prospective randomized trial that compared a low-calorie diet with a now discarded method of stapled gastroplasty showed significantly better weight maintenance in the surgically treated group 2 years after intervention.[12] These results suggest that involuntary gastric restriction of oral intake is necessary for long-term weight control in morbidly obese patients.

In 1992 the National Institutes of Health Consensus Development Panel on gastrointestinal surgery for severe obesity recommended criteria for consideration of surgical treatment.[13] The panel recommended that surgical treatment be considered for any patient with a BMI of 40 kg/m^2 or higher who had failed serious attempts at nonsurgical treatment. The panel also recommended

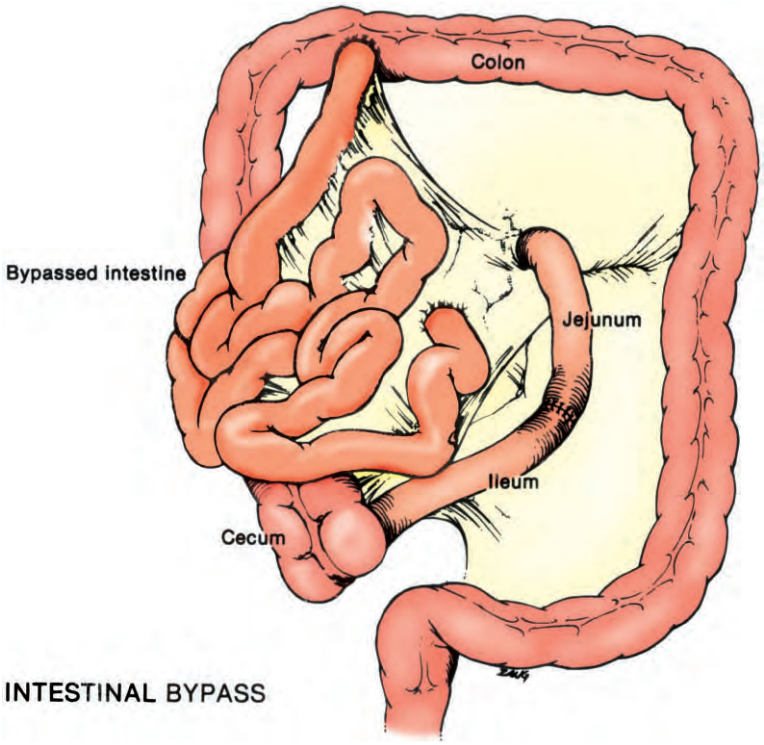

Figure 63–2. Jejunoileal bypass in which a 12-inch segment of jejunum is anastomosed end to end to 6 inches of terminal ileum. The remainder of the small bowel *(dark shaded)* is totally excluded from digestive continuity. The distal end of the excluded bowel is anastomosed to the transverse colon. (From Miller TA [ed]: Modern Surgical Care: Physiologic Foundations and Clinical Applications, 2nd ed. Chapter 68. St. Louis, Quality Medical Publishing, 1998.)

that surgery be considered for patients with a BMI of 35 kg/m^2 or greater who have serious coexisting medical problems such as diabetes, hypertension, hyperlipidemia, or sleep apnea.

Psychological stability should be assessed in some reliable manner before the operation, although standardized psychological tests and interviews with psychologists or psychiatrists have not reliably predicted postoperative outcome after obesity operations. However, many insurance carriers now require a formal psychological evaluation of prospective patients. Patients should also be carefully queried regarding the abuse of addictive drugs and alcohol before having surgery. All patients who undergo surgical treatment of obesity should be admonished that sustained long-term weight loss is not guaranteed merely by having an operation. This understanding is particularly important for patients who undergo gastric restrictive operations, which can be defeated by consuming large quantities of high-calorie liquids and soft junk food.

EARLY BARIATRIC OPERATIONS

Jejunoileal Bypass

The concept of surgery for morbid obesity was introduced by Kremen et al. in 1954 in the form of malabsorption-induced weight loss.[14] After experimenting with various lengths of jejunum and ileum, satisfactory weight loss was reported in patients in whom 30 to 35 cm of jejunum was anastomosed to 10 to 15 cm of terminal ileum (Fig. 63–2). During the 1960s and 1970s, thousands of intestinal bypasses were performed for the treatment of morbid obesity. However, by the mid-1970s, reports of serious late complications appeared in the literature, including hepatic failure, urinary calculi, arthritis, and major nutritional deficiencies. Bacterial overgrowth of the distal bypassed bowel was suspected as the cause of the bypass enteritis syndrome, which was characterized by intermittent episodes of abdominal pain, bloating, arthralgia, rash, and diarrhea. The first public repudiation of jejunoileal bypass was delivered in 1979. Within less than 2 years jejunoileal bypass fell into a status of disrepute. Jejunoileal bypass is no longer recommended for the treatment of morbid obesity.[15]

Gastric Restrictive Operations

The concept of gastric restriction as treatment of morbid obesity was introduced by Mason and Ito in 1967.[16] All the current gastric operations are designed to restrict intake of solid food. Conversely, intake of liquids is not limited by these operations. In 1977, Mason et al. defined the anatomic parameters of restriction that were considered necessary for adequate weight loss with the gastric bypass operation, including a calibrated 1.2-cm-diameter gastrojejunostomy stoma and a small 50-ml-capacity upper gastric pouch.[17] Complication rates with gastric bypass decreased after introduction of the concept of stapling the stomach in continuity rather than dividing it. Use of the Roux-en-Y technique eliminated the problems with bile reflux esophagitis that were common after loop gastric bypass.

Stapled gastric partitioning was introduced in 1979. However, an unacceptably high incidence of early staple line failure led to a proliferation of modifications of gastric stapling in the hope of finding a more reliable technique. Gastroplasty techniques have evolved in favor of stapling in a vertical direction along the lesser curvature of the stomach. Stapling along the lesser curvature has also facilitated reinforcement of the outlet with prosthetic

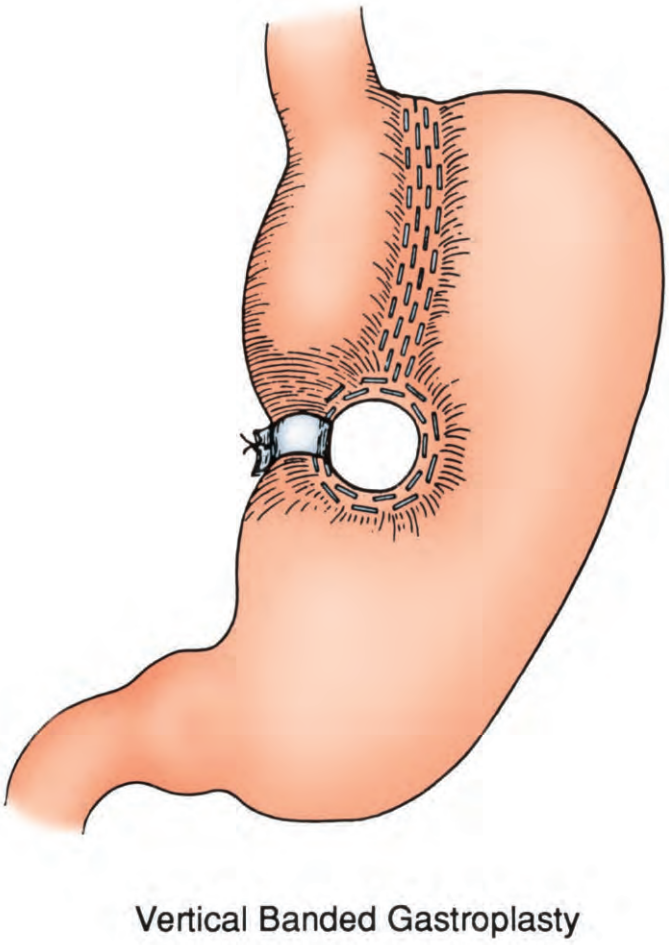

Figure 63–3. Vertical banded gastroplasty in which an upper gastric pouch with a capacity of 15 to 20 ml empties into the remainder of the stomach through a calibrated stoma 5.0 cm in circumference. The stoma is reinforced with a strip of polypropylene (Marlex) mesh. The mesh is placed around the stoma through a "window" created by firing a circular stapling instrument alongside a 32-French bougie. (From Miller TA [ed]: Modern Surgical Care: Physiologic Foundations and Clinical Applications, 2nd ed. Chapter 68. St. Louis, Quality Medical Publishing, 1998.)

materials to prevent progressive stomal dilatation. Horizontal gastroplasty techniques have now been abandoned because of an unacceptably high incidence of staple line disruption, stomal dilation, and pouch dilation.

In 1982 Mason introduced vertical banded gastroplasty (VBG), as shown in Figure 63–3.[18] In VBG the stoma is reinforced with a strip of polypropylene (Marlex) mesh measuring 5.0 cm in circumference to create a stoma with an internal diameter of 1.0 to 1.2 cm. The mesh is placed around the stoma through a hole or window created by firing a circular stapling instrument alongside a 32-gauge-diameter bougie. The mesh is sutured to itself rather than the stomach, a modification that has greatly reduced the incidence of outlet stricture and leaks.

Morbidity and mortality rates with VBG have been low. An overall morbidity rate of less than 10% and a mortality rate of 0.25% were reported in a series of more than 1200 VBGs.[19] Early weight loss results have generally been acceptable. MacLean et al. reported a mean 60% excess weight loss in 57 patients monitored for 5 years after VBG.[10] However, a substantial number of patients in this series required surgical revision for either complications or inadequate weight loss during the study period. There are remarkably few reports of long-term weight loss results after VBG. Weight loss maintenance after VBG has been somewhat problematic in that many patients regain at least 20% of their lost weight between 3 and 5 years postoperatively, perhaps in part because of increased intake of liquid or soft high-calorie foods that easily pass through the banded stoma.

CURRENT OPERATIONS

Roux-en-Y Gastric Bypass

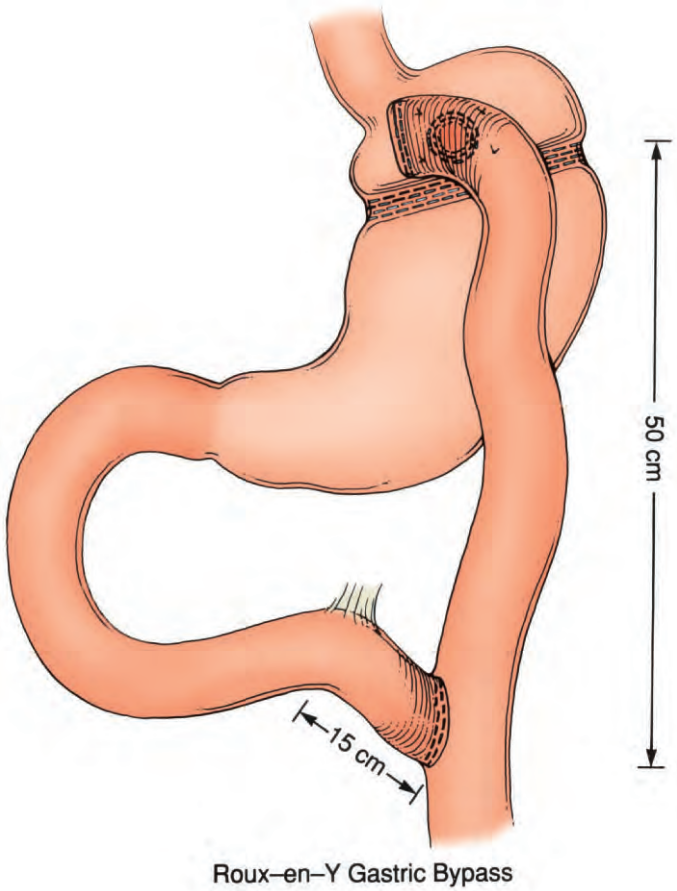
RYGB is illustrated in Figure 63–4. Gastric bypass combines gastric restriction with a small amount of malabsorption. Many surgeons consider RYGB to be the "gold standard" bariatric operation because it has produced durable weight loss for most patients with an acceptable incidence of postoperative complications. Weight loss is in the range of 70% to 80% of the excess weight at 2 years with maintenance in the range of 50% to 60% after 5 years.[7,10] The East Carolina group showed maintenance of approximately 50% of the excess weight loss 14 years after RYGB.[7] No difference in weight loss has been found between the open and laparoscopic approach. There have been several large prospective randomized comparisons of RYGB with different gastric restrictive operations, each of which showed significantly better weight loss after gastric bypass and similar early morbidity rates.[9,20,21]

Currently, laparoscopic RYGB is the most commonly performed bariatric operation in the United States. RYGB was first performed via laparoscopy by Wittgrove and Clark in 1994.[22] Although the physiology and weight loss outcome of open and laparoscopic RYGB are essentially the same, there are considerable differences between the open and laparoscopic approach with respect to the required instrumentation and surgical skill set. Laparoscopic RYGB is a technically demanding procedure with a considerably longer learning curve than for the open approach.

Five distinct technical components are involved in performing laparoscopic RYGB: (1) abdominal access/trocar placement, (2) creation of the gastric pouch, (3) mobilization and positioning of the Roux limb, and (4) performance of the gastrojejunostomy and (5) jejunojejunostomy.

Most surgeons place five or six access ports in the upper part of the abdomen. The location of individual ports is influenced by the type of staplers to be used. Access is achieved with either a Veress needle or a 12-mm visualization port placed just below the left costal margin in the midclavicular line. After the abdomen is entered, CO_2 is insufflated at a pressure of 15 mm Hg. A 30-degree laparoscope is then inserted. The remaining ports are placed sequentially under direct visualization.

Creation of the upper gastric pouch begins by dividing the phrenoesophageal ligament at the angle of His with ultrasonic shears. The angle of His defines the end



A

B

Figure 63–4. Roux-en-Y gastric bypass (RYGB). **A,** The upper part of the stomach is stapled closed in continuity, which was typical of procedures performed in the 1980s and 1990s. An upper pouch with a capacity of 30 ml is created with exclusion of more than 95% of the stomach, all of the duodenum, and approximately 15 cm of proximal jejunum from digestive continuity. The Roux limb between the upper gastric pouch and jejunojejunostomy measures 50 cm in length. (From Brolin RE, Kenler HA, Gorman RC, Cody RP: The dilemma of outcome assessment after operations for morbid obesity. Surgery 105:337-346, 1989.) **B,** Transected retrocolic, antegastric RYGB typical of current laparoscopic techniques. (Courtesy of Inamed Health, Santa Barbara, CA.)

point of the gastric transection. Sliding-type hiatal hernias should be reduced before transection to prevent the creation of a large pouch. The lesser sac is then entered by dividing the vasa brevia along the lesser curvature of the stomach, starting 3 to 4 cm below the gastroesophageal junction. The stomach is then stapled horizontally with a 45-mm linear stapler. Subsequent stapling is directed vertically toward the angle of His until the stomach is completely transected. Usually, four or five firings of the 45-mm stapler are required to create a gastric pouch with a capacity of 15 to 30 ml.

The gastrojejunostomy can be performed with either a linear or a circular stapling device. In the circular approach, the anvil of the 21 mm or 25 mm EEA stapler is introduced into the gastric pouch either transorally attached to a percutaneous endoscopic gastrostomy (PEG)-type tube or with an endoscope or directly through a laparoscopic port site. In the transabdominal approach, a gastrotomy is required to place the EEA anvil into the gastric pouch before the stomach is completely transected. The gastrotomy site is then stapled shut after the anvil is properly positioned within the pouch. Integrity of the gastrojejunostomy can be evaluated by several methods. Some surgeons pass an orogastric tube into the gastric pouch and instill 10 to 30 ml of a methylene blue dye/saline mixture. Others perform intraoperative upper endoscopy and air insufflation with the pouch submerged in normal saline. Anastomotic defects should be repaired immediately, after which a second test for integrity is performed.

The intestinal portion of the procedure begins with identification of the ligament of Treitz at the base of the transverse mesocolon. The jejunum is measured for a distance of 20 to 50 cm and divided with a 45-mm linear stapler. The Roux limb is then positioned in either an antecolic or retrocolic location before anastomosis to the gastric pouch. At this point the surgeon must avoid twisting the mesentery of the Roux limb. Division of the greater omentum is usually required when the antecolic route is chosen so that tension on the Roux limb is minimized. The circular stapler is placed in the abdomen via the left upper quadrant port site and inserted into the

Table 63–2 Complications After Open and Laparoscopic Gastric Bypass

Complication	No. (%) of Patients		
	Open GBP	Laparoscopic GBP	*P* Value
Intraoperative

Comparison of postoperative complications between open and laparoscopic gastric bypass (GPB).
Data from Podnos YD, Jimenez JC, Wilson SF, et al: Complications after laparoscopic gastric bypass. A review of 3464 cases. Arch Surg 138:957-961, 2003.

proximal end of the Roux limb. The spike of the circular stapler is advanced through the antimesenteric border of the Roux limb and engaged with the anvil protruding from the pouch. The stapler is fired and removed. The redundant open end of the Roux limb is then resected flush with the gastrojejunostomy with a linear stapler to avoid a long afferent limb, which can increase reservoir capacity.

Creation of the jejunojejunostomy begins by measuring the Roux limb distally for a distance of 75 to 150 cm from the gastrojejunostomy. Most surgeons perform a side-to-side, stapled anastomosis with a linear stapler. Several techniques can be used to close the enterotomies that remain after side-to-side stapling, including stapling in a perpendicular orientation to the previous stapling and laparoscopic suture closure. Alignment after stapled closure of the enterotomy defects must be precise to avoid kinking and obstruction. Several so-called antiobstruction stitches should be placed between the distal Roux limb and the biliopancreatic limb to prevent kinking at the anastomosis. Many surgeons are fastidious in closing mesenteric defects at the jejunojejunostomy site, including mesocolic defects (in the retrocolic technique) and Petersen's space. Closure of mesenteric defects should be performed with a nonabsorbable suture.

Postoperative morbidity and mortality rates observed with current techniques of RYGB are in the range of 10% and 1%, respectively. Table 63–2 shows a comparison of postoperative complications during open and laparoscopic RYGB.[23] The incidence of incisional hernia and wound infection is significantly lower with laparoscopic RYGB than with the open approach. Conversely, the incidence of bowel obstruction from internal hernia is significantly higher after the laparoscopic approach and ranges from 2% to 8%.[23] The majority of internal hernias occur in mesenteric defects at the jejunojejunostomy or at Petersen's space. Internal herniation can be manifested as mild intermittent distention with crampy abdominal pain or as complete bowel obstruction with or without bowel infarction. Symptoms may be intermittent. The single most useful radiologic test in evaluating the possibility of internal hernia, small bowel obstruction, or both in patients after RYGB is probably computed tomography (CT) with oral contrast. Prompt passage of oral contrast into the colon and absence of distention in the bypassed stomach and duodenum are reassuring signs that an internal hernia with obstruction is unlikely. Although radiographic imaging aids in diagnosis, persistent symptoms in the face of equivocal radiographs should prompt exploration.

Typical mortality statistics of large published series of bariatric surgical patients were challenged in an article by Flum et al., which showed 30-day and 1-year death rates of 2.0% and 4.6%, respectively, in a series of 16,155 Medicare patients who underwent bariatric operations between 1996 and 2002.[24] The 30-day and 1-year mortality rates in the age 65 and over Medicare patients were an astounding 4.8% and 11.1%, respectively. Mortality rates were significantly less for high-volume surgeons versus low-volume (≤35 procedures annually) surgeons. Two findings in this important study warrant emphasis:

1. The mortality rate of bariatric operations (and likely other complex surgical procedures) is lowest in the hands of the most experienced surgeons.
2. The mortality rate of bariatric operations published in peer-reviewed journals is considerably better than that of the community at large.

Gastric bypass is occasionally associated with symptoms of "dumping syndrome," including nausea, bloating, diarrhea, and colic. These symptoms are thought to be due to rapid emptying of the small gastric pouch directly into the small bowel. Vasomotor symptoms of dumping are associated with hypoglycemia and include lightheadedness, palpitations, and sweating. These symptoms occur in a smaller percentage of patients. The severity of dumping after gastric bypass is variable, with some patients reporting no symptoms, others having symptoms associated with eating specific foods such as milk products or sweets, and a few patients reporting troublesome symptoms after almost every meal.

Several metabolic complications are inherent in gastric bypass surgery, including iron, folate, and vitamin B_{12} deficiencies, each of which may result in anemia. Because of the relatively high incidence of these micronutrient deficiencies, prophylactic multivitamin/mineral supplements are routinely given to all patients who undergo gastric bypass. However, the efficacy of multivitamin supplements in prevention of both iron and calcium deficiency is problematic. In our experience, a daily multivitamin supplement does not consistently prevent the development of iron deficiency and anemia in women who have undergone gastric bypass. Additional supplements of specific vitamins or minerals in addition to multivitamins are frequently necessary to correct these deficiencies. Fortunately, the vast majority of vitamin and mineral deficiencies after gastric bypass are subclinical and easily corrected with oral supplements of the deficient micronutrients. Injection therapy is rarely required in patients who are willing to take oral supplements. Hospitalization for treatment of these vitamin and mineral deficiencies is rare.

Malabsorption of protein, carbohydrate, and fat has not been documented after conventional gastric bypass.

Gastric Banding

Gastric banding is the most commonly performed bariatric operation in Europe and Australia. Early techniques of gastric banding incorporated a premeasured strip of prosthetic material to restrict oral intake. However, these techniques lacked precision in measuring the volume of stomach above the band. The circumference of the band was generally in the range of 5.0 cm, similar to the measurements used for VBG. The band is sutured to both itself and the stomach to prevent "slipping." Complication rates with nonadjustable techniques of gastric banding were relatively high, with morbidity and mortality rates in the range of 30% and 3%, respectively.[25] Band erosion occurred in 10% to 15% of cases. Erosion occasionally resulted in leaks and obstruction that frequently required reoperation. The concept of an inflatable silicone band was introduced by Kuzmak in 1988.[26] The diameter of the inflatable band is adjusted by infusion of saline through a subcutaneous reservoir. The reported weight loss results and the complication rate with inflatable bands are better than those observed after nonadjustable banding techniques in which strips of polypropylene or Teflon were used.

Kuzmak's concept of adjustability was incorporated into laparoscopic approaches. Currently, there are two major brands of laparoscopic adjustable gastric bands: the Lap-Band (Inamed Health, Santa Barbara, California) and the Swedish adjustable gastric band (Obtech Medical, Baar, Switzerland). The Food and Drug Administration approved the Lap-Band device for use in the United States in June 2001. This device is illustrated in Figure 63–5. Adjustable gastric bands are placed laparoscopically via five or six access ports. The original technique used to position the adjustable gastric band involved perigastric dissection high along the lesser curvature of the stomach and entering the omenta bursalis. The band is passed around the upper part of the stomach through this space. Because the perigastric approach was associated with an excessive rate of pouch enlargement and prolapse, the pars flaccida technique was introduced.[27] Dissection with this technique begins at the angle of His, where the phrenoesophageal ligament is opened. The pars flaccida along the lesser curvature of the stomach is then incised to expose the anterior border of the right diaphragmatic crus. A grasper is advanced behind the upper part of the stomach toward the angle of His.

The adjustable band is then inserted into the abdomen. One end of the band is grasped at the angle of His, pulled behind the stomach, and locked anteriorly to create a small proximal gastric pouch. Several nonabsorbable stitches are then placed in the stomach to secure the band as shown in Figure 63–5. The tubing is pulled from the band through the subcutaneous tissue and connected to the access port. The port is secured to the abdominal wall fascia with four nonabsorbable sutures placed through the eyelets on the port. The presence of a hiatal hernia makes band placement more difficult because the normal anatomic landmarks are distorted. Some surgeons consider hiatal hernia an absolute contraindication to banding. Others recommend repair of the crus concomitant with band placement. The gastric band gradually forms a fibrous membrane that fixes its position around the stomach.

Adjustments begin approximately 6 to 8 weeks after placement and fixation of the band. These adjustments are essential for weight loss and regulate the amount of solid food that can be consumed at one sitting. Usually, four to six adjustments are required during the first year after placement.

Perioperative complications are rare after adjustable gastric banding, with the most common being infection at the access port, which occurs in about 1% of cases and usually requires removal of the port.[27,28] Occasionally, the tubing and band can be spared from port site infection by capping the tubing and reducing it intraperitoneally while the wound heals. After the infection has cleared, the tubing can be reconnected to a new port.

Late complications after adjustable laparoscopic banding are more common and include difficulty with accessing the subcutaneous port, tubing problems, gastric prolapse or "slip," band erosion, esophageal obstruction/dilatation, and dilatation of the gastric pouch. Tubing breaks and problems with access to the

subcutaneous port for adjustments occur in 1% to 5% of patients.[28,29] The fixation sutures may occasionally become separated from the fascia and result in angling of the port away from the skin. Although fluoroscopy can facilitate access in these cases, some malrotated ports require repositioning or replacement.

"Slippage" of the band encompasses a spectrum of problems, including gastric pouch dilatation because of placement of the band too low on the stomach and prolapse of the distal part of the stomach beneath the band. Herniation of the distal fundus through the band with resulting necrosis is a rare life-threatening complication. Prolapse may occur on either the anterior or posterior aspect of the stomach. Causes of band prolapse include excessive perigastric dissection, the presence of a sliding hiatal hernia, and protracted, forcible vomiting. Another cause of gastric pouch dilatation is overinflation of the band. It is important to distinguish prolapse from gastric pouch dilatation because prolapse requires operative treatment. Conversely, deflation of the band frequently resolves simple dilatation. Widespread adoption of the pars flaccida technique has reduced the incidence of pouch enlargement and prolapse to approximately 1% and 3% of cases, respectively.[28-30]

Erosion or intragastric migration of adjustable gastric bands occurs in 1% to 3% of patients.[28,30] Possible causes include gradual pressure necrosis and subclinical injury to the stomach adjacent to the band. Band erosion requires operative removal of the band and repair of the residual defect. These procedures may be difficult because of intense inflammatory scarring.

Esophageal dilatation may occur either in the perioperative period or, more commonly, months to years after surgery. Acute esophageal obstruction is rare, whereas late dilatation of the esophagus may be relatively common.[31] The clinical significance of this problem is disputed because most cases are easily remedied by deflation of the band. Conversely, cases associated with dysphagia and complete esophageal obstruction have been reported. Band erosion should be ruled out as the cause of obstruction in these cases.

Weight loss with most techniques of gastric banding has been less consistent than weight loss reported after banded gastroplasty and RYGB. Weight loss after gastric banding is slower (3- to 5-lb weight loss per month) than after other bariatric procedures, but it tends to be protracted over a longer time frame (3 to 4 years).[28,30] Weight loss with the laparoscopic adjustable gastric band is better at international centers than in the United States. International series report mean percent excess weight loss ranging from 40% to 70% with a follow-up of 3 to 8 years.[28-30,32] Results in the United States have been mixed and range between 32% and 58% excess weight loss with a follow-up of 4 years.[31,32]

Biliopancreatic Diversion

Biliopancreatic diversion combines a modest amount of gastric restriction with substantial malabsorption. The concept of biliopancreatic diversion was introduced by Scopinaro during the late 1970s.[33] The technique includes performance of subtotal gastrectomy, with an approximately 400-ml-capacity gastric remnant anastomosed to the proximal ileum. All of the jejunum is excluded from digestive continuity and is anastomosed end to side to a "common channel" of ileum 50 cm proximal to the ileocecal junction. Because this degree of malabsorption predisposes to cholelithiasis, cholecystectomy is also routinely performed. In 1987 DeMeester introduced the duodenal switch procedure for treatment of refractory bile reflux gastritis.[34] Hess, Marceau, and colleagues independently modified this technique of biliopancreatic diversion for bariatric patients.[35,36] A conventional modification of the duodenal switch is illustrated in Figure 63–6. This procedure preserves enough parietal cells that vitamin B_{12} deficiency and marginal ulcers are unusual late complications.

Early postoperative complications are reported in 30% of patients who undergo biliopancreatic diversion, with a 1.3% mortality rate. However, the incidence of metabolic complications within the first postoperative year has been high, including a 30% incidence of anemia, an 8% to 10% incidence of marginal ulcers, and a 20% incidence of hospitalization for treatment of protein-calorie malnutrition.[33] Deaths from hepatic failure have been reported in patients who underwent biliopancreatic diversion. Weight loss results with biliopancreatic bypass have been almost uniformly good. A mean loss of 70% of preoperative weight was reported in a series of 57 patients monitored for more than 18 years, with excellent weight maintenance after stabilization.[37] Other surgeons have reported an average weight gain of only 5% from the point of maximum weight loss at 5 years after biliopancreatic diversion.[35]

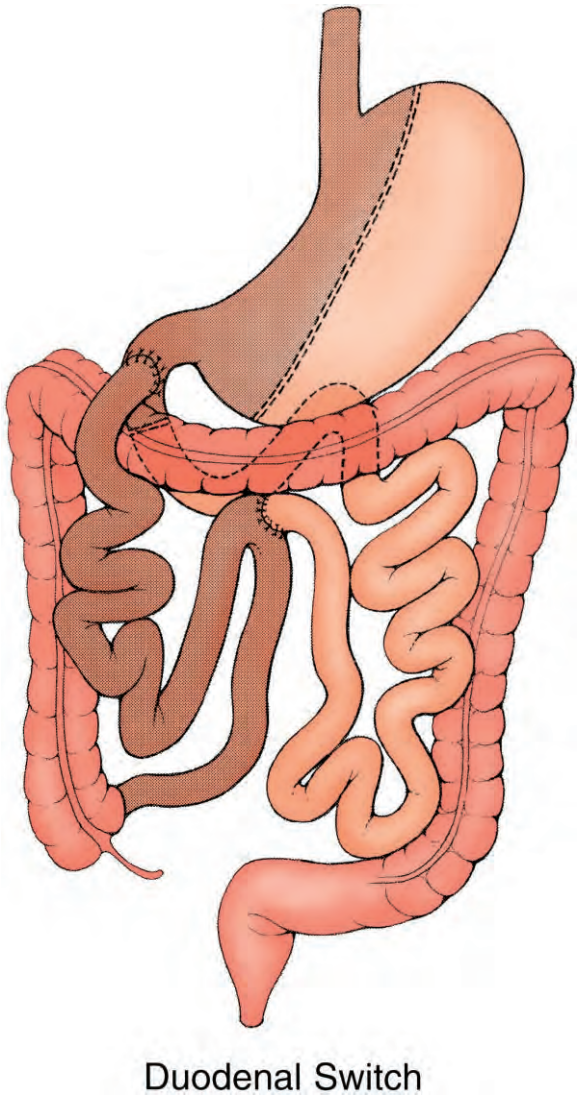

Figure 63–6. Biliopancreatic diversion with duodenal switch. Two thirds of the stomach is excised along the greater curvature with linear staplers. The duodenum is dissected from the head of the pancreas for a distance of 5 cm beyond the pylorus and transected. The ileum is then transected at a point 250 cm proximal to the ileocecal junction. The distal end of the transected ileum *(shaded)* is anastomosed to the proximal duodenum. The remainder of the small bowel *(unshaded portion)* is diverted from the digestive stream. The distal end of the bypassed segment is reanastomosed to the ileum 100 to 150 cm proximal to the ileocecal junction to create the common channel. (From Miller TA [ed]: Modern Surgical Care: Physiologic Foundations and Clinical Applications, 2nd ed. Chapter 68. St. Louis, Quality Medical Publishing, 1998.)

REVISION OPERATIONS

Occasionally, bariatric operations require revision for either inadequate weight loss or late complications. The incidence of major postoperative complications after revision of bariatric procedures is high, with reports ranging from 15% to 60% and a mortality rate ranging from 0% to 15%. The reoperating surgeon must be aware of a persistent gastrogastric fistula and ischemic or undrained gastric remnants (or both). Patients who undergo revision operations for complications frequently have lost a sufficient amount of weight after their initial procedure. These patients should generally be offered a gastric restrictive rather than a malabsorptive procedure. Patients who require takedown of an intestinal bypass for metabolic complications and are no longer overweight are best managed by conversion to a banded gastroplasty for weight maintenance. Conversely, intestinal or biliopancreatic bypass patients who remain substantially overweight are best converted to RYGB in the hope of providing further weight loss through the added gastric restriction. Gastroplasty patients with stomal stenosis and an intact staple line may undergo stomal dilatation by upper endoscopy. Endoscopic dilatation is usually performed with balloon-tip dilators. Unfortunately, less than 50% of patients with stomal stenosis obtain permanent relief with dilatation. Patients who do not respond to dilatation require operative revision, which is best accomplished by conversion to RYGB.

Reversal of bariatric operations without conversion to another weight reduction procedure is invariably associated with prompt regaining of previously lost weight. Gastroplasty patients with unsatisfactory weight loss are best converted to RYGB or, in some cases, biliopancreatic diversion. Gastroplasty or RYGB patients with staple line disruption require transection of the stomach between staple lines. There is a high incidence of subsequent staple line disruption in patients who undergo restapling in continuity. Gastric bypass patients with anatomically intact operations and unsatisfactory weight loss have almost certainly "outeaten" the operation. These patients may be converted to a biliopancreatic diversion procedure with anticipation of further weight loss. A small number of morbidly obese patients will "outeat" any bariatric operation or die trying. Whenever a patient has failed a second technically sound and intact operation, surgeons should approach the prospect of further revision with considerable caution and skepticism. Rejection of such patients for another operation is frequently a prudent decision.

PERIOPERATIVE CARE

All candidates for obesity operations should be interviewed in an outpatient setting before being considered for surgery. During the screening interview, the surgeon should provide prospective patients with a clear understanding of the risks and goals of the operation and explain the mechanism by which the proposed procedure produces weight loss. At the same time, the surgeon should obtain a complete medical history and make a preliminary assessment of the patient's operative risk. Psychological stability should also be evaluated, particularly in terms of the patient's willingness to adjust to the permanent postoperative side effects of gastric restriction and malabsorption. At the conclusion of the interview, the patient should have obtained sufficient information to give informed consent.

Routine preadmission tests include a complete blood count, Chem-21 screen, urinalysis, chest radiograph, electrocardiogram, testing for *Helicobacter pylori* antigen, and ultrasound of the gallbladder. *H. pylori* testing is performed to rule out a treatable cause of postoperative peptic ulcer disease. Patients with a positive test are treated with a combination of antibiotic and proton pump inhibitor therapy. Patients who have symptoms of gastroesophageal reflux disease or peptic ulcer disease should undergo upper endoscopy. An active peptic ulcer is a contraindication to bariatric surgery. The reported incidence of biliary tract disease in the morbidly obese ranges from 25% to 45%, which is three to four times higher than that in the normal-weight population. Hence, preoperative or intraoperative screening for gallstones is recommended in all bariatric surgical patients who have not undergone cholecystectomy. Ultrasonography is the most popular method of evaluation. The reported incidence of symptomatic cholelithiasis after obesity operations ranges from 3% to more than 50%, depending on the type of operation performed. Because symptomatic gallstones developed in more than 50% of patients after Scopinaro's biliopancreatic bypass, it has been recommended that routine cholecystectomy be included as an integral part of that operation. The incidence of gallbladder disease after gastric restrictive operations varies from 3% to greater than 30%. Most surgeons do not perform prophylactic cholecystectomy during gastric restrictive operations, even though the risk of adding cholecystectomy to these procedures is negligible. Ultrasound of the gallbladder is performed to rule out unsuspected gallstones. Patients scheduled to have gastric or biliopancreatic bypass operations should also undergo testing for serum iron, iron-binding capacity, and vitamin B_{12}. Levels of fat-soluble vitamins should be obtained in patients before biliopancreatic diversion. All patients scheduled to undergo revision of a failed bariatric procedure should have blood cross-matched for possible transfusion because blood transfusion is often necessary in patients who undergo revision of failed gastric restrictive operations. All patients should be given intravenous (IV) prophylactic antibiotics during the perioperative period.

Although bariatric surgical patients do not require admission to the intensive care unit (ICU) postoperatively, all patients with sleep apnea, congestive heart failure, or severe asthmatic bronchitis should be considered for admission to the ICU for close monitoring of their cardiopulmonary status. Occasionally, patients who undergo open operations require overnight intubation. Conversely, virtually all patients who undergo laparoscopic operations are extubated within the first several hours postoperatively.

Because obesity is considered a risk factor for postoperative pulmonary embolism, a variety of methods of prophylaxis have been used in an attempt to prevent this feared complication, including subcutaneous low-dose heparin or enoxaparin (Lovenox), pneumatic compression stockings, IV low-molecular-weight dextran, and use of the Trendelenburg position intraoperatively. However, none of these methods have been proved to decrease the incidence of postoperative venous thromboembolism in bariatric surgical patients. Early postoperative ambulation is strongly encouraged and almost certainly contributes to the low incidence of postoperative venous thromboembolism reported in laparoscopic patients. All patients should get out of bed on the night of their operation and walk on the first postoperative day. Prophylactic superior vena cava filters should be considered in patients with a history of deep venous thrombosis or pulmonary embolism.

We routinely use IV patient-controlled analgesia (PCA) in postoperative bariatric patients. PCA provides more consistent pain relief than do intermittent intramuscular injections of narcotic analgesics. Oral narcotics are usually begun on the second or third postoperative day after administration of IV fluids has been stopped. All pills and tablets are crushed and administered as a slurry with a liquid beverage. Patients are instructed to not swallow whole pills during the first 4 weeks postoperatively.

A limited upper gastrointestinal contrast study is routinely performed on the first or second day to examine the integrity of the staple line and outlet stoma, although some experts have questioned the utility of this

approach. If the contrast study is unremarkable, a clear liquid diet is begun. IV fluids are discontinued after clear liquids are tolerated without difficulty. A maximum 1000-calorie full-liquid diet is started on the next day, followed by a pureed diet shortly thereafter. Patients are usually discharged on the second or third postoperative day. Hospitalization for more than 4 days is unusual in the absence of major complications.

Severe distention of the bypassed stomach is an unusual, but serious complication that can be managed by percutaneous decompression or Stamm gastrostomy.

FOLLOW-UP AND DIETARY MANAGEMENT

Postoperative follow-up is extremely important in bariatric surgical patients. During the first year postoperatively, visits are scheduled at 1 week, at 4 weeks, and then at 3-month intervals thereafter. Two follow-up visits are scheduled at 6-month intervals during the second year, with subsequent annual visits. All patients should have easy access to both the operating surgeon and a clinical nutritionist.

Postoperative dietary counseling is essential to the long-term success of bariatric operations. Patients are instructed to follow a full liquid pureed diet for 4 weeks after discharge. A liquid or chewable multivitamin supplement is taken during this phase of the diet. The purpose of the pureed liquid diet is to (1) allow time for patients to adjust to their tremendously restricted stomach capacity by consuming foods that are relatively easy to chew and swallow and (2) minimize the likelihood of vomiting during the early postoperative period. Repeated episodes of vomiting during the early postoperative period have been associated with staple line disruption and leaks. Patients are started on a soft solid diet at the 4-week visit and then gradually progress to a normal diet. Patients can resume swallowing whole pills and tablets after solid food is well tolerated.

Patients who undergo gastric bypass or biliopancreatic diversion require periodic blood tests to check for possible nutritional deficiencies. These patients should take a multivitamin supplement with minerals daily for the rest of their lives. Menstruating women who have undergone gastric or biliopancreatic bypass should also take additional prophylactic iron supplements. Oral calcium supplementation of at least 1 g daily should be taken by all bypass patients. After biliopancreatic diversion, many patients require additional protein and other nutritional supplements, particularly fat-soluble vitamins.

AMELIORATION OF OBESITY-RELATED DISEASES

Amelioration of obesity-related medical problems is a primary goal of all bariatric operations. The incidence of type 2 diabetes mellitus in the morbidly obese ranges from 10% to 20%. Improvement or resolution of morbid obesity–associated diabetes, including a significant decrease in insulin resistance after weight reduction surgery, has been reported by many investigators. Postoperative changes in glucose metabolism in morbidly obese diabetic patients have been studied extensively. Pories, Schauer, and colleagues independently reported that nearly 85% of patients with either overt diabetes or impaired glucose tolerance become euglycemic after open and laparoscopic RYGB.[38,39] Fasting insulin and glycosylated hemoglobin concentrations were also reduced to normal levels, whereas insulin release, insulin resistance, and utilization of glucose were substantially improved.

There is relatively little information about the effects of weight reduction surgery on obesity-related cardiovascular dysfunction. Echocardiography was used to measure a number of parameters of ventricular function in 63 morbidly obese patients. Surgically induced weight loss was associated with significant improvement in left ventricular ejection fraction and smaller, but measurable improvements in mean blood pressure, cardiac chamber size, and ventricular wall thickness.[40] Two groups have independently reported the response of blood pressure to weight loss in hypertensive patients after RYGB. Although each group noted improvement or resolution of high blood pressure in approximately 70% of patients after weight stabilization, there were conflicting results relative to the magnitude of the weight loss. One group found a significant correlation between improved blood pressure and proximity to ideal weight.[41] The other reported a correlation between improved blood pressure and the absolute quantity of weight lost.[42]

The ameliorative effects of weight reduction surgery on obesity-related hyperlipidemia have been documented by a number of investigators. Independent reports have demonstrated significant decreases in both total cholesterol and triglyceride levels after both gastroplasty and gastric bypass. Several investigators reported high-density lipoprotein/low-density lipoprotein ratios after gastric bypass and suggested that the risk for atherosclerosis may be decreased by surgically induced weight loss.[43] Our group and others have shown that these lipid reductions persist for as long as weight loss is satisfactorily maintained.[44] Occasionally, patients who regain a substantial portion of their lost weight are able to maintain the salutary changes in lipid profile.

Obesity-hypoventilation syndrome probably poses the greatest immediate risk to life of any of the obesity-related comorbid conditions. There have been a number of independent reports of complete resolution of sleep apnea symptoms and significant improvement in both arterial blood gas parameters and lung volumes after gastric restrictive operations. Significant reductions in mean pulmonary artery pressure have also been reported in patients with obesity-hypoventilation syndrome after RYGB.[45] Many patients in these reports were incapacitated by their condition preoperatively but, after losing weight, were able to lead normal lives.

Morbidly obese women of childbearing age are known to have a high incidence of infertility, as well as other menstrual and hormonal problems. Perioperative abnormalities have been reported in sex hormone–binding globulin (SHBG) in infertile morbidly obese women who were attempting pregnancy. However, after gastroplasty-induced weight loss, there were significant improvements

in SHBG levels and a significantly decreased incidence of irregular menses.[46] A number of previously infertile women became pregnant and delivered normal babies after surgically induced weight loss. Similar results were reported by another group after gastric bypass. Despite restricted intake, both the mother and the developing fetus maintained adequate nutritional status. Pregnancy is not recommended during the period of active postoperative weight loss (the first 18 months postoperatively).

Although the proliferation in numbers of bariatric surgical procedures has slowed during the past 2 years, it appears that a need for surgical treatment will continue to exist in the absence of an effective alternative treatment. The current gastric restrictive operations appear to be safe and effective enough to justify their continued use. At present, surgery offers the only realistic hope for successful weight loss in the morbidly obese.

Foreign Bodies and Bezoars of the Stomach and Small Intestine

Karen A. Chojnacki

FOREIGN BODIES

Foreign bodies in the stomach and duodenum are relatively common, and nearly 80% of cases of foreign body ingestion occur in the pediatric population.[1] Such ingestion is usually inadvertent and a result of the natural oral curiosity of an infant or child. In several series, coins are the most commonly ingested objects by infants and children.[2-7] Other foreign bodies frequently found in this population are listed in Table 64–1. The foreign bodies most commonly ingested by adults are listed in Table 64–2. Several adult populations are at risk for foreign bodies in the gastrointestinal (GI) tract. The elderly, demented, and intoxicated have an increased risk for accidental foreign body ingestion. Denture wearers have decreased tactile sensation of the palate and are also at risk for accidental foreign body ingestion.[8,9] Psychiatric patients and prisoners are more apt to intentionally swallow foreign bodies for secondary gain. This population often swallows multiple objects on multiple occasions.[10]

Eighty percent to 90% of ingested foreign bodies pass through the GI tract spontaneously without injury,[11] 10% to 20% require endoscopic removal, and 1% require surgery.[11,12] Perforation, obstruction, and failure of an object to progress though the GI tract are all complications of foreign bodies that require surgical or endoscopic intervention. Obstruction and perforation can occur at any point along the GI tract. Obstruction is most likely to take place at the pylorus, the duodenal sweep, the ligament of Treitz, and the ileocecal valve. Objects greater than 5 cm in length or 2 cm in diameter are unlikely to pass through the pylorus.[13] Patients with a history of pyloric stenosis, previous pyloric surgery, or ulcer disease are at increased risk for obstruction.[14]

One percent of foreign body ingestions result in perforation of the GI tract. Perforation by a foreign body is often secondary to accidental ingestion of a sharp or pointed object such as a fish or chicken bone or a toothpick. The duodenal sweep is at increased risk for perforation from long or pointed objects (or both) because of its C shape.[4] In cases of perforation, the diagnosis of foreign body ingestion is often made intraoperatively because the patient is rarely aware of the ingestion.

Interestingly, once foreign bodies travel beyond the ligament of Treitz, complications are rare. In the small bowel lumen, objects are subject to axial flow and reflex relaxation of the muscle wall. This tends to orient objects with the blunt end leading and the sharp end trailing, thus decreasing the risk for bowel injury.[15] Within the colon, objects become centered in stool, which further protects the bowel wall and allows the objects to safely exit the GI tract.[16]

Diagnosis

The diagnosis of foreign bodies within the stomach and small intestine is established by patient history, radiology studies, or endoscopy (or any combination). Most communicative adults will be able to provide an accurate history of how, what, and when an object was ingested. Symptoms most commonly occur when the ingested object is in the esophagus and include dysphonia, dysphagia, and odynophagia. Retrosternal pain, pharyngeal discomfort, and respiratory compromise are also symptoms of a foreign body lodged in the esophagus. Patients will be able to localize an object when lodged at the cricopharyngeal muscle, but localization becomes less accurate as the object moves distally. Patients are able to accurately localize ingested foreign bodies in the esophagus in 30% to 40% of cases but are rarely able to localize objects when in the stomach.[17] Sudden resolution of symptoms often indicates that the object has passed to

the stomach. Once a foreign body has reached the stomach, patients are usually asymptomatic unless perforation or obstruction develops.

The history and symptoms are less reliable with children and psychiatric patients. Most often the ingestion is a witnessed event or suspected by a caregiver. Recurrent foreign body ingestion is reported in 3.3% to 10% of psychiatric patients and prisoners.[4,18] Symptoms of foreign body ingestion in these patient populations include choking, vomiting, blood-stained saliva, respiratory distress, and stridor. Children may also fail to thrive or refuse to eat.[19] Thirty-three percent of children and infants may be asymptomatic after foreign body ingestion, but the true percentage may even be higher.[20]

All patients with suspected foreign body ingestion should have anteroposterior and lateral radiographs of the chest and abdomen taken to aid in determining the presence, type, and location of the foreign body. Plain films may also identify signs of perforation such as pneumoperitoneum, pleural effusion, or subcutaneous air.[4,21] Lateral films help distinguish between objects in the tracheobronchial tree versus the esophagus. Some objects, such as glass, bone, aluminum, plastic, and wood, are radiolucent and can be difficult to detect on plain radiography. If ingestion of one of these objects is suspected, flexible endoscopy is recommended to confirm and treat the ingestion.[4] In patients with a contraindication to endoscopy, a thin barium contrast study can be used to evaluate the upper GI system.[11] Barium esophagograms should not be performed if there is concern of perforation or obstruction.

Patients who remain symptomatic with normal imaging studies should undergo flexible endoscopy because it provides safe and effective management of foreign bodies in the upper GI tract. Multiple series report success rates for endoscopic management of foreign bodies in excess of 95%.[4,5,22,23]

Management

Once a foreign body has reached the stomach, the risk for complications diminishes greatly. Nearly 90% of objects in the stomach will progress through the GI tract without complication. Most patients can be managed conservatively. Patients who have ingested small or blunt objects, such as coins, can be observed with daily or weekly radiographs to document progression of the foreign body. Endoscopic removal of certain objects is recommended before passage from the stomach, as discussed in the next section. Surgery is indicated if signs or symptoms of perforation, hemorrhage, fistula formation, or obstruction of the small or large bowel develop. Failure of a sharp or pointed object in the small intestine to progress after 3 days is also an indication for surgery.[10] Several authors have reported success with laparoscopic removal of ingested foreign bodies.[24-26]

Certain foreign bodies deserve special consideration.

Sharp/Pointed or Long Foreign Bodies

Toothpicks, nails, needles, bones, razor blades, safety pins, and dental prostheses are the most commonly ingested sharp foreign bodies. Surgical intervention is most often required for bones and toothpicks.[21,27] The terminal ileum is the most frequent site of perforation by a sharp foreign body. Because 15% to 35% of these sharp foreign bodies will cause perforation, they should

Figure 64–1. A 36-year-old woman ingested a drill bit while working on home repairs. By the time that she arrived at the emergency department and this radiograph was taken, the bit had passed through the stomach into the small bowel.

Figure 64–2. After 24 hours, the drill bit had progressed to the terminal ileum. Here it lies in the right lower quadrant with the blunt end leading.

be removed by flexible endoscopy while still in the stomach. Objects longer than 5 cm are unlikely to pass through the duodenum and should also be removed.[13] Sharp or pointed objects that do pass through the duodenum into the small intestine can be treated conservatively unless symptoms of perforation or obstruction develop (Figs. 64–1 and 64–2). If the foreign body fails to reach the colon within 3 days, it should be surgically removed. When removing a sharp object with the endoscope, the foreign body should be positioned so that the sharp end trails distal to the endoscope.[10] This follows Jackson's axiom: "Advancing points puncture, trailing points do not" (Fig. 64–3).[28]

Button Batteries

Several common devices, such as hearing aids, calculators, cameras, computers, watches, and electronic games, are powered by small, often coin-like "button batteries." Ingestion of these batteries is widely reported.[29-33] Ten percent of ingested button batteries will become symptomatic. Batteries larger than 21 mm are more likely to cause problems. The most common battery systems contain an alkaline electrolyte solution that is a 26% to 45% solution of potassium or sodium hydroxide. This

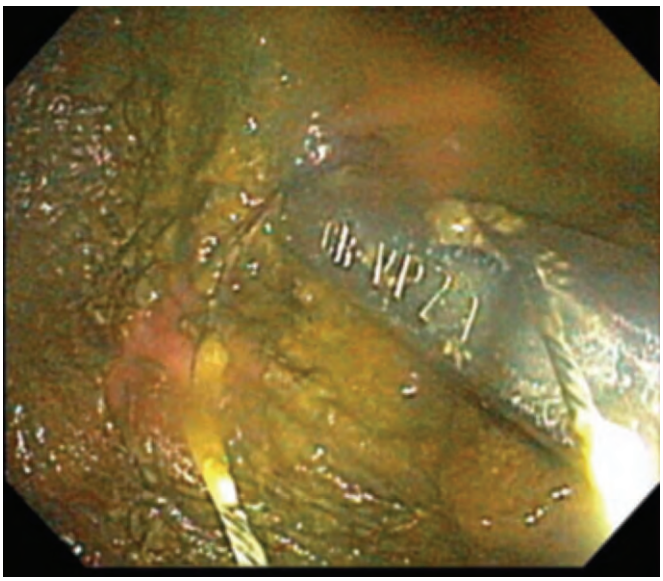

Figure 64–3. The drill bit failed to progress into the colon over the next 3 days. It was removed by colonoscopy from the terminal ileum with a snare.

alkaline electrolyte can cause rapid liquefaction necrosis of tissues if it leaks into the GI tract. Batteries can also cause tissue damage by low-voltage burns and pressure necrosis.[31,34]

Button batteries lodged within the esophagus should be removed by endoscopy as soon as the diagnosis is established to prevent burn, perforation, or stricture of the esophagus. Once a battery has reached the stomach, it will usually pass without difficulty. Daily radiographs should be obtained. If the battery has not progressed beyond the pylorus by 36 to 48 hours, it should be retrieved by endoscopy. Emesis should not be induced to avoid aspiration of the battery into the trachea.[29,32,35] If symptoms of epigastric pain, fever, or peritonitis develop, the patient should be considered for surgical exploration.

Once in the small intestine, complications from an ingested button battery are quite rare. Only one complication has been reported in nearly 100 cases involving the intestine. In this case, the battery lodged in Meckel's diverticulum and caused perforation.[36] Most batteries will pass through the entire GI tract in 72 hours, with a range of 12 hours to 14 days.[29] After the battery has passed the pylorus, radiographs are obtained every 3 to 4 days. Surgery is warranted if the battery fails to progress or symptoms of perforation or obstruction develop.

Double AA and triple AAA alkaline batteries will usually pass from the stomach to the anus without complications.[4]

Illicit Drugs

Because of the ongoing popularity and profitability of heroin and cocaine, these drugs continue to be smuggled into the United States by "body packers" or "mules." Body packers ingest multiple small packages containing heroin or cocaine. The packets are usually condoms stuffed with 3 to 5 g of an illicit drug.[37] The packets are then swallowed so that they are concealed in the GI tract. Body packers often take high doses of anticholinergic drugs to postpone passage of the packets through the GI tract. Cocaine is lethal at a dose of 1 to 3 g; therefore, rupture of only one packet can be fatal.[38]

Body packers can have a variety of symptoms; however, they are often asymptomatic and are brought to medical attention by drug enforcement officials. These patients may also have signs and symptoms of bowel obstruction.[39] Plain radiographs will demonstrate the drug packets in 70% to 90% of cases (Fig. 64–4).[40] Patients may also have symptoms of toxicity from the carried drug, indicative of packet rupture. Patients with toxicity or obstruction, or both, should be stabilized and undergo urgent surgical evaluation. Gastrostomy, multiple enterotomies, or colotomies (or any combination) may be required to remove all drug packets.[41] Endoscopic retrieval is contraindicated because of the risk for perforation of the packet.[37] If a patient comes to medical attention within 24 hours of packet ingestion and is stable, conservative management can be attempted. These patients require close observation, whole-gut lavage, and serial radiographs to document evacuation of all packets.[42]

Figure 64–4. Plain abdominal radiograph showing multiple drug-containing packets within the bowel lumen. This patient is a "body packer" or "mule" attempting to smuggle drugs. (From Miller JS, Hendren SK, Liscum KR: Giant gastric ulcer in a body packer. J Trauma 45:617, 1998.)

BEZOARS

Bezoars are retained collections of indigestible foreign material that accumulate in the GI tract. Most bezoars are located in the stomach, but they may be encountered in the esophagus, small intestine, and rectum.[43] Altered gastric physiology with impaired gastric emptying and decreased acid production is often the cause of bezoar formation. These changes are usually consequences of previous gastric surgery, which is present in 70% to 94% of patients with bezoar formation.[44] Vagotomy with pyloroplasty or antrectomy is a predisposing factor for bezoar formation.[45] Patients with gastroparesis, diabetes, end-stage renal disease, and prolonged mechanical ventilation are at increased risk for bezoars.[46] In some patients, ingestion of large amounts of indigestible material is the only risk factor for bezoar formation.

There are four types of bezoars: phytobezoars, trichobezoars, pharmacobezoars, and lactobezoars. Phytobezoars are the most frequent type of bezoar and occur most commonly with the foods listed in Table 64–3.

Table 64–3 Contents of Various Bezoars

Phytobezoar	Trichobezoar	Pharmacobezoar
Celery	Hair	Nifedipine
Pumpkin	Carpet fibers	Procainamide
Grape skins	String	Verapamil
Prunes	Clothing	Theophylline
Raisins		Cholestyramine
Leeks		Meprobamate
Beets		Sucralfate
Persimmons		Kayexalate resin
		Guar gum
		Enteral feeding formulas
		Vitamin C tablets
		Vitamin B_{12}
		Lecithin
		Ferrous sulfate

Figure 64–5. Computed tomography scan revealing a dilated stomach with an intraluminal mass consistent with a trichobezoar. (From Phillips MR, Zaheer S, Drugas GT: Mayo Clin Proc 73:653-656, 1998.)

These foods are composed of large amounts of nondigestible fiber such as cellulose, lignin, and fruit tannin.[47] A high concentration of tannins, exposed to gastric acid, can form a coagulum leading to bezoar formation.[48] Phytobezoars are typically dark brown, black, or green when visualized by endoscopy.

Trichobezoars are composed of hair or hair-like fibers (see Table 64–3). They are observed most commonly in children and women younger than 30 years.[49] Frequently, these patients have underlying mental retardation or psychiatric disorders. Trichotillomania is an impulse control disorder characterized by the repeated urge to pull out scalp and body hair. Trichophagia is the compulsion to eat or chew on hair. These behavioral disorders are associated with trichobezoar formation. Hair and fibers in the stomach become trapped in gastric folds. Trichobezoars are typically black regardless of the color of the hair ingested because of enzymatic oxidation of gastric acid on the hair fibers. Some gastric trichobezoars have a long extension of hair that trails into the duodenum, a condition known as the Rapunzel syndrome.[50] It has been reported to cause jaundice and pancreatitis as a result of obstruction of the ampulla of Vater by hair.[51,52]

Pharmacobezoars are composed of medications or vitamins (see Table 64–3). Resin-coated, extended-release products or other products designed to resist digestion are most often the nidus for this type of bezoar formation.[46] Pharmacobezoars can result in reduced medication efficacy because the active agent is trapped in the bezoar and cannot be absorbed. Alternatively, toxicity can result when the previously bound active agent is released in excessive amounts. Fatality secondary to pharmacobezoars has been reported. At autopsy the patient was found to have a serum theophylline concentration of 190.1 mg/ml (normal, 10 to 20 mg/ml). A 318-g pharmacobezoar containing 29 g of theophylline in sustained-release tablets was found within the stomach.[53]

Lactobezoars are a compact mass of undigested milk concretions located within the GI tract of infants and toddlers. These rare bezoars have been linked to nearly every commercially available infant formula and breast and cow milk.[54]

Symptoms and Signs of Bezoars

The most common symptom present in 80% of patients with bezoars is vague epigastric discomfort. Other symptoms include nausea, vomiting, anorexia, early satiety, and weight loss. If a bezoar reaches a large size and is present for a prolonged period, it may cause pressure necrosis and ulcers. Ulceration can lead to bleeding or obstruction. Once in the small bowel, bezoars most commonly result in obstruction.[55]

Physical examination is often unrevealing. Occasionally, a palpable mass may be present. Patients with trichotillomania and trichobezoars may have patchy baldness.[56]

Diagnosis

Bezoars can be demonstrated on plain films and computed tomography scans (Fig. 64–5). Barium studies will reveal a gastric filling defect (Fig. 64–6).[47] Up to 75% of bezoars may be missed on radiography. Endoscopy is the gold standard for the diagnosis of bezoars. The endoscopic appearance of phytobezoars consists of an amorphous mass of brown, green, or black material (Fig. 64–7). Trichobezoars are black, hard, and concrete-like. Pharmacobezoars contain whole pills or pill frag-

ments.[47,56] Lactobezoars are most commonly identified on contrast-enhanced upper GI series or ultrasound.[54]

Treatment

Treatment of bezoars involves removal of the mass and prevention of recurrence. Some small bezoars can be managed medically. Once a diagnosis is established by endoscopy, institution of a clear liquid diet and a prokinetic agent may clear the bezoar. Nasogastric lavage may be useful for these small bezoars.[57]

Most bezoars require endoscopic therapy. Using biopsy forceps or polypectomy snares, a bezoar can be fragmented and the pieces removed with multiple passes of the endoscope. The reported success rate of this technique is 85% to 90%. In addition to endoscopic fragmentation, success has been reported with the use of electrohydraulic lithotripsy, pulsed water jets, Nd:YAG laser, and needle-knife bezotome.[58-60] Enzymatic dissolution of bezoars has also been described with cellulose, papain (meat tenderizer), *N*-acetylcysteine, and Coca-Cola.[61-63]

Surgical intervention is required if endoscopic therapy fails or complications of bleeding, obstruction, or perforation occur. Trichobezoars are the most likely to require surgical management and can be removed by open or laparoscopic gastrostomy.[57,64] During surgery, the small bowel should be examined for a concomitant bezoar, which should be removed by enterostomy or milked into the cecum for passage through the large bowel.

In addition to removal of the bezoar, attempts must be made to prevent recurrence. Avoidance of foods causing a phytobezoar is necessary. Prophylactic treatment with cellulose can be considered. Patients with a motility disorder may benefit from prokinetic agents such as metoclopramide.[57] Patients with an underlying psychiatric disorder require specific therapy, which may include selective serotonin uptake inhibitors, hypnosis, or play therapy (children) to avoid recurrence.[65]

Lactobezoars are treated by withholding oral feedings and instituting intravenous hydration.[66] Gentle gastric lavage may decrease treatment time.[67] Although some recommend switching these infants to elemental formula, this may be unnecessary because recurrence has never been reported.[54]

Surgical Diseases of the Stomach and Duodenum in Infants and Children

Harsh Grewal ▪ William H. Weintraub

Surgical diseases of the stomach and duodenum in infants and children are often the result of developmental anomalies. This chapter reviews congenital and acquired diseases of the stomach and duodenum in infants and children that a surgeon may encounter.

EMBRYOLOGIC DEVELOPMENT

At the beginning of the fourth week of development, the primordial gut forms from lateral and craniocaudal folding of the embryo. The distal part of the foregut dilates to form the stomach around the fourth to fifth week of development. During the 6th to 10th week, as the stomach enlarges, it also rotates 90 degrees in a clockwise direction. These differential rates of growth and subsequent rotation result in the stomach assuming its final position: the cranial part (gastric fundus) on the left and the caudal part (pylorus) on the right of the midline, the lesser curvature facing cranially and to the right, and the greater curvature located caudally.

The transition from foregut to midgut occurs at the second portion of the duodenum, just distal to the entry of the bile duct. The celiac arterial trunk supplies this part of the stomach and duodenum, whereas the superior mesenteric artery supplies the midgut (the bowel distal to the entry of the bile duct). The proximal duodenum moves superiorly and to the right as the distal duodenum rotates down and to the left, thereby resulting in the "C-loop" configuration of the duodenum around the 6th to 10th week of development. Elongation of the midgut around the fifth to sixth week causes herniation of the midgut into the umbilical cord (physiologic umbilical herniation). The midgut then rotates nearly 270 degrees counterclockwise around an axis formed by the superior mesenteric artery, which results in fixation of the fourth portion of the duodenum to the left of the aorta. At the 10th to 12th week, the extraembryologic coelomic gut returns to the abdominal cavity. Subsequent shortening of the duodenal mesenteric base plus fusion with the parietal peritoneum fixes the duodenum in its retroperitoneal location at the ligament of Treitz to the left of the midline. The ampulla of Vater, in the second part of the duodenum, is medial and is the site where the common bile duct and often the pancreatic ducts enter into the duodenum.[1]

During this period of development, the proximal duodenum undergoes epithelial proliferation, and a transitional solid cord is created that obliterates the lumen. Around the eighth week, this transitional solid phase undergoes vacuolization with resultant recanalization. Vascular accidents or aborted recanalization can result in congenital duodenal obstruction. The pancreas develops from the rotation and fusion of paired buds arising from the dorsal and ventral duodenal entodermal epithelium, so abnormalities in development can result in an annular pancreas and in heterotopic pancreatic rests in the proximal duodenum or pylorus.[1]

INTESTINAL OBSTRUCTION IN THE NEWBORN

Because congenital and acquired diseases of the stomach and duodenum in the newborn may cause proximal intestinal obstruction, a brief review of the signs and symptoms and a diagnostic approach are presented in this section. Neonatal intestinal obstruction is often accompanied by bilious vomiting and alterations in the passage of meconium. Bilious vomiting in a newborn or infant should be presumed to be secondary to malrota-

tion with midgut volvulus, and this condition should always be ruled out with an upper gastrointestinal (GI) study because untreated midgut volvulus can rapidly lead to intestinal ischemia and gangrene with loss of intestine and possibly death. The differential diagnosis of neonatal intestinal obstruction, especially with bilious vomiting, covers both proximal and distal obstructive lesions, including congenital gastric or duodenal obstruction, proximal and distal small intestinal atresia, meconium ileus secondary to cystic fibrosis, GI duplications, Hirschsprung's disease, colonic atresia, meconium plug syndrome, small neonatal left colon syndrome, and imperforate anus. Spontaneous gastric perforation and necrotizing enterocolitis may also be manifested as feeding intolerance and bilious vomiting. Clinically, neonatal sepsis with ileus may suggest intestinal obstruction.

Clinical Features and Diagnosis Proximal intestinal obstruction is usually accompanied by vomiting and a nondistended abdomen, whereas abdominal distention characterizes a distal intestinal obstruction; however, localized upper abdominal distention can suggest duodenal atresia or gastric outlet obstruction. Abdominal wall discoloration plus peritonitis may be associated with intestinal necrosis or perforation and indicates the need for immediate laparotomy. Plain abdominal radiography, followed by an upper GI series, is the usual sequence of studies in the evaluation of proximal intestinal obstruction. A plain film revealing pneumatosis suggests necrotizing enterocolitis. The "double bubble" from a distended stomach and duodenal bulb, with a gasless lower abdomen on a plain radiograph in a neonate, is suggestive of duodenal atresia. The presence of distal gas with a "double bubble" suggests malrotation with midgut volvulus. Distention of the small and large intestine is difficult to distinguish on plain radiographs in a newborn; therefore, differentiation of distal from proximal obstruction relies on the number of distended air-filled loops because with proximal obstruction there will be fewer air-filled loops. A prone cross-table lateral radiograph to determine the presence of gas in the distal end of the rectum may also help identify the level of obstruction.

Suspicion of a proximal obstruction will then suggest the need for an upper GI study, and distal obstruction, a lower GI study. In the absence of an acute abdomen on examination, an infant or newborn with bilious vomiting should have an upper GI study performed urgently to rule out malrotation with possible volvulus (Fig. 65–1A and B). The study should demonstrate the ligament of Treitz in its normal location to the left of the spine and at or above the level of the duodenal bulb to exclude malrotation. An upper GI study may also demonstrate malrotation without volvulus (see Fig. 65–1C), atresia, or stenosis, although in the absence of suspicion for midgut volvulus, it may not be necessary to perform this study urgently.

The following discussion of surgical diseases of the stomach and duodenum in infants and children is separated into congenital and acquired conditions.

CONGENITAL CONDITIONS

Gastric Duplications

Incidence and Etiology Duplications in the stomach and duodenum are uncommon and constitute less than 15% of all GI duplications. There are a number of theories on the embryogenesis of duplications, including the "split notochord" and "partial twinning" theory; additionally, duplications may be related to disordered recanalization of the solid-cord transitional embryonic phase. Duplications are usually found along the mesenteric border and share the blood supply of the adjacent functional stomach or intestine.[2,3]

Clinical Features In neonates or infants, gastric and duodenal duplications may be associated with signs and symptoms of gastric outlet obstruction. Less acute manifestations include a palpable mass or a mass detected on imaging (including fetal ultrasound), failure to thrive, abdominal discomfort, or GI bleeding. Duplications occasionally first come to attention as an emergency because of either a perforation or bleeding secondary to peptic ulceration. Gastric duplications are typically cystic, usually appear along the greater curve, and rarely communicate with the gastric lumen. Tubular duplications, which communicate with the gastric lumen and are also found along the greater curve, are less common. Communications between gastric duplications and intrathoracic esophageal duplications have been reported, and these patients may have respiratory symptoms such as effusions and occasionally vertebral anomalies.[2,4,5] Communications between a gastric duplication and the pancreatic ductal system have been reported and are associated with pancreatitis.[6] Duodenal duplications occur along the posterior aspect of the first or second part of the duodenum. Besides proximal intestinal obstruction and bleeding, duplications can obstruct the biliary and pancreatic ductal system and result in jaundice or pancreatitis. Malignant degeneration of the cyst lining to an adenocarcinoma or carcinoid tumor has been rarely reported in adults.[7,8]

Diagnosis Ultrasound, computed tomography (CT), or an upper GI study can define the duplication, which is usually cystic (Fig. 65–2A). Antenatal ultrasound may detect gastric duplication in a fetus. Technetium 99m imaging will identify duplications that contain ectopic gastric mucosa, which is more prone to bleeding; all histologic types of GI epithelia can be present ectopically in GI duplications.[2,3]

Management Resection of the cyst may be preferable (see Fig. 65–2B), but stripping of the mucosal lining and internal drainage into the duodenal lumen may be a safer alternative to avoid damage to the biliary and pancreatic ductal systems. Duodenal duplications may be drained into a Roux-en-Y jejunal limb. Recently, laparoscopic resection has been described for managing duplications in newborns and infants.[9]

Gastric Volvulus

Incidence and Etiology Gastric volvulus is a rare condition in childhood. It occurs more commonly as a chronic condition, but acute gastric volvulus can be a surgical emergency.[10-12] Anomalies in rotation and fixation of the stomach are responsible for most cases of childhood gastric volvulus; the presence of a wandering spleen or asplenia may be a predisposing factor.[12,13] The multiple ligamentous attachments of the stomach probably account for its rarity. The peritoneal attachments and the gastrophrenic, gastrosplenic, and gastrohepatic ligaments along with the retroperitoneal position of the duodenum stabilize its position in both the longitudinal and transverse axes. In organo-axial volvulus, the stomach remains fixed at the gastroesophageal junction and the duodenum, which allows it to twist along its longitudinal axis. Mesenterico-axial volvulus is a more common cause of acute gastric volvulus in children, with rotation around the transverse axis of the stomach through the greater and lesser curvatures.[11]

Clinical Features and Diagnosis Typical symptoms range from an acute proximal intestinal obstruction and gastric necrosis to a chronic picture of postprandial pain with intermittent volvulus. Plain radiographs and an upper GI study are used to make the diagnosis of gastric volvulus.

Management In acute gastric volvulus, hydration, correction of electrolyte abnormalities, and gastric decompression with nasogastric suction are essential; if not possible, emergency surgery is indicated. Derotation and anterior gastropexy along with crural repair may be sufficient if the stomach has no evidence of necrosis. If possible, gastric perforations are typically closed around a tube gastrostomy to fix the stomach to the anterior abdominal wall and create an anterior gastropexy. Management of chronic gastric volvulus is controversial, and some patients with intermittent primary volvulus may respond to nonoperative therapy.[10] There are recent case reports in which laparoscopic-guided gastropexy has been used for the management of gastric volvulus.[14,15]

Microgastria

Congenital microgastria is another rare condition of the distal foregut that results in a disproportionately small stomach. The infant initially has failure to thrive or gastroesophageal reflux (GER), or microgastria is observed at surgery performed for another intra-abdominal problem. The diagnosis is confirmed with an upper GI study, which demonstrates a dilated esophagus and a transverse lie of a small tubular stomach. Initial management includes multiple small feedings through a feeding tube and medical management of GER. If unsuccessful, surgery is indicated to provide adequate nutrition, but the size of the stomach limits the ability to perform an antireflux procedure and gastrostomy at the initial surgery. A feeding jejunostomy followed by creation of a jejunal reservoir (Hunt-Lawrence pouch) may be required.[16,17] Most of these children have multiple anomalies, including malrotation, situs inversus, megaesophagus, and asplenia, as well as cardiovascular, renal, and skeletal abnormalities.[18,19]

Gastric Outlet Obstruction

Incidence and Etiology Congenital gastric outlet obstruction, which may be caused by antral and pyloric webs, diaphragms, and atresia, is another uncommon cause of newborn obstruction. The embryologic cause of antral and pyloric atresia is not well understood.

Clinical Features Antral webs or partial diaphragms cause prepyloric obstruction and have varied clinical manifestations, depending on the severity or completeness of the obstruction. Pyloric atresia is usually ac-

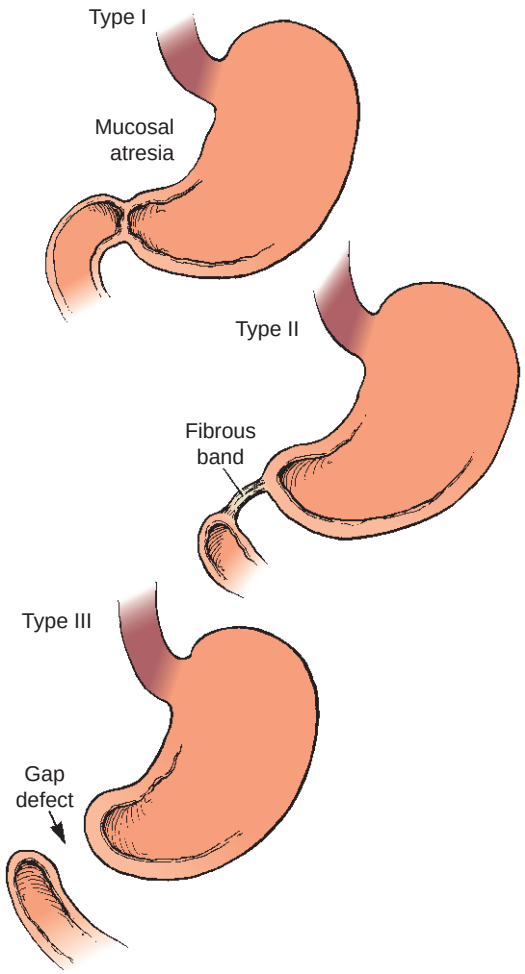

Figure 65–3. Illustration showing the different types of congenital pyloric atresia. (From O'Neil JA Jr [ed]: Principles of Pediatric Surgery, 2nd ed. St Louis, CV Mosby, 2003, p 486.)

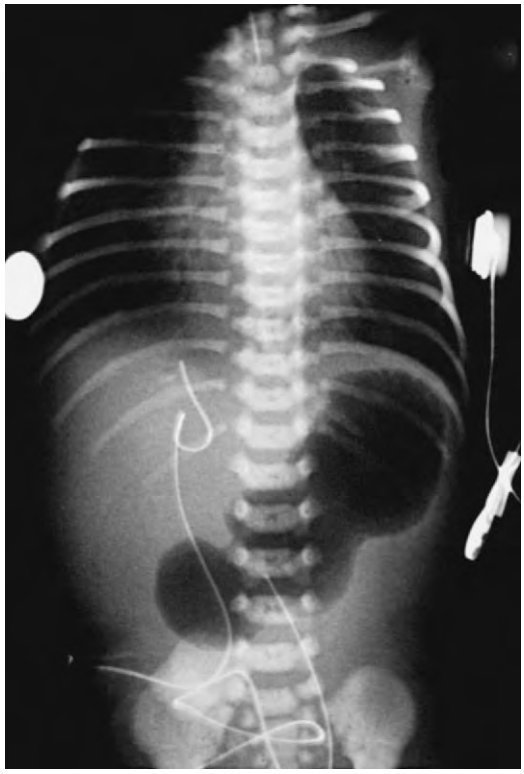

Figure 65–4. Classic plain film radiograph showing gastric outlet obstruction.

companied by nonbilious vomiting and gastric distention consistent with complete obstruction. If the diagnosis is delayed, a complete gastric outlet obstruction can become a surgical emergency with gastric perforation occurring within the first few days of life.[20] An incomplete web or diaphragm causes partial gastric outlet obstruction and may be associated with insidious findings of epigastric pain, failure to thrive, halitosis, and postprandial nonbilious vomiting; the diagnosis of an incomplete web may be delayed into adulthood.[21] The association of other anomalies, including epidermolysis bullosa with pyloric atresia, should be evaluated before surgery.[22,23]

Types Congenital pyloric anomalies are more frequent than antral anomalies. Pyloric webs are more common than atresia. The following three varieties of pyloric atresia have been described: type I, the most common type, is an intraluminal pyloric membrane or web; in type II, the pyloric channel is a solid cord; and in type III, there is a gap between the stomach and duodenum (Fig. 65–3).

Diagnosis The diagnosis may be indicated prenatally on ultrasound examination by the presence of polyhydramnios, a dilated stomach, and a narrowed gastric outlet. Postnatally, plain radiographs may show a large gastric bubble (Fig. 65–4); gastric outlet obstruction or the presence of a web may be seen on an upper GI study. Endoscopy is useful in the diagnosis of an incomplete web, especially if the results of radiographic studies are equivocal.

Management Nasogastric decompression and preoperative fluid and electrolyte resuscitation are indicated to correct the electrolyte abnormalities associated with gastric outlet obstruction. The type of congenital obstruction will dictate the surgical procedure.[20] Type I pyloric atresia requires a longitudinal gastrotomy to identify the web, followed by extension into the pylorus, excision of the web, and transverse closure of the pylorus as a pyloroplasty. Before closure, a catheter should be passed distally to ensure that no additional atresias are present. If there is difficulty in performing a transverse closure, a serosal or omental patch may be considered. Type II or III atresia is repaired by performing a gastroduodenal anastomosis or a pyloric reconstruction. Postoperatively, the stomach should be decompressed with a nasogastric tube; in patients with associated anomalies, a gastrostomy with a transanastomotic gastrojejunal feeding tube may be needed. Prepyloric membranes can become redundant and act as a "windsock" that produces an obstruction distal to the actual origin of the web; in

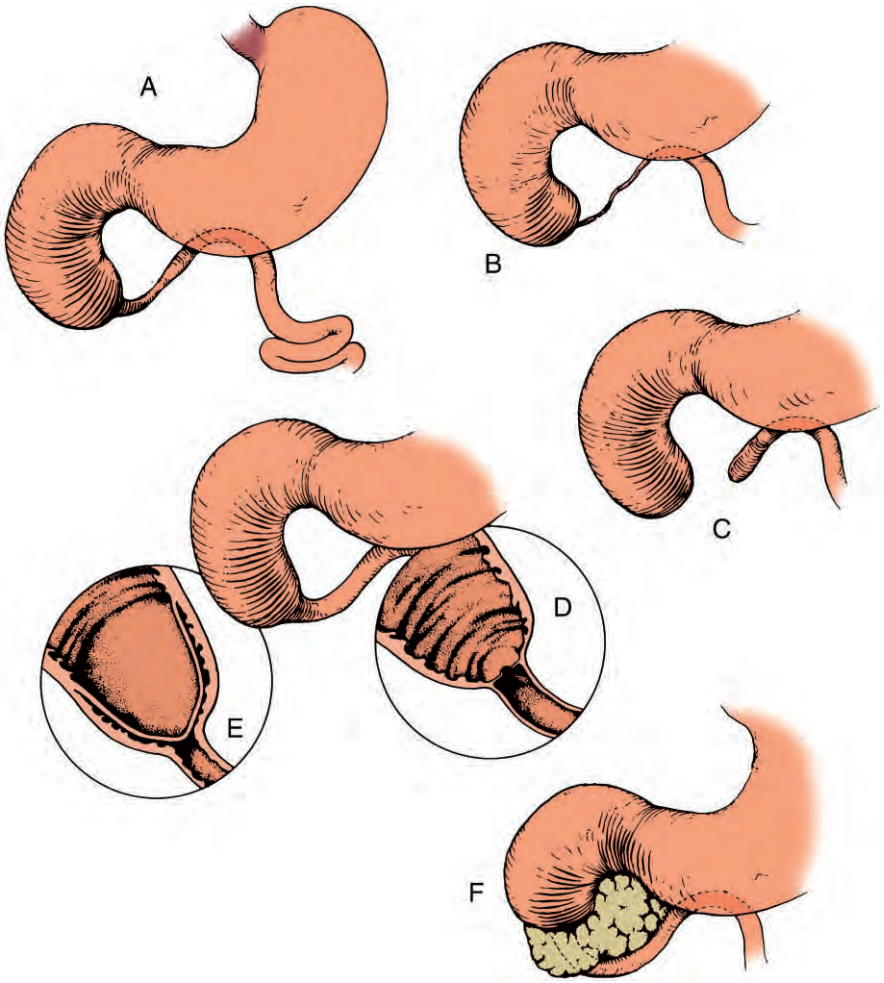

Figure 65–5. Classification of anomalies causing duodenal obstruction. **A,** Type I atresia with intact membrane producing marked discrepancy in size between proximal and distal segments. **B,** Blind ends (type II) of duodenum connected by a fibrous cord. **C,** Blind ends (type III) are separated, and the mesentery is absent at the separation. **D,** Intraluminal membrane with a perforation. **E,** Windsock anomaly. An incision in the distal portion of the dilated segment is still beyond the obstruction. **F,** Annular pancreas. (From O'Neil JA Jr [ed]: Principles of Pediatric Surgery, 2nd ed. St Louis, CV Mosby, 2003, p 472.)

such instances the surgeon can mistakenly think that the obstruction is more distal. Longitudinal enterotomy, partial web excision, and transverse closure are sufficient. Incidentally noted ectopic pancreatic tissue or hamartomas in the pylorus should be excised.

The survival of infants and children with isolated congenital gastric outlet obstruction is excellent. In neonates with multiple anomalies, however, survival is lower. The presence of epidermolysis bullosa is associated with higher mortality and morbidity.[23]

Duodenal Obstruction

Incidence and Epidemiology The overall incidence of congenital duodenal obstruction is approximately 1 in 5000 to 10,000 live births; it appears to be more common in males. The most common causes of congenital duodenal obstruction are atresia and stenosis. Duodenal atresia is associated with trisomy 21 in up to 30% of cases.[24-27] A rare familial duodenal atresia has been described as part of the "Feingold syndrome," which has associated microcephaly, limb anomalies, and tracheoesophageal anomalies; it appears to be autosomal dominant.

Embryology and Etiology The embryonic duodenum is formed by the terminal part of the foregut and the cephalic portion of the midgut. Simultaneously, epithelial proliferation and recanalization occur in the duodenum. Vacuolization of the solid cord of proliferating epithelium results in recanalization. Abnormalities in recanalization or vascular accidents result in congenital duodenal anomalies, which may be associated with coexistent pancreatic and biliary anomalies. Around the third to fourth week the paired dorsal and ventral pancreatic buds originate from the duodenal entodermal epithelium and migrate to form the pancreas. The dorsal bud forms the body and tail; the ventral bud rotates 180 degrees and joins the dorsal gland to form the uncinate process. Abnormalities in rotation and fusion of the paired ventral buds around the pancreas result in an "annular" pancreas, which can cause extrinsic obstruction and may coexist with duodenal atresia.

Types Duodenal obstruction can result from an intrinsic obstruction secondary to congenital atresia, stenosis, or a web, or it can result from an extrinsic obstruction secondary to GI duplications, compression by Ladd's bands, or an annular pancreas. The three morphologic types of intrinsic congenital duodenal obstruction are the following: type I, in which the duodenal wall is intact but there is an intraluminal membrane or web (Fig. 65–5A); type II, in which the atretic proximal and distal ends are connected by a fibrous cord (see Fig. 65–5B); and type

Figure 65–6. Classic plain film radiograph showing the "double bubble" in a patient with duodenal atresia. (Courtesy of Dr. Polly Kochan.)

III, in which there is a gap between the atretic ends, as well as a mesenteric defect (see Fig. 65–5C).

Clinical Features and Diagnosis Upper abdominal fullness with a flat or scaphoid lower abdomen is usual; feeding intolerance and bilious vomiting are classic signs. Congenital duodenal obstruction is associated with other congenital anomalies and trisomy 21, with more than 50% of patients having anomalies of the cardiac, renal, tracheoesophageal, anal, skeletal, and central nervous systems.[25-27] In addition, up to a third of these neonates may have an associated annular pancreas (see Fig. 65–5F) or malrotation. The diagnosis may be made prenatally by maternal ultrasound, which may also demonstrate polyhydramnios. Most often the diagnosis is made by the classic plain film radiographic image of a "double bubble" secondary to a distended stomach and duodenum (Fig. 65–6). Complete duodenal obstruction is associated with a gasless distal bowel. The presence of distal luminal air may indicate an incomplete membrane, a partially obstructing lesion, and most worrisome, a possible midgut volvulus causing the duodenal obstruction. In a neonate with a "double bubble" and distal air or one in whom it is uncertain whether the obstruction is related to a midgut volvulus, an urgent upper GI study needs to be performed because volvulus requires an immediate operation.

In the absence of any suspicion of volvulus, surgery can be performed less urgently. Patients with type I atresia can have a redundant intraluminal web that extends for a distance, thereby resulting in a windsock morphology (similar to antral or pyloric webs) (see Fig. 65–5E). Stenosis is usually secondary to an incomplete diaphragm (Fig. 65–7A and B) or mucosal web with a central opening (see Fig. 65–5D). If the web has a larger opening, clinical detection may be delayed. Atresias usually cause postampullary obstruction, although up to 10% of cases can be preampullary.[24]

Management The stomach should be decompressed with an orogastric tube and all fluid and electrolyte abnormalities corrected. Associated anomalies should be investigated expeditiously before surgical repair. Chromosomal analysis for possible trisomy and a preoperative cardiology evaluation should be performed. A supraumbilical, right upper quadrant transverse incision is the usual surgical approach. Intestinal rotation is first inspected, and if malrotation is present, a "Ladd" procedure is performed before repair; if normal rotation is present, an extended "Kocher" maneuver is performed to expose the duodenum, pancreas, and root of the mesentery. The duodenum and distal bowel should be inspected to evaluate for additional coexisting distal atresia, which can occur in up to 5% of patients.

Type I atresias with a web and possible "windsock" should have the origin of the web confirmed by passage of an orogastric tube (Fig. 65–8A) or a balloon catheter into the duodenum or through a gastrotomy and withdrawal with the balloon inflated. A longitudinal duodenotomy is performed over the origin of the web (see Fig. 65–7B), and the location of the ampulla of Vater is identified; the web is then excised while taking care to avoid injury to the ampulla. The duodenotomy is closed transversely with interrupted sutures. The presence of distal atresia is excluded by passage of a balloon catheter distally through the duodenotomy.

Type II and III atresias may be repaired by a number of techniques, including side-to-side duodenoduodenostomy (see Fig. 65–8, *C1*), an end-to-side "diamond-shaped" duodenoduodenostomy (see Fig. 65–8, *C2*) and duodenojejunostomy (see Fig. 65–8B). The diamond-shaped duodenoduodenostomy appears to be the technique of choice and requires a transverse incision in the proximal duodenum with a longitudinal incision in the distal duodenum and an end-to-side duodenoduodenostomy (Fig. 65–8, *C2*). This technique results in a wider anastomosis that functions earlier and has reduced stasis from a blind loop or stenosis.[28] The side-to-side duodenoduodenostomy is often associated with delayed anastomotic transit times and megaduodenum.[29]

An annular pancreas causes duodenal obstruction in infancy and early childhood, although it is less frequent than intrinsic duodenal obstruction (see Fig. 65–5F).[26,30] A recent review of six case series since 1954 revealed a total of 66 reported cases of annular pancreas.[30] Such children are more likely to initially be seen in the neonatal period with nonbilious vomiting; they often have trisomy 21 and tracheoesophageal anomalies. Management is similar to that for type II and III duodenal atresia, with the diamond-shaped duodenoduodenostomy being the technique of choice to bypass the obstruction.[26,30] In the absence of significant comorbidity, the outcome is excellent.

Although we prefer using parenteral nutrition, enteral feeding after repair may be achieved early via a transanas-

tomotic feeding tube because duodenal emptying is often delayed. Normal peristalsis is slow because of the dilated proximal duodenum, and in selected cases in which the proximal duodenum is markedly dilated, a tapering duodenoplasty is useful. A feeding gastrostomy is sometimes helpful in a complicated duodenal repair. The outcome depends on the associated comorbid conditions, such as congenital cardiac defects and chromosomal abnormalities.[25] Long-term follow-up studies have shown delayed morbidity in 12% and delayed mortality in 6% of patients undergoing repair of congenital duodenal anomalies.[29] GER disease and megaduodenum with upper GI motility disorders were the most common delayed morbidities identified in these studies. It appears that the dilated proximal duodenum is associated with disturbed transit.[31] Plication or a tapering duodenoplasty is recommended for the management of these delayed complications.[29,31]

ACQUIRED CONDITIONS

Hypertrophic Pyloric Stenosis

Incidence and Epidemiology Hypertrophic pyloric stenosis (HPS) is one of the most common disorders of the stomach and duodenum in infants that requires surgical correction. The reported incidence is 1 to 2 per 1000 live births.[32-34] It is more common in males at a 4 : 1 to 5 : 1 ratio and more common in white and Hispanic infants than in Asian and black infants. First-degree relatives have an almost fivefold increase in risk for HPS.[35]

Etiology and Pathogenesis Hypertrophy of the pyloric muscle obstructs the passage of gastric contents through the pyloric canal. The pathogenesis has not been fully understood despite the frequency of its occurrence. A lack of nitric oxide synthase in pyloric muscle causes pylorospasm, and the loss of nitric oxide–mediated relaxation of smooth muscle may result in the hypertrophied and contracted pyloric muscle.[36] Abnormalities in peptide-containing nerve fibers, including a loss of peptide immunoreactivity in nerve fibers in the circular muscle, have also been described in the hypertrophied muscle.[37] Possible changes in hormonal control of pyloric sphincter function have been implicated, including abnormalities in gastrin and prostaglandins. Defects of the intestinal pacemaker (interstitial cells of Cajal), as well as abnormalities in extracellular matrix proteins and growth factors, are being reported as possible etiologic factors in the development of HPS.[38,39]

Clinical Features Typically, infants are 3 to 6 weeks old when they are initially evaluated for vomiting. They may start vomiting, however, as early as 2 weeks, or it may be delayed up to 12 weeks. The vomiting is usually nonbilious, postprandial, projectile, and progressive. HPS is most commonly seen in otherwise normal infants, but it occurs more frequently, at a 1% to 10% incidence, in patients who have undergone correction of esophageal

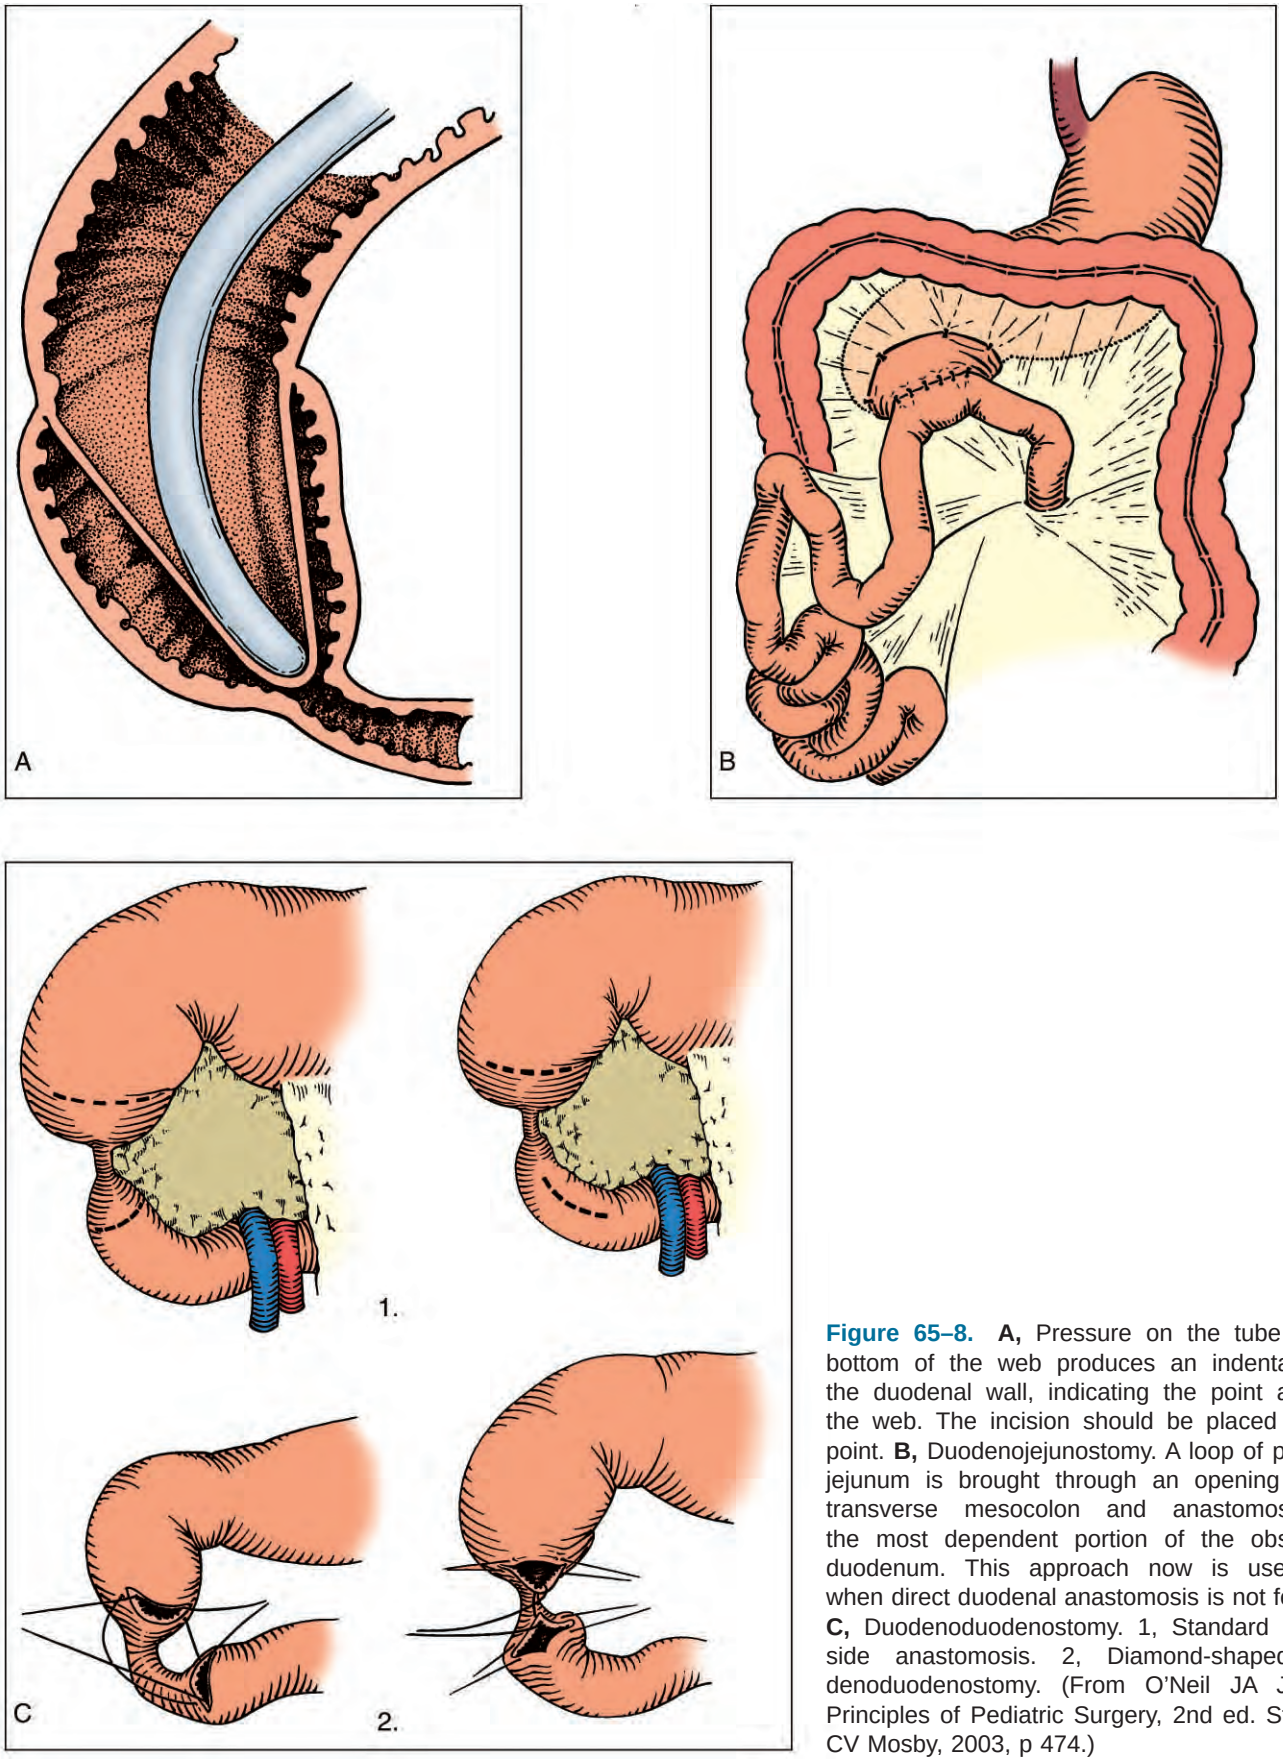

Figure 65–8. **A,** Pressure on the tube at the bottom of the web produces an indentation in the duodenal wall, indicating the point apex of the web. The incision should be placed at that point. **B,** Duodenojejunostomy. A loop of proximal jejunum is brought through an opening in the transverse mesocolon and anastomosed to the most dependent portion of the obstructed duodenum. This approach now is used only when direct duodenal anastomosis is not feasible. **C,** Duodenoduodenostomy. 1, Standard side-to-side anastomosis. 2, Diamond-shaped duodenoduodenostomy. (From O'Neil JA Jr [ed]: Principles of Pediatric Surgery, 2nd ed. St Louis, CV Mosby, 2003, p 474.)

atresia.[32,40] Intestinal malrotation and obstruction of the urinary tract also occur more frequently in association with this disorder.[32] A transient self-limited unconjugated hyperbilirubinemia secondary to a glucuronyl transferase deficiency similar to Gilbert's syndrome is seen in 1% to 2% of infants.[41] The differential diagnosis of nonbilious vomiting should include GER and overfeeding, gastroparesis, pylorospasm, other congenital gastric outlet obstruction (as discussed earlier in the chapter), and peptic ulcer disease.

Diagnosis An infant with a typical history and a palpable hypertrophic pylorus does not need additional diagnostic testing. The ability to successfully palpate a hypertrophic pylorus is variable, and this clinical ability appears to be decreasing with the increased reliance on imaging studies.[42] In a study of infants with HPS, for example, the pyloric mass was palpated in 87% during 1974 to 1977, as compared with 49% during 1988 to 1991.[43] In a more recent report (2000 to 2002), only 32% had a palpable "olive."[44] To successfully palpate the pyloric "olive," the infant needs to be quiet with a relaxed abdominal wall. One technique is to allow the infant to suck a pacifier, and while standing on the infant's left side and holding the legs flexed at the hips in the left hand, the fingertips of the right hand are gently swept from the liver edge toward the umbilicus. Increased serum bicarbonate and decreased serum chloride levels favor a diagnosis of HPS.[45]

In the absence of a palpable "olive," either an upper GI study or an ultrasonogram may be performed. An upper GI study is approximately 95% sensitive, although error rates of up to 11% have been reported.[46] On an upper GI study, a "string" sign indicating a narrowed elongated pyloric canal that does not relax is seen; a "shoulder" sign caused by the hypertrophied muscle indenting the antrum and a "double-track" sign caused by the redundant mucosa may be observed.[46,47] Real-time ultrasonography, however, appears to be the most reliable diagnostic test; it is almost 100% accurate in the hands of an experienced operator, it does not involve radiation exposure, and the examiner does not have to wait for the stomach to empty.[46,47] Sonographic measurements that are reported to be diagnostic include a pyloric wall thickness of at least 4 mm and a channel length of at least 17 mm.[48] The actual measurements may not be as important as evaluation of the overall morphology of the antrum and pylorus and evaluation of gastric emptying.[46] Measurement of the volume of gastric aspirate in a vomiting (nonbilious) infant can help determine whether an upper GI study or ultrasonography should be performed, and this has been suggested as a more cost-effective approach in deciding the appropriate imaging study.[49]

Management In an infant with normal fluid and electrolyte status, surgical correction with general anesthesia as soon as logistically feasible is appropriate. Some infants will need correction of their fluids and electrolytes, and about 10% to 15% will be significantly dehydrated and have a hyponatremic, hypochloremic, hypokalemic metabolic alkalosis.[42] In a severely dehydrated infant, initial resuscitation is begun with a 10- to 20-ml/kg bolus of normal saline. Correction of both electrolyte losses and intravascular depletion is essential before surgery because pyloric stenosis is not a surgical emergency. Once adequate hydration and normal urine output are achieved, potassium is added to the intravenous fluids. The metabolic alkalosis is chloride responsive; further fluids (5% dextrose with 0.45% saline and 20 mEq of potassium chloride per liter) are given at 150% of the maintenance requirement. A serum bicarbonate level of 28 mEq/L or lesser is usually the target for correction before surgical repair. Keeping the stomach empty before the repair by using a gastric tube may help limit further vomiting.

The procedure of choice is a Ramstedt-Fredet extramucosal pyloromyotomy performed with the infant under general anesthesia. A number of incisions to perform the pyloromyotomy have been described, including a transverse right upper quadrant incision, vertical midline incision, and circumumbilical incision (Fig. 65–9A-D),[50,51] as well as three-port laparoscopic approaches. There does not seem to be a significant difference in outcome between the laparoscopic and open approaches, although more complications may occur in the laparoscopic group.[52-54] In the open approach, after the peritoneum is opened and the hypertrophied pylorus is delivered to the surface, a seromuscular incision is made into the pyloric muscle. The pyloromyotomy incision extends from just proximal to the duodenum (pyloric vein) onto the antrum of the stomach. The initial myotomy is deepened bluntly with the back of a scalpel handle or a Benson pyloric spreader. Protrusion of the gastric submucosa and mucosa into the myotomy site indicates that the obstruction has been relieved (see Fig. 65–9D). If an inadvertent duodenal perforation occurs, the enterotomy can be managed by mucosal closure with fine absorbable suture and reinforced with omentum (Fig. 65–10A). An alternative approach is to perform a two-layer closure of the pylorus, followed by a second myotomy at a site rotated 90 to 180 degrees from the repair (see Fig. 65–10B). In an uncomplicated pyloromyotomy, feeding is resumed within 4 to 6 hours. A number of different feeding protocols that include incremental advances from sugar water to increased amounts of formula volume and osmolarity every 2 to 3 hours have been used. The type of feeding protocol may influence postoperative vomiting but does not appear to affect the time to full feeding or discharge.[55,56] Regardless of whether a feeding schedule or early ad libitum feeding is used, most infants will reach their feeding goal within 24 hours postoperatively. In an infant with a duodenal perforation that is repaired, a period of gastric decompression and antibiotics may be prudent. If there is persistent vomiting and clinical deterioration, an upper GI study to rule out a leak is appropriate. Complications include persistent emesis in up to 10%, mucosal perforation in less than 5%, and wound infection in up to 10% of infants.[42,56,57] Incomplete myotomy is a rare complication that may be suspected in an infant with persistent vomiting beyond the second week after pyloromyotomy. An upper GI study is helpful in showing the vomiting to be secondary to GER, which is a more likely diagnosis in this situation.

Neonatal Gastric Perforation

Incidence Gastric perforations are uncommon in neonates, but they may be seen in both term and preterm newborns and usually occur in the first week of life.[58-61] Perforations often occur in newborns who have undergone neonatal resuscitation.

Etiology There is no consensus regarding the cause of neonatal gastric perforation, and even whether these perforations are "spontaneous" or secondary to other factors is controversial.[58,59] "Mechanical" causes secondary to gastric dilatation from resuscitation and mechanical ventilation, as well as "low-flow" or "ischemic" causes from hypoxia and prematurity, have been postulated.[59,61] The cause is probably multifactorial; possibly, the cause of perforation in a preterm newborn may be a low-flow state, whereas in a term newborn it may be a mechanical cause.[59-61]

Clinical Features and Diagnosis Gastric perforation may be manifested as feeding intolerance, abdominal distention, upper GI bleeding, respiratory distress, or a picture of "sepsis." The diagnosis of perforation is almost always evident on plain film radiographs with massive pneumoperitoneum. A cross-table lateral or decubitus film

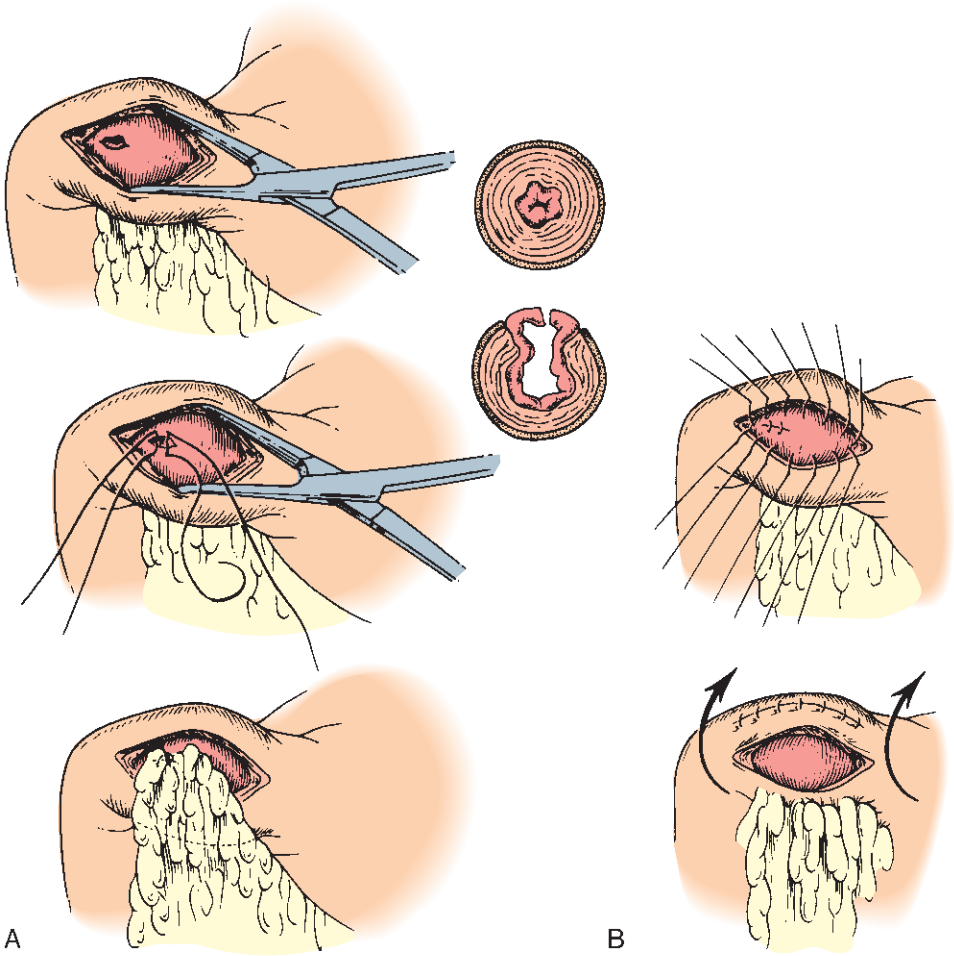

Figure 65–10. **A** and **B,** Alternative techniques for closure of an inadvertent enterotomy.

may clarify the presence of pneumoperitoneum. In neonates with rapid deterioration and ventilation difficulty because of significant abdominal distention, decompressive peritoneocentesis may relieve the acute respiratory distress. There is usually a single perforation on the anterolateral aspect of the greater curvature near the fundus, although the perforation may be seen along the lesser curvature and rarely posteriorly near the gastroesophageal junction.[58-61] The differential diagnosis includes perforation from necrotizing enterocolitis, pyloric atresia, colonic atresia, and Hirschsprung's disease.

Management Early surgical exploration is lifesaving, and the usual surgical approach is a transverse right supraumbilical incision. The posterior aspect of the stomach and the gastroesophageal junction should always be inspected by opening the lesser sac. Most isolated gastric perforations can be repaired primarily in one or two layers without major resection of the stomach. The addition of a gastrostomy or drain depends on individual preference. Cases of significant gastric necrosis from necrotizing gastritis may require subtotal gastrectomy. In up to 20% of infants with possible neonatal gastric perforation based on the clinical picture and radiographs, a perforation may not be identified at surgery and presumably a small perforation has sealed itself by the time that surgery is performed.[61] In preterm newborns maintained on ventilator support, air leaks can track from the lungs into the peritoneal cavity.[62] These newborns will usually have an obvious pneumomediastinum and pulmonary interstitial emphysema and do not show signs of sepsis from intestinal perforation. Despite the presence of perforation and peritonitis, most of these neonates have a good surgical outcome.

Gastric Tumors

Incidence Gastric tumors are rare in infants and children.[63] A 10-year review of 1403 reports of gastric disease at a single institution revealed only three pediatric gastric tumors.[64] Another review of 39 children with gastrointestinal tumors over a 20-year period revealed one leiomyosarcoma of the stomach.[65]

Clinical Features and Diagnosis Although rare, the most common gastric tumors are teratomas. They usually occur in males and are marked by a mass, abdominal distention, vomiting, and rarely, upper GI bleeding or perforation.[63,66] The diagnosis can be made with a combination of imaging modalities; usually, ultrasonog-

Figure 65–12. A large trichobezoar that caused gastric obstruction removed surgically.

raphy and CT will identify the characteristic cystic and solid areas with densities of soft tissue, fat, and calcium or bone.[63,66] Most gastric teratomas are benign, with less than a dozen reported immature teratomas in children.[66]

Management Treatment of gastric teratoma is complete surgical excision with reconstruction of the remaining stomach. In an immature gastric teratoma, a strategy of monitoring the α-fetoprotein level after resection seems prudent rather than giving these children chemotherapy.[66] After complete excision the prognosis for these benign tumors is excellent.

Foreign Bodies

Incidence Children swallow foreign bodies as a result of their exploration of the environment. The peak incidence is between 6 months and 3 years of age. Coins are the most commonly ingested objects. Most foreign bodies in the GI tract are asymptomatic and probably pass spontaneously in stool.

Clinical Features and Diagnosis Swallowed foreign bodies are diagnosed when plain radiographs are obtained for symptoms related to the airway or the esophagus. Transient coughing or choking, pain in the pharynx or retrosternal region, and excessive salivation, drooling, or retching are the common symptoms in a child with a foreign body in the esophagus. A plain radiograph, including a lateral view, can differentiate an esophageal from a tracheal foreign body; the lateral view demonstrates the foreign body's posterior relationship to the tracheal air column.

Management All esophageal foreign bodies confirmed by plain radiography should be removed by flexible or rigid esophagoscopy (Fig. 65–11).[67] If the foreign body passes into the stomach, extraction can usually be avoided because most of these foreign bodies will pass spontaneously. Expectant management is appropriate for smaller rounded objects, with occasional serial radiographs taken after several weeks; exceptions include sharp objects and button batteries. If symptoms occur that are suggestive of obstruction or perforation or if the object remains lodged in the stomach for more than 4 weeks, endoscopic retrieval is recommended. Sharp objects, such as needles and safety pins, should be extracted if they are localized in the stomach because of the risk for perforation.[68] Button batteries are a special case, especially if they are larger than 15 mm, because of the risk of corrosive damage if lodged in the esophagus or the stomach.[69] Removal of an esophageal button battery as soon it is detected is recommended. Although most foreign bodies usually pass through the GI tract once they enter the stomach, button batteries should be extracted to avoid gastric perforation.[67]

Bezoars

Definition and Types Bezoars are foreign bodies in the lumen of the stomach or rarely the intestine that increase in size over time because of continued deposition of ingested food or fibers. There are principally three types: trichobezoars, composed of hair, are the most common; phytobezoars are composed of vegetable matter; and lactobezoars are derived from milk precipitates.

Clinical Features and Diagnosis Bezoars are an uncommon cause of gastric outlet obstruction and are associated with early satiety, abdominal pain, vomiting, and abdominal distention. They can usually be diagnosed by CT, upper GI study, or endoscopy.[70]

Management Although endoscopic and laparoscopic removal has been described, surgical removal is generally required because of their large size (Fig. 65–12).[71,72] Trichobezoars are often associated with trichotillomania,

a psychiatric disorder associated with pulling and ingestion of hair, and psychiatric management is recommended to avoid recurrence. Phytobezoars can be digested with enzymes such as papain or fragmented endoscopically. Lactobezoars are often seen in newborns receiving formula feedings and usually respond to nasogastric lavage and decompression.

Gastrostomy

Short-term enteral access can be obtained in infants and children with a nasogastric tube; however, they occlude easily and can contribute to airway obstruction in an infant, who is an obligate nasal breather.

Indications The primary indication for a gastrostomy tube is the need for long-term enteral access for fluids and nutrition. Other indications include the need for gastric decompression in a neurologically impaired infant with a fundoplication, after repair of atresia, or the need for urgent gastric decompression in a newborn with a congenital tracheoesophageal fistula and ventilatory difficulty. A rare indication is for the management of gastric volvulus. A gastrostomy may be contraindicated in those with uncontrolled ascites and coagulopathy, and a relative contraindication is a terminal condition in an infant or child.

Types of Gastrostomy

Open Gastrostomy The Stamm gastrostomy, the most commonly used surgical gastrostomy, has the advantage of not requiring a surgical procedure for closure if the need for the gastrostomy is temporary. An upper midline or left paramedian muscle-splitting incision is used. A site on the anterior wall of the stomach at the junction of the body and antrum is chosen, not too close to the pylorus because the tube could act as an obstruction. Two concentric purse-string sutures are placed to invert the seromuscular layer of the anterior gastric wall around the tube, thus creating a tunnel. The exit site on the abdominal wall should be chosen so that it avoids tension between the stomach and abdominal wall; a separate stab incision is made for the exit site, or it may exit from the incision, and four-quadrant sutures secure stomach to the abdominal wall (see Chapter 52 for a detailed description). Usually, feeding can be started within 24 hours of gastrostomy placement. Any child who may need an esophageal replacement, such as those with long-gap esophageal atresia or a corrosive esophageal injury, should have the gastrostomy placed closer to the lesser curvature of the stomach to avoid injury to the gastroepiploic vessels because these vessels would be the blood supply for a potential gastric tube.

The Witzel gastrostomy is a modification of the Stamm gastrostomy that consists of imbrication of an additional anterior seromuscular layer of stomach over the tube to make a longer tunnel (see Chapter 52 for a detailed description).

The Janeway gastrostomy, the least common type of gastrostomy, is a permanent gastrostomy fashioned from a gastric flap that is tubularized (see Chapter 52 for a detailed description).

Percutaneous Endoscopic Gastrostomy A percutaneous, endoscopically assisted gastrostomy (PEG) was introduced by Gauderer et al. to allow placement of a feeding gastrostomy without laparotomy (see Chapter 52 for details).[73]

Once gastric access is obtained, the gastrostomy tube can be replaced by a gastrostomy button after 6 weeks (to ensure a mature gastrocutaneous tract). The gastrostomy button is a low-profile skin-level device with a valve that can also be placed primarily at the initial surgery.

Laparoscopic-Assisted Gastrostomy This technique involves percutaneously accessing the stomach for placement of a gastrostomy under visual control with the laparoscope. Sutures passed through the abdominal wall or "T-fasteners" are used to stabilize the anterior wall of the stomach while the tube is inserted. This technique is useful if the child is already undergoing a laparoscopic procedure; it may also be a safer alternative to PEG if there is concern regarding the anatomy of the colon.[74]

Percutaneous Image-Guided Gastrostomy There are a number of image-guided gastrostomy placement techniques. The retrograde percutaneous fluoroscopic technique is commonly used and involves fluoroscopic visualization of a needle puncture of the stomach followed by the creation of a tract over a guidewire.[75] A "pull" technique similar to PEG can also be used for image-guided gastrostomy.

Complications Gastrostomies have a number of reported complications. Major complications include dislodgement of the tube with peritonitis, inadvertent enteric perforation, gastrocolic fistula, GI bleeding, and peritonitis. Leakage around the gastrostomy occurs if the stomach separates from the abdominal wall. Placement close to the pylorus or inadvertent advancement of the tube toward the pylorus can cause gastric outlet obstruction. Local erythema, cellulitis, and tissue necrosis can occur if there is excess tension at the exit site. Surrounding tissue necrosis can result in an enlarging gastrostomy stoma with peristomal leakage. Granulation tissue often develops around the stoma and needs to be cauterized with silver nitrate. A review of PEG in children reported an overall 27% complication rate, including infection, abscess, vomiting, malposition of the gastrostomy, and one death.[76] A review of 208 children with image-guided gastrostomy or gastrojejunostomy tubes revealed a major complication rate of 5% and a minor complication rate of 73% after the insertion of gastrostomy and gastrojejunal tubes by the image-guided retrograde percutaneous route. Major complications included peritonitis, septicemia, abscess, GI bleeding, and death. Minor complications included tube dislodgement, leakage, skin infection, tube migration, and obstruction.[77]

There are reports of worsening GER after gastrostomy, which can be prevented by placing the gastrostomy closer to the lesser curve.[78] In neurologically impaired patients, an upper GI study and pH probe monitoring should be done, and in the absence of significant GER, a gastrostomy without a protective antireflux procedure is adequate. If GER is significant, some recommend

that a fundoplication be performed along with the gastrostomy.[79]

The gastrocutaneous tract matures during a 3- to 6-week period. Removal of a Stamm-type gastrostomy can result in closure of the tract within 24 hours; therefore, immobilization of the tube at the exit site is important to avoid dislodgement. Inadvertent removal of the tube before a mature tract has formed warrants placement of a small catheter through the tract and confirmation of tube position by fluoroscopy and a water-soluble contrast study. If the tract cannot be safely accessed in the office, the tube should be replaced under fluoroscopic guidance.

Peptic Ulcer Disease

Definition and Types Clinically significant peptic ulcer disease is an uncommon condition in infancy and childhood, and with improved diagnosis and medical management, there are few indications for surgical therapy. The pediatric surgeon is usually consulted for complications of peptic ulcer disease, such as persistent life-threatening upper GI bleeding, acquired gastric outlet obstruction from chronic ulceration and scarring, and perforation.[80,81]

Peptic ulcers in infants and children are usually classified as primary or secondary ulcers. A primary ulcer occurs in the absence of any predisposing illnesses or factors and is often associated with gastric acid hypersecretion. A secondary ulcer is generally associated with increased stress from illness, trauma, burns, or medications such as steroids and nonsteroidal anti-inflammatory drugs (NSAIDs).

Etiology Primary ulcers may have a genetic basis and occur more frequently in association with blood group O. They are located in the duodenum and pyloric channel and are rarely seen in the stomach. Although increased or excessive acid secretion is important in the pathophysiology of primary peptic ulcer disease, no direct relationship has been established between consistently elevated levels of acidity in children with primary ulcer disease. There appears to be increasing evidence that the chronic relapsing ulcer disease characteristic of a primary peptic ulcer is linked to coexisting, chronic, active antral gastritis secondary to *Helicobacter pylori* infection.[82,83]

H. pylori is a gram-negative spiral-shaped organism that has been associated with the presence of chronic gastritis. *H. pylori* infection appears to be very common in developing countries, but it may also be seen in about 10% of children in the United States by the time that they are 10 years old.[82-84] It appears that up to 10% of cases of *H. pylori* gastritis will result in duodenal ulcers, especially in children older than 10 years.[83,84] In addition, it is a significant risk factor for the development of gastric cancer in adults. Eradication of *H. pylori* reduces the recurrence of ulcers to less than 5%.[86] Children with *H. pylori* infection and peptic ulcer disease should be treated with a 10- to 14-day triple-therapy regimen.[82,85,86]

Zollinger-Ellison syndrome, which results from a functional gastrinoma, G-cell hyperplasia, or G-cell hyperfunction, is a rare condition associated with acid hypersecretion. The increased gastrin levels lead to increased gastric acid output, which in turn results in diarrhea and multiple or recurrent peptic ulcers. These ulcers may also involve the proximal jejunum (see Chapter 58 for a discussion on Zollinger-Ellison syndrome).

Secondary peptic ulcers are more common in infants and children than primary ulcers are. They are also called "stress" ulcers because they occur with stresses that increase acid secretion or reduce mucosal defense mechanisms, or both. Drugs such as aspirin and NSAIDs decrease mucosal blood flow by inhibiting prostaglandin synthesis and stimulating inflammatory mediators. In addition, protective mucosal secretions can be inhibited by pharmacologic agents. Ulcers associated with head trauma are characterized by increased gastric acid secretion ("Cushing ulcer"); however, ulcers associated with thermal injury have normal gastric acid secretion (Curling's ulcer). Other stresses, such as sepsis, cardiac insufficiency, surgical trauma, and hypoxia, may result in ulcer disease. Secondary ulcers are usually located in the stomach, although they can occur in the duodenum as well. Secondary ulcers do not usually recur if they are treated and the associated factors are controlled.

Clinical Features Primary peptic ulcer disease in an older child is usually manifested as abdominal pain and vomiting and rarely as significant GI bleeding. In addition, iron deficiency anemia from occult blood loss may be an initial sign. Gastric outlet obstruction and perforation from peptic ulcer disease are rare in children. Stress ulcers are seen in critically ill infants and children, most often with GI bleeding from diffuse erosive mucosal lesions of the stomach. Perforation from stress ulceration is an unusual event, although more common than a perforated primary peptic ulcer in a child.

Diagnosis The diagnosis of peptic ulcer disease is based on endoscopic examination of the gastric and duodenal mucosa. Although an upper GI contrast study can be helpful in defining gastric outlet obstruction, it is inadequate for the diagnosis of mucosal ulceration. Antral and duodenal biopsy with the rapid urease test plus histopathologic examination is the current diagnostic standard for *H. pylori*.

Management The initial treatment of peptic ulcer disease is medical therapy. The goal is to heal the ulcer, prevent recurrence, and avoid the complications of bleeding, perforation, and obstruction. Secondary ulcers are treated by eliminating the stressful event; those related to NSAIDs are treated by discontinuing their use. Additionally, treatment involves the use of acid suppression and mucosal protection with antacids, H_2 blockers, proton pump inhibitors, or mucosal coating agents, alone or in combination. Secondary ulcers can be prevented by H_2 blockers or mucosal coating agents. In children with a diagnosis of *H. pylori* and documented peptic ulcer, it is essential to initiate a 7- to 14-day triple-therapy regimen. The traditional indications for surgical treatment include perforation, uncontrolled bleeding,

gastric outlet obstruction, and intractable pain. Children with peptic ulcer disease may have complications requiring surgery in adulthood. Although the incidence of surgery has declined over time, the incidence of obstruction as an indication for surgery appears to be unchanged.[81] In a child with a refractory primary ulcer or multiple recurrences, or both, Zollinger-Ellison syndrome should be ruled out by evaluation of gastrin levels both at baseline and after secretin challenge. If a benign gastrinoma is suspected, localization and excision will result in cure.

Initial treatment of a bleeding peptic ulcer is medical and includes resuscitation, pharmacologic therapy, and diagnostic endoscopy. Endoscopic sclerotherapy or treatment with a heater probe is initiated by the gastroenterologist. Persistent bleeding after failed medical and endoscopic therapy, as indicated by the loss of half a blood volume in 8 hours or one blood volume in 24 hours, is an indication for surgery. The surgical approach is dictated by the location and the hemodynamic status and age of the patient. In a younger child with bleeding gastric ulcers, oversewing the ulcer along with intensive pharmacologic medical therapy is usually adequate. In an older child with a bleeding duodenal ulcer, management is similar to that for an adult: oversewing the bleeding ulcer and vagotomy with pyloroplasty or selective vagotomy. Perforations are treated by plication and an omental patch followed by intensive medical therapy; an acid reduction procedure is not usually needed in a child. Children with gastric outlet obstruction generally require vagotomy with a drainage procedure or vagotomy and antrectomy. Because of the lack of large series of children who have undergone these procedures, adult surgical recommendations are often extrapolated to these patients. A detailed description of the management of ulcer disease and vagotomy and drainage procedures may be found in Chapters 55 and 56.

Anatomy and Physiology of the Duodenum

John M. Kellum · Roberto C. Iglesias · Jarrod Day

GROSS ANATOMY

The duodenum is so named because its length is approximately 12 fingerbreadths, or 20 to 30 cm. This first portion of the intestine begins at the end of the gastric pylorus, at the right of the spine, in the plane of the first lumbar vertebra. The duodenum then extends in a C-shaped curve around the head of the pancreas and connects with the jejunum to the left of the second lumbar vertebra. It is the most proximal portion of the intestine and the widest, shortest, and least mobile segment. The duodenum is divided into four parts: the first (or superior) portion, also known as the duodenal bulb or cap; the second, or the vertical or descending portion; the third, or the horizontal or transverse portion; and the fourth, or the oblique or ascending portion (Fig. 66–1).

The duodenal cap is freely mobile in the peritoneal cavity, and it is the area where 90% of duodenal ulcers occur. It has longitudinal mucosal folds, whereas the remainder of the duodenum displays prominent transverse folds. The anterior and posterior layers of the peritoneum join over the duodenal cap's upper aspect to form the hepatoduodenal ligament, which contains the portal triad (common bile duct, hepatic artery, and portal vein). The anterior border of the foramen of Winslow is formed by the free margin of this ligament (Fig. 66–2). Immediately above the duodenal cap are the gallbladder and the quadrate lobe of the liver. Below and behind the cap is the head of the pancreas. Also behind the bulb lies the gastroduodenal artery; thus, by eroding into this vessel, peptic ulcers can cause bleeding.

The mobility and circumferential serosal coating of the duodenal bulb facilitate operations on the pylorus and duodenum. Pyloroplasties and gastroduodenal resections are performed with greater ease when the pylorus and the adjoining second portion of the duodenum are mobilized forward into the abdominal cavity by Kocher's maneuver (Fig. 66–3). The proximity of the superior duodenum to the gallbladder explains the sometimes spontaneous passage of gallstones into the duodenum via a cholecystoduodenal fistula. The peritoneum covers the distal 2.5 cm of the first portion of the duodenum only ventrally. Its range of movement depends on the peritoneal coat. The posterior wall of the first portion of the duodenum is often intimately opposed to the structures of the hepatoduodenal ligament.

The second portion of the duodenum is retroperitoneal and fixed in position through fusion of its lateral visceral peritoneum to the parietal peritoneum of the lateral abdominal wall. By dividing the peritoneum at the right lateral edge of the segment (Kocher's maneuver), one mobilizes the descending duodenum to render the retroduodenal and intrapancreatic bile ducts surgically accessible. The right kidney and its hilar structures, the adrenal gland, and the vena cava lie posterior to the second portion of the duodenum (Fig. 66–4). Horizontally across the descending midpoint of the duodenum, folds of peritoneum come together from above and below to form the mesocolon. At the superior duodenal flexure, the descending second portion of the duodenum forms an acute angle with the first portion and descends about 7 to 8 cm to the inferior duodenal flexure. The transverse colon crosses it anteriorly and may or may not possess a mesocolon at this point. One must reflect the hepatic flexure of the colon anteromedially to fully mobilize the duodenum. About halfway down the posteromedial wall of the second portion of the duodenum is the papilla of Vater (see Fig. 66–1), which contains the opening of the common bile duct and the main pancreatic duct of Wirsung. The opening of the accessory pancreatic duct (of Santorini) is more proximal and may inadvertently be injured during gastrectomy for ulcer or distal gastric cancer. The superior pancreaticoduodenal branch of the gastroduodenal

artery runs in the groove between the head of the pancreas and the descending duodenum; this intimate association of the duodenum with the pancreatic head generally mandates excision of the pancreatic head with attempted duodenum resection.

The third portion of the duodenum is about 12 to 13 cm in length; runs horizontally to the left in front of the aorta, inferior vena cava, lumbar column, and ureter; and ends at the left of the third lumbar vertebra. The root of the jejunoileum mesentery crosses it near its termination. The superior mesenteric artery runs downward over the anterior surface of the transverse duodenum to enter the root of the mesentery (Fig. 66–5). The inferior pancreaticoduodenal artery separates the pancreas from the upper border of this segment.

The fourth part of the duodenum runs upward and slightly to the left for 2 to 3 cm along the left side of the spine to the duodenojejunal angle at the root of the transverse mesocolon. At the left of the second lumbar vertebra, the terminal portion of the duodenum bends sharply downward, forward, and leftward to form the duodenojejunal flexure. At this point the suspensory ligament of the duodenum (ligament of Treitz) attaches (Fig. 66–6). This ligament is a small, triangular band of muscular and fibrous tissue that extends retroperitoneally, behind the pancreas and splenic vein, in front of the left renal vein, from the left or right crus of the diaphragm, to attach retroperitoneally to the upper margin of the terminal duodenum and sometimes to the adjacent jejunum. The ligament of Treitz is usually tenuous and is not invariably present. The duodenojejunal flexure is a readily recognized landmark that can be used to guide the search for obstruction in the small bowel and to locate a loop of upper jejunum for gastrojejunostomy. At laparotomy, it is found by passing the hand backward to the posterior abdominal wall below the transverse mesocolon and palpating upward along the left of the spine until the flexure is identified by its fixation. The bend is in contact with the inferior margin of the pancreas through the root of the transverse mesocolon.

Fusion of the pancreaticoduodenal visceral peritoneum with the primitive posterior parietal peritoneum anchors the entire duodenum, except part of the first portion. Variation in fusion of the duodenum to the posterior abdominal wall accounts for variation in mobility. The right colic flexure, the fixed portion of the transverse mesocolon, and vascular and ampullary connections anchor the duodenum still more firmly. In its deep position, the duodenum appears to be well protected from injury, yet it is sometimes crushed and even torn against the spine with severe blunt abdominal trauma, in part because of its comparatively unyielding peritoneal fixation.

Arterial Supply

The arterial supply of the duodenum is derived from the anterior and posterior pancreaticoduodenal arcades, which form a major arterial anastomosis between the celiac and superior mesenteric arterial circulations. The duodenum shares its blood supply with the proximal portion of the pancreas, thus making resection of either the duodenum or the pancreas alone usually impossible and always hazardous. The superior pancreaticoduodenal artery is a branch of the gastroduodenal artery, and the inferior pancreaticoduodenal is a branch of the superior mesenteric artery. These two arteries split and run in posterior and anterior grooves between the descending and transverse portions of the duodenum and the head of the pancreas, where they anastomose to form continuous anterior and posterior arcades (Fig. 66–7; see also Fig. 66–5). This rich periduodenal anastomotic network of arteries often frustrates attempts to control bleeding secondary to posterior duodenal ulcers.

Venous Supply

The veins that parallel the pancreaticoduodenal arteries are arranged in anterior and posterior pancreaticoduodenal arcades that accompany the arteries (Fig. 66–8). The posterior arcade ends in the portal vein above and the superior mesenteric vein (SMV) below. The posterosuperior pancreaticoduodenal vein may follow its companion artery anterior to the bile duct, or it may run behind the duct. The vein terminates inferiorly on the left border of the SMV. Here, it may be joined by a jejunal vein or by the anterior inferior pancreaticoduodenal vein. The gastrocolic trunk (Henle's trunk) drains most of the anterior arcade.[1] Several small branches drain the duodenal bulb and empty into the pancreaticoduodenal, right gastroepiploic, or portal vein; a key landmark for the pylorus is the prepyloric vein.

During pancreaticoduodenectomy, the SMV may be located by following the middle colic vein to its junction with the SMV just inferior to the neck of the pancreas. Sometimes, incision of the avascular peritoneum along the lower border of the gland to the left of the SMV facilitates identification. Superior to the pancreas, division of the common bile duct and gastroduodenal artery readily exposes the portal vein. Occasionally, a tortuous hepatic artery may be mistaken for the gastroduodenal artery; therefore, before ligation of the gastroduodenal artery, it should be transiently occluded with a vascular clamp or the surgeon's fingers while the hepatic artery pulse is palpated in the hilum of the liver.

Lymphatic Drainage

The lymphatic drainage of the duodenum generally parallels the vasculature. Lymph passes through several levels of lymph nodes that are located adjacent to the bowel wall, adjacent to the mesenteric arcades, and along the superior mesenteric and celiac arteries. Primary duodenal carcinomas may invade the pancreas via direct extension or lymphatic infiltration, but they usually first spread to the periduodenal lymph nodes and liver. Nodes at the superior duodenal flexure and retroduodenal nodes are commonly involved in metastatic pancreatic carcinoma.

Histology of the Duodenum

The wall of the duodenum is made up of four layers: an outer peritoneal coat, the serosa; a muscular coat made up of longitudinal and circular fibers, the muscularis; the submucosa; and the mucosa, which forms its inner lining (Fig. 66–9). Portions of the posterior and lateral walls of the duodenum are retroperitoneal and therefore lack the peritoneal or serosal coat. The serosa is an extension of the peritoneum. It consists of a single layer of flattened mesothelial cells overlying loose connective tissue.

Two layers of smooth muscle make up the muscularis, an outer or longitudinal layer and an inner or circular layer. The myenteric plexus of Auerbach lies between these two layers. Meissner's plexus is found in the submucosa along with a network of loose connective tissue rich in lymphatics and small blood vessels. Here, in the submucosa, are found the characteristic histologic features of the mammalian duodenum: the glands of Brunner, which empty into the crypts of Lieberkühn through small secretory ducts (Fig. 66–10). Brunner's gland secretion is viscous, alkaline (pH 8.2 to 9.3), and clear. These mucoid, viscous, alkaline secretions probably contribute to protection of the duodenal mucosa against the corrosive action of gastric juice.

The intestinal mucosa is thrown into numerous finger-like projections, or villi, that greatly increase the mucosal surface area. The columnar cell–lined epithelium contains both mucus and HCO_3^--secreting surface cells and absorptive cells. The mucosa can be divided into three layers: the deepest is the muscularis mucosae, the middle layer is the lamina propria, and the inner layer consists of a continuous sheet of a single layer of columnar epithelial cells lining both the crypts and the villi.

The main known functions of the crypt epithelium include (1) cell renewal; (2) exocrine, endocrine, water, and ion secretion; and (3) absorption of salt, water, and specific nutrients. The crypt epithelium is composed of at least four distinct cell types: Paneth, goblet, undifferentiated, and endocrine cells.

Innervation of the Duodenum

The gastrointestinal (GI) tract is innervated by the autonomic nervous system, which may be divided into extrinsic and intrinsic or enteric nervous systems. The extrinsic innervation of the duodenum is parasympathetic from the vagus nerves (anterior and celiac branches) and sympathetic from the splanchnic nerves of the celiac ganglion. Intrinsic innervation is from Auerbach's myenteric plexus and Meissner's submucosal plexus. Processes from these neurons innervate target cells such as smooth muscle, secretory, and absorptive cells, but they also connect to sensory receptors and interdigitate with processes from other neurons located both inside and outside the plexus. Thus, pathways within the enteric nervous system can be multisynaptic, and integration of activities can take place entirely within the enteric nervous system (Fig. 66–11).

Adult Anatomic Abnormalities That May Require Surgery

The main anatomic abnormalities of the duodenum that the surgeon may be asked to treat in adult patients are duodenal diverticula, vascular anomalies, and

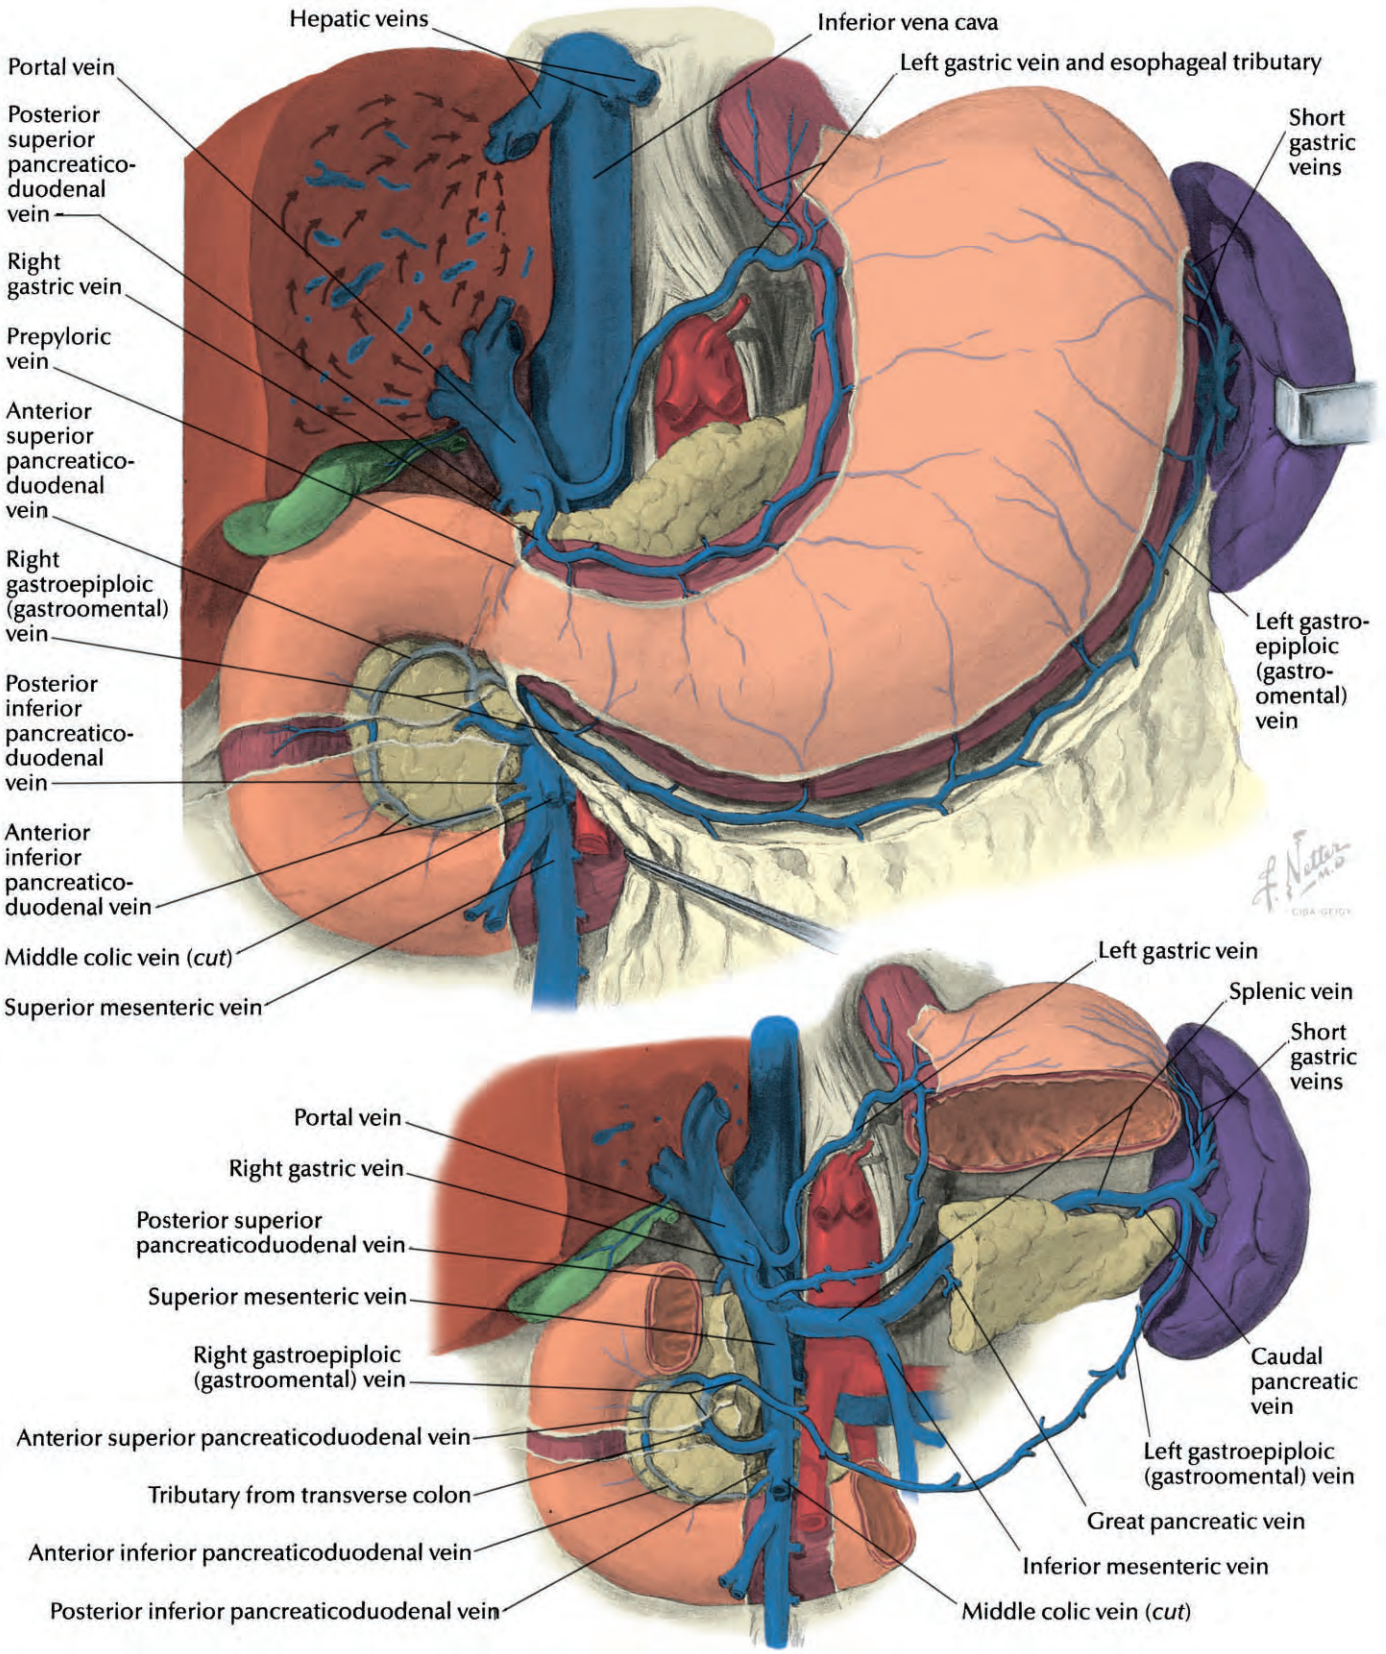

Figure 66–8. View of the veins of the duodenum and pancreas, with the stomach removed. (From Netter FH: Atlas of Human Anatomy. East Hanover, NJ, Ciba-Geigy, 1989, plate 294. Copyright, 1999. paraduodenal hernias. Although duodenal atresia or stenosis, malrotation, and annular pancreas are sometimes found in adults, they are more commonly seen in pediatric surgical patients and are discussed elsewhere.

Preduodenal Portal Vein

A rare, but important venous anomaly of which the duodenal surgeon should be aware is the preduodenal portal vein. In this congenital anomaly the portal vein passes anterior to the duodenum rather than lying in its normal posterior position. The anomaly is due to abnormal development of the vitelline veins, as described by Bower and Ternberg (Fig. 66–12).[2] The majority of cases reported in the literature involve infants or children, and there is a very high association with additional congenital anomalies such as (in decreasing order) malrotation, situs inversus, and cardiac lesions.[3] Most patients have acute or chronic high intestinal obstruction or symptoms of gastric outlet obstruction. The diagnosis is rarely made preoperatively.

At surgery, when the duodenum is found to be obstructed and a preduodenal portal vein is present, it is important to accurately determine whether the obstruction is caused by the anomalous vein, by associated anomalies, or by both. If the preduodenal portal vein is not causing obstruction, it is left undisturbed, and associated abnormalities are treated. If the anomalous vein is causing obstruction, relief can be obtained via one of two surgical procedures: (1) transection of the proximal duodenum with end-to-end duodenoduodenostomy anterior to the portal vein[2] or (2) duodenojejunostomy or gastrojejunostomy.[3] Both procedures have been used successfully.

Superior Mesenteric Artery Syndrome

Rokitansky first described compression and obstruction of the third portion of the duodenum by the superior mesenteric artery more than 100 years ago. Synonyms include Wilkie's syndrome, cast syndrome, and arteriomesenteric duodenal ileus or compression.[4] Despite intermittent waves of enthusiasm for this diagnosis, surgeons are generally reluctant to ascribe upper GI symptoms to this relatively rare abnormality (0.2% of 6000 upper GI examinations).[5] It is generally thought that for vascular compression to cause duodenal obstruction, some combination of three mechanical factors must be present: (1) an abnormally narrow aortomesenteric angle, (2) an abnormally highly fixed transverse duodenum, and (3) an abnormal course of the mesenteric

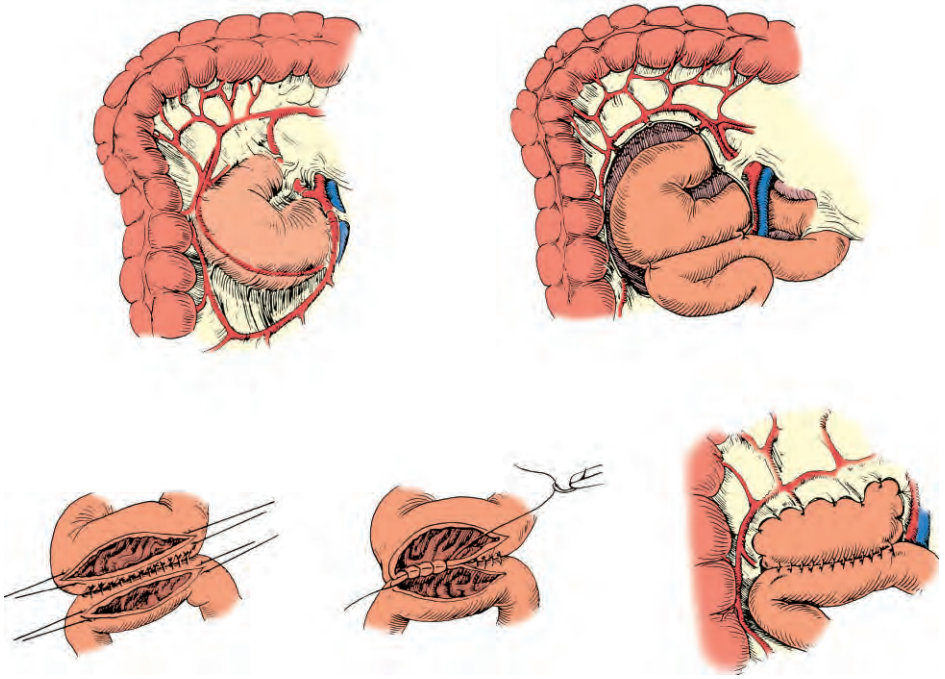

Figure 66–14. Duodenojejunostomy for vascular compression of the duodenum. (From Mansberger AR: Vascular compression of the duodenum. In Sabiston DC [ed]: Textbook of Surgery, 13th ed. Philadelphia, WB Saunders, 1986, p 877.)

artery continuing inferiorly, anterior to the unyielding vertebral column (Fig. 66–13). Hyperextension of the spine (as may occur after the application of a body cast or skeletal traction) and weight loss (associated with depletion of retroperitoneal fat) further narrow the aortomesenteric angle and are associated with progressive symptoms of distal duodenal obstruction in patients with this diagnosis. This syndrome has also been described in patients with severe scoliosis after so-called spine-straightening surgery.

The preferred method of surgical treatment is duodenojejunostomy, which can be performed in side-to-side fashion between the dilated proximal jejunum after the mesocolon of the hepatic flexure has been opened (Fig. 66–14). Gastrojejunostomy is a poor second choice because it relies on retrograde decompression of the duodenum through the pylorus. A third option is extensive mobilization of the ligament of Treitz after mobilization of the hepatic flexure of the colon. After this maneuver, the distal duodenum and small bowel are passed under the mesenteric vessels, and the C loop of the duodenum is straightened out (Fig. 66–15). Although this third option does not involve opening the GI tract, it does require division of some small vessels to the distal duodenum. Segmental ischemia apparently has not been a problem.

Paraduodenal Hernia

Paraduodenal (or mesocolic) hernias and hernias of the foramen of Winslow are the two most frequent types of congenital internal hernia.[6] They most commonly cause

symptoms of acute small bowel obstruction, and frequently plain radiographs of the abdomen are suggestive of the diagnosis. Some patients have symptoms of chronic intermittent obstruction for years before a definitive diagnosis is made. Bowel strangulation is commonly found at surgery for these disorders.

The most common paraduodenal hernia is the so-called left paraduodenal hernia (Fig. 66–16).[7] In this condition, variable amounts of small intestine herniate through the so-called vascular arch of Treitz formed by the inferior mesenteric vein and the left colic artery. The herniated small bowel is therefore posterior to the mesocolon. The cecum and terminal ileum are in their normal anatomic configuration. Operative treatment of a left paraduodenal hernia involves opening the retroperitoneum just to the right of the inferior mesenteric vein and artery. The bowel can be reduced to its normal anatomic position, and the root of the mesentery of the left colon can be joined to the peritoneum anterior to the aorta to obliterate the arch of Treitz.

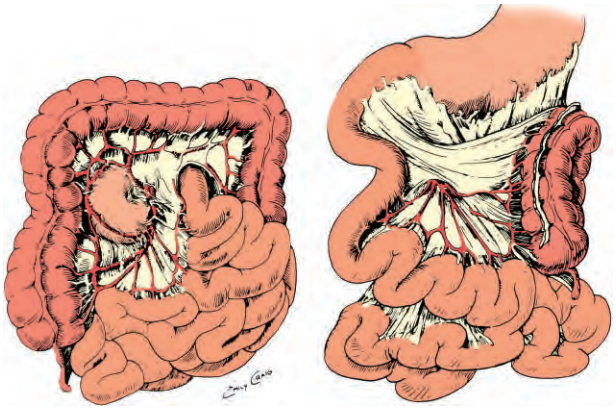

Figure 66–15. Operation to straighten the duodenum and return it to its prerotation position. (From Sabiston DC [ed]: Textbook of Surgery, 13th ed. Philadelphia, WB Saunders, 1986, p 877.)

The more unusual right paraduodenal hernia is due to an abnormality in embryonic intestinal rotation.[8] The cecum is usually in the right upper quadrant, and Ladd's bands are apparent. In this hernia, the small bowel is trapped in a hernia sac, the anterior wall of which is formed by the mesentery of the small bowel. It is as though the herniated bowel has rotated under the superior mesenteric artery and is trapped in the right upper quadrant. The hernia is best approached by incising the attachments of the right colon rather than attempting to open the hernia sac from the medial side because this might involve the division of critical mesenteric arteries.

The least common paraduodenal hernia is a hernia of the foramen of Winslow.[9] It is almost always associated with an unusually patulous foramen of Winslow, which allows the bowel or right colon to herniate through the foramen into the lesser peritoneal sac (Fig. 66–17). The radiographic diagnosis is usually made in retrospect. Operative treatment involves gentle traction on the herniated bowel in an attempt at reduction. If reduction cannot be achieved, the lesser sac should be opened by incising the gastrocolic omentum, and the hernia can be reduced by both pulsion and traction. Rarely, strangulated bowel within the lesser peritoneal sac must be resected before reduction of the remaining contents. Once reduction has been completed, the patulous foramen of Winslow should be closed with interrupted sutures.

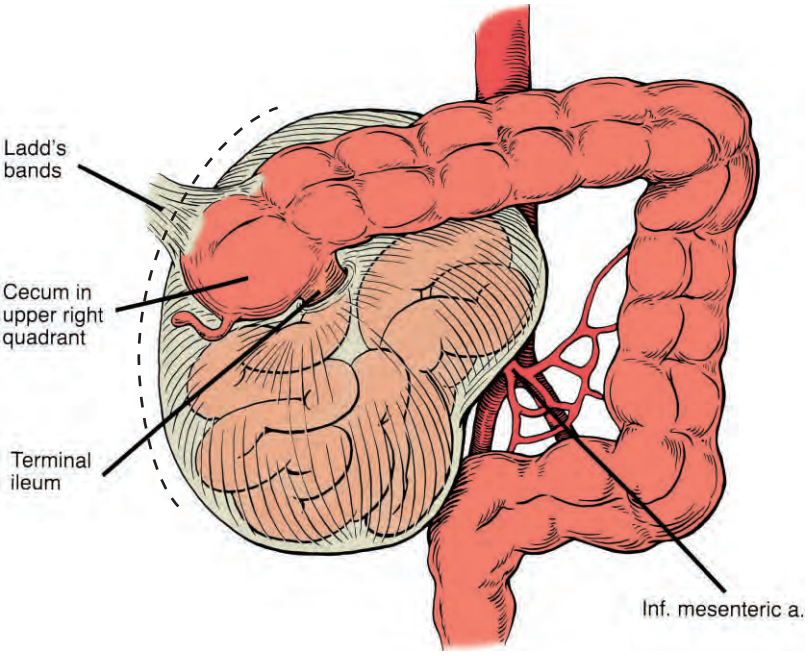

Figure 66–16. Right mesocolic hernia. The prearterial segment *did not* rotate during the second stage. The postarterial segment *did* rotate and has trapped most of the small bowel behind the ascending mesocolon containing the ileocolic, right colic, and middle colic vessels. The *dashed line* shows the incision for release of the hernia. (From Nyhus LM, Harkins HN (eds): Hernia. Philadelphia, JB Lippincott, 1978, p 493.)

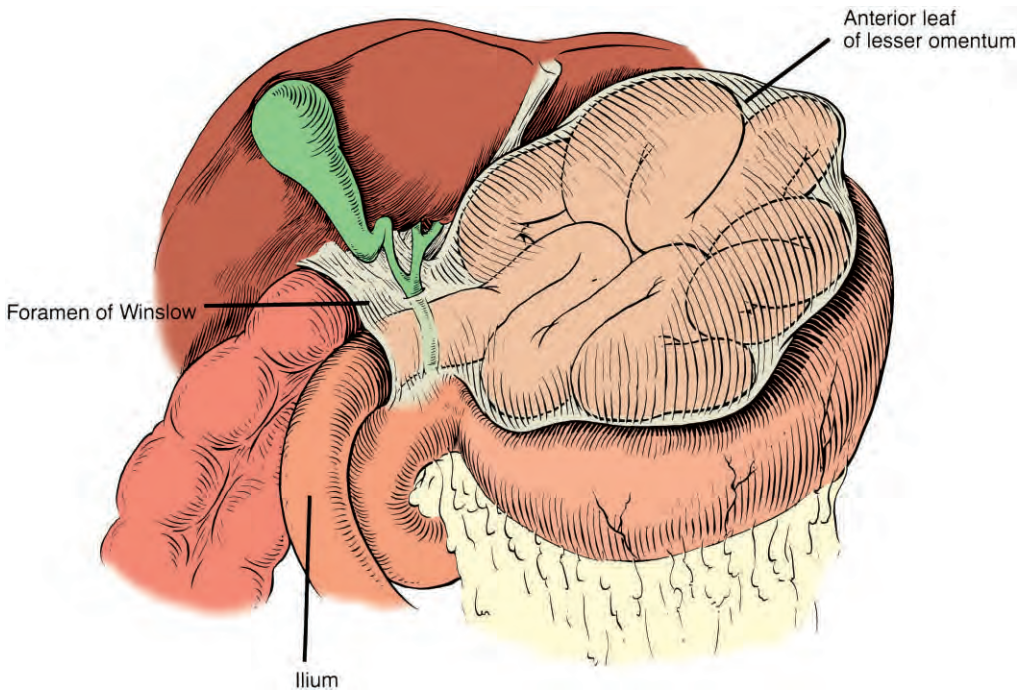

Figure 66–17. Diagrammatic illustration of a hernia into the lesser sac through the foramen of Winslow. (From Nyhus LM, Harkins HN [eds]: Hernia. Philadelphia, JB Lippincott, 1964, p 598.)

Duodenal Diverticula

Most duodenal diverticula are asymptomatic and come to the attention of the clinician during routine barium examination. They may be acquired or congenital, and up to 15% of the adult population is affected. Duodenal diverticula are probably true diverticula because the few resected specimens appear to have a complete, though attenuated, muscularis propria. The vast majority of patients with GI symptoms and duodenal diverticula have other causes for these symptoms, which is why excision should be undertaken with a great deal of circumspection. Another reason for caution is that most duodenal diverticula are located along the posteromedial surface of the second portion of the duodenum, where they are intimately related to the pancreatic head and occasionally contain the ampulla of Vater. About 20% occur in the third portion and 10% occur in the fourth portion of the duodenum.

Although usually asymptomatic, duodenal diverticula occasionally require emergency surgery because of perforation or association with massive hemorrhage.[10] Peri-Vaterian diverticula have been implicated in the pathogenesis of primary choledocholithiasis and pancreatitis. Elective surgery is occasionally undertaken because of chronic abdominal pain or symptoms of bacterial overgrowth. Bleeding is treated by excision and duodenal closure, although duodenal diverticularization, or duodenostomy, should be considered and peritoneal drainage of the paraduodenal space should always be performed.

DUODENAL PHYSIOLOGY

The duodenum is a complex organ with a unique set of structural and physiologic properties that differentiate it from the stomach and the remainder of the small intestine. It is here that the process of digestion and absorption truly begins, where meal contents are alkalinized and mixed with digestive enzymes and bile. The main functions of the duodenum are to (1) alkalinize acidic chyme from the stomach, (2) serve as a reservoir for pancreaticobiliary secretions, (3) be the main site of calcium and iron absorption, (4) further the breakdown of food products, and (5) exert neuroendocrine control of upper GI motility. Thus, duodenectomy can disrupt the relationship between cycles of both interdigestive GI motility and insulin secretion and can lead to anemia, secondary hyperparathyroidism, and other diseases caused by malabsorption.[11,12]

Exocrine Physiology

The duodenum is unique in that there are no tight junctions that provide inherent protection as in the stomach. Instead, it has a leaky epithelium between duodenocytes, and as a result, it must use alternative defense mechanisms against concentrated gastric acid and other irritants discharged by the stomach. Many compounds have been implicated in stimulating bicarbonate secretion after duodenocyte exposure to acid, including vagally produced acetylcholine; prostaglandins (especially

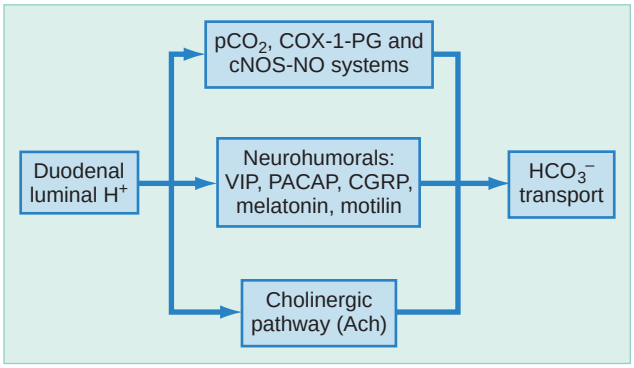

Figure 66–18. The mechanism of duodenal HCO_3^- secretion in response to gastric H^+ involves a variety of neurotransmitters, P_{CO_2}, cyclooxygenase-1–prostaglandin (COX-1–PG), and the constitutive nitric oxide synthase–nitric oxide (cNOS-NO) system. (From Konturek PC, Konturek SJ, Hahn EG: Duodenal alkaline secretion: Its mechanisms and role in mucosal protection against gastric acid. Dig Liver Dis 36:505-512, 2004.)

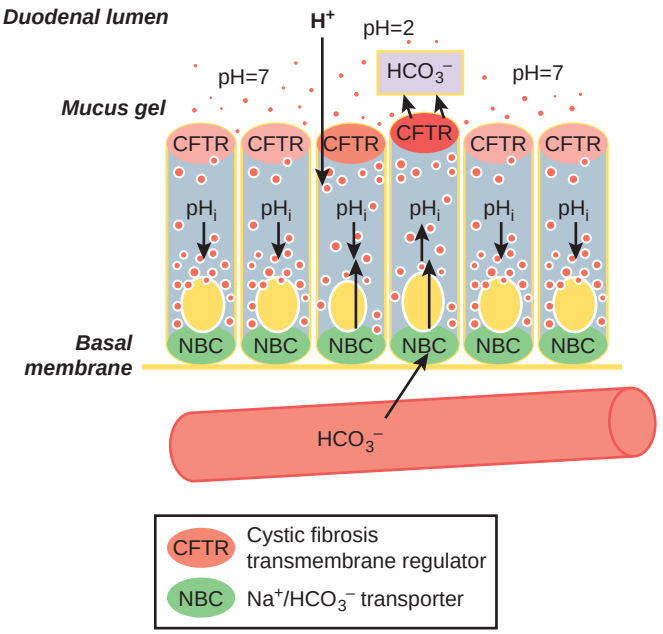

Figure 66–19. In the duodenocyte membrane transport system, HCO_3^- is exchanged for Cl^- at the apical cell membrane. This bicarbonate then neutralizes gastric acid entering the proximal duodenum. (From Konturek PC, Konturek SJ, Hahn EG: Duodenal alkaline secretion: Its mechanisms and role in mucosal protection against gastric acid. Dig Liver Dis 36:505-512, 2004.)

PGE)[13]; vasoactive intestinal polypeptide (VIP) and its analogue PACAP (pituitary adenylate cyclase activating polypeptide); melatonin[14,15]; motilin; and P_{CO_2}, prostaglandin, and nitric oxide (NO) (Fig. 66–18).[16]

One defensive barrier lies in the bicarbonate secreted by the pancreas and liver in response to duodenal acidification and release of duodenal secretin; however, the majority of protection is inherent within the duodenal bulb, which coordinates a complex array of titrating mediators that ultimately produce neutralizing bicarbonate.

The duodenocyte membrane transport system is believed to be coordinated with phase II/III of the migrating motor complex (MMC) and functions as follows (Fig. 66–19)[16]:

1. Luminal H^+ diffuses into duodenocytes through their apical membrane and reduces their intracellular pH.
2. The acidification of duodenocytes promotes movement of extracellular bicarbonate into the cell through basolateral Na^+/HCO_3^- transporter (NBC) channels.
3. This base loading causes apical cystic fibrosis transmembrane conductance regulator (CFTR)-related HCO_3^-/Cl^- exchangers to transport bicarbonate into the duodenal lumen and thus further buffer the acid load.

Another alkaline-secreting mechanism relies on H^+ activation of capsaicin-sensitive afferent nerves within the axon-reflex pathway that stimulate the release of sensory neuropeptides such as enteroglucagon and calcitonin gene–related peptide (CGRP), which in turn activate the release of NO and cyclooxygenase-prostaglandin (COX-PG).[16] In addition, this system is self-perpetuating; as HCO_3^- is hydrolyzed to increase the partial pressure of CO_2 (P_{CO_2}), duodenocytes further increase HCO_3^- secretion. The cumulative sum of these factors leads to the following (Fig. 66–20):

1. Stimulation of goblet cells and Brunner's glands to increase the thickness of the mucus gel layer
2. Stabilization of the pH gradient and prevention of acid from entering epithelial cells
3. NO-mediated mucosal vasodilation leading to hyperemia and increased blood flow

In support of this capsaicin–CGRP mechanism, COX inhibitors abolish this response and patients with duodenal ulcers have been shown to have decreased bicarbonate secretion as a result of *Helicobacter pylori* production of the NO inhibitor, asymmetric dimethylarginine (ADMA).[17] Finally, the last mechanism for maintaining cell integrity is repair from injury.

Absorption and Digestion

The duodenum receives largely undigested food particles from the stomach; it is the function of a duodenocyte's brush border to begin the process of nutrient absorption via a variety of complex transport systems. This process is aided by pancreaticobiliary secretion and a host of hormones that make the food content more manageable. The main nutrients absorbed are discussed.

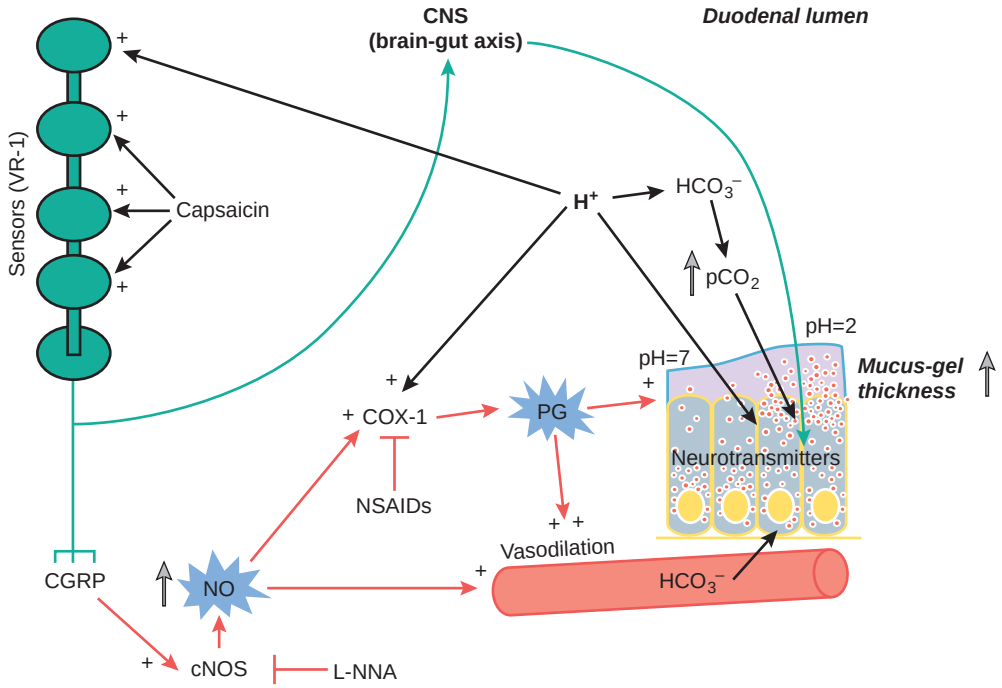

Figure 66–20. Involvement of capsaicin-sensitive nerves, calcitonin gene–related peptide (CGRP), nitric oxide (NO), prostaglandin (PG), and an increase in P_{CO_2} in the stimulation of mucus HCO_3^- secretion by duodenal mucosa in response to acidification. cNOS, constitutive nitric oxide synthase; CNS, central nervous system; COX-1, cyclooxygenase-1; L-NNA, *N*(ω)-nitro-L-arginine; NSAIDs, nonsteroidal anti-inflammatory drugs. (From Konturek PC, Konturek SJ, Hahn EG: Duodenal alkaline secretion: Its mechanisms and role in mucosal protection against gastric acid. Dig Liver Dis 36:505-512, 2004.)

Calcium

The duodenum plays a major role in calcium absorption, especially when oral dietary calcium is low, at which time as much as 80% to 100% is absorbed through an active transport–dependent transcellular system that upregulates and thus increases calcium absorption through three steps[18,19]: entry through the brush border, diffusion into the cytosol via the calcium binding protein calbindin D9k, and extrusion into blood through basal membrane Ca^{2+}-ATPase and Na^+/Ca^{2+} exchangers. This mechanism is confined to the duodenum and proximal jejunum and is dependent on vitamin D, which is essential for the biosynthesis of calbindin and possibly for increasing the number of extrusion pumps.[19]

Although calcium can also be absorbed through paracellular regulation throughout the small intestine, this mechanism is not as efficient because it absorbs only 20% to 60% and is time and concentration gradient dependent and thus most effective with high levels of dietary calcium intake or slow transient time.[18] The existence of this paracellular system ensures calcium absorption in the absence of vitamin D, as may be the case with northern winters, malabsorption, or inadequate oral intake.

The importance of this transcellular regulation mechanism is highlighted in patients in whom metabolic bone diseases develop after Roux-en-Y gastric bypass (RYGBP). Through bypassing the duodenum, this weight loss operation forces the body to become strictly dependent on paracellular regulation, which when not appropriately supported with a high-calcium diet, can result in calcium deficiency. In addition, the procedure can cause poor mixing of bile salts with fats and thus lead to malabsorption of fat-soluble vitamin D and, as a result, secondary hyperparathyroidism, osteoporosis, and osteomalacia.[20] Although the incidence of secondary hyperparathyroidism after RYGBP is unknown, Rhode and MacLean[21] reported elevated parathyroid hormone (PTH) in 14% and Amaral and colleagues[22] observed an increase in alkaline phosphatase in 34% of patients. Johnson et al.[23] found that elevated PTH was common after RYGBP and correlated with low vitamin D levels. The deficiency was progressive over time.

Iron

Another important function of duodenocytes is to serve as the main check point for iron homeostasis. Iron is an essential constituent of many important metabolic processes, including oxygen transport as a component of hemoglobin; however, too much iron can lead to free radical formation and thus toxic states such as hemochromatosis.

The mechanism by which duodenocytes regulate iron is a subject of debate. Whereas older theories support the programming of immature crypt cells to absorb more or less iron, depending on body stores,[24] more recent studies support the action of a number of molecules responsible for iron transport by mature enterocytes.[25]

The components of the current intestinal iron absorption pathway stem from direct action of the iron circulating inhibitor hepcidin on mature villus enterocytes; the process involves the following steps[25] (Fig. 66–21):

1. Dietary iron in the gut lumen is mainly in the Fe^{3+} form.
2. In the lumen, Fe^{3+} is reduced to Fe^{2+} by the ferrireductase Dcytb.
3. Fe^{2+} is transported intracellularly across the brush border membrane (BBM) by the divalent metal transporter DMT1.
4. Fe^{2+} is then transferred to the basolateral membrane (BLM) by the ferroxidase hephaestin.
5. Finally, Fe^{2+} is transferred across the BLM into the body by Ireg1.

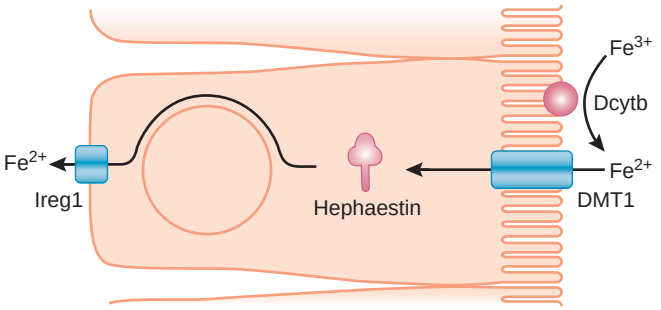

Figure 66–21. Components of the intestinal iron absorption pathway. (1) Luminal Fe^{3+} is reduced to Fe^{2+} by Dcytb. (2) Fe^{2+} is transported intracellularly across the brush border membrane (BBM) by the divalent metal transporter DMT1. (3) Fe^{2+} is transferred to the basolateral membrane (BLM) by hephaestin. (4) Fe^{2+} is transferred across the BLM into the body by Ireg1. (From Frazer DM, Anderson GJ: The orchestration of body iron intake: How and where do enterocytes receive their cues? Blood Cells Mol Dis 30:288-297, 2003.)

The complexity of this system is beyond the scope of this chapter; however, it is a negative feedback system dependent on continuous monitoring of transferrin levels by the liver, and it ultimately produces the so-called humoral factor hepcidin, which regulates Ireg1 expression. When iron stores are high, the liver increases hepcidin production and thus decreases Ireg1 expression, which in turn leads to decreased iron absorption.

The importance of the duodenum in iron absorption is highlighted in patients whose duodenum is bypassed during RYGBP, and the incidence of iron deficiency in such patients is at least 14% to 16% and up to 49% to 52%.[26,27] This deficiency is usually corrected by oral supplementation with multivitamins, but additional iron supplementation is frequently required, especially in menstruating females.

Macronutrients

Luminal macronutrients are absorbed via the BBM by a variety of transport systems.

Carbohydrates The duodenum plays a crucial role in the process of starch hydrolysis because pancreatic amylase is required, so by the time that the carbohydrate load reaches the proximal jejunum, this process is almost complete. After hydrolysis into simpler compounds, the monosaccharide fructose is passively absorbed through a GLUT5 transporter, whereas glucose and galactose are actively absorbed via the BBM sodium-glucose cotransporter SGLT-1.[28] Absorption occurs mostly in the early and midportion of the small intestine by mature enterocytes on the upper third of the villi.[29]

Protein Although protein digestion begins in the stomach by the action of pepsin, most proteolysis occurs in the proximal part of the small intestine. The duodenocyte brush border enzyme enteropeptidase (enterokinase) plays a key role in initiating proteolytic digestion by converting trypsinogen into trypsin, which in turn activates all other pancreatic zymogens.[30] Furthermore, the majority of protein digestion occurs through dipeptide and tripeptide proton-coupled cotransporters, or PepT1, which are found mostly in the duodenum and jejunum.[31] As much as 50% of the protein ingested is digested and absorbed in the duodenum.

Lipids Most dietary fat is absorbed in the duodenum and upper jejunum. Entry of fat into the duodenum stimulates secretion of cholecystokinin (CCK) from the duodenal mucosa, which in turn promotes the release of pancreatic lipase. Duodenal hydrolysis of dietary lipids and biliary phospholipids and cholesterol is carried out by pancreatic lipase, colipase, phospholipase A_2, and cholesterol esterase. Bile acid solubilization starts in the duodenum and results in mixed micelles and liposomes, which are delivered to the brush border for passive diffusion of their lipid contents via fatty acid transport proteins.

Endocrine Physiology

The duodenum produces a diverse group of hormones that are crucial for initiating and coordinating digestion and absorption throughout the small intestine. Ingested nutrients stimulate the secretion of GI hormones that are necessary for the coordinated processes of digestion and absorption of food. The most clinically relevant are reviewed (Table 66–1).

Secretin

Bayliss and Starling[32] discovered secretin in 1902. Secretin is a helical peptide that shares structural similarities with pancreatic glucagons and VIP. It is released from S cells in the duodenal mucosa in response to fat, protein, and bile acids, but the most important is intraluminal acid, especially with a pH less than 3.0.[33] Release is neurally mediated by secretin-releasing peptide (SRP).[34,35]

Secretin is known as nature's antacid because it stimulates large volumes of alkaline pancreatic secretions. Other functions include (1) synergy with CCK in stimulating the exocrine pancreas; (2) stimulation of biliary bicarbonate, chloride, and water secretion; (3) decreasing the bile salt concentration; (4) stimulation of pepsin release; (5) antagonism of gastrin and thus acid production; (6) inhibition of gastric emptying, lower esophageal sphincter tone, and colonic contraction; and (7) increasing mucus production by gut mucosa.

Clinically, secretin paradoxically elevates gastrin levels in patients with Zollinger-Ellison syndrome and is thus often used as a diagnostic tool; it is also used to dilate the pancreatic duct for improved ductal evaluation during endoscopic retrograde cholangiopancreatography.

Cholecystokinin

CCK was discovered and named by Ivy and Oldberg,[36] who found that lipid infusion into the proximal part of

Table 66–1 Physiologic Functions of Gastrointestinal Hormones

CCK	Stimulates gallbladder contraction
	Stimulates exocrine pancreas secretion
	Growth of the pancreas
	Satiety
	Sphincter of Oddi relaxation
	Inhibits gastric emptying
GIP	Glucose-dependent insulin release
	Inhibits gastric secretion
Motilin	Initiation of the migrating motor complex
	Stimulates gastric emptying
	Stimulates pepsin secretion
NO	Smooth muscle relaxation
	Stimulates intestinal secretion
Secretin	Stimulates exocrine pancreaticobiliary function
	Growth of the pancreas
	Stimulates gastric pepsin secretion
	Stimulates colonic mucin
	Inhibits gastric acid secretion
	Inhibits gastrointestinal motility
Serotonin	Gastric relaxation
	Stimulates intestinal secretion
	Stimulates intestinal motility
Somatostatin	Inhibits gastric acid and biliary secretions
	Inhibits pancreatic secretions
	Inhibits gastrointestinal secretion/motility
	Inhibits gallbladder contraction
	Inhibits cell growth
Gastrin	Stimulates gastric acid secretion
	Gastric trophic factor
Ghrelin	Growth hormone secretagogue
	Stimulates appetite
GRP	Stimulates gastrin release
Melatonin	Stimulates bicarbonate secretion
	Antioxidant
Neurotensin	Stimulates pancreas secretion
	Inhibits gastrointestinal motility
NPY	Inhibits intestinal motility
	Inhibits intestinal fluid/electrolyte absorption
	Vasoconstrictor
Opioids	Inhibit gastrointestinal motility
	Stimulate bicarbonate production
PP	Stimulates GI and pancreaticobiliary secretion
	Causes satiety
	Stimulates UGI motility
PYY	Causes satiety
	Inhibits gastrointestinal motility
Substance P	Stimulates GI motility
	Smooth muscle contractility
	Immune activity
	Simulates GI secretion
	Stimulates CCK release
	Gastric protection
VIP	Stimulates water and electrolyte secretion
	Smooth muscle relaxation
	Inhibits intestinal absorption
	Immunomodulator

CCK, cholecystokinin; GI, gastrointestinal; GIP, gastric inhibitory polypeptide; GRP, gastrin-releasing peptide; NO, nitric oxide; NPY, neuropeptide Y; PP, pancreatic polypeptide; UGI, upper gastrointestinal; VIP, vasoactive intestinal polypeptide.

the small intestine resulted in gallbladder contraction. In 1943, Harper and Raper[37] found that the same physiologic stimulus resulted in pancreatic enzyme release and named it *pancreozymin*. It was not until 25 years later that Jorpes[38] sequenced these peptides and found that they were the same.

In a highly coordinated manner CCK regulates the ingestion, digestion, and absorption of nutrients. This hormone is a dipeptide produced by I cells and is present throughout the small intestine but concentrated in the duodenum and secreted into blood after the ingestion of proteins and fats. There are reports that acidification of the intestine can also release CCK. The physiologic actions of CCK include (1) stimulation of pancreatic enzyme secretion, (2) acetylcholine-mediated gallbladder contraction, (3) VIP/NO-mediated sphincter of Oddi relaxation, (4) potentiation of the pancreatic exocrine stimulatory effects of secretin, and (5) induction of satiety.[39]

Other less well known functions have been attributed to CCK, including relaxation of the lower esophageal sphincter, VIP-mediated regulation of gastric emptying, and slowing of intestinal transit, which have been attributed to CCK-mediated interruption of the MMC. CCK may also function to decrease gastric acid release, stimulate insulin release, and stimulate pancreatic growth, and it has been found to be a central nervous system neurotransmitter responsible for panic and anxiety conditions.

Clinically, CCK has limited uses, but it has been suggested to reduce the incidence of acalculous cholecystitis and is being investigated as an anxiolytic. It can also be used during biliary imaging to stimulate gallbladder contraction.

Gastric Inhibitory Polypeptide (Glucose-Dependent Insulinotropic Peptide)

Gastric inhibitory polypeptide (GIP) was first purified and sequenced by Brown and Dryburgh in 1971,[40] who found it to have remarkable homology to secretin. GIP, along with glucagon-like peptide-1 (GLP-1), an

enteroglucagon, is an incretin hormone, or a hormone responsible for endocrine enhancement of insulin secretion. Incretins, secreted from endocrine cells located in the intestinal mucosa, act to enhance meal-induced insulin secretion by the endocrine pancreas and are believed to inhibit meal-stimulated gastric secretion. They are stimulated by the presence of glucose and fat in the intestinal lumen. Direct contact of glucose and fat with these open-type K cells (GIP) and L cells (GLP-1) releases these hormones, although GIP release is postulated to be more dependent on the rate of absorption. K cells are found primarily in the duodenum but can be found throughout the small intestine; in contrast, L cells are found throughout the small intestine but predominately in the distal ileum.

Though not fully delineated, suggested mechanisms for neural modulation of incretin release include muscarinic, β-adrenergic, hormonal, and peptidergic (gastrin-releasing peptide [GRP]) fibers, and secretion is restrained by α-adrenergic stimulation, glucagon, insulin, peptide YY (PYY), and somatostatin.[41]

The importance of incretin hormones lies in their possible contribution to the early pathogenesis of type 2 diabetes in that it is believed that the incretin effect is greatly impaired in such patients. Thus, these hormones are being evaluated as potential treatment targets.[42]

Somatostatin

Somatostatin has been identified in nerves and cell bodies in the central and peripheral nervous system, including the intramural enteric nervous system and endocrine-like D cells of the stomach and small intestine.[43,44] It is a hormone present throughout the mammalian organism and has paracrine, endocrine, and neurocrine activity. Over two thirds of the circulating concentration of somatostatin is derived from the GI system, especially the distal part of the stomach, duodenum, jejunum, and pancreas. Although the mechanism of somatostatin secretion remains poorly understood, it has been shown that a significant increase occurs in response to the ingestion of a meal, more specifically, the presence of fat, protein, and to a lesser extent, carbohydrate in the distal portion of the stomach and duodenum. CGRP and catecholamines are also stimulants for somatostatin release. Release of acetylcholine from cholinergic neurons inhibits somatostatin release. Plasma somatostatin fluctuations are found during the interdigestive period and are controlled by a complex interplay between cholinergic and adrenergic neural input, prostaglandins, and circadian rhythms. Additional hormones affect circulating concentrations, including the stimulants gastrin, CCK, secretin, GIP, and bombesin.

A wide spectrum of GI actions has been attributed to somatostatin. In the stomach, somatostatin inhibits gastric acid and pepsin secretion by reducing the response to gastrin in addition to attenuating gastrin release. This effect is believed to be due to a paracrine effect of the hormone. Furthermore, it inhibits the absorption of amino acids in the duodenum and attenuates glucagon-induced jejunal water and electrolyte secretion. In the pancreas, somatostatin inhibits enzymatic, but not bicarbonate secretion and blocks the response to CCK and secretin. Somatostatin reduces the frequency of the MMC of the stomach and small intestine, which may be due to direct inhibition of acetylcholine release from peripheral neurons. Because of its role as a universal inhibitor of GI activity, much research has been invested in the production of somatostatin analogues for the treatment of many GI diseases.

Motilin

Motilin is a regulatory polypeptide of 22 amino acid residues that originates in nonargentaffin endocrine cells, which are scattered in the absorptive epithelial cells covering the villi of the duodenum and upper jejunum.[45] It is released into the general circulation at about 100-minute intervals during the interdigestive state and is an important factor in initiation of phase III contractions in the stomach, also known as the MMC. Additionally, motilin has a stimulatory effect on gastric pepsin secretion and pancreatic exocrine secretion[46-48] while causing gallbladder contraction, including the sphincter of Oddi.[49,50] Previously, it was believed that changes in duodenal pH were stimulatory for motilin release (i.e., duodenal acidification). However, more recent data have refuted this theory.[51] Nevertheless, it is clear that the presence of nutrients in the duodenum, especially fat, is strongly inhibitory for motilin release.[52] Although the mechanism of action of motilin remains a mystery, it has generally been accepted that it exerts its effect on gastric smooth muscle by a vagal-dependent and vagal-independent pathway. Motilin has been shown to increase serum concentrations of insulin and pancreatic polypeptide (PP). Clinical application of motilin as a prokinetic agent has become possible since erythromycin and its derivatives were proved to be nonpeptide motilin receptor agonists.

Serotonin

Serotonin (5-hydroxytryptamine [5-HT]) is a nonpeptide hormone important in intestinal secretion and motility. Although it is now recognized to be localized throughout the enteric neuronal system, over 90% of total-body serotonin is contained in the enterochromaffin (EC) cells lining the mucosa of the intestine, including the duodenum.[53] It is widely accepted that in the GI tract serotonin acts as both a neurotransmitter and a mucosal signaling molecule. As a neurotransmitter, serotonin is involved in gastric relaxation through vagally induced activation of an inhibitory neural circuit containing serotoninergic neurons.[54] 5-HT also has a role in induction of the slow excitatory postsynaptic potentials in enteric neurons. As a mucosal signaling agent, the EC cell is purported to be a signal transducer such that mucosal distention or the presence of intraluminal nutrients (e.g., glucose, fat), or both, stimulates these cells to release 5-HT into the bowel wall, which initiates a cascade of physiologic events.[55-57] Included in these events are increased intestinal secretions via enhanced electrolyte transport and increased intestinal motility. The multitude of responses initiated by serotonin is attributed to

the various serotonin receptor subtypes identified throughout the enteric smooth muscle, mucosal, and neuronal milieu. In fact, pharmacologic manipulation has become an area of intense investigation in the treatment of both constipation-prone and diarrhea-prone irritable bowel syndrome (IBD) inasmuch as serotonin is thought to be intricately involved in such pathologic phenomena. Serotonin is also a product of carcinoid tumors and is implicated in most of the symptoms seen in carcinoid syndrome.

Nitric Oxide

The inhibitory mechanism of nonadrenergic, noncholinergic (NANC) neurotransmission in the GI tract was discovered to be primarily mediated by NO.[58-60] First known as endothelium-derived relaxing factor, NO is an inorganic gas important in the neural and hormonal regulation of intestinal physiology. It is produced from the conversion of L-arginine to L-citrulline by nitric oxide synthase (NOS), an enzyme that exists as inducible and constitutive isoforms, the latter being present in neurons and the endothelium.[61] NO was first shown to be an inhibitory NANC neurotransmitter in isolated superperfused segments of canine intestine, in which it caused smooth muscle relaxation that was inhibited by NOS inhibitors. In the stomach, NO release is important in vagally mediated receptive relaxation and gastric distention–induced pyloric relaxation. NO is also an inhibitory neurotransmitter in duodenal and jejunal smooth muscle in the neuronal regulation of intestinal transit. In addition, it causes relaxation of the sphincter of Oddi, the pyloric sphincter, and the gallbladder smooth muscle. Moreover, NO has a role in intestinal secretion. It has been shown that the addition of NO donors to isolated rat gastric cells in suspension causes secretion.[62] Furthermore, in rat distal colon, NO has been suggested to be a secretomotor neurotransmitter responsible for increasing electrolyte transport initiated by serotonin.[63] Not only may NO be important in gastric acid secretion but also it has been implicated in pancreatic exocrine and endocrine function. In addition, it may serve to protect gastric mucosal integrity against various noxious intraluminal contents through inhibition of endothelial smooth muscle, thus increasing gastrin blood flow in times of stress.

Other Hormones

Other hormones are secreted by the duodenum but are not necessarily predominant in that region; such hormones include the following: VIP, neurotensin (NT), substance P (SP), GRP, ghrelin, enkephalins and endorphins, peptide tyrosine tyrosine (PYY), PP, neuropeptide Y (NPY), melatonin, and gastrin. Their relationships to the duodenal control of gastric and intestinal function remains poorly understood.

Vasoactive Intestinal Peptide VIP is a gut neuropeptide with similar structure to secretin and glucagon. It is released by intraduodenal hydrochloric acid, ethanol, fat, and vagal stimulation. VIP is a smooth muscle relaxant of blood vessels and sphincters, although it is best known for increasing intestinal secretion of water and electrolytes via stimulation of adenylate cyclase. Excess secretion of VIP into the blood by secretory tumors, which are most commonly localized in the pancreas, leads to the watery diarrhea hypokalemia achlorhydria (WDHA) syndrome, also known as a VIPoma or the Vernor-Morrison or *pancreatic cholera* syndrome. In addition, VIP is also known to inhibit intestinal absorption, increase bile flow, induce gallbladder relaxation, and inhibit acid and pepsin secretion, and it has a small glycogenolytic effect in the liver.[64] Recently, VIP has been recognized as an immunomodulator and possibly as a cytokine-like molecule[65]; a decrease in this function in the lamina propria and submucosa has been implicated in the pathophysiology of IBD.[66]

Neurotensin NT is most abundant in the ileum, with a lesser amount in the jejunum and duodenum; this tridecapeptide is also found in the brain to a lesser degree, where it has been linked to clinical disorders hypothesized to involve dopamine circuits, such as schizophrenia, Parkinson's disease, and drug abuse.[67] NT is present in the endocrine cells labeled N cells,[68] which are of the open type. NT is also present in nerves of the myenteric plexus, in the muscular layer, and in the submucosa of the stomach and duodenum. Release of NT is stimulated by intraluminal fat, and it functions to stimulate pancreatic secretion and inhibition of gastric and small bowel motility.

NT has been implicated in facilitating fatty acid translocation and stimulating the growth of various GI tissues, including cancer cells. It also stimulates colonic contraction and defecation; its release is accelerated in patients with dumping syndrome. The NT gene is developmentally regulated in the gut of both rats and humans in a distinctive temporally and spatially specific pattern[69]; therefore, this gene is an excellent model for defining differentiation pathways leading to gut development, maturation, and neoplasia. Some of the effects of NT are inhibited by COX inhibitors, thus suggesting prostaglandin-mediated release.

Substance P The first brain-gut peptide discovered, SP belongs to a group of neuropeptides called tachykinins, and it plays an important role as a neurotransmitter in the central and peripheral nervous system. In response to intraluminal food, SP leads to excitatory action on GI motor activity, which is seen virtually at all levels and in all layers of the mammalian gut, with the highest concentrations in the duodenum and jejunum. SP regulates smooth muscle contractility, epithelial ion transport, vascular permeability, and immune function in the GI tract.[70] It appears to increase the contraction of intestinal and gallbladder smooth muscle, reduce bile flow, and increase pancreatic juice outflow. This neurotransmitter has been suggested to play a role in the pathophysiology of inflammatory diseases such as arthritis, colitis, and intestinal inflammation. Elevated levels of SP have been reported in the rectum and colon of patients with IBD and correlate with disease activity. Preventing the proinflammatory effects of SP with tachykinin receptor

antagonists may have therapeutic potential in inflammatory diseases such as asthma, sarcoidosis, chronic bronchitis, IBD, and rheumatoid arthritis. In gut-associated lymphoid tissue (GALT), the high concentrations of SP in intestinal nerve endings and expression of a specific SP receptor on T and B cells in murine Peyer's patches suggest that SP may act as a trophic factor, a homing factor, or a differentiation factor for IgA-secreting plasma cells.[71]

Gastrin-Releasing Peptide Bombesin was discovered in 1970 in extracts taken from the skin of amphibians.[72] It was later noted to have a mammalian counterpart that was named GRP, which has been detected throughout the digestive tract but is particularly prominent in both the acid- and gastrin-secreting portions of the stomach. It is known to modulate acid and gut peptide secretion, and it stimulates CCK release from the GI tract. Secretion of GRP causes the release of endogenous gastrin, which activates sensory neurons, and it is modified by somatostatin. Studies have shown that activation of sensory neurons causes increased production of NO through activation of constitutive NOS, thereby leading to increased gastric mucosal blood flow and thus protection from damage by irritants.[73] In addition to activation of capsaicin-sensitive sensory neurons, GRP requires endogenous prostaglandins to fully exert its gastroprotective actions.[74] This process is reminiscent of that described in protecting the duodenal mucosa. Clinically, GRP has been shown to improve maintenance of gut mucosal integrity after severe burns by decreasing burn-induced gut mucosal atrophy and epithelial cell apotosis.[75]

Ghrelin *Ghrelin* is a recently identified peptide important in the peripheral regulation of energy balance. Endocrine cells of the gastric oxyntic mucosa are the primary site of production; they are responsible for over 70% of the circulating ghrelin concentration.[76] Through ultrastructural analysis these ghrelin cells are distinct from the histamine-producing enterochromaffin-like (ECL) cell, the somatostatin-producing D cell, and the serotonin-producing EC cell. Ghrelin cells have also been discovered in the small intestine and pancreas.[77] Ghrelin dose-dependently stimulates release of growth hormone from pituitary cells and is in fact the most potent growth hormone secretogogue discovered. Although the exact mechanism of action is not clearly defined, its orexigenic effect is well documented, and it increases appetite in a circadian fashion.[78] These findings suggest a role for ghrelin as a humoral signal from the stomach for meal initiation. This increase in appetite is associated with an increase in body weight via increased adipogenesis and reduced lipid metabolism.[79] It has been postulated that ghrelin may be a signal to the central nervous system regarding acute and chronic changes in food intake, metabolism, or body fat mass, thereby initiating efferent responses that regulate energy homeostasis.[80] Circulating levels of ghrelin are inversely related to body mass index, adipose tissue mass, and insulin plasma levels such that dysregulation of ghrelin gene expression may explain the impaired regulation of body weight in obesity.[81] Moreover, ghrelin has a motilin-like effect on gastric motility and stimulates the release of somatostatin and PP by increasing glucose and decreasing insulin levels.[80]

Endorphins and Enkephalins Endorphins and enkephalins are opioid peptides found in a variety of tissues. Though present in lower concentration in the gut than in the central nervous system, the proximal portion of the intestine has a particularly high concentration of enkephalins. Both are present in enteric nerves, especially in the myenteric plexus. Enkephalins are found in the intrinsic nerves of the stomach and innervate the pyloric sphincter; in contrast, endorphins have been found in pyloric antral G cells and in the submucosal plexus of the duodenum and ileum.[82]

Although their specific effects on the GI system are unknown, opioid peptides have been associated with several functions, including motility, acid secretion, and intestinal electrolyte and fluid transport. They have also been implicated in stimulating duodenocyte HCO_3^- production in response to duodenal acid. The antimotility effects of opioid drugs arise from changes in both motility and secretion caused by activation of opioid receptors located in the gut wall,[83] which leads to interruption of the enteric nerve pathways governing acetylcholine and other excitatory transmitters that stimulate muscle contraction. Allescher et al.,[84] in a naloxone-sensitive system, demonstrated that opioid-active drugs modify the peristaltic reflex by reducing the efficacy of the reflex response and modulating the timing of the ascending excitatory and descending inhibitory reflex pathway. Clinically, exogenous opioids, including morphine, have been well known to cause constipation, and other medications that interact with opioid receptors have been used for antidiarrheal therapy.

Peptide YY and Pancreatic Polypeptide PYY and PP belong to the NPY family, which contain several tyrosine residues within their homologous sequences. These peptides activate G protein–coupled Y receptors.

PP is restricted to endocrine cells mainly in the duodenal portion of the pancreas, but it is also found throughout the GI tract. It is released into blood in response to a meal rich in protein and especially fats. PP is known to stimulate gastric, pancreaticobiliary, and intestinal secretion, and it stimulates motility of the upper GI system. PP, along with PYY, has been implicated as an anorexigenic peptide promoting satiety.[85]

NPY is a neuropeptide widely distributed in the central and peripheral nervous system; its nerve fibers are widely located through the intestinal tract, with the largest numbers in the duodenum and upper part of the small intestine. Functionally, NPY is known to regulate large and small intestinal motility, vasoconstriction of surrounding vessels, and inhibition of small intestinal fluid and electrolyte secretion.

PYY is secreted in response to intraluminal carbohydrates and lipids, and it is expressed in both endocrine cells and enteric neurons throughout the gut. L cells that secrete GLP-1 also secrete PYY.[86] These cells predominate in the ileum, colon, and especially the rectum; however,

enteric nerve fibers that innervate myenteric plexus smooth muscle are found in highest number in the stomach and duodenum.[87] The dual localization of PYY in endocrine cells and intestinal nerves suggests that it is important in several gut functions similar to NPY, including motility and secretion. Furthermore, its presence during early fetal development suggests that it may play a role in promoting development and maturation of the digestive tract.

Melatonin A product of intestinal EC cells and the pineal gland, melatonin is a potent stimulant of duodenal mucosal HCO_3^- secretion in the rat. Melatonin receptors are distributed throughout the GI tract. The effects of melatonin are mediated by specific high-affinity membrane-associated melatonin receptors that belong to the superfamily of G protein–coupled receptors. On the basis of pharmacologic evidence, three subtypes are reported. The total amount of melatonin in the alimentary tract is much higher (400-fold) than that in the central nervous system, but the role of melatonin in GI function has been largely unknown.[88] Melatonin may also exert a potent anti-inflammatory effect that may be useful in the treatment of IBD. These effects are attributed partly to its antioxidant property, which stems from eliminating NO in the inflamed colon.[89]

Gastrin A peptide hormone produced by G cells in the gastric antrum and duodenum, gastrin is induced by the presence of protein or calcium in the gastric lumen or by antral/duodenal distention. Gastrin stimulates gastric acid secretion by parietal cells in the stomach. Zollinger-Ellison syndrome is caused by a gastrinoma, or a gastrin-secretin tumor, which is usually localized in the pancreas or duodenum. Gastrin has also been documented to have trophic action and may contribute to the growth of gastric and colorectal carcinoma.[90] *H. pylori*–associated antrum gastritis produces hypergastrinemia by disinhibition of gastrin release and thereby contributes to hypersecretion of acid in *H. pylori*–associated gastritis and duodenal ulcer disease.[91] Pentagastrin, a gastrin analogue, is used clinically to measure maximal gastric secretion.

DUODENAL MOTILITY

Intrinsic Control

The intrinsic rhythm of small intestinal contractions probably originates from the MMC of the distal part of the stomach. It has been demonstrated that slow-wave and spike activities take place in preparations of neuron-free intestinal smooth muscle. The low-resistance junctions that exist between adjacent smooth muscle cells allow rapid propagation of electrical activity.[92] This intrinsic activity is modified by neural input and by hormones working in an endocrine, paracrine, or neurocrine pattern. Baseline duodenal peristalsis generally occurs at higher frequency (10 to 12/min) than in the jejunum or ileum. The electrical activity of duodenal smooth muscle is such that longitudinal waves of contraction continue for some distance down the small bowel, possibly resulting in a strong propulsive forward movement of duodenal contents.

Extrinsic Control

Extrinsic control of duodenal motility is primarily regulated by the autonomic nervous system.[93] Afferent and efferent vagal fibers innervate the entire small intestine, including the duodenum. The sympathetic innervation consists of preganglionic neuronal processes originating from T9 and T10. These run in the splanchnic nerves and synapse with the celiac ganglia. Thus, the duodenum derives its sympathetic innervation from both celiac (proximal duodenum) and superior mesenteric (distal duodenum) ganglia. These fibers consist of both cholinergic and noradrenergic neurons; however, the sympathetic innervation of the stomach and duodenum is largely inhibitory.

The preganglionic vagal efferent neurons have cholinergic excitatory and inhibitory interneuronal connections before intestinal innervation. Therefore, the vagus nerve can elicit several responses in the stomach and duodenum, and there is a delicate interplay between stimulatory and inhibitory effects in the net response to vagal activity. In the stomach, vagal stimulation causes gastric acid secretion, and it has been shown that truncal vagotomy causes incoordination of antral contractions and loss of receptive relaxation and gastric emptying. In the duodenum, vagal stimulation has been linked to inhibition of duodenal motility. In addition, a large number of receptors have been identified on smooth muscle cells that are important in the initiation of contraction,[94] including receptors for CCK, gastrin, SP, bombesin, and acetylcholine. Other agents have been identified as smooth muscle relaxants, such as VIP and adenosine triphosphate. This is a testament to the complex interplay of local and extrinsic hormonal and neural input in the regulation of intestinal motility.

ACKNOWLEDGMENT

We would like to acknowledge the excellent work of the previous writers of this chapter, Vicky B. Tola and David I. Soybel; much of the material in the anatomy section has been retained.

Small Intestine

Mary F. Otterson · David Binion · Seth J. Karp · David I. Soybel · Edward C. Mun · Jeffrey B. Matthews

ANATOMY

The duodenum, jejunum, and ileum make up the small intestine. The duodenum is anatomically distinct, but the jejunum (proximal two fifths) and ileum (distal three fifths) have no true anatomic border between them.

The duodenum is divided into four parts: the first portion or the bulb, the second or descending portion, the third or transverse portion, and the fourth or ascending portion. The first portion begins at the pylorus and sweeps to the right; it is anchored by the hepatoduodenal ligament and is referred to as the bulb of the duodenum. Just beyond the bulb, Kerckring's folds begin. These circular folds of mucosa and submucosa extend for the length of the small bowel. Radiographically, Kerckring's folds are referred to as the *valvulae conniventes*. Posterior to the bulb of the duodenum are the gastroduodenal artery and the pancreas. Blood supply is from the supraduodenal and gastroduodenal arteries; both arise from the hepatic artery. The second portion of the duodenum travels posteriorly and caudad to the level of the first lumbar vertebra, where it is retroperitoneal and attached to the head of the pancreas. Posterior is Gerota's fascia and the kidney, anterior is the hepatic flexure of the colon, and medial lies the inferior vena cava. The arterial supply is from the celiac axis through the gastroduodenal artery to the anterosuperior and posterosuperior pancreaticoduodenal arteries and from the superior mesenteric artery (SMA) through the anteroinferior and posteroinferior pancreaticoduodenal arteries. The common bile duct and the main pancreatic duct enter in the middle of the second portion of the duodenum, about 10 cm distal to the pylorus at the ampulla of Vater. The sphincter of Oddi surrounds and controls the ampulla of Vater. When an accessory pancreatic duct is present (6% of normal patients), it usually enters about 2 cm proximal to the ampulla.[1] The third portion begins as the duodenum sweeps to the left at the level of the third lumbar vertebra and ends at the aorta. It is associated with the uncinate process of the pancreas and is dorsal to the superior mesenteric artery. Subtle anatomic anomalies can result from a high ligament of Treitz, prolonged immobilization, spinal surgery, rapid height gain, or scoliosis and can cause compression of the duodenum by the SMA and result in obstruction (variously called *SMA syndrome, cast syndrome, Wilkie's syndrome, duodenal ileus,* or *duodenal compression syndrome*).[2] The fourth portion of the duodenum begins at the aorta, extends to the left, and passes ventral to the left psoas. It emerges into the peritoneum at the duodenojejunal flexure, which is fixed to the posterior abdominal wall at the ligament of Treitz, striated fibromuscular tissue that arises from the right crus of the diaphragm. Defects in the mesentery of the flexure may give rise to internal hernias. Venous drainage from the duodenum is through the splenic, superior mesenteric, and portal veins.

The jejunum and ileum are suspended from the posterior aspect of the peritoneal cavity by mesentery that travels obliquely from the left upper quadrant to the right lower quadrant of the abdomen (Fig. 67–1). The mesentery begins at the ligament of Treitz, where a double fold of peritoneum is pulled up as the bowel exits the retroperitoneum. From a base of about 15 cm, this mesentery fans out to connect to the entire 2.5 m of small intestine. The intestinal blood supply, as well as fat and lymphatic tissue, resides within the mesentery. The blood supply of the jejunum and ileum derives from the SMA, which has an extensive anastomotic network (the vasa recta) near the mesenteric border of the bowel called the *marginal artery*. This artery runs along the length of the small bowel. At the ileal branch of the ileocolic artery, the marginal artery breaks up as the anastomotic network of the vasa recta increases in complexity. Venous drainage follows the course of the arteries.

Although there is no true anatomic distinction between the jejunum and ileum, a number of anatomic features progress in an orderly fashion over the course of the intestine and help distinguish the two portions of

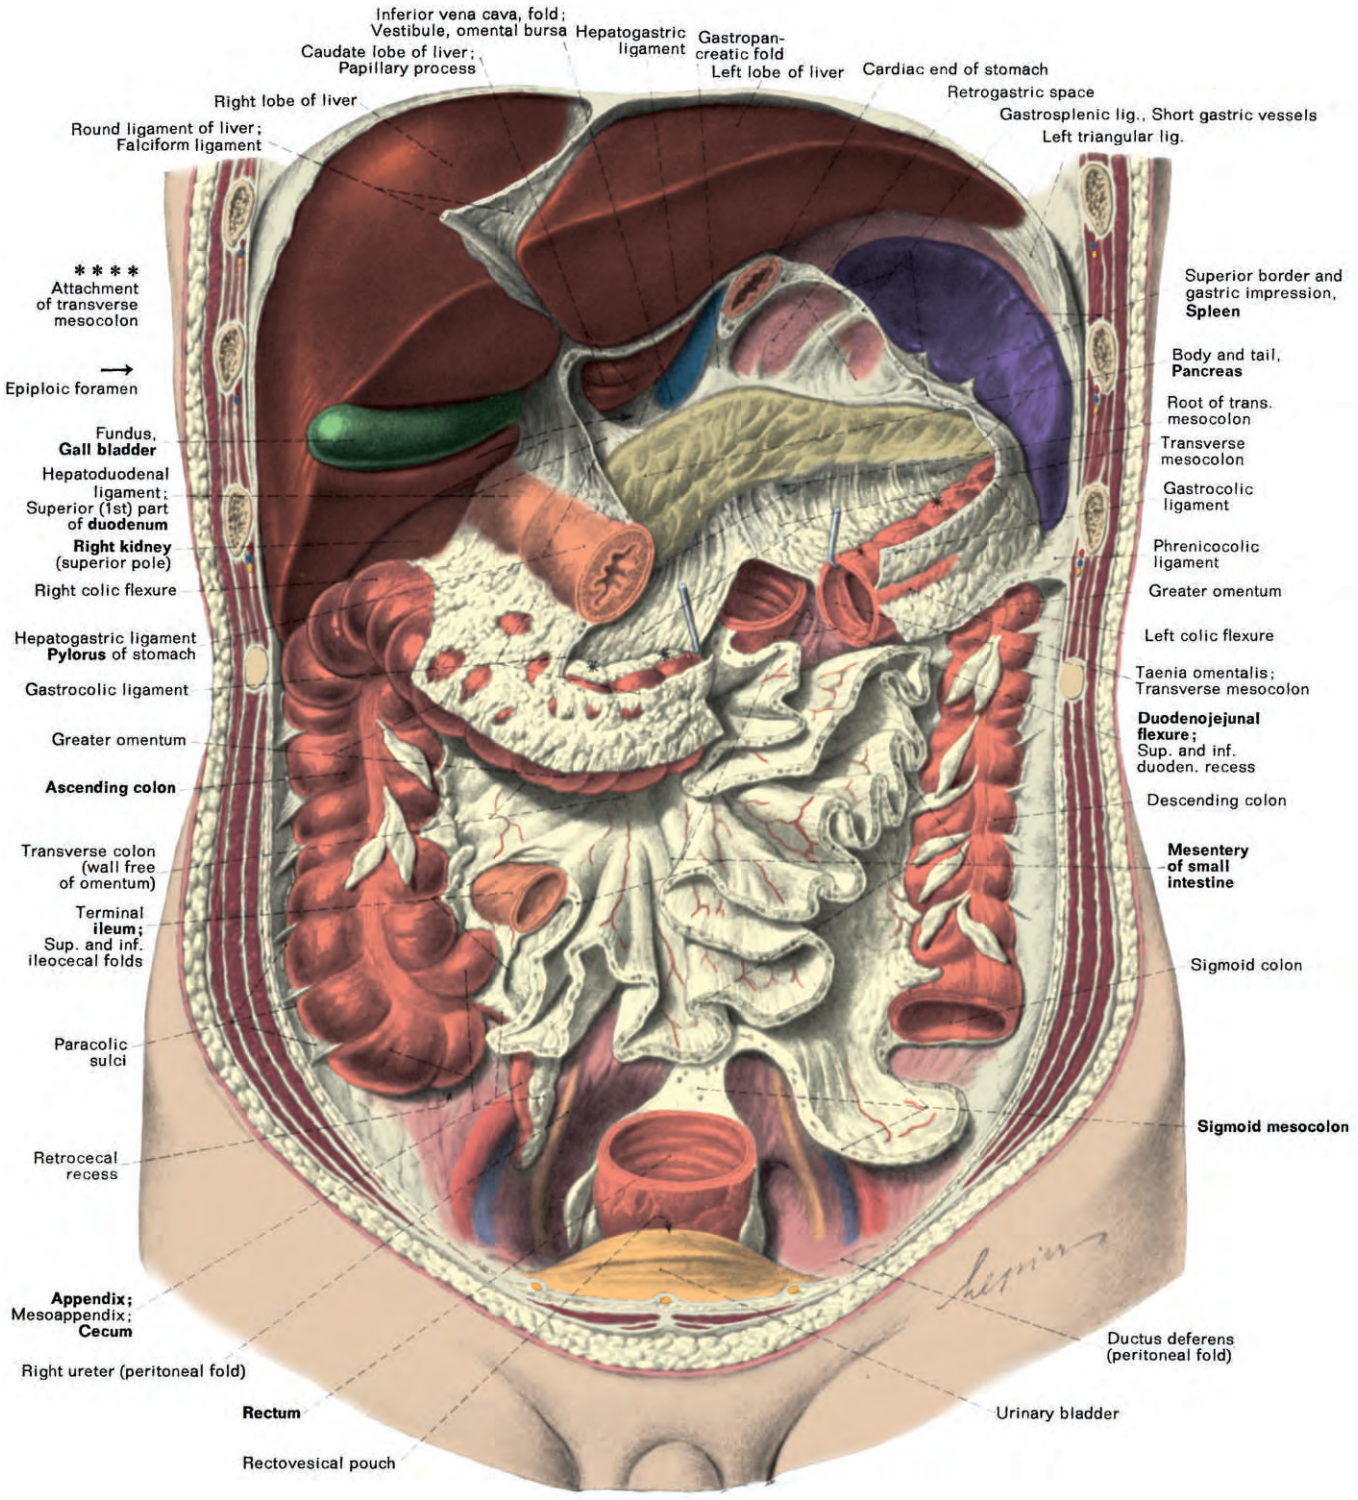

Figure 67–1. View of the mesentery and attachments of the small intestine. The small intestine has been removed, as has the sigmoid colon. (From Clemente CD: Anatomy: A Regional Atlas of the Human Body. Philadelphia, Lea & Febiger, 1975, plate 305.)

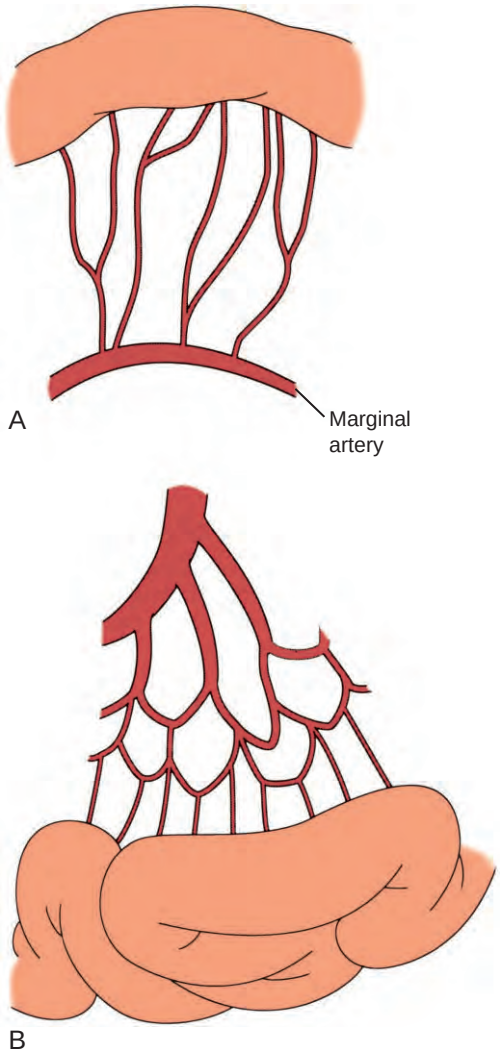

Figure 67–2. Schematic of the arterial network to different regions of the small intestine. **A,** Typical jejunal pattern. **B,** Typical ileal pattern. (From Greenfield LT, Mulholland MW [eds]: Surgery: Scientific Principles and Practice. Philadelphia, Lippincott-Raven, 1997, p 2036.)

bowel. The jejunum tends to have a single marginal artery from which arise long, relatively straight branches of the vasa recta (Fig. 67–2A). This pattern gradually blends into arcades that travel close to the mesenteric edge of the bowel and give rise to short branches in the ileum (see Fig. 67–2B). The amount of fat along the mesenteric border tends to increase distally, at times encroaching on the bowel in the distal aspects. The intestine tends to become thinner and paler distally, along with a decrease in diameter. Lymphatic tissues unique to the small intestine and called *Peyer's patches* are most numerous in the distal ileum, whereas plicae circulares are more prominent in the proximal jejunum. Small intestinal lymphatic drainage courses through a hierarchy of mesenteric nodes following the vascular arcades: through the wall of the small intestine into the mesenteric arcade and then to a lymphatic trunk around the SMA. The lymph ultimately drains into the *cisterna chyli*. In addition to its usual reticuloendothelial function, the small intestinal lymphatic drainage serves as a major transport route into the circulation for absorbed lipid.

HISTOLOGY

The intestine has four distinct functional layers. The innermost is the mucosa, followed by the submucosa, muscularis, and serosa (Fig. 67–3). The mucosa is subdivided into three layers. Innermost is an epithelial layer, the middle layer is a lamina propria, and the outer layer is the muscularis mucosae. The epithelial layer consists of a single thickness of columnar cells supported by a basement membrane. The lamina propria consists of connective tissue, and the muscularis mucosae is a true muscular layer. Morphologically, the mucosa is arranged into finger-like projections called *villi* that serve to increase the surface area for absorption. Villi are covered with columnar cells and goblet cells. The former are responsible for absorption, and the latter secrete mucus. At the base of the villi, mucosal invaginations form crypts that contain secretory Paneth cells. The submucosa is the next layer radially outward and contains blood vessels, lymphatics, and nerves, including the parasympathetic ganglion, which make up Meissner's plexus. Continuing outward, the muscularis consists of an inner layer of circular muscle and an outer layer of longitudinal muscle. Between these muscular layers is the myenteric or Auerbach plexus. Finally, the serosa is an extension of the peritoneum and consists of a single layer of mesothelial cells and loose connective tissue.

The duodenum is distinguished histologically by the presence of Brunner's glands. These glands are spiral tubes that form an interconnected network beginning in the submucosa—below the lamina propria—and opening into the crypts between the villi. They secrete a thin, alkaline mucus that protects the duodenum and aids in acid neutralization. Additional features that mark the duodenum as a small intestinal structure include circular folds of mucosa and submucosa called *plicae circulares* or *Kerckring's valves*. Crypts in the small intestine termed *Lieberkühn's crypts* secrete bactericidal and digestive enzymes.

INNERVATION

Innervation to the small intestine is through the autonomic nervous system and includes sympathetic, parasympathetic, and enteric divisions. Sympathetic fibers arising from thoracic segments of the spinal cord synapse in the celiac ganglion before sending axons to the intestine. Parasympathetic fibers arise from the vagus nerve and synapse in the submucosal (Meissner's) and myenteric (Auerbach's) plexus. The myenteric plexus is responsible for basal electrical activity of the gut. Stimulation of the parasympathetic neurons in general prepares the intestine for activity by increasing blood flow, contractility, and secretion. These functions are antagonized by the sympathetic system.

The enteric nervous system is an integrative system distinct from the central nervous system (CNS) that

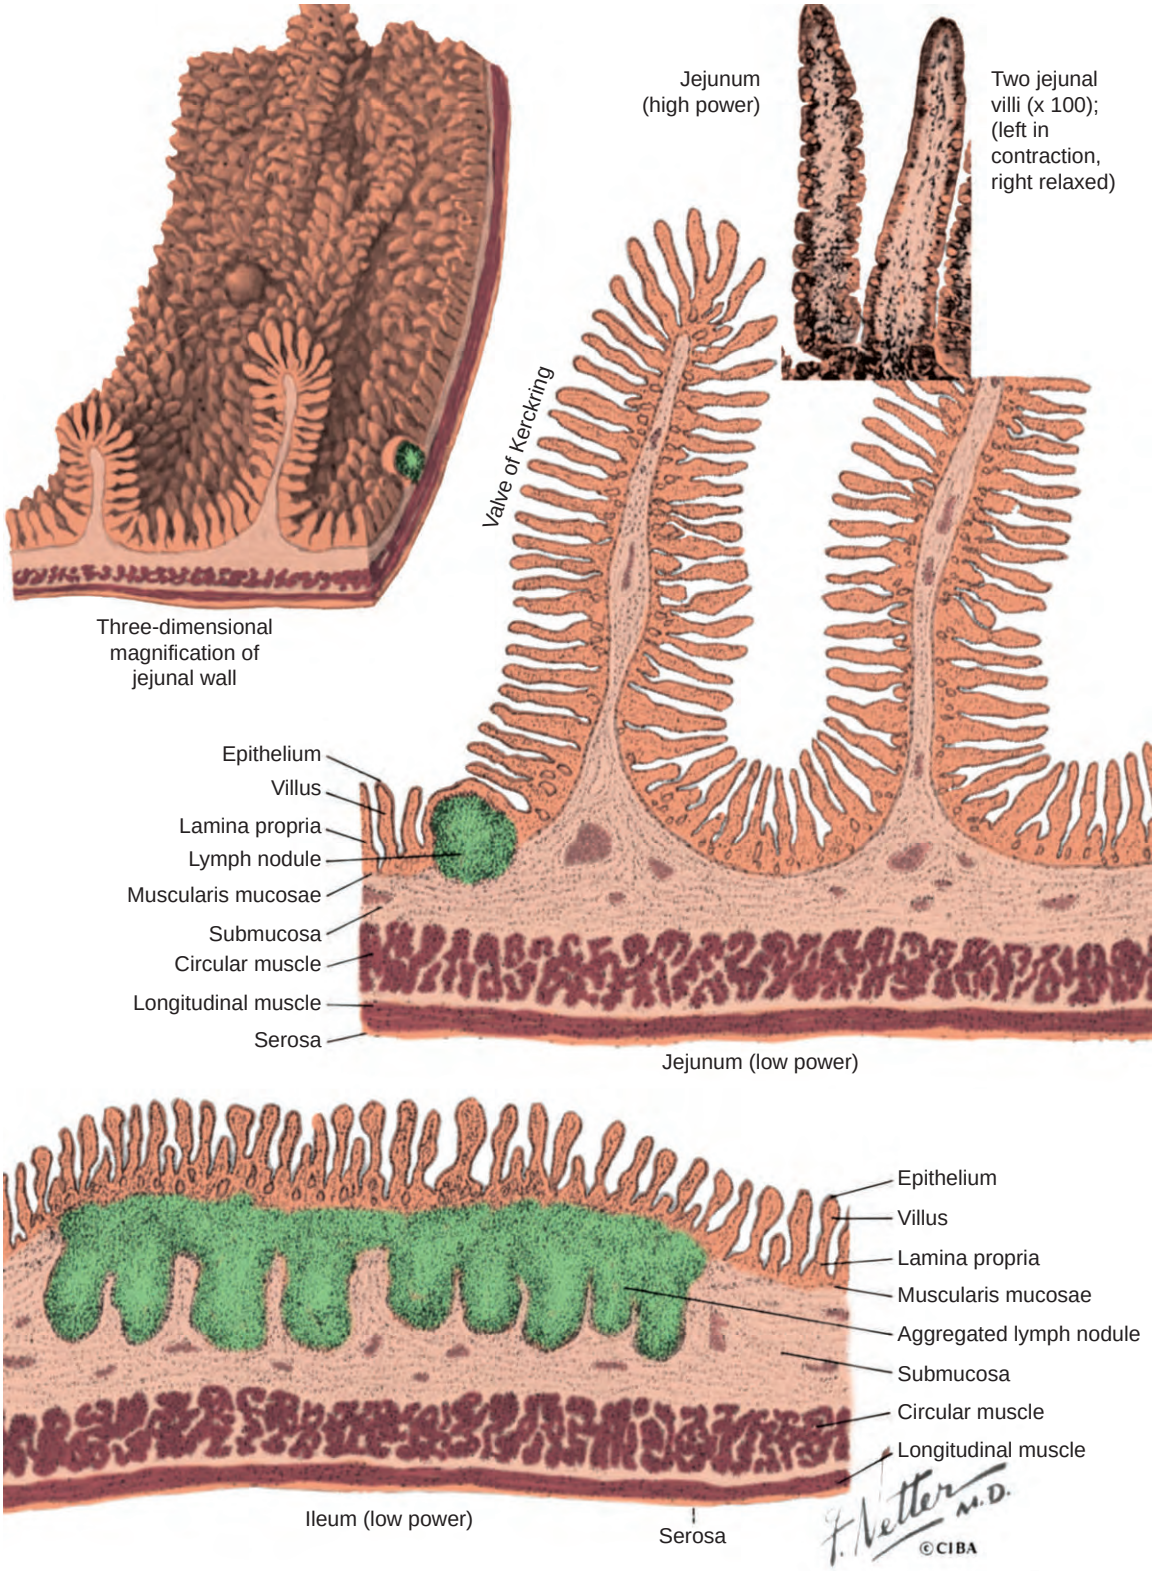

Figure 67–3. Schematic views of the histology of the jejunum and ileum. (Copyright, 1997. Icon Learning Systems, LLC, a subsidiary of Havas MultiMedia USA Inc. Reprinted with permission from ICON Learning Systems, LLC, illustrated by Frank H. Netter, MD. All rights reserved.)

ramifies throughout the submucosal and myenteric plexus of the gut. It senses the composition and characteristics of the luminal contents and integrates digestive functions that require motor or epithelial cell response. In particular, it regulates gut function by integrating smooth muscle tone and endocrine and exocrine secretion via input from afferent neurons sensitive to mechanical, chemical, osmotic, and thermal stimuli. Neurons of this system synthesize and secrete peptides that can act as neurotransmitters, paracrine factors, or endocrine factors.[3]

Pain from the small intestine is divided into visceral and somatic components. The clinical manifestations of each type of pain can be attributed to the type of innervation. Visceral pain occurs as a result of irritation of the visceral peritoneum, contraction of a tube against resistance, or distention of a tube and is carried by the autonomic nerves. Representation for these fibers is bilateral, and the pain tends to occur in the midline at the corresponding sensory level, which for the small bowel is in the epigastrium or periumbilical region. In general, this pain tends to be dull and deep in character. In contrast, parietal pain occurs as a result of irritation of the peritoneum lining the abdominal wall and is carried by somatic (spinal) nerves. This pain tends to be well localized, severe, and sharp.

LYMPHOID FUNCTIONS AND ARCHITECTURE

The intestine is protected from its tremendous bacterial load by mucosal defense mechanisms and a network of lymphatic tissue. At the mucosal level, three populations of lymphoid tissue form the first barrier to infection. Peyer's patches lie in the mucosa and submucosa and sample antigens to begin specific host responses. The lamina propria contains a separate collection of lymphoid cells consisting of T cells, B cells, and plasma cells. Intraepithelial lymphocytes form the final level of mucosal host defense. Three sets of nodes drain the small intestine. The first set lies in proximity to the mesenteric border, the second set is at the level of the arcades, and the third set is along the SMA.

MICROVASCULATURE

The vascular supply to the small intestine arises from the left side of the SMA.[4] The arterial branches derived from the SMA pass through the two layers of the mesentery into the gut at the mesenteric margin of the small bowel. Within the mesentery, the SMA branches into arcades that enter the gut wall via the vasa recta. In the jejunum, the arcades are comprised of long vasa recta (3 to 5 cm), whereas in the distal ileum the arcades are elongated and the vasa recta are relatively short. Venous drainage from the intestine parallels the arterial supply, with the superior mesenteric vein being the major venous collecting system; it also lies within the mesentery to the right of the SMA.

The vasa recta entering the bowel wall reach intramural distributive vessels located within the submucosa. These vessels in the submucosa extend to the antimesenteric border of the intestine and form plexuses that are interconnected throughout the length and circumference of the small intestine. Blood supply to the outer muscle layers of the intestine is largely derived from this submucosal plexus, as is the venous drainage, although smaller direct branches from the vasa recta can also be demonstrated. Despite housing the submucosal vascular plexus, the submucosa itself is sparsely vascularized. This is in marked contrast to the mucosa, which contains a rich microvascular network. The extensive vascularization of the mucosa is arranged in microvascular capillary and venular arcades that form a subepithelial network within the small bowel villi.

The mucosal microvasculature in the small bowel differs from other vascular beds in the body by its high rate of blood flow, oxygen utilization, and transcapillary exchange of fluid and solutes. This distinct mucosal vascular physiology is thought to result from the high metabolic demand required by the epithelial layers, which receive up to 80% of intestinal blood flow during resting conditions.[5] The highly vascularized mucosal anatomy also accommodates the physiologic need demonstrated during nutritive function, when significant portions of cardiac output are shunted into the gut. Intestinal perfusion via the SMA ranges from a low of 29 to 70 ml/min/100 g intestinal tissue, whereas in the fed state, splanchnic hyperemia increases perfusion 28% to 132%. Resistance arterioles located in the submucosa beneath the muscularis mucosae play a major role in the regulation of intestinal perfusion. The molecular physiology underlying human intestinal microvascular function was assessed directly by Hatoum et al., who characterized vasodilator responses in isolated gut resistance arterioles 50 to 150 μm in diameter by measuring in vitro vasodilatory capacity in response to acetylcholine.[6] Normal intestinal microvessels vasodilate in response to acetylcholine via predominantly nitric oxide– and cyclooxygenase-dependent mechanisms. Interestingly, microvessels from patients with chronically inflamed inflammatory bowel disease (Crohn's disease, ulcerative colitis) and radiation enteritis demonstrated a significantly diminished vasodilator capacity in comparison to control microvessels.[6,7] These findings suggest that impaired vasodilator capacity is linked to an ischemic contribution found in both classic chronic inflammation (i.e., inflammatory bowel disease) and stricture formation (i.e., long-term complication of radiation enteritis).

EMBRYOLOGY

Gastrulation

Shortly after gastrulation specifies the three embryonic germ layers, the endoderm undergoes rapid elongation. At the rostral end of the embryo, invagination of the head fold results in formation of the foregut tube. In similar fashion, the hindgut is formed by invagination of the caudal aspect of the embryo. The midportion of the tube remains in broad communication with the yolk sac and is called the *midgut* (Fig. 67–4).[8] At 18 days'

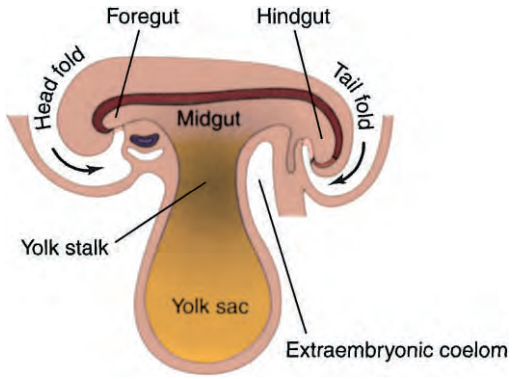

Figure 67–4. Schematic view of a 16-day-old human embryo showing the derivation of the foregut, midgut, and hindgut regions from endoderm. (From Moore KL, Persaud TVN: The Developing Human, 6th ed. Philadelphia, WB Saunders, 1998, p 84.)

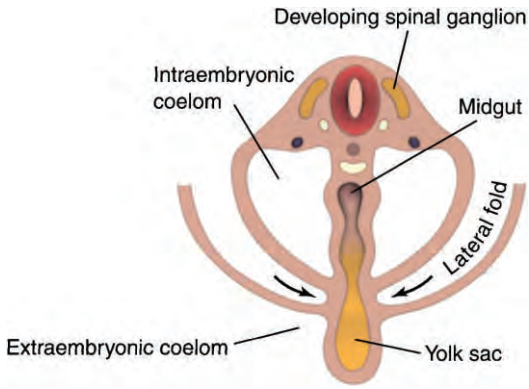

Figure 67–5. Schematic view of an 18-day-old embryo showing the derivation of the mesentery. (From Moore KL, Persaud TVN: The Developing Human, 6th ed. Philadelphia, WB Saunders, 1998, p 84.)

gestation, bilateral body folds ingress below the embryo and begin to separate it from the yolk sac. This causes splanchnic mesoderm to envelop the gut and defines the dorsal and ventral mesentery (Fig. 67–5).[8] The resulting increased distance between the neural tube and the gut may be important in preventing congenital gut duplications or diverticula, which occur at this time.[9] This separation may be necessary to remove the gut from the influence of secreted signaling molecules produced in the notochord. Consistent with this hypothesis, partial gut duplications can be induced in transgenic mice that overexpress one of these notochord-derived factors in the pancreatic region.[9]

At 28 days' gestation, continued elongation of the endoderm converts the open midgut into a tube with its midportion still connected to the yolk sac through the yolk stalk. The liver forms within the ventral mesentery, whereas the leaves of mesentery become the falciform ligament; the dorsal mesentery gives rise to the adult mesentery and within it the blood supply to the gut.

At 35 days' gestation, the foregut, midgut, and hindgut all have a distinct blood supply, which serves to distinguish them throughout adult life. The foregut is supplied by the precursor of the celiac trunk and consists of the alimentary canal proximal to the ampulla of Vater. The midgut is supplied by the precursor of the SMA and consists of the small bowel distal to the ampulla and the proximal two thirds of the transverse colon. The hindgut consists of the distal third of the transverse, descending, and sigmoid colon and is supplied by the precursor of the inferior mesenteric artery. At this time, the yolk stalk separates from the intestine and the vitelline duct is obliterated. Failure of this process can result in diverticula (Meckel's diverticulum), cysts, cords, or combinations of these abnormalities.

At 42 days' gestation, the differentiated smooth muscle envelops the gut. This process is probably regulated by members of the "hedgehog" family of proteins secreted by the endoderm, which act as inductive signals on the mesoderm.[10] Mesodermal factors important in this process include members of the transforming growth factor-β family. There is evidence that these molecules initiate preprogrammed expression of *Hox* genes, which serve to establish the regional identity of the foregut, midgut, and hindgut.[10] At this point, elongation of the midgut is so rapid that the midgut can no longer be contained in the abdominal wall previously defined by the body folds and thus herniates out. The cecum is visible as a dilation of the midgut distal to the axis of the SMA. This location of the cecum distal to the SMA is important for understanding subsequent rotation. At about this time, innervation of the gut is under way, a process that is increasingly being appreciated as essential for normal gut development.

At 60 days' gestation, the herniated gut rotates counterclockwise 180 degrees around the axis of the SMA (Fig. 67–6). This rotation causes the cecal swelling to lie superior to the more proximal small bowel. If such rotation does not occur, the small bowel will lie on the right, with the cecum in the middle and the colon on the left.

At 10 weeks' gestation, the intestines return to the abdomen in a proximal-to-distal progression, with the proximal bowel being located in the dorsal aspect of the abdominal cavity and the cecum passing ventral to the small bowel. Failure of this return causes omphalocele. At this point a final additional 90 degrees of counterclockwise rotation sets the cecum in its final location in the right lower quadrant, with the transverse colon being ventral to the small bowel (see Fig. 67–6). Failure of this final rotation leads to a variety of anatomic anomalies.

At 12 weeks' gestation, the intestines become fixed in permanent position. The mesocolon of the ascending colon fuses with the parietal peritoneum to fix the ascending colon in a retroperitoneal position. In similar fashion, the left side of the mesocolon of the descending colon fuses with the parietal peritoneum of the dorsal body wall to fix the descending colon in a retroperitoneal location. Failure of this process can lead to spaces into which herniations can occur.

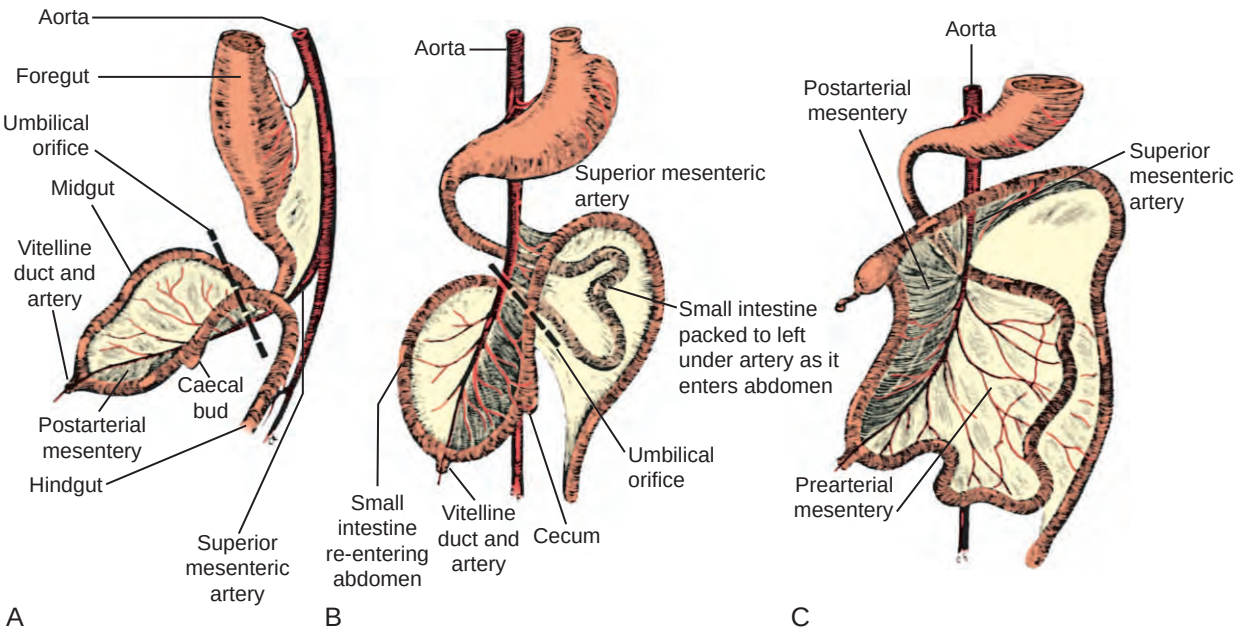

Figure 67–6. Rotation of the midgut. **A,** First stage: the loop has rotated 90 degrees counterclockwise. **B,** Second stage: the physiologic umbilical hernia is reducing; the small gut is reentering the abdomen on the right side of the superior mesenteric vessels and passing to the left side of the abdomen behind the vessels. The cecum still lies outside the umbilicus. **C,** Completion of the second stage: the cecum is in contact with the posterior abdominal wall in the right pelvis; the midgut loop has rotated 270 degrees counterclockwise. (From Louw JH: Embryology and developmental abnormalities of the small and large intestines. In Bockus HL [ed]: Gastroenterology, vol 2. Philadelphia, WB Saunders, 1978, p 8.)

CLINICAL ASPECTS OF DEVELOPMENTAL ANOMALIES

Duplications

Duplications occur early during development as described previously. The duplication may communicate with the normal gut lumen and share its blood supply. Management of duodenal duplications can be particularly difficult because of the involvement of surrounding structures, including the biliary tree, pancreatic duct, and pancreas.[9] Small bowel duplications may serve as a lead point for intussusception or create a fixed axis for the development of volvulus. Enlargement of the duplication may cause compression of adjacent structures. These abnormalities frequently contain ectopic gastric mucosa whose acid secretion can cause bleeding, pain, or perforation.

Vitelline Duct Abnormalities (Meckel's Diverticulum and Others)

The vitelline duct connects the midgut to the yolk sac during development. Any portion of this duct can remain as either a tube or a fibrous cord (Fig. 67–7). Persistence of the entire duct results in an enterocutaneous fistula. If the intestinal portion does not obliterate, Meckel's diverticulum results, the most common gut malformation. It occurs on the antimesenteric border of the intestine and is present in about 2% of the population. The diverticulum can be attached (25%) or unattached (75%) to the anterior abdominal wall by a remnant of the vitelline duct.[2] This abnormality generally occurs within 2 ft of the ileocecal valve and is always on the antimesenteric border of the intestine. Meckel's diverticulum is most commonly manifested as bleeding, usually resulting from acid-secreting ectopic gastric mucosa that causes ulceration of the nearby intestine. This abnormality also increases the risk for intussusception, with the diverticulum serving as the lead point. If the yolk sac side of the vitelline duct does not obliterate, an umbilical sinus results. Occasionally, a fibrous band with or without a cystic component (omphalomesenteric cyst) remains and can serve as an attachment point around which the bowel can rotate and lead to volvulus.

Omphalocele and Ventral Hernias

Failure of the intestine to return to the abdominal cavity can result in abdominal wall defects and omphalocele or gastroschisis. Omphalocele occurs when the intestines herniate through the anterior abdominal wall with only a peritoneal covering (Fig. 67–8). Most cases occur in association with other abnormalities, including those of the cardiac, neurologic, skeletal, or genitourinary system.[11] Gastroschisis occurs when an entire portion of the anterior abdominal wall is absent and abdominal viscera herniate without a peritoneal covering. Associated defects are much less common than with

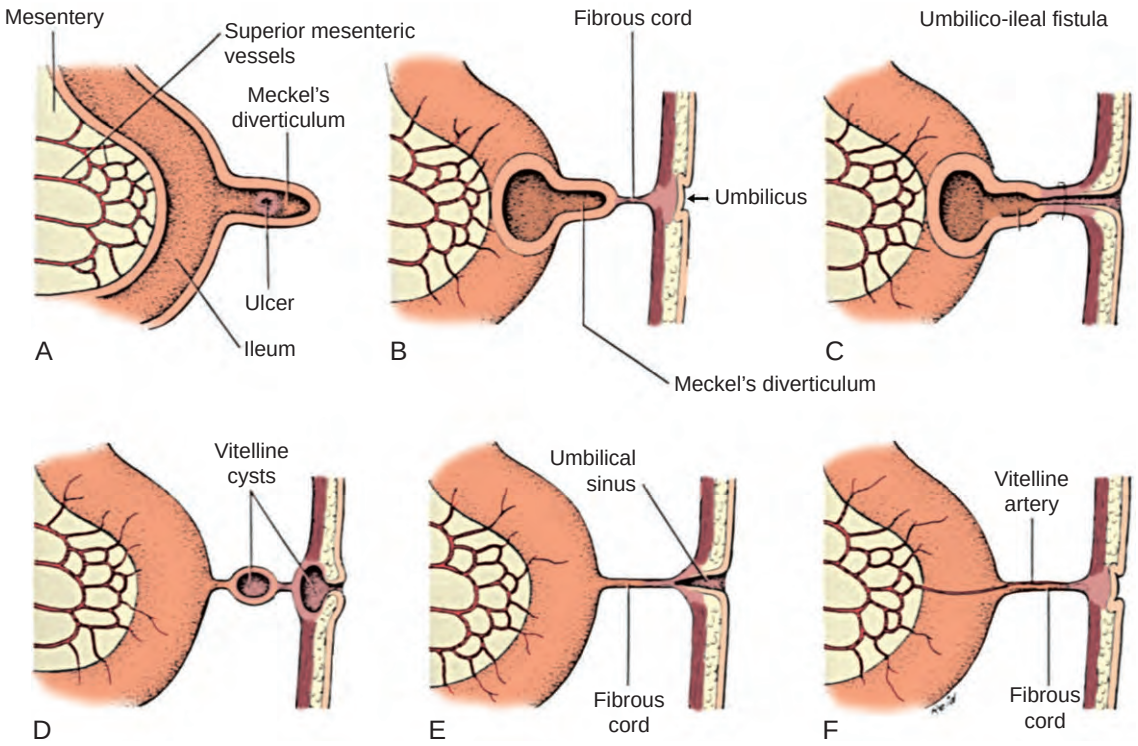

Figure 67–7. Meckel's diverticulum and other remnants of the yolk stalk. **A,** Section of the ileum and Meckel's diverticulum with an ulcer. **B,** Meckel's diverticulum connected to the umbilicus by a fibrous cord. **C,** Umbilicoileal fistula resulting from persistence of the entire intra-abdominal portion of the yolk stalk. **D,** Vitelline cysts at the umbilicus and in a fibrous remnant of the yolk stalk. **E,** Umbilical sinus resulting from persistence of the yolk stalk near the umbilicus. The sinus is not always connected to the ileum by a fibrous cord as illustrated. **F,** The yolk stalk has persisted as a fibrous cord connecting the ileum with the umbilicus. A persistent vitelline artery extends along the fibrous cord to the umbilicus. (From Moore K: The Developing Human: Clinically Oriented Embryology. Philadelphia, WB Saunders, 1982, p 245.)

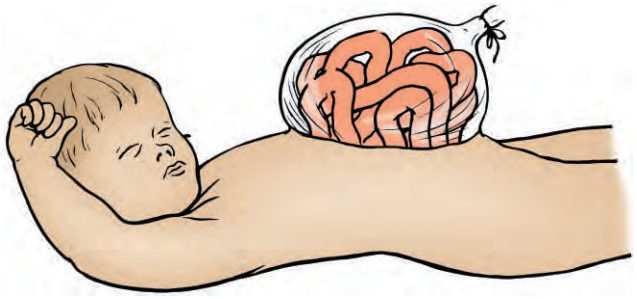

Figure 67–8. Exomphalos (omphalocele). The intestines fail to return to the abdomen in the first stage of intestinal rotation and fixation. (From Gray SW, Skandalakis JE: Embryology for Surgeons: Embryological Basis for Treatment of Congenital Defects. Philadelphia, WB Saunders, 1972, p 136.)

omphalocele and include intestinal abnormalities such as stenosis and atresia.[11]

Rotational Abnormalities

Midgut malrotation may occur in as many as 0.2% of live births.[12] These abnormalities are associated with a variety of other anomalies, including abdominal wall or diaphragmatic hernias, intestinal atresia, imperforate anus, and cardiac defects.[2] Down's syndrome is not as common with malrotation as with other anomalies, such as duodenal atresia.[2]

Rotational abnormalities of the small bowel can be divided into mixed rotation, nonrotation, and reversed rotation (Fig. 67–9).[2] In mixed rotation, partial failure of rotation may result in an abnormally high cecum or a duodenum that does not pass dorsal to the SMA. Such cases are often associated with adhesive bands (Ladd's bands) that course from the ligament of Treitz to the ileocecal junction. These bands may traverse the duodenum and can result in duodenal obstruction. This problem is associated with duodenal, pancreatic, and biliary abnormalities.

Nonrotation occurs when failure of rotation results in return of the bowel in a distal-to-proximal fashion; the small intestine is located on the right side of the abdomen with the cecum in the middle and the colon on the left. The mesentery is usually short, and fibrous bands are common. These bands may result in obstruction or volvulus.

Reversed rotation occurs when the initial counterclockwise rotation is only 90 degrees and subsequent rotation is 180 degrees clockwise. This results in a

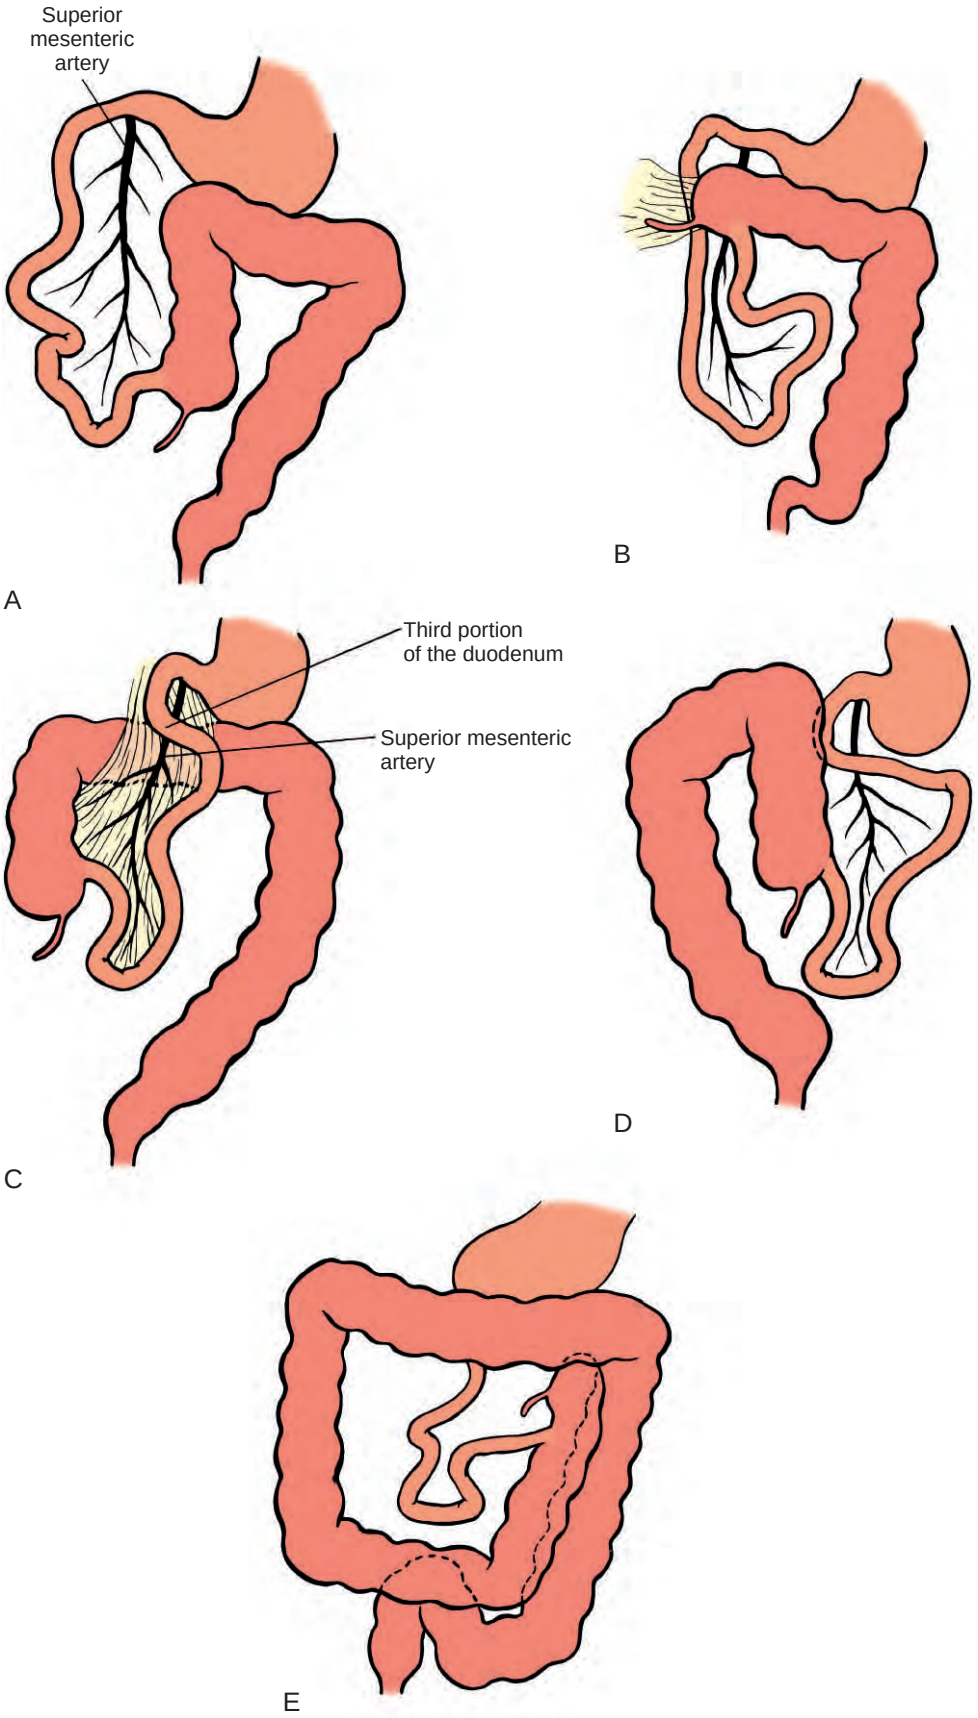

Figure 67–9. Different rotational abnormalities of the small intestine. **A,** *Nonrotation.* Return of the postarterial segment leaves the whole colon on the left and the small intestine on the right. **B,** *Mixed rotation.* The prearterial segment has failed to rotate, so the cecum is fixed to the abdominal wall and now lies anterior to the second portion of the duodenum. **C,** *Reversed rotation.* The third portion of the duodenum is anterior to the superior mesenteric artery, which in turn is anterior to the transverse mesocolon; the postarterial segment has entered the abdomen ahead of the prearterial segment. **D,** *Reversed rotation.* The colon occupies the right half of the abdomen, and the small intestine occupies the left half. **E,** *Hyperrotation.* The colon is longer than normal and the cecum has reached the splenic flexure. (From Gray SW, Skandalakis JE: Embryology for Surgeons: Embryological Basis for Treatment of Congenital Defects. Philadelphia, WB Saunders, 1972, p 178.)

transverse colon that passes dorsal to the duodenum and the SMA. Obstruction may result from various fibrous bands that may fix the colon.

Atresia and Stenosis

Atresias are divided into four types (Fig. 67–10).[2] Type I occurs when a membrane of mucosa and submucosa obstructs the bowel lumen. Type II is characterized by a fibrous band that replaces a portion of the intestine. In type III, the bowel is discontinuous, with proximal and distal blind ends. Type IV occurs when multiple areas of the intestine become fibrous bands. Duodenal atresia is probably due to failure of recanalization, whereas jejunal and ileal atresia is thought to occur as a result of intestinal ischemia. Patients with duodenal atresia have Down's syndrome in 30% of cases.[13] This abnormality is also associated with esophageal atresia, midgut malrotation, annular pancreas, imperforate anus, congenital anomalies of the heart, and intrauterine growth retardation.[13]

Internal Hernias

A variety of congenital hernias may result from abnormal rotation or fixation of the bowel on the abdominal wall. By far the most common type is a paraduodenal hernia, which results from abnormal fixation of the ascending or descending colon.

PHYSIOLOGY

The small intestine absorbs water, electrolytes, and nutrients. The process of digestion involves mechanical grinding of food, as well as chemical enzymatic digestion. For adequate absorption to occur, regulated fluid secretion and proper peristalsis must take place in concert to facilitate luminal surface hydration and mixing of food. The small intestine performs a number of other functions in addition to digestion. It is an important endocrine organ from which a host of gut-associated hormones are released. The epithelial barrier function of the small intestine protects the internal milieu against noxious luminal substances, such as bacteria and ingested toxins. The small intestine is also a major lymphoid organ where foreign antigens initially encounter the body's immune cells. The importance of the mucosal immune system is increasingly being appreciated as its involvement in the pathogenesis of intestinal disorders is elucidated.

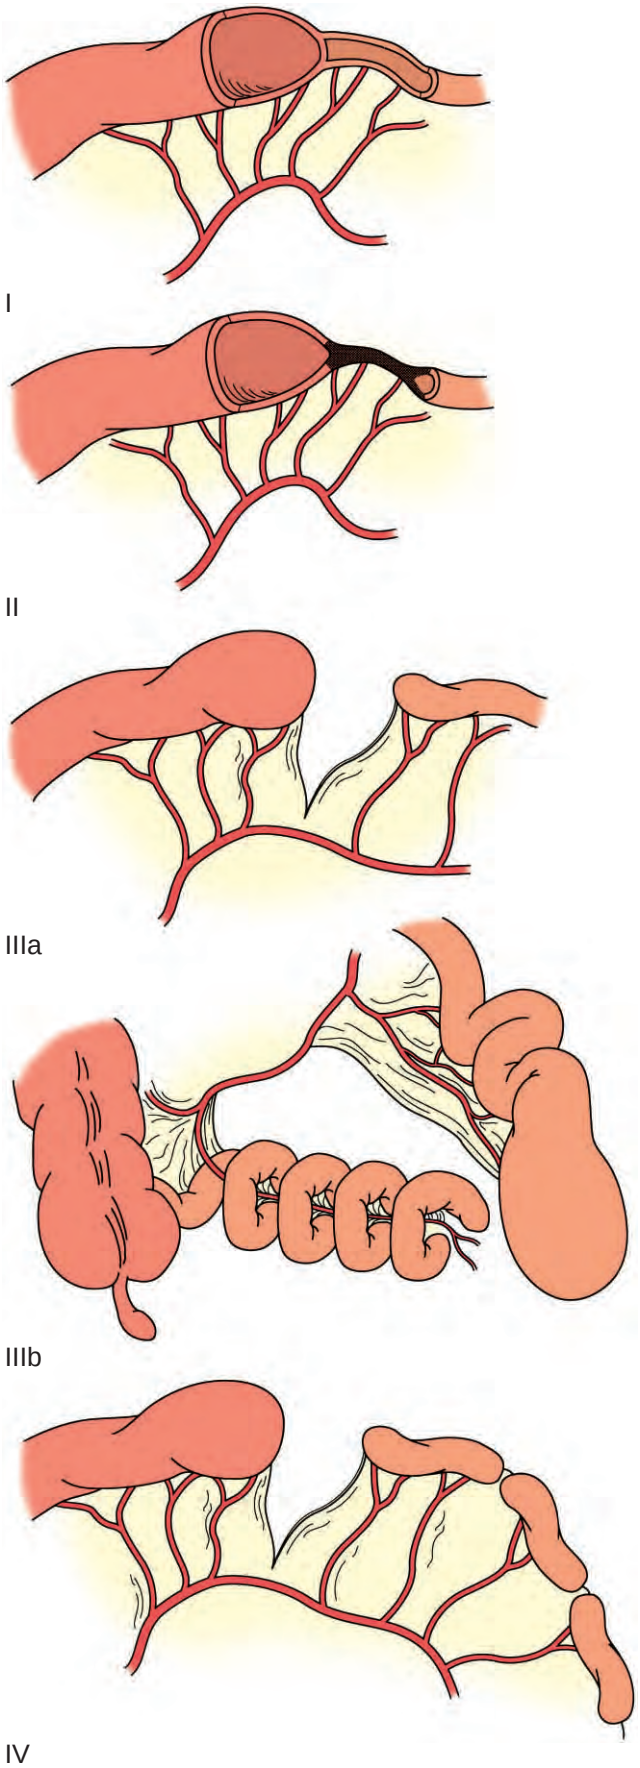

Figure 67–10. Different types of intestinal atresia. **Type I,** Continuity of mesentery and bowel with an incomplete web. **Type II,** The mesentery is intact, but the bowel has reduced to a fibrous cord. **Type IIIa,** The bowel and mesentery are focally disconnected. **Type IIIb,** The mesentery and bowel are completely separated, a so-called apple peel or Christmas tree deformity. **Type IV,** Multiple atresias (can be seen in combinations of type IIIa and IIIb). (From Welch KJ, Randolph JG, Ravitch MM, et al [eds]: Pediatric Surgery, 4th ed. Chicago, Year Book Medical Publishers, 1986.)

Layers of the Bowel Wall

The small bowel wall consists of the innermost *mucosa,* followed by the *submucosa, muscularis propria,* and the outermost *serosa.* The serosa is contiguous with the peritoneal lining and is absent in the posterior aspect of the duodenum because of its retroperitoneal location. The smooth muscle cells of the muscularis provide the motor activity necessary for intestinal peristalsis, and this smooth muscle consists of a thick inner circular layer and a thinner outer longitudinal layer. Gap junctions found on the plasma membrane of intestinal smooth muscle cells permit efficient propagation of peristaltic signal by allowing electrical coupling between adjacent cells. Ganglion cells and neural fibers form an extensive plexus throughout the layers of small intestine. The myenteric (Auerbach's) plexus is located between the circular and longitudinal layers of the muscularis.

The submucosa is a strong connective tissue layer that contains rich networks of vessels, nerves, and lymphoid tissue. The mucosa of the small intestine is structurally characterized by finger-like projections called *villi* and consists of three microscopic layers: the epithelium, the lamina propria, and the muscularis mucosae. The innermost epithelium is lined by a single layer of columnar epithelial cells of various types. The apical surface of these cells is covered by brush-border microvilli that project into the lumen of the intestine. The architectural arrangements of the villi and microvilli further contribute to the vast surface area of the small intestine. The lamina propria is located between the intestinal epithelium and the muscularis mucosae and consists of various connective tissue cell types and a rich microvascular network between artery and vein that enables efficient secretion and absorption of water, electrolytes, and nutrients. In addition, a central lymphatic vessel called a *lacteal* facilitates transport of fats and immunologic substances. The muscularis mucosae consists of a thin layer of smooth muscle cells between the mucosa and submucosa.

INTESTINAL EPITHELIUM AND ITS FUNCTIONS

Intestinal epithelial cells form a layer that separates the internal milieu from an external environment full of potentially harmful entities, such as luminal bacteria, toxins, digestive enzymes, xenobiotics, and ingested chemicals. The intestinal epithelium plays a central role in digestion and absorption of nutrients, as well as transport of water and electrolytes. Additionally, the epithelium is a major participant in intestinal immune function. These complexly regulated and multiple functions of the epithelium are accomplished by heterogeneous populations of specialized epithelial cells.

Architecture

The mucosal surface of the intestine is characterized by two structural features: villi and the crypts of Lieberkühn (Fig. 67–11). A single layer of simple columnar epithelial cells rests on a thin basement membrane overlying the lamina propria (Fig. 67–12). The lamina propria of the villus core contains numerous connective tissue cells, including fibroblasts, lymphocytes, plasma cells, eosinophils, smooth muscle cells, and nerve fibers. The function of the overlying epithelial cells is closely influenced by humoral factors released by cells in the lamina propria and by the matrix components of the basement membrane.

The intestinal epithelium is renewed continually, with an enterocyte life span of 3 to 7 days. Pluripotent stem cells located near the base of the crypt migrate along the so-called crypt-villus axis while differentiating into one of the four major cell types: absorptive enterocytes, enteroendocrine cells, goblet cells, and Paneth cells. Frequent mitoses are observed in the crypt zone as these cells differentiate into mature absorptive cells during their migration toward the villus tips. Villus enterocytes then undergo apoptosis and are subsequently shed from the epithelium. The spontaneous rate of apoptosis is lower in colonic epithelium than in the small intestine. The difference may reflect altered expression of the anti-apoptotic survival gene *bcl-2* and may be one of many factors that contribute to the lower incidence of cancer in the small intestine.[14]

Several distinct cell types are found in the crypts. Enterochromaffin cells, also known as *enteroendocrine cells,* do not maintain direct contact with the intestinal lumen. The contents of their secretory granules are released into blood in response to regulatory stimuli. Paneth cells reside at the base of the crypts and are the only cell type to undergo downward migration from the proliferative zone. They resemble pancreatic or parotid acinar cells morphologically and may contribute to mucosal immunity by secreting antimicrobial peptides, including α-defensins.[15] Goblet cells are seen in both the villi and crypts and secrete a protective mucous layer onto the mucosal surface. Villus columnar epithelial cells are primarily responsible for the absorption of fluid and electrolytes, whereas secretion occurs mostly in the crypts, although recent observations suggest that villi and crypts can both absorb and secrete to some extent.[16,17] Microscopically, the luminal border of the villus cells has a fuzzy appearance (brush border) because of the presence of microvilli in the apical plasma membrane. In addition to increasing absorptive surface area, microvilli directly enhance digestion through the presence of high concentrations of membrane-associated digestive enzymes.

Barrier Function

One of the most distinctive functions of epithelial cells is the ability to establish a barrier or a seal at the interface between the external and internal environments of the tissue. In the intestine, the barrier function of the epithelium protects the internal milieu from the permeation of potentially harmful luminal substances. This function is attributed to several morphologically distinct components of the intercellular junctional complex, a structure that circumferentially seals adjacent epithelial cells.[18,19]

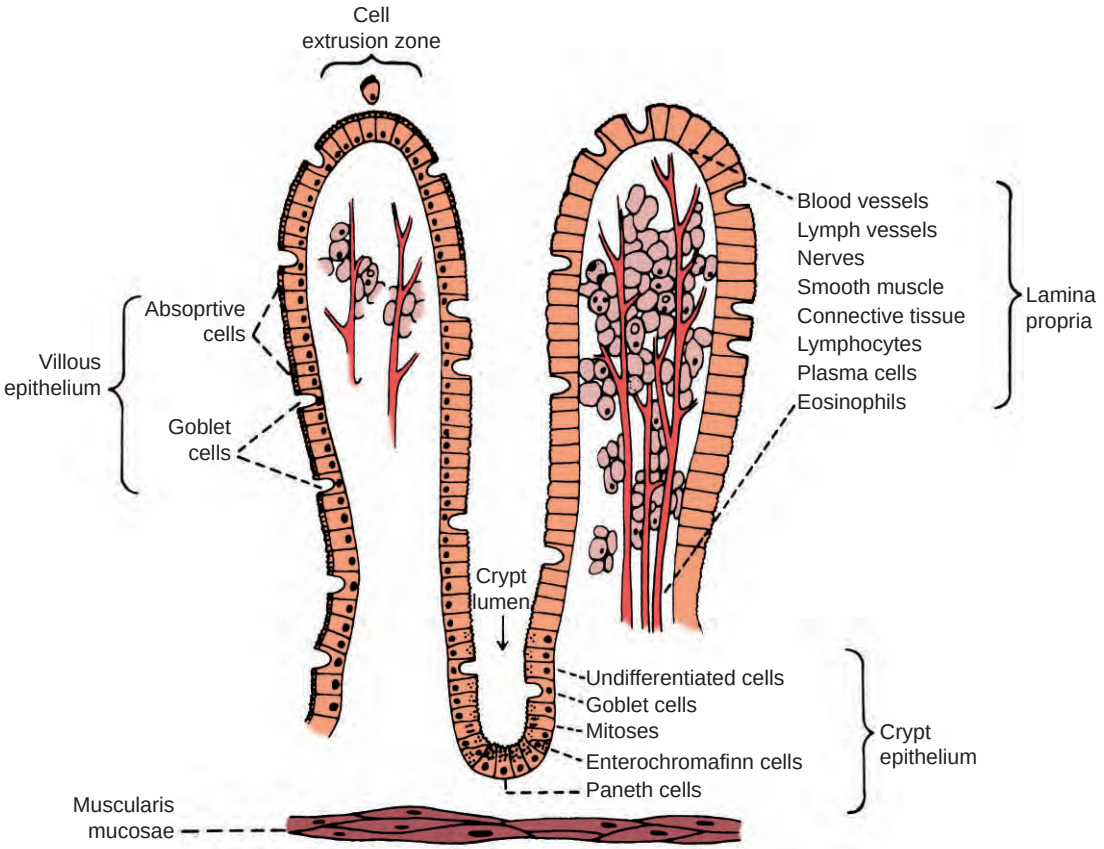

Figure 67–11. Schematic diagram of two sectioned villi and a crypt of the small intestinal mucosa. (From Trier JS, Winter HS: Anatomy, embryology, and developmental abnormalities of the small intestine and colon. In Sleisenger MH, Fordtran JS [eds]: Gastrointestinal Disease: Pathophysiology, Diagnosis, Management, 5th ed. Philadelphia, WB Saunders, 1993, p 796.)

The tight junction, or zonula occludens, forms a continuous contact at the apical-most aspect of the lateral membrane border between enterocytes (Fig. 67–13). The intercellular barrier is formed in part by the homotypic interactions of occludin between adjacent cells. *Occludin* is a transmembrane protein whose cytoplasmic tail is bound to a complex of cytoplasmic plaque proteins, including ZO-1 and ZO-2. A novel family of tight junction–associated transmembrane proteins known as *claudins* may account for the permselectivity characteristics of the intercellular junctional complex.[20] Adjacent and deep to the tight junction is the intermediate or adherens junction (zonula adherens), which also forms continuous contact by similar homotypic interaction of the transmembrane protein E-cadherin between adjacent cells. Intracellularly, E-cadherin associates directly with the cytoplasmic proteins α-, β- and γ-catenin and thereby with a contractile ring of actin and myosin that may regulate junctional permeability. Thick bands of perijunctional actin connect the adherens junction to the cytoplasmic plaque proteins of the tight junction. The tight junctions and adherens junctions are closely arranged spatially and behave as an integrated functional unit. Regulatory proteins of various tyrosine and serine-threonine kinase–based signaling pathways are localized in the vicinity of this apical junctional complex, thus reflecting the potential for regulatory control of junctional permeability by multiple cellular signaling mechanisms. Beneath the zonula occludens and zonula adherens are the desmosomes and gap junctions, which form focal contacts between neighboring cells.

The epithelial intercellular junctional complex does not present a static barrier. Solute permeability characteristics vary widely across different epithelia. The small intestine is classified as a "leaky" epithelium in comparison to the colon or urinary bladder. The influence of various humoral factors and other mediators on paracellular permeability is tissue and cell specific.[21,22] Tight junctions in absorptive cells become dilated by luminal glucose.[23-25] Physiologic regulation of junctional integrity can also occur in response to activation of Na^+-coupled transporters in the apical plasma membrane.[26] Intestinal barrier function is altered in many pathologic conditions. Bacterial toxins such as those elaborated by *Clostridium difficile* directly perturb intestinal barrier function by disrupting the interaction between junctions and the actin cytoskeleton.[27] ZO toxin from *Vibrio cholerae* has also been shown to disrupt actin and junctional integrity in a protein kinase C–dependent manner.[28] Translocation of bacteria and bacterial products as a result of increased intestinal paracellular permeability (associated with junctional disruption) in critically ill patients has

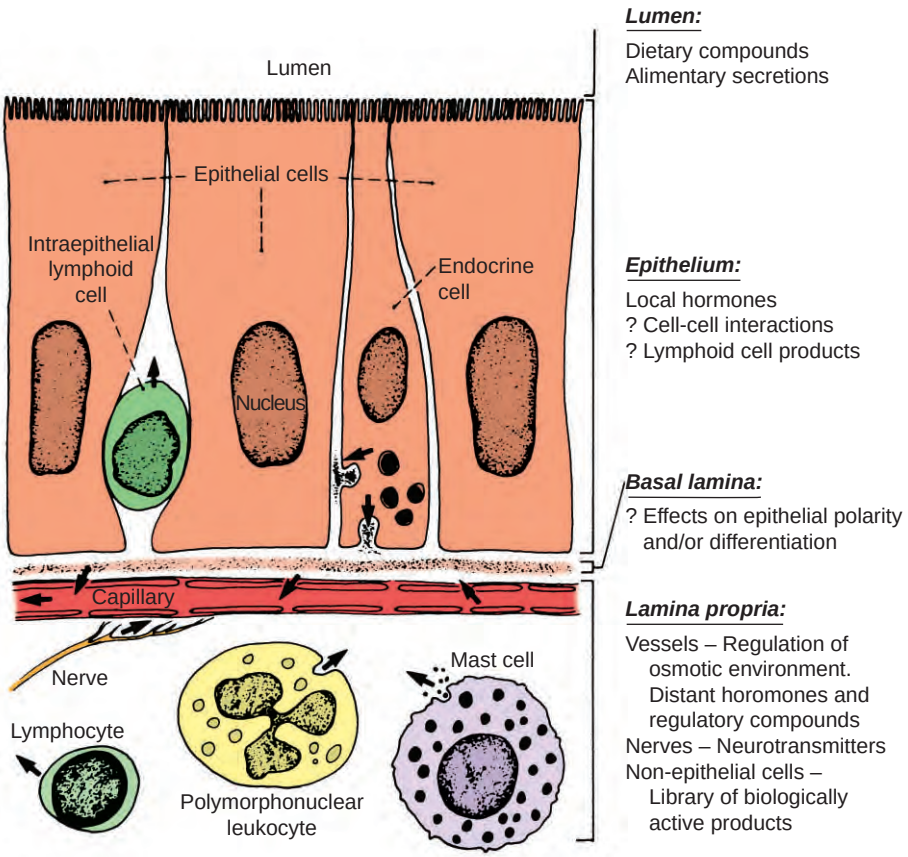

Figure 67–12. Schematic illustration of some factors in the microenvironment of intestinal epithelial cells that may influence their function. With the exception of extravascular polymorphonuclear leukocytes, all elements are normally present at this site. (From Madara JL: Functional morphology of epithelium of the small intestine. In Handbook of Physiology: The Gastrointestinal System. Bethesda, MD, American Physiological Society, 1991, p 85.)

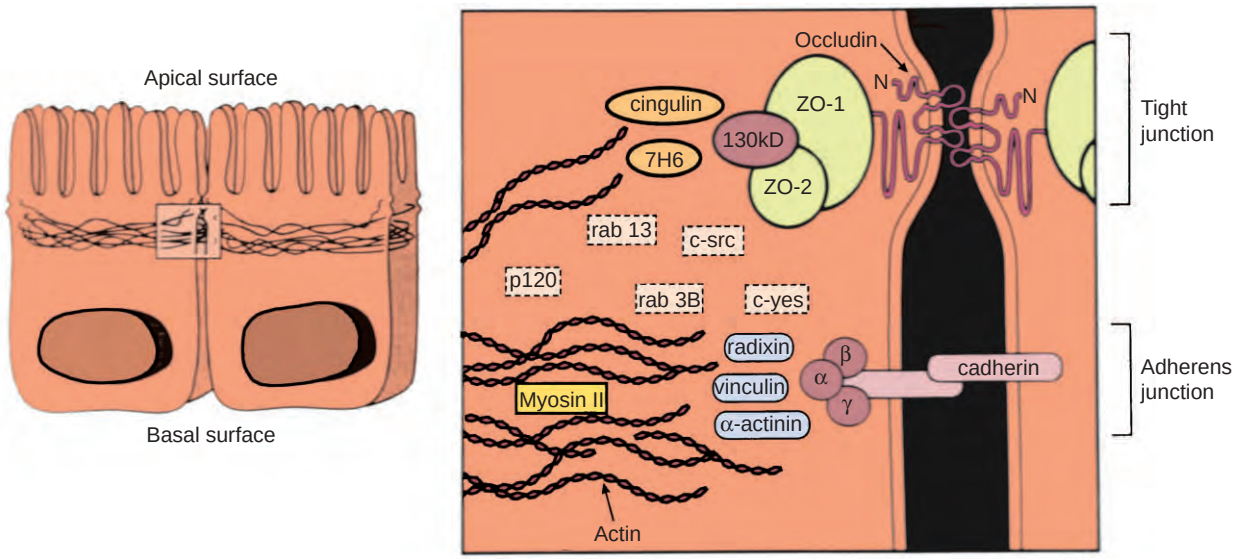

Figure 67–13. **Left,** Tight junctions are positioned as continuous contacts at the apical-lateral membrane borders between enterocytes. The *boxed region* is enlarged at the right. **Right,** Hypothetical model of protein interactions at the tight junction and adherens junction of two simple columnar epithelial cells. The intercellular barrier at the tight junction is formed by homotypic contacts of the transmembrane protein occludin, which is bound on the cytoplasmic surface directly to ZO-1. The ZO-1/ZO-2 heterodimer binds an uncharacterized 130-kD protein. Binding interactions of cingulin and the transmembrane protein cadherin are shown; they associate directly with the cytoplasmic proteins α-, β-, and γ-catenin. A thick band of perijunctional actin is positioned under the adherens junction with connections to tight junction plaques. been postulated to underlie the development of a sepsis-like state in multiorgan failure. However, direct evidence in support of this hypothesis has been difficult to establish. Various cytokines have been shown to alter junctional permeability, including interferon-γ and tumor necrosis factor-α.[29,30]

Digestion and Absorption

The vast total surface area of the small intestine enables it to absorb large quantities of water, electrolytes, and nutrients. The small intestine receives 8 to 10 L of fluid daily, including 1 to 1.5 L of ingested fluid. The remainder consists of salivary, gastric, pancreaticobiliary, and small intestinal secretions. Most of this fluid load is absorbed by the small intestine before reaching the ileocecal valve. Absorption of specific luminal components is accomplished by complex mechanisms that consist, to varying degrees, of intraluminal processing, epithelial uptake, and transport into the portal or lymphatic circulation. These processes display distinct patterns of expression along the longitudinal axis of the gut.

Water

The absorptive capability of the small intestine is estimated to be 12 L/day. Water movement across the epithelial layer is driven by the active transport of Na^+ and Cl^- and by the absorption of small molecules such as glucose and amino acids. The principal energy for many of these transport processes derives from the Na^+ gradient generated by the action of a basolateral Na^+,K^+-ATPase pump. The low intracellular Na^+ concentration maintained by this pump allows uptake of Na^+ and other solutes through coupled ion exchangers (Na^+/H^+ and Cl^-/HCO_3^-) and Na^+-coupled nutrient transporters. The precise route of water movement across an epithelium (transcellular, paracellular, or both) is controversial. The paracellular route (across the intercellular junctional complex) was previously thought to be the dominant pathway. However, this concept has been questioned on the basis of a number of recent observations, including attempts to directly measure water flow through junctions.[31] It is now recognized that water movement across plasma membranes can be greatly facilitated by members of a specialized family of proteins known as aquaporins (Table 67–1), which function as water channels.[32]

Another possible mechanism of bulk water transport has been proposed on the basis of observations that water may move in substantial quantities through the solute pocket of Na^+-coupled transporters. For example, water movement through the Na^+-glucose cotransporter SGLT1 appears to occur with a fixed stoichiometry of 2 Na^+, 1 glucose, and 210 H_2O in human SGLT1.[45] The physiologic relevance and relative contributions of these nonclassic routes of water transport in the intestine are not yet clear (see Table 67–1).

Sodium

Sodium absorption is driven by active transcellular uptake. Passive transport through the paracellular pathway also contributes to overall Na^+ absorption to a varying degree along the length of the gastrointestinal tract. A sizable, if not the major fraction of Na^+ and water

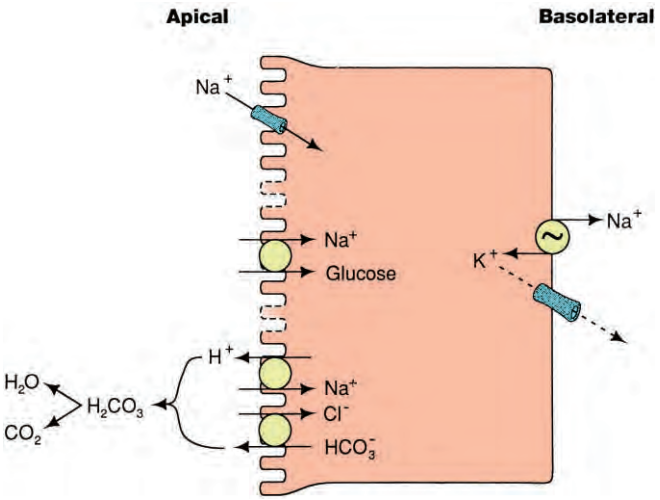

Figure 67–14. Apical sodium transporters. Luminal sodium enters the absorptive epithelial cell down an electrochemical gradient. Mechanisms for this transport include an ion-specific channel sensitive to amiloride, a carrier that couples the movement of sodium and nutrients (i.e., glucose), or a carrier that allows electroneutral entry of sodium in exchange for intracellular hydrogen (antiport). The common exit pathway across the basolateral membrane is the sodium pump. (From Sellin JH: Intestinal electrolyte absorption and secretion. In Sleisenger MH, Fordtran JS [eds]: Gastrointestinal Disease: Pathophysiology, Diagnosis, Management, 5th ed. Philadelphia, WB Saunders, 1993, p 960.)

absorption in the proximal part of the small intestine occurs paracellularly across the relatively leaky and nonselective intercellular junctions. The junctions become "tighter" and more cation selective distally in the ileum and colon, which enables active transport mechanisms to absorb Na^+ against a large osmotic gradient.

The engine driving active transcellular Na^+ absorption is the Na^+,K^+-ATPase pump, which generates electric and chemical gradients by extruding Na^+ in exchange for K^+ in a 3:2 stoichiometry across the basolateral cell membrane (Fig. 67–14). This energy-dependent pump action establishes a transmembrane potential difference with the cell interior of about −35 mV and maintains a low intracellular Na^+ concentration and a high intracellular K^+ concentration. Na^+ and Cl^- absorption across the apical membrane from the intestinal lumen involves three different mechanisms.

The apical Na^+/H^+ exchangers (NHEs) are members of the mammalian Na^+/H^+ exchanger gene family.[42,43] Among these exchangers, NHE2 and NHE3 are present in the apical membrane of human small intestinal epithelia, more specifically, the ileum.[44] NHE3 appears to be the major functional brush-border isoform in mammalian intestine, whereas the role of NHE2 is less clear (see Table 67–1).

Carbohydrates

Carbohydrates provide a major portion of adult dietary energy requirements. Human intestine is incapable of digesting and processing certain complex carbohydrates, such as cellulose-containing β-linked glucose molecules. Unlike the α bond found in starch, the β bond 1-4 is resistant to the digestive activity of amylase, although cellulose can be converted to absorbable fatty acids to some extent by colonic bacteria. Dietary fiber from "unavailable carbohydrates" also comes from pectins, gums, alginates, and lignins and helps reduce constipation by retaining water and increasing fecal bulk. Major dietary digestible carbohydrates include, in order of abundance, starch, sucrose, and lactose. Starch consists of amylose and the more abundant amylopectin. Sucrose is a disaccharide of glucose and fructose and is commonly found in fruit and sugar cane. The major source of lactose, a disaccharide consisting of glucose and galactose, is milk products.

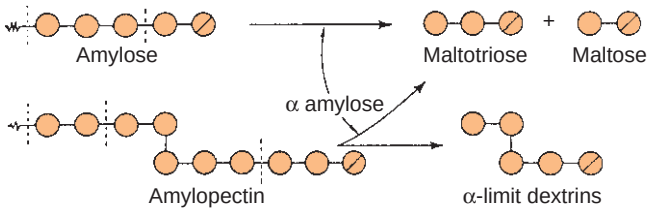

Figure 67–15. Action of α-amylase on amylose and amylopectin molecules. Because the a 1-6 link in the latter is resistant to amylase, the products include α-limit dextrin. (From Gray GM: Carbohydrate absorption and malabsorption. In Johnson LR [ed]: Physiology of the Gastrointestinal Tract. New York, Raven Press, 1981, p 1064.)

Digestion of carbohydrates begins in the mouth, where salivary amylase is active. Ingested starch is broken down into smaller oligosaccharides by the action of amylase. The resulting digestive products therefore include maltose, maltotriose, short oligosaccharides, and α-dextrins, as well as short-branched oligosaccharides from amylopectin (Fig. 67–15). Because salivary amylase is promptly inactivated at low gastric pH, pancreatic amylase in the duodenum is thought to be the major enzyme for starch digestion. The resultant short-chain oligosaccharides from amylase digestion, along with ingested sucrose and lactose, are further digested into basic monosaccharides in the small intestine before absorption into enterocytes. The brush-border membrane of villus enterocytes contains three hydrolase activities: lactase, sucrase, and isomaltase. The final products of carbohydrate digestion consist primarily of three major diet-derived hexoses: glucose, galactose, and fructose.

Absorption of these major monosaccharides into enterocytes can occur by several different transport mechanisms. Glucose transporters are categorized into two broad categories: Na^+ dependent (SGLT) and Na^+ independent (GLUT, Table 67–2) (Fig. 67–16).[71]

Proteins

Although ingested dietary proteins constitute the main source of amino acids, a significant amount of the

Table 67–2 Carbohydrates, Proteins, and Lipids

Nutrient	Receptor	Comment	References
Carbohydrates			
		The α bond (found in starch) is disrupted by amylase The β bond (found in cellulose) is resistant to human digestive activity and contributes to dietary fiber	
Glucose	SGLT (Na^+ dependent)	SGLT1 actively absorbs glucose and galactose against a concentration gradient	
	GLUT (Na^+ independent)	GLUT2 is the major transporter for intestinal absorption (moves in the direction of the glucose concentration) GLUT5 absorbs fructose (fructose is also absorbed paracellularly through glucose-activated solution drag)	46-48
Proteins			
Single amino acids (neutral, acidic and basic)	Na^+-dependent active transport		49
Oligopeptides	Pep T-1	Transports dipeptides and tripeptides through H^+-coupled active transport (very sensitive to luminal and intracellular pH; absorbed peptides are hydrolyzed by cytoplasmic peptidases)	50-62
Lipids			
Short- and medium-chain fatty acids		Diffusion into the cell	63, 64
Long-chain fatty acids	Fatty acid transport proteins (FATPs)	FATP4: apical membrane of mature enterocytes	65-67
	Fatty acid binding proteins (FABPs)	Promote the intracellular transport of fatty acids by decreasing the amount of fatty acids that my otherwise bind to immobile membranes	68-70

protein content in the intestinal lumen is derived from endogenous sources such as salivary, gastric, and pancreaticobiliary secretions, as well as desquamated epithelial cells. Digestion of proteins starts in the stomach by the action of pepsins, which are specialized proteolytic enzymes. Their precursor pepsinogens, released from chief cells, are converted into active enzyme pepsins with the truncation of a small peptide by low gastric pH.[72] When in the duodenum, pepsins are irreversibly inactivated by the alkaline pH. Further digestion of luminal proteins is facilitated by the action of pancreatic proteases in the small intestine. Unlike amylase and lipase, which are secreted in their active forms, all pancreatic proteases are released as proenzymes that require proteolytic digestion for activation. Initiation of the activation cascade requires conversion of trypsinogen to trypsin by

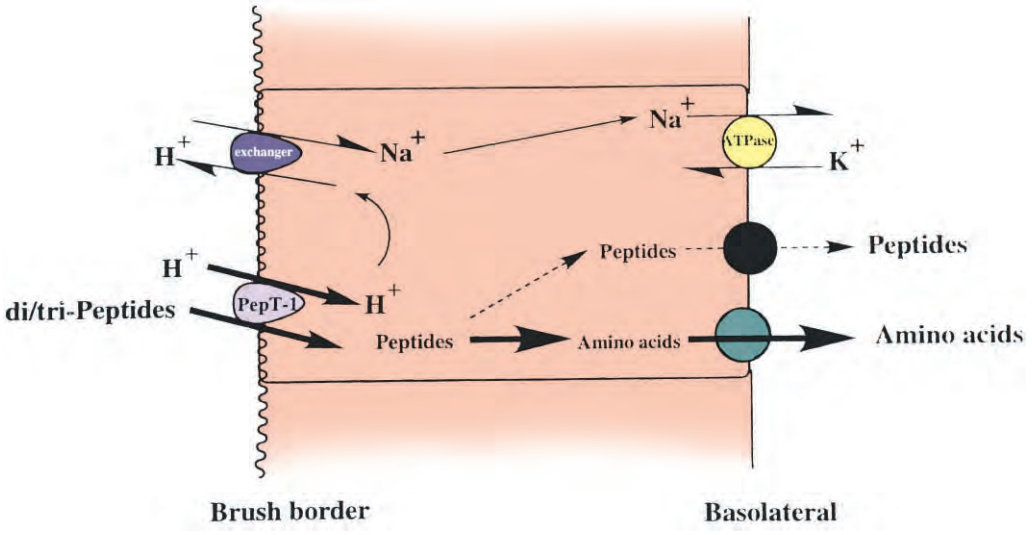

Figure 67–17. Cellular processes that are involved for optimal function of the intestinal oligopeptide transporter (Pep T-1). (From Adibi SA: The oligopeptide transporter [PepT-1] in human intestine: Biology and function. Gastroenterology 113:336, 1997.)

brush-border enterokinase (enteropeptidase), which involves removal of a six–amino acid peptide from the proenzyme. Trypsin in turn activates other proteolytic enzyme precursors. Activated proteases are classified into two groups according to their relative site of action: endopeptidases and exopeptidases. Endopeptidases such as trypsin, chymotrypsin, and elastases display digestive activity against peptide bonds adjacent to specific amino acids within a polypeptide chain. Exopeptidases include carboxypeptidase A and B and release a single amino acid from the carboxyl terminal end. The digestive activities of these proteases in the small intestine result in the release of luminal amino nitrogen in the form of 30% single amino acids and 70% oligopeptides.[73]

Transport of luminal amino nitrogen involves the uptake of both single amino acids and oligopeptides. Multiple transport mechanisms exist for the 20 single amino acids, including carrier-mediated active transport, facilitated diffusion, and simple diffusion.[74] Separate Na^+-dependent active transport processes have been characterized for neutral, acidic, and basic amino acids. Since cloning of the first γ-aminobutyric acid and cationic amino acid transporters, the cDNA of more than 20 mammalian amino acid transporters has been isolated.[49] Facilitated diffusion may play a role, though a minor one, in the absorption of charged amino acids. Exit of absorbed intracellular amino acids through the basolateral membrane involves similar transport mechanisms.

The significance of the transport of oligopeptides in protein absorption has been demonstrated in several kinetic studies when it was shown to be more efficient than the absorption of single amino acids.[50-53] This oligopeptide transporter (Pep T-1) has recently been cloned as a 708–amino acid membrane protein[54] that transports only dipeptides and tripeptides through H^+-coupled active transport and thus is very sensitive to luminal and intracellular pH (Fig. 67–17, see Table 67–2).[55] In patients requiring enteral nutrition, Pep T-1 provides enhanced absorption of total protein in the form of dipeptides and tripeptides (1) through superior oligopeptide absorption over that of single amino acids, (2) by facilitating an alternative route of delivery of unstable glutamine and poorly soluble tyrosine, and (3) by decreasing the hypertonicity of elemental diets.[56] The clinical importance of Pep T-1 is further displayed by its ability to transport orally administered β-lactam antibiotics, whose structure resembles that of tripeptides.[57,58] Enterocytes consume about 10% of absorbed amino acids when glutamine appears to be a major source of energy.

Lipids and Cholesterol

Dietary fat, made up primarily of triglycerides, is an efficient source of energy that is derived from both animal and vegetable fat. A triglyceride consists of a glycerol backbone with three attached fatty acid chains of various length. Most dietary triglycerides consist of both saturated and unsaturated fatty acids of 16 and 18 carbons and include palmitic (C16:0), oleic (C18:1), stearic (C18:0), and linoleic (C18:2) fatty acids. About 10% of triglycerides consist of medium-chain (6 to 12 carbons) and short-chain (4 carbons) fatty acids. Phospholipids such as lecithin exist in smaller amounts.

Digestion of dietary fat begins in the stomach by acid hydrolysis and gastric lipase. Because of the insoluble nature of fat in water, however, digestion and absorption of lipids predominantly occur in the small intestine by emulsification. Optimal emulsion requires bile salts and phospholipids (either ingested or lecithin) and results in stable small emulsion droplets with a large surface area (Fig. 67–18). Triglycerides in this stable emulsion are then exposed to pancreatic lipase for hydrolysis in the duodenum. Binding of lipase to triglyceride, a prerequisite for hydrolysis, is inhibited by luminal bile salts. Colipase, secreted by the pancreas as an inactive proenzyme,

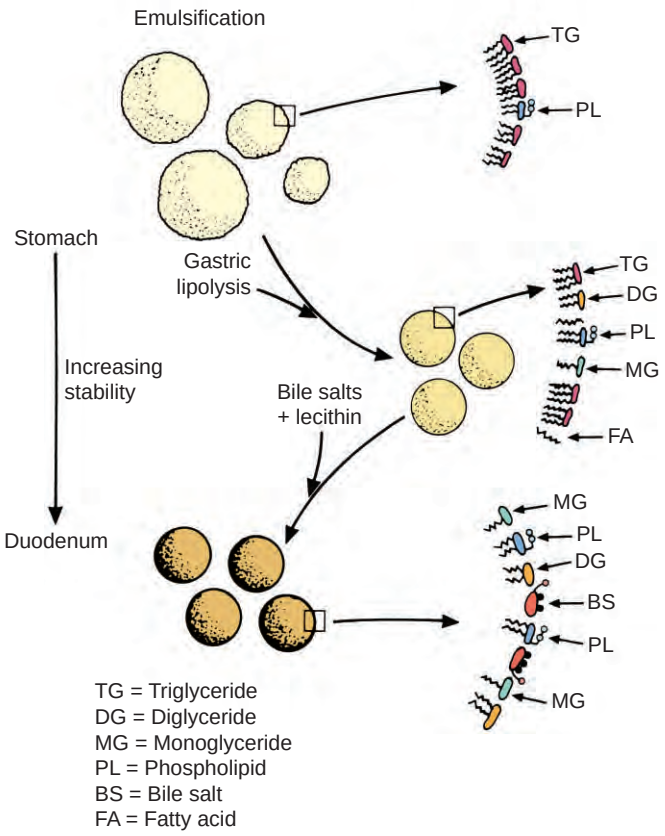

Figure 67–18. Diagram of steps leading to an increasingly stable emulsion. Gastric lipolysis yields fatty acids and diglyceride, which enhance emulsification, and this is further enhanced in the duodenum by bile salts and phospholipid. (From Tumberg LA, Riley SA: Digestion and absorption of nutrients and vitamins. In Sleisenger MH, Fordtran JS [eds]: Gastrointestinal Disease: Pathophysiology, Diagnosis, Management, 5th ed. Philadelphia, WB Saunders, 1993, p 984.)

is activated by luminal trypsin and facilitates exposure of the lipolytic site after binding to lipase in the presence of bile.[75] Sequential hydrolysis of the two outer ester bonds of the triglyceride molecule by the lipase-colipase complex yields two molecules of free fatty acid and a 2-monoglyceride molecule. Lipase helps present the products of hydrolysis to the mucosal absorptive surface by binding to the brush-border membrane. A specific lipase inhibitor, orlistat (tetrahydrolipstatin), is currently used clinically as a treatment of obesity. Ingested phospholipids are digested by pancreatic phospholipase A_2. Cholesterol is liberated from its esterified form by pancreatic cholesterol esterase.

For the products of lipolysis to be absorbed optimally, they must form micelles with bile salts because of their poor solubility in water. The amphipathic nature of bile salts allows solubilization of free fatty acids, monoglycerides, and cholesterol (but not triglyceride) within the lipophilic area of the micelles.[76] Micelles, shaped like disks, are much smaller (50 to 80 nm in diameter) than emulsion droplets and can form only when the bile salts are above a critical concentration. Alternatively, droplets containing the products of lipolysis may form smaller spherical lipid droplets from their surface in the absence of an adequate bile salt concentration.[77,78] This nonmicellar lipid transport to the mucosal surface, though a minor mechanism, may account for significant triglyceride absorption when bile salts are absent.

At the brush border the lipid contents of the micelle pass into the enterocytes, whereas bile salts remain within the intestinal lumen. Liberation of fatty acids and glycerides at the surface of the brush border may in part be explained by the presence of an "unstirred water layer."[63] This layer is thin (about 40 µm[64]) and is thought to maintain an acidic microenvironment by the action of surface NHE. A low luminal pH in this layer decreases the solubility of the fatty acids in micelles and thus may enhance their liberation. Additionally, fatty acids are uncharged when protonated at an acidic pH and may thereby diffuse across lipid membrane more easily. Once inside cytoplasm, the near-neutral pH may trap them in their ionized form. Uptake of short-chain and medium-chain fatty acids across the brush-border membrane occurs predominantly by simple diffusion. Long-chain fatty acids (LCFAs), however, are transported into enterocytes by a saturable and specific uptake mechanism. Recently, a family of homologous fatty acid transport proteins (FATPs, see Table 67–2) has been identified and cloned, and these proteins were demonstrated to transport LCFAs across the plasma membrane.[65,66] Overexpression of FATP4 in nonenterocytes can facilitate uptake of LCFAs with the same specificity as enterocytes, whereas reduction of FATP4 expression in primary enterocytes inhibits fatty acid uptake significantly,[67] thus making such reduction a potential target for novel antiobesity therapy.

Once within the cell, fatty acids are transferred to the endoplasmic reticulum for re-esterification back to triglyceride. Intracellular movement of free fatty acids is facilitated through codiffusion with fatty acid binding proteins (FABPs, see Table 67–2), a group of low-molecular-weight cytosolic proteins capable of binding hydrophobic molecules.[68] In the endoplasmic reticulum, resynthesis of triglyceride can occur by two processes. The more predominant monoglyceride pathway involves sequential esterification to diglyceride and triglyceride by acetylcoenzyme A derived from activated fatty acids. The minor pathway involves acylation of α-glycerophosphate by glycerol and fatty acids and may become important during fasting.

After they are synthesized, triglycerides, along with cholesterol and phospholipids, coalesce with apoprotein to form a large lipoprotein complex called a *chylomicron.* During fasting, instead of chylomicrons, very-low-density lipoproteins with different apoproteins and fatty acids are mainly formed. Packaged vesicles containing chylomicrons from the Golgi apparatus then migrate to the basolateral membrane to be released by exocytosis (Fig. 67–19). Chylomicrons subsequently enter the lacteals and pass through the lymphatics into the system's venous circulation. Medium-chain fatty acids and polyunsaturated fatty acids are capable of passing directly into the portal circulation.

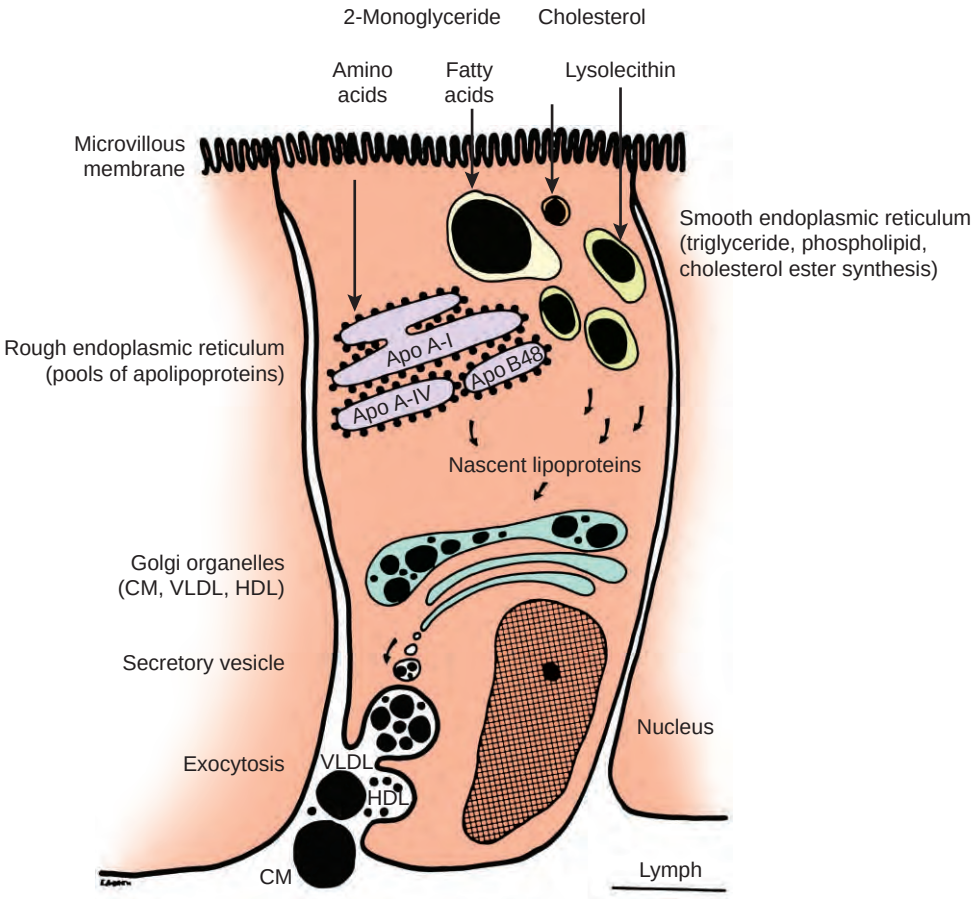

Figure 67–19. Enterocyte lipoprotein assembly. Lipid and amino acid products of digestion are absorbed from the intestinal lumen across the microvillous membrane, where they serve as substrates for the resynthesis of protein and lipid in the rough and smooth endoplasmic reticulum. Apolipoproteins are mobilized from the intracellular pool of protein to form nascent lipoproteins. Lipoproteins are progressively modified within Golgi organelles and secretory vesicles and then secreted into the intracellular space. Apo A-I, A-IV, and B_{48}, apolipoproteins A-I, A-IV, and B_{48}, respectively; CM, chylomicron; HDL, high-density lipoprotein; VLDL, very-low-density lipoprotein. (From Davidson NO, Magun AM, Glickman RM: Enterocyte lipid absorption and secretion. In Handbook of Physiology: The Gastrointestinal System. Bethesda, MD, American Physiological Society, 1991, p 516.)

Intestinal cholesterol absorption is dependent on luminal bile salts and follows steps similar to those for triglyceride absorption. Free cholesterol, derived from the hydrolysis of esterified cholesterol by pancreatic cholesterol esterase, is transported to the brush-border surface in micelles. After entering the cells by simple diffusion, cholesterol is re-esterified, mainly with oleic acid, and then incorporated into chylomicrons for subsequent lymphatic release. De novo cholesterol synthesis, particularly in the liver, increases when intestinal cholesterol absorption is reduced. Although cholesterol absorption is not significantly enhanced by increased intake of dietary cholesterol, certain dietary fats, such as saturated fats and short-chain fatty acids, may increase cholesterol absorption in the intestine.

Vitamins

Water-soluble vitamins were previously thought to be absorbed by simple passive diffusion; however, it is now clear that specific carrier-mediated mechanisms are involved. Additionally, some of these vitamins undergo hydrolysis before absorption because of attached conjugates or coenzymes.

Primates are incapable of synthesizing ascorbic acid (vitamin C) and thus require dietary supplementation.[75] In the small intestine, an active Na^+-dependent process transports vitamin C in the form of sodium ascorbate (Table 67–3).[80]

Folic (pteroylglutamic) acid is present in the diet in the form of polyglutamates and requires hydrolysis by a brush-border hydrolase (carboxypeptidase, see Table 67–3).[81] Ethanol inhibits the hydrolysis (but not uptake) of polyglutamates and may account for the folate deficiency seen in alcoholics.[82,83]

Vitamin B_{12} (cobalamin; see Table 67–3) is derived almost entirely from animal sources and has a multistep process for absorption. Vitamin B_{12} deficiency can therefore arise from multiple sources: loss of intrinsic factor (gastric resection), defective pancreatic proteolysis of cobalamin from R protein (pancreatic insufficiency or biliary obstruction), or loss of ileal receptors (distal ileal disease or resection).

Other water-soluble vitamins, such as thiamine, riboflavin, biotin, and pantothenic acid, also use specific Na^+-dependent active transport processes for their absorption.[74] After absorption into an enterocyte, thiamine exits through the basolateral membrane into the portal circulation. Ethanol decreases thiamine absorption by inhibiting this exit step, an effect that may account for thiamine deficiency in alcoholics.

Fat-soluble vitamins include vitamins A, D, E, and K, and they are primarily absorbed from the small intestine through passive diffusion, with absorption being dependent on their structure and hydrophobicity.[87] After they are absorbed, these vitamins enter the intestinal lymphatic system in chylomicrons and join the systemic venous circulation through the thoracic duct. Vitamin A

Table 67–3 Vitamins and Minerals

Nutrient	Receptor	Comment	References
Vitamins			
Ascorbic acid (vitamin C)		Na^+-dependent active absorption	79, 80
Folic acid (pteroylglutamic acid)		Hydrolysis by carboxypeptidase at the brush border (inhibited by ethanol)	81-83
		Hydrolysis is also inhibited in celiac sprue; subsequent uptake is carrier mediated and Na^+ dependent	
Cyanocobalamin (vitamin B_{12})	R protein Intrinsic factor	Bound to salivary binding protein (R protein) in the stomach until freed by hydrolysis in the duodenum Binds to intrinsic factor (secreted by the parietal cells of the stomach) to protect B_{12} from proteolytic digestion In the terminal ileum, specific brush-border receptors bind the cobalamin–intrinsic factor complex	83a, 83b
Thiamine	Na^+-dependent active transport	Exits through the basolateral membrane into the portal circulation (inhibited by ethanol)	74
Riboflavin	Na^+-dependent active transport		74
Biotin	Na^+-dependent active transport		74
Pantothenic acid	Na^+-dependent active transport		74
Vitamin A	Passive diffusion		87
Vitamin D	Passive diffusion		
Vitamin E	Passive diffusion		
Vitamin K	Passive diffusion		
Minerals			
Calcium	Passive paracellular process (throughout the small intestine)	Enhanced by vitamin D and luminal-associated increases in junctional permeability	
	Active, transcellular process (duodenum)	Occurs down its electrochemical gradient Binds to calbindin and transported out of the cell across the basolateral membrane by calcium-dependent ATPase Calbindin is up-regulated in villus enterocytes by vitamin D	84, 85
Magnesium	Passive diffusion, carrier-mediated process	Occurs primarily in the ileum	86
Iron	Non–transferrin receptor–mediated process	Modulated by the degree of transferrin receptor saturation	88, 89
Iron	Divalent cation transporter (DCT-1)		
Bile salts	Apical Na^+-dependent carrier transporter (ASBT)	Located on the luminal surface of ileal epithelial cells (ileal specific)	90, 91
	Liver Na taurocholate cotransporting polypeptide (NTCP)	Expressed on the basolateral membrane of hepatocytes	92

(retinol) is derived from dietary carotenoids, of which β-carotene is a principal form. β-Carotene undergoes hydrolysis by a brush-border oxygenase into two retinol molecules. Absorbed vitamin A is then released into the lymphatics in the form of retinyl palmitate. Two physiologically significant vitamin D sterols, vitamin D_2 (ergocalciferol) and vitamin D_3 (cholecalciferol), are converted from their precursor sterols by ultraviolet irradiation in skin. Vitamin E consists of several related tocopherols, of which the α-isomer is the most potent species. Dietary vitamin D and vitamin E are absorbed in the small intestine by simple diffusion and pass into the lymphatics largely unchanged. Vitamin K consists of two forms: plant-derived K_1 (phytomenadione) and colonic

bacteria-produced K_2 (prenyl menaquinones). Absorption of vitamin K_1 occurs through a carrier-mediated process in the small intestine and is facilitated by luminal bile salts[93]; vitamin K_2 is passively absorbed in the ileum and colon.[94]

Minerals

Several essential divalent cations, such as calcium, magnesium, phosphorus, and iron, must be absorbed by the intestine; only trace amounts of other minerals are needed, such as zinc, copper, and selenium.

Intestinal absorption of calcium is mediated by two processes: an active, transcellular transport process occurring predominantly in the duodenum and passive, paracellular diffusion throughout the small intestine (see Table 67–3).[95] Magnesium, unlike calcium, is absorbed predominantly in the ileum, and its absorption involves both passive diffusion and a carrier-mediated process.[96]

Iron is an essential constituent of myoglobin and hemoglobin because of its flexible redox potential. Because excessive amounts of iron are toxic, sophisticated mechanisms exist for transport regulation and detoxification. Circulating iron in serum is tightly bound by transferrin, an 80-kD glycoprotein that can bind two molecules of ferric iron.[88] Because of the abundance of serum transferrin, full saturation of transferrin is seen only in pathologic conditions such as hereditary hemochromatosis and transfusion-related iron overload. Diferric transferrins bind to the transferrin receptor, a specific cell membrane protein ubiquitously present on cellular membranes. The receptor-ligand complex, along with bound iron, is then internalized by receptor-mediated endocytosis, a process regulated by post-transcriptional modulation of transferrin receptor mRNA expression.[89] The bulk of iron absorption from the intestine, however, appears to involve a non–transferrin receptor–mediated mechanism, although it is modulated through an unknown mechanism by the degree of transferrin receptor saturation.

Although mammalian divalent cation export systems have previously been characterized for zinc and copper,[97,98] only recently has a mammalian uptake system been identified. Divalent cation transporter 1 (DCT-1), an H^+-coupled divalent cation and metal ion transporter, has recently been characterized as the major iron transport protein in the intestine.[99-101] DCT-1 is a 561–amino acid transmembrane protein expressed highly in the proximal part of the duodenum and has a broad substrate specificity for many divalent metal ions, including Fe^{2+}, Zn^{2+}, Mn^{2+}, Co^{2+}, Cd^{2+}, Cu^{2+}, Ni^{2+}, and Pb^{2+}. In the intestine, dietary ferric (Fe^{3+}) iron is reduced to ferrous (Fe^{2+}) iron by ferrireductase or ascorbic acid and transported by DCT-1 into enterocytes of the villus tip.[102] Similar to regulation of transferrin receptor expression, iron levels appear to modulate the expression of DCT-1 mRNA.

The hemochromatosis *(HFE)* gene, which encodes a novel major histocompatibility complex class I–like protein, has also been cloned recently.[103] HFE protein interacts with transferrin receptor with high affinity at the plasma membrane and modulates the binding of diferric transferrin to the transferrin receptor.[103] HFE is prominently expressed in the crypt cells of the duodenum, where most iron absorption occurs. HFE protein in the duodenal crypts is thought to modulate the uptake of transferrin-bound iron, where these cells may act as sensors of the level of body iron stores (Fig. 67–20). In patients with a defect in the *HFE* gene, transferrin receptor–mediated iron uptake into crypt cells appears to be inappropriately modulated by HFE such that a false signal is sent that serum iron stores are low. Consequently, expression of DCT-1 and intestinal iron absorption are subsequently up-regulated, thereby leading to iron overload in these patients.

Bile Salts

Bile is synthesized from cholesterol in the liver as two primary bile salts: cholate and chenodeoxycholate. They are secreted into the small intestine conjugated with taurine or glycine. Bile salts in the intestinal lumen mix with ingested lipids and form micelles, thus facilitating their digestion. Reabsorption of bile acids from the lumen involves both passive and active reuptake, with active reabsorption in the ileum accounting for most of the total enterohepatic circulation. Absorbed bile salts return to the liver through the portal circulation and are resecreted into bile, thus completing the cycle of enterohepatic circulation. Active uptake of bile acids is mediated by an Na^+-dependent carrier transporter (apical Na^+-dependent bile acid transporter [ASBT]) located on the luminal surface of ileal epithelial cells.[90,91] A related, but distinct bile salt transporter (liver Na^+-taurocholate cotransporting polypeptide [NTCP]) is expressed on the basolateral membrane of hepatocytes.[92] Substrate (bile salt) specificity for ASBT is much narrower than that for NTCP, which suggests that in the lumen of the ileum, efficient recovery of bile acids accompanies elimination of non–bile acid metabolites and xenobiotics, whereas the multispecific transporter in the liver facilitates hepatic clearance of organic anion metabolites.[90] ASBT expression is ileal specific; this transporter is not induced in more proximal gut segments after resection.

Secretion

Intestinal fluid secretion is thought to derive primarily from cells lining the crypts and is dependent on the secondary active transcellular transport of Cl^-. This process facilitates the mixing of luminal nutrients for enhanced absorption and may be important in mucosal defense by diluting or "flushing" harmful toxins and organisms away from the epithelial surface. The driving force for epithelial secretion comes from Na^+,K^+-ATPase, which establishes a low intracellular Na^+ concentration (Fig. 67–21). Na^+ then enters the cell along this gradient coupled to the movement of K^+ and Cl^- through a basolateral Na^+-K^+-$2Cl^-$ cotransporter (NKCC1). Intracellular Cl^- is then extruded across the apical membrane through Cl^- channels, including the cystic fibrosis conductance regulator (CFTR). Na^+ and possibly water

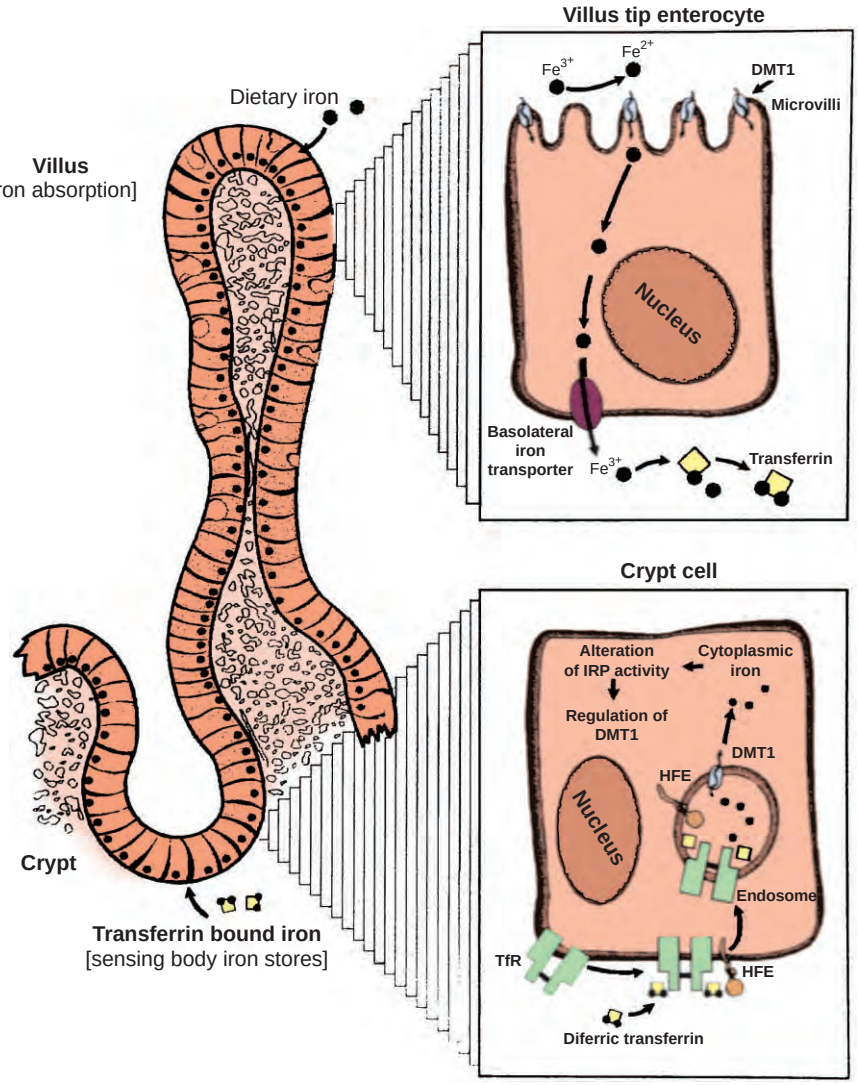

Figure 67–20. Hypothesis of the regulation of iron absorption by the hemochromatosis gene *(HFE).* An intestinal villus is shown with *insert* enlargements of an enterocyte on the villus tip (where iron is absorbed from the intestine) and a deep crypt cell (where the body iron stores are sensed by means of transferrin-mediated and HFE-modulated iron transport). Ferric iron is reduced in the intestine to ferrous iron and absorbed through the divalent metal transporter (DMT-1, also known as DCT-1) into the enterocyte on the villus tip. In the enterocyte, iron is oxidized to ferric iron and transported through an unidentified basolateral iron transporter into the circulation. In the deep crypt, HFE bound to the transferrin receptor (TfR) modulates the uptake of diferric transferrin. The level of cytoplasmic iron then acts through the binding of iron regulatory proteins (IRPs) to iron response elements (IREs) on the production of DMT-1 transporter mRNA. Mutations in *HFE* cause lack of cell surface expression of HFE, dysregulation of TfR-mediated iron uptake, and consequent alterations in DMT-1 production. (From Bacon BR, Powell LW, Adams PC, et al: Molecular medicine and hemochromatosis: At the crossroads. Gastroenterology 116:197, 1999.)

(see earlier) follow passively through the paracellular space into the lumen.

At least three major signal transduction pathways activate Cl^- secretion, including cyclic nucleotides (cyclic adenosine monophosphate [cAMP] and cyclic guanosine monophosphate [cGMP]), as well as intracellular calcium.[104] Vasoactive intestinal peptide (VIP), adenosine, prostaglandins, and certain bacterial enterotoxins elevate intracellular cyclic nucleotides, which leads to protein kinase A–dependent CFTR phosphorylation and subsequently to an increase in apical membrane permeability to Cl^-. Secretory responses depend on the extent of the increase in cAMP and the duration of the stimulus. Calcium-dependent agonists such as histamine and acetylcholine, on the other hand, activate Cl^- secretion primarily through the opening of Ca^{2+}-activated K^+ channels in the basolateral membrane. Ca^{2+}-mediated secretory responses, in contrast to that activated by cyclic nucleotides, are transient in duration despite the continued presence of agonist and sustained elevation of intracellular Ca^{2+}.[104-106] Cyclic nucleotides and Ca^{2+} regulatory pathways are synergistic for secretion.[107,108] Overall secretory capacity may be largely determined by the activity of basolateral NKCC1, which may be affected at the level of gene transcription by multiple proinflammatory and anti-inflammatory factors.[109]

INTESTINAL IMMUNE SYSTEM

The human intestinal tract is the single largest organ of the immune system. The immune apparatus in the intestine has a dual role of modulating both local and systemic immune responses. Locally, the lymphoid tissue in the intestine plays an important role in defense against various toxic and pathogenic agents from the intestinal lumen. Both the epithelial cells per se and the various lymphoid cells in the lamina propria participate in the delicate balancing of mucosal defense with potential overstimulation of the immune system by the considerable foreign antigen load presented to the intestine daily.

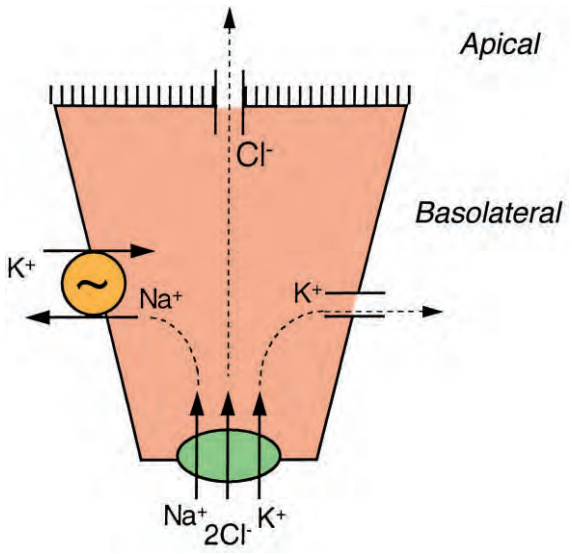

Figure 67–21. Chloride secretion. Na^+,K^+-ATPase generates the driving force for epithelial Cl^- secretion by establishing a low intracellular Na^+ concentration. The Cl^- entry step through the basolateral membrane Na^+-K^+-$2Cl^-$ (NKCC1) cotransporter involves the movement of sodium, potassium, and chloride in a 1:1:2 stoichiometry. Accumulated Cl^- above its electrochemical equilibrium exits the cell across the apical membrane through a Cl^- channel. Recycling of intracellular Na^+ and K^+ is facilitated by the sodium pump and a basolateral potassium channel, respectively.

Secretory Immunoglobulin A and Epithelial Immune Function

Immunoglobulins are synthesized and secreted by B lymphocytes. In the gut, immunoglobulin A (IgA) and IgM play a protective role of neutralizing luminal antigens. IgG antibodies in intestinal secretions are derived mainly from the serum, fix complement, and play an important role in inflammatory reactions and tissue injury. IgE appears to mediate the inflammatory response to antigens that penetrate the intestinal mucosa, as seen in bacterial invasion of the intestinal tract. The most abundant immunoglobulin secreted in the intestine is IgA, with IgM being secreted to a lesser extent. Their secretion into the lumen involves binding to the polymeric immunoglobulin receptor present on the basolateral membrane of the epithelial cells (Fig. 67–22). IgA interaction with microbial antigens prevents them from penetrating the epithelial layer. Although not lymphoid cells per se, intestinal epithelial cells (IECs) clearly participate to some degree in the immune function of the gut. These cells express major histocompatibility class I and II molecules on their surface, possess antigen-presenting activity for T cells,[110] produce cytokines to regulate the proliferation of mononuclear cells in the lamina propria,[111] and express functional receptors for several T-cell–derived cytokines and chemokines.[112] Thus, the epithelial cell layer may transmit important immune regulatory information to the underlying lymphocytes.

M Cells and Gut-Associated Lymphoid Tissue

The major route of passage of luminal antigens to resident lymphoid follicles occurs by means of specialized cells overlying Peyer's patches called *M cells*.[113] These cells rapidly internalize foreign antigens by the endosomal pathway through specialized apical membrane invaginations (Fig. 67–23). Lymphocytes and macrophages in these compartments then process the antigens from the delivered luminal substance. Antigen can also be taken up directly across the enterocytes by either transcellular or paracellular pathways. When the information from these antigen-processing cells reaches the underlying follicle, antigen-specific B-cell proliferation and subsequent IgA production occur. Antigen-specific B cells migrate from Peyer's patches to regional lymph nodes into the systemic circulation, from which they migrate back to the intestine to populate the mucosa diffusely within the lamina propria (Fig. 67–24). In Peyer's patches, B cells are segregated in the germinal centers from the T cells occupying the interfollicular area. Intraepithelial lymphocytes (IELs), however, are predominantly T lymphocytes. They are specialized T cells found in the paracellular space between absorptive enterocytes and are thought to mediate crosstalk between epithelial cells and the underlying immune cells of the lamina propria. Lamina propria lymphoid tissue contains numerous immune cell types, including plasma cells, mast cells, lymphocytes, and macrophages. These cells produce cytokines, chemokines, and immunoglobulins. In addition to these local actions, IgA-producing lymphocytes of Peyer's patches migrate to regional lymph nodes and into the systemic circulation.

Regulation of Gut Immune Activity

A remarkable feature of the mucosal immune system is its overall "hypoactive" or immunosuppressed tone. Despite the enormous antigenic load that passes through the gastrointestinal tract each day, spontaneous inflammatory responses are rare except in pathologic conditions such as inflammatory bowel diseases. This is partly explained by the production of secretory IgA, which unlike other immunoglobulins, does not participate in the proinflammatory response, fix complement, or serve as opsonizing antibody. Additionally, IELs appear to contribute to the overall tone of immunosuppression. Most IELs express the γδ-receptor instead of the αβ-receptor expressed in the more abundant T cells found in most peripheral lymphoid sites. Activation of the immune system by IECs that are capable of presenting antigen and triggering the immune response is also attenuated. The level of uptake and processing of antigens by IECs is quite low[114] because of the absence or minimal expression of appropriate processing enzymes (cathepsins) in the endosomal compartments. Even when the enzymes are present within normal epithelial cells, they are there in reduced amounts.[115] Thus, these cells may have only a limited ability to process intact protein antigens and elicit potent immune responses.

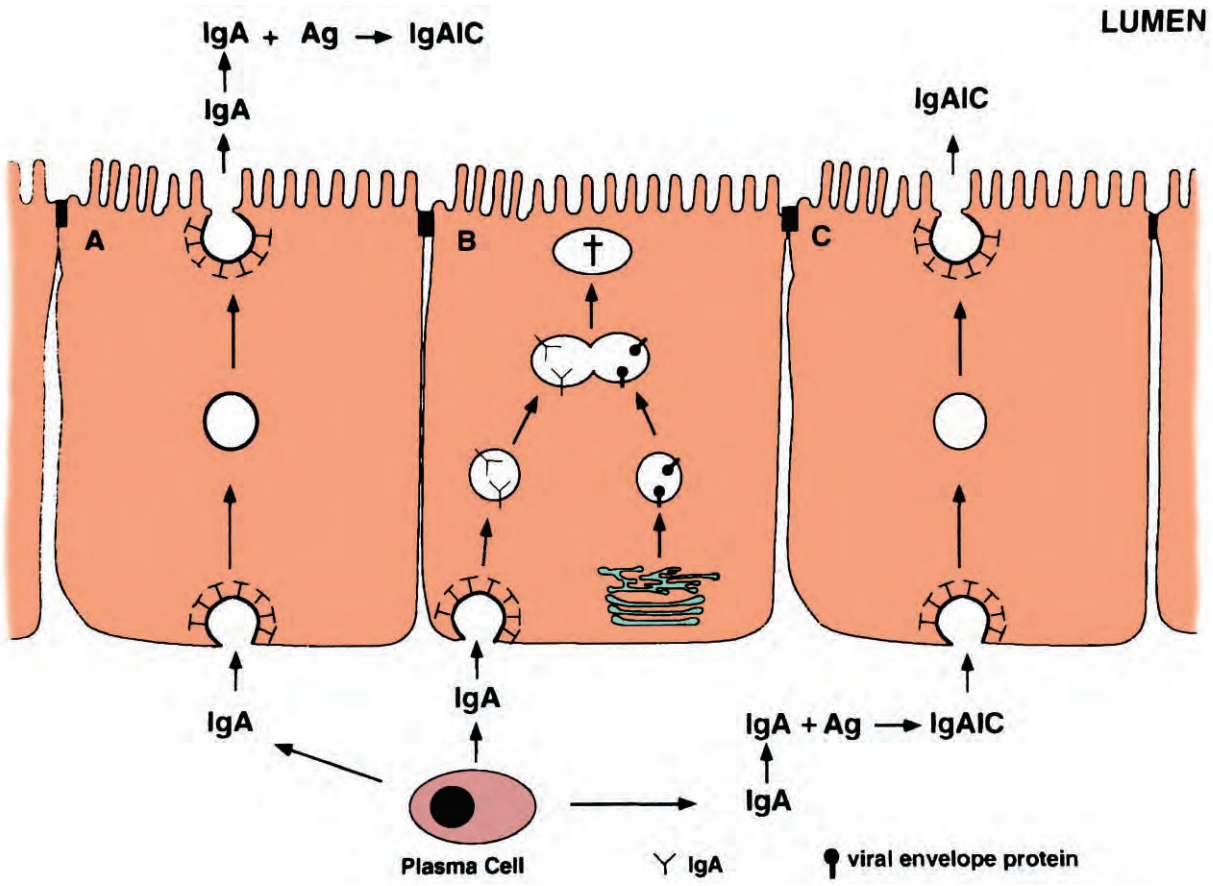

Figure 67–22. Compartments where immunoglobulin A (IgA) can potentially function in relation to mucosal epithelium. The lumen is above the layer of epithelial cells, which are interconnected by apical tight junctions. The lamina propria is below. Plasma cells (not drawn to scale) in the lamina propria secrete polymeric IgA. *Cell A* shows that polymeric IgA can be endocytosed at the basolateral surface (by pIgR), transcytosed, and secreted into the lumen, where it can combine with antigen (Ag) to form immune complexes (IgAIC). In *cell B,* which has been infected by a virus, it is suggested that a transcytotic vesicle containing IgA antibody to viral envelope protein can fuse with a post-Golgi vesicle containing newly synthesized envelope protein, which provides an opportunity for the antibody to disrupt the production of new virus. In the lamina propria below *cell C,* IgA antibody combines with antigen. The immune complex is endocytosed (by pIgR) and transported intact across the cell and into the lumen. (From Lamm ME: Current concepts in mucosal immunity. IV. How epithelial transport of IgA antibodies relates to host defense. Am J Physiol 274:G615, 1998.)

Immune Regulation of Gut Function

Intestinal epithelial function is also influenced by the gut immune system. Evidence for immune regulation of gastrointestinal water and electrolyte transport has recently accumulated. Mast cells play an important role in gut immune effector function and are distributed throughout the intestine but are most abundant in the small intestine. Mast cells secrete various mediators and cytokines upon degranulation after stimulation (e.g., IgE-mediated type I hypersensitivity reaction). Some of these mediators are preformed and stored in vesicles (e.g., histamine); others are newly synthesized as needed (e.g., prostaglandins, leukotrienes, interleukins). In the intestine, these mediators can affect smooth muscle function, vascular permeability, and the epithelial transport of electrolytes, water, acid, and mucin. Histamine activates H_1 receptors on the intestinal epithelial cell surface and stimulates chloride secretion. Histamine also synergistically enhances secretory responses to cAMP-dependent secretagogues such as adenosine, also a mast cell product. Important roles of mast cells in gut function are demonstrated by experimental manipulations of knockout animals. In genetically mast cell–deficient (W/W^v) mice, the intestinal secretory response associated with anaphylaxis is diminished.[116] They also exhibit reduced colonic mucin secretion from goblet cells and prostaglandin E_2 release in response to stress.[117] In addition, histamine-mediated intestinal epithelial chloride secretion plays an important role in parasitic nematode infections, in which mast cell hyperplasia is a predominant feature.

Immune regulation of intestinal epithelial water and electrolyte transport is manifested by the increased

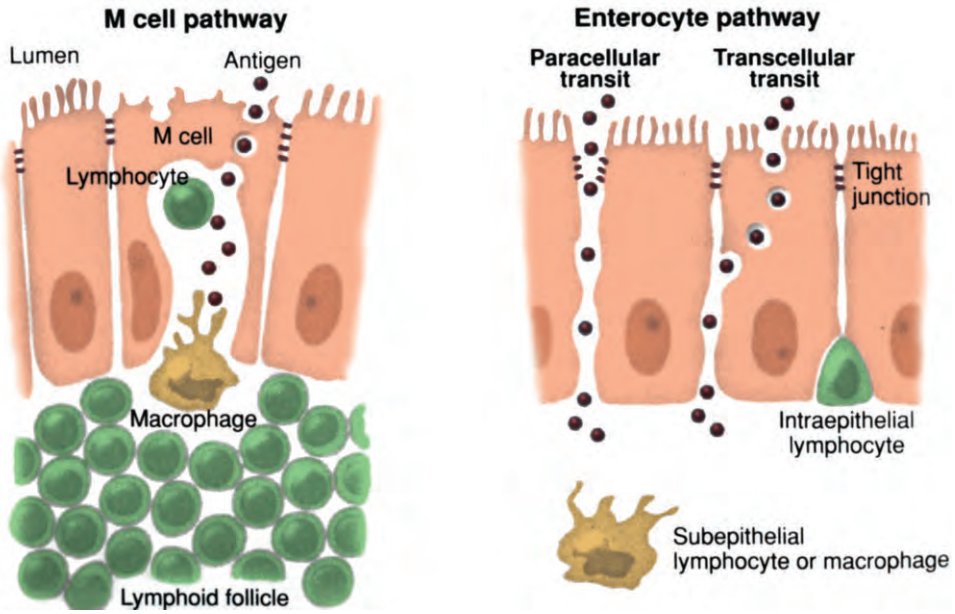

Figure 67–23. Paths across the lining of the gut. Antigen can enter the body from the gut through rare M cells *(left)* specialized to deliver antigen directly to underlying immune cells or through the more common enterocytes *(right),* the epithelial cells that line the gut. (From Madara JL: The chameleon within: Improving antigen delivery. Science 277:910, 1997.)

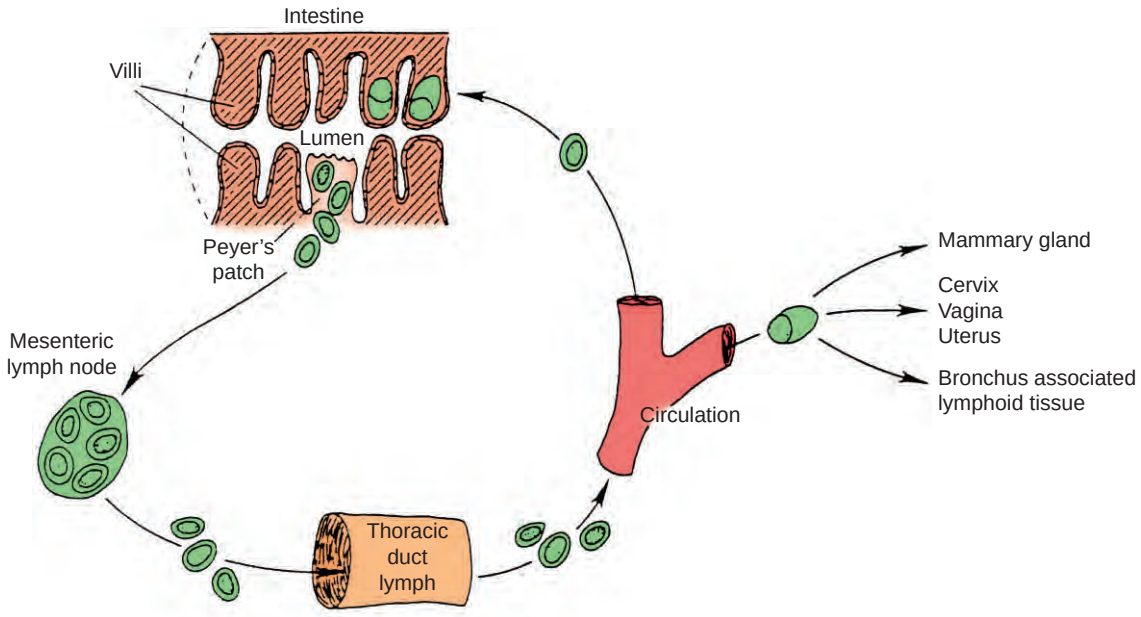

Figure 67–24. Migration of lymphoid cells from Peyer's patches. Lymphocytes travel from the mesenteric lymph nodes through the thoracic duct to the systemic circulation. These cells can disseminate to the lamina propria of the intestine or to extraintestinal sites, such as the mammary gland, female genital tract, and bronchus-associated lymphoid tissue. gastrointestinal fluid secretion and diarrhea seen in patients with food allergies, inflammatory bowel diseases, and various enteric infections.

MOTILITY OF SMALL INTESTINE

The primary goal of the small intestine, digestion, is facilitated by the contractile movements of the smooth muscle layers, which provide antegrade propulsion of the luminal contents combined with mixing action through segmentation. Organized periodic motor activity is present in the absence of luminal nutrients. Regulation of these motor activities in the intestine is complex and involves an autonomous intrinsic neural network that not only senses and responds to local mechanical and chemical signals but also communicates with central neurons in the spinal cord and brain.

Intestinal Smooth Muscle Cells

Smooth muscle cells form the outer longitudinal and inner circular muscle layers of the intestinal wall and the muscularis mucosae layer. Smooth muscle cells of the intestine derive their contractile force from the interaction between actin and myosin filaments. The actin content relative to myosin is much higher in smooth muscle cells than in skeletal muscle. Additionally, smooth muscle can maintain contractile tension at a lower rate of ATP hydrolysis. Smooth muscle cells of the small intestine display spontaneous electrical depolarizations and are able to propagate this signal to neighboring smooth muscle cells through gap junctions, thus resulting in a coordinated muscle contraction as a syncytium. The dominant intestinal pacemaker that initiates cyclic electrical impulses and contractions is localized in the proximal portion of the duodenum. Recently, the interstitial cell of Cajal (ICC) has been identified as the cell type responsible for the generation of pacemaker currents.[118,119] ICCs and smooth muscle cells originate from common mesenchymal precursor cells.[120-122] ICCs are found within the circular muscle layer of the intestinal wall and are interconnected by long processes containing gap junctions (Fig. 67–25).

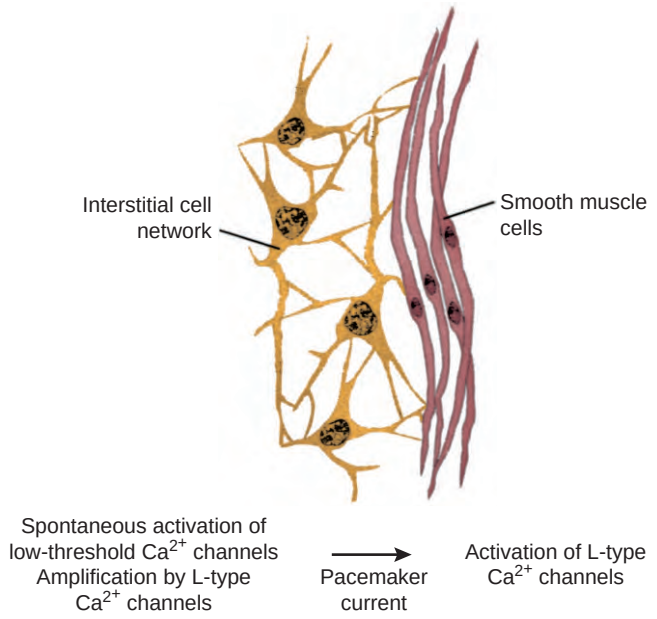

Figure 67–25. Model for initiation of pacemaker activity. Pacemaker activity appears to originate in the interstitial cell of Cajal. Spontaneous activation of low-threshold Ca^{2+} channels occurs near the resting potentials of these cells. As depolarization proceeds, L-type Ca^{2+} channels are also activated and amplify the current. The pacemaker current spreads to smooth muscle cells that are coupled through occasional gap junctions. In smooth muscle cells, L-type Ca^{2+} channels are activated, thus coupling the electrical activity to contraction. (From Sanders KM: A case for interstitial cells of Cajal as pacemakers and mediators of neurotransmission in the gastrointestinal tract. Gastroenterology 111:503, 1996.)

Patterns of Contractions

The small bowel accomplishes the absorption of ingested nutrients by using specific spatial and temporal patterns of contractile activity or motility. The contractions mix and propel ingested food at a rate that facilitates digestion; keep the intestinal tract clear of debris, secretions, and bacteria between meals; and in special situations, propel the intestinal contents rapidly over great distances. The contractile activity of the small intestine is under a variety of control mechanisms, including myogenic, neural, and chemical control.

Myogenic Control

Myogenic control refers to the electrical activity generated by the smooth muscle of the gut. Electrical control activity (ECA; slow waves, basic electrical rhythm, pacesetter potential)[123-126] is the omnipresent rhythmic depolarization of the cell membranes of the smooth muscle of the small intestine. This electrical activity may be recorded with either intracellular or extracellular electrodes. In humans, periodic depolarizations in membrane potential occur 11 to 13 times per minute in the proximal part of the small intestine and decrease to 8 to 10 times per minute in the ileum. With neural or chemical stimulation, membrane depolarization exceeds an excitation threshold and a contraction results. The electrical correlate of a contraction is called *electrical response activity* (ERA; spike burst, action potentials).[123-126] These ERA bursts have a 1:1 relationship with contractions. Because ERA occurs only during the depolarization phase of the ECA cycle, the frequency of contractions is limited to and determined by the frequency of ECA. Neural and chemical stimulation may not be present during each depolarization of ECA, and thus contractions then do not occur at the maximum possible frequency.

The spatial coordination of contractions along the small intestine is coordinated by ECA. Adjoining cells interact, and when electrical coupling is greater, ECA is phase locked such that oscillation of ECA between cells will occur with a fixed time lag. Cells with higher intrinsic frequency drive those with lower intrinsic frequency.

ECA frequency decreases as one progresses from the duodenum to the terminal ileum. There appears to be a *pacemaker region* in the proximal duodenum, similar to the pacemaker region of the stomach, that has an intrinsic ECA frequency that drives or paces the distal part of the small intestine.[127] In the duodenum and proximal jejunum, the electrical coupling is so strong that all the cells oscillate at the same frequency.[124,128] In the more distal portion of the small intestine, the electrical coupling between cells is not strong enough to entrain surrounding cells, and these cells have greater intrinsic frequency variation than do cells of the duodenum. Because individual contractions of the distal variable-frequency region[124,128] are not as coordinated and do not propagate over great distances in the proximal part of the gut, the transit time in the distal portion of the small intestine is longer than that of the proximal portion.[129]

Although both spatial and temporal patterns of contractile activity are ultimately under myogenic control, whether a contraction will occur at any given site depends on local neurochemical stimulation.

Neural Control

Small intestinal smooth muscle contractile activity is influenced by both extrinsic autonomic (parasympathetic and sympathetic) neural activity from the CNS and the intrinsic neurons of the enteric nervous system.

Extrinsic Neural Control The small intestine derives its parasympathetic innervation through the vagus nerve. The vagus nerve contains both afferent and efferent fibers. Efferent motor fibers arise from the dorsal motor nucleus in the region of the fourth ventricle. Relative to the intrinsic enteric neurons, the efferent potion of the vagus is really quite small; however, each vagal efferent fiber may influence about 2000 enteric neurons.[130,131]

In contrast, the sensory component of the vagus nerve is much greater. Sensory fibers account for 80% of all vagal fibers[132] and have their cell bodies primarily in the nodose ganglia. Vagal afferents detect both mechanical and chemical stimulation of the small intestine and relay this information centrally for processing.

Sympathetic innervation of the small intestine arises from the thoracic and lumbar spinal nerves (generally T5 through L3). These nerves pass through the paravertebral ganglia and form the splanchnic nerves, which go to the prevertebral ganglia—the celiac, superior mesenteric, and inferior mesenteric. Within these ganglia, cell bodies receive synaptic input from interganglionic mesenteric neurons. These ganglia intercommunicate and relay sensory information from the gut to the CNS, thereby allowing interactions between different areas of the gut. Stimulation of vagus fibers produces contractile activity within the upper part of the small intestine.[130,131] Electrical stimulation of the mesenteric sympathetic nerves releases norepinephrine and other neuroregulatory substances that inhibit small intestinal contractions.[133]

The enteric nervous system, or the "little brain" of the gut,[134] consists of an intricately coordinated network composed of all neurons having their cell bodies within the bowel wall. Though less well studied than the CNS, the enteric nervous system is quite complicated in that it contains nearly as many neurons as the CNS does.[135]

The enteric nervous system is made up of interconnected neural plexuses and ganglia, which contain the nerve cell bodies. The subserous plexus lies between the serosal and the external muscle of the small intestine. The longitudinal muscle plexus is made of fine nerve bundles that run parallel to the muscle cells and provide innervation to the longitudinal muscle. The myenteric (Auerbach's) plexus is located between the longitudinal and circular muscle layers. The myenteric plexus integrates sensory, extrinsic, and enteric neural information. As in the longitudinal muscle layer, the circular muscle layer has a plexus running parallel to the muscle fibers. This layer communicates with both the myenteric and the deep muscular plexus.[135,136] The deep muscular plexus is located in the inner aspect of the circular muscle layer and separates a thin layer of muscle cells from the bulk of the circular muscle. The fibers of this plexus originate with the myenteric ganglia. The submucosal (Meissner's) plexus also contains ganglia. The muscularis mucosae is a fine layer of smooth muscle just deep to the mucosa that contains a plexus of delicate nerve fibers. Finally, the mucosal plexus intertwines amid the lamina propria of the intestinal crypts and villi.

The majority of neurons controlling contractile activity in the small intestine have their cell bodies in the myenteric plexus.[137,138] Two classes of postsynaptic neurons innervate small intestinal smooth muscles: cholinergic excitatory and nonadrenergic noncholinergic (NANC) inhibitory neurons. Acetylcholine is the excitatory neurotransmitter, but NANC inhibitory neurotransmission is accomplished by nitric oxide,[139-144] ATP, and VIP.[145-148]

The enteric nervous system interfaces directly with the intestinal smooth muscle and provides moment-to-moment control of contractile activity. Neural isolation from the CNS has only a minor effect on the orderly propulsion of chyme within the small intestine.[149] Intrinsic neural pathways may extend 100 to 150 cm proximal and distal to any given point in the small intestine.[1501]

The *peristaltic* or *myenteric reflex* is a classic enteroenteric reflex. Bayliss and Starling[151] described excitation orad and relaxation aborad to the site of mechanical stimulation or chemostimulation. This reflex implies that chyme is propelled in an aborad direction. Although the precise significance of this reflex in normal postprandial contractile activity is uncertain, it reflects the coordinated neurocircuitry within the enteric nervous system.[152] Descending inhibition and ascending excitation are not seen with individual phasic contractions. However, in special situation such as giant migrating contractions (GMCs), both ascending and descending inhibition can be demonstrated.[153] It may be that the greater strength and duration of this special-situation contraction are needed to elicit the peristaltic reflex.

Chemical Control

Chemical control involves the stimulation or inhibition of smooth muscle contractile activity by humoral substances[124] that may act through either a neurocrine, paracrine, or endocrine mode. Examples of these regulatory substances include serotonin, histamine, opioids, cholecystokinin (CCK), motilin, somatostatin, VIP, and substance P. These and many other putative neuroregulatory substances administered exogenously can modulate contractile activity within the small intestine.

There is an intimate relationship between the immune system of the gut and the enteric nervous system that may extend to the motor activity of the small intestine. The best-recognized immune modulator is histamine, which is found within the mast cells of the gut. When mast cells degranulate in response to antigenic stimulation, the enteric nervous system is activated and specific patterns of contractile activity may be initiated.[154-157] Although the precise mechanism by which inflammatory cells and inflammatory mediators affect

small intestinal motility is unknown, it is clear that an interaction exists.

Organization of Contractile Activity

Contractions of the small intestine may be divided into individual phasic contractions, organized groups of contractions, and special propulsive contractions (Box 67–1). The specific characteristics of these contractions or groups of contractions and how they relate to the previously described control mechanisms are explored in the following sections.

Individual Phasic Contractions

Individual phasic contractions are the basic contractile activity of the small intestine. They occur in both the fasted and the fed state. In the proximal portion of the small intestine, contractions occur more regularly and propagate caudally over a variable distance that tends to be greater than what occurs in the distal portion of the small intestine. Contractions in the distal part of the small intestine are much less coordinated, and consequently, the rate of propulsion in the distal part of the small bowel is less than that in the proximal part.

Oscillations of ECA directly determine the maximum frequency and duration of individual phasic contractions. When neurochemical stimulation is superimposed, a contraction occurs. Phasic contractile activity does occur without recordable ECA from extracellular electrodes. In this unique situation after drug administration and during some enteric infections, ECA gradually decreases in amplitude and becomes progressively unstable in the distal portion of the small intestine.[155,158] Rapidly migrating contractions may then occur without the tethering influence of ECA. These contractions are similar in amplitude and duration to individual phasic contractions, but they migrate at a velocity as great as 30 cm/sec over distances of up to 200 cm within the proximal part of the small intestine; these rapidly migrating contractions do not occur in the distal portion. Under these conditions, the absence of ECA has been called *amyogenesia*. This electrical and contractile pattern can be disrupted by an event such as feeding, and a special-situation contraction called a *GMC* frequently occurs.

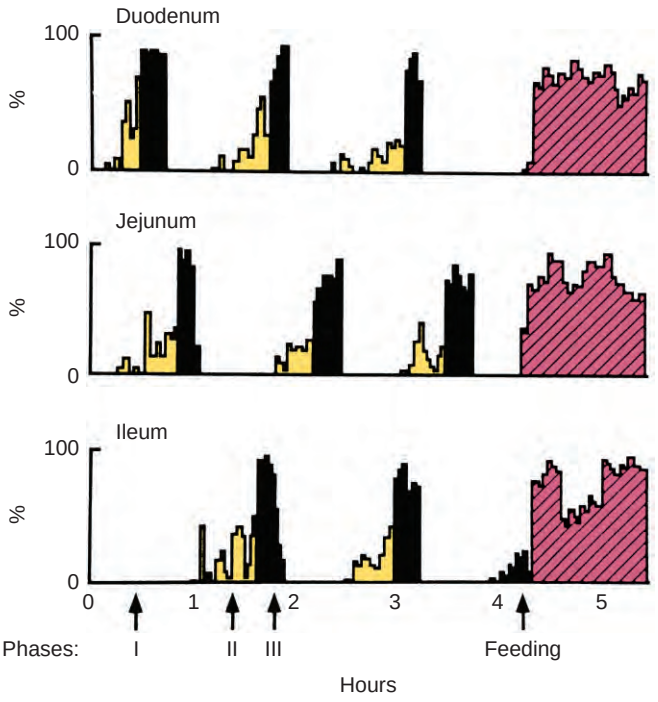

Figure 67–26. The migrating motor complex. *Bars* are used to show the level of intensity in phases II *(open bars)* and III *(solid bars).* The periodicity of activity in fasting *(left)* is interrupted by feeding, when activity rises to a more constant level *(hatched bars).* (From Christensen J: Motility of the intestine. In Sleisenger MH, Fordtran JS [eds]: Gastrointestinal Disease: Pathophysiology, Diagnosis, Management, 5th ed. Philadelphia, WB Saunders, 1993, p 829.)

Organized Groups of Contractions

Migrating Motor Complex The migrating motor complex (MMC) is a cyclic pattern of phasic contractile activity that occurs in the interdigestive state. The MMC originates in the proximal portion of the small intestine and migrates to the distal ileum, with cycling every 90 to 120 minutes (Fig. 67–26).[125,159] The MMC cycle is divided into four distinct phases. Phase I is an interval of contractile quiescence; phase II consists of intermittent contractions that eventuate into phase III, which consists of regular phasic contractions of large amplitude that occur at maximum frequency for approximately 6 to 8 minutes. Phase IV of the MMC consists of a short transition of intermittent contractions. In humans, the MMC occurs only during the fasted state (Fig. 67–27). Its purported function is to cleanse the small intestine of residual food, desquamated cells, and enteric secretions and keep bacterial growth to a minimum.[161] Many people refer to phase III of the MMC as "the MMC."

These patterns of small intestinal motor activity develop as the fetus matures.[161,162] Early in gestation, motor activity is irregular and disorganized, but as the fetus develops, the MMC pattern appears.[162] This maturation may occur postnatally in preterm infants.[161] MMCs are preserved in the small intestine throughout the process of aging.[163]

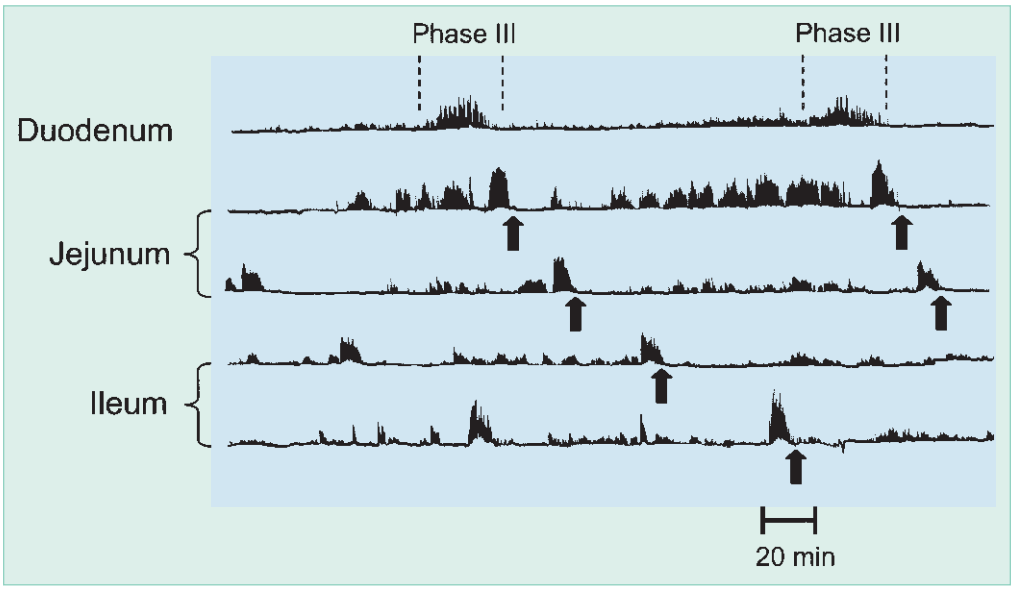

Figure 67–27. Migrating motor complex (MMC). The MMC migrates along the length of the small intestine from the duodenum to the terminal ileum. During the most intense period of contractile activity (phase III), contractions are occurring at their maximum frequency.

The MMC is not under direct CNS control. Truncal vagotomy,[126,164,165] superior and inferior mesenteric ganglionectomy,[166] sympathectomy,[135,167] and even total extrinsic denervation[149] do not abolish MMC cycling. It is likely, however, that the CNS modulates the MMC cycle, particularly during periods of stress.[168,169] Cyclic alterations of circulating regulatory peptides, in particular, motilin, appear to have an influence on the MMC.[170-172] When exogenous motilin is administered, a premature MMC cycle is initiated.[173] During spontaneous cycling of the MMC, plasma motilin concentrations are in their nadir during phase I, increase during phase II, and peak a few minutes after phase II in the duodenum.[174,175] Phase I of the MMC may be produced by ascending inhibition caused by the distally migrating phase III activity. This ascending inhibition may compete with other factors that stimulate contractile activity.

Overall control of the MMC appears to reside in periodic activation of the enteric nervous system, which initiates the cyclic contractile activity we recognized as the MMC. If a segment of the small intestine is isolated as in a loop of small intestine, MMCs cycle above and below as well as within the loop independent of one another.[176,177] Simple transection of the small intestine will disrupt normal migration of the MMC along its flanks.

Migrating Clustered Contractions Migrating or discrete clustered contractions last 1 to 3 minutes, and aborad migration over distances of 10 to 30 cm have been documented to occur.[178-181] Because they do not occur as regularly and predictably as MMCs, the mechanisms of initiation of propagation of the contractions have been less well studied. These migrating clustered contractions are highly effective at propulsion.[182] They usually occur during phase II of the MMC.

Special Propulsive Contractions

The small intestine usually propels chyme slowly in the aborad direction. In special situations, it is advantageous to the organism to expel ingested material rapidly. The small intestine is capable of generating special propulsive contractions to achieve rapid movement of chyme. If aborad propulsion is necessary, retrograde giant contractions (RGCs) occur. These small intestinal contractions immediately precede vomiting. When rapid aborad evacuation of the small bowel is necessary, GMCs rapidly propel chyme into the colon.

Retrograde Giant Contractions An RGC is a large-amplitude, long-duration contraction that originates in the midportion of the small bowel and rapidly propels the intestinal contents in the stomach for subsequent expulsion. It is one of the gastrointestinal motor correlates of vomiting. An RGC travels at a rapid velocity of 8 to 10 cm/sec.[183] By contrast, the MMC migrates at 2 to 8 cm/min.[125,159] RGCs have been extensively studied in the canine model.[183] RGCs also occur in primates but have not yet been documented in the human gastrointestinal tract. The powerful and rapid nature of this contraction may preclude recording with the manometric or solid-state methods currently used in human studies.

RGCs precede spontaneous or drug-induced emetic episodes but may also occur without subsequent vomiting.[183] This appears to be a dose-dependent response. For example, with low doses of an emetic agent, an RGC is initiated; higher doses generate an RGC followed by vomitus expulsion.

An RCG is associated with a series of unique electrical and contractile changes in the small intestine. The first to occur is the obliteration or disorganization of ECA.[183] This change inhibits normal phasic contractions of the

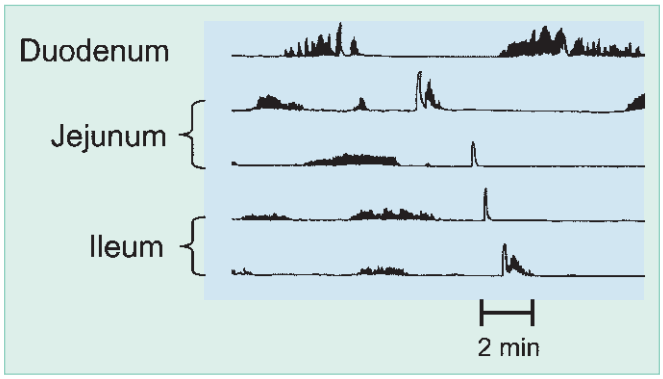

Figure 67–28. Giant migrating contraction. This giant migrating contraction begins in the proximal part of the small intestine and rapidly propels intestinal contents into the colon. In healthy humans, these contractions occur very infrequently and are limited to the distal end of the small intestine. In disease states, they may originate more proximally and are associated with the sensation of abdominal cramping.

small intestine, thus enhancing the propulsive efficiency of the subsequent RGC. An RGC then occurs and may or may not be followed by the somatomotor response of vomitus expulsion. The myoelectric correlate of an RCG is a large potential change, sometimes with a superimposed brief ERA burst.[183] RCGs are followed by a group of phasic contractions throughout the small intestine that last longer distally than proximally.[183] These contractions may propel distal intestinal contents into the colon just as the RGC propels proximal enteric contents into the stomach. Although an RGC itself is not controlled by ECA, the post-RGC phasic contractions are under myogenic control.

Spontaneous RGCs or those initiated by apomorphine or mucosal irritants are abolished by vagotomy.[183] Postvagotomy studies suggest that an RGC requires vagal involvement, but the actual mechanism for the initiation or propagation of an RGC exists within the intestinal wall, and they may be activated by high doses of the hormone CCK-8.[184] Atropine blocks the occurrence of RGCs, which suggests that the final neurotransmitter involved in the contraction is acetylcholine. Interestingly, atropine does not disrupt the ECA slowing and post-RGC phasic contractions, thus suggesting that other neurochemical transmitters may be involved.

Giant Migrating Contractions GMCs, also called *prolonged propagated contractions* (Fig. 67–28), are large-amplitude, long-duration contractions that propagate rapidly in an aborad direction. Their amplitude is approximately 1.5 times that of the phasic contractions of the MMC.[180,185] Once initiated, these contractions usually propagate uninterruptedly to the ileocolonic junction. GMCs are even more propulsive than the MMC.[182] In the normal, healthy state, these contractions occur intermittently in the distal part of the small intestine and are never seen postprandially. In pathologic states or after the administration of certain drugs, GMCs are more frequent and originate more proximally in the small intestine.[153,155,157,185-187] In patients with irritable bowel syndrome, GMCs are associated with the sensation of abdominal cramping.[188] These powerful contractions may generate abdominal pain because they stimulate nociceptive receptors within the bowel wall above their threshold level and hence produce discomfort. Another theory is that effective propulsion of intestinal chyme by GMCs distends the distal intestinal wall and thereby produces pain.

A function of small intestinal GMCs may be to return fecal contents refluxed from the ileum into the colon.[186] In pathologic states, frequent GMCs may contribute to diarrhea by propelling bile and intestinal secretions rapidly through the gastrointestinal tract without allowing sufficient time for reabsorption.[155,187] Postprandial GMCs that propel undigested food into the colon would contribute to diarrhea[187]; partially digested food exposed to bacterial degradation in the colon would result in gas production and increase the colonic osmotic load.

The myoelectric correlate of the GMC is a brief burst of ERA at the beginning of the contraction. Sometimes the GMC has phasic contractions superimposed on the down-stroke of the contraction. When this occurs, the electrical recording is followed by one or two ERA bursts during the down-stroke.[185] The velocity of GMCs is not bound by the normal constraints of ECA. These contractions require the enteric nervous system for propagation and for generation of the descending inhibition associated with them. Interestingly, ascending inhibition associated with GMCs requires neural input extrinsic to the bowel wall.[153]

The small intestine produces a large number of different contractions in various spatial and temporal patterns that promote efficient digestion, absorption, and propulsion of ingested material. The small intestine also serves a protective role through the use of special-situation contractions that rapidly propel enteric contents into the stomach or colon, from which they may be expelled. Contractile activity of the small intestine is coordinated by the interplay of myogenic, neural, and chemical control.

INTESTINAL NEUROENDOCRINE FUNCTION

The small intestine is a major source of peptides that regulate various aspects of gut function and influence events in the body as a whole. Since the discovery of secretin by Bayliss and Starling in 1902,[189] an increasing number of regulatory peptides have been identified from the gut. These substances are released by local, luminal, or neural stimuli and elicit biologic actions by binding to membrane receptor proteins. Some of the peptides act locally in a paracrine fashion, whereas others work at distant sites in an endocrine fashion as circulating hormones. Many of the receptors for these peptides belong to the superfamily of G protein–coupled receptors. Examples include receptors for secretin, VIP, and pituitary adenylate cyclase activating peptide (PACAP).[190] Some

representative gastrointestinal peptides are categorized in Box 67–2.

Secretin and Related Peptides

Secretin is a 27–amino acid peptide released from the enteroendocrine cells of duodenal mucosa in response to luminal acid, bile salts, and fat. Its main function is to facilitate digestion by stimulating pancreatic and biliary bicarbonate and water secretion and, to a certain extent, pancreatic exocrine enzyme secretion.[191] At high concentrations, secretin inhibits gastrin release, gastric acid secretion, and postprandial gastric emptying and stimulates secretion of bicarbonate and epidermal growth factor from Brunner's glands.[192,193] Intravenous infusion of secretin stimulates rather than inhibits gastrin release in patients with Zollinger-Ellison syndrome and forms the basis of the diagnostic test for this condition.[194]

VIP is one of the major inhibitory neurotransmitters in the gut and induces relaxation of smooth muscle. Its receptor, a G protein–coupled receptor, elevates intracellular cAMP by means of adenylate cyclase. It is localized, along with PACAP, to the nerve terminals in humans[195] and is released as a neurotransmitter to act on smooth muscle cells to regenerate nitric oxide.[196] It relaxes many sphincter muscles, including the sphincter of Oddi, and mediates relaxation of the peristaltic reflex.[197] VIP also stimulates intestinal epithelial chloride secretion, as well as pancreatic bicarbonate, water, and enzyme secretion.[198-200] More recently, VIP has been shown to affect normal and neoplastic cell growth. It stimulates the growth of astrocytes and certain non–small cell lung cancer cells and inhibits the growth of colonic adenocarcinoma cell lines, probably by virtue of elevated intracellular cAMP.[201]

PACAP was isolated from bovine hypothalamus[202] and shares 68% sequence homology with VIP. PACAP activates both exocrine and endocrine pancreatic secretion in mammals.[203,204] More recently, PACAP activation of pancreatic fluid, bicarbonate, and protein secretion in rats was shown to involve release of secretin and CCK independent of cholinergic stimulation.[205]

Other members of the secretin family, including glucagon, gastric inhibitory polypeptide (GIP), glucagon-like peptide 1 (GLP1), and enteroglucagon, share substantial sequence homology and bind similar G protein–coupled receptors.[206-208] GIP is a 43–amino acid polypeptide released primarily from enterochromaffin cells of the jejunum when stimulated postprandially by carbohydrates and fat, and it subsequently elevates the serum insulin level. Enteroglucagon is primarily released in the distal portion of the small intestine on stimulation by carbohydrate and LCFA and inhibits intestinal motility. GLP1 may be the major hormonal factor responsible for gut adaptation and glucose homeostasis.[209]

Cholecystokinin

CCK is a 33–amino acid polypeptide released by specialized small intestinal mucosal cells in response to luminal amino acids and medium-chain to long-chain fatty acids, and its release is inhibited by intraluminal trypsin and bile salts.[210] The C-terminal tetrapeptides of CCK and gastrin are identical and possess the activity of both hormones. CCK enhances emptying of the gallbladder and bile flow by stimulating simultaneous contraction of the gallbladder and relaxation of the sphincter of Oddi, thus facilitating digestion by luminal mixing of bile with ingested food.[211] Additionally, CCK stimulates pancreatic enzyme secretion, intestinal mucosal cell growth, insulin release, and gut motility. The prostimulatory effect of CCK on gallbladder contraction is clinically used as a provocative test in patients with suspected acalculous biliary disease.[212,213]

Somatostatin

Somatostatin is a cyclic peptide consisting of 14 amino acids[214] and is released in various tissues, including the

brain and gut. In the gastrointestinal tract and pancreas, somatostatin, released by specialized enteroendocrine and nerve cells, acts locally in an autocrine, paracrine, or neuronal regulatory manner to perform a wide variety of inhibitory functions.[215,216] It inhibits neurotransmission, smooth muscle contraction, intestinal and pancreaticobiliary secretion, the function of activated immune cells, and cell growth.[215-218] Synthetic analogues of somatostatin, such as octreotide, are used clinically in patients with enterocutaneous and pancreatic fistulas, as well as various hormone-secreting tumors.[218]

Motilin

Motilin, a peptide containing 22 amino acid residues, is released in the small intestine, primarily in the jejunum. Its major actions include local enhancement of smooth muscle contraction and acceleration of gastric emptying.[212] Its prokinetic activity is used clinically in the form of macrolide antibiotics such as erythromycin, a motilin receptor agonist. Erythromycin improves not only emptying of the stomach and gallbladder but also colonic motility.[219-221]

Guanylin and Uroguanylin

Guanylin and uroguanylin, peptides secreted in the intestine, are endogenous ligands for guanylate cyclase, the membrane receptor for the cGMP signaling pathway. Guanylin contains 15 amino acid residues, whereas bioactive uroguanylin exists as 13-, 14-, and 15-residue peptides.[222,223] Both guanylins are highly expressed in the small and large intestines as inactive propeptides that require enzymatic digestion to yield active peptides.[224,225] Heat-stable enterotoxin (Sta) from *Escherichia coli* causes traveler's diarrhea by means of the cGMP signaling pathway by binding the same guanylate cyclase receptor on the intestinal luminal surface.[222,226] Activation of guanylate cyclase by these ligands leads to stimulation of transepithelial secretion of Cl^- and HCO_3^- through the intracellular accumulation of cGMP and thereby results in enhanced fluid secretion and modulation of intraluminal pH.[222,227,228] In particular, uroguanylin, highly expressed in the proximal duodenum, appears to play an important role in neutralizing luminal acid by enhanced anion secretion at low pH.[227]

Other Peptides

Peptide YY is a 36–amino acid polypeptide released in the distal part of the small intestine. Its functions in the gastrointestinal tract are most inhibitory: it inhibits gastric acid secretion and decreases intestinal motility, pancreatic secretion, and release of various intestinal hormones.[229,230] Neurotensin is released from the ileum and enteric nerves and is thought to affect various gastrointestinal functions, such as gastric acid secretion, gastric emptying, and intestinal motility and secretion. Some of the peptides are released from enteric nerves and function primarily as neurotransmitters; such peptides include galanin, bombesin, neuropeptide Y, and substance P, among many others.[231,232] Although efforts to understand their precise physiologic roles are ongoing, these substances appear to influence multiple aspects of gut physiology, such as motility, local blood flow, and epithelial and exocrine secretion.

SUMMARY

The small intestine provides the largest interface with the outside world, provides immune integrity, allows the absorption of most nutrients required by our bodies, and functions largely independently of our perception. Our understanding of the complex mechanisms that allow these functions to occur is expanding.

ACKNOWLEDGMENT

The authors would like to acknowledge the authors of the previous chapters on small intestinal disorders in this textbook: Drs. Seth J. Karp, David I. Soybel, Edward C. Mun, and Jeffery B. Matthews. Their work formed the basis of the current revised chapter.

Small Bowel Obstruction

Soo Y. Kim · Jon B. Morris

Small bowel obstruction (SBO) is one of the most common admitting diagnoses in surgery, and yet these patients may be the most difficult to manage. They account for 12% to 16% of surgical admissions for acute abdominal complaints. Manifestations of SBO can range from a fairly good appearance with only slight abdominal discomfort and distention to a state of hypovolemic or septic shock (or both) requiring an emergency operation. The process of determining appropriate management can at times be extremely difficult. Despite our advances in the technology of diagnostic procedures, the decision to treat operatively or nonoperatively is still dependent on the surgeon's clinical experience and acumen. There has been some improvement in patient outcome over the years, however, with mortality from SBO declining from 50% in 1900 to less than 3% today. This reduced mortality may be due to multiple factors, including improved imaging techniques that prompt earlier operative intervention versus appropriate conservative management, as well as more advanced methods of resuscitation and intensive care in more severe cases.

CLASSIFICATION

Obstruction can be classified according to its mechanism. For instance, *mechanical* obstruction is the inability of contents to pass through an area because of physical blockage. It can be further divided into extrinsic or extraluminal (e.g., adhesions), intrinsic or mural (e.g., duodenal hematoma), and intraluminal (e.g., gallstone or intussusception) causes. Neoplastic processes may cause any of these mechanical obstructions by way of extrinsic compression of carcinomatosis, mural compression as a result of lymphoma or smooth muscle tumor, or mucosal tumor (Table 68–1).

In contrast, *functional* obstruction is caused by dysmotility of bowel without a physical obstacle to luminal flow. Neurogenic disturbances may contribute to this dysfunction of normal gut motility and peristalsis. Examples include ileus and pseudo-obstruction (Ogilvie's syndrome).

Obstruction can also be categorized as *partial* or *complete*. Partial obstruction may allow gas or liquid stool, or both, to pass the point of narrowing, whereas complete obstruction would not allow the passage of any substance at all. Similarly, obstruction may be labeled *low grade* or *high grade* to indicate the severity of obstruction as interpreted from radiology studies. This category is not to be confused with the designation *high* and *low* obstruction, which is used to stratify the location of pathology within the small bowel, that is, proximal versus distal.

MOTILITY

In the fasted state, migrating myoelectric complexes start in the duodenum and progress to the distal ileum. They occur every 90 to 150 minutes and normally last 90 minutes during their course through the small intestine.

In the case of early obstruction, these propulsive forces work aggressively to pass through the point of blockage and subsequently increase as intraluminal pressure increases. They subside and then recur episodically, alternating with quiescent periods. When the site of obstruction is high, or proximal, the duration of quiescence is shorter. In contrast, when the site is low, or distal, the duration is much longer. Bowel proximal to the site of obstruction becomes increasingly distended, and the distal bowel becomes increasingly inhibited.

In the case of partial obstruction, some intraluminal contents are able to pass through, whereas with complete obstruction, retrograde propulsion develops after bowel contents have accumulated.

PATHOPHYSIOLOGY OF OBSTRUCTION AND STRANGULATION

The clinical course of SBO is variable, depending on the site and severity of the obstruction, and it is even unpredictable. However, a common entity is volume depletion or *third spacing*. One method of fluid loss is net secretion into the lumen of the bowel. The small bowel secretes

Table 68–1 Classification of Small Bowel Obstruction

Extrinsic	Intrinsic	Intraluminal
Adhesions	Tumors of the bowel wall	Intussusception
Hernias	Carcinoid	Gallstones
External	Lymphoma	Bezoars
Inguinal	Leiomyosarcoma	Foreign body
Femoral	Inflammation	Mucosal tumors
Incisional	Crohn's disease	
Obturator	Tuberculosis	
Internal	Hematoma	
Paraduodenal	Endometriosis

Abscess		
Diverticulitis		
Pelvic inflammatory disease		
Crohn's disease		

8.5 L of fluid daily, most of which is reabsorbed in the small intestine. The net flux of fluid in cases of SBO, however, results in fluid secretion into the lumen. The process is believed to be due to prostaglandin release as a response to bowel distention. It may be manifested in varying degrees of severity, from symptoms of thirst and dry mucous membranes to systemic consequences of renal failure and shock.[1]

Another route of fluid loss is into the wall of the bowel secondary to venous congestion and edema. This loss then results in ascites as the serosal layer of the bowel wall secretes fluid into the peritoneal cavity. The degree of wall edema corresponds to the duration of the obstruction process. In addition, bowel obstruction causes nausea and vomiting, which further contributes to the volume-depleted state of patients with SBO. Furthermore, if a nasogastric tube is placed to suction drainage, copious amounts of fluid, as well as electrolytes, may be lost via this route, and aggressive intravenous replacement may be required.

Early in the obstructive state, a patient is found to have isotonic volume depletion secondary to vomiting or nasogastric tube decompression, as well as third spacing of fluid. As the obstruction persists, hypokalemia occurs as a result of emesis, as well as hyperaldosteronism, which is a response to hypovolemia. In addition, bicarbonate is lost as it is expelled within pancreatic and enteric fluid.[2]

As more air and fluid accumulate within the obstructed bowel, the normal absorptive capabilities of the gut deteriorate and the distention is further exacerbated. In addition, bacterial colonization increases with protracted stasis of the bowel. As a result, more gas is produced by the bacteria, thereby worsening the luminal distention.[3] The risk for bacteremia, peritonitis, and subsequent bacterial translocation is also increased as more bacteria accumulate. If the obstruction is unresolved and the bowel lumen continues to enlarge, vascular compromise becomes more likely. As a result, strangulation occurs, with the later development of necrosis and, ultimately, perforation.[4] Examples include volvulus and mesenteric torsion, which may progress to strangulation, ischemia, and infarction. In these cases, fluid accumulation occurs as well as derangement of bowel motility. In addition, venous obstruction caused by strangulation results in bloody ascites and release of toxins from the bowel wall. Subsequently, toxic metabolic effects may lead to septic conditions and, ultimately, even circulatory collapse.

Closed-Loop Obstruction

Closed-loop obstruction is caused by obstruction of both the afferent and efferent limbs of the involved loop of bowel (Fig. 68–1). Such patients may not have the usual distended abdomen on physical examination because only a limited loop of bowel is usually affected and therefore dilated. Progression to strangulation may occur much sooner than with other forms of obstruction because of an inability to decompress proximally or distally, with subsequent vascular compromise. Causes of closed-loop SBO include mesenteric torsion, adhesive bands, and internal as well as abdominal and inguinal hernias. In the colon, any obstructing lesion may

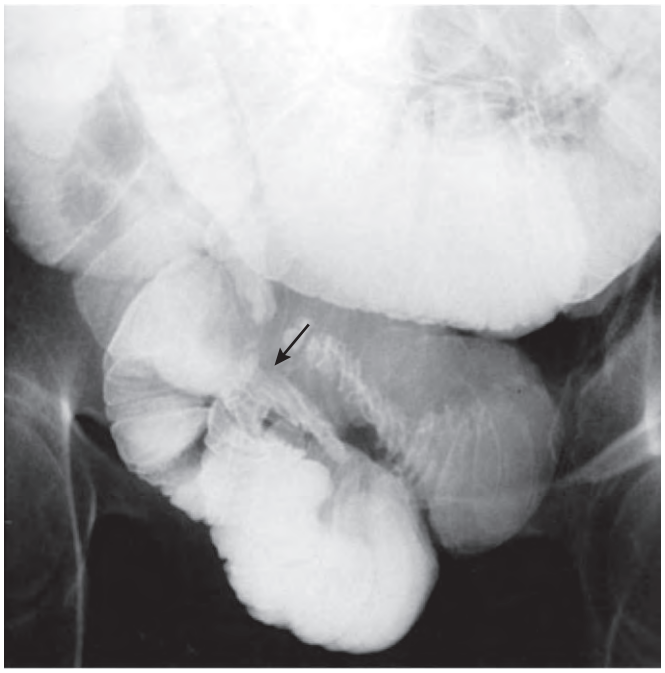

Figure 68–1. Enteroclysis film showing closed-loop obstruction. Apposition of the entering and exiting limbs at the point of constriction is caused by an adhesive band *(arrow).*

cause a closed-loop phenomenon if the ileocecal valve is competent.

ETIOLOGY

The most common cause of SBO is peritoneal adhesions postoperatively, which constitutes about 75% of all cases of SBO.[5] Pelvic or lower abdominal procedures are blamed for adhesion formation more commonly than upper abdominal procedures are, although any abdominal operation can be responsible.

Hernias, particularly inguinal hernias, are considered the next most common cause of SBO (25%).[4] However, femoral hernias are thought to be more likely to cause incarceration and, possibly, strangulation. Internal hernias can also occur, such as obturator and paraduodenal hernias, as well as hernias through the foramen of Winslow.

Inflammatory processes may likewise cause obstruction by way of secondary angulation of bowel, such as diverticulitis and appendicitis. The remaining causes include Crohn's disease, ischemia, radiation, intussusception, volvulus, and mass lesions such as neoplasms, gallstones, and bezoars.[1]

Adhesions account for the majority of early postoperative obstructions that develop after violation of the peritoneum, reportedly occurring in up to 92% of patients requiring surgical treatment.[6] They result in an inflammatory cascade involving the activation of complement and coagulation. Fibrinogen is produced during this response and is converted to fibrin by thrombin. If fibrin persists, it adheres to injured surfaces and initiates the formation of a matrix of collagen and fibroblasts, thereby forming *fibrous* adhesions from *fibrinous* adhesions. Fibrin degradation should then occur and allow the fibrinous adhesions to disintegrate and mesothelial regeneration to occur. An abdominal operation causing peritoneal injury dramatically inhibits this process of fibrin degradation by increasing levels of plasminogen activator inhibitors[7] and decreasing levels of tissue plasminogen activator.[8] Thereafter, adhesions are permitted to form and can be potential causes of bowel obstruction.

Another cause of postoperative SBO is internal herniation through defects created at the time of surgery. This category includes mesenteric or omental defects that occur after partial bowel resection. In addition, peritoneal defects that arise around a colostomy or enterostomy, as well as those that occur in the pelvic floor after abdominoperineal resection, can be sites of obstruction. In general, large defects do not seem to pose as much a threat as small defects do.[9] Therefore, controversy still exists regarding whether to close or leave mesenteric defects open after bowel resection or peritoneal defects after abdominoperineal resection.

Inflammatory processes can also cause bowel obstruction early in the postoperative period. Examples are abscesses after bowel surgery, which may form adhesions to nearby loops of bowel and thereby cause partial obstruction. Because of the time frame in which this situation may occur, differentiation between actual obstruction and postoperative ileus may be difficult.

Other consequences of bowel surgery include intramural bleeding with hematoma formation and intussusception. Postoperative anticoagulation can result in hemorrhage within the bowel wall or in the mesentery. Intussusception may occur with or without a lead point, particularly in pediatric patients. A well-described cause in this patient population is an inverted appendicular stump after appendectomy.[10] Another cause in adults is obstruction after retrocolic gastrojejunostomy for gastric bypass without concomitant gastrectomy when the jejunal limb intussuscepts into the gastric lumen.[11]

RISK FOR SMALL BOWEL OBSTRUCTION AFTER LAPAROSCOPY

With the advent of more and more laparoscopic procedures, surgeons are gaining increasing knowledge and experience with associated complications, as well as benefits. Less adhesion formation is one potential benefit of laparoscopy over laparotomy.

Theoretical advantages ensue from less abdominal wall injury as a result of smaller incisions, less use of foreign body materials (talc, gauze, lint from drapes), less tissue desiccation, and less tissue trauma and hemorrhage. However, because of the lack of uniform classification of adhesions in clinical and experimental studies, only suggestions rather than conclusions can be made.

Recent studies have compared adhesion formation after laparoscopy and laparotomy at various sites. With

regard to adhesion formation at the operative site, more studies favored laparoscopy over laparotomy. As for adhesions at the incision site, studies consistently supported laparoscopy as causing less adhesion formation. Finally, there are few data assessing the adhesive effects of laparoscopy versus laparotomy at distant sites, such as within abdominal viscera or interenteric surfaces. Experimental studies, however, again favor laparoscopy over laparotomy.[12]

CLINICAL FINDINGS

The most common symptoms of SBO are nausea, vomiting, crampy abdominal pain, distention, and obstipation. Mechanical obstruction usually causes pain before the onset of nausea and emesis, whereas nonmechanical obstruction causes earlier emesis, perhaps followed by subsequent pain. In addition, the site of obstruction may be discernible by the pattern and type of symptoms. Proximal obstruction tends to cause early and more frequent nausea and vomiting, whereas distal obstruction causes crampy pain and obstipation with delayed nausea and vomiting.

Early in the process, the vomitus will represent partially digested food and light-colored liquid. However, later in the process, the vomitus becomes bilious and even feculent. As the luminal contents persist and conglomeration of intestinal bacteria takes place, the emesis becomes malodorous and more consistent with feces.

Abdominal distention develops as the bowel loops proximal to the site of obstruction accumulate gas and fluid. This is less likely in very proximal obstructions, such as those in the duodenum, and occurs more frequently in midgut obstructions. Because up to 10 L can be secreted and reabsorbed by the small intestine in normal situations, the bowel may become quite distended in the setting of obstruction in which routine absorption is hampered (Table 68–2).

Symptoms of obstipation may not be apparent initially because residual gas and stool in the bowel distal to the obstruction may continue to evacuate. In partial obstruction, patients may continue to pass flatus and feces, in conjunction with the other symptoms. However, in complete obstruction, nothing is able to traverse the problem area.

Symptoms of postoperative ileus are often confused with those of bowel obstruction, particularly after abdominal surgery. Extended hospital stay and associated complications, including nosocomial infections, arise as a result. Therefore, many clinicians have investigated various methods of preventing or diminishing the extent of postoperative ileus. One technique that has been published by various centers is gum chewing as an adjunct to postoperative care in which gastrointestinal motility is stimulated via *sham feeding*. This technique has been studied after laparoscopic colon surgery in the hope of further decreasing hospital stay in these patients. Interestingly, when patients were randomly assigned to gum chewing, earlier passage of flatus and feces than in the control group was reported by some authors.[13]

PHYSICAL EXAMINATION

Symptoms may range from minimal discomfort with few physical abnormalities to toxicity and sepsis. Patients may show signs and degrees of dehydration from poor skin turgor and dry mucous membranes to tachycardia, hypotension, oliguria, and mental status changes.

Abdominal examination may reveal distention of varying severity. Auscultation may reveal rushing or tinkling high-pitched bowel sounds or absent bowel sounds in more advanced stages.[14] The abdomen may be tympanitic to percussion if bowel loops are filled with gas, but it may be dull if filled with fluid. Palpation may elicit tenderness if strangulation is present or impending. Signs of guarding and peritonitis would also indicate strangulation and perhaps ischemia or perforation, and they are usually sufficient evidence for exploration. In addition, as part of the abdominal examination, previous surgical scars should be noted because they can be used to predict the location and degree of adhesions likely to be encountered at the time of exploration. When examining a patient with SBO, abdominal and inguinal hernias should always be sought as possible causes of the condition.

Table 68–2 Clinical Findings in Small Bowel Obstruction

Features	Proximal/High Obstruction	Distal/Low Obstruction
Onset of symptoms	Sudden	Gradual
Pain	Epigastric, intense, colicky, usually relieved by vomiting	Periumbilical, colicky
Vomiting	Early, bilious, voluminous, frequent	Later, infrequent, feculent
Tenderness	Epigastric or periumbilical, usually mild unless strangulated	Diffuse and progressive
Distention	Absent	Diffuse and progressive
Obstipation	Absent or mild	Mild or moderate
Radiologic findings	Distended proximal small bowel loops or gasless	Diffusely distended small bowel loops, air-fluid levels

Rectal examination should always be performed in these patients to search for rectal masses that could be obstructing. The finding of hematochezia is a possible indication of a more proximal mass, inflammation, or strangulation and infarction of bowel. Fecal impaction is not an uncommon finding in older patients and often mimics bowel obstruction. As an extension of the rectal examination, proctoscopy and sigmoidoscopy are helpful in the diagnosis and treatment of distal colonic volvulus.

LABORATORY TESTS

Patients with early or partial SBO who are initially seen soon after symptoms have started may have completely normal laboratory studies. However, evidence of dehydration may be evident in the form of abnormal electrolytes and elevated blood urea nitrogen, creatinine, and hematocrit levels. Hyponatremia and hypokalemia are also common abnormalities. Metabolic acidosis occurs as a result dehydration, starvation, ketosis, and loss of alkaline fluid by way of secretion. In the setting of severe vomiting, metabolic alkalosis can occasionally be seen secondary to vomiting of acidic juices.

Mild elevation in the white blood cell count can occur in patients with bowel obstruction, but severe leukocytosis and the presence of many immature polymorphonuclear cells suggest strangulation with possible ischemia. In the case of ischemia, hyperkalemia, lactic acidosis, and elevated amylase levels may be present. It is important, however, to keep in mind that bowel ischemia may be present despite normal laboratory studies and that clinical suspicion should prompt expeditious surgical intervention.

RADIOLOGIC INVESTIGATIONS

Plain Radiographs

Although the diagnosis of SBO may be made with only a thorough history and careful physical examination, diagnostic imaging is often used to verify, locate, and assess the severity. Plain radiographs in the form of an obstruction series, otherwise known as an abdominal series, are usually the initial study obtained in a patient with abdominal symptoms. Studies include an upright chest radiograph, a supine abdominal or kidney-ureter-bladder (KUB) film, and a left lateral decubitus abdominal radiograph. The goal of these films is to rule out free intra-abdominal air, delineate the severity of bowel distention, and possibly identify the location of obstruction.

Plain films are diagnostic in only 50% to 60% of cases of SBO and are only 66% sensitive in proven cases of SBO by experienced radiologists.[15] In addition, specificity has been reported to be low because both mechanical and functional large bowel obstructions may show similar findings on plain radiographs. Nevertheless, they remain a vital initial radiographic tool because of their low cost, availability, noninvasiveness, and value as a gauge of disease progression (Fig. 68–2).

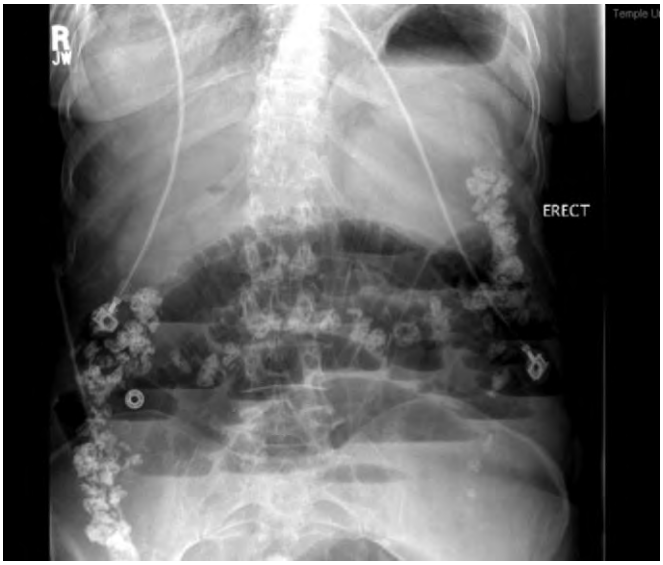

Figure 68–2. Upright abdominal radiograph showing multiple dilated small bowel loops with air-fluid levels.

Figure 68–3. Plain abdominal radiograph showing extremely distended small bowel loops with very minimal air in the colon, representative of high-grade obstruction.

Patterns suggestive of SBO include multiple loops of small bowel filled with gas or fluid and a moderate amount of gas in the colon. The finding of colonic gas indicates partial SBO, early complete SBO, or ileus. This pattern is often nondiagnostic and may require further investigational studies such as computed tomography (CT). A more definitive diagnosis of SBO can be made when dilated gas- or fluid-filled small bowel loops are seen with minimal or no gas in the colon[16] (Fig. 68–3)

Figure 68–4. Small bowel follow-through film showing distention of multiple small bowel loops, representative of distal obstruction.

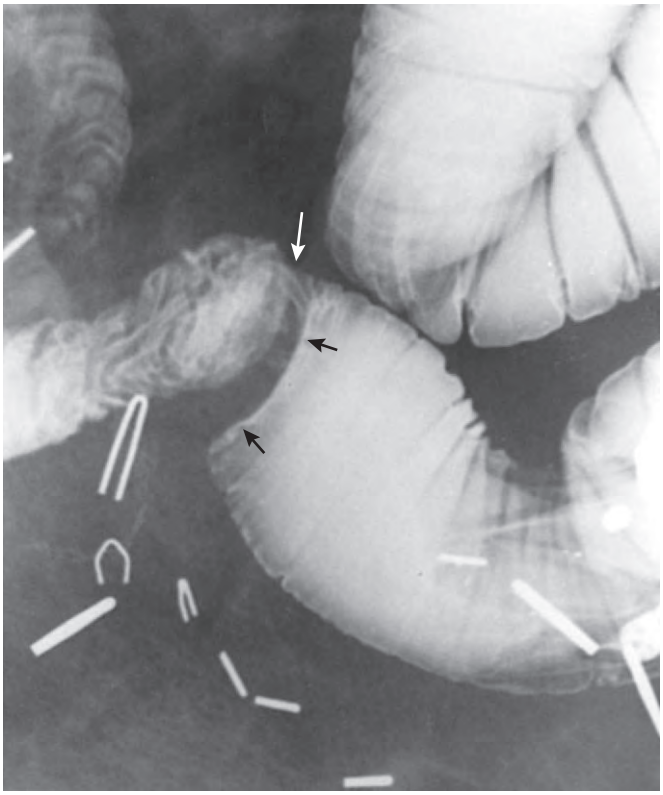

Figure 68–5. Partial small bowel obstruction with an adhesive band at the transition point *(white arrow)* between dilated proximal bowel and decompressed distal bowel. The *black arrows* point to the site of constriction caused by the band.

Contrast Radiographs

Barium films can be used for small bowel evaluation by either oral ingestion of contrast, as for **small bowel follow-through,** or as a retrograde study by way of an enema (Fig. 68–4). In the setting of high-grade SBO, these techniques have some limitations, such as dilution of barium as a result of fluid-filled dilated loops of bowel, which results in poor elucidation of mucosal detail. In addition, slow transit of contrast through the obstructed bowel may prohibit identification of sites of partial blockage or smaller lesions.[17]

Enteroclysis allows intubation of the jejunum and direct infusion of contrast boluses toward the site of obstruction regardless of the degree of peristalsis in the dilated proximal bowel. This technique has been shown to be extremely predictive of obstruction, as well as its absence, its site, and its cause. A positive diagnosis is made when a transition in luminal size is seen (Fig. 68–5). The upper limit of normal small bowel diameter by enteroclysis is 3 cm in the jejunum and 2.5 cm in the ileum.[17] This method can be especially helpful in discriminating between various causes of obstruction such as adhesions, tumors, and radiation.[18]

However, the use of enteroclysis is limited because of requirements for conscious sedation, nasojejunal tube placement, experienced staff, and extensive, time-consuming radiation exposure. In addition, once barium enteroclysis is performed to rule out obstruction, secondary imaging studies are obscured by the barium contrast. Therefore, small bowel follow-through with fluoroscopy is adequate is most situations.[19]

The therapeutic effect of water-soluble contrast is controversial. Some have shown that oral diatrizoate meglumine (Gastrografin) may have a therapeutic effect on SBO[20] and predict the need for early surgical intervention. It has been used as a mode of differentiating partial from complete SBO, thereby leading to operative intervention sooner when the latter situation is identified. After 24 hours, an operation is performed if Gastrografin is not found to have passed into the colon. In patients with partial SBO treated conservatively, hospital stay was found to be shorter and tolerance of a soft diet was noted to occur earlier. The incidence of surgery for SBO, however, was not found to be affected by Gastrografin administration.[21]

Computed Tomography

CT can be a valuable tool in the work-up for SBO. It is helpful in distinguishing SBO from other causes of bowel dilatation and can aid in the decision-making process between operative and nonoperative therapy. Although the sensitivity of CT may be as low as 48% in identifying low-grade obstruction, it is reported to be as high as 81% for high-grade obstruction.[22] CT is also very successful in delineating the cause of obstruction in greater than 90% of cases[19] and in diagnosing ischemic bowel, as well as its precipitating factors, including bowel volvulus, torsion, and intussusception (Fig. 68–6). Additionally, CT is a particularly helpful study for diagnosing external and internal hernias, such as an obturator hernia.

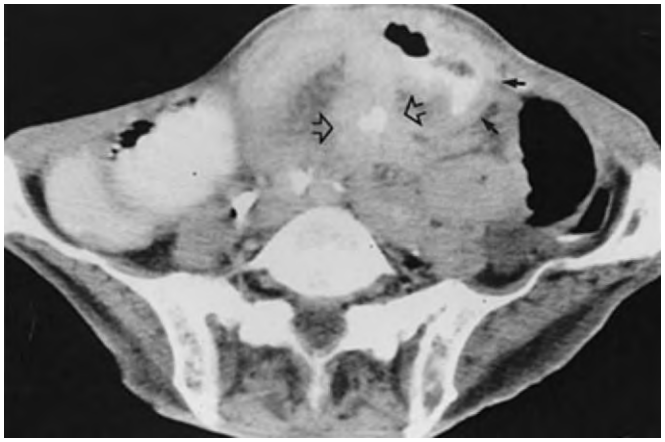

Figure 68–6. Computed tomography scan of the lower part of the abdomen. Dilated bowel loops surround a large mesenteric mass *(open arrows).* In one bowel loop, wall thickening is demonstrated *(solid arrows).*

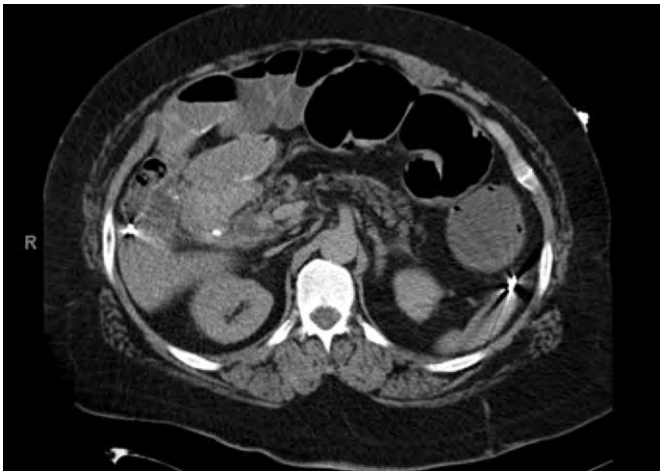

Figure 68–8. Computed tomography scan of the upper part of the abdomen showing high-grade or complete bowel obstruction with decompressed colon.

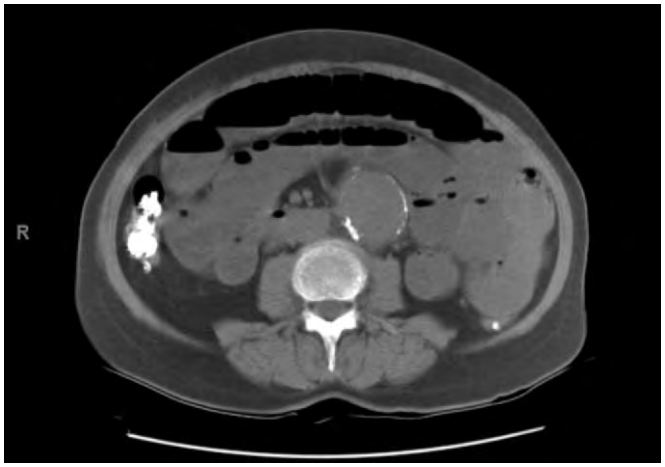

Figure 68–7. Computed tomography scan of the abdomen showing high-grade partial distal small bowel obstruction.

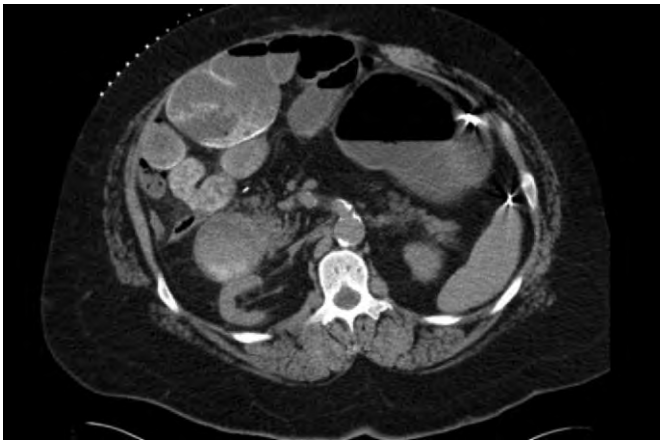

Figure 68–9. Computed tomography scan of the upper abdomen showing dilated loops of proximal small bowel with air-fluid levels adjacent to less dilated, more distal loops of small bowel.

Findings of partial SBO on CT include mildly dilated small bowel loops (>2.5 cm in diameter) with an ill-defined transition point and incompletely collapsed distal bowel in the setting of a moderate amount of gas and fluid in the colon (Figs. 68–7 to 68–9). To distinguish partial SBO from early high-grade SBO, oral contrast is expected to enter the colon within 6 hours, which may be confirmed by follow-up radiography or CT.[23]

For chronic, intermittent partial SBO, CT performed during the symptomatic period may be diagnostic. Alternatively, CT enteroclysis in this setting better delineates findings that may otherwise be missed, such as adhesions or small tumors, but still require surgical intervention. CT enteroclysis combines infusion of water-soluble contrast via a nasointestinal tube into the jejunum with CT imaging. This technique may also improve the low-yield results in cases of low-grade SBO by improving mucosal detail and the distensibility of the small bowel.

When high-grade obstruction, volvulus, torsion, intussusception, other causes of strangulation, or ischemia or infarction is not apparent on CT, conservative management with avoidance of an operation is reasonable. This strategy may prevent significant morbidity and mortality in patients who are at high risk for general anesthesia and abdominal surgery.

In cases of closed-loop obstruction, the involved segment of bowel is nearly completely filled with fluid, and the more proximal portion of the bowel is likely to contain air-fluid levels. The mesentery may also show a whorl sign, suggestive of twisted mesenteric vessels.[24] As for bowel strangulation, its findings are those of ischemic bowel, represented by ascites, a thickened wall, increased

mural attenuation, and the target sign when intravenous contrast is administered. Additionally, pneumatosis, portal venous gas, mesenteric congestion, and hemorrhage may be seen in advanced ischemia.[19]

Another useful situation for CT imaging of SBO is in patients with preexisting pathology, such as abdominal malignancy or inflammatory processes. As a fairly noninvasive, reproducible, and readily available study, it serves a generally useful purpose as an early diagnostic study after initial plain radiographs are obtained. In addition, in the acute setting of evaluation for abdominal pain in the emergency department, CT is a reliable initial study to rule out other causes of pain.

MEDICAL TREATMENT

A patient in whom SBO is diagnosed should be admitted to the hospital, hydration instituted, electrolytes corrected, and a nasogastric tube placed. If the diagnosis is **partial** SBO with no evidence of complete obstruction, strangulation, or ischemia, conservative, nonoperative management may be instituted. Such management entails ensuring adequate intravenous hydration, close monitoring of urine output with or without a Foley catheter, nasogastric tube drainage, and frequent assessment of the patient's abdominal examination. A central venous pressure or pulmonary capillary wedge pressure monitor may also be necessary for fluid management in more complex cases. Approximately 80% to 90% of partial SBO cases resolve spontaneously with conservative measures.

In cases of postoperative SBO, long-tube decompression, such as with a Miller-Abbott tube, may be helpful. This topic is discussed further in the following section.

Long-Tube Decompression

Long-tube decompression has been used since the 1930s when Wangensteen reported advancing a long tube into the jejunum to the point of obstruction during exploratory laparotomy. Recovery was seen in 80% of these patients with no other intervention.[25] Later, Abbott and Johnston passed the Miller-Abbott tube via the nose into the duodenum and inflated the distal balloon, which then allowed the tube to reach the point of obstruction by peristalsis. This technique was successful in relieving the obstruction in 80% of cases.[26] A major disadvantage was the time delay inconvenience caused by the dependence on peristalsis for advancement of the tube to the appropriate position.

In the 1970s and 1980s, endoscopic placement of long tubes into the small bowel was introduced and eliminated the need to wait for spontaneous migration of the tube. This technique was reported to take as little as 20 minutes for placement into the jejunum,[27] with immediate decompression. Success rates were reported to be as high as 90%.[28]

SURGICAL TREATMENT

Surgery is indicated early in the management of complete SBO or high-grade partial SBO. If there is any indication of bowel incarceration, strangulation, or ischemia, an urgent operation should be performed after adequate resuscitation. Exceptions to early operative intervention may be cases of inflammatory bowel disease, radiation enteritis, and some cases of carcinomatosis in the absence of clinical signs of deterioration. These situations may best be managed conservatively in light of the limited benefits and potential high risks associated with operative management.

In cases of nonoperative management of partial SBO, factors prompting surgical intervention include (1) worsening abdominal pain and distention; (2) findings of peritonitis, fever, and leukocytosis; (3) failure of resolution of complete obstruction within 12 to 24 hours; and (4) failure of improvement of partial obstruction after 48 to 72 hours or progression to complete obstruction. Most cases of partial SBO secondary to adhesions resolve when managed conservatively, with only 10% to 20% requiring operative correction.

The decision to operate for SBO is not as straightforward in cases of early postoperative obstruction. Most surgeons initially manage these cases expectantly up to 4 weeks before operative intervention is performed. If reoperation is attempted before this time, dense and vascular adhesions may cause significant morbidity with an increased risk for enterotomy and bleeding. Pickleman and Lee reported resolution of postoperative obstruction in 96% of patients within 2 weeks, with the unlikelihood of resolution after 10 days.[29] Certainly, if symptoms or physical findings worsen during the waiting period, as well as the previously mentioned laboratory or radiologic abnormalities, surgical intervention should be implemented in timely fashion.

Laparoscopic Versus Open Adhesiolysis

Since laparoscopic cholecystectomy was introduced in the 1980s, increasing experience by surgeons has broadened the use of minimally invasive techniques in both elective and urgent situations. Laparoscopic adhesiolysis was first described in 1991,[30] and many other reports have been published ever since. Advantages over laparotomy include less postoperative pain, shorter time to return of bowel function, shorter hospital stay, shorter recovery time, fewer wound complications, and decreased adhesion formation. Although no prospective randomized trials comparing laparoscopic and open adhesiolysis for SBO are available at present, retrospective studies, albeit with short follow-up, indicate the safety of laparoscopy with the aforementioned benefits in the appropriate patient population.

Laparoscopy should be avoided in patients with peritonitis or free air requiring emergency exploration. Emergency laparoscopic adhesiolysis has been reported to result in a 36% conversion rate to laparotomy versus 7% when performed electively.[31] In addition, the degree of abdominal distention, bowel diameter (<4 cm),[32] and site of obstruction are important factors when considering laparoscopy. A correlation between the number of previous abdominal operations and successful laparoscopic adhesiolysis is controversial.[33]

Regardless of the method of surgery, adequate resuscitation of patients preoperatively is invaluable. Electrolytes should be corrected, urine output closely monitored, usually with a Foley catheter, and a nasogastric tube placed for decompression. Antibiotics should also be given approximately 1 hour before an incision is made.

Operative Treatment

The surgical approach depends on the suspected cause of obstruction, as well as the intra-operative findings. If adhesions are the presumed cause, laparoscopy or laparotomy is performed with careful and gentle handling of the inflamed, distended, and edematous bowel and friable mesentery. Once the point of obstruction is located and the adhesions released, the entire bowel should be inspected, and depending on the severity and comorbid conditions of the patient, placement of gastric or enteral draining tubes or feeding tubes (or both) should be considered. For example, when faced with a particularly lengthy or complex case, placement of a draining gastrostomy tube may allow early postoperative removal of the nasogastric tube and prevent its potential complications.

If an incarcerated or strangulated hernia is the culprit, the contents should be reduced after induction of general anesthesia if it can be accomplished without difficulty. Before repair of the defect, the visceral contents should be inspected to ensure viability, particularly in cases of suspected strangulation and ischemia.

When mass lesions are the cause of obstruction, partial bowel resection is performed with or without primary anastomosis, as determined on a case-by-case basis. In less common cases of obstruction from carcinomatosis or radiation, intestinal bypass may be warranted as a palliative measure. Obstruction secondary to Crohn's disease should be resected if minimal inflammation is present and fibrosis is the major component of this mostly isolated area of disease.

Prevention of Adhesion

Adhesions after abdominal surgery are the most common cause of SBO. In particular, colorectal surgery is noted to be one of the largest offenders, especially after proctocolectomy and ileal pouch–anal anastomosis. In addition to the morbidity and mortality caused by SBO and its treatment modalities, the financial burden is also noteworthy. In 1996, more than $3.2 billion was paid by Medicare for adhesion-related complications, and more than $1.3 billion was attributed to adhesiolysis costs in 1994 in the United States.[34] In fact, recurrent SBO developed in approximately a third of patients who underwent adhesiolysis for SBO, with most occurring in the first 5 years postoperatively. However, a quarter were found to have SBO complications more than 10 years later.

Various substances and methods have been used for the prevention of adhesions over the past 100 years. Technical efforts such as gentle tissue handling, minimal use of foreign materials, careful hemostatic measures, and prevention of infection, ischemia, and desiccation have failed to achieve satisfactory results. Substances have also been used with minimal success, including amniotic fluid, bovine cecum, shark peritoneum, fish bladder, vitreous of calf's eye, lubricants, gels, polymers, and various physical barriers.

One notable form of physical barrier is a sodium hyaluronate–based bioresorbable membrane, Seprafilm, which persists in the abdomen for 5 to 7 days.[35] It has been studied in multiple large populations undergoing colorectal surgery. Studies showed decreased incidence, severity, and extent of adhesions after abdominopelvic procedures involving colorectal and gynecologic surgery at the locations of application.[36] In a large, prospective, randomized, multicenter, single-blind controlled study, it also was found to cause fewer cases of adhesive SBO requiring surgery. The number of cases of SBO, however, was not different from that of the control group.[37] Other anti-adhesive substances and techniques are also undergoing extensive research for safety and efficacy.

Volvulus of the Stomach and Small Bowel

Rebekah R. White ▪ Danny O. Jacobs

The term *volvulus* derives from the Latin word *volvere,* meaning to turn or roll. Clinically, *volvulus* refers to a greater than 180-degree twisting of a hollow organ about its mesentery and results in luminal obstruction, impaired venous return, and eventually ischemia. Though much less common than volvulus of the cecum and sigmoid colon (discussed elsewhere), small bowel volvulus and gastric volvulus are clinical problems that when not recognized promptly, can lead to necrosis of the involved organ with resultant high morbidity and mortality.

SMALL BOWEL VOLVULUS

Etiology

Small bowel volvulus is typically categorized as primary or secondary. Primary small bowel volvulus is relatively rare in the United States but is one of the most common causes of small bowel obstruction in many African and Asian populations. The reported annual incidence ranges from 1.7 to 5.7 per 100,000 population in Western countries as compared with 24 to 60 per 100,000 population in Africa and Asia.[1] Young adults are primarily affected, with a strong male preponderance. Small bowel volvulus is responsible for less than 5% of small bowel obstructions in Western series[2-4] and over half of small bowel obstructions in some African and Asian series.[5,6] The incidence of small bowel volvulus varies not only by country but also by region within certain countries and correlates with lower socioeconomic status.[7] These patterns have been attributed to the high-fiber, vegetarian diet consumed in these populations, as well as to the high proportion of laborers and farmers, who tend to eat infrequent, large meals.[7,8] An increased incidence of small bowel volvulus has been observed during Ramadan, when Muslims ingest large quantities of high-fiber food after prolonged fasting.[8] The incidence of small bowel volvulus is also higher in regions with endemic parasitism, which is known to increase bowel motility.[1] A particularly high incidence of small bowel volvulus was discovered in a Ugandan tribe that consumed a large amount of a beer rich in serotonin,[9] and laxative bowel preparation has been described as a precipitating factor.[10] In 80% of cases the intestinal torsion is clockwise, as it is for midgut volvulus associated with congenital malrotation.[11] However, although congenital malrotation can rarely be manifested in delayed fashion as midgut volvulus, only a minority of adolescent and adult patients with primary small bowel volvulus have an identified lack of mesenteric fixation. Anatomically, the small bowel in high-risk populations is longer and has a longer mesentery with a narrower insertion and a lack of mesenteric fat.[11] Interestingly, patients with small bowel volvulus are not usually emaciated but rather have firm, muscular abdomens, which theoretically might limit the mobility of bowel in the anterior-posterior plane.[5] Whether these observed differences are causative or merely correlative is unclear. Taken together, however, such observations support a popular theory that rapid filling of a segment of proximal intestine with high-bulk chyme pulls it down into the pelvis and displaces empty distal bowel upward, thereby initiating the torsion.

In contrast, secondary small bowel volvulus is much more common than primary small bowel volvulus in the United States. In secondary small bowel volvulus, the intestine is twisted around an underlying point of fixation; as the loop fills with fluid, peristalsis exacerbates the torsion. By far the most common point of fixation is a postoperative adhesion. Case reports have described a number of other causes, however, including internal hernias,[12] tumors,[13] mesenteric lymph nodes,[14] Meckel's diverticulum,[2] and pregnancy.[15] In the most recently published Western series, Roggo and Ottinger from Massachusetts General Hospital (MGH) reported 35 patients with small bowel volvulus; these patients represented 4% of all small bowel obstructions over the 10-year study

Table 69–1 Modern Series of Small Bowel Volvulus

Author	Roggo	Ghebrat
Country	USA	Ethiopia
Study period	1980-1990	1995-1997
Number of patients	35	51
Male-female ratio	1:1.2	12:1
Average age	67	37
Primary small bowel volvulus	14%	92%
Gangrenous small bowel	46%	18%
Mortality overall	9%	12%
Mortality from gangrene	17%	NS

NS, not stated.

period (1980 to 1990).[2] In five patients (all men), the volvulus was primary. In 29 of the remaining 30 patients, the volvulus was secondary to postoperative adhesions. Unlike primary small bowel volvulus, secondary small bowel volvulus affected both sexes equally and mainly older adults. This study is compared with a contemporary series by Ghebrat et al. from Ethiopia[5] in Table 69–1, which illustrates some of the differences between primary and secondary small bowel volvulus.

Diagnosis

Clinically, the findings in patients with small bowel volvulus are nonspecific. Patients have signs and symptoms of small bowel obstruction that are usually sudden in onset. Central abdominal pain is almost always present.[1,2,5] In some cases, careful questioning may elicit a previous history of intermittent obstructive symptoms such as crampy epigastric or periumbilical abdominal pain. "Pain out of proportion" to the degree of obstruction should raise suspicion of vascular compromise, as should fever, tachycardia, peritoneal signs, acidosis, and leukocytosis. However, none of these signs alone are sensitive or specific enough to reliably rule bowel ischemia in or out. For example, in the MGH series, 9 of 35 patients (26%) with small bowel volvulus had peritoneal signs and two thirds of these patients had gangrenous bowel; 10 of the 26 patients without peritoneal signs had gangrenous bowel.[2]

Plain films are usually nonspecific and demonstrate dilated loops of bowel or air-fluid levels, or both. However, in a closed-loop obstruction such as volvulus, the loops may be filled with fluid and have little or no air. Thus, plain films may reveal a "gasless" abdomen or even be interpreted as normal.[16] In patients with gangrenous bowel, plain films may reveal pneumatosis or portal venous gas. However, these findings are notoriously insensitive and late signs. Gastrointestinal contrast studies may show a corkscrew pattern or an abrupt "bird beak" at the point of obstruction, and angiography may demonstrate a spiraling pattern of the mesenteric vessels.[14] However, these modalities have largely been replaced in the evaluation of acute small bowel obstruction by computed tomography (CT), which is rapid, noninvasive, and widely available. CT findings characteristic of a closed-loop obstruction include a radial distribution of dilated bowel loops converging toward a point of torsion or a C- or U-shaped loop of horizontally oriented, fluid-filled bowel.[17] The rotation of the mesentery may generate a "whirl" sign, which is virtually pathognomonic for small bowel volvulus (Fig. 69–1). Mesenteric thickening may be present as a result of previous intermittent, incomplete volvulus. Though not specific for volvulus, small bowel wall thickening, pneumatosis, portal venous gas, and free intraperitoneal fluid suggest small bowel ischemia.

Treatment

Evidence of ischemia mandates immediate exploration and resection of the involved, gangrenous small bowel. Suspicion of volvulus clinically or radiographically should also prompt immediate exploration because of the associated risk for ischemia. In Western series, up to 50% of patients with small bowel volvulus will require resection for gangrenous small bowel.[2] The rarity of small bowel volvulus in our society may lead to a delay in diagnosis and a higher incidence of gangrenous small bowel than in Asian and African series. Overall mortality in patients undergoing exploration for small bowel volvulus ranges from 10% to 35%,[1] which is considerably higher than that for small bowel obstruction in general. These overall mortality rates are attributable to the large proportion of patients with gangrenous bowel, in whom mortality rates are between 20% and 60% in most series.[1]

For patients without ischemic bowel, the optimal treatment is less clear. No prospective, randomized

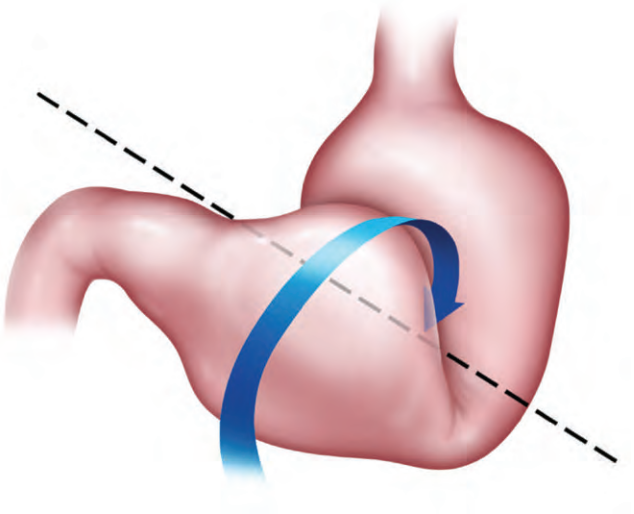

Figure 69–2. Organoaxial rotation occurs when the stomach rotates around a transverse line between the pylorus and gastroesophageal junction.

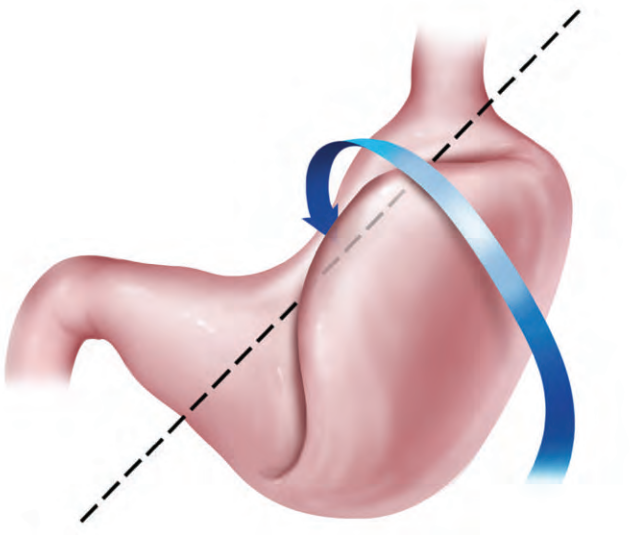

Figure 69–3. Mesenteroaxial rotation occurs when the stomach rotates around a longitudinal line parallel to the gastrohepatic omentum.

studies or even retrospective studies have addressed the issue of recurrence. Most studies describe simple detorsion without resection but rarely include long-term follow-up. The risk for recurrent volvulus is therefore not well established. Intestinopexy of a long segment of bowel is technically difficult and not recommended. In neonatal midgut volvulus caused by malrotation, intestinopexy is not routinely performed, and rates of recurrence are considered acceptably low. It is believed that the formation of intraperitoneal adhesions after laparotomy should prevent most recurrences. However, some authors have recommended resection of involved, nongangrenous intestine in order to prevent recurrent volvulus,[1] although the risk for short-gut syndrome prohibits this approach if a long segment of bowel is involved.

GASTRIC VOLVULUS

Etiology

Similar to small bowel volvulus, gastric volvulus occurs when the stomach or a portion of the stomach is rotated at least 180 degrees along its transverse or longitudinal axes. Gastric volvulus can be classified according to anatomy, etiology, or onset (acute or chronic). As defined by Singleton, organoaxial rotation is the most common (two thirds of cases) and occurs when the stomach rotates around a transverse line between the pylorus and the gastroesophageal junction (Fig. 69–2).[18] Mesenteroaxial rotation is less common (one third of cases), and the stomach rotates around a longitudinal line parallel to the gastrohepatic omentum (Fig. 69–3).

In 10% to 30% of cases the gastric volvulus is considered primary and results from laxity of the stomach's ligamentous attachments (gastrohepatic, gastrocolic, gastrolienal, and gastrophrenic).[19] Primary gastric volvulus has been seen in association with congenital asplenia and with "wandering spleen."[20] Primary gastric volvulus is usually mesenteroaxial, with the pylorus rotating anteriorly (more common) or posteriorly from right to left.[21] Rarely, the fundus rotates around the same axis. As the stomach fills with fluid, the torsion is exacerbated. This type of volvulus is usually incomplete (less than 180 degrees) and is accompanied by chronic or intermittent symptoms.[19]

In the majority of cases, gastric volvulus is secondary to another anatomic abnormality, the most common of which is diaphragmatic hernia. Gastric volvulus is therefore commonly referred to as an intrathoracic "upside-down" stomach. Most cases of secondary gastric volvulus are organoaxial, with the greater curvature rotating up into the chest either anteriorly (more common) or posteriorly with respect to the fixed duodenum and esophagus.[19] Despite the rich blood supply of the stomach, strangulation can occur with torsion greater than 180 degrees and is much more common with organoaxial than with mesenteroaxial volvulus.[22] Paraesophageal hiatal hernia is the most common cause in adults as well as in children, whereas congenital diaphragmatic hernia (left-sided Bochdalek) is an additional common cause in children.[23] However, gastric volvulus has also been described in association with traumatic diaphragmatic hernia, diaphragmatic eventration,[24] and even Morgagni hernia.[25] Although secondary gastric volvulus is typically intrathoracic and occurs as a result of diaphragmatic hernia, secondary intra-abdominal gastric volvulus has also been reported to occur as a result of tumors[26] and after a variety of surgical procedures, including Nissen fundoplication[27] and gastric banding.[28]

Diagnosis

The clinical manifestation of acute gastric volvulus can be quite dramatic. In 1904, Borchardt described the triad

of epigastric pain, retching with an inability to vomit, and difficulty or inability to pass a nasogastric tube. This triad describes acute organoaxial volvulus; the gastroesophageal junction is open in acute mesenteroaxial volvulus, and nasogastric tube placement should not be difficult. For patients with intrathoracic gastric volvulus, the abdominal findings may be minimal. Rather, the "gastrothorax" may cause chest pain, shortness of breath, and symptoms secondary to mediastinal compression, including arrhythmia and tamponade.[22,29,30] When gastric strangulation or perforation has occurred with either intra-abdominal or intrathoracic gastric volvulus, signs of gastrointestinal bleeding and septic shock may be evident.

In contrast, the signs and symptoms of chronic gastric volvulus may be vague and intermittent, or it may be an incidental finding on an imaging study. Symptoms of chronic primary gastric volvulus include upper abdominal discomfort, vomiting, early satiety, and dysphagia.[19,31] In addition to these obstructive symptoms, patients with chronic intrathoracic gastric volvulus may describe postprandial chest pain or shortness of breath. The differential diagnosis is broad and includes many much more common diseases, such as gastroesophageal reflux disease and peptic ulcer disease.

Radiographically, the diagnosis of primary gastric volvulus may be difficult to establish because the volvulus is often intermittent. Plain films may demonstrate a spherical stomach on supine views and a double air-fluid level on upright views. A retrocardiac air-fluid level on a lateral chest radiograph is highly suggestive of secondary gastric volvulus with an intrathoracic stomach. In the right clinical situation, further imaging studies may not be necessary. However, an upper gastrointestinal contrast study will confirm the diagnosis by demonstrating a contrast-filled stomach above a normally located gastroesophageal junction with narrowing at the site of the volvulus (Figs. 69–4 and 69–5).

Figure 69–4. Upper gastrointestinal contrast study demonstrating a paraesophageal hernia with organoaxial volvulus. The greater curvature is intrathoracic, and the pylorus is in close proximity to the normally positioned gastroesophageal junction.

Treatment

For acute gastric volvulus, the traditional treatment is emergency laparotomy with reduction of the volvulus. Mortality rates as high as 30% to 50% have been reported for this condition, with the major cause of death being sepsis secondary to gastric strangulation.[19,22] Strangulation leads to gastric necrosis with or without perforation and requires resection by either local excision, subtotal gastrectomy, or even total gastrectomy. Other reported complications include ulceration, gastrointestinal hemorrhage, omental avulsion, splenic rupture, and pancreatic necrosis. Once the volvulus has been reduced and emergency conditions addressed, the goal of surgery is to prevent recurrence by fixing the stomach to the abdominal wall and correcting any predisposing conditions. Anterior gastropexy is easily accomplished by placement of a gastrostomy tube. The short gastric vessels should be preserved, if possible, both to retain their blood supply and to help anchor the greater curvature. In the case of gastric volvulus secondary to diaphragmatic hernia, the diaphragmatic defect should be repaired, although in septic or medically high-risk patients, reduction and gastropexy alone may be safer and sufficient, particularly in those with limited life expectancy. Otherwise, the best way to repair the diaphragmatic defect is debatable. Although retrospective data suggest that prosthetic mesh prevents recurrence, the risk for infection in the setting of gastric necrosis may be increased, and mesh should therefore be used selectively.[32]

For chronic gastric volvulus, the more important issues are whether and when to operate. It is difficult to know the percentage of patients with a diaphragmatic hernia and intrathoracic stomach who will progress to acute gastric strangulation. However, the high morbidity and mortality associated with such strangulation justify expeditious repair, even in asymptomatic patients. In contrast, chronic primary gastric volvulus is often intermittent and is much less likely to become strangulated. In the pediatric population, primary gastric volvulus has been successfully managed with nonoperative "postural" therapy and does not routinely require surgical intervention.[33]

More recently, endoscopic and laparoscopic approaches to both acute and chronic gastric volvulus have been popularized. In select cases of acute gastric

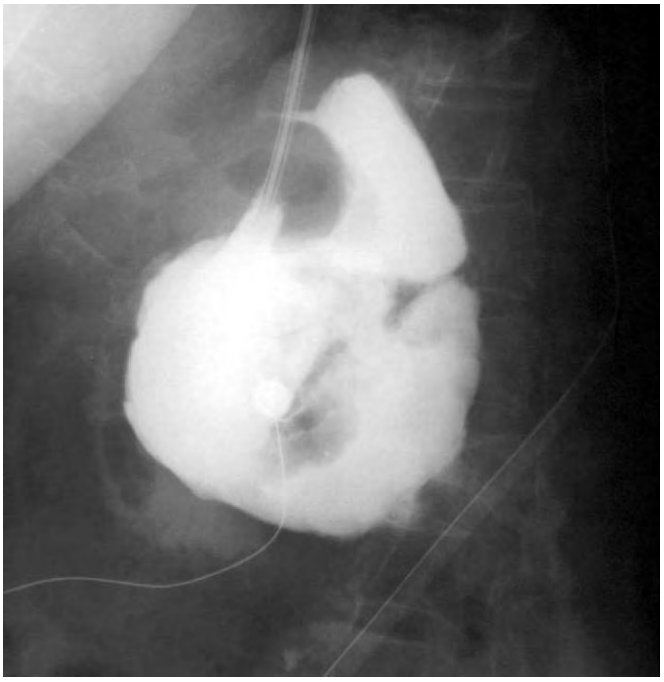

Figure 69–5. Upper gastrointestinal contrast study demonstrating a paraesophageal hernia with complete obstruction of the stomach because of volvulus. The patient was found to have gastric necrosis at exploration.

volvulus without gastric necrosis, gastric decompression—either by placement of a nasogastric tube or endoscopically—may convert an emergency to an urgent operation or even avoid an operation altogether. Endoscopic reduction of an intrathoracic stomach is relatively difficult. Various techniques have been described, including the use of two endoscopes[34] and expansion of an intragastric balloon.[35] Once the stomach has been reduced, gastropexy is relatively simple and is achieved by placement of a percutaneous endoscopic gastrostomy (PEG) tube. In the first description of endoscopic reduction, two PEG tubes were placed to help prevent recurrent volvulus.[36] Purely endoscopic techniques, however, are best reserved for high-risk patients because these techniques do not address the underlying pathology. In contrast, laparoscopic approaches[37] and combined laparoscopic and endoscopic approaches[38] have the potential to combine minimally invasive techniques with repair of the diaphragmatic defect. Although no randomized, controlled studies have been conducted, Teague et al. compared the results of open (13 patients) and laparoscopic (18 patients) repair in patients with acute or chronic gastric volvulus. Laparoscopic repair was technically difficult (three conversions to open procedures) but was safe and associated with a shorter hospital stay.[39]

SUMMARY

Small bowel volvulus and gastric volvulus are uncommon problems in this country and are often diagnosed in delayed fashion. Early recognition and treatment may help prevent the morbidity and mortality associated with small bowel and gastric ischemia.

ACKNOWLEDGMENT

The authors acknowledge William M. Thompson, MD, for providing the radiographic images of small bowel and gastric volvulus.

Crohn's Disease: General Considerations, Medical Management, and Surgical Treatment of Small Intestinal Disease

D. Wayne Overby · Mark J. Koruda

GENERAL CONSIDERATIONS, MEDICAL THERAPY

Crohn's disease is a transmural inflammatory disease that can involve any part of the gastrointestinal tract from the mouth to the anus. Despite the large body of published literature and ongoing study dedicated to Crohn's disease, it remains an incurable disease of unknown etiology. Clinicians are faced with the difficulty of diagnosing and treating patients with a heterogeneous disease that has an array of features and manifestations.

Epidemiology

Wide variations in the incidence and prevalence of Crohn's disease have been reported. These differences may be due to diagnostic variations compounded by variations in reporting, or they may be due to real differences in genetic and environmental factors among geographically distinct populations.[1] Interestingly, these differences seem to follow political borders rather than natural boundaries. There have been studies showing increasing incidence at greater latitudes, but these results have not been universally observed.[1,2] Differences related to socioeconomic status have also been reported, with increasing affluence imparting increased risk, but this association has not been borne out in more recent studies. Moreover, it is useful to remember that with differences in affluence come differences in diet, hygiene, and population density,[2] all of which are the essence of cultural westernization.

The prevalence of Crohn's disease in North America has been estimated to be 26.0 to 198.5 cases per 100,000 people (recently, 144 to 198 cases per 100,000). Given the prevalence reported in the two most recent studies and given a population estimated to be 300 million, there are 400,000 to 600,000 cases of Crohn's disease in North America. Recent studies have demonstrated higher prevalence rates with relatively stable rates of incidence, thus suggesting that patients may be living longer with the disease. The incidence of Crohn's disease in recent studies has varied from 3.1 to 14.6 cases per 100,000 person-years. Again assuming a population of 300 million, Crohn's disease is diagnosed in 9000 to 44,000 people in North America yearly. There appears to be a slight female preponderance, with female prevalence ranging from 50% to 60% in most studies. The mean age at diagnosis in most North American cohorts is between 33 and 39 years, with the disease being diagnosed in the majority of patients in their second or third decade of life; a second peak was found in the sixth or seventh decade in roughly half of cohorts, which has given rise to the idea of bimodal distribution of disease with regard to age.[1] The second peak may be due to differences in environment leading to differences in disease expression or variations in diagnosis, or it may in fact represent a delay in diagnosis as the disease relapses.[1,2]

Natural History

The severity of disease observed in any group of patients with Crohn's disease will exist on a continuum from asymptomatic, to medical or surgical remission, to mild, moderate, or severe disease. There are European and North American cohorts that are probably the best-studied populations outside specialty referral centers. These studies indicate that among patients in their first year after diagnosis, 80% had high disease activity, 15% had low activity, and 5% were in remission.[3] At any point in time after the first year, examination of a group of patients with Crohn's disease will find a majority (approximately 65%) in remission, with another 25% experiencing low activity and 10% experiencing high activity; 13% will have chronically active disease. About 43% of cohort patients required steroids during the course of their disease, whereas 10% of patients in any given year required steroids and 30% of patients in any given year required sulfasalazine or 5-aminosalicylate products. Up to 57% of patients required at least one surgical resection. In most patients, Crohn's disease has a relapsing and remitting course, with relatively small numbers of patients experiencing prolonged remission or unremitting disease.[1] Mortality in patients with Crohn's disease is slightly increased in cohort studies with long-term follow-up; the absolute difference in survival at 20 years was 6% to 7%.[4-6] The most unfortunate aspect of Crohn's disease may be that it strikes the majority of patients in the prime of their lives, which increases the potential for early long-term or permanent disability, so aside from direct medical costs, there are indirect costs associated with decreased productivity.[7]

Risk Factors and Pathogenesis

Respected authors bemoan the lack of knowledge regarding the underlying causes of Crohn's disease. It is generally accepted that a combination of environmental and genetic factors are at work to produce altered mucosal integrity of the gastrointestinal tract and complex alterations in local and systemic immune response.

Environmental Factors

A number of environmental factors have been implicated in Crohn's disease, including microorganisms of both infectious and commensal varieties; smoking; various components of diet; medications, including antibiotics, nonsteroidal anti-inflammatory drugs, and oral contraceptives; and hygienic factors, with increasing hygiene imparting increased risk. It is generally accepted that cigarette smoking, though not a cause, makes Crohn's disease worse, but no other single environmental factor or combination of environmental factors has been convincingly implicated as causative. One widely held hypothesis suggests that Crohn's disease is manifested when genetically predisposed individuals are exposed to an environmental trigger or triggers.[8-11]

Genetic Factors

As for genetic predisposition, it has long been known that there exist familial aggregations of inflammatory bowel disease. The finding that disease concordance is much higher in monozygotic twins (44%) than dizygotic twins (3.8%)[12] adds weight to the argument that genetics plays a significant role in the development of inflammatory bowel disease while at the same time suggesting a potentially complex relationship between environmental factors, genetic susceptibility, and incomplete phenotypic penetrance.[13] Recent studies using DNA screening and linkage analysis of members in affected kindreds have identified nine genetic susceptibility loci for inflammatory bowel disease (*IBD1* to *IBD9*). Mapping of the *IBD* loci led to the identification of a gene that increases susceptibility to Crohn's disease.[14]

Variants of a gene in the *IBD1* locus (16q12), which was named *NOD2* on discovery and later renamed *CARD15* (for caspase activation and recruitment domain), cause susceptibility to ileal Crohn's disease; *CARD15* polymorphisms are not linked to ulcerative colitis. The *CARD15* gene product and the pathway in which it is involved have been studied extensively. After stimulation with lipopolysaccharide or proinflammatory cytokines such as tumor necrosis factor-α (TNF-α), the *CARD15* gene is expressed in cells such as monocytes, macrophages, dendritic cells, and small intestinal Paneth cells (Paneth cells are most numerous in the terminal ileum). The *CARD15* gene product is a cytoplasmic protein that probably acts as a pattern recognition receptor for a breakdown product of the peptidoglycan that is a cell wall component of gram-negative and gram-positive bacteria; the proteolysis occurs in phagocytes and the resulting substance is called muramyl dipeptide. Muramyl dipeptides are subsequently transported into the cytoplasm of cells, where they bind to the CARD15 protein, which in turn activates a signaling cascade that leads to translocation of nuclear factor κB (NF-κB) into the nucleus. Translocation is followed by activation of NF-κB responsive genes, which leads to the production of proinflammatory cytokines. In this way, CARD15 is a part of the innate immune system. It may be that the CARD15 polymorphisms found in patients with Crohn's disease lead to decreased cellular apoptosis, which could in turn cause the overexpression of NF-κB that is seen in Crohn's lesions. Although CARD15 variants increase susceptibility to Crohn's disease, the relationship is complex and not fully understood.[12-14]

The three common mutations that account for 82% of mutated alleles of the *CARD15* gene can be found in up to 50% of patients with Crohn's disease, but they can also be found in 20% of normal individuals, so *CARD15* mutations are neither necessary nor sufficient for expression of the disease; *CARD15* variants account for only 20% of the genetic susceptibility to Crohn's disease in white individuals, whereas *CARD15* variants are absent in Asian and sub-Saharan African populations. However, when compared with normal individuals, the odds ratio for the development of Crohn's disease in heterozygous carriers is 2 to 3, and for homozygous carriers it is 20 to 40. Questions about the benefit of genetic screening of

the general population or family members of carriers are sure to arise; detailed answers to such questions are beyond the scope of this text, but the bottom line answer is that there is no benefit.[13,14] For a more detailed understanding of the current work regarding genetic susceptibility to Crohn's disease, the authors recommend reading the references cited for this section.

Pathology

Crohn's disease is a transmural inflammatory disease with discontinuous lesions that can involve any part of the gastrointestinal tract from the mouth to the anus, but most commonly it involves the ileocecal region. The relapsing and remitting course of Crohn's disease is marked by pathologic changes that are manifested in the clinical course; as the disease flares and abates, the gross and microscopic findings change.

Gross Features

The active phase of the disease is marked initially by the formation of aphthous ulcers that can involve any part the gastrointestinal tract mucosa. The ulcers are small, flat, and soft with a whitish center and red border. As the inflammation continues, the ulcers deepen; eventually they become transmural, and in turn they may lead to deep fissures that can cause abscess formation, fistulization, and in rare cases, free perforation as penetration occurs. The ulcers are scattered at first, but as they progress, they coalesce; the islands of normal mucosa that remain give the mucosal surface a cobblestone appearance (Fig. 70–1). When the involved organ is intestine, continued inflammation causes thickening of the bowel wall with narrowing of the lumen, concomitant thickening of the adjacent mesentery, and wrapping of the outer surface by fat that creeps from the mesentery. The mesenteric involvement includes engorged lymphatic channels and enlarged lymph nodes. As the disease abates and heals, fibrosis and stricture of previously inflamed areas can occur (Fig. 70–2).[8,15,16]

Anatomically, the disease is discontinuous and segmental, which has given rise to the descriptive term *skip lesions;* 29% of patients have disease confined to the small intestine, in 27% it is confined to the colon, and 41% have disease involving both the colon and small intestine, so overall, 70% of patients with Crohn's disease have small bowel involvement.[17] Although the exact incidence and prevalence of upper gastrointestinal Crohn's disease is not known and such involvement is historically rare, it is thought that improvements in diagnostic techniques have led to an increasing incidence in recent reports. Careful examination and biopsy of the upper gastrointestinal tract in patients with known distal disease will reveal histologic evidence of proximal Crohn's disease in a significant number (in as many as 30% to 50% of patients in recent studies), although many will lack upper gastrointestinal symptoms. Upper gastrointestinal Crohn's disease has been most frequently found in the gastric antrum and duodenum, with only rare involvement of the esophagus and remainder of the stomach.[18]

Microscopic Features

The microscopic pathologic changes begin as inflammatory cells, including lymphocytes, macrophages, and neutrophils, aggregate; in the intestine, such aggregations are associated with intestinal crypts. These cellular aggregations represent microabscesses that underlie the superficially appearing aphthous ulcers and penetrate to form fissures (Fig. 70–3). Continued influx of inflammatory cells may lead to noncaseating granulomas with multinucleated giant cells, which is the lesion that is essentially pathognomonic for Crohn's disease (Fig. 70–4). However, the reported incidence of these granulomas varies widely, and they are absent in 50% or more of Crohn's patients, which means that finding granulomas

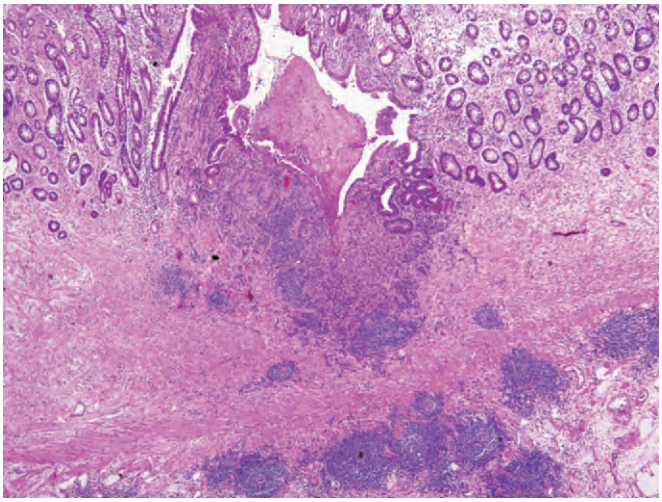

Figure 70–3. Fissuring ulceration extending into the submucosa with associated abundant chronic inflammation. This is a characteristic lesion of Crohn's disease and can progress to form a fistula (ileal resection, hematoxylin-eosin stain). (From Dilworth HP, Montgomery E, Iacobuzio-Donahue CA: Non-neoplastic and inflammatory disorders of the small intestine. In Iacobuzio-Donahue CA, Montgomery E [eds]: Gastrointestinal and Liver Pathology. Philadelphia, Churchill Livingstone, 2005, p 172.)

helps rule the disease in but the absence of granulomas does not rule the disease out.[15,16,19]

Clinical Features

The variability that is evident in every aspect of Crohn's disease underlies the heterogeneity of its findings. The nature, location, and extensiveness of the gastrointestinal lesions give rise to the assortment of gastrointestinal symptoms while dictating the disease's severity and clinical course. Extraintestinal manifestations are a frequent accompaniment of the gastrointestinal disease.

Classification of Crohn's Disease

As it becomes obvious that Crohn's patients are a heterogeneous group, it follows that different subgroups will manifest their disease in different ways; these variations in the natural history and clinical features among subgroups will affect a clinician's interpretation of a patient's prognosis and the treatment decisions. In addition to aiding clinicians, a better understanding of the variables that create the different subgroups may lay the groundwork for understanding the relationship between the environmental and genetic factors that underlie Crohn's disease.[20] Attempts to develop a reasonably simple and objective method for categorizing patients with Crohn's disease led to the Vienna classification system, which groups patients on the basis of age (<40 or ≥40), disease location (terminal ileum, colon, ileocolon, upper gastrointestinal), and disease behavior (inflammatory, stricturing, penetrating).[21] Recent studies that used the Vienna classification system to examine Crohn's disease in a variety of settings have provided significant insight into its clinical findings.

Manifestations

Crohn's disease will be diagnosed in the majority of patients, on the order of 70%, within a year of becoming symptomatic; however, the time between symptom onset and diagnosis can be much longer, with 14% of patients having at least 5 years between symptom onset and diagnosis. Patients who are older at diagnosis tend to have a longer time between the onset of symptoms and diagnosis of their disease. Time to diagnosis will typically be shorter in younger patients, and there tends to be a higher proportion of patients with a young age at disease onset in referral centers.[22] As stated earlier, almost all patients (95%) will have active disease during the first year after diagnosis, whereas only 35% of patients will have active disease in any following year.[3] There are differences reported in the initial location of disease, although studies agree that the greatest proportion of patients will have disease involving the small intestine or a combination of the small and large intestine at diagnosis.[22,23] In a substantial number of patients (85%) the location of the diseased segment will be the most stable aspect of Crohn's disease over time; inflammation will tend to extend and regress within the involved segment and does not usually extend to other segments.[23] Most patients will have strictly inflammatory versus stricturing

or penetrating disease,[23,24] although referral centers, which tend to see more complicated disease at initial contact, will have a greater proportion of patients with stricturing and penetrating disease at diagnosis.[22] In sharp contrast to anatomic location, which tends to remain stable over time, disease behavior in an individual patient tends to progress over time, with the majority of patients who initially have strictly inflammatory disease progressing to stricturing or penetrating disease over the course of their illness.[23,24] Studies have found that the initial location of disease correlates with later disease behavior; isolated small bowel disease is more likely to be associated with strictures, colonic and ileocolonic disease is more likely to be associated with penetration,[23-25] and in long-term (20 years) follow-up, complications develop in 94% of patients with terminal ileal disease versus 78% of patients with colonic disease.[24]

With the aforementioned findings in mind, there is a logical progression to the typical gastrointestinal and extraintestinal manifestations of Crohn's disease.

- Abdominal pain—The abdominal pain experienced by patients with Crohn's disease is usually obstructive in nature, which gives rise to intermittent, crampy pain. It is caused by the narrowing of the lumen of the gastrointestinal tract, usually small bowel, that develops as segments become inflamed and eventually stricture. It occurs as an initial symptom with similar frequency (approximately 60% to 70% of patients) across age groups and genders.[26-28]
- Diarrhea—Diarrhea may be caused by decreased absorption in inflamed segments; in particular, decreased absorption of bile acids and steatorrhea may be an underlying cause in patients with terminal ileal disease. Resection of the terminal ileum and ileocecal valve may be causative in surgically treated patients. As an initial symptom, it occurs with a frequency similar to abdominal pain (roughly 60% to 70% of patients).[26-28]
- Bleeding—Bleeding is not a constant feature of Crohn's disease, but it may still be the initial symptom in a significant number of patients (23.5% in one large series). The bleeding may be slight and detectable only with Hemoccult testing. Severe acute hemorrhage is rare (0.9% to 6%); in most studies it is more common in patients with colonic involvement, although it may emanate from any part of the gastrointestinal tract from the upper to the lower, which is why localization of the bleeding will be of extreme importance in treatment.[29,30]
- Weight loss—Weight loss and malnutrition obviously follow on the heels of abdominal pain, obstruction, and malabsorption. It is a part of the initial symptom complex in about 25% to 30% of adults. It is, significantly, almost twice as frequent in children.[26-28] The specifics of malnutrition in patients with Crohn's disease are covered later in the chapter.
- Fever—Fever may be due to ongoing inflammation of diseased segments, dysregulation of systemic immunity, or infection secondary to penetrating disease. It occurs as an initial symptom in approximately 15% of patients.[27,28]
- Fatigue/malaise—Malaise is probably caused by both malnutrition and dysregulation of the immune system, which changes the balance of immune cells and the inflammatory mediators that they release. It occurs in roughly 10% to 15% of patients.[27,28]
- Perianal disease—Although this chapter is focused on upper gastrointestinal and small bowel Crohn's disease, it is worth mentioning that perianal disease is frequently (about 10% of the time[27,28]) a part of the initial symptom complex, and in some (in as many as 5% of patients) it will be the sole indicator of Crohn's disease.[31]
- Extraintestinal manifestations—There are a number of chronic inflammatory disorders of unknown etiology that are diagnosed in patients with inflammatory bowel disease so frequently (in up to 50% of patients in some studies) that they are considered to be extraintestinal manifestations of the disease. Of those found in Crohn's disease, the most common are iritis/uveitis (0% to 6.4%), primary sclerosing cholangitis (0.4% to 1.2%), ankylosing spondylitis (excluding asymptomatic sacroiliitis, 1.2% to 8%), peripheral arthritis (12.8% to 23%), pyoderma gangrenosum (0.6% to 1.2%), and erythema nodosum (1.9% to 7.2%). There is some disagreement among recent studies regarding the overall (from 6% to 40%) and individual incidence of these disorders, which is due at least in part to different study populations and study methodologies. Many studies do attempt to separate and compare the rates of occurrence of the various extraintestinal manifestations of Crohn's disease versus ulcerative colitis, and the most constant difference is a higher rate of primary sclerosing cholangitis in ulcerative colitis than in Crohn's disease.[32-34]

Laboratory Findings

Traditionally, the diagnosis of inflammatory bowel disease has relied on clinical, endoscopic, histopathologic, and radiologic findings. Although it is true that the etiology and pathophysiology of inflammatory bowel diseases remain incompletely solved mysteries, it is becoming clear that a dysregulated immune response develops in genetically predisposed individuals exposed to one or more environmental factors. It is reasonable to expect quantifiable evidence of this dysregulation in the form of clinical laboratory abnormalities that are both generalized with respect to inflammation, such as leukocytosis, and specific to inflammatory bowel disease, such as the formation of unique serum antibodies that can be measured as markers in serologic tests.[35]

Nonspecific measures of inflammation include an elevated white blood cell count, platelet count, erythrocyte sedimentation rate, and C-reactive protein. Although these findings usually correlate with increased Crohn's disease activity,[36] their usefulness is limited, both in initial diagnosis and in monitoring of disease activity, because of their lack of specificity.

A number of antibodies to both self and non-self proteins that occur in patients with inflammatory bowel disease have been identified. The best studied

antibodies by far are perinuclear antineutrophil cytoplasmic antibodies (pANCAs), which are found primarily in patients with ulcerative colitis (48% to 82% of patients) and less frequently in patients with Crohn's disease (5% to 20% of patients), and anti–*Saccharomyces cerevisiae* antibodies (ASCAs), which are found primarily in patients with Crohn's disease (48% to 69% of patients) and less frequently in patients with ulcerative colitis (5% to 15% of patients). A number of other antibodies have received attention, including antibodies to outer membrane porin C (anti-OmpC), which are antibodies to the *Escherichia coli* cell wall protein and are found in patients with Crohn's disease; antibodies to I2, which are antibodies to an antigen derived from the DNA of *Pseudomonas fluorescens* and are found inside macrophages from the intestinal mucosa of patients with Crohn's disease; and antibodies to pancreatic antigens, which are found in patients with Crohn's disease. To date, a single serologic test that discriminates patients with inflammatory bowel disease from those without it or that discriminates patients with Crohn's disease from those with ulcerative colitis and does so with high sensitivity and specificity has not been found.[35] There is evidence that using panels of serologic tests, for instance, combining pANCA plus ASCA or combining pANCA, ASCA, and anti-OmpC, will increase their specificity, but at the expense of decreased sensitivity. The specificity and sensitivity for diagnosing Crohn's disease and ulcerative colitis in adults when pANCA and ASCA are combined are on the order of 95% and 50%, respectively.[35,37-39] Studies of the utility of serologic testing in patients with inflammatory bowel disease are ongoing, and the degree of utility will probably be a moving target for years to come as new antigens are identified and compared with or combined with tests for other antigens and validated.

In addition to their potential usefulness in diagnostic testing, investigations that identify antibodies unique to patients with inflammatory bowel disease may lead to a better understanding of the underlying causes of the disease or to better immunomodulatory treatments directed more specifically at points of immune system dysregulation. Serologic testing has the potential to identify patients who are susceptible to the development of inflammatory bowel disease, to identify subgroups of patients who will have more or less aggressive forms of disease, and to predict or monitor response to therapy.[35,38] For a more detailed understanding of serologic testing in inflammatory bowel disease, the authors recommend reading the references cited for this section.

Radiographic Imaging

Gastrointestinal imaging continues to evolve on all fronts, including imaging of the small intestine. Various forms of contrast-enhanced axial imaging using computed tomography (CT) and magnetic resonance imaging (MRI) vie with better techniques in ultrasound to improve on the results that can be obtained with conventional barium studies of the small intestine. In the future, some combination of these modalities may eventually supplant barium studies of the small intestine for the diagnosis of small bowel Crohn's disease in much the same way that push endoscopy has largely replaced barium studies for evaluation of the mucosa of the upper and lower gastrointestinal tract.

All endoscopic and radiographic imaging studies used in Crohn's disease attempt, with varying degrees of effectiveness, to accomplish one or more of the following goals: confirm the diagnosis; localize lesions while gauging their extent, severity, and degree of inflammatory activity; identify the presence of extraintestinal manifestations; and ultimately aid in medical and surgical decision making.[40]

Small Bowel Follow-Through and Enteroclysis

In many clinical situations, push endoscopy has replaced barium studies as the preferred method for evaluating the mucosa of the upper gastrointestinal tract and colon.[41] On the other hand, "conventional" radiographic studies using intraluminal contrast agents, either small bowel follow-through or small bowel enteroclysis (also known as small bowel enema), are still considered to be first-line studies for the evaluation of small bowel disease in general and Crohn's disease in particular.[42-45] Small bowel follow-through is performed after the oral administration of barium; the protocol for the examination is variable between operators and institutions, with some performing a few plain radiographs and others performing extensive fluoroscopic evaluations with multiple compression views to separate bowel loops in order to provide detailed anatomic information and assessment of motility. Enteroclysis is performed by introducing the barium suspension directly into the small intestine via a tube; when compared with small bowel follow-through, the technique for enteroclysis is more uniform between operators.[44,46] There is still debate about which conventional radiographic method is best when evaluating the small bowel to make or exclude the diagnosis of Crohn's disease, and there is literature to support both views; it is likely that the aforementioned operator and institutional variability accounts for some of the perceived difference and that preferences reflect local demands by clinicians and available expertise.[41] Although enteroclysis does not evaluate gastroduodenal disease and is considered to be more uncomfortable for the patient, it is generally accepted that it produces superior small bowel images with better mucosal detail.[42,46] That being said, a detailed, fluoroscopy-based small bowel follow-through, augmented to demonstrate the distal ileum if necessary, is adequate for the initial assessment of small bowel Crohn's disease. The sensitivity and specificity of small bowel enteroclysis for the diagnosis of Crohn's disease have been reported to be 93% to 100% and 97% to 98%, respectively.[41]

A number of possible radiologic findings can be seen on small bowel follow-through and enteroclysis in patients with Crohn's disease; given the heterogeneity of the disease, it follows that these findings can appear in combination and can vary significantly from patient to patient. Imaging of the terminal ileum is of particular importance because many patients have disease involving this part of the gastrointestinal tract and disease may be

limited to the terminal ileum on initial evaluation. Findings seen on small bowel follow-through and enteroclysis (Figs. 70–5 and 70–6) include discrete ulcers, fissures or longitudinal ulcers, fistulas and sinus tracts, cobblestoning, thickened and distorted mucosal folds, wall thickening; enlargement of the ileocecal valve, short or long and single or multiple areas of luminal narrowing with pre-stenotic dilation, and skip lesions, which are areas of diseased bowel interspersed with areas of normal bowel or asymmetric involvement of a portion of bowel.[44]

Cross-Sectional Imaging in Crohn's Disease

Traditional push endoscopy, which is increasingly being supplemented with capsule endoscopy, and barium studies are currently the preferred methods for diagnosing the more subtle mucosal lesions associated with early Crohn's disease. However, when evaluating the transmural, extramural, or extraintestinal extent of disease, cross-sectional imaging, CT for the majority of providers and MRI for a growing number, has distinct advantages over intraluminal imaging modalities and can compensate for the limitations of conventional imaging. Moreover, as cross-sectional imaging technology continues to improve with faster image acquisition times and increased resolution, its role in imaging of Crohn's disease will probably grow.[40] In a comparison of spiral CT and conventional enteroclysis, the sensitivity and specificity of CT for the diagnosis of Crohn's disease were reported to be 94% and 95%, respectively, versus 96% and 98% for enteroclysis.[47] MRI has a similar profile. Both MRI and CT are probably less sensitive than conventional radiographic studies for early lesions.[40]

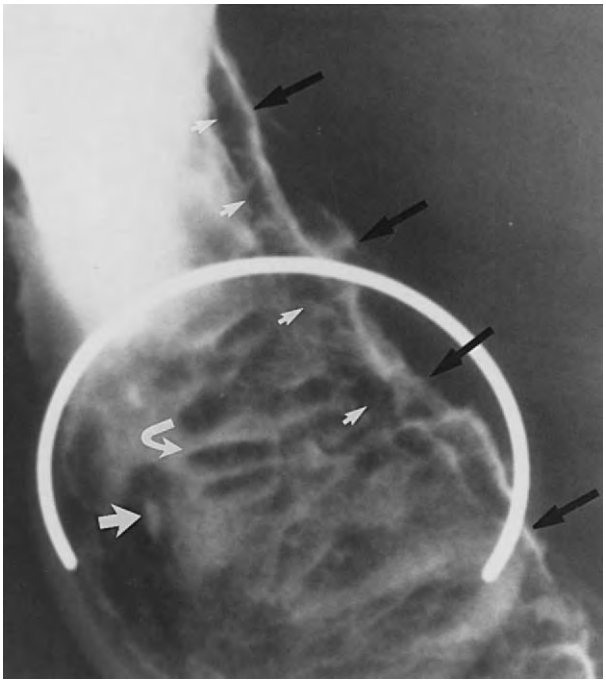

Figure 70–5. This image of the terminal ileum contains a long mesenteric border ulcer *(black arrows)* with a radiolucent line along its luminal aspect *(small white arrows).* Interrupted, thickened folds *(curved arrow)* are present. Aphthoid ulcers have enlarged and deepened *(large white arrow).* (From Herlinger H, Caroline DF: Crohn's disease of the small bowel. In Gore RM, Levine MS [eds]: Textbook of Gastrointestinal Radiology, vol 1, 2nd ed. Philadelphia, WB Saunders, 2000, p 732.)

Narrowed terminal ileum in active Crohn's disease. **A,** There is marked narrowing of the terminal ileum with probable tiny ulcers *(arrows).* **B,** Enteroclysis in double contrast widens the lumen to reveal an extensively fissured stenotic stage of advanced Crohn's disease *(arrows).* (From Herlinger H, Caroline DF: Crohn's disease of the small bowel. In Gore RM, Levine MS [eds]: Textbook of Gastrointestinal Radiology, vol 1, 2nd ed. Philadelphia, WB Saunders, 2000, p 735.)

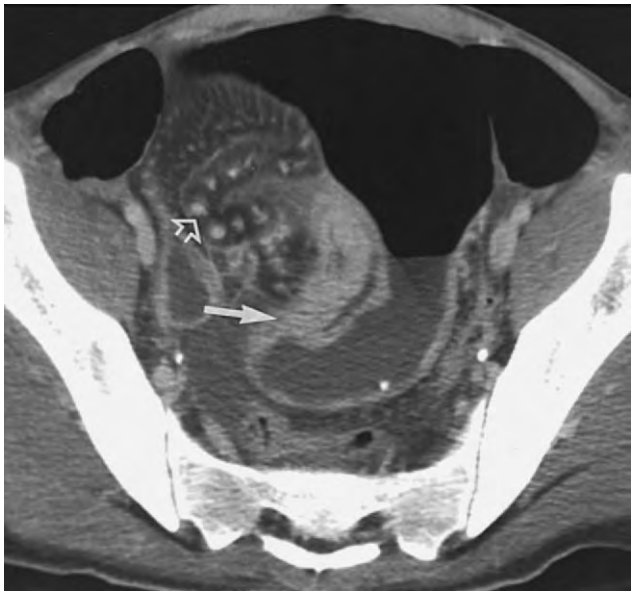

Figure 70–7. High-grade obstruction as a result of Crohn's disease. Computed tomography demonstrates a grossly dilated, gas-filled small bowel proximal to a narrowed, thick-walled, enhancing segment of Crohn's disease *(solid arrow)* that was causing obstruction. Dilated vessels are seen in the mesentery *(open arrow).* (From Herlinger H, Caroline DF: Crohn's disease of the small bowel. In Gore RM, Levine MS [eds]: Textbook of Gastrointestinal Radiology, vol 1, 2nd ed. Philadelphia, WB Saunders, 2000, p 737.)

When using CT and MRI for Crohn's disease, a combination of intravascular and intraluminal contrast is generally used. The intraluminal contrast may be positive (high attenuation, e.g., diatrizoate meglumine [Gastrografin] in CT, iso-osmolar polyethylene glycol solution in MRI) or negative (low attenuation, e.g., methylcellulose in CT, dilute barium in MRI); the lumen must be clean and fully distended with contrast because undistended bowel loops can mimic abscesses, masses, enlarged lymph nodes, or a segment with wall thickening. Full luminal distention requires a large volume of contrast (1.5 to 2 L or more) given relatively rapidly (over a period of 45 to 90 minutes); it can be given orally or via a nasogastric/jejunal tube. Motion artifacts can be problematic, so antiperistaltic agents may be given before scanning, particularly with MRI. In addition, rapid distention with large volumes of intraluminal contrast can induce reflex atony, and faster multidetector scanners allow the acquisition of images during a single breath hold. Please see referenced material for descriptions of CT and MRI scanning protocols.[40,48]

Cross-sectional images (Figs. 70–7 and 70–8) should be analyzed for the following[40,49]:

- Length of involved segments.
- Skip lesions.
- Wall thickening—Normal wall thickness is 1 to 2 mm for distended small intestine and 3 mm for colon. Bowel wall thickness exceeding 4 to 5 mm is considered abnormal. Bowel wall thickening is the most consistent feature of Crohn's disease on cross-sectional imaging. Adequate distention with intraluminal contrast is a necessity.
- Degree of enhancement and patterns of attenuation—After the administration of intravenous contrast, active lesions have increased enhancement, which is a marker of inflammation; alternating layers of mural enhancement and attenuation (double-halo or target sign) can also be seen in active lesions.
- Stenosis and pre-stenotic lesions—The small bowel lumen is normally 2.5 cm in diameter; luminal dilation proximal to areas of stenosis and luminal narrowing is easily identified on cross-sectional imaging. Adequate distention with intraluminal contrast is required because inadequate contrast beyond stenotic lesions may lead to underestimation of more distal disease.
- Abscess and fistula—A phlegmon or abscess is easily identified on cross-sectional imaging; however, CT and MRI are less sensitive in identifying fistulas and sinus tracts than conventional enteroclysis is.
- Fibrofatty proliferation—Also known as creeping mesenteric fat, it is seen adjacent to involved bowel segments as slightly increased attenuation on CT and slightly decreased attenuation on MRI.
- Increased vascularity of the vasa recta (comb sign).
- Mesenteric adenopathy—Abnormally large mesenteric lymph nodes from 3 to 8 mm can be identified; nodes larger than 10 mm should increase suspicion for carcinoma and lymphoma.
- Early-stage lesions—Small aphthous ulcers, subtle distortions of bowel folds, and slight enlargement of lymph follicles may not be appreciated on cross-sectional imaging because of limitations in spatial resolution.

Ultrasound

The idea that ultrasound is useful in the diagnosis of abdominal surgical diseases, particularly in those that involve transmural inflammation and wall thickening of hollow viscera, should not seem unusual given its usefulness in cholecystitis and appendicitis; it is no surprise that the use of ultrasound for the assessment of a variety of inflammatory disorders of the small and large intestine is gaining increasingly widespread acceptance. Although transabdominal ultrasound for the evaluation of Crohn's disease is well supported in the literature and is becoming more commonplace in Europe, it remains a rarity in the United States. The oft-cited advantages of ultrasound, including cost, availability, noninvasiveness, and lack of ionizing radiation, have been augmented by technologic advances that have improved resolution. These improvements not only allow good cross-sectional imaging of the gut wall but, like CT and MRI, also allow examination of the surrounding mesentery and abdominal cavity for evaluation of extramural disease manifestations. It is now possible to visualize, localize, and gauge the extent of transmural inflammation while

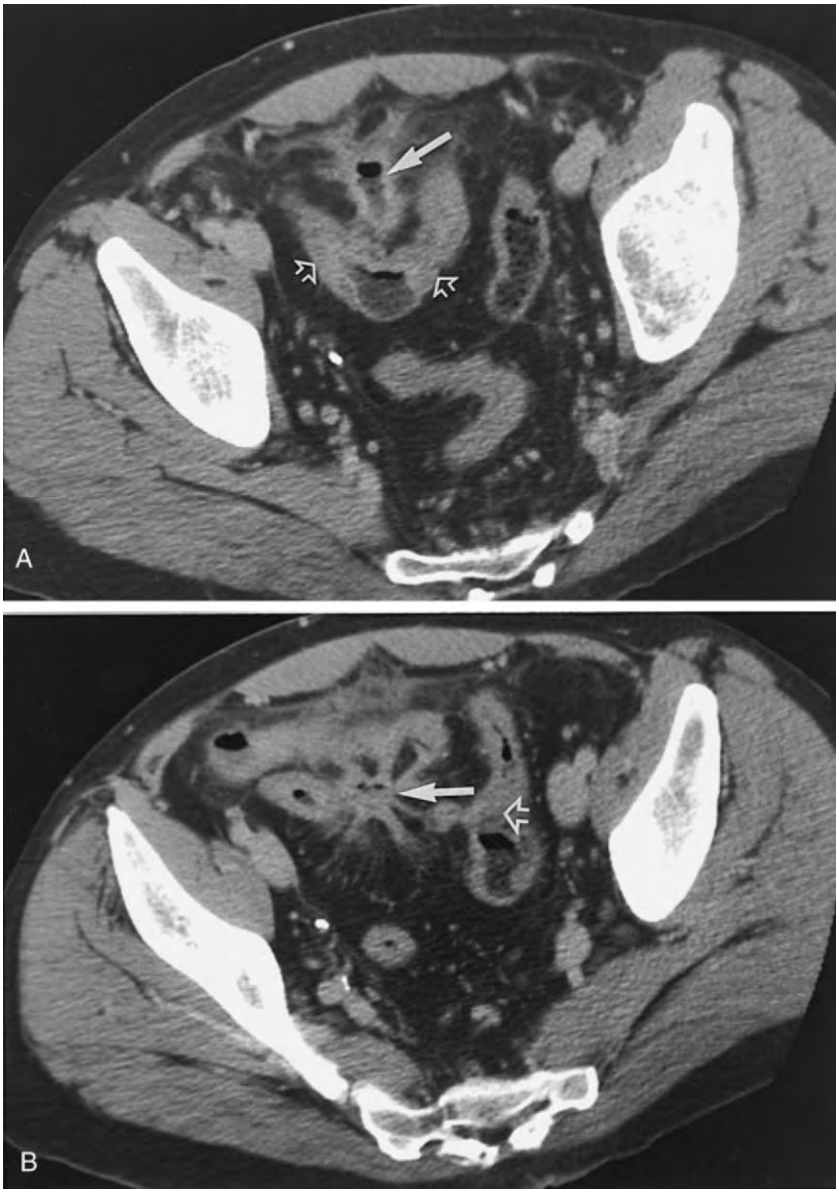

Figure 70–8. Ileal Crohn's disease with tracts and abscesses. **A,** A gas-containing mesenteric abscess *(solid arrow)* is close to transmural Crohn's disease of the terminal ileum *(open arrows).* **B,** Top of the abscess in the mesentery *(solid arrow)* with a fistula to the adjacent Crohn's disease–involved ileum *(open arrow).* Multiple tracts are related to the abscesses. (From Herlinger H, Caroline DF: Crohn's disease of the small bowel. In Gore RM, Levine MS [eds]: Textbook of Gastrointestinal Radiology, vol 1, 2nd ed. Philadelphia, WB Saunders, 2000, p 740.)

detecting extraintestinal complications such as strictures, abscesses, and fistulas. Techniques that use anechoic intraluminal contrast or intravenous contrast agents with Doppler ultrasound will probably improve ultrasound's diagnostic capabilities even more. As is so often the case with complex ultrasound studies, their advantages can be offset by the degree of expertise required of the ultrasound technologists and radiologists; this shortcoming can lead to concerns regarding intraoperator variability and can engender questions regarding the applicability of study results to widespread practice. In addition, like CT and MRI, ultrasound is not sensitive enough to detect the subtle mucosal lesions that may be the only radiographic sign of early disease. Furthermore, ultrasound has been found to be less effective in the imaging of Crohn's disease localized to the anorectum. Finally, patient characteristics that make transabdominal ultrasound technically difficult in other settings, such as obesity or intraluminal gas, make transabdominal ultrasound in Crohn's disease more difficult as well. Even so, recent prospective studies comparing the accuracy of bowel ultrasound as the first imaging procedure in diagnosing Crohn's disease with the accuracy of endoscopy, radiologic studies, or surgical exploration followed by pathologic examination of the surgical specimens found sensitivities and specificities of 76% to 88% and 98% to 100%, respectively, results that support continued investigation.[50]

Endoscopy

Radiology and endoscopy have complementary roles in the diagnosis and subsequent management of Crohn's disease[51]; despite continued evolution in the state of the art for both, neither has gained primacy.

Push Endoscopy

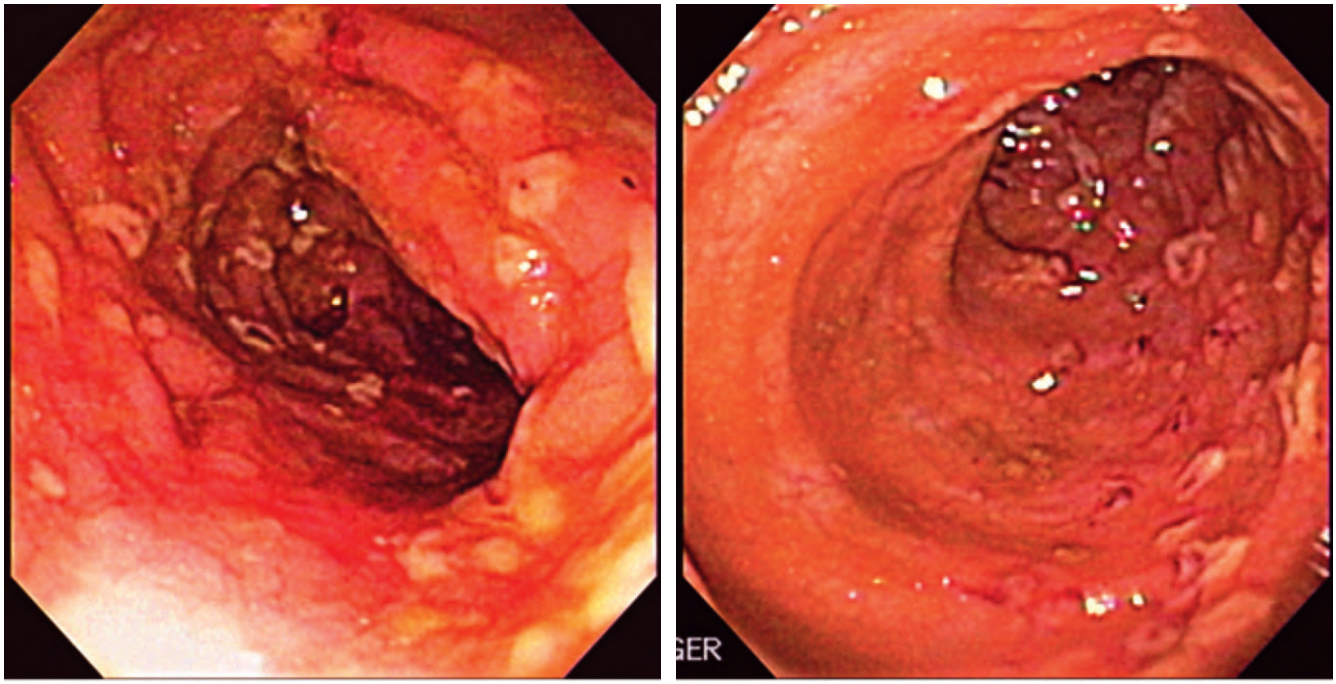
The advantages afforded by push endoscopy, including colonoscopy with ileoscopy and esophagogastroduodenoscopy, in the diagnosis and management of Crohn's disease are many: the ability to detect subtle mucosal lesions, which in many cases are the only sign of early disease; the ability to obtain biopsy samples for histologic examination; and increasingly, the ability to perform intraluminal therapeutic interventions.

Patients with Crohn's disease most commonly have abdominal pain and chronic diarrhea as their initial complaints. The majority of patients with chronic diarrhea will undergo some type of endoscopy, and if the remainder of the antecedent clinical evaluation is suggestive of inflammatory bowel disease, colonoscopy with the addition of ileoscopy is a good first choice of diagnostic procedure[51] because it can help differentiate between Crohn's disease and ulcerative colitis on the basis of mucosal changes, disease distribution, and histology (multilevel biopsy specimens that include the terminal ileum, along with histologic examination, significantly increase the diagnostic sensitivity and specificity of endoscopy in inflammatory bowel disease[52]).

In the differentiation of Crohn's disease from ulcerative colitis, the most important colonoscopic findings are aphthous ulcers (Fig. 70–9), cobblestoning, and discontinuous lesions.[53] In addition, terminal ileal involvement and rectal sparing are strongly suggestive of Crohn's disease. Although there may be "backwash ileitis" on ileoscopy in patients with ulcerative colitis, this finding is observed in the setting of pan-colitis with continuous involvement of the colon from the rectum to the cecum[52,54]; in patients with inflammatory bowel disease and isolated terminal ileal involvement, the diagnosis of Crohn's disease is secure.[55,56] Because rectal involvement is essentially a prerequisite for the diagnosis of ulcerative colitis, rectal sparing, which occurs in about 40% of patients with Crohn's disease, is useful in differentiation between the two forms of inflammatory bowel disease, although there are caveats: the rectal mucosa may appear normal despite histologic evidence of pathology on biopsy, and rectal sparing can occur in up to 40% of medically treated patients with ulcerative colitis.[57]

Because Crohn's disease may involve the upper gastrointestinal tract, esophagogastroduodenoscopy plays a role in diagnosis and management. Indeed, because the frequency of upper gastrointestinal tract Crohn's involvement seems to be much higher than previously reported, the role that upper endoscopy plays will probably increase. For example, in patients with indeterminate colitis, involvement of the upper gastrointestinal tract provides strong evidence in favor of Crohn's disease; in patients with known Crohn's disease who have upper gastrointestinal symptoms, upper endoscopy can facilitate diagnosis of the underlying cause, whether it be Crohn's or some other disease; and it is certainly possible that patients might have Crohn's disease isolated to the upper gastrointestinal tract.[58,59]

The use of endoscopy in the clinical management of Crohn's disease subsequent to diagnosis is evolving. With regard to monitoring of disease activity after initiation of



A B

Figure 70–9. **A** and **B,** Multiple aphthous ulcers seen in recurrent Crohn's disease in the neoterminal ileum of the ileocolonic anastomosis 3 months after resection. (From Krok KL, Lichtenstein GR: Inflammatory bowel disease. In Ginsberg GG, Kochman ML, Norton ID, et al [eds]: Clinical Gastrointestinal Endoscopy. Philadelphia, WB Saunders, 2005, p 317.)

medical therapy, endoscopy does not have a firmly established role. Although endoscopic indices of disease activity have been developed and validated, with the most extensively studied being the Crohn's Disease Endoscopic Index of Severity (CDEIS) and the newest being the Simplified Endoscopic Activity Score for Crohn's Disease (SES-CD), they have not seen widespread use for a variety of reasons. Though reliable and reproducible, CDEIS is complex, which limits its use in clinical trials and day-to-day practice. The SES-CD is probably easier to use, but because of its recent development, it is has yet to be widely applied. Neither CDEIS nor SES-CD has been shown to correlate especially well with clinical disease activity, nor have studies shown that steroid-induced clinical remission is closely linked to mucosal healing. In contrast, studies of treatment with immune modulators such as infliximab and azathioprine have shown correlation between mucosal healing and clinical improvement, so evidence of healing on endoscopy is becoming an important therapeutic target.[60,61] When considering surveillance after curative resection, endoscopic severity evaluated with the Rutgeerts' score predicts the likelihood of symptomatic recurrence.[61] Endoscopy also has an important role in cancer surveillance in patients with long-standing colonic Crohn's disease.[62] From an interventional perspective, endoscopic balloon dilation with or without steroid injection may offer an alternative to surgical therapy for primary and postsurgical Crohn's strictures, although randomized controlled trials are needed for comparisons of safety and efficacy with more standard therapies.[63]

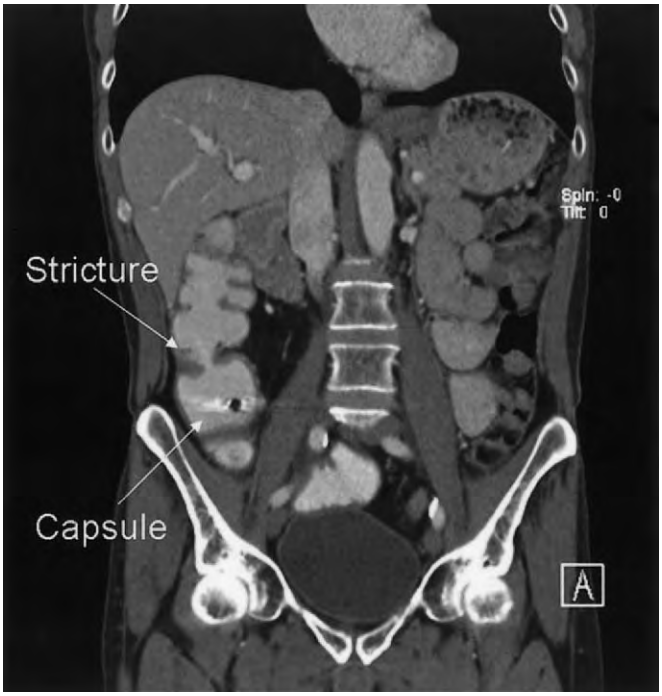


Figure 70–10. Abdominal computed tomography scan illustrating Crohn's stricture of an ileocolonic anastomosis trapping a video endoscopy capsule.

Wireless Video Capsule Endoscopy

Wireless video capsule endoscopy requires a system made up of several components. There is a single-use capsule 26 mm long by 11 mm in diameter that contains a color camera chip, lens, light source from a light-emitting diode, radiofrequency transmitter, antenna, and batteries. Two images are acquired every second, for a total of about 50,000 in an 8-hour study. The images are sent to a belt-worn receiver with a 5-gigabyte hard drive. Images are then downloaded to a computer workstation and viewed as continuous video, with viewing and interpretation typically requiring 1 to 2 hours. Study length is dictated by the capsule's battery life, so the belt is worn for approximately 8 hours after ingestion of the capsule, during which time patients are able to continue their normal daily activities. The capsule's movement is completely passive and relies on peristalsis to progress distally, and it is designed to be passed spontaneously.[64,65] Studies report complete evaluation of the small intestine in as few as 50% and as many as 85% of cases, with most studies reporting 65% to 80% success rates.[66]

Before the introduction of wireless capsule endoscopy in the year 2000, a majority of the small intestine's length was essentially inaccessible to endoscopy performed in the nonsurgical setting. A subsequent pilot study in 2002 reported the use of capsule endoscopy for obscure gastrointestinal tract bleeding, and it has rapidly become the test of choice for obscure small bowel bleeding.[64]

Because 70% of patients with Crohn's disease have involvement of the small intestine[25] and subtle mucosal lesions may be the only signs of early disease, it follows that capsule endoscopy could be extremely useful in the diagnosis and subsequent management of Crohn's disease. Early investigators were understandably reluctant to use the capsule in Crohn's patients; given the capsule's size and the propensity for stricture formation in Crohn's disease, the fear of capsule-induced mechanical obstruction must have loomed large.[67] The rate of "non-natural excretion," that is, capsules requiring endoscopy or surgery for removal, has been reported to be as low as 0% and as high as 15%, depending on study indications and patient populations.[66,68] Even so, a number of studies have been completed in which the diagnostic utility of capsule endoscopy was evaluated in patients with Crohn's disease.[68] Capsules that do not pass spontaneously in patients with Crohn's disease are usually due to strictures (Fig. 70–10), with many of these patients having undergone radiographic studies before ingestion that showed no evidence of stenosis. To reduce the likelihood of retained capsules and possibly obviate the need for radiographic studies before capsule ingestion, a similarly sized, dissolvable "patency capsule" has been developed. When they are retained, wireless endoscopy capsules do not usually cause acute small bowel obstruction; instead, the diagnosis is typically made several days after ingestion based on patient suspicion and intermittent obstructive symptoms. Separate from concerns about obstruction caused by

capsules, other problems inherent in the interpretation of these studies in patients with Crohn's disease still remain[64,68]:

- Study results from institutions with special expertise in capsule endoscopy may not be generalizable to everyday practice.
- Prospective studies to determine the sensitivity, specificity, accuracy, and positive and negative predictive values have not been completed for want of a clear nonsurgical gold standard for diagnosis and for want of a group of prospective patients with long-term follow-up.
- Capsule endoscopy gives information about mucosal lesions and possibly stenosis, leaving aside information about wall thickening or any extraluminal findings.
- The commonality and importance of scattered mucosal breaks, aphthous ulcers, or erosions in various groups of patients, from asymptomatic volunteers to those with suspected or known Crohn's disease, need to be determined, and diagnostic standards need to be created and validated.

Despite these problems, capsule endoscopy is destined to become an important part of the armamentarium for the diagnosis and management of Crohn's disease.

Medical Therapy

All modes of therapy for Crohn's disease have similar goals, which are to reduce symptoms while maintaining or improving patient quality of life. As previously stated, patients with Crohn's disease are usually initially seen with active disease, so typically, a sequential approach to therapy is used in which remission is first induced and then maintained. Current medical regimens require careful consideration of disease location and the level of disease activity (mild, moderate, or severe). Therapy should be individualized according to the patient's disease activity, as well as response to and tolerance of the medical intervention (Fig. 70–11).[20]

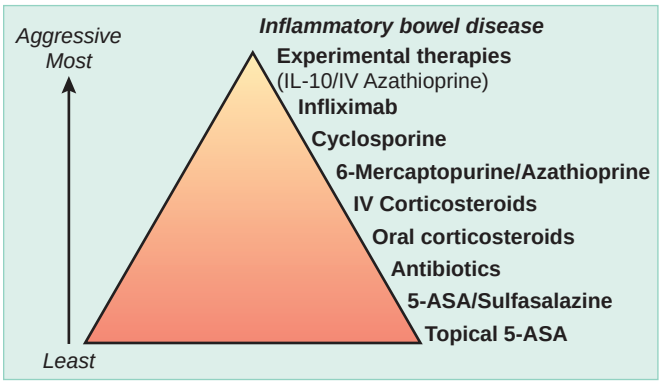

Figure 70–11. Therapeutic pyramid for escalation of medical therapy for Crohn's disease. ASA, acetylsalicylic acid. (From Johns Hopkins University Crohn's Disease Resource Web Page. Copyright Johns Hopkins 2000.)

Inducing Remission in Patients with Active Disease

Corticosteroids have long been used to induce remission in patients with Crohn's disease, and randomized controlled trials have proved the effectiveness of conventional steroids such as prednisone in patients with mild or moderate disease. However, the benefits of conventional steroid treatment may be offset by serious adverse effects in some patients (giving rise to steroid-intolerant patients), little or no improvement in others (steroid-resistant patients), and disease flares during or shortly after tapering (steroid-dependent patients). More than 35% of patients treated acutely with conventional steroids will become steroid dependent or steroid resistant. Budesonide is a corticosteroid with extensive first-pass liver metabolism that results in low systemic bioavailability, which gives it the potential to reduce side effects; the oral version for use in Crohn's disease (inhaled versions are used for the treatment of allergic rhinitis and asthma) is an enteric-coated, controlled-release formulation. Unfortunately, budesonide is effective in a limited number of patients: 30% to 40% of patients will not respond, and studies show that it is useful in patients with ileal and right-sided colonic disease, but not in those with left-sided colonic disease.[20,69] Steroids are not useful in maintaining remission.[70]

Aminosalicylates, including 5-aminosalicylic acid (mesalamine and the controlled-release forms Asacol and Pentasa) and sulfasalazine (a sulfonamide antibiotic, sulfapyridine, linked to mesalamine), can be used selectively to induce remission. Sulfasalazine has been proved effective for inducing remission in patients with colitis or ileocolitis and mildly to moderately active Crohn's disease; it is not useful in maintaining remission. The studies evaluating mesalamine, including Asacol and Pentasa, in active Crohn's disease have been mixed, and experts disagree with regard to their usefulness in inducing and maintaining remission, although they are still considered to be first-line therapy at many centers.[20,69,71]

Antibiotics, including metronidazole and ciprofloxacin, are currently used clinically and have been studied singly, together, and in combination with budesonide for induction of remission (although not for maintaining remission) in mild to moderately active Crohn's disease. Metronidazole has not been proved to be superior to placebo for inducing remission, although one Scandinavian crossover trial found it to be as effective as sulfasalazine.[69,72] The data for ciprofloxacin in Crohn's disease are mixed; controlled trials have shown the superiority of ciprofloxacin over placebo for inducing remission, but another showed that in combination with metronidazole, it is less effective than prednisone. Combinations with budesonide and prednisolone have not been demonstrated to be more effective than monotherapy with these agents.[71,72] Besides inconsistently proven efficacy, significant side effects can occur with the long-term use of either drug, and the development of antibiotic-resistant organisms is a justifiable concern.[20]

For patients with mild to moderate disease that fails to respond to first-line treatment with steroids

(including budesonide) or sulfasalazine or for patients with more severe disease, treatment with immunomodulators is appropriate.[69] *Azathioprine* is the prodrug of 6-mercaptopurine, which is a precursor to intracellular purine antimetabolites that have an antiproliferative effect on mitotically active lymphocyte populations. Multiple randomized studies and a meta-analysis of these studies support the use of azathioprine and 6-mercaptopurine in the treatment of active Crohn's disease, although it may take 4 to 8 weeks for them to begin to take effect.[69,73] Side effects include pancreatitis, bone marrow suppression, allergic reactions, and increased rates of infection.[73]

Methotrexate is a folic acid structural analogue that competitively inhibits the binding of dihydrofolic acid to the enzyme dihydrofolate reductase, which is involved in purine and pyrimidine synthesis; thus, the drugs impair DNA synthesis. The relevant mechanism of action in inflammatory bowel disease, however, has not been fully elucidated.[73] Methotrexate has been shown in randomized controlled trials to be more effective than placebo in treating active Crohn's disease and will induce remission in a significant proportion of patients with corticosteroid- and azathioprine/6-mercaptopurine–resistant disease; it usually requires at least 4 to 6 weeks to take effect.[69,73,74] Liver toxicity is the most serious potential side effect in patients taking methotrexate, and nausea is a common complaint. In addition, methotrexate is teratogenic and an abortifacient.[73]

Infliximab is a chimeric mouse-human monoclonal antibody against TNF-α. In a study that established the use of infliximab in Crohn's disease, a single infusion allowed 33% of patients to enter remission as compared with a placebo rate of 4%, it improved disease in 81% as compared with 17% of controls, and response to infliximab can be seen in as little as 1 to 2 weeks.[69] The effectiveness of infliximab has led to the development of a number of new biologic agents for the treatment of Crohn's disease, including a variety of antibodies with TNF-α as their target, as well as antibodies to interleukins, interferon-γ, and leukocyte adhesion molecules, all of which are in various phases of clinical trials.[75]

Maintaining Remission

A vitally important goal of therapy for Crohn's disease is maintenance of remission. Daily azathioprine and 6-mercaptopurine have been proved in randomized controlled trials to be more effective than placebo in maintaining remission after medical induction; a retrospective study suggests that azathioprine may prevent recurrence after surgery as well.[74] Because of their side effects, potential for significant toxicity, and toxicity-monitoring requirements, important questions remain concerning the discontinuation of azathioprine and 6-mercaptopurine therapy. A recent study of patients with Crohn's disease in remission for at least 42 months found that withdrawal of azathioprine led to an 18-month relapse rate of 21% versus 8% in the group randomized to continue treatment.[69] Another study found that the efficacy of azathioprine is maintained over a period of at least 5 years.[74] Weekly methotrexate has a proven role in maintaining remission of Crohn's disease, with its use generally preceded by methotrexate induction; the optimum duration of therapy has yet to be confirmed, although it is suggested that it could be effective for 3 to 4 years. Given methotrexate's primary adverse effects, it is best avoided in patients with risk factors for liver disease or established liver disease and in those desiring to conceive.[69,74] Infliximab infusions given every 8 weeks have been shown to be effective in maintaining remission in those who respond to the initial infusion. Patients may form antibodies to infliximab, and these antibodies are responsible for acute and delayed hypersensitivity reactions, as well as loss of responsiveness in those who responded previously; this has led to the use of concomitant immunosuppression in Crohn's patients receiving infliximab.[69,74,75] Steroids are not effective in maintaining remission of Crohn's disease, although budesonide can prolong the time to relapse. The use of 5-aminosalicylates for maintaining remission is controversial, with current evidence not supportive of their use in medically induced patients, although they do show some promise in maintaining remission in surgically treated patients.[69,74]

Because most patients will relapse after medical induction, a reasonable approach to maintenance would include azathioprine, 6-mercaptopurine, methotrexate, or infliximab and, in select cases, budesonide (in patients with distal small intestinal or right-sided colonic disease, with the understanding that the treatment effect will probably last less than a year).[69] Infliximab is very expensive (the average third-party reimbursement per dose administered to a 70-kg patient is more than $5200),[76] so it should probably be reserved for patients refractory to other agents, thus leaving azathioprine, 6-mercaptopurine, and methotrexate for most patients. Given the toxicity profiles of infliximab and the immunosuppressive agents, it is reasonable to give patients at least one trial free of maintenance therapy; if symptoms recur within 6 to 12 months, repeat induction should be followed by maintenance therapy with the aforementioned agents indefinitely as patient tolerance allows.[69,71]

Nutrition

Nutrition is an important consideration in the care of patients with Crohn's disease, both in terms of supportive care, which is directed at correcting malnutrition, and potentially as an alternative means of treatment.[77]

Malnutrition

Deficiencies in macronutrients (protein, energy) and micronutrients (vitamins, minerals, and electrolytes) are common in patients with Crohn's disease.[78] The degree of malnutrition depends on disease location, extent, and activity. The long-term malnutrition seen in patients with Crohn's disease may have a multitude of consequences, including growth failure and pubertal delay in children, bone loss, delayed healing of fistulas, poor wound healing after surgery, and increased susceptibility to infection.[79] Assessment of nutritional status includes a

history, physical examination, and laboratory studies focusing on intake, body mass index, serial body weight, muscle wasting, edema, serum albumin, and iron studies; more detailed assessment may include anthropometry and the use of scoring systems such as the Subjective Global Assessment.[77] Factors that contribute to malnutrition in patients with Crohn's disease include the following[78]:

- Anorexia—Decreased appetite is probably due to the high levels of inflammatory cytokines, such as TNF-α, that result from dysregulation of systemic immunity.
- Bowel obstruction—Caused by stricture or abscess.
- Abdominal pain—Caused by inflammation or obstruction.
- Malabsorption—Caused by altered or reduced absorption as a result of inflammation, postinflammatory changes, or surgical resection.
- Losses from the gut—Protein-losing enteropathy may develop in patients with mucosal injury; components of serum, including proteins, iron, lipids, and trace elements, are lost intraluminally because of leaky capillaries in inflamed areas of bowel.
- Direct drug effects and drug-nutrient interactions.
- Increased metabolic requirements, particularly in the setting of complicated disease.
- Prescription of restricted diets.

Specific nutrient deficiencies include the following:

- Vitamin B_{12} (cobalamin)—Deficiency is secondary to decreased absorption of the vitamin B_{12}–intrinsic factor complex in diseased or resected ileum. Vitamin B_{12} deficiency may contribute to anemia in Crohn's patients, and it is a cofactor in homocysteine metabolism (for more detail, see discussion of folate later).[78]
- Calcium—Patients with Crohn's disease do have malabsorption of calcium as a result of complexes formed with unabsorbed intraluminal fats and decreased absorption of vitamin D (a fat-soluble vitamin), although serum calcium levels are maintained by the action of parathyroid hormone, potentially at the expense of bone density. Osteopenia is common in patients with Crohn's disease, with steroid use, along with patient factors such as genetics, contributing to the problem.[77,78,80]
- Fat-soluble vitamins—The adequacy of vitamins A, E, D, and K may be affected as a result of fat malabsorption secondary to disease affecting any part of the small intestine and as a result of alterations in bile acid metabolism, particularly with terminal ileal disease or resection.[81]
- Folate—Folate deficiency is common in patients with Crohn's disease; it is caused by dietary deficiency, increased utilization, and drug treatments, including sulfasalazine, which can bind folate and thereby make it unavailable for absorption, and methotrexate, which is a folic acid antagonist. Inadequate levels of folate may play a role in development of anemia in patients with Crohn's disease. Increased levels of folate may have a protective effect with regard to the development of dysplasia and colorectal cancer, so decreased levels may be another factor in the increased cancer risk seen in Crohn's patients. Folate is a cofactor in homocysteine metabolism, and deficiency may lead to elevated plasma homocysteine levels, which may induce a hypercoagulable state and increase the incidence of thromboembolic events in patients with inflammatory bowel disease.[77]
- Iron—Deficiencies may result from loss secondary to intraluminal bleeding, from decreased absorption because of small bowel disease or resection, and from dietary restrictions, all of which can contribute to the anemia seen in Crohn's disease.[82]
- Selenium—A number of studies have demonstrated decreased selenium concentrations in Crohn's disease patients with a concomitant decrease in glutathione peroxidase activity; the catalytic action of this enzyme protects cells from oxidative damage by lipid peroxides.[80,83]
- Zinc—Deficiencies are difficult to assess because serum levels correlate poorly with total-body zinc stores, but deficiencies are thought to be fairly common in patients with Crohn's disease as a result of decreased absorption or increased loss because the diets of adults with Crohn's disease typically contain a similar amount of zinc as the diets of control subjects. In addition to detrimental effects on wound healing, severe zinc deficiency leads to clinical features of acrodermatitis, such as alopecia, anorexia, diarrhea, dermatitis, poor growth, and impaired immune function.[84]

Supportive nutritional therapy is aimed at improving the nutritional status of the malnourished patient, and unless absolutely contraindicated, the enteral route is preferred. Oral or tube feeding supplementation with protein, calories, and micronutrients can be implemented with any number of commercially available formulas; the decision about which oral or tube feeding formula to use should be based on cost, palatability, and patient tolerance. Initial electrolyte monitoring and replacement are important in severely malnourished patients to prevent the refeeding syndrome. Given its cost and potential for complications, total parenteral nutrition (TPN) as a means of nutritional supportive care should be limited to short-term use in those with bowel obstruction or fistulas, with long-term use reserved for those with short-gut syndrome; there is some, albeit limited, evidence to support the use of TPN in severely malnourished Crohn's disease patients in preparation for surgery.[77]

Nutrition as Primary Therapy

There is evidence to support the use of restricted diets based on enteral nutrition formulas as therapy to induce remission of Crohn's disease, and although potential mechanisms of action such as decreased antigenic presentation have been postulated, the physiology underlying the treatment effect is unknown. There are three meta-analyses and a Cochrane review of randomized

control trials involving enteral therapy as primary treatment of Crohn's disease.[77] They have found that elemental formulations do not have greater efficacy than nonelemental formulations do in induction of remission and that enteral nutrition is not as effective as steroids for induction of remission.[85] Although enteral nutrition has not been compared with placebo, the response rates in studies to date have been greater than one would expect from placebo.[77] Given the side effects associated with steroid treatment and the benign nature of nutritional therapy, there is continued interest in enteral nutrition as primary therapy for Crohn's disease.[77,85]

SURGICAL THERAPY

In addition to general considerations and medical therapy for Crohn's disease, this chapter focuses on surgical therapy for Crohn's disease involving the small intestine. Studies that have monitored patients with Crohn's disease after diagnosis have found variable rates for the requirement for intestinal surgery, but the rates are consistently high[86]; 57% of patients studied in a population-based American cohort required at least one surgical resection,[1] whereas 78% of patients in the National Cooperative Crohn's Disease Study required surgery by 20 years after symptom onset.[87] Because the majority of patients with Crohn's disease have small bowel involvement, a discussion focused on the surgical management of small bowel Crohn's disease is of particular importance. However, surgical management of Crohn's disease can be made complicated by the potential for involvement of any part of the gastrointestinal tract, the segmental nature of involvement, the likelihood of recurrence requiring multiple procedures, penetrating disease causing abscesses and fistulas, adhesions, malnutrition, and medical therapy with immunosuppressive agents. Indications for surgical therapy and subsequent decisions with regard to technique must be carefully considered.

Indications

Surgical therapy for diseased segments does not cure Crohn's disease; therefore, it should be used only to treat complications that are not amenable to medical therapy, and with the potential for recurrence and the need for reoperation in mind, all procedures should be performed with consideration for the conservation of small intestinal length. Indications for operative intervention are directly related to the site of intestinal involvement (Box 70–1)[88]:

- Failure of medical therapy—Medical therapy has failed when maximal medical therapy proves inadequate, successful medical induction is followed by failure of maintenance therapy, and significant complications related to medical treatment develop. As medical therapies improve, definitions for failure of medical therapy will continue to evolve.
- Penetrating disease—Patients with a penetrating pattern of disease may also require surgical therapy. Although penetrating disease is not always an absolute indication, it may require operative intervention if complicated (see Box 70–1). If feasible, abscesses may be treated by percutaneous drainage and systemic antibiotics, thereby delaying definitive surgery until it can be safely performed.
- Free perforation—Although a rare complication, perforation requires immediate surgical intervention.
- Obstruction—Obstruction as a result of single or multiple, sometimes lengthy strictures may require stricturoplasty or resection; patients should be decompressed and resuscitated before surgery.

Box 70–1 Indications for Surgery in Patients with Crohn's Disease

Failure of medical treatment
- Persistence of symptoms despite corticosteroid therapy for longer than 6 months
- Recurrence of symptoms when high-dose corticosteroids are tapered
- Worsening symptoms or new onset of complications with maximal medical therapy
- Occurrence of steroid-induced complications (cushingoid features, cataracts, glaucoma, systemic hypertension, aseptic necrosis of the head of the femur, myopathy, or vertebral body fractures)

Obstruction
- Intestinal obstruction (partial or complete)

Penetrating disease
- Fistula if
  - Drainage causes personal embarrassment (e.g., enterocutaneous fistula, enterovaginal fistula, fistula in ano)
  - Fistula communicating with the genitourinary system (e.g., enterovesical or colovesical fistula)
  - Fistula producing functional or anatomic bypass of a major segment of intestine with consequent malabsorption and/or profuse diarrhea (e.g., duodenocolic or enterorectosigmoid fistula)
- Inflammatory mass or abscess (intra-abdominal, pelvic, perineal)
- Free perforation

Hemorrhage

Carcinoma

Fulminant colitis with or without toxic megacolon

Growth retardation

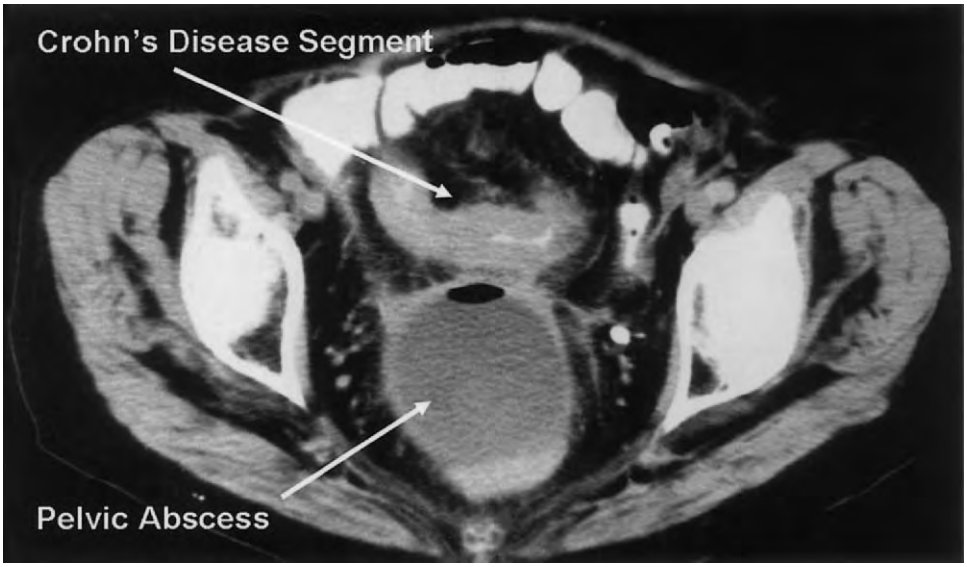

Figure 70–12. Pelvic abscess associated with diseased ileum.

- Other less frequent complications such as massive gastrointestinal hemorrhage, cancer, toxic megacolon, and growth retardation are also indications for surgery.

Preoperative Evaluation and Preparation

Proper preparation of a patient with Crohn's disease for surgery cannot be overemphasized. Every effort should be made to optimize the patient's medical status before surgery, including identifying and mitigating any medical comorbid conditions. If infectious complications secondary to penetrating disease are suspected, cross-sectional imaging is essential because it allows identification of potential abscesses. To minimize the risk for anastomotic leak and the need for diversion, any abscesses that are found should be drained, with percutaneous techniques if possible, before embarking on operations that may require resection (Fig. 70–12). In some instances, complete evaluation of the entire gastrointestinal tract should be undertaken preoperatively to localize areas affected by disease; such evaluation can be accomplished with a combination of endoscopy, contrast studies, cross-sectional imaging, and capsule endoscopy. Complete evaluation of the gastrointestinal tract may not be possible when emergencies arise, which leaves intraoperative evaluation as the primary means of diagnosis. When urgent or emergency intervention is required, patients should not be denied appropriate resuscitation, antibiotics for treatment or surgical prophylaxis, or thromboembolism prophylaxis.

Any patient in whom construction of an intestinal stoma is even a remote possibility should be adequately prepared for the eventuality. Preparation should include preoperative consultation with an enterostomal therapist and, at the very least, marking of an appropriate site or sites for the potential stoma. Blind intraoperative selection of an intestinal stoma site frequently leads to inappropriate placement; a location that is too close to an incision, in a body crease, or in a belt line can make postoperative stoma management difficult.

When operative therapy can or must be delayed, attention should be paid to assessing and correcting malnutrition and metabolic abnormalities. If patients have lost more than 5% of their baseline weight in the preceding 3 months or if they have an albumin concentration that is less than 3.0 g/dl, their nutritional status puts them at increased risk for perioperative complications, and if possible, they should be considered for nutritional intervention before surgery. The enteral route is always preferred if it can be tolerated and when disease complications allow. There is limited evidence to support the use of TPN in the preoperative setting, although a severely malnourished patient may benefit.[88]

With regard to mechanical bowel preparation, a number of randomized controlled trials and meta-analyses have concluded that it is not beneficial and potentially harmful in colorectal surgery[89]; it should certainly be avoided in small bowel procedures.

Patients with suppressed adrenal function because of treatment with corticosteroids should continue steroid treatment in the perioperative period, and although the use of superphysiologic so-called stress-dose steroids in patients who are not critically ill is of unproven benefit, it is still recommended by some experts,[88,90] which should not be confused with steroid use in critically ill patients with hypotension requiring vasopressors, in whom current and mounting evidence suggests that testing for adrenocortical insufficiency and treatment with stress-dose steroids may be beneficial.[91]

Operative Strategies and Techniques

Abdominal Incision

In patients with Crohn's disease who are undergoing abdominal operations, the importance of selection and placement of incisions cannot be overemphasized. Many of these patients will require multiple abdominal operations during the course of their disease. Some will

Figure 70–13. Pfannenstiel incision and diverting ileostomy.

require a stoma, if not at the time of their initial procedure, then in the future, so the placement of scars may potentially have long-term consequences. Transverse incisions or incisions off the midline for either open or laparoscopic surgery should be avoided because scars at these sites may preclude their use for future stoma placement; moreover, because future laparotomies may require an incision that is entirely different from the initial transverse incision, the patient may be put at increased risk for hernia formation.

In our practice, a low, transverse Pfannenstiel incision has been used in more than 300 Crohn's disease patients with excellent results. It is a useful approach for procedures involving the small intestine, the lower part of the abdomen, and the pelvis, and with the use of mechanical retractor systems and headlights, access to the upper part of the abdomen may be achieved. The incision yields excellent cosmetic results with a negligible rate of hernia in our hands, and the literature reports similarly low hernia rates (0% to 3.7% versus as high as 42% with midline incisions).[92,93] It allows ample room to pack away the abdominal contents, and it facilitates stoma placement (Fig. 70–13). We use a retractor consisting of two elastic rings connected by a clear plastic sleeve to facilitate exposure through these smaller incisions (Alexis Wound Retractor, Applied Medical, Rancho Santa Margarita, CA, 92688) (Fig. 70–14).

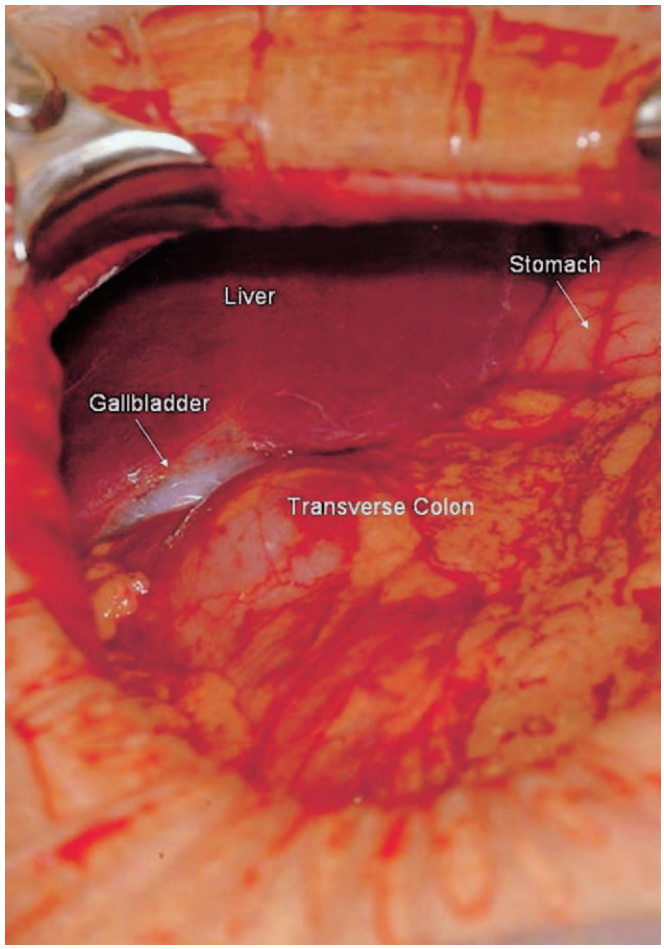

Figure 70–14. Exposure afforded by a Pfannenstiel incision.

Abdominal Exploration and Identification of Diseased Segments

Complete exploration of the abdomen with a focus on identifying diseased segments of the gastrointestinal tract should be performed. Crohn's involvement may be

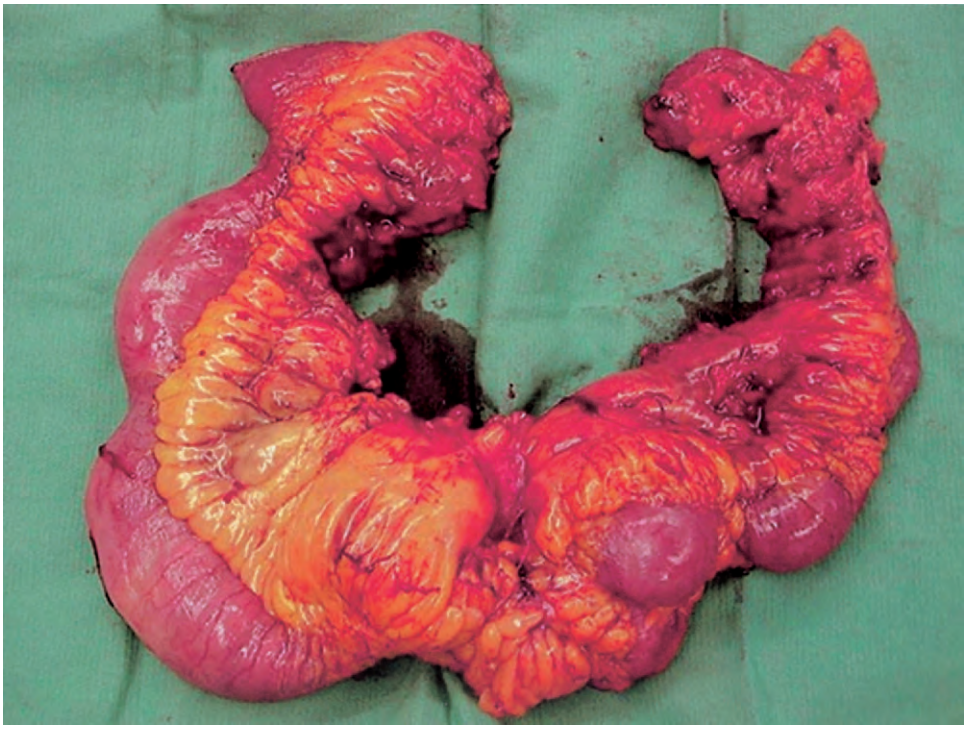

Figure 70–15. Specimen from ileocecectomy for Crohn's disease depicting serosal hyperemia and extension of mesenteric fat onto the serosal surface, which is commonly referred to as "fat wrapping" or "creeping fat."

obvious with thickened bowel wall and adjacent mesentery, serosal hyperemia, and extension of mesenteric fat onto the serosal surface, commonly referred to as "fat wrapping" or "creeping fat" (Fig. 70–15). If the mesenteric border is examined by visual inspection and palpation, more subtle disease may be identified at sites where the bowel wall becomes indistinguishable from the mesentery.[94] Another method for identifying clinically significant obstructing disease that we use infrequently involves the use of a Foley catheter; after creating an enterotomy over a known area of disease or stenosis that is to be resected or is to undergo stricturoplasty, an 18-French Foley catheter on an introducer is placed in the lumen, and the small bowel is telescoped onto the Foley catheter until the duodenum or ileocecal valve is reached. After inflating the balloon to 2 to 2.5 cm in diameter, it is gently pulled through the small intestine; strictures are identified when passage of the balloon is arrested.[95]

Bowel Resection Versus Stricturoplasty

Surgical techniques for the treatment of small intestinal Crohn's disease can be broadly classified into two groups: those that involve bowel resection and those that do not. Because surgery does not cure Crohn's disease nor prevent its recurrence, surgical strategies are focused on relieving its symptoms and complications while minimizing the amount of intestine that is removed.

Historically, the surgical approach to Crohn's disease was much like the surgical approach to cancer; a complete resection for cure with wide surgical margins and even intraoperative frozen sections to identify microscopic involvement seemed logical and was widely practiced. However, significant recurrence rates were seen even after extensive resections. It has since been established that recurrence is not negatively affected by disease at the surgical margins or positively affected by increased length of resection. This understanding, as well as the fear of iatrogenic short-bowel syndrome, has led to a bowel-sparing approach to surgical therapy for Crohn's disease that has made short-bowel syndrome in modern centers very rare[86] (one study of 464 patients with Crohn's disease undergoing surgery found that 21 [5%] had residual intestine <180 cm with just 7 of them requiring home TPN[96]). The bowel-sparing approach to surgical therapy for Crohn's disease has evolved to include techniques that avoid resection altogether. The application of stricturoplasty to small bowel stenoses caused by Crohn's disease is a relatively recent innovation, with the first report being published in 1982 by Lee and colleagues.[97] Since then, multiple studies have shown it to be safe and effective without an increased risk for recurrence.[86,95]

Indications for stricturoplasty include single or multiple fibrotic strictures within diffusely involved segments of small bowel, previous extensive (>100 cm) resections of small bowel, short-bowel syndrome, rapid recurrence of disease with obstruction (within 12 months), duodenal strictures, and strictures at previous anastomotic sites. Contraindications to stricturoplasty include perforation of the small bowel with or without peritonitis; phlegmonous inflammation, abscess, or fistula at the intended stricturoplasty site; likelihood of tension on closure of the stricturoplasty; and location of the intended stricturoplasty site in close proximity to a segment requiring resection.[95]

Given the contraindications to stricturoplasty, it is obvious that resection continues to be an important part of the surgical armamentarium in the treatment of Crohn's disease. A common indication for resection continues to be small bowel obstruction, and in many cases of obstruction, resection may be the treatment of choice, particularly in those with septic complications or those that involve the terminal ileum. Other indications for resection include penetrating disease with or without sepsis, major hemorrhage, and carcinoma.

Stricturoplasty Techniques

There are two main types of stricturoplasty: the Heineke-Mikulicz technique and its variations and those involving some form of side-to-side anastomosis. Stricture length is perhaps the most important consideration when choosing the type of stricturoplasty to be performed. Short strictures, or those less than 10 cm in length, may be treated with the Heineke-Mikulicz technique. Longer strictures or many short strictures close together require side-to-side techniques; the Finney stricturoplasty can be used with strictures that are 10 to 25 cm long,[95] and Michelassi and Upadhyay report using side-to-side isoperistaltic stricturoplasty in diseased segments averaging 51 cm and as long as 109 cm.[98]

The Heineke-Mikulicz stricturoplasty is performed by opening the antimesenteric wall of the strictured bowel longitudinally through all layers and reorienting the incision so that it is closed transversely with seromuscular interrupted or running absorbable suture (Fig. 70–16). Variations include the following[95,99]:

- Judd stricturoplasty, which allows longitudinal elliptical resection of a small portion of bowel wall, followed by transverse closure in situations in which there is a small area of penetration or damaged wall within a short stricture (Fig. 70–17).
- Moskel-Walske-Neumayer stricturoplasty, which uses a Y-shaped enterotomy rather than a longitudinal one, followed by transverse closure, which helps avoid undue suture line tension when performing stricturoplasty in segments with mismatched diameters, such as those with pre-stenotic dilation (Fig. 70–18).

Techniques for longer strictures that involve the use of side-to-side anastomosis include the following[95,99]:

- Finney stricturoplasty, which is performed by creating a longitudinal antimesenteric enterotomy, which is then oriented in side-to-side fashion by creating a U-shaped bend, followed by closure with absorbable suture in running fashion beginning on the posterior wall (Fig. 70–19).
- Jaboulay stricturoplasty, which is similar to the Finney technique in many respects in that it orients the intestine in a U shape, but instead of a single antimesenteric enterotomy, two separate enterotomies are made with the most strictured portion left unopened; subsequent closure creates a side-to-side enteroenterostomy (Fig. 70–20).

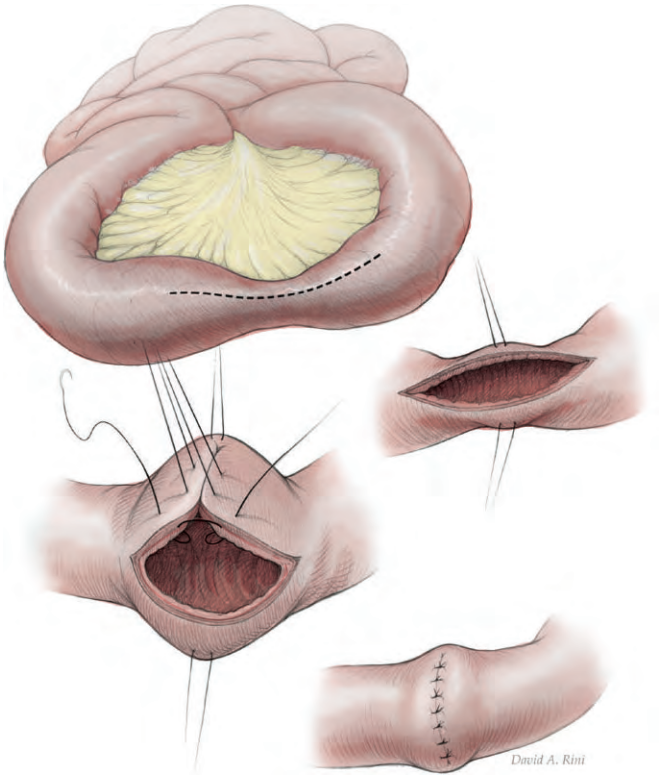

Figure 70–16. Heineke-Mikulicz stricturoplasty using an interrupted Gambee stitch. A longitudinal enterotomy over the stricture is followed by transverse closure. (From Talamini M: Stricturoplasty in Crohn's disease. In Cameron JL [ed]: Current Surgical Therapy, 8th ed. Philadelphia, CV Mosby, 2004, p 117.)

- Side-to-side isoperistaltic stricturoplasty, which is begun by dividing the small bowel mesentery at the midpoint of the affected segment, followed by division of the bowel itself between atraumatic bowel clamps; the proximal loop is then placed over the distal loop, antimesenteric enterotomies are made, the ends of the small bowel are tapered to avoid any blind pouches that could result after closure, and a running two-layer closure results in a long enteroenterostomy (Fig. 70–21).[95,98,99]

Bowel Resection and Anastomotic Techniques

After gaining safe entry into the abdomen, mobilizing diseased segments as required, and identifying the extent of diseased segments as described earlier, the proximal and distal margins may be divided with a linear cutting gastrointestinal stapler. If there is significant obstruction with dilated, fluid-filled loops, it may be necessary to decompress the intestine before stapling by milking the small bowel contents proximally or distally, followed by the application of atraumatic bowel clamps or umbilical tape, or by careful enterotomy and suction. The mesentery may be taken just beneath the small bowel; because it is often thickened, shortened, and hyperemic, this can present a technical challenge.

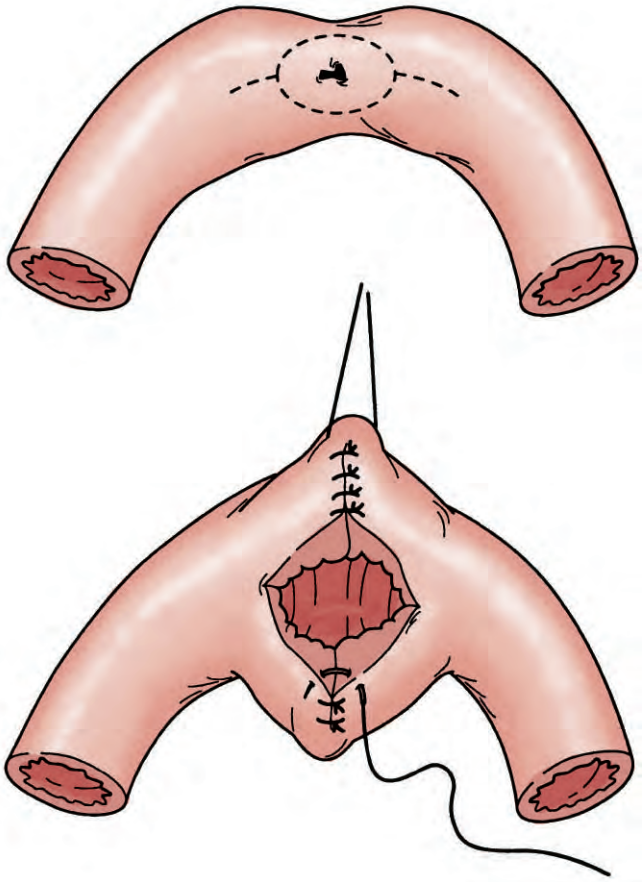

Figure 70–17. Judd stricturoplasty. The fistulous site is resected as part of the longitudinal enterotomy, which is then closed transversely. (From Michelassi F, Hurst RD: Stricturoplasty in Crohn's disease. In Cameron JL [ed]: Current Surgical Therapy, 7th ed. St Louis, CV Mosby, 2001, p 134.)

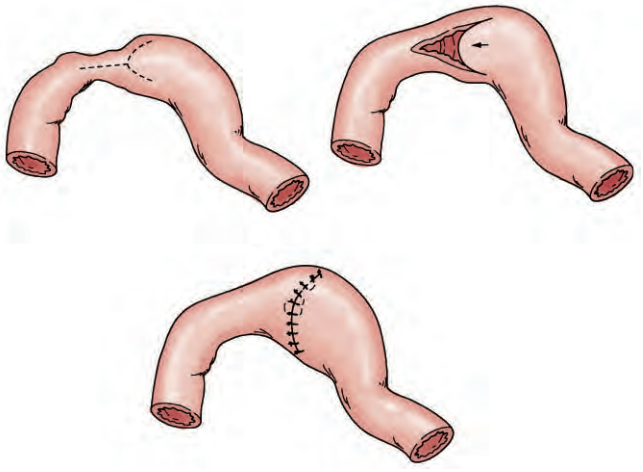

Figure 70–18. Moskel-Walske-Neumayer stricturoplasty. A Y-shaped enterotomy is performed before transverse closure. The Y-shaped enterotomy facilitates tailoring the large lumen of the proximal intestinal loop into the small lumen of the distal loop. (From Michelassi F, Hurst RD: Stricturoplasty in Crohn's disease. In Cameron JL [ed]: Current Surgical Therapy, 7th ed. St Louis, CV Mosby, 2001, p 134.)

After resection, the decision to perform a primary reanastomosis, a primary reanastomosis with a proximally placed loop stoma for diversion, or resection with an end stoma depends on factors such as urgency or emergency, stability of the patient in the operating room, patient nutritional status, the degree and temporality of steroid use, the condition of the bowel undergoing resection and anastomosis, and the condition of the abdomen in general, with septic complications such as abscess being of particular concern.[88] As in any bowel anastomosis, close attention must be paid to all technical details, including the blood supply to the bowel undergoing anastomosis, ensuring a tension-free anastomosis, consideration of proximal and distal bowel diameter, and avoidance of any distal obstruction. Although resection and anastomosis may be performed in areas of active disease and small ulcers should not place the anastomosis at risk, wherever possible, large longitudinal ulcers should not be incorporated into the anastomosis.[100]

With regard to recurrence and the need for reoperation, there is some evidence to support the superiority of a functional end-to-end stapled anastomosis over other stapled or hand-sewn techniques. Moreover, complication rates are low, the technique is quick and easy to perform, and it lends itself well to anastomosis of bowel with different calibers.[65] We typically use a 75-mm linear cutting stapler to create the common channel and close the remaining defect with a noncutting linear stapler.

A summary of salient issues regarding resections in patients with Crohn's disease includes the following points:

- Resection of gross disease is appropriate.
- Wide margins and frozen sections are unnecessary.
- The available evidence does not absolutely compel the use of any appropriate stapled or sewn anastomotic technique.

Stoma Formation

All patients undergoing operative therapy for Crohn's disease should be reasonably prepared, including mental preparation and stoma site marking, for the possibility of stoma creation to the extent dictated by clinical circumstances. Although permanent stomas are rarely required in the treatment of small bowel Crohn's disease, a poorly placed or constructed stoma, even if temporary, is at best a daily inconvenience and at worst a source of major morbidity.[101]

Selection of the stoma site is the first step in stoma construction; ideally, site selection occurs before surgery. Consultation with a certified enterostomal therapist can facilitate all aspects of patient preparation and stoma management, including ideal site selection. In general, stomas should be located within the rectus muscle. A scar-free portion of the abdominal wall should be chosen to allow good appliance seal. Care should be taken to avoid bony prominences such as ribs or the iliac crest. Evaluation of the stoma site should be performed by taking into account the proposed incision and using a template of the stoma appliance with the patient lying, sitting, and standing, especially in obese individuals,

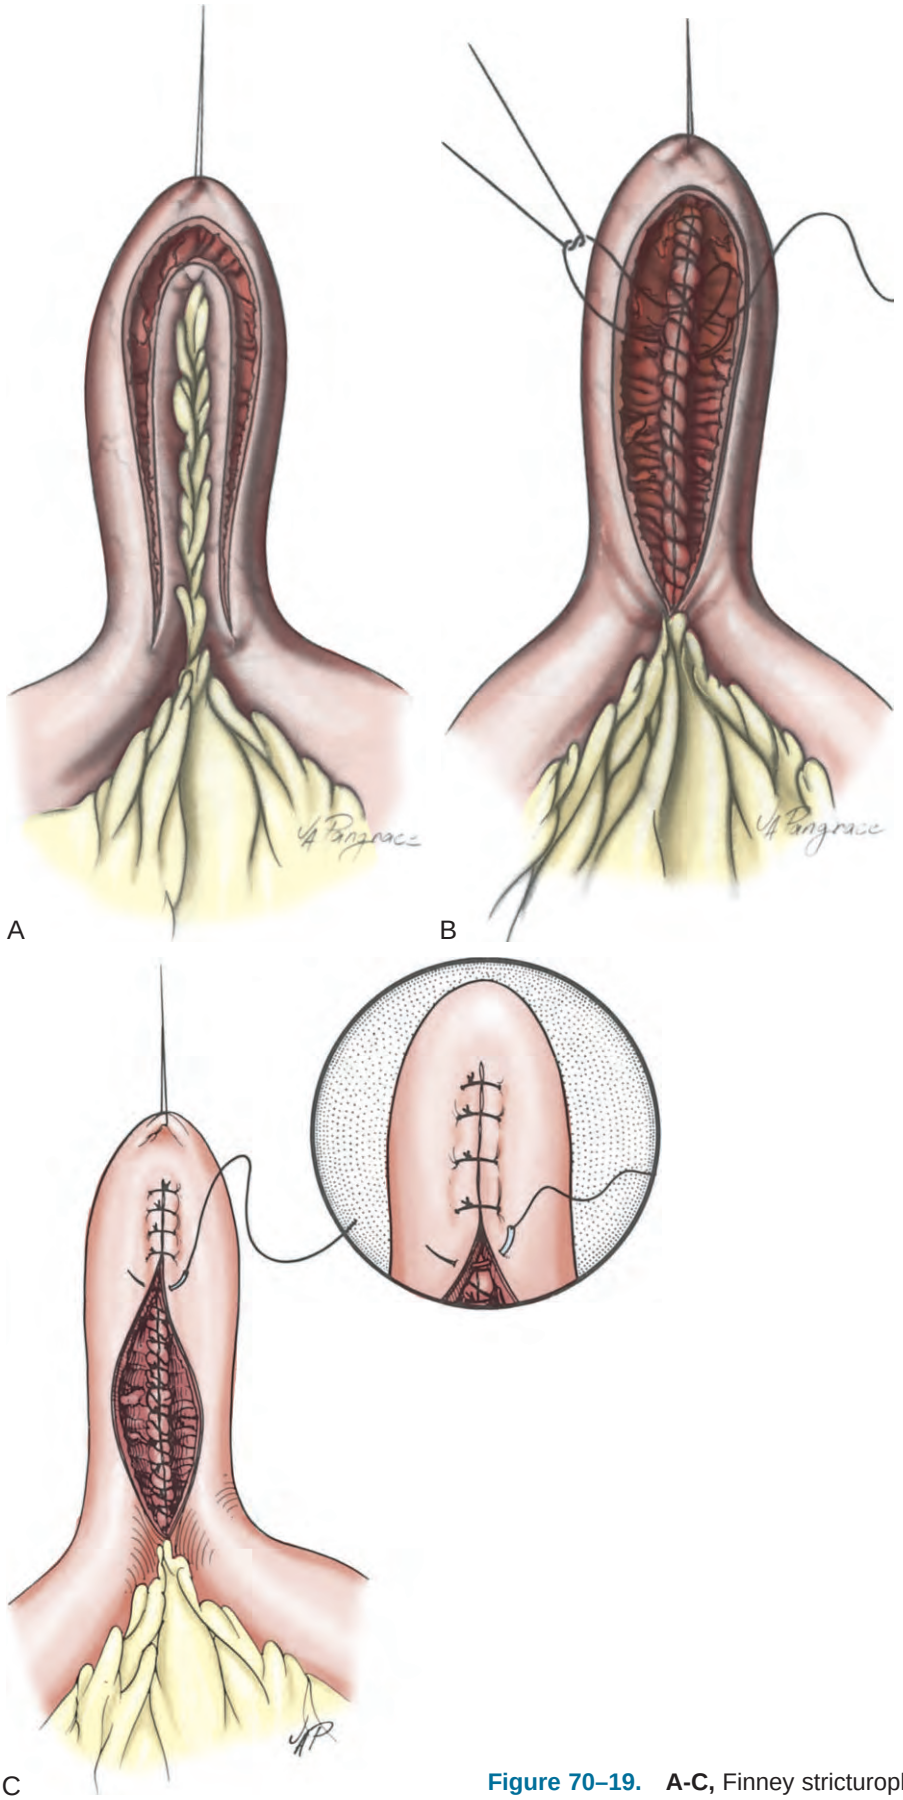

Figure 70–19. **A-C,** Finney stricturoplasty. Enteroenterostomy is performed after the affected bowel is folded onto itself into a U-shape. (From Talamini M: Stricturoplasty in Crohn's disease. In Cameron JL [ed]: Current Surgical Therapy, 8th ed. Philadelphia, CV Mosby, 2004, pp 118-119.)

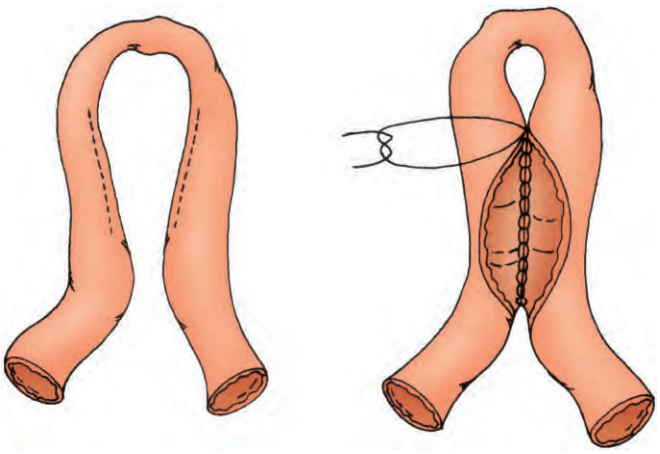

Figure 70–20. Jaboulay stricturoplasty. Two separate enterotomies are made, with the most strictured portion left unopened. Subsequent closure creates a side-to-side enteroenterostomy. (Adapted from Tichansky D, Cagir B, Yoo E, et al: Strictureplasty for Crohn's disease: Meta-analysis. Dis Colon Rectum 43:911, 2000.)

because shifting of the abdominal wall can reveal creases or protrusions that can interfere with appliance seal and the patient's ability to see or reach the stoma site. If the patient has a history of multiple abdominal operations, abdominal sepsis, the potential for a shortened mesentery, or other factors that could interfere with the bowel reaching a proposed stoma site, several alternative sites should be chosen and marked. Marking should be done with indelible ink, and the marking should be reinforced in the operating room immediately before surgery by re-inking or lightly scratching the skin so that the mark can be found after preparing the abdomen.[101]

Standard techniques are used to create and mature the end or loop stoma (we do not use bars in the creation of our loop stomas): a 2-cm disk of skin is sharply excised, the subcutaneous fat is opened to the level of the rectus fascia, a cruciate incision is made with electrocautery in the anterior rectus sheath, the rectus muscle is spread in the direction of its fibers, the posterior sheath and peritoneum are opened with a cruciate incision, the tract is dilated with two fingers, the bowel is brought through the abdominal wall with the mesentery

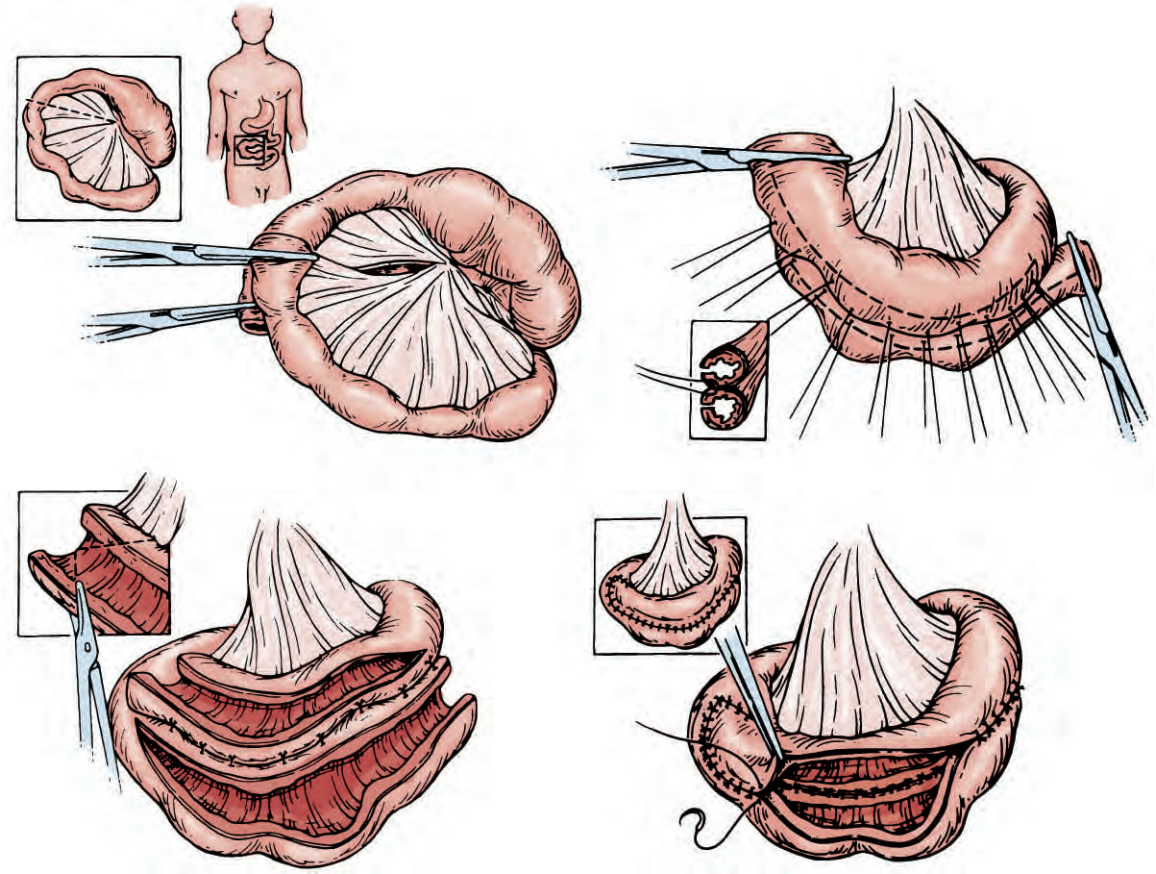

Figure 70–21. Side-to-side isoperistaltic stricturoplasty. A long side-to-side isoperistaltic enteroenterostomy is performed after dividing the diseased intestinal segment and moving the proximal loop over the distal loop in a side-to-side fashion. (From Michelassi F, Hurst RD: Stricturoplasty in Crohn's disease. In Cameron JL [ed]: Current Surgical Therapy, 7th ed. St Louis, CV Mosby, 2001, p 136.)

cephalad to ensure that the dependent portion of the stoma is well formed, the abdominal incision is closed, the bowel is opened, and the stoma is matured so that 2 to 3 cm of everted bowel projects from the abdominal wall.[101] It is important to pull the fascia to the midline with a midline incision or caudad with a Pfannenstiel incision before creating the abdominal wall defect to ensure that all openings are aligned, thus preventing kinking of the bowel, which can lead to obstruction or ischemia of the stoma.

Bypass Procedures

Intestinal bypass or exclusion procedures are rarely, if ever indicated in the treatment of Crohn's disease that involves the jejunum and ileum. However, treatment of Crohn's disease of the duodenum may require bypass procedures such as gastrojejunostomy or duodenojejunostomy.[94]

Laparoscopic Surgery in Crohn's Disease

Crohn's disease presents an array of challenges to surgeons approaching treatment of the disease laparoscopically, including multiple previous abdominal operations, intense inflammation, mesenteric thickening, penetrating disease, and segmental involvement. Patients, many of whom are acutely aware of the high likelihood that they will require surgical therapy at some point in the course of their disease, are eager to pursue laparoscopic approaches that promise better cosmetic outcomes and reduced recovery time. The laparoscopic, laparoscopically assisted, or hand-assisted approach in Crohn's disease may lend itself to diagnosis in cases in which previous attempts at work-up have been nondiagnostic; to diversion in the treatment of more distal disease, particularly in complicated disease; and to resection using primarily hand-assisted techniques and the endoscopic Ligasure (10-mm Ligasure Atlas or 5-mm Ligasure V), which allows safe laparoscopic division of the thickened mesentery. Although the overwhelming majority of evidence to date supporting the benefits of laparoscopy over open approaches has not come from prospective randomized controlled trials, there do seem to be advantages in terms of blood loss, postoperative pulmonary function, duration of postoperative ileus, and length of hospital stay. Characterization of the long-term results after laparoscopic surgery for Crohn's disease awaits adequate numbers of patients with long-term follow-up.[102]

Indications for laparoscopic surgery are essentially the same as those for open surgery. Contraindications to a laparoscopic approach include the following[102]:

- Diffuse peritonitis
- Acute obstruction with distention accompanied by dilated of loops of intestine
- A history of multiple previous laparotomies or known dense intra-abdominal adhesions
- Coagulopathy not correctable at the time of surgery
- Portal hypertension with known intra-abdominal varices

Management of Complicated Small Bowel Crohn's Disease

The Vienna classification system groups Crohn's disease patients on the basis of age (<40 or ≥40), disease location (terminal ileum, colon, ileocolon, upper gastrointestinal), and disease behavior (inflammatory, stricturing, penetrating).[21] Because surgical therapy does not cure Crohn's disease, it is used only to treat complications that are not amenable to medical therapy.[88] Although any of the three types of disease behavior may require surgical therapy, the most common indications involve stricturing or penetrating types of disease behavior.

Stricturing Disease

Patients with Crohn's disease and a primarily stricturing pattern of disease behavior may have an array of symptoms with a wide range of severity reflecting the degree of underlying obstruction, from chronic and low-grade to acute and high-grade or complete. Patients may have abdominal pain, nausea, vomiting, distention, and even obstipation leading to food avoidance, weight loss, failure to thrive, malnourishment, or hospital admission for medical or surgical therapy. Patients with obstructive symptoms caused by stricturing disease who require admission should be initially treated with nonoperative therapy, including bowel rest, nasogastric suction, and resuscitation. If patients have evidence of active disease on colonoscopy or contrast radiography, it is reasonable to treat them with aggressive medical therapy because inflammation may contribute to the partial obstruction. A low-residue diet may reduce the incidence of subsequent episodes of partial bowel obstruction. Patients with recurrent bouts of partial obstruction, those who fail to respond to nonoperative therapy, and patients with complete bowel obstruction require surgery.[103] It bears mentioning again that to the extent possible dictated by the urgency of their operation, patients should always be resuscitated and decompressed before their arrival in the operating room.

The decision to treat strictures with resection or stricturoplasty will be influenced by a variety of factors, including the surgeon's comfort and experience with stricturoplasty techniques for strictures of various length; patient factors such as malnutrition, steroid use, or sepsis; concomitant penetrating disease with phlegmon, abscess, fistula, or free perforation; and the condition of the bowel to be treated. Many authors advocate stricturoplasty as the first choice for patients with almost any type of stricturing disease, including complicated strictures or anastomotic strictures, whereas others argue that resection should generally be the first choice, with stricturoplasty being reserved for patients with short-bowel syndrome or those with multiple recurrences. Depending on the clinical scenario, patients may be served best by a combination of resection and stricturoplasty.

Enteric Fistulas

Patients with Crohn's disease and a primarily penetrating pattern of disease behavior are subject to the formation of fistulas, which are abnormal passages from

a normal cavity or hollow organ to a free surface (external fistulas) or to another cavity or hollow organ (internal fistulas). Fistulas involving the small intestine are discussed in this chapter. Examples include small intestine to small intestine (enteroenteric); small intestine to colon (enterocolonic); small intestine to any part of the urogenital tract, including the bladder (enterovesical), ureters (enteroureteral), and vagina (enterovaginal); and small intestine to skin (enterocutaneous fistula). The transmural nature of Crohn's disease leads to fistula formation, and although downstream obstruction or stricture is not a prerequisite for fistula formation, obstruction may contribute to fistula formation or decrease the likelihood that a fistula will heal. In a recent population-based study, fistulas developed in 35% of patients with Crohn's disease, with 20% of the fistulas being perianal (which is considered in another chapter).[104,105] A prospective study of the features, indications, and surgical treatment in 513 consecutive patients affected by Crohn's disease from 1985 to 1996 found that although fistulas were present in nearly a third of patients, they were rarely the primary indication for operative therapy.[96] This indicates that many of the fistulas found in patients with Crohn's disease, particularly those between loops of small bowel, will be asymptomatic and found incidentally on radiographs or during surgical exploration for treatment of septic complications or obstruction. However, small bowel fistulas may cause complications requiring surgery when long segments of bowel are bypassed, thereby leading to diarrhea or malabsorption; when the genitourinary or biliopancreatic systems are involved; or when the fistula results in external drainage.[100] Medical therapy has shown little promise in the treatment of Crohn's disease–induced enteric fistulas until recently; immunomodulator therapy for enteric fistulas, particularly with infliximab, has been modestly successful in the treatment of enteric fistulas, although the majority of patients in studies to date had perianal disease. It is probably justifiable to give patients who are otherwise reasonably well a trial of medical therapy, but not at the exclusion of indicated surgical therapy.[106]

Enteroenteric Fistulas

Crohn's disease–induced fistulas from one loop of small bowel to another are usually, in and of themselves, of little clinical consequence, although the active disease and inflammation that are the underlying cause typically require treatment. A simple enteroenteric fistula that encompasses a short length of bowel between connections may be found incidentally on radiographs, on abdominal exploration, or in a resected specimen and does not require further surgical intervention. An enteroenteric fistula can be symptomatic and require surgical therapy if a long section of small bowel is bypassed. Short-segment fistulas that are in close proximity should not be separated, but taken en bloc. Long-segment fistulas in which en bloc resection would sacrifice significant bowel length should be separated close to bowel that will undergo resection while leaving the possibility of primary repair for the healthy segment. Most ileocecal fistulas behave clinically like enteroenteric fistulas and are treated similarly.[88,104]

Ileosigmoid Fistulas

Ileosigmoid fistulas occur in up to 6% of all Crohn's disease patients and in 16% to 26% of Crohn's disease patients with internal fistulas. They are generally the result of penetration from the small intestine into the sigmoid, and the sigmoid is not usually affected primarily by Crohn's disease. As with enteroenteric fistulas, ileosigmoid fistulas are frequently asymptomatic, but they can be associated with abdominal pain, diarrhea, and malabsorption. Commonly, they are not detected with endoscopic or contrast studies. These fistulas can generally be treated without sigmoid resection by taking down the fistula and, after débridement of the sigmoid, closing the colon primarily. Sigmoid resection is reasonable if colonic Crohn's disease is present or if technical difficulties prevent easy primary closure, such as local inflammation with rigidity and thickening of the colonic wall, a large defect after débridement, or involvement of the colon wall close to the mesentery. If sigmoid resection is required, primary reanastomosis for restoration of intestinal continuity can usually be performed; temporary proximal diversion may be necessary in patients with long-term steroid use or extensive inflammation that precludes safe primary closure of the fistula defect.[88,100,104]

Enterovesical and Enteroureteral Fistulas

The reported incidence of fistulas from the gastrointestinal tract to the genitourinary system in patients with Crohn's disease has been 1% to 8%.[107] They originate most commonly from the ileum, colon, or rectum; they may also result from anastomotic leak after resection.[104] Although they may be the initial complaint in patients with Crohn's disease, they typically occur in patients with established disease. Common symptoms include dysuria, urinary urgency, urinary frequency, suprapubic discomfort, pneumaturia, and fecaluria. Chronic or recurrent urinary tract infections and urogenital tract infections such as prostatitis or epididymitis may give rise to fever and hematuria.[107] The diagnosis should be suspected in a patient with history, physical examination, and laboratory findings that are typical. The diagnosis can be confirmed and the lesion localized with the aid of cystoscopy, plain radiography, including small bowel follow-through or small bowel enteroclysis, or axial imaging with CT or MRI.[104] The fistulas rarely close spontaneously, and although medical therapy may be mitigating, definitive treatment generally requires surgical therapy. The dome of the bladder is most commonly involved and the trigone is usually spared, thus allowing a relatively straightforward approach. The basic operative steps are division of the fistula, resection of the involved portion of bowel, and débridement and primary closure of the bladder with postoperative Foley catheter drainage.[88,100]

Enterocutaneous Fistulas

Most enterocutaneous fistulas in patients with Crohn's disease occur in the postoperative setting; the involved bowel is essentially normal, and the fistulas, which tend to drain through surgical scars, are the result of anastomotic leak after resection or unrecognized bowel injury. Although reported numbers vary, it seems that spontaneous enterocutaneous fistulas that are the direct result of penetration from a diseased segment of small bowel to the exterior are relatively rare. *Even though it may be difficult to definitively say which is more common, it is worth considering that spontaneous enterocutaneous fistulas that occur before a patient has undergone surgery or after a patient is far removed from surgery are probably the result of penetrating Crohn's disease and that those that occur in the postoperative setting are probably the result of surgical misadventure.* These observations necessarily have an impact on decision making with regard to treatment of enterocutaneous fistulas because postoperative fistulas involving bowel not affected by Crohn's disease will behave differently from spontaneous fistulas that are the result of penetration from bowel affected by Crohn's disease. Fistulas that are not a direct result of Crohn's disease should respond to conventional treatment in a fairly predictable fashion; long, low-output fistulas have an increased probability of closing with nonoperative therapy such as bowel rest, strategies to decrease the output of the gastrointestinal tract, and TPN support, whereas short, high-output fistulas are more likely to require operative therapy. In contrast, spontaneous fistulas that are the direct result of penetrating Crohn's disease rarely close without operative therapy, although as mentioned earlier, newer medical therapies with immunomodulators such as infliximab may be of benefit. Of course, operative therapy should not be delayed when there is distal obstruction, if fistula output or wound care becomes difficult to manage, or if medical treatment has obviously failed. Operative therapy relies on division of the fistula, resection of the involved bowel, débridement of the entire fistulous tract, and safe repair of the ensuing bowel defects.[88,106]

Enterogenital Fistulas

Fistulas from the rectum to the vagina are common in women with Crohn's disease (9% of all fistulas observed in a recently published, population-based study[105]), and although fistulas from the small intestine to the female genital tract, including enterovaginal, enterosalpingeal, and enterouterine, do occur, they are less common. Symptoms of an enterovaginal fistula include malodorous vaginal discharge and passage of air from the vagina; enterosalpingeal and enterouterine fistulas may be difficult to identify preoperatively, with diagnosis occurring at the time of abdominal exploration. The common themes continue, including division of the fistulous tract with resection of involved bowel and débridement of the victim organ, although effort should be made to preserve reproductive, endocrine, and sexual function, especially in women of childbearing age.[94]

Abscesses

Abscesses in patients with Crohn's disease are common (reports indicate that 10% to 30% of patients with Crohn's disease will have an abscess at some point in their illness[108]); they can be an intermediate step in the formation of fistulas, and like fistulas, they may be the result of penetrating disease from a segment of bowel affected by Crohn's disease, or they may be the result of surgical misadventure (see Fig. 70–12). Patients may have few, if any symptoms because the abscesses are frequently contained in loops of bowel, between leaves of mesentery, by abdominal viscera, in the retroperitoneum, or in the pelvis; symptoms may also be quelled by medical therapies such as steroids or immunomodulators. If patients do have signs and symptoms, they are those typical of intra-abdominal infections, including fever, ileus or obstruction, abdominal pain, tenderness, or a palpable mass. Diagnosis and localization are aided most by axial imaging. Classically, treatment was strictly operative, with abscess drainage as a first stage followed by bowel resection as a second stage. With the advance of radiographically guided percutaneous techniques, abscesses can be effectively drained outside the operating room; concomitant medical therapy for any active Crohn's disease, along with resuscitation, antibiotics for systemic infection, nutritional support, and bowel rest as indicated, can be administered. If the abscess cavities collapse and the patient's Crohn's disease is controlled, no further therapy may be needed. If operative therapy is required, the patient will benefit in terms of physiologic preparedness and technical ease, which may make the operation less extensive, preserve bowel length, and allow restoration of bowel continuity without diversion in a single stage.[30,108]

Ureteral Obstruction

The majority of cases of ureteral obstruction in patients with Crohn's disease are not caused by stones, with 50% to 73% of cases of ureteral obstruction in patients with Crohn's disease being acalculous. Acalculous ureteral obstruction was seen in 4.7% to 14.3% of Crohn's patients who had diagnostic intravenous pyelography studies performed; in contrast, intravenous pyelograms performed on asymptomatic Crohn's patients reveal acalculous ureteral obstruction in 18% to 50% of those tested, which suggests that acalculous obstruction in these patients is a more prevalent problem that probably goes unrecognized fairly frequently. When symptoms do occur, they can be nonspecific, with patients reporting urinary frequency and urgency, flank pain, and fever and, on examination, a palpable abdominal mass is possible. The results of urinalysis and culture are often normal. The diagnosis is most often confirmed with axial imaging. The inflammation associated with ileocecal disease is usually the cause of acalculous ureteral obstruction, so it occurs more commonly on the right and less commonly on the left or bilaterally. Current recommendations advocate a staged approach to treatment consisting of medical control of active Crohn's disease, ureteral stenting for significant obstruction, and

percutaneous drainage of any associated abscess, followed by resection of diseased bowel and ureterolysis as required if nonoperative therapy fails.[107]

Free Perforation

Free perforation in patients with Crohn's disease is rare; as alluded to in the sections on abscess and fistula, the adhesions that are a result of the transmural inflammatory nature of Crohn's disease create an environment around affected segments that does not favor free perforation. Free perforation usually occurs in Crohn's patients with toxic colitis, distal obstruction, or cancer and after endoscopy or surgery. Perforation in patients with prodromal signs and symptoms will generally be heralded by a sudden worsening in their clinical course; as usual, such assumptions are dangerous in patients treated with steroids and immunomodulators, in whom a high index of suspicion is required for diagnosis. Plain films showing free air confirm the diagnosis, and in cases in which the diagnosis goes unsuspected, CT scans will show the same. It should go without saying that emergency exploration is required when free perforation is suspected; while the operating room is being prepared, the patient should be resuscitated, treated prophylactically with broad-spectrum antibiotics, receive stress-dose steroids if appropriate, have laboratory tests performed, including blood type and crossmatch, and be marked for stoma placement. Débridement and primary repair of gastroduodenal perforation or resection with primary anastomosis after jejunoileal perforation is often possible, and proximal diversion with a loop or end stoma should be considered if conditions are unfavorable.[30]

Crohn's Disease of the Duodenum

As stated previously, the exact incidence and prevalence of upper gastrointestinal Crohn's disease are not known, and even though it is historically rare, the incidence has increased in recent reports. Careful examination and biopsy of the upper gastrointestinal tract in those with Crohn's disease will reveal histologic evidence of disease in as many as 30% to 50% of patients, although many will lack upper gastrointestinal symptoms. The duodenum can be primarily affected by Crohn's disease, or it can be secondarily affected as the victim organ of penetrating disease (Fig. 70–22). Symptoms of duodenal involvement include dyspepsia or epigastric pain, anorexia, and proximal obstructive symptoms such as early satiety, nausea, vomiting, and weight loss. Complications of proximal Crohn's disease are similar to those found with more distal disease; inflammation, strictures, and fistulas (almost all of which are the result of penetration into a normal duodenum) occur along with an increased risk for cancer in areas of long-standing disease. Because the majority of patients with upper gastrointestinal disease have concomitant lower gastrointestinal disease and because medical therapy for proximal Crohn's disease has not been well studied, the course of medical treatment is typically determined by the clinical course of the distal disease. Many of the principles of surgical

Figure 70–22. Upper gastrointestinal series demonstrating multifocal Crohn's disease of the duodenum.

management discussed in previous sections apply to complicated duodenal disease: after medical therapy has been instituted for active Crohn's disease, the patient should receive nutritional support with preference given to the enteral route; frank abscesses that are accessible should be percutaneously drained; fistulas should be divided and the bowel segments from which they arose should be resected; minimal débridement of the duodenum may allow primary closure with the Heineke-Mikulicz technique, although more extensive débridement may require a duodenojejunostomy, gastrojejunostomy, or Roux-en-Y anastomosis for reconstruction; and strictures can be treated with a stricturoplasty when technically feasible or may require a duodenojejunostomy, gastrojejunostomy or Roux-en-Y anastomosis for reconstruction.[109]

Postoperative Care

In most respects, the postoperative care of patients who have undergone surgery for Crohn's disease is not different from that in patients who have undergone any other type of gastrointestinal surgery. Routine use of postoperative nasogastric suction is not required for distal procedures, but it may be considered for procedures involving the upper gastrointestinal tract. If stress-dose steroids were required, they can be tapered quickly if the patient is not critically ill.[94]

Recurrence of Crohn's disease after resection, which usually occurs at the site of surgical anastomosis, is seen in almost all patients when they are monitored long-term. First, there is endoscopic recurrence, which in a significant number of patients is followed by

symptomatic recurrence. One study found endoscopic evidence of Crohn's disease recurrence in 73% of patients 1 year after surgery, with only 20% of patients having symptoms; when observations were repeated 3 years after surgery, the endoscopic recurrence rate had increased to 85%, and symptoms were present in 34%. Perhaps the most important measure of recurrence is the need for reoperation, with about half of patients undergoing ileocolonic resection requiring reoperation within approximately 10 years of surgery.[86]

There is evidence to support the use of some types of medical therapy to prevent both endoscopic and symptomatic recurrence of Crohn's disease after surgery. Besides being inappropriate for maintenance therapy in nonsurgical Crohn's patients, steroids have proved ineffective for prophylaxis against disease recurrence in the postoperative setting. Sulfasalazine has not been shown to be consistently helpful in preventing postoperative recurrence. Although there is evidence to support the efficacy of other 5-acetylsalicylate preparations in the maintenance of postsurgical remission in Crohn's disease, the overall beneficial effect of mesalamine is small. Only a modest benefit has been shown with azathioprine and 6-mercaptopurine in the postoperative setting, but because there is much stronger evidence supporting their use in maintenance therapy after medically induced remission, they are probably justified in high-risk postoperative patients.[65,86]

Finally, smoking cessation is advised in all postoperative Crohn's disease patients; smokers have double the rate of recurrence, and smokers who quit have decreased rates of recurrence.[65]

Ileostomy

Riaz Cassim · David W. McFadden

HISTORICAL PERSPECTIVES

An ileostomy is a communication constructed between the distal part of the small intestine and the abdominal wall. It may be temporary or permanent and is classified according to the anatomic configuration upon creation. When performed after removal of the entire colon and rectum, it takes the form of a permanent end ileostomy. With the growing popularity and success of restorative proctocolectomy for ulcerative colitis, familial adenomatous polyposis, and low rectal cancer, the number of permanent ileostomies being performed has shown a downward trend.[1] Protection of these low-lying anastomoses has brought about the need for temporary diversion of the intestinal contents. This has been accomplished with the use of a temporary loop ileostomy.

The first recorded case of creation of an ileostomy is credited to Baum in 1879 for relieving an obstruction secondary to cancer of the ascending colon.[2-4] During the early half of the 20th century the ileum was simply brought out several inches through the abdominal wall for subsequent drainage.[5] Initially, the ileum was exteriorized via the inferior portion of the abdominal incision. It was not until the 1930s that the ileostomy was created through a separate right lower quadrant incision.[2] Healing was achieved by the formation of scar tissue between the serosa of the small bowel and the abdominal wall. This led to inflammation of the exposed serosa and ultimately resulted in stricture formation at the ileostomy exit site and subsequent intestinal obstruction with signs of abdominal cramping, voluminous ileostomy output, and hypovolemia. This condition was termed *ileostomy dysfunction* and was described by Warren and McKittrick in 1951.[6] In an effort to expedite healing and prevent irritation of the abdominal wall, Dragstedt in 1941 started covering the ileostomy with a skin graft, which led to a long and unsightly stoma.[4]

Ileostomy, as we know it today, has been around only for past 50 years. Dr. Bryan N. Brooke described it in 1952 when he inverted the end of the ileum before maturing the stoma in the operating room, and it has thus come to bear his name.[2,7,8] In 1953 Turnbull advised a similar technique whereby the seromuscular layer of the distal half of the exteriorized small bowel was removed and the mucosal tube was everted over the proximal half, thereby covering the exposed serosa.[2,8,9]

Significant advances were made by the development of a practical ileostomy appliance in 1936. Strauss, a Chicago surgeon, Koenig, his patient, and Rutzen, who made it commercially available, share the credit.[2,8,10] In addition, a major step in ileostomy care was establishment of the first ileostomy club by Turnbull at the Mount Sinai Hospital in New York.[2,10,11] As of 2001 there are over 450 chapters in the United Ostomy Association with 25,000 members. Turnbull also initiated the training program for enterostomal therapists in 1961 at the Cleveland Clinic.[2,9,10]

INDICATIONS

Total proctocolectomy with a permanent end Brooke ileostomy still remains the gold standard operation for patients with ulcerative colitis and familial polyposis. An end ileostomy may be potentially reversible if it is deemed that an ileoanal anastomosis may be hazardous, such as in patients with severe malnutrition, peritoneal contamination, or vascular compromise. A total abdominal colectomy with end ileostomy can then be performed, with completion proctectomy and ileoanal pouch anastomosis done as a second-staged precedure.[1]

Many conditions require temporary decompression and diversion after colorectal surgery. Few studies have compared the morbidity and mortality associated with diverting loop colostomy and loop ileostomy for protection of a colorectal anastomosis, and the results have been divided.[12-16] Rullier et al. have shown that the morbidity after loop ileostomy construction and closure, including the risk for reoperation, is significantly lower for loop ileostomy than for loop colostomy.[16] Other studies have also shown excellent results with loop ileostomy.[17,18] Quality of life, although altered in all patients with stomas, is less impaired after a loop ileostomy because the effluent is odorless and the stoma is less bulky and less prone to prolapse.[13,19-21]

A temporary loop ileostomy may be warranted for the following conditions[15,22,23]:

- Anastomotic factors
  - Protecting a complicated anastomosis, such as coloanal and ileoanal anastomoses
  - Proven anastomotic leakage at surgery
  - Technical difficulties, such as incomplete staple rings and tension
  - Anastomosis in an irradiated field
  - Anastomosis in the presence of mild peritonitis or contamination
  - Multiple distal anastomoses
- Crohn's disease
- Carcinomatosis with distal obstruction
- Abdominal trauma
- Congenital anomalies

PHYSIOLOGY

An ileostomy starts to function 48 to 72 hours after construction. A mature ileostomy produces between 400 and 700 mL of effluent per day. This volume remains relatively constant for an individual. The contents are weakly acidic (pH 6.1 to 6.5). Sodium excretion is 60 to 120 mEq/day, which is two to three times higher than in normal feces. Equilibrium is established by renal conservation of salt and water.[24] If the ileostomy output is excessive and leads to dehydration, the urine becomes concentrated and acidic. This may result in the formation of uric acid calculi, which have been reported in 3% to 13% of ileostomates.[11,25]

Cholelithiasis after permanent ileostomy has been reported in up to 30% of patients.[25,26] Patients older than 50 years and females are at a slightly higher risk for unknown reasons.[26] Cholesterol stones are precipitated by disruption of the enterohepatic circulation of bile acids by removal or inflammation of the terminal ileum.[27]

PREOPERATIVE PREPARATION

The thought of a stoma, whether permanent or temporary, is frightful and anxiety provoking for most patients. It is important to relieve patient fear about living with a stoma. Providing patients with literature on their disease and the proposed surgery is often helpful. Getting a patient in touch with ostomy support groups, especially with an individual of similar age, gender, and socioeconomic status, will aid the patient in realizing that a normal life is possible with an ileostomy.

Proper positioning of the stoma and meticulous surgical technique are the two most important factors that ensure success with a well-functioning ileostomy. A preoperative visit with the enterostomal therapist is essential. The latter can provide important preoperative counseling and perform proper marking of the stoma site, which has a direct bearing on the subsequent outcome of the ileostomy and management.[28,29] Ileostomy effluent is liquid, corrosive to the skin, and voluminous. An ileostomy that is properly located will often prevent complications such as leakage resulting in skin breakdown, prolapse, and peristomal hernia.[29,30]

Typically, the ileostomy is positioned in the right lower portion of the abdomen through the rectus abdominis muscle. This point usually corresponds to a third of the distance on an imaginary line stretching from the umbilicus to the right anterior superior iliac spine. The stoma should lie on the bulge of the infraumbilical skin fold.[21] Another way to determine the location is to draw a vertical line through the umbilicus and another horizontal line through the inferior margin of the umbilicus. The faceplate of the appliance is positioned in the right lower quadrant so that it abuts against the two imaginary lines. The opening of the faceplate usually corresponds to the outer half of the rectus muscle.[22]

Previous scars, bony prominences, the waistline, the beltline, the inguinal crease, the costal margin, the umbilicus, and skin folds should be avoided if at all possible. These sites interfere with proper placement and management of the ileostomy appliance and thus lead to poor clinical outcomes. The faceplate of the ileostomy appliance should be placed on the patient and its appropriateness confirmed by having the patient bend, stand, sit, and lay down. In patients who are obese, it should be placed at the level of the umbilicus or higher for ease of management. Ostomates have to be able to visualize the stoma if they are to participate effectively in stoma care. Once the ideal stoma site has been determined, it is marked with a permanent marking pen or preferably by intradermal injection of methylene blue dye.

TECHNIQUES

For an optimal outcome one must focus on potential complications and postoperative care while constructing an ileostomy. Adhering to the basic surgical principles of gentle tissue handling, good hemostasis, and prevention of tension will ensure good results. Placing the ileostomy in the main incision should be condemned because this prevents the placement of a well-fitting appliance and leads to a higher incidence of wound infection, dehiscence, and incisional hernia.[28]

END ILEOSTOMY

The patient is placed in the supine or the perineolithotomy position, depending on the resection being performed (Fig. 71–1). A hypodermic needle is used to scratch a mark at the preoperatively marked stoma site in the right lower part of the abdomen because if the site is marked with a pen, it will be erased with vigorous surgical preparation. For most operations, a midline approach passing to the left of the umbilicus is preferable to help minimize scars and preserve the remaining quadrants of the abdomen should revision or relocation of the ileostomy be required in the future. Such an approach is particularly important in patients with Crohn's disease.

Preparation of the terminal or distal ileum is an important aspect of the procedure. The ileocolic artery is divided as part of the right colectomy, but the

remaining small bowel mesentery and vascular arcades are preserved. The mesentery of the distal small bowel is mobilized along the right posterior abdominal wall all the way to the duodenum to ensure adequate mobilization and construction of a tension-free stoma. Once the ileum is exteriorized, it should lay there without any mechanical effort.

After the appropriate resection has been performed, the ileum is divided with a GIA stapler or between clamps. It is important to preserve as much terminal ileum as possible, especially in patients with benign disease.[1] The bowel is divided 2 to 3 cm proximal to the ileocecal valve and should be free of any visible inflammatory changes, which is important in patients with Crohn's disease. The distal 2 to 3 cm of ileum to be exteriorized is cleansed of its mesentery so that eversion can take place without difficulty.

Before making a skin incision at the stoma site, all layers of the abdominal wall are apposed to reduce the shearing effect of the layers of the abdominal wall on the stoma. Such shearing predisposes to stenosis. Apposition is achieved by placing clamps on the cut edge of the fascia, peritoneum, and dermis of the skin and applying traction to keep the layers at the same level. A 2-cm disk of skin is removed at the previously marked stoma site and can be effectively accomplished by grasping and elevating the skin with a Kocher clamp and removing the skin with a horizontal sweep of the knife. The subcutaneous fatty tissue is divided and not excised to help provide support for the ileostomy, as well as the appliance.[1] In obese patients, a cylinder of subcutaneous fatty tissue may be excised to provide room for the bulky exteriorized bowel. With good retraction the anterior rectus sheath is easily identified and incised in a cruciate fashion. The rectus muscle is separated in the direction of its fibers with scissors or a blunt clamp. The posterior rectus sheath is identified and made prominent by pushing it through the separated rectus muscle fibers with the index and middle fingers introduced through the midline abdominal wound. A vertical incision is made in the posterior sheath. The newly constructed stoma opening should permit the passage of two fingers.

Babcock clamps are introduced into the peritoneal cavity through the stoma opening and used to grasp and deliver the end of the ileum out onto the abdominal surface. About 4 cm of ileum should be exteriorized and should lie without tension. Greater lengths of ileum need not be exteriorized because the everted ileostomy does not have to be more than 2 cm in height. Care is taken to ensure that the mesentery of the distal portion of the small bowel is not twisted, the divided edge of the mesentery points cephalad, and the proximal portion of the small bowel occupies the left side of the abdomen.

If the ileostomy is to be permanent, intraperitoneal fixation of the bowel and mesentery to the posterior rectus sheath is performed. Such fixation helps distribute the tension evenly around the stoma. Three or four interrupted sutures with fine (4-0) absorbable material are used. Seromuscular bites are taken through the ileum and secured to the parietal peritoneum. This step is omitted in patients with Crohn's disease because inadvertent full-thickness bites through the bowel may lead to the development of fistulas. The right lateral aspect of the abdomen is left open. However, closure may be accomplished by suturing the mesentery of the distal ileum to the anterior abdominal wall. This maneuver is believed to prevent herniation of the small bowel around the intra-abdominal portion of the ileostomy. Superiorly, the mesentery may be sutured to the falciform ligament to ensure complete closure. It is important to completely obliterate this space. If there is any tension on the

mesentery, it is better to leave the defect wide open. Alternatively, performing an extraperitoneal ileostomy can close this defect.[29] Closure of the lateral abdominal space has not been shown to decrease the subsequent development of small bowel obstruction.[31,32]

Once it is deemed that the ileostomy is viable and there is no twist in the small bowel mesentery, the midline incision is closed. The skin is approximated and the incision is covered so that it is protected from coming in contact with the intestinal contents, which would increase the risk for wound infection.

The staple line is divided with a knife or electrocautery. Fresh bleeding from the mucosal edges ensures viability of the ileostomy. Maturation is begun by placing a three-point stitch in each of the four quadrants.[1] Fine (3-0 or 4-0) absorbable sutures are used for incorporating full-thickness bites of the open end of the ileum, a seromuscular bite just proximal to the anterior fascia, and finally a bite through the dermis of the skin. By placing traction on these sutures the ileum is easily everted. Before tying down the sutures, one or two further sutures are placed in each quadrant. These are simple sutures that incorporate full-thickness bites of the edge of the open bowel and the dermis of the skin. Tying down all the sutures should result in a "rosebud" or spigot formation. Sutures through the full thickness of the skin should be avoided because scarring will prevent the application of a watertight appliance seal. The ileostomy should be protruding 1 to 2 cm above the abdominal wall to allow the placement of a well-fitting appliance. This is extremely important because the ileal effluent is very irritating and, if allowed to bathe the peristomal skin, will result in skin breakdown.

The skin surrounding the stoma is painted with skin adhesive, and a transparent ileostomy appliance is placed and allowed to hang to the right side of the patient. This facilitates emptying of the appliance in the immediate postoperative period, as well as inspection of the stoma without having to remove the ileostomy bag. The opening in the faceplate should be 2 mm wider than the stoma to allow for postoperative edema. The appliance is usually changed after the second postoperative day once the midline dressing is removed. If there is leakage around the appliance at any time, the device should be changed immediately.

LOOP ILEOSTOMY

A loop ileostomy is also located in the right lower quadrant (Fig. 71–2). The site is chosen preoperatively just as for an end ileostomy. At the completion of the appropriate procedure a loop of bowel is chosen for creation of the diverting ileostomy. It should be as distal as possible in the small intestine at a point where the bowel can be brought up onto the abdominal wall without tension. The proximal or distal limb should be marked with a suture so that orientation is maintained before maturation of the stoma.

A small opening is created in an avascular part of the mesentery at the apex of the loop. A ¼-inch Penrose drain is placed through this opening to help place traction and deliver the bowel to the anterior abdominal wall. The skin incision for the stoma site is made exactly as for an end ileostomy. Subcutaneous fat may have to be removed to accommodate the two loops of bowel along with its mesentery.

Some authors prefer to position the proximal limb in the dependent inferior position, but such positioning requires twisting the mesentery of the small bowel. Although placing the functional proximal end inferiorly theoretically achieves complete diversion and drainage, this is easily and very well achieved by maturing the stoma with the proximal end more prominent as described.

Because the stoma will be temporary, there is no need to anchor it to the posterior sheath. The Penrose drain is substituted for a commercially produced plastic ileostomy bridge, which is available in different lengths. This rod is anchored to the skin with nonabsorbable sutures and should protrude just beyond the stoma so that it does not interfere with proper placement of the ileostomy appliance. After ensuring that the bowel is oriented properly, the abdominal incision is approximated and protected. The small bowel is opened by making an incision two thirds of the way along the antimesenteric wall of the distal loop just above the skin surface. Three-point anchoring sutures are placed toward the proximal limb as described for the Brooke ileostomy. Three such sutures are placed, one on each side of the mesentery and the third bisecting these. The remaining bowel wall, including the distal limb, is matured by using simple fine absorbable sutures that incorporate full-thickness bites of the cut end of the bowel and the dermis of the skin, which should result in an accentuated proximal limb and a recessive crescent-shaped distal limb flush with the skin. A watertight ileostomy appliance is placed in the operating room. The ileostomy bridge is removed after about a week when the edema has partially subsided and the ileostomy is functioning.

DIVIDED-LOOP ILEOSTOMY

In 1984, Abcarian and Prasad described their experience in constructing a modified loop ileostomy (Fig. 71–3). The segment to be exteriorized is identified and the ileum is divided near the apex of the loop with a GIA stapler. The proximal end is pulled through the right lower quadrant stoma opening, and 5 cm is exteriorized. The antimesenteric staple line of the distal limb is brought up through the same opening and positioned cephalad to the proximal limb. The entire staple line of the proximal limb is removed and the stoma constructed as for an end Brooke ileostomy. One corner of the recessive limb staple line is excised, and it is matured as a mucous fistula flush with the skin, thus allowing for distal decompression. Two transitional sutures are placed between the adjoining walls of the two limbs to create a completely diverting, perfectly circular stoma, which allows for a better appliance fit.[25,33]

END-LOOP ILEOSTOMY

This rarely performed procedure should be in the armamentarium of all abdominal surgeons because it can be

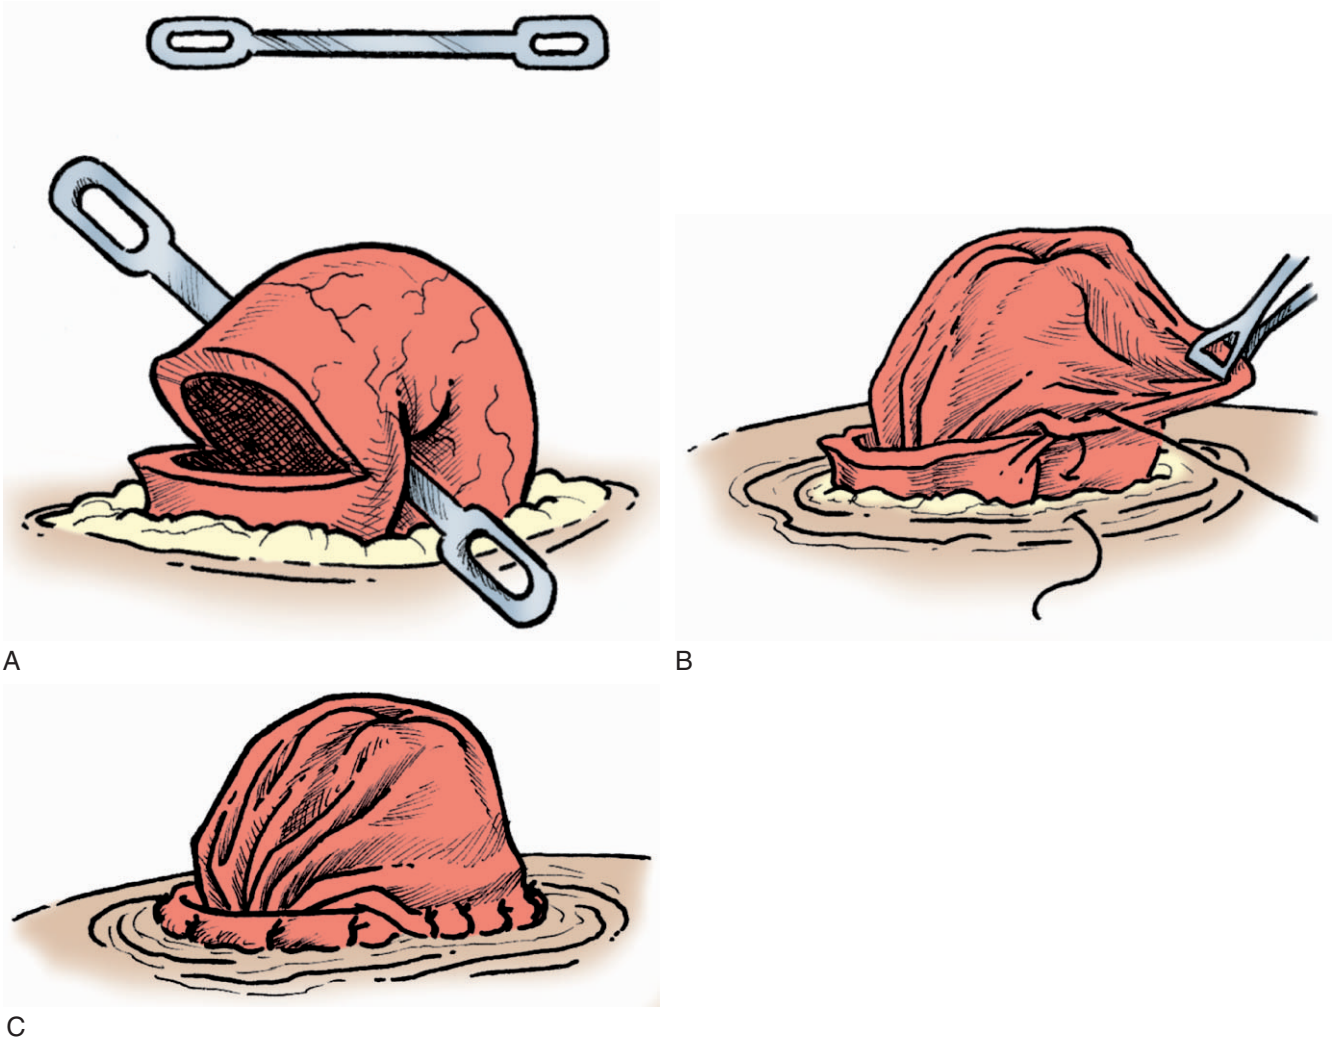

Figure 71–2. Maturation of a loop ileostomy. **A,** Commercially available plastic rod (shown separately) supporting the ileal loop. of great benefit when tension on the mesentery of the small intestine precludes construction of a viable end Brooke ileostomy (Fig. 71–4). This circumstance can be seen in patients with Crohn's disease who possess a thick short mesentery, in morbidly obese patients with thick anterior abdominal walls,[1] or in abdominal catastrophes in which edema and circulatory deficiencies prevent safe construction of an end ileostomy.

The distal part of the small bowel is transected as for an end ileostomy. The staple line may be oversewn and reinforced with absorbable seromuscular suture. A segment of bowel proximal to the closed end is chosen so that it can be exteriorized through the stoma opening on the right lower abdominal wall without tension. The construction then proceeds exactly as it would for a loop ileostomy. If the stoma is to be permanent, the bowel and its mesentery are anchored to the peritoneum and the posterior sheath with fine absorbable sutures.[22,25]

CLOSURE OF A LOOP ILEOSTOMY

Closure can be accomplished in most cases by a local procedure, thus eliminating performance of a formal celiotomy (Fig. 71–5). Closure is undertaken once it is ascertained that the distal anastomosis has healed completely and its integrity has been confirmed by contrast studies. In most cases the loop is closed a minimum of 6 weeks after the initial procedure to allow adequate tissue healing and softening of intra-abdominal adhesions. In a nonrandomized prospective study, Menegaux et al. have shown that temporary small bowel stomas may be closed safely on postoperative day 10 in healthy patients.[34]

The patient is positioned supine and a circumferential skin incision is made close to the mucocutaneous junction. Allis clamps can be used for vertical traction on the ileostomy. Circumferential subcutaneous dissection is carried out with electrocautery or scissors to reach the

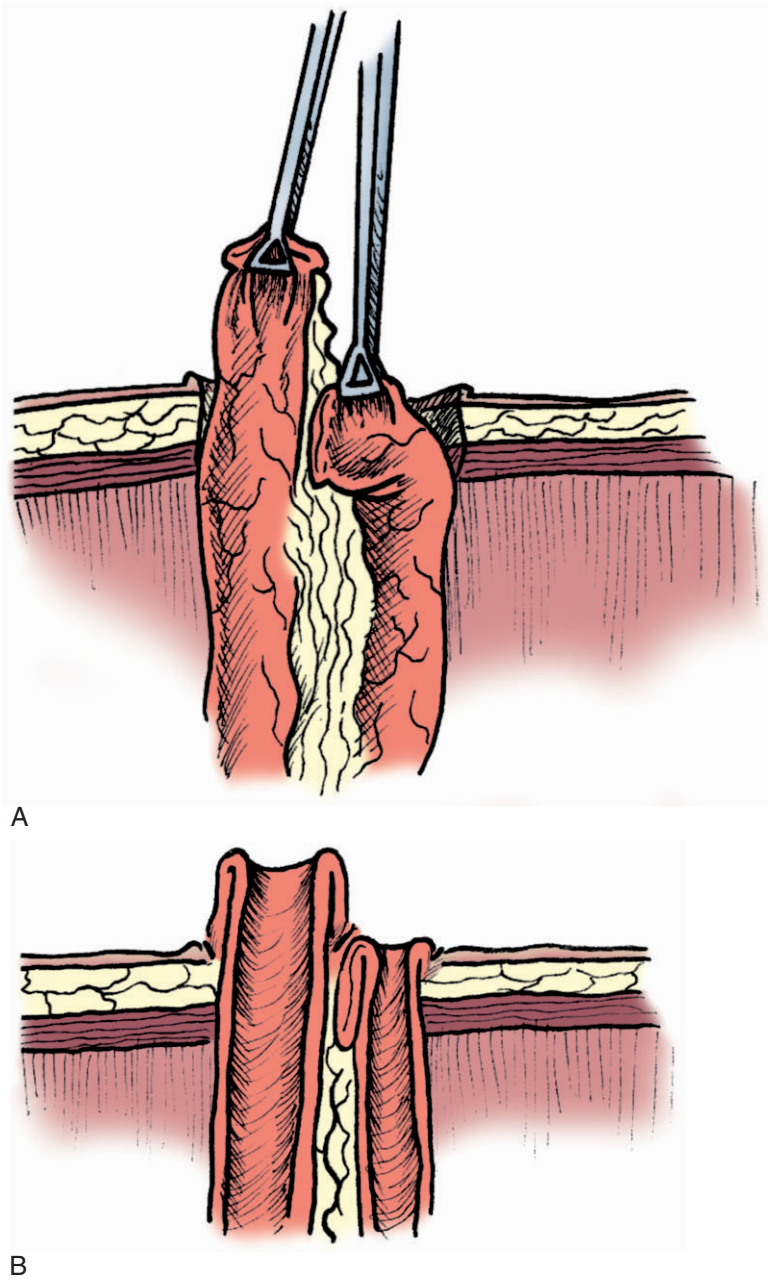

Figure 71–3. Divided-loop ileostomy. **A,** Proximal limb of the divided ileum delivered as for an end ileostomy. Only the antimesenteric border of the distal limb is brought up to the skin surface. **B,** On maturation it appears as an end ileostomy.

base of the ileostomy and identify the anterior fascia. Care is taken to prevent injury to the small intestinal wall or mesentery. The anterior sheath is incised close to the bowel wall to gain access to the peritoneal cavity. The intestine is circumferentially freed from peritoneal attachments by sharp dissection. The excess scar and skin are trimmed away from the bowel wall. The closure can be accomplished in various ways. The enterotomy can be closed transversely via a two-layer hand-sewn technique with an inner full-thickness layer and an outer seromuscular layer. Fine absorbable sutures are used for both layers. Alternatively, a linear stapler can be used to accomplish the same transverse closure.

If there is any concern about luminal narrowing, a linear cutting stapler is used to form a stapled side-to-side functional end-to-end anastomosis. The antimesenteric walls are aligned, and a GIA stapler is deployed to create the anastomosis. With a second GIA stapler placed transversely, the excess skin and ostomy opening are transected to complete the anastomosis.[1,29] No major difference in morbidity has been demonstrated between stapled and sutured closure, although stapled closure can be accomplished faster.[35] Hasegawa et al. have shown that postoperative bowel obstruction is less common after staple than after suture closure.[36]

The small bowel is returned to the peritoneal cavity and the fascia approximated with nonabsorbable suture. The subcutaneous space is thoroughly irrigated. The skin can be packed open or loosely approximated with staples and intervening Telfa wicks to drain the subcutaneous

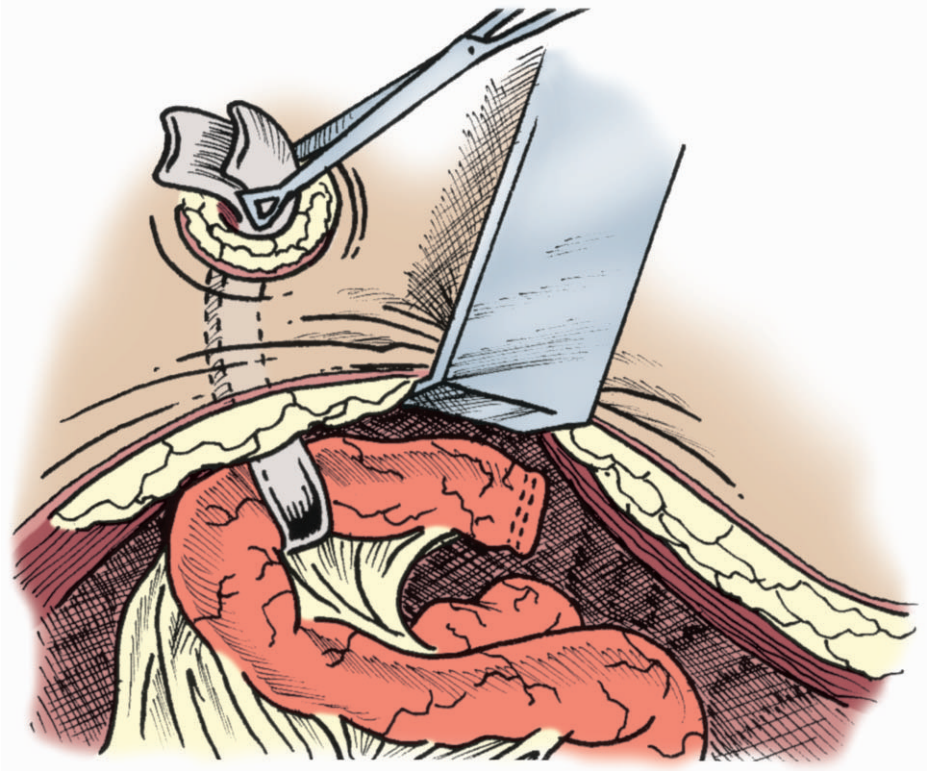

Figure 71–4. End-loop ileostomy. A loop of ileum proximal to the stapled end is delivered through the stoma site. Maturation takes place as for a loop ileostomy.

space. They can be removed after 48 to 72 hours. Sutton et al.[37] propose closing the skin with circular subcuticular nonabsorbable suture. The suture is tightened to draw the wound edges together while leaving a small 5- to 10-mm central defect, which allows the subcutaneous space to drain and heal by secondary intention. The suture is removed around the 14th postoperative day. They performed such a closure in 51 patients, with wound infections developing in none of them.

COMPLICATIONS OF ILEOSTOMY

Meticulous surgical technique and proper location of the stoma can minimize complications attributable to ileostomy construction and closure. The reported complication rates vary from 7% to 76%.[17,18,38-45]

Stoma Necrosis

Stoma ischemia with necrosis has been reported in 1% to 5% of patients undergoing construction of an ileostomy.[17,18,21,31,32,46] It is more often seen in the obese and after emergency procedures.[46] The most common cause is devascularization secondary to overzealous skeletonization of the terminal ileum for eversion. The viability of the stoma should be ascertained in the operating room. If the mucosa appears dusky, the ileostomy should be revised before leaving the operating suite. If discovered postoperatively (usually within 48 hours), one must determine the depth of viability, which can be accomplished by placing a test tube through the stoma opening and illuminating the lumen with a flashlight. If the ischemia is limited to the subcutaneous space and above the fascia, the patient can be treated by observation with revision performed later if stenosis develops. If the necrosis extends below the peritoneum, immediate revision is required.

Bowel Obstruction

Small bowel obstruction can occur after creation or closure of the ileostomy. It is important to differentiate between mechanical blockage because of food indiscretion (high-fiber foods), which occurs more distally at the stoma site just below the fascial level, and more proximal obstruction from intra-abdominal disease, such as adhesions, internal herniations, and recurrent strictures secondary to Crohn's disease. Bowel obstruction may also be caused by skin-level stoma stenosis as a result of ischemia. The clinical signs and symptoms are the same regardless of the cause and include cessation of ileostomy output, abdominal distention, crampy abdominal pain, nausea, vomiting, and dehydration. Patients with partial obstruction may have increased output. Treatment begins by instituting aggressive resuscitation, intravenous hydration, and nasogastric decompression. Kodner[22] proposed a logical algorithm to deal with this complication. A Foley catheter (24 French) is inserted into the stoma and held in place by partially inflating the balloon. Irrigation is performed with 50 ml of warm water. If there is return of food particles, the irrigation is carried out slowly until the return is clear and the mechanical food obstruction is relieved. If the initial fluid return is clear, one can

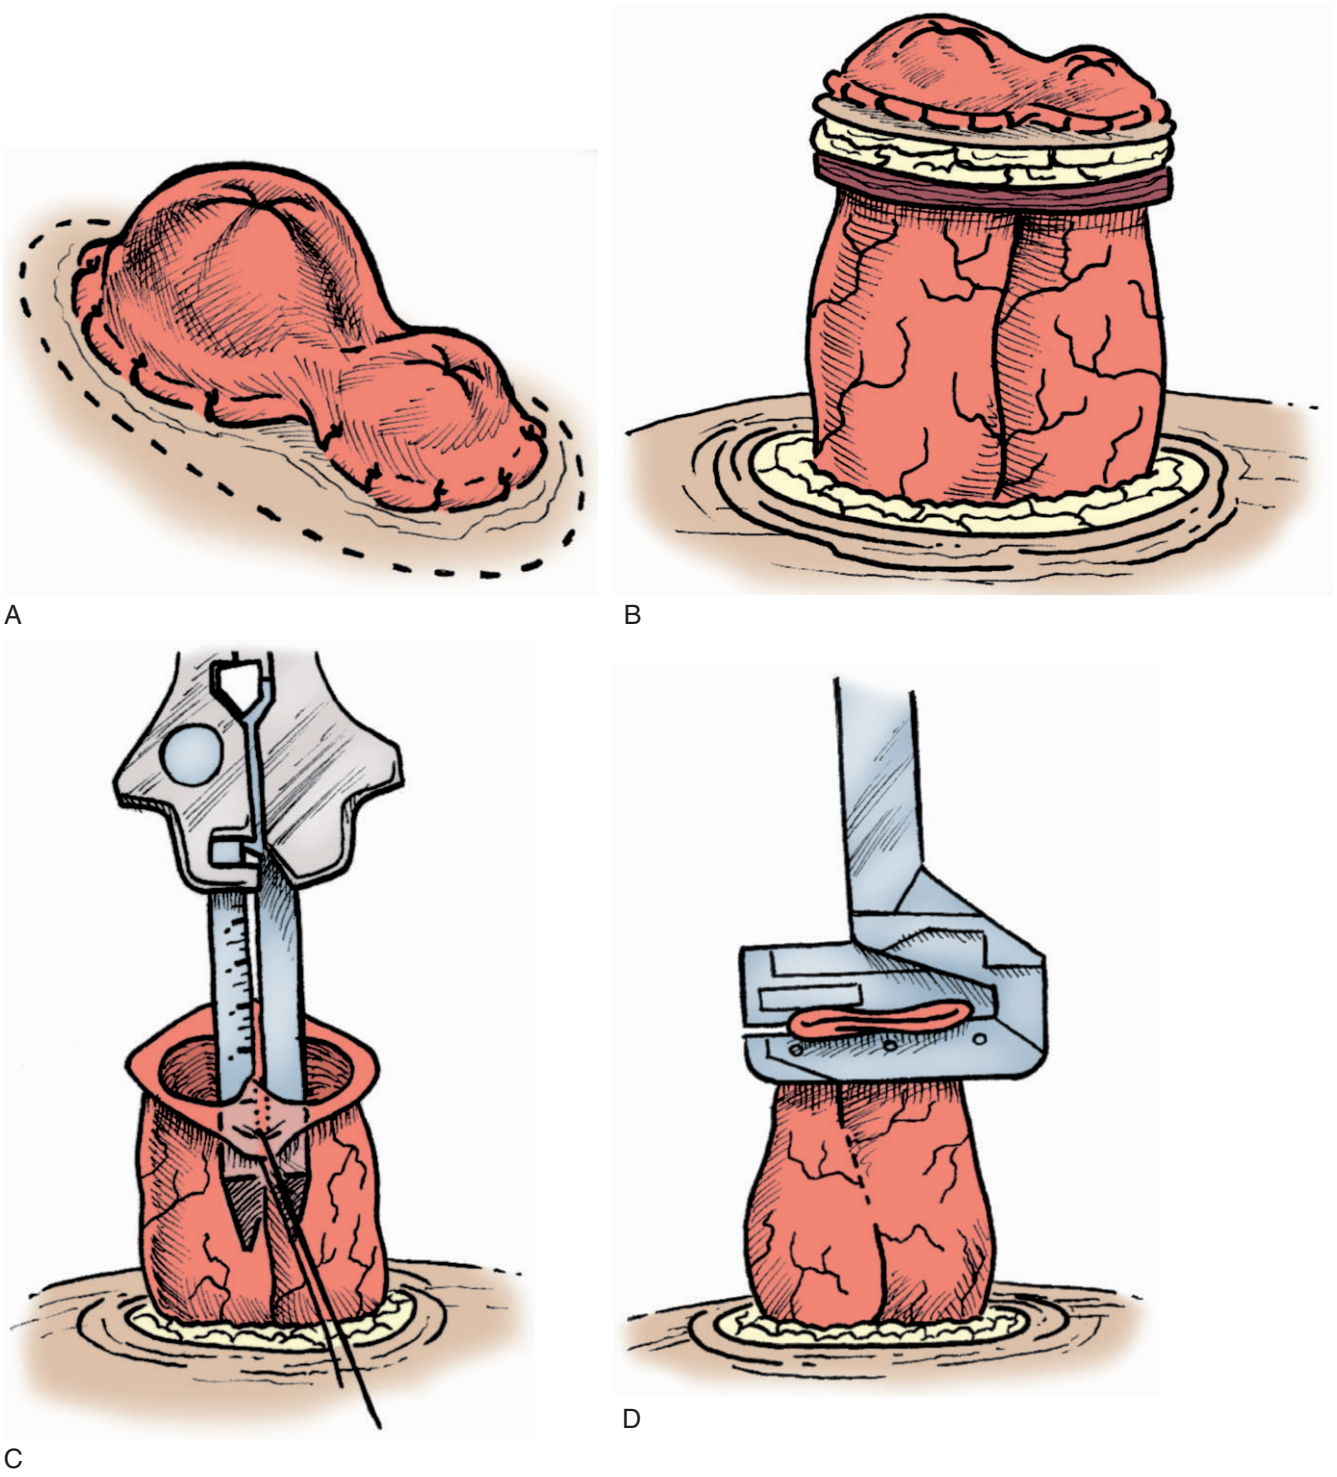

Figure 71–5. Loop ileostomy closure. **A,** Skin incision made around the ileostomy close to the mucocutaneous junction. **B,** Stoma and small bowel elevated after the intraperitoneal adhesions are divided. **C** and **D,** Stapled side-to-side anastomosis.

assume a proximal obstruction and perform a water-soluble contrast study to delineate the site of obstruction. This may be therapeutic if the obstruction is due to food particles. Patients should show signs of rapid improvement within 24 to 48 hours after conservative therapy. If any signs of impending bowel ischemia are present, early surgery is the prudent course.

Bowel obstruction has been reported in 3% to 17% of patients with ileostomies.[42,43,47-50] Feinberg et al.[42] had an 11% incidence of bowel obstruction after creation of a loop ileostomy. Senapati et al.[43] reported a bowel obstruction rate of 11.4% after ileostomy closure; two thirds of these obstructions were treated conservatively, whereas 11 (4.2% of all ileostomy closures) patients

required operative intervention. In Feinberg and colleagues' study, no patient had bowel obstruction after resection with anastomosis, and such treatment was better than a hand-sewn anastomosis or simple closure, although it did not reach statistical significance.

Mucocutaneous Separation

The newly matured stoma may separate from the surrounding skin if the tissue is friable, as in patients taking high-dose steroids, stoma site infections, and excessive tension on the maturing sutures. Management is conservative, with aggressive enterostomal therapy provided until the skin opening heals and a new mucocutaneous junction forms.[1]

Stoma Stenosis

Stomal stenosis develops in 2% to 10% of ileostomies.[21,31,32] It may occur if the fascial opening is made too small. The surgeon's middle and index fingers should pass through the stoma opening in the abdominal wall to ensure an adequate aperture size. Skin-level stenosis develops as a result of stomal ischemia or subcutaneous infection. Initial management is gentle dilation, which can be accomplished with Hegar dilators. If there is no relief from obstructive symptoms, surgical revision is undertaken. The stenosis may be corrected with a local procedure by taking down the mucocutaneous junction, dissecting down to the fascia, and making the opening larger with re-creation of the stoma. Laparotomy may be necessary if exteriorization of the bowel was initially inadequate.

Stoma Retraction

Retraction has been reported in 3% to 17% of all ileostomies.[17,18,21,31,36,46] Goldblatt et al. reported that 30% of their revisions were performed because of stenosis and retraction.[51] Tension on the small intestinal mesentery and lack of fixation of the mesentery and bowel to the peritoneum may result in this complication. A flush stoma may also occur as a result of weight gain and is seen in morbidly obese patients, who have a higher rate of stoma retraction.[52] With a skin-level ileostomy the effluent leaks onto the surrounding skin, causes breakdown, and prevents secure application of the appliance. It may be managed with skilled enterostomal therapy, but many patients require revision of the stoma.

Stoma Prolapse

Ileostomy prolapse has been reported in 0% to 11% of patients.[13,17,21,31,32,53,54] Causes include too large an abdominal wall fascial opening, lack of fixation of the mesentery to the abdominal wall, and placement of the ileostomy outside the rectus muscle or in previous incisions. It is usually associated with a parastomal hernia.[54] The prolapse may be intermittent or fixed. If the appliance can still be applied without leakage and the prolapse is stable and not bothersome to the patient, it need not be corrected. Repair is accomplished by a local approach that involves resecting the excess ileum and re-creating a Brooke ileostomy. Laparotomy for intraperitoneal fixation may be needed to preserve bowel length.

Parastomal Hernia

Parastomal hernia is seen less frequently after ileostomy than after colostomy construction.[53-55] It affects 1.8% to 28.3% of end ileostomies and 0% to 6.2% of loop ileostomies.[55] Patients with poor tissue characteristics, such as obesity, use of high-dose steroids, chronic obstructive pulmonary disease, malnutrition, raised intra-abdominal pressure, and previous herniations, are at risk.[53,54,56] No difference in incidence rates has been demonstrated with regard to location of the stoma through the rectus muscle, fascial fixation, or closure of the lateral space.[55-58]

The majority of patients are asymptomatic. Operative indications include symptoms of small bowel obstruction, localized discomfort, an enlarging mass, and poor appliance fit that may result in leakage of effluent and peristomal skin breakdown. About 30% of patients with peri-ileostomy hernias require operative repair.[59]

Repair may be accomplished by direct fascial approximation, prosthetic mesh repair, and relocation of the stoma to new site. Although fascial reapproximation is the simplest option because it avoids a formal laparotomy, it carries with it an unacceptably high rate of hernia recurrence (46% to 100%).[55,59,60] The prosthetic mesh may be placed intraperitoneally or as a fascial onlay. There is a small risk of mesh infection and erosion into the bowel (3%).[59] Recurrence rates after mesh repair are reported to be between 0% and 39%.[55,59,60] Reiger et al., in their series of 41 patients who underwent 51 repairs, showed that the lowest recurrence rates were seen after stoma relocation (24%).[60] The reported rates vary between 0% and 76%.[55,59,60] If the hernia defect is large, the ileostomy can be relocated via the paraileostomy incision and thereby avoid a formal laparotomy. No clinical trials have compared the aforementioned procedures, and the reported numbers are small.[55]

Laparoscopic repair of paraostomy hernias has been reported, but the series are small and not limited to paraileostomy hernias. Recurrence rates of 0% to 44% are reported.[61-63] Safadi reviewed 11 studies with a total of 37 patients and added 9 of his own. He described a recurrence rate of 44.4% within 6 months of the operation.[61] As experienced is gained and techniques are refined, the results may improve. The advantage of this approach is that it avoids stoma relocation and reduces postoperative pain and wound complications.

Peri-ileostomy Fistula

The incidence of peri-ileostomy fistula is unknown. Older studies reported rates of 24% to 40%.[51,64] A fistula may result from recurrent Crohn's disease, operative

injury when an anchoring stitch incorporates the full thickness of the bowel wall, ischemic injury to the stoma, or ill-fitting appliances.[65] Greenstein et al.[66] reported a series of 214 patients with an ileostomy constructed for Crohn's disease. Parastomal fistulas developed in 14 patients (6.5%), and all cases were a consequence of recurrent Crohn's disease.

Because fistulas pose a difficult proposition of maintaining a secure ostomy appliance, treatment consists of reconstruction of the ileostomy either at the same location or at a new one, depending on the complexity of the fistula.[66] Medical therapy has not been successful in treating these fistulas, although infliximab may be of benefit.

Hemorrhage and Peri-ileostomy Varices

Trauma to the stoma from ill-fitting appliances may cause mucosal tears or shallow ulcers that result in troublesome bleeding. These lesions heal spontaneously with proper stomal care and enterostomal therapy.

Sclerosing cholangitis leading to cirrhosis is seen in patients with inflammatory bowel disease. These patients may manifest parastomal varices in addition to anorectal and esophageal varices. Local treatment with sclerosing agents or variceal ligation provides temporary control. Definitive treatment consists of portosystemic shunting or selective splenorenal shunting.[67,68]

Peri-ileostomy Skin Problems

Peristomal skin irritation has been reported in 15% to 79% of patients with an ileostomy.[42,53,54,69] It commonly accompanies flush or retracted stomas, which result in poor appliance fit and leakage of effluent. Skin problems are seen more frequently after emergency procedures because preoperative stoma positioning is not usually possible.[52] The peristomal skin may secondarily become infected with bacterial or fungal organisms (11%), most commonly *Candida albicans*.[30] Treatment consists of local antifungal powder and enterostomal therapy.

Paraileostomy skin ulceration can be secondary to recurrent Crohn's disease or be a manifestation of pyoderma gangrenosum. The latter is due to underlying active inflammatory disease and resolves after removing the diseased segment of bowel. Aggressive enterostomal therapy is needed in the interim.[69]

Ileostomy Diarrhea

Increased ileostomy output may be seen with gastroenteritis, partial small bowel obstruction, radiation enteritis, short-bowel syndrome, and Crohn's disease.[54] Ileostomy effluent totaling greater than 1000 ml/day may lead to dehydration and sodium depletion requiring hospitalization and intravenous fluid replacement. In the first month after construction of a new ileostomy, dehydration secondary to stomal water and electrolyte loss is common. Treatment includes intravenous fluid resuscitation, dietary manipulation, antidiarrheal agents, and fiber. The risk of dehydration requiring hospitalization from a loop ileostomy can be as high as 20%.[42,54] Chronic dehydration leads to acidic urine and predisposes to the formation of uric acid calculi.[54]

CONCLUSION

Living with an ileostomy is a major life-altering event for patients. With thorough preoperative preparation, patient education, meticulous surgical technique, and patient access to enterostomal therapy, complications can be prevented and the patient's quality of life improved.

Chapter

72

Suturing, Stapling, and Tissue Adhesives

John Migaly • Rolando Rolandelli

The healing of a bowel anastomosis proceeds in a stepwise, time-dependent fashion. At the time of transection of the bowel, there is an immediate inflammatory response elicited by activation of the clotting cascade, recruitment of platelets, and perpetuation of the inflammatory cascade via the elaboration of inflammatory mediators stored in platelet granules. Neutrophils are subsequently recruited into the wound. During these first 3 to 5 days, termed the inflammatory phase of wound healing, the collagen matrix undergoes degradation by metalloproteinases. It is in this initial phase that the integrity of the anastomosis depends almost entirely on technical factors, suture materials, or the integrity of stapled margins of bowel.[1]

Around the fifth postoperative day there is a crucial switch from collagen degradation to collagen deposition, which corresponds to the transition from the inflammatory phase to the fibroplasia phase (Fig. 72–1). The fibroplasia phase reaches its maximal level at day 7.[2] Any delay or impairment of the fibroplasia phase can result in the potentially catastrophic consequence of anastomotic dehiscence.[3] Indeed, it is at the end of the first postoperative week that anastomotic dehiscence usually occurs and becomes clinically evident.

Although it may seem that surgical stapling devices have completely supplanted hand-sewn suturing of bowel anastomoses, hand suturing remains a crucial skill in every surgeon's armamentarium. Certain situations are not amenable to surgical stapling, and it is in these situations that the surgeon's facility with suturing techniques can vastly affect the outcome of an intestinal anastomosis.

Hand suturing uniformly invokes an inflammatory response from dragging the suture material through the bowel. The choice of suture material used by surgeons is not based on a strong preponderance of scientific evidence. Everting and inverting anastomoses have come in and out of favor over the last 2 centuries, as have many anastomotic techniques.

SURGICAL SUTURING AND TECHNIQUE

Suture Material

All sutures produce some degree of inflammation as they are dragged through tissues. The degree of inflammation corresponds to the amount of collagenases and metalloproteinases produced in the local wound environment and the subsequent loss of tensile strength in both the wound and the suture material itself.[4]

The ideal suture material should elicit minimal tissue reaction and be easy to handle and tie without fraying. It should also be relatively easy to sterilize while maintaining all of the ideal characteristics after sterilization.[5]

The type of suture used has traditionally been tailored to the particular layer of the intestinal tract that the suture material is being used to approximate. Chromic catgut is the most commonly used as an inner layer of suture in a two-layer intestinal anastomosis.

In the 1950s, Madsen studied 12 different suture materials and concluded that absorbable suture materials display a marked tissue reaction with delay of collagen formation.[6-8] Because chromic catgut is reabsorbed between 18 and 21 days, it is not the material of choice for single-layer applications such as bilioenteric anastomoses.[9] The absorbable synthetic sutures of polydioxanone (PDS) and polyglyconate (Maxon) are the commonly used sutures in these anastomoses because of their longer retention time in wounds and sustained breaking strength.

The absorbable synthetic suture materials polyglactin (Vicryl) and polyglycolic acid (Dexon) are used interchangeably with chromic catgut but have the added benefits of decreased inflammatory response and increased strength. The downside of these sutures is that they are braided and produce more drag across the intestinal wall.

Silk suture is still the traditional nonabsorbable suture most commonly used for intestinal anastomoses, and it

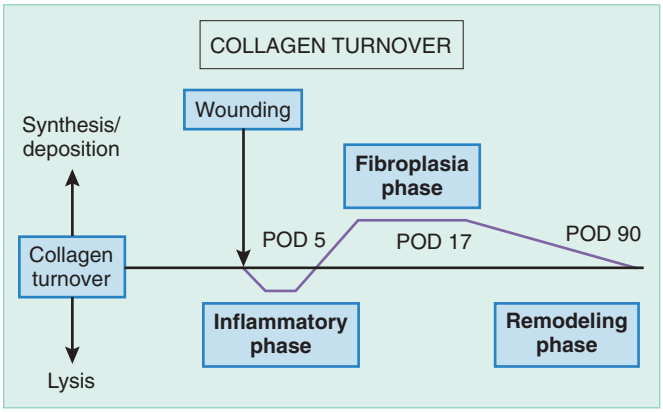

Figure 72–1. Collagen deposition and lysis as a function of time in intestinal healing. POD, postoperative day. (From Migaly J, Lieberman J, Long W, et al: Effect of adenoviral-mediated transfer of transforming growth factor-beta1 on colonic anastomotic healing. Dis Colon Rectum 47:1703, 2004.)

was lauded as the most reliable suture by Halstead as far back as 1913.[10] Silk is used most often as the outer layer of a two-layer anastomosis and is most commonly used as an interrupted seromuscular stitch.

In conclusion, in two-layer anastomoses, the inner layer is usually an absorbable suture such as chromic catgut, Dexon, or Vicryl, with the outer seromuscular stitch being silk. If a one-layer anastomosis is to be performed, a nonabsorbable suture such as silk is used. Bilioenteric anastomoses are commonly performed as one-layer anastomoses with more durable absorbable synthetics such as PDS or Maxon.

Suture Material and Infection

As in the case of any implantable foreign body, suture material can potentiate bacterial infection in an intestinal anastomosis. The particular properties of a suture determine its ability to thwart or encourage bacterial infection. Bacterial adherence is variable among the various suture types.

Chu and Williams examined 10 types of suture ranging from absorbable to nonabsorbable, monofilament to braided, and synthetic to natural origins and quantitatively determined the adhesion of radiolabeled bacteria to these various sutures. They found that PDS sutures exhibited the lowest affinity to the adherence of *Escherichia coli* and *Staphylococcus aureus*. Dexon sutures exhibited the highest affinity to these species.[11]

Katz et al. confirmed these results and, furthermore, demonstrated via an in vivo model of wound infection that suture materials potentiate bacterial growth and cause infection in mice. They injected suspensions of staphylococci into subcutaneous pockets in mice and found that 10^9 bacteria were necessary to cause wound infection in mice in the absence of suture whereas only 10^5 were necessary to elicit significant wound infection in the presence of suture. They also found that the inflammatory response and infectivity scores correlated nicely with the adherence indices of the various types of suture. The fastest removal of bacteria was from nylon, and the slowest was from silk.[12] Consideration should be given to the type of suture used in the event of gross fecal soilage.

Suture Material and Tumor Cell Adherence

Both in vitro and animal data support the theory that certain suture materials support the growth of tumor cells more than others do.[13] Using a rodent model, Reinbach demonstrated that radiolabeled tumor cells adhere more avidly to silk suture used to close enterotomies of the colon than they did to PDS sutures.[14] Further investigation is obviously warranted before deciding which suture truly conveys an oncologic advantage in bowel anastomoses.

Methods of Suturing

Suture lines can be created either in a simple or interrupted fashion or in a continuous or running manner. The advantage of a continuous suture is that the suture line is more watertight, with the disadvantage being that the integrity of the entire suture line is based on one stitch. Hemostasis is also improved with a continuous suture, with the converse effect being that continuous suturing may constrict anastomotic blood flow more than interrupted suturing does.

Regardless of whether the suture is run in continuous or interrupted fashion, a bowel anastomosis must adhere to the following principles. The anastomosis must be watertight and must have mucosal apposition. The submucosa, which supplies much of the strength to a bowel anastomosis, must be incorporated into the closure. Care must be taken to not strangulate the edges of the bowel during closure in order to avoid stricture or necrosis and subsequent anastomotic leakage.

Lembert Suture

Lembert suture is the most commonly used suture in gastrointestinal surgery (Fig. 72–2). It is used as the outer layer of a two-layer bowel anastomosis and is also used to repair seromuscular tears in the bowel wall. The stitch is started approximately 3 to 4 mm lateral to the incision and placed at a right angle to the long axis of the incision. It incorporates only the seromuscular layer; care must be taken to not incorporate the full thickness of the bowel wall. The tip of the needle is brought out close to the edge of the incision and is then reinserted in the apposing wound edge and brought out 3 to 4 mm lateral to the wound edge. The suture is then tied down to a tension that approximates the tissue, but not tight enough to tear the tissue. The most commonly used material for a Lembert suture is either silk or PDS suture. This stitch can be performed in an interrupted or continuous manner.

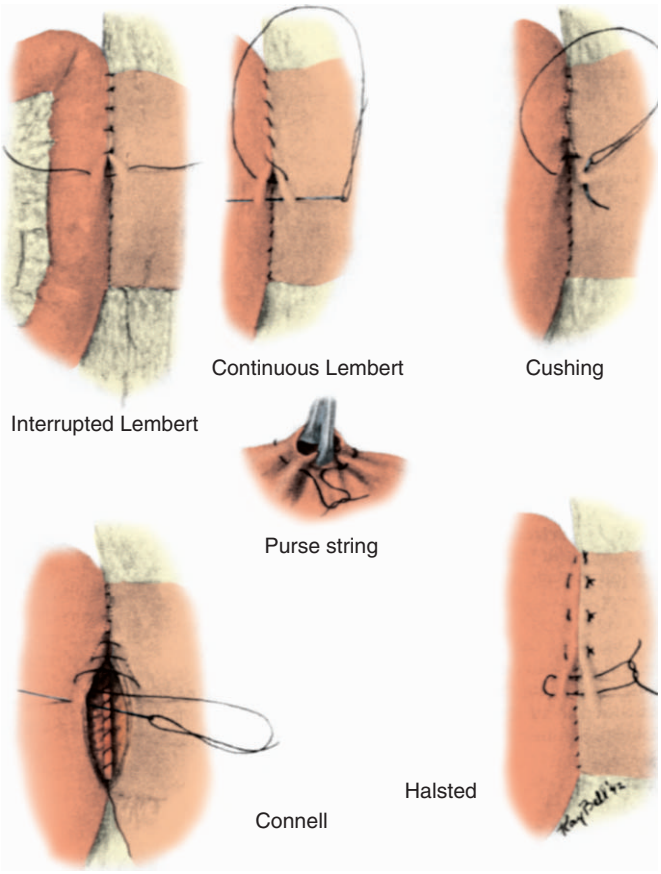

Figure 72–2. Common methods of intestinal suturing. (From Orr TG: Operations of General Surgery, 2nd ed. Philadelphia, WB Saunders, 1949.)

Horizontal Mattress Suture (Halsted Suture)

A horizontal mattress suture, or Halsted suture, is predominantly used for seromuscular apposition in multilayer bowel anastomoses (see Fig. 72–2). The suture is passed through the seromuscular layer 2 to 3 mm lateral to the wound edge and brought out at the wound edge; the needle is then passed through the opposing edge of the wound and brought out 2 to 3 mm lateral. On that same side of the wound approximately 2 mm distal, the suture is passed through both edges of the wound to create two free ends of the suture on one side of the wound edge with the loop of the suture on the other side. This stitch is particularly useful in damaged, inflamed, or abnormal tissue where a Lembert suture pulls through the tissue. Because the horizontal mattress stitch distributes tension in a plane perpendicular to that of a Lembert suture, it allows for apposition of tissues with less crushing effect on them.

Purse-String Suture

A purse-string suture is used to invert appendiceal stumps or to secure feeding tubes or drainage tubes in place. It is basically a circular continuous Lembert suture about a fixed point or opening in the gastrointestinal tract. It is most commonly performed with nonabsorbable suture (see Fig. 72–2).

Connell Suture

The Connell suture is a full-thickness, usually continuous suture that allows for the mucosa to be inverted into the lumen of a bowel anastomosis (see Fig. 71–2). The suture is started at the edge of the anastomosis and brought, full thickness, from inside to out on one side and then outside to in on the opposite side. The suture is tied so that the knot is inside the lumen. The suture is then passed through the tissues from inside to out on one side to begin the Connell stitch. On the other limb of the anastomosis the suture is driven through the tissues, full thickness, from outside to in. On the inside of the bowel lumen the stitch is advanced 2 to 3 mm along the wall and then driven through the bowel wall from inside to out on the *same* side. With the suture now on the outside of the bowel, the next throw is performed on the opposite side in an identical manner. This creates a U-shaped, full-thickness, running inverted suture line. It usually serves as an inner layer of a two-layer anastomosis. Absorbable sutures such as chromic or Vicryl are generally used for these applications.

Inverted Versus Everted Intestinal Anastomosis

The concept of inverting versus everting intestinal anastomoses has long been debated. The overwhelming majority of hand-sewn anastomoses are currently performed in an inverting fashion in either one or two layers.

Gambee and associates, in 1956, published a 156-patient series of various large bowel anastomoses in which they used a single-layer, full-thickness, interrupted, inverting technique with silk suture (Fig. 72–3).[15] They reported five deaths as a result of anastomotic leaks with a mortality of 3%. The incidence of all anastomotic complications was 8.6%, with the majority being radiographic leaks that were not clinically evident.

In 1966, Getzen published a clinical series of 136 everted gastrointestinal anastomoses in which only one leak occurred (resulting in death).[16] Getzen compared inverting and everting bowel anastomoses in a canine model. In 293 anastomoses in dogs, there was no evidence of mucocele or fistula formation. Anastomotic edema was more pronounced in the everted group up to 21 days after surgery. The tensile strength of the inverted anastomosis was two thirds that of the everted group up to 21 days after surgery. Anastomotic strength was comparable in the two groups after 21 days. There were no deaths attributable to everted mucosa.[17]

As with any other wound, the ideal form of intestinal healing is by primary intention. This is accomplished when the individual layers of the intestine reconnect at each side of the anastomosis. Of all layers, the submucosa is particularly important because it harbors fibroblasts, which will produce the collagen that ultimately holds the anastomosis together. Inversion of the anastomosis presents the ends of mucosa to the lumen, where

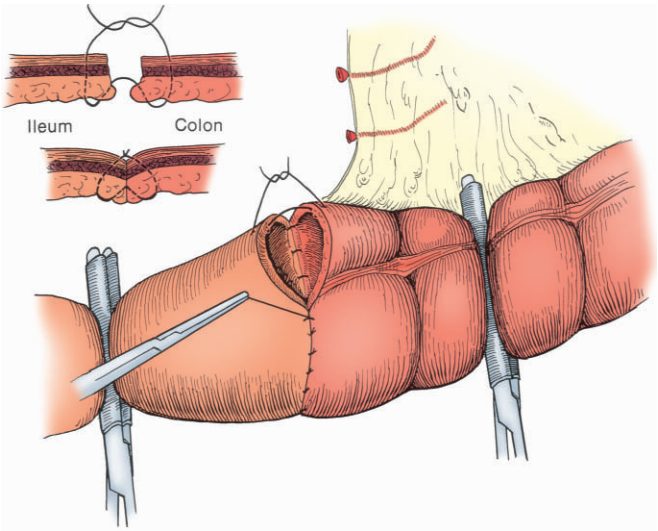

Figure 72–3. The Gambee method of intestinal suturing involving the use of interrupted, inverting sutures. (From Gambee LP, Garnjobst W, Hardwick CE: Ten years' experience with a single layer anastomosis in colon surgery. Am J Surg 92:222, 1956.)

they are further degraded until the submucosa of one side is apposed to the submucosa on the other side. In an inverted anastomosis, the exposed submucosa tends to become adherent to any surrounding structure, thereby eliciting adhesions and delaying healing into a secondary-intention process. It is from this experience that most surgeons have adopted the inverting method for intestinal anastomosis.

STAPLERS AND STAPLING TECHNIQUES

Surgical staplers have become the standard for the creation of bowel anastomoses. In 1826, Henroz first described a device made from two rings that would approximate two open ends of bowel. He successfully tested the device on dogs.

One of the first stapling devices used in humans was the Hültl stapler (Fig. 72–4). This stapler was used to close the stomach during gastrectomies. The array of staplers now available has virtually eliminated the need for hand-sewn anastomoses and has subsequently reduced operative times drastically.

Modern-day staplers deliver staples of either fixed or variable staple height. Linear staplers deliver staples of fixed height, whereas circular staplers can be adjusted to variable heights. A vascular stapler has a closed staple length of 1.0 mm. Tissue staplers have "blue" cartridges and "green" cartridges, which are used for thin tissues and thick tissues, respectively. The closed staple length of a "blue" stapler is 1.5 mm, and it is used for standard tissues such as the small bowel, colon, and esophagus. The closed staple length of a "green" stapler is 2.0 mm. These staplers are used for thicker tissues such as the stomach or rectum. Variable-length staplers are discussed later.

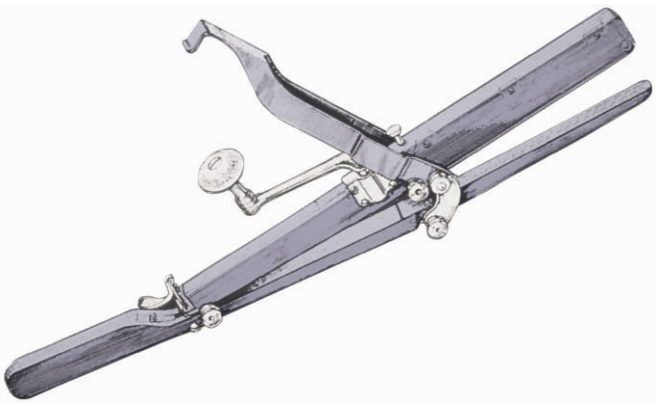

Figure 72–4. Depiction of the Hültl stapler. (From Feil W, Lippert H, Lozac'h P, et al: Atlas of Surgical Stapling. Heidelberg, Germany, Johann Ambrosius Barth, 2000.)

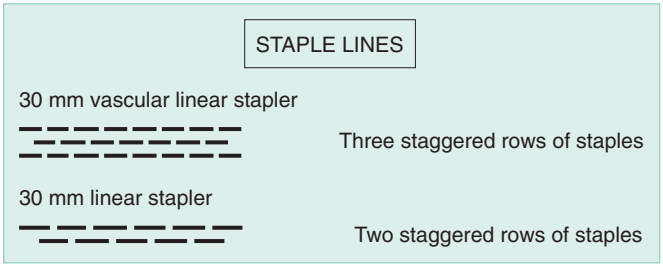

Figure 72–5. Vascular staple lines versus intestinal staple lines. (From Feil W, Lippert H, Lozac'h P, et al: Atlas of Surgical Stapling. Heidelberg, Germany, Johann Ambrosius Barth, 2000.)

Tissue staplers deliver two staggered rows of staples, whereas vascular staplers are used to divide large-caliber vessels while maintaining hemostasis. Vascular staplers deliver three staggered rows of staples (Fig. 72–5).

Types of Staplers

Linear staplers (TA staplers) deliver a double staggered row of staples. They are used in a wide variety of situations, including closure of a hollow viscus, such as the common enterotomy in a side-to-side bowel anastomosis, closure of gastrotomies, and division of large vessels (Fig. 72–6). They can be of variable staple length or fixed staple length, and they can be articulating and nonarticulating.

Linear cutters (GIA staplers) both transect and resect tissues by delivering two double staggered rows of staple lines and deploying a knife to divide the tissue between the staple lines (Figs. 72–7 and 72–8). They are used for a variety of gastrointestinal procedures, such as the formation of enteroenterostomies and gastroenterostomies and the resection of solid organs such as the liver or pancreas.

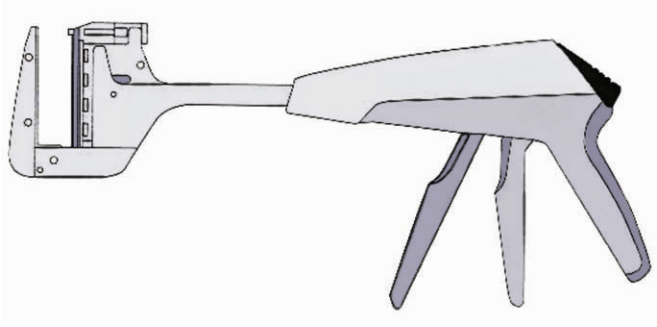

Figure 72–6. Depiction of a TA stapler. (From Feil W, Lippert H, Lozac'h P, et al: Atlas of Surgical Stapling. Heidelberg, Germany, Johann Ambrosius Barth, 2000.)

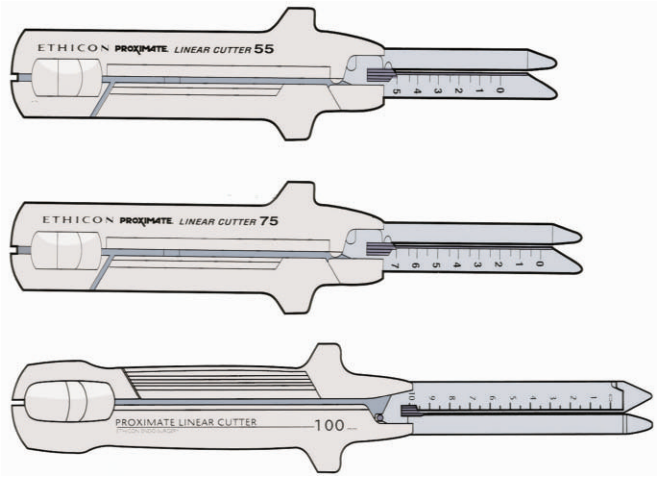

Figure 72–7. Various sizes of linear cutting staplers. (From Feil W, Lippert H, Lozac'h P, et al: Atlas of Surgical Stapling. Heidelberg, Germany, Johann Ambrosius Barth, 2000.)

Circular staplers (EEA, ILS, PPH staplers) are used for inverted end-to-end and end-to-side anastomoses. These staplers usually have a detachable head and lay down a circular, double staggered row of staples. The staples can be variably tightened to a closed length of 2.5 to 1.0 mm, depending on the thickness of the tissue. Circular staplers with nondetachable shafts are used to suspend and excise prolapsed hemorrhoidal tissue.

Techniques/Pitfalls in Surgical Stapling

Functional End-to-End Anastomosis

A functional end-to-end anastomosis (Fig. 72–9), first described in the 1960s, involves apposing the antimesenteric surfaces of two segments of bowel and placing each arm of the GIA stapler in each lumen and firing the stapler to create a common lumen.[18] The lumen is examined and the staples are checked for hemostasis; bleeding points along the staple line in the lumen may be

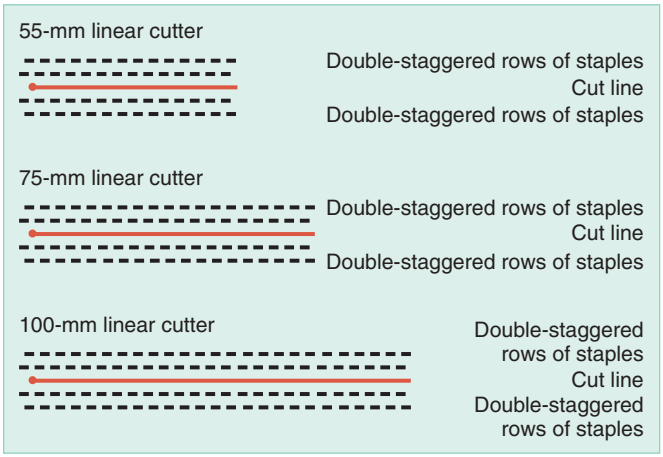

Figure 72–8. Configuration of the staple lines of linear cutting staplers in relation to the knife. (From Feil W, Lippert H, Lozac'h P, et al: Atlas of Surgical Stapling. Heidelberg, Germany, Johann Ambrosius Barth, 2000.)

controlled with 3-0 PDS figure-of-eight sutures. Application of cautery above the staple lines should be discouraged because the current is transmitted along both sides of the staple line and thus can subsequently harm otherwise healthy tissue below the staple line. The common enterotomy is grasped, full thickness, at its edges with Allis clamps to ensure that the serosa and muscularis do not slip under the staple after the stapler is approximated. A single firing of the TA stapler is used to close the common enterotomy. Before firing the TA across the common enterotomy, an important technical point is to ensure that the anterior termination and posterior termination of the GIA staple line are staggered to avoid the crossing of three staple lines.[19] When multiple staple lines cross at the same point, the staples may not close properly, which could lead to anastomotic leakage (see Fig. 72–9).

Stapled End-to-End Anastomosis

This type of anastomosis is performed with a circular stapler (EEA) and is commonly used for the creation of a coloproctostomy but also for esophagostomies and gastroenterostomies. In the case of a colorectal anastomosis, the proximal end of the two ends to be anastomosed is opened, and EEA sizers are placed into the lumen to assess the size of the stapler to be used. Optimal size for these anastomoses should be either 29 or 31 mm. Care should be taken to not create serosal or muscular tears in the colon. Muscular tears of the colon may not always be evident because they might be hidden by the mesentery. The anvil for the EEA is then placed into the open end of the colon, and a Prolene purse-string suture is placed around the rod of the anvil and tied tightly around the rod. If there are any gaps in the purse-string suture, the staple line might be incomplete and a leak could ensue. A mattress suture may be placed around the

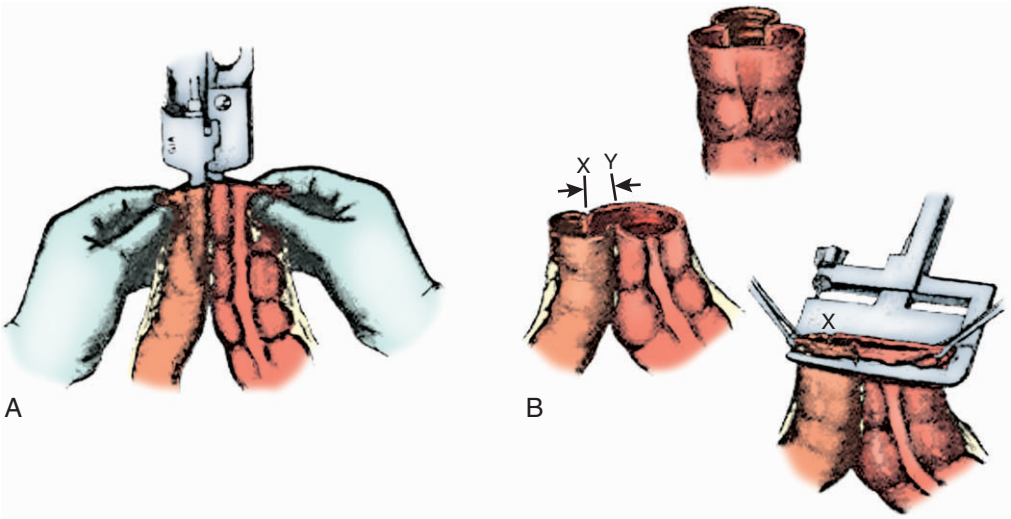

Figure 72–9. Example of a side-to-side, functional end-to-end stapled intestinal anastomosis. When closing the common enterotomy, care must be taken to stagger the anterior and posterior staple lines. (From Chassin JL, Rifkind KM, Turner JW: Errors and pitfalls in stapling gastrointestinal tract anastomoses. Surg Clin North Am 64:447, 1984.)

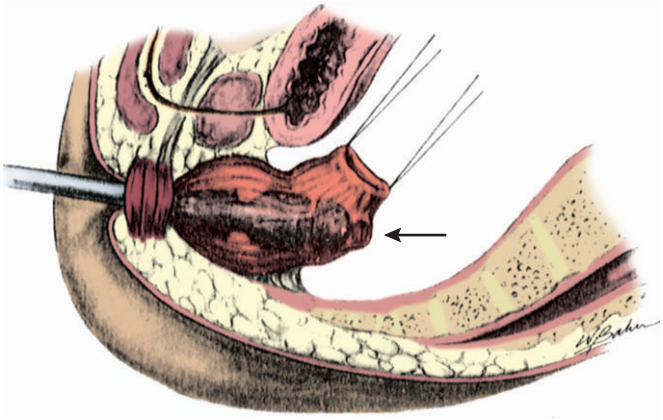

Figure 72–10. When passing a circular stapler for a coloproctostomy, care must be taken to follow the contour of the rectum and sacrum to avoid inadvertently pushing the stapler through the back of the rectum. (From Chassin JL, Rifkind KM, Turner JW: Errors and pitfalls in stapling gastrointestinal tract anastomoses. Surg Clin North Am 64:451, 1984.)

rod to reinforce the purse-string suture. Care must be taken to ensure that the both ends of the bowel are freed up because any fat incorporated into the staple lines may predispose the anastomosis to leakage. The blood supply should also not be too close to the ends for fear of intraluminal bleeding after the stapler is fired.

The stapling device is inserted into the rectum transanally. Care must be taken to follow the contour of the rectum and sacrum to avoid perforating the back wall of the rectum (Fig. 72–10). At the top of the rectum, the stapler should be positioned so that the pin of the EEA comes out right in the middle of the staple line at the portion of rectum that has been cleaned rather than advancing the pin at any other point, such as through the mesorectum. Once the pin is advanced, the anvil and stapler are engaged and the device is screwed tightly. Before firing the EEA, the stapler should be gently rotated to ensure that no other tissue, such as vagina or bladder, has been inadvertently incorporated into the staple line.

Hand-Sewn Versus Stapled Bowel Anastomoses

Beart and Kelly randomized 80 patients to hand-sewn versus stapled coloproctostomies and found no differences in postoperative complications.[20]

In a prospective multicenter randomized study, Docherty et al. compared manually constructed and stapled colorectal anastomoses in 732 patients.[21] Despite a significant increase in radiologic leak rates in the sutured group (14% versus 5%), there was no difference in clinical anastomotic leak rates, morbidity, and postoperative mortality. Univariate analysis correcting for tumor stage demonstrated that the rate of tumor recurrence and cancer-specific mortality was higher in the sutured patients (7.5% and 6.5%, respectively) and in patients with anastomotic leaks.

A meta-analysis of 13 studies that examined manual versus stapled colon and rectal anastomoses found no differences in leak rate, morbidity, mortality, and cancer recurrence. It did, however, demonstrate a higher rate of intraoperative technical problems and a higher rate of anastomotic strictures after stapled anastomoses.[22] This higher rate of stricture in stapled anastomoses is contraintuitive based on the fact that in animal models, the blood flow rate through stapled anastomoses is significantly higher than the flow rate through the standard two-layer and the Gambee anastomoses.[23]

Another observation in experimental animals is that stapled anastomoses tend to heal by secondary intention as compared with hand-sewn anastomoses, which heal by primary intention.[24] This is most noticeable in the functional end-to-end type. Leakage from this anastomosis tends to take place at its closure with the TA stapler and often occurs weeks after being created rather than in the typical first week. During reoperation, the anastomosis is found to be attached by the TA line to some raw surfaces of the laparotomy.

TISSUE ADHESIVES

Ever since the first use of fibrin powder for hemostasis in 1909, the utility of fibrin and fibrin glue products has rapidly increased in a wide spectrum of different areas of surgery.[25,26] Though more commonly used for hemostasis, skin grafting, bone sealing, and other straightforward tissue repairs, its use in the formation of sutureless anastomoses or in the reinforcement of bowel anastomoses is controversial.

Fibrin glue promotes the coagulation of blood by accelerating the conversion of fibrinogen to fibrin. Fibrin glue contains fibrinogen, plasma proteins, factor VIII, aprotinin, and calcium chloride. It is generally packaged as two separate vials that need to be mixed before use. The first vial usually contains fibrinogen, factor VIII, and plasma proteins. The second usually contains thrombin, calcium chloride, and aprotinin. As the two components are mixed, factor VIII is activated and fibrin is subsequently cross-linked, which results in the hemostatic effect and more importantly has effects of varying degree on wound-breaking strength and tissue adhesion.

Data on fibrin glue reinforcement of surgical anastomoses are inconsistent but seem to point to a detrimental effect on bowel anastomoses. In a rat model of intestinal anastomosis, sutureless anastomoses performed with fibrin glue were associated with a higher leak rate than traditional sutured anastomoses were. Furthermore, the bursting pressure of the fibrin glue anastomoses, when compared with sutured anastomoses, was lower at 4 and 7 days postoperatively, which is the critical period in intestinal healing and is also the period associated with anastomotic leakage.[27]

Reinforcement of intestinal anastomoses with fibrin sealant also has a detrimental effect on anastomotic strength. Van der Ham demonstrated in a rat model that reinforcement of the suture lines in intestinal anastomoses had a detrimental effect on anastomotic strength, bursting pressure, and hydroxyproline content. Thus, these anastomoses were both physiologically and biologically inferior.[28,29] These results were duplicated by Byrne, who showed quite clearly not only the negative effects on bursting pressure but also impressive rates of perianastomotic adhesions, toxic sepsis, and death in rats.[30]

Microscopically, there is an intense perianastomotic inflammatory reaction, and levels of hydroxyproline and subsequently collagen are significantly lower in the fibrin glue anastomoses.[28-30] More importantly, high levels of fibrin have been found to inhibit macrophage migration.[31] Fibrin has also been shown to predispose to residual abscess formation in rat peritonitis models. Fibrin inhibits neutrophil phagocytosis of radiolabeled bacteria through a reversible, but dose-dependent mechanism.[32] Thus, fibrin not only acts as an inhibitor to macrophage migration but also inhibits neutrophil function and thus can be a potential nidus for bacterial infection.

In conclusion, the routine use of tissue adhesives for the reinforcement of bowel anastomoses cannot be recommended.

Octyl-2-cyanoacrylate (Dermabond), commonly used for superficial lacerations, was evaluated in a rat model of high-risk and uncomplicated intestinal anastomoses. The results confirmed that there was no significant advantage to the use of octyl-2-cyanoacrylate over the use of traditional intestinal anastomoses in either uncomplicated or high-risk anastomoses. No appreciable difference was noted in gross perianastomotic appearance, adhesions, or hydroxyproline concentrations in rats with and without the use of octyl-2-cyanoacrylate. There was, however, a marked reduction in postoperative day 7 anastomotic bursting pressure in the rats that received octyl-2-cyanoacrylate.[33] This is, of course, significant because it coincides with the fibroplasia phase of anastomotic healing and thus the period for anastomotic leakage should wound healing be altered. The use of octyl-2-cyanoacrylate cannot be recommended at this time.

SUTURELESS INTESTINAL ANASTOMOSES

Biofragmentable Anastomosis Ring

In 1985, Thomas G. Hardy, Jr. described a biofragmentable anastomosis ring (Valtrac) intended to facilitate sutureless intestinal anastomosis.[34] The device consists of two identical circular rings composed of Dexon and 12% barium sulfate. Prolene sutures are used to create purse-string stitches at the two cut ends of the bowel, and the sutures are tightened around the rings after the rings are placed inside the bowel lumens (Fig. 72–11). The device is closed by applying pressure to both sides of the anastomosis. An audible or palpable click of the device signifies proper closure of the device. The device is broken down and passed in stool at some later time.

Hardy et al. validated the feasibility and safety of this device in a dog model.[34] The safety and efficacy of the Vatrac device for human use was examined in a prospective, randomized, multicenter clinical study involving 438 patients. The patients were randomized to sutured or stapled intestinal anastomoses versus use of the biofragmentable anastomotic ring. There were no significant differences in age, gender, or comorbidity. The overwhelming majority of patients underwent oncologic resections. In 13% of the patients, a technical complication such as a serosal tear or inability to fit the device into the lumen of the bowel precluded use of the device. No difference was found in the postoperative complications of anastomotic leak, fistula, hemorrhage, wound infection, ileus, or small bowel obstruction between groups. There was no advantage or difference in length of stay,

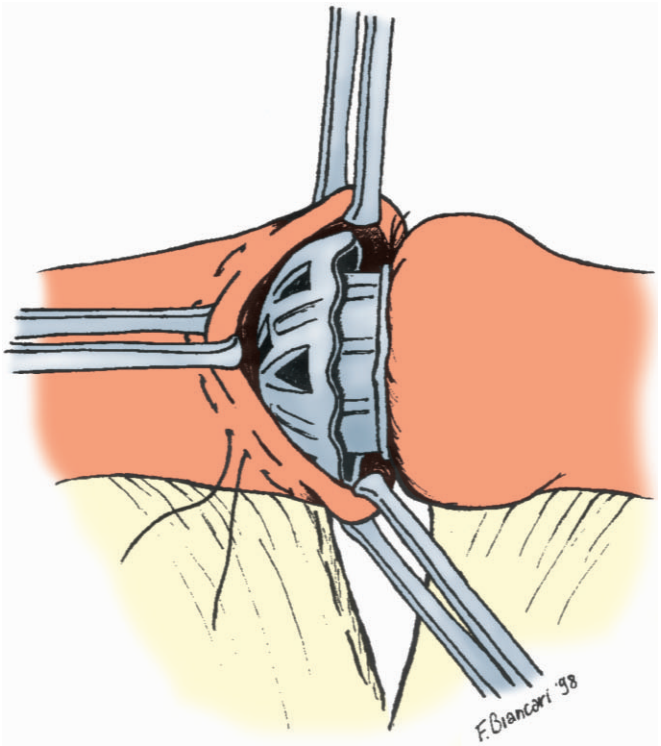

Figure 72–11. Example of the biofragmentable anastomosis ring. (From Di Castro A, Biancari A, Brocato R, et al: Intestinal anastomosis with the biofragmentable anastomosis ring. Am J Surg 176:473, 1998.)

diet, or return to bowel function.[35] Therefore, the biofragmentable anastomosis ring was found to be at least as efficacious as traditional sutured or stapled anastomoses. Di Castro et al. published similar results in a retrospective series of 453 patients with anastomoses created by the biofragmentable anastomosis ring in both elective and emergency situations.[36] They reported a 3% anastomotic leak rate with a 1% rate of reoperation. There were no postoperative intestinal obstructions, but late anastomotic strictures requiring endoscopic dilatation developed in four patients.

The use of biofragmentable anastomosis rings is not superior to traditional suturing or stapling; it does, however, offer a slightly quicker method of anastomosis and allows uniformity of bowel anastomoses throughout the small and large bowel.

CONCLUSION

At the present time, it is not possible to categorically state which is the ideal method of intestinal anastomosis that will work well in every patient. Therefore, it is up to the surgeon to decide in the course of an operation which method is most appropriate. Much of this decision-making process is based on well-established scientific principles. However, part of the decision is also based on the surgeon's skill and experience. Our current inability to scientifically test these factors places them in the realm of art. As in many other biologic processes, further technologic progress will enable us to apply scientific principles even to what is now considered the art of surgery.

Gastric, Duodenal, and Small Intestinal Fistulas

Michael S. Nussbaum · David R. Fischer

The word *fistula* comes from the Latin meaning "pipe" or "flute" and is defined as an abnormal communication between two epithelialized surfaces. Gastrointestinal fistulas continue to cause significant morbidity and mortality, even though many factors important in their management are known. Over the past 35 to 40 years, the mortality associated with gastrointestinal fistulas has diminished from approximately 40% to 60% to about 15% to 20%.[1] This improvement in prognosis is attributable to general advances in fluid and electrolyte/acid-base therapy, blood administration, critical care, ventilatory management, antibiotic regimens, and nutritional management. Formerly, malnutrition and electrolyte imbalance were the causes of death in the majority of these patients. In the present era of fistula treatment, mortality is largely attributable to uncontrolled sepsis and sepsis-associated malnutrition.

The mechanism of fistula formation is varied. Congenital fistulas are caused by errors in development. Acquired fistulas may occur as a result of inflammatory disease, abdominal trauma, surgical complications, radiation, and benign or malignant neoplasm. Spontaneous causes account for 15% to 25% of gastrointestinal fistulas and include radiation, inflammatory bowel disease, diverticular disease, appendicitis, ischemic bowel, perforation of gastric and duodenal ulcers, pancreatic and gynecologic malignancies, and intestinal actinomycosis or tuberculosis. The remaining 75% to 85% of gastrointestinal fistulas are of iatrogenic origin and occur as a result of technical complications of surgical procedures and trauma. Such complications include dehiscence of anastomoses, mechanical injury to the gastrointestinal tract during dissection, cautery injury, retractor injury, indwelling tubes, and misplacement of a suture through the bowel during abdominal closure. Other technical complications resulting in fistulas are those that occur at delayed periods after surgery, such as intraperitoneal bleeding and abscess formation with or without suture line dehiscence. Fistulas may also develop after drainage of a percutaneous abscess, with a connection created between the intestine and abdominal wall.

Treatment of patients with gastrointestinal fistulas requires an understanding of metabolic and anatomic derangements. For patient mortality to be minimized, nutrition, volume, and electrolyte derangements must be promptly corrected. Additionally, ongoing losses must be anticipated and prevented. Malnutrition is easier to prevent than correct. Once established, malnutrition is difficult to correct, especially in the face of continuing sepsis. After the initial stabilization period, including control of sepsis and establishment of nutritional support, management can be divided into phases, starting with determination of the anatomy of the fistula and the likelihood of spontaneous closure. This may then be followed by definitive surgical therapy for a fistula that does not close spontaneously, but a waiting period of at least 6 weeks is usually required. The final process is healing. The critical points in successful management of gastrointestinal fistulas are recognition of the fistula, control of infection and further contamination, restoration of fluid and electrolyte losses, and re-establishment of a positive nutritional balance before undertaking major definitive corrective procedures.

GENERAL CONSIDERATIONS

Gastrointestinal fistulas result from perforations that communicate with adjacent organs or intestine (internal fistulas) or communicate externally with the abdominal wall (enterocutaneous fistulas). Although they may resolve spontaneously, specific intervention or operative therapy may be needed. The small intestine's length, as well as its unique convoluted anatomy, predisposes it to involvement in a variety of diseases, and almost any surgical procedure involving the abdomen can result in iatrogenic injury to the small intestine and subsequent fistula formation. The development of a fistula between

the small intestine and an internal structure can be a life-threatening event, as with exsanguination from an aortoenteric fistula or cholangitis from communication with the intestine and subsequent bacterial contamination of the biliary tree. Other fistulas, particularly internal fistulas between loops of small intestine, may be asymptomatic. Enterocutaneous fistulas are the most common form of small intestinal fistula. Though not usually lethal, an enterocutaneous fistula mandates careful and multitiered management to avoid further complicating the well-being of the patient.

Multiple factors make a gastrointestinal fistula a complex and potentially lethal condition. First, the patients in whom such fistulas develop are usually systemically ill. Sepsis is a recognized antecedent risk factor for the development of a gastrointestinal fistula, and the high metabolic requirement of the septic state can preclude spontaneous closure of the fistula. In fact, sepsis is often secondary to the factor leading to the fistula itself. Malnutrition is also a common occurrence that results both from the hypermetabolic state of the septic, postoperative patient and from the large volume of protein-rich fluid produced, and subsequently lost, by the small intestine. Fluid and electrolyte abnormalities, including hypovolemia, hypokalemia, hypomagnesemia, and metabolic acidosis, are common and result from the continued loss of intestinal fluid. Such losses are not limited to fistulas communicating externally because internal fistulas, such as enterocolic fistulas, can bypass the normal intestinal continuity and overwhelm the absorptive capacity of the recipient organ. Malabsorption and malnutrition from bacterial overgrowth may complicate gastrocolic or enterocolic fistulas. Finally, local wound excoriation and discomfort from the enzymatically active intestinal effluent can complicate potential abdominal wall reconstruction and recovery after surgical attempts to repair a fistula. Furthermore, operating on a fistula before control of sepsis and nutritional optimization can lead to increased mortality and often further fistula formation.

ETIOLOGY

Gastric and Duodenal Fistulas

The vast majority of gastric and duodenal fistulas still occur after surgical, endoscopic, or interventional procedures. Postoperative anastomotic or suture line leaks account for 80% to 85% of all fistulas. Basic general surgical principles of adequate blood supply, lack of tension, no distal obstruction, and uncompromised technique are essential. External fistulas that occur in conjunction with large abdominal wall defects are particularly difficult to treat and often require multiple staged operations, with mortality rates of 20% to 60%.[2] Before 1950, greater than 60% mortality was observed in patients with gastric and duodenal fistulas, but as of 1975, with improved perioperative care and the advent of total parenteral nutrition (TPN), the mortality rate had decreased to just below 25%.[3] The gastric and duodenal fistula rate of just 0.6% at this time was ascribed in part to the liberal use of catheter duodenostomies after gastrectomy.[3] Around 1990, Schein and Decker noted a 17% mortality rate for gastric and duodenal fistulas, with a 13% mortality rate for duodenal stump fistulas.[2] Reconstruction of the common bile duct uncommonly results in duodenal injury and fistula. Numerous comparisons of sutured versus stapled anastomoses show comparable results, without an obvious superiority of either. The ease of stapler use does not compensate for edematous or inflamed tissues, for which better tissue approximation may be achieved with hand-sewn techniques, although anastomoses in these types of tissue may be doomed to failure no matter which technique is used. Postoperative leaks from gastric staple or suture lines after ulcer surgery have accounted for most perforations in the past. However, the decline in gastric resection for ulcer disease, along with the broad application of new endoscopic and laparoscopic techniques for other diseases, accounts for many other newer causes of perforation.

Gastric operations for morbid obesity include vertical banded gastroplasty, Roux-en-Y gastric bypass, gastric banding with adjustable prosthetics, and the duodenal switch procedure. Gastric staple line disruption may develop in the early postoperative period or can occur many months after surgery. Importantly, early anastomotic leaks after gastrojejunostomy in this patient population are highly morbid and often lethal. A high index of suspicion is required to detect these leaks, and they should be controlled early in the process. Mortality may occur even before the development of a fistula. Internal gastric fistulas after gastric stapling are well known, with subsequent weight gain after a fistula has formed between the proximal gastric pouch and the distal part of the stomach. For gastric bypasses, the 10% to 30% incidence rate of internal fistula formation after simple stapling has been reduced to 3% to 6% by either gastric division after stapling or up to three applications of the stapler without division.[4,5]

In a series of 318 partial gastrectomies, Pickleman et al. reported a 1.3% anastomotic leak rate, all from gastrojejunostomy and without any duodenal stump leaks. After total gastrectomy with Roux-en-Y esophagojejunostomy, anastomotic leaks occurred in 4.8%.[6] A perforation rate of 1.5% has been reported after vertical banded gastroplasty for morbid obesity,[7] and a rate as high as 6% has been reported after divided gastric bypass, again from the gastrojejunostomy.[8] Gastric perforation is also a risk in patients who have undergone splenectomy as a result of greater curvature partial-thickness ligatures with devascularization. The incidence of eventual perforation at stapled gastric closures may be increased with the use of cautery to control bleeding at the stapled edge, intersecting staple lines within an anastomosis, and the use of a stapler on a thickened, edematous gastric wall, which causes overcompression, tearing, and devascularization at the line of closure. In such tissue, a hand-sewn closure more adequately approximates tissue without excessive tension.

Duodenal stump leakage has been long feared, although the overall incidence has declined, in part because of the decreased use of antrectomy for ulcer disease and the increased use of reliable staplers for

duodenal division and closure. Duodenal stump leakage is more common after difficult gastric resections, for example, after antrectomy for giant duodenal ulcer disease.[9] Reports indicate a very low incidence of stump leakage after gastric resection. In a high-risk patient, morbidity and mortality can be decreased and possibly prevented by placement of a duodenostomy tube along with closed suction drains external to the duodenum. Duodenal diverticulectomy or lateral duodenotomy for periampullary procedures may result in leakage in edematous or inflamed tissue or with poor hand-sewn technique. Biliary tract surgery is not usually associated with duodenal injury, with the exception of dissection of a markedly inflamed or chronically fibrotic gallbladder, an adherent choledochal cyst, or an unsuspected duodenal diverticulum.

Gastrojejunocolic internal fistula, a rare complication after distal gastrectomy with gastrojejunostomy, is due to marginal ulceration causing perforation at the gastrojejunostomy and a fistula to the adjacent transverse colon. Typical symptoms include diarrhea, pain, gastrointestinal bleeding, and weight loss. Neoplastic causes of internal fistulas are uncommon. Gastrocolic fistulas have resulted from gastric ulcer erosion and invasion of the transverse colon by gastric adenocarcinoma or lymphoma. Primary hepatic flexure or transverse colon adenocarcinoma may in rare instances invade and create a fistula to the duodenum or stomach.

The ongoing extension of laparoscopic techniques to gastric surgery has not eliminated the risk of perforation. Veress needle insertion for establishing pneumoperitoneum may result in the perforation of any intra-abdominal organ, as can the other varied techniques of abdominal access for laparoscopy, especially in a reoperative abdomen. Laparoscopic fundoplication and laparoscopic Heller myotomy are now widely used for the surgical management of gastroesophageal reflux disease and achalasia, respectively. Although morbidity rates are low, the esophagus or stomach may be perforated during the procedures, with the majority occurring in the first 10 to 25 fundoplications or myotomies performed by the surgeon. The incidence of esophageal or gastric perforation during fundoplication ranges from 0.3% to 1.9%,[10-12] with a large retrospective review of 2453 procedures by Perdikis et al. showing an overall incidence of 1.0%.[13] These perforations are acquired in at least four ways:

1. During retroesophageal dissection, the gastric fundus that is adherent to the left crus of the diaphragm may be lacerated during the right-to-left dissection through fatty tissue.
2. Direct injury can be inflicted on the anterior aspect of the stomach with graspers while retracting in a caudad and anterior direction. These graspers are often temporarily out of the laparoscopic field of view. The fundus may also be lacerated as a result of excessive tension while maneuvering it behind the esophagus.
3. Esophageal bougie insertion can cause perforation at the gastroesophageal junction or along the greater curvature.
4. Full-thickness suture placement while securing the fundoplication, with eventual tearing of the gastric wall, may result in delayed recognition of the perforation.

Laparoscopic fundoplication may also result in delayed gastric perforation along the greater curvature from inadvertent thermal or cautery injury during division of the short gastric artery. If the diaphragmatic crura are not approximated adequately, the fundoplication can herniate into the chest during postoperative straining, vomiting, or heavy lifting, with subsequent gastric ischemia and perforation. Laparoscopic revision of a previous fundoplication requires more gastric traction and division of adhesions, with a 3% risk for gastric laceration.[14] Other laparoscopic procedures that have caused perforation include diaphragmatic hernia repair, paraesophageal hernia repair (perforation in 6%), Heller myotomy, splenectomy, pyloromyotomy, and gastrostomy tube placement. The laparoscopically placed adjustable silicone gastric band, positioned around the proximal part of the stomach for the treatment of morbid obesity, has also resulted in gastric perforation in less than 1% of patients.[15,16]

Laparoscopic cholecystectomy may produce duodenal injury if the duodenum and gallbladder are densely adherent to one another as a result of either direct cutting action or cautery and thermal injury. Laparoscopic cholecystectomy may also result in colonic injury by the same mechanisms. In addition, improperly insulated instruments may cause electrical arcing to the duodenum, small bowel, or colon with resultant perforation. These injuries may not be immediately apparent. Coincident bile spillage from the gallbladder may also mask a duodenal injury. Likewise, duodenal perforation and bile duct injury may coexist. Laparoscopic bile duct exploration usually risks cystic duct or common bile duct injuries more than injuries to the duodenum. However, advanced procedures such as antegrade sphincterotomy and antegrade stent insertion may also result in duodenal injury.

Crohn's disease is a rare cause of gastrocolic, duodenocolic, or duodenocutaneous fistulas. Primary gastric or duodenal involvement is reported in less than 1% of patients with Crohn's disease; duodenocutaneous fistulas may develop from the first or second portion of the duodenum. However, most gastric or duodenal fistulas are internal and result from involvement of primary Crohn's disease of the transverse colon or, more commonly, from recurrence at the ileocolic anastomosis after previous resection. Those with gastrocolic fistulas have a 40% incidence of vomiting, which may be feculent; duodenocolic fistulas are often asymptomatic, with only a 4% incidence of vomiting, which is not usually feculent.[17]

Inflammatory fistula formation can result from gallstone erosion through the gallbladder and migration into the contiguous second portion of the duodenum, which causes a persistent cholecystoduodenal fistula. It may remain asymptomatic (as should a similar surgically created cholecystojejunostomy) but should be suspected in patients with the uncommon finding of gallstone ileus

with distal small bowel obstruction because of the stone. Renogastric fistula has been reported secondary to a staghorn calculus.[18] Duodenal hematomas may also lead to fistula formation. Severe necrotizing pancreatitis requiring necrosectomy, with subsequent open packing or closed drainage, has resulted in both gastric and duodenal fistulas. These fistulas may already exist at the time of initial laparotomy, or they may develop as late as 1 to 3 months later, either from the inflammatory process or from an iatrogenic cause. Although they may be more frequent after open packing, spontaneous closure is common (up to 54%).[19,20]

The capacity and compliance of the stomach make endoscopic examination routine, with a low incidence of injury. However, endoscopic polypectomy or attempts at tumor removal with a snare and cautery may cause either immediate full-thickness perforation or deep penetration with thermal injury to the remaining tissue and subsequent delayed perforation. Similar injury may occur with the use of thermal contact methods (heater probe, multipolar electrocoagulation, laser) or dilute epinephrine injections into bleeding ulcers and arteriovenous malformations, with exacerbation of the injury by successive treatments. Esophageal dilatation performed with a semirigid dilator over a wire has caused gastric perforation from the end of the wire. Percutaneous endoscopic gastrostomy tube placement, though often routine, has also resulted in perforation, either from dislodgment of the tube before complete gastric adhesion to the abdominal wall or from trauma during placement. Lack of adhesion to the abdominal wall may be more common in immunosuppressed patients taking steroids, for instance. Gastric necrosis may also occur as a result of ischemia and subsequent gastric leakage from a tube that is pulled too tight. Improper tube placement along the posterior wall below the greater curvature, while the stomach is distended, can result in excessive tension on the posterior gastric wall when traction is applied, with subsequent leakage into the lesser sac. Tube placement that is too proximal in the stomach has also caused perforation because of excessive gastric wall tension and eventual tube dislodgment through the wall. In addition, tube insertion may perforate the adjacent jejunum or transverse colon and result in a persistent gastrojejunal or gastrocolic fistula, even after the gastrostomy tube has been removal. This complication may also require early laparotomy to address peritonitis and sepsis. A percutaneously placed gastrostomy tube results in a thin fibrous cylinder connecting the stomach to the anterior abdominal wall; manual replacement of the gastrostomy tube can perforate this cylinder and give liquid feeding solutions direct access to the peritoneal cavity, with resultant peritonitis. Gastrostomy tube placement may cause a persistent gastrocutaneous fistula that enlarges through erosion or infection of fascia and skin. These fistulas may be difficult to control, with continued drainage of gastric fluid onto the surrounding skin. The substitution of a larger gastrostomy tube will not control the leakage and usually results in enlargement of the opening. Persistent drainage may require either tube removal or placement of a smaller tube, along with direct or nasogastric suction until the tract contracts down around the tube. Surgical closure is required for a persistent gastrocutaneous fistula that does not respond to such measures.

Because many endoscopic duodenal procedures involve the second portion of the duodenum, perforation is usually retroperitoneal. Failure to recognize an injury or a delay in treatment markedly increases morbidity and mortality. Perforation after endoscopic retrograde cholangiopancreatography (ERCP) with ampullary sphincterotomy for stone extraction or biliary stent placement is one of the more frequent postendoscopic indications for urgent surgical intervention. Repair of the distal bile duct, as well as repair of the duodenum, may be required. Controlled leaks confined to the retroperitoneum can often be monitored with very close clinical observation in stable patients. Retroperitoneal perforation is more common during therapeutic ERCP, with an incidence of 0.6% to 1.8% and a mortality rate of up to 25%.[21,22] Delayed duodenal perforation from the biliary stent itself may be caused by partial extrusion and impingement of the end of the stent on the distal second or proximal third portion of the duodenum, with eventual erosion and perforation. Proximal stent migration into the common bile duct may cause a choledochoduodenal fistula to subsequently form if the stent reenters the duodenum away from the papilla. Similarly, pancreatic duct stents may produce a pancreaticogastric fistula with proximal migration of the stent into the gastric antrum. Other procedures at risk for the development of duodenal perforation include endoscopic polyp or tumor removal, push enteroscopy, endoscopic ultrasound with transduodenal biopsy, and endoscopically assisted transgastric jejunal feeding tube placement.

An aortoduodenal fistula involving the third portion of the duodenum must be suspected in any patient with a previous abdominal aortic graft and upper gastrointestinal bleeding or a patient with graft infection without gastrointestinal bleeding. An aortogastric fistula may occur intra-abdominally in a patient with a ruptured abdominal aortic aneurysm without previous aortic surgery,[23] as well as intrathoracically after esophagectomy at the esophagogastric suture line (treated successfully by direct repair and endovascular graft placement).[24] Reconstruction of the inferior vena cava with a stented polytetrafluoroethylene (Teflon) graft has also resulted in a fistula to the adjacent duodenum.[25]

Percutaneous transhepatic wire and biliary stent placement may lead to duodenal perforation. However, a transhepatic biliary drain also provides effective duodenal decompression if subsequent operative repair is needed. Because of the proximity of the duodenum and inferior vena cava, caval filter placement has resulted in duodenal penetration from the filter hooks. Percutaneous drainage of upper abdominal abscesses uncommonly results in duodenal injury. Swallowed foreign bodies that are small enough to traverse the pylorus may not escape the duodenum; typically, toothpicks and fish bones may penetrate the duodenum and form a phlegmon or an abscess. Stiff feeding tubes or nasogastric tubes passing through the pylorus have also resulted in duodenal perforation.

Nonoperative causes of perforation include strangulated paraesophageal hernia, foreign body ingestion, and

esophageal intubation with gastric overpressure. Gastric adenocarcinoma may uncommonly result in perforation. Treatment of gastric lymphoma with chemotherapy or radiation (or both) has caused perforation along with cytoreduction. Mycotic infection with eventual gastric perforation has been reported in immunosuppressed heart, lung, and liver transplant recipients.[26]

Small Intestinal Fistula

Small intestinal fistulas can form in a number of ways. External small intestinal fistulas (enterocutaneous fistulas) are by far the most frequent type of small intestinal fistula. Enterocutaneous fistulas most commonly follow postoperative complications and are often the result of technical errors at the time of an abdominal procedure. Of 35 fistulas originating in the jejunum or ileum reported by MacFadyen and associates, 75% drained externally.[27] The ileum is the most common site of origin of an enterocutaneous fistula. Reber and colleagues found that of 120 small intestinal enterocutaneous fistulas, 72 originated from the ileum and 48 from the jejunum.[28] Enterocutaneous fistulas can be classified according to the daily volume of drainage. A high-output fistula drains 500 ml/day or more of fluid. In most instances, a high-output fistula is associated with greater morbidity and mortality and a decreased likelihood of spontaneous closure. Soeters and associates found that patients with high-output fistulas had a greater incidence of malnutrition and fluid and electrolyte disturbances.[3] Mortality increased, and the rate of fistula closure was low. In contrast, excellent results with high-output fistulas were reported in Graham's series, in which 35 of 39 consecutive patients underwent spontaneous fistula closure with a 3% mortality rate.[29] In general, high-output fistulas usually originate from a proximal portion of the small intestine. Conditions that are independent of the surgical technique, such as previous intestinal irradiation, intra-abdominal sepsis, or the presence of diseased or ischemic intestine, can also give rise to external fistulas. Enteroenteric or enterocolic fistulas develop almost exclusively from the transmural inflammation associated with Crohn's disease.

Webster and Carey proposed five general mechanisms for fistula formation[30]:

Congenital A rare form of congenital small intestinal fistula involves complete failure of the vitellointestinal duct to obliterate, which results in an enterocutaneous fistula to the umbilicus. When incomplete obliteration of the duct occurs, the enteric portion of the duct is the usual portion that persists and forms a Meckel diverticulum. Rarely, the entire omphalomesenteric duct remains patent and forms an external fistula. The diagnosis should be suggested by the appearance of fecal material at the umbilicus after postnatal slough of the umbilical cord.

Trauma Traumatic injury to the small intestine that results in fistula formation usually occurs from an internal source, such as a swallowed fish bone, toothpick, or metallic object. Erosion of these objects into an adjacent loop of small intestine results in an internal enteroenteric fistula. Major penetrating trauma, such as knife or bullet wounds, rarely results in fistula formation because these cases are usually explored surgically and the intestinal injuries repaired. Locally unexplored knife wounds, however, have resulted in the development of an enterocutaneous fistula when minor intestinal injuries were not diagnosed in timely fashion.

Infection An abscess or invasive intestinal infection may erode through the intestine and create a fistula. Amebiasis, coccidiomycosis, tuberculosis, cryptosporidiosis, actinomycosis, and salmonellosis have all been implicated in the development of intestinal fistulas. Intestinal perforation at the ileum from tuberculosis and typhoid fever is still occasionally seen, especially in countries where these diseases are endemic. *Actinomyces* is a common cause of enterocutaneous fistulas after appendectomy. Fistulas may also result from the proximity of the small intestine to an abscess involving a solid organ, such as when rupture of a perinephric abscess results in a nephroenteric fistula.

Perforation or Injury with Abscess Perforation of the intestinal wall by tumor, inflammation, or operative injury may result in the local formation of an abscess. A fistula may develop if this abscess subsequently erodes into an adjacent structure. Most enterocutaneous fistulas develop as a result of injury to the small intestine during surgery or from exposure of the bowel to a large abdominal defect or prosthetic mesh used to repair such defects. An enterocutaneous fistula rarely develops spontaneously. In fact, most develop after an abdominal surgical procedure. In most large series, 60% to more than 90% of enterocutaneous fistulas were caused by operative complications. Faulty operative technique involving injury to the intestine during handling, lysis of adhesions, or abdominal fascial closure often results in fistulas. In addition, enterocutaneous fistulas may be caused by leakage from an intestinal anastomosis or enterotomy closure. Fistulas may also develop as a result of percutaneous drainage of an intra-abdominal abscess. After perforation, an abscess may develop at the site of injury and then drain either internally into another loop of intestine or externally through the abdominal wall or wound. Commonly, a fistula has been found to have feculent drainage from the wound after the wound is opened for a presumed wound infection.

Inflammation, Irradiation, or Tumor The small intestine and an adjacent structure can become densely adherent from chronic inflammatory conditions, abdominal radiation injury, or tumor erosion. Subsequent degeneration of the common wall results in fistula formation. Inflammatory bowel disease, particularly Crohn's disease, is well known to create enteroenteric, enterocolic, perineal, enterocutaneous, and other fistulas in this fashion. In Crohn's disease, the diseased intestine makes fistula formation after anastomosis more likely. Although a spontaneous external fistula can develop as a direct result of Crohn's disease, most occur only after a previous

operation has caused the diseased intestine to adhere to the abdominal wall. Postoperative fistulas in the setting of Crohn's disease are just as likely to develop after simple exploration, bypass, or appendectomy as after primary resection. Fistula formation after laparotomy is usually an early complication, especially when arising from an anastomosis, whereas a late fistula generally indicates recurrent Crohn's disease. Erosion of the intestine by a foreign body such as swallowed objects or polypropylene mesh, abdominal wall dehiscence with evisceration, and strangulation of a hernia with infarction and perforation of the intestine have all been implicated in the development of external fistulas. Enlarging carcinomas of the stomach or colon may adhere to and erode into adjacent small intestine with some frequency. Fistula formation is particularly apt to occur after irradiation of a pelvic malignant lesion. Fistulas that arise secondary to radiation injury rarely, if ever close spontaneously.

DIAGNOSIS OF PERFORATIONS AND FISTULAS

Acute intraoperative perforations are best handled by maintaining a strong index of suspicion for technical errors, recognizing the injury before the end of the procedure, and immediately repairing, suturing, or reinforcing weakened tissues. Especially during prolonged laparoscopic procedures, the tendency for potential injuries must be recognized and overcome. Serosal injuries should be carefully examined and sutured. Intraluminal instillation of methylene blue and saline or direct endoscopic examination can demonstrate a small perforation or provide reassurance that an area of concern is not a full-thickness injury.

Postoperatively, unrecognized perforations caused during surgery or leaks that develop at suture or staple lines are manifested as instability or failure to improve as expected. A gastrointestinal fistula can be obvious in some patients and extremely difficult to identify in others. Fistula formation is frequently heralded by fever and abdominal pain until gastrointestinal contents discharge through an abdominal incision or the umbilicus. Spontaneous fistulas from neoplasm or inflammatory disease usually develop in a more indolent manner. Enterocutaneous fistulas often have intestinal contents or gas exiting from a drain site or through the abdominal incision after an operation. The drainage fluid is usually typical of intestinal contents, with obvious bile staining, and intestinal gas may accompany the effluent. At times the initial fistula drainage may initially appear clear rather than yellow or green, and the fistula may be misdiagnosed as a seroma or wound infection. At other times a heavy purulent component may also mask the enteric communication and instead suggest a wound infection. If the drainage persists and the diagnosis is uncertain, the patient may be given activated charcoal or indigo carmine by mouth and the drainage inspected for these substances.

Endoscopic gastroduodenal perforations are suspected when fever, tachycardia, or abdominal tenderness is present after the procedure. Initial chest and abdominal radiographic films may demonstrate free intraperitoneal air or retroperitoneal air outlining the duodenal wall. Unexplained fever, ongoing or new tachycardia, hypotension, worsening leukocytosis, new or continuing abdominal pain, persistent ileus, and persistent oliguria all raise suspicion for a pathologic intra-abdominal process.

STAGING/CLASSIFICATION

Gastrointestinal fistulas can be classified by their anatomic characteristics, and they are either internal or external (enterocutaneous). The actual anatomic course of the fistula should be defined. Typically, the name of a fistula is derived from the involved and connected organs or structures. Examples include gastrocolic, jejunoileal, and aortoenteric fistulas. In general, the anatomy of a fistula will suggest the cause and help predict whether spontaneous closure will occur.[31,32] Fistulas can be classified physiologically in terms of output over a 24-hour period. They can be classified as low (less than 200 ml/day), moderate (200 to 500 ml/day), and high (greater than 500 ml/day).[3,31] An accurate measure of fistula output, as well as the chemical make-up of the effluent, can provide assistance in preventing and treating metabolic deficits and correcting ongoing fluid, electrolyte, and protein losses. The anatomic and etiologic factors are much more important in predicting spontaneous closure than the actual output of the fistula. The underlying disease process will help in prognisticating both the closure rate and mortality.

External or enterocutaneous fistulas are by far the most common type of small intestinal fistula and are usually readily recognizable. In contrast, internal fistulas that communicate between the intestine and another hollow viscus or structure may not be suspected for some time because the symptoms may be minimal or may mimic the underlying disease process. Relatively rare, such fistulas have been reported between adjacent segments of the gastrointestinal tract, as well as between the small intestine and the biliary tree, genitourinary system, and arterial and venous trees.

COMPLICATIONS

The loss of gastrointestinal contents either prematurely by diversion to the body surface or by "short-circuiting" within the gastrointestinal tract may result in profound fluid and electrolyte deficits, the specific nature of which depends on the portion of the gastrointestinal tract whose contents are lost. Malabsorption with severe nutritional and vitamin deficiencies may also ensue. Fistulas are commonly associated with one or more abscesses, which often drain incompletely with fistulization. Therefore, persistent sepsis may occur as a result of contamination of a normally sterile space or organ system by gastrointestinal flora traversing the fistula. Gastrointestinal hemorrhage, intestinal obstruction, and excoriation and erosion of the skin by gastrointestinal secretions may also complicate the course of a patient with a fistula. These problems may be superimposed on other

abnormalities inherent to the underlying disease that produced the fistula.

Fluid and Electrolyte Abnormalities

Fluid and electrolyte disturbances occur commonly in patients with enterocutaneous fistulas. Secretions from the salivary glands, stomach, duodenum, pancreas, liver, and small intestine amount to 8 to 10 L/day, and this fluid is rich in sodium, potassium, chloride, and bicarbonate. The degree of volume depletion and electrolyte imbalance depends on the anatomic location of the fistula and can vary from 50 to 3000 ml/day.[27] Duodenal fistulas are particularly prone to volume and electrolyte loss, and aggressive fluid management is necessary for patients with such high-output fistulas. A distal fistula, such as one arising from the terminal ileum in a patient with Crohn's disease, is usually associated with less fluid loss because considerable absorption occurs in the proximal part of the gut.

Fluid and electrolyte imbalances were noted in 35 of 128 patients with gastrointestinal fistulas reported by Soeters and associates from 1970 to 1975.[3] The most common abnormalities were hypovolemia, hypokalemia, and metabolic acidosis. Hypokalemia occurs primarily from potassium loss in the fistula effluent, although hypovolemia also contributes by causing renal retention of sodium in exchange for potassium secretion. Sepsis contributes to the hypovolemic state by altering the metabolic rate and increasing insensible water loss through fever. Metabolic acidosis is generally caused by the loss of pancreatic juice rich in bicarbonate and is thus more common with proximal intestinal fistulas. Gastric fistulas, especially in conjunction with gastric outlet obstruction, will cause a hypokalemic, hypochloremic metabolic alkalosis secondary to the loss of a large volume of hydrochloric acid.

Patients with fistulas causing fluid and electrolyte abnormalities have a higher mortality rate.[33] Advances in critical care, invasive monitoring, and aggressive fluid and electrolyte management can reduce this early mortality considerably, as evidenced by data from the Massachusetts General Hospital. Before 1960, nearly all patients at this institution died when an electrolyte deficit complicated a fistula involving the small intestine. Improvements in therapy and control of sepsis have resulted in a substantial decrease in the mortality rate.[3]

Malnutrition

The small intestine contains fluid rich in ingested nutrients and endogenous proteins, such as enzymes and albumin. Thus, malnutrition develops in almost all patients with a small intestinal fistula if the absorptive surface area is bypassed or the enteric contents are lost externally. Nutritional deficiency may be exacerbated by the extra metabolic demands of sepsis or additional surgery. Soeters and associates reported moderate to severe malnutrition in 86 of 128 patients.[3] Before the introduction of TPN, 74% of patients with intestinal fistulas exhibited malnutrition, and 59% of these patients died.

Sepsis

With advances in fluid replacement, management of electrolyte deficits, and nutritional support, sepsis remains the major determinant of mortality in patients with fistulas of the small intestine. Most fistulas develop after contamination of a sterile space by gastrointestinal bacteria. Abscesses not only cause but can also complicate fistulas of the intestine. Uncontrolled abdominal sepsis can lead to bacteremia, local and distant infection, and multisystem organ failure. Local extension usually results in wound infection. Distant bacterial seeding may cause splenic and hepatic abscess or endocarditis. Large defects in the abdominal wall predispose the patient to repeated episodes of sepsis and consequently a high mortality rate. In a large series by Schein and Decker, the overall mortality rate associated with fistulas of the small bowel was 33%.[34] However, when a large abdominal wall defect accompanied the fistula, the mortality rate rose to 60%, with the main cause of death cited as infection.

Abdominal Wall and Wound Abnormalities

Skin erosion and excoriation commonly occur from an externally draining gastrointestinal fistula. The local digestive action of the gastrointestinal secretions, particularly pancreatic enzymes, can result in considerable discomfort to the patient. The degree of local skin excoriation depends on the output and contents of the fistula effluent and is most severe with proximal intestinal fistulas. Malnutrition contributes to this process by delaying the formation of scar or granulation tissue.

Other Complications

Other complications of small intestinal fistulas occur with less frequency. Massive gastrointestinal hemorrhage can result from the formation of a fistula between the small intestine and a blood vessel. One or more "herald bleeds" may be a prelude to exsanguinating hemorrhage. More commonly, anemia develops chronically and is associated with slow blood loss from a friable fistula tract. Colonization and overgrowth of the small intestine by colonic bacteria can occur with enterocolic fistulas and may result in malabsorption and severe, malodorous diarrhea. Distal obstruction of the fistula tract from adhesions or other disease can develop and result in an increase in fistula output or failure of the proximal tract to close. Finally, carcinoma has been reported in chronic fistulas, especially those associated with Crohn's disease. It is believed that chronic irritation of the epithelium promotes the development of such malignancies.[35]

MANAGEMENT

Management of a gastrointestinal fistula is a difficult and complex process. However, if one uses a systematic

approach in dealing with these difficult problems, their treatment becomes manageable and potentially rewarding. In general, management can be compartmentalized into five stages: stabilization, investigation, decision, definitive therapy, and healing.[36]

The ultimate goal when treating gastrointestinal fistulas is restoring continuity of the gastrointestinal tract. However, most fistulas are not treated simply by taking the patient back to the operating room. Rather, many weeks and perhaps months of care is often required to manage most patients successfully. As just outlined, management of patients with such fistulas can be conceptualized as a series of steps to control life-threatening abnormalities rapidly and to intervene in a timely and controlled manner with convalescent or surgical care. Although these steps address the physical well-being of the patient, one should not underestimate the impact of a fistula on mental and emotional health. A gastrointestinal fistula places a great deal of stress on a patient's self-esteem. Therefore, family members, social workers, and mental health professionals can play a vital role during the prolonged convalescence that is typical with this disease process.

The present approach and understanding of fistula management have developed significantly over the past 40 years. In their classic paper in 1960, Edmunds, Williams, and Welch called attention to the serious nature and the high mortality of such fistulas and pointed out the relationship between infection, malnutrition, fistula output, and mortality.[33] In addition, they advocated earlier surgical intervention for all high-output fistulas and recommended total resection of the fistula with end-to-end anastomosis or complete bypass of the fistula when resection was not possible. With early correction of fistulas, malnutrition and its attendant complications were thereby less likely to develop. The overall mortality in their series was 44%.[33] Modern fistula management has evolved significantly and mortality has decreased substantially. Urgent surgery in a debilitated, malnourished patient is rarely necessary nowadays.

Stabilization

As outlined earlier, the first step in the management of any intestinal fistula is stabilization of the patient, which is usually accomplished within the first 24 to 48 hours of management. These patients are typically in a vulnerable state of health. They may be febrile and septic from what was thought to be a wound infection that was treated by opening the wound. The wound drainage contains succus entericus and the patient may be deteriorating. Alternatively, they may be immunocompromised secondary to ongoing therapy (e.g., cancer radiation treatment, chemotherapy) or additional infectious processes. Therefore, the most important priority is to stabilize the patient. Patients typically require correction of obligate third-space losses, as well as emesis, fistula output, urine output, or a combination of these and other causes. Initial efforts should be directed toward intravenous fluid resuscitation, control of infection, ongoing measurement of fistulous and urine output, and protection of the surrounding skin. The incision should be examined for fascial integrity, and any remaining subcutaneous collections should be drained. Thereafter, attention is shifted to identification of the fistulous source, the nature of the tract, and associated fluid collections or abscesses.

Resuscitation

Restoration of a normal circulating blood volume and correction of electrolyte and acid-base imbalances are top priority. Rehydration usually requires isotonic fluid until the patient is euvolemic again. Depending on the site of the fistula, replacement of fistula output varies. High-output fistulas, those exceeding 500 ml/day, continue to result in the highest mortality rate, up to 35%, because of malnutrition, electrolyte imbalance, and sepsis. Moderate-output fistulas range from an output of 200 to 500 ml/day, whereas low-output fistulas produce less than 200 ml/day and are associated with low mortality rates and high spontaneous closure rates. Small bowel, pancreatic, and biliary losses are isotonic. Colonic losses may be hypotonic, and gastric fistulas may be associated with the classic hypokalemic, hypochloremic metabolic alkalosis. Although certain patterns can be predicted, electrolyte levels in an aliquot of the fistula output, as well as electrolyte levels in the patient's serum, should be measured and corrected appropriately according to the particular electrolyte profile. Because most patients require considerable volume replacement, close monitoring of the patient's physiologic parameters is essential to ensure the safety and efficacy of therapy.

The natural course of an improperly managed high-output fistula is dehydration, electrolyte abnormalities, malnutrition, infection and sepsis, renal failure, and death. Initial management should address any existing hypovolemia; anemia; hypoalbuminemia; sodium, chloride, or potassium depletion; and acid-base disorders. Strict intake and output measurements are essential, and central venous pressure monitoring and urinary catheterization are especially helpful with high-output fistulas. Invasive monitoring is often necessary because it is usually difficult to estimate antecedent fluid deficits accurately. A central venous catheter can be extremely useful in this capacity and provides the additional benefit of supplying access for parenteral nutrition. The patient's urine output should be restored to greater than 30 ml/hr, assuming that renal function has not been impaired. In patients with cardiovascular impairment or evidence of shock, a pulmonary artery catheter may be needed to guide ongoing fluid repletion after initial fluid boluses have not resulted in adequate urinary output.

Ongoing fluid losses should be fully replaced, and potassium, calcium, phosphorus, and magnesium deficits should be corrected. These electrolyte deficits may take time to correct because the measured serum levels reflect only a small percentage of what can be a massive depletion of intracellular ions. Sodium bicarbonate administration may be required to correct the metabolic acidosis that usually develops with a high-output or proximal fistula. Because the deficit in circulating blood volume is

caused primarily by extracellular fluid losses, replacement should be in the form of an isotonic solution. Normal saline or lactated Ringer's solution is most appropriate for this purpose. However, specific parenteral fluids may be selected on the basis of the initial electrolyte levels. Transfusion of red blood cells may be necessary because of chronic blood loss and anemia of chronic disease. To optimize the patient's hemodynamic status, blood transfusion may be required. There is no specific hemoglobin or hematocrit level that requires transfusion; rather, transfusion should be based on the patient's overall hemodynamic status, oxygen-carrying capacity, and oxygen delivery.

Often, these patients are in a severe catabolic state and have extremely low protein and albumin levels. This is important for several reasons. First, patients will have low capillary oncotic pressure, which may contribute to profound edema, especially after resuscitation has begun. Severe hypoalbuminemia will take weeks to correct through nutritional repletion alone. Supplemental intravenous salt-poor albumin administration for a limited period will help increase oncotic pressure and minimize edema and may improve wound healing.[37] More importantly, however, the patient is in a state of nutritional emergency. For this patient to be stabilized and to potentially heal the fistula, positive nitrogen balance must be achieved. If nutritional therapy is not started early, these patients are at great risk for multisystem organ failure, infection, and other complications of severe malnutrition that could lead to death. An initial infusion of albumin will not correct these problems, and nutritional repletion will take weeks to accomplish.

Nutrition

Ongoing nutritional assessment and institution of nutritional support have improved the overall outcome in patients with small intestinal fistulas. The signal study in 1964 by Chapman et al. emphasized that the key to successful management was to "get control of fistula," combat sepsis, and from the very beginning maintain adequate nutritional support.[38] They stressed the vital role of nutrition and reported a decreased mortality rate of 14% in patients treated with an excess of 3000 calories per day via a combination of intravenous (peripheral administration of protein hydrolysates) and tube feedings and 55% mortality in patients receiving a suboptimal nutritional regimen. They also emphasized that supportive and surgical treatment go hand in hand; the two are not mutually exclusive. Their indications for operative closure of the fistula included the presence of distal intestinal obstruction, continued massive loss of fluid from the fistula despite control of the infection and an adequate nutritional regimen, and persistence of the fistula even without high losses over a prolonged period. In a follow-up report in 1971, Sheldon et al. documented the success of such a treatment regimen and noted that most patients could be given adequate nutrition by standard methods such as tube and enterostomy feedings. At the time of their report, TPN was a new technique that had been used only in a select few patients.[39] Roback and Nicholoff reported closure of 73% of enteric fistulas in patients with adequate caloric supplementation, but only 19% healed when nutritional support was inadequate.[40]

Provision of sufficient calories and protein is necessary to minimize further skeletal muscle breakdown and organ dysfunction. Fluid, electrolyte, and trace element losses must be repleted. With the widespread advent of parenteral nutrition in the 1970s, the overall reduction in mortality to a range of 15% to 20% was achieved consistently in a variety of reports. In their reviews of large series of patients, Reber et al. in 1978 (786 patients) and Soeters and associates in 1979 (404 patients) reported that the addition of parenteral nutrition in large scale to the treatment of gastrointestinal fistulas improved the spontaneous closure rate.[3,28] Parenteral nutrition, however, had no impact on fistula mortality; maintenance of adequate nutrition with more conventional methods was equally effective.[3,28] Nevertheless, parenteral nutrition has greatly simplified the nutritional management of patients with gastrointestinal fistulas. Once a patient is both malnourished and septic, it becomes quite difficult to replete such a patient. Even though these patients often have abdominal abscesses and bacteremia, parenteral nutrition is safe and the overall incidence of septic complications from the central line or parenteral nutrition is no greater than that in other clinical situations.

It is much better to begin to provide nutritional support as soon as the patient is stabilized. Full caloric and nitrogen replacement can be provided within a few days of instituting nutritional support.[37] Nutrition can be given by several routes. Frequently, these patients may be too ill to eat, or they cannot consume enough calories even if they can take some oral nutrition. Usually, either enteral tube feeding or parenteral nutrition will be required. The choice of which to use depends on the fistula anatomy. It is advantageous to provide at least a portion of the calories through the enteral route because the gastrointestinal tract is a much more efficacious way of providing nutrition, maintaining the intestinal mucosal barrier and immunologic integrity, and stimulating hepatic protein synthesis, which has been found to be of critical value in determination of the outcome in fistula patients.[41] Thus, whenever possible, enteral nutrition is preferable to parenteral nutrition and probably decreases the incidence of multisystem organ failure and sepsis if administered appropriately.

Enteral nutrition is not without complications, however, and the process should be closely monitored. Complications such as diarrhea, aspiration, and bowel ischemia are not uncommon without careful clinical monitoring. Enteral nutrition can be given for upper gastrointestinal fistulas, especially when the feeding tube can be placed beyond the fistula (for instance, a feeding tube placed beyond the ligament of Treitz for a gastric, duodenal, or pancreatic fistula). In general, feeding tubes should be placed when possible beyond the ligament of Treitz to decrease the potential risk for aspiration. Enteral feeding should also be used for distal fistulas (e.g., a colonic fistula), as long as feedings do not significantly increase fistula output. On the other hand, parenteral nutrition can be a valuable tool in the

treatment of fistulas as well. Patients with small bowel fistulas may not be able to tolerate enteral nutrition without increasing fistula output. In these cases and in others in which patients cannot tolerate enteral feeding, parenteral nutrition is indicated. In patients with a persistent adynamic ileus and before the fistula tract is well established, parenteral nutrition is very useful. Parenteral nutrition techniques and advantages are well known, although complications also occur with some frequency. In the Reber et al. study of 91 patients with gastrointestinal fistulas managed with TPN, 28% had complications, with catheter-related sepsis and subclavian vein thrombosis occurring most frequently.[28] Hyperglycemia is common when initiating TPN in patients with gastrointestinal fistulas. New-onset hyperglycemia in a patient with an established TPN regimen should alert the treating physician to the possibility of new or ongoing sepsis (e.g., intra-abdominal abscess, wound infection, line sepsis, pneumonia).

The presence of a gastric or duodenal fistula will not usually permit oral alimentation, unless it is of low output and eating does not markedly worsen losses. If a feeding tube beyond the ligament of Treitz or a tube jejunostomy is in place, enteral nutrition should be started; with normal small and large intestinal function, all nutritional needs can be met. However, the presence of distention or diarrhea will limit the rate of tube feeding and may necessitate parenteral nutrition and fluid repletion. TPN via central venous access enables the delivery of full caloric and fluid requirements, unless poorly controlled hyperglycemia or hypercapnia limits caloric delivery. Those with low-output fistulas require 30 to 35 kcal/kg/day, with 1.0 to 2.0 g protein per kilogram body weight per day. Those with high-output fistulas require more calories—up to 1.5 to 2.0 times normal energy expenditure, with a protein supply of 1.5 to 2.5 g/kg/day.[37] This is especially the case with duodenal fistulas because of the loss of gastric, duodenal, biliary, and pancreatic exocrine protein-rich secretions. Short-turnover protein (prealbumin, retinol-binding protein, transferrin) levels should be measured at least weekly to assess the adequacy of protein delivery. An ongoing catabolic state will adversely affect short-turnover protein levels, even with maximal protein delivery. Those with high-output fistulas may benefit from twice the recommended daily allowance of vitamins, trace elements, and zinc and up to 5 to 10 times the daily requirement for vitamin C.[37] The daily delivered volume should include both maintenance fluids and ongoing fistulous losses.

Historically, high output from a fistula was a relative contraindication to enteral nutrition. Both human and animal data, however, suggest that even these complicated fistulas can be adequately managed with enteral nutrition, although the parenteral route may still succeed in further reducing fistula output. Enteral nutrition, both orally and by tube feeding, has been used increasingly when treating small intestinal fistulas because of its trophic effect on the intestine. The overall success with nutritional supplementation by the enteric route rivals that of parenteral nutrition. Indications for enteral supplementation depend on the site of the fistula and the extent of the remaining small intestine that can be used for absorption. By using a combination of enteral nutrition techniques along with parenteral nutrition, adequate caloric and nitrogen intake should be achieved rapidly. As little as 20% to 25% of the nutrition supplied enterally is usually sufficient to provide the advantages of enteral nutrition, and the remainder can be supplied via parenteral nutrition. Conversely, the decreased fistula output that usually accompanies the institution of parenteral nutrition can greatly simplify the management of high-output fistulas. In addition to this adjunctive role in conjunction with parenteral nutrition, tube feeding continues to be an important measure in the complete nutritional management of some fistula patients with distal and low-output fistulas, when the fistulas are nearly healed, or when parenteral nutrition is difficult or impossible to institute. The ability to provide TPN may also be limited by recurrent line infections, which can lead to endocarditis, or the lack of adequate access sites secondary to thrombosis in patients maintained on long-term TPN. A single-lumen catheter dedicated solely to TPN is preferable and may decrease infectious and thrombotic complications.

Because both enteric and parenteral feeding has advantages and disadvantages, the source of nutritional supplementation should depend on the individual patient and the surgeon's preference and experience. In most cases, parenteral nutrition should be instituted as soon as possible. Thereafter, steps to localize the fistula and control infection can be taken. Normal intestinal motility and function generally return once abdominal sepsis is controlled and fluid and electrolyte imbalances are corrected. If the fistula location is such that enteric access and alimentation are possible, enteral nutrition can be instituted and parenteral nutrition phased out. By using a combination of approaches, adequate nutrition can be maintained throughout the patient's course.

Control of Sepsis

Uncontrolled sepsis remains the major factor contributing to mortality in patients with small intestinal fistulas. Aggressive management of all ongoing infections and careful surveillance for new septic foci are thus absolutely necessary for successful management. Tachycardia, persistent fever, and leukocytosis usually portend inadequate control of the fistula or abscess formation. Frequent physical examination and judicious use of ultrasonography and computed tomography (CT) are mandatory.

Advances in patient monitoring, correction of fluid, electrolyte, and acid/base imbalances, and the use of parenteral nutrition have largely alleviated electrolyte disturbances secondary to high-output fistulas and malnutrition. In the present era, mortality is mostly determined by uncontrolled sepsis and sepsis-associated malnutrition. Malnutrition in the presence of uncontrolled sepsis cannot be treated without effective surgical drainage of the septic source. As long as uncontrolled sepsis persists, the patient's condition will continue to deteriorate. The stabilization phase often involves control of a septic source. Typically, drainage of an intra-abdominal abscess is required, which is ideally accom-

plished in an image-guided, percutaneous fashion. In addition, fistula drainage must be controlled and the skin of the abdominal wall protected. Local control is an extremely important component of the early management of a fistula. Discontinuation of oral intake and initiation of parenteral nutrition are important steps. Placement of a nasogastric tube or a nasoenteric tube positioned proximal to the fistula may be helpful with enteric fistulas involving the duodenum or proximal jejunum. Egress of the fistula output from the abdominal cavity must be facilitated with an immature enterocutaneous fistula because inadequate external drainage results in internal loculation, abscess formation, or peritonitis. It is extremely important to prevent the severe local skin excoriation that frequently develops around the site of an enterocutaneous fistula. Fistulas that have been controlled with a tube should cause minimal injury to fascia, subcutaneous tissue, and skin. Such injuries typically include perforations with abscesses that have been percutaneously drained or have been converted at surgery to a controlled fistula with an indwelling tube or an adjacent drain.

Drainage should be collected to measure the output and provide a gauge for fluid and electrolyte replacement. The method of controlling fistula drainage must be individualized for each patient. Precautionary steps should be instituted early because once excoriation is present, healing is difficult in the presence of ongoing drainage. A fistula should be exteriorized on a flat portion of the abdominal wall with avoidance of bony prominences and skin folds. This permits secure application of an ostomy bag or other device to collect and monitor fluids and protect the skin. Specialized nursing assistance by an enterostomal therapist or wound care specialist is frequently necessary and can be quite helpful in the management of these often complex wounds. Drainage with a single catheter placed into the site generally fails because the catheter becomes occluded or the volume of fluid expelled with peristalsis exceeds the capacity of the catheter. In some instances, a sump suction catheter can be placed through the external opening and gentle continuous suction applied to control fistula drainage (a sump catheter can be constructed by inserting a soft rubber catheter in the wound with an angiocatheter placed in the side of the rubber catheter to create a sump system by applying low continuous wall suction through the catheter). A surrounding ostomy appliance can then be placed around the tube to collect any excess drainage. When fistula drainage has been controlled, the sump catheter should be gradually withdrawn or progressively replaced with smaller-caliber tubes. This allows the tract to contract and close. Sump suction can eventually be replaced by gravity drainage in most patients. D'Harcour and associates reported an 81% overall closure rate with this method in 147 patients with both high-output (93 patients) and low-output (54 patients) fistulas.[42]

One useful modification of fistula wound management has been described by Suripaya and Anderson (Fig. 73–1). A disposable ileostomy bag with adhesive backing is fitted to the fistula site.[43] The opening in the ileostomy bag is cut to fit the fistula as exactly as possible. Two 18-French or larger catheters with multiple side perforations are tied together and passed into the fistula through the open end of the bag. All perforations are placed within the fistula below skin level. A third 18-French catheter with multiple perforations is placed in the ileostomy bag, and the open end of the bag is tied securely around all three catheters. One of the two catheters within the fistula and the catheter lying free in the bag are set for continuous suction at a minimum of 40 mm Hg of negative pressure. The adjacent catheter in the fistula serves as an air vent. When functioning, the bag is completely collapsed, and fluid leaking from the tract is immediately aspirated away. The surrounding skin must be protected from excoriation and erosion because skin breakdown can cause discomfort and also increase metabolic requirements. Protection can best be accomplished by attaching a disposable ostomy appliance with either a Stomahesive or a karaya ring around the fistula. The surrounding skin can be protected with Stomahesive paste, karaya gum powder, aluminum paste, tincture of benzoin, or zinc oxide/menthol cream.

Alternatively, a wound vacuum (V.A.C. [vacuum-assisted closure] device) drainage system works very well to control fistula drainage and protect the skin (Fig. 73–2). With negative pressure application to the wound, the V.A.C. apparatus allows for excellent control of drainage, minimizes the size of the abdominal wound, simplifies management by decreasing the frequency of dressing changes, and may actually promote healing of the fistula.[44,45] By simplifying wound care and control of output, patients can be discharged from the hospital sooner and the V.A.C. can easily be managed in a home care or extended care setting. For the majority of enterocutaneous fistulas, this has become our method of choice for controlling fistula drainage and protecting the surrounding skin.

The therapeutic use of appropriate antibiotics for intra-abdominal abscess and sepsis should be carefully reserved for septicemia and cholangitis, as well as in preparation for surgery. Once signs of intra-abdominal sepsis have occurred, the use of antibiotics does not obviate the necessity of treating the process surgically or via percutaneous drainage. Adequate drainage of an abscess cavity must be accomplished. If possible, general anesthesia and major surgical procedures should be avoided or postponed until the patient's condition has stabilized. Although drainage of the abscess must be complete, it is important to choose the least traumatic procedure that is consistent with this goal. Ultrasound and CT are most often used to search for peritonitis or an intra-abdominal abscess. These two modalities not only localize such processes but also permit guided percutaneous drainage, an invaluable procedure in a critically ill patient who may not tolerate an operative procedure (Fig. 73–3). Abdominal exploration may be required in septic patients who are losing ground, even if diagnostic studies have not pinpointed an abscess. If exploratory laparotomy is required for drainage, it is best to avoid definitive operative repair of the fistula because such attempts are usually unsuccessful in the setting of adjacent sepsis. Failure of repair may make subsequent attempts more difficult and possibly result in spread of

infection to previously uninvolved areas of the abdomen. Control of the fistula should be established during the operation by allowing complete drainage to the skin surface or by actually exteriorizing the fistula.

The fistula effluent should be cultured for both bacteria and fungi. Sputum, urine, wound, and blood cultures, including those from central venous lines, should also be obtained. Wound or drain site collections should be evacuated. The wound should be débrided of all grossly infected and necrotic tissue. Culture results and the eventual patient systemic response should modify subsequent antibiotic therapy, particularly if *Enterococcus,* resistant gram-negative bacteria, or fungus is cultured. Percutaneous drainage can often temporize the situation until the patient's condition stabilizes and may, in some cases, lead to eradication of the fistula.

Once sepsis is controlled or when no sepsis is present, parenteral/enteral nutrition should result in improved nutritional status and allow skin lesions to heal and the future operative field to become quiescent. Early operative intervention in the presence of malnutrition is not necessary and may be detrimental. Even if the regimen of bowel rest in conjunction with intravenous and enteral nutrition does not lead to successful spontaneous fistula closure, the patient is generally in better nutritional and metabolic condition to withstand an operation to correct the fistula.

Pharmacologic Support

Use of the long-acting somatostatin analogue octreotide for decreasing pancreatic and enterocutaneous fistulous output has been popularized during the 1990s. An inhibitory effect on gastric, biliary, and pancreatic secretions is generally observed in clinical use. With typical subcutaneous dosages of 100 to 250 μg every 8 hours, fistulous output is reduced by 40% to 60% after the first day regardless of fistula site or volume of output.[46] Side effects are not usually severe and include hyperglycemia, decreased bowel motility, and elevated cholesterol levels. Placebo-controlled studies indicate that octreotide decreases fistula-related complications, reduces fistulous output, and decreases fistula healing time and the time required for TPN.[47] Octreotide has been shown to promote fistula closure within a significantly shorter time than TPN alone does, even with malignant enterocutaneous disease, and is particularly helpful in decreasing secretions in high-output fistulas to a manageable

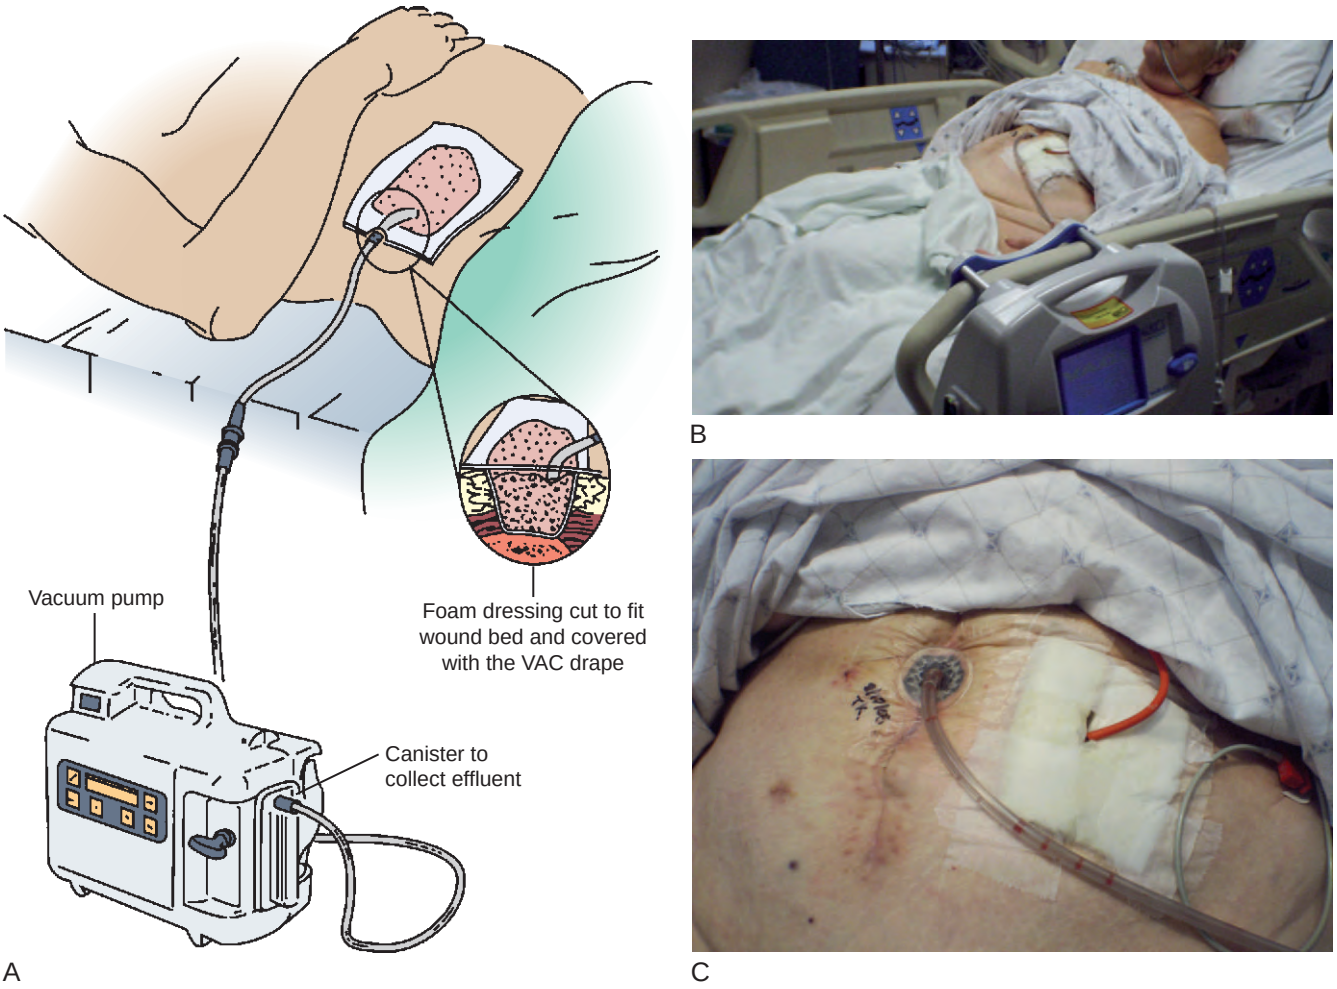

Figure 73–2. **A,** The wound V.A.C. apparatus allows for excellent control of drainage, minimizes the size of the abdominal wound, and simplifies management. level.[48-50] However, the mortality rate, hospitalization time, and overall fistula closure rate were not improved, although even in the fistulas that eventually required operative closure, octreotide in general both reduced their output and simplified management.

Proton pump inhibitors or histamine H_2 receptor antagonists are advisable both to reduce gastric acid production and to reduce gastric secretions. These medications may be useful in decreasing fistula output, particularly with proximal fistulas or when the amount of gastric secretions is high. Patients with refractory fistulas related to Crohn's disease have been successfully treated with short courses of cyclosporine. In five patients with a total of 12 fistulas, Hanauer and Smith used an infusion of 4 mg/kg/day for 6 to 10 days, followed by oral dosing at 8 mg/kg/day adjusted to maintain serum cyclosporine levels of 100 to 200 ng/ml.[51] All fistulas responded to cyclosporine infusion with decreased drainage and improvement in both local inflammation and patient comfort. Complete resolution occurred in 10 of the 12

fistulas after a mean of 8 days. Therapy was continued for a mean of 6 months, with five recurrences, two of which were related to inadequate cyclosporine serum levels. Similar results with cyclosporine were reported by Present and Lichtiger.[52] Side effects consisted of infectious complications, mild hypertension, paresthesias, and hirsutism. Although useful for short-term treatment, long-term administration of cyclosporine is generally avoided because of the potentially septic complications of immunosuppression, as well as hypertension and nephrotoxicity. In addition, the use of immunosuppressive drugs such as cyclosporine may theoretically impair healing of the fistula.

Azathioprine and 6-mercaptopurine are both effective in treating active Crohn's disease and in maintaining remission, with the cumulative dose being the primary factor in predicting response. Associated small bowel fistulas may also improve with such treatment. Adverse reactions such as leukopenia, pancreatitis, and nausea may preclude therapy with these agents. Combination therapy with tacrolimus and either azathioprine or 6-mercaptopurine may be useful when treating perineal fistulas related to Crohn's disease. In one study involving 11 patients, 7 had a complete response and 4 had a partial response.[53] The most common side effects with such combination therapy are nausea, paresthesias, nephrotoxicity, and tremor.

More recently, infliximab (Remicade), a chimeric monoclonal antibody to tumor necrosis factor-α, was developed as treatment of Crohn's disease. Infliximab is effective in closing fistulas in patients with Crohn's disease. In a randomized, multicenter trial investigating infliximab administered intravenously at 0, 2, and 6 weeks and dosed at 5 mg/kg for the treatment of 94 adult Crohn's patients with chronic fistulas, partial resolution of multiple lesions occurred in 68% and complete closure occurred in 55% of patients.[54] Other studies also support the efficacy of infliximab in treating Crohn's disease–related small bowel fistulas.[55,56] In 282 patients with fistulizing Crohn's disease, infliximab, 5 mg/kg every 8 weeks, significantly reduced hospitalizations, surgeries, and procedures in comparison to placebo.[57] Complications of this therapy occur in more than 60% of patients and include headache, abscess, upper respiratory tract infection, and fatigue.

Investigation

The next phase of management is investigation. After stabilization is accomplished in the first 24 to 48 hours, investigation usually takes place over the next 7 to 10 days. Investigation implies a thorough evaluation of the gastrointestinal tract, definition of the anatomy of the fistula, and identification of any complicating features such as abscess, stricture, or distal obstruction.[31,32] Investigative studies should be designed to not only determine the presence and location of the fistula but also provide information regarding its cause. This objective can be accomplished by several investigational methods. Oral administration of indigo carmine or charcoal can be used to demonstrate the presence of a connection between the gastrointestinal tract and the abdominal wall or urinary bladder. These tests, however, prove only the presence of a fistula and do not identify its site or source. Probably the most important first test is a fistulogram, which will define the length and width of the fistula, as well as its anatomic location. A fistulogram can be performed by inserting a small catheter through the drainage site into the fistula tract and then slowly injecting water-soluble contrast under fluoroscopy (Fig. 73–4). It is best performed by the responsible surgeon in collaboration with the radiologist. The value of the procedure is enhanced by close involvement of the surgeon

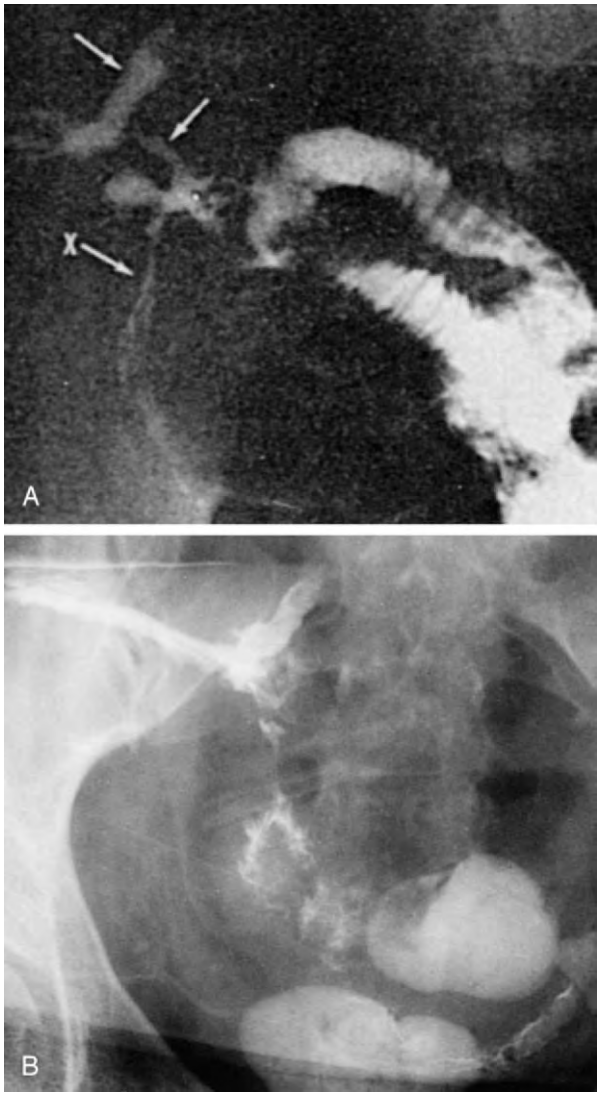

Figure 73–4. **A,** Fistulogram. Injection of a cutaneous fistula demonstrates several tracts *(arrows)* leading to the ileum. Crohn's disease is present in one loop *(arrow with X).* **B,** Fistulogram demonstrating an enterocutaneous fistula in a patient after appendectomy for acute perforated appendicitis. **(A,** From Goldfarb WB, Monafo W, McAlister WH: Clinical value of fistulography. Am J Surg 108:902, 1964.)

and the radiologist as the study is performed. The procedure is safe and can be performed even in seriously ill patients.[58,59]

Fistulography performed early in the course of the disease will help determine (1) the site of the fistula, (2) intestinal continuity with the fistula, (3) the presence or absence of distal intestinal obstruction, (4) the nature of the intestine immediately adjacent to the fistula, and possibly (5) the presence or absence of an intra-abdominal abscess. Other tests such as an upper gastrointestinal series with small bowel follow-through and barium enema are helpful in further elucidating the exact anatomy and location of the fistula. Performing the fistulogram first is prudent because contrast from an upper gastrointestinal series, contrast enema, or even CT may make it difficult, if not impossible to interpret a fistulogram until all of the contrast has passed. Fistulography should be followed by a complete contrast study of the gastrointestinal tract either orally or through existing intraluminal tubes. Such study is valuable both for identifying the internal source of the fistula and for defining its size and complicating factors such as distal obstruction. The fistulogram should always be performed before the complete contrast study because the latter will not usually define the fistula and may decrease visualization or make fistulography impossible. Internal fistulas may be more difficult to evaluate. Patients with enteroenteric fistulas often suffer a delay in diagnosis because of a lack of symptoms or symptoms that mimic the primary disease or event creating the fistula. An internal small intestinal fistula may be asymptomatic, particularly if the amount of absorptive area bypassed by the fistula is small. Other internal fistulas may not be readily recognized because the symptoms may mimic those of the primary disease. For example, an enteroenteric fistula, which is most often secondary to Crohn's disease, is frequently accompanied by abdominal pain, diarrhea, weight loss, or fever. These symptoms are similar to those accompanying an acute exacerbation of Crohn's disease itself. Thus, at times the diagnosis is not made until surgery in these patients. If the colon is involved with the fistula, a fluoroscopic water-soluble or barium enema will assist in definition of both the fistula and any associated colonic disease.

Additional useful tests in the early stage of investigation are CT and ultrasonography. These tests can further define the anatomy of the vicinity of the fistula and evaluate for any ongoing or unrecognized intra-abdominal processes or abscesses, as well as distal obstruction. A CT scan will be required in almost all patients for these reasons, especially to rule out any undrained collections. CT scanning with oral and intravenous contrast media is highly sensitive and specific for intra-abdominal free air and will assist in locating the fistula and identifying adjacent fluid collections and concomitant bowel obstruction. The use of CT, however, within the first week after surgery is associated with the expected presence of postoperative air within the abdominal cavity and thus may be difficult to interpret. Obviously, extravasation of intraluminal contrast on CT examination is diagnostic of perforation. CT and ultrasound are useful adjuncts when an intra-abdominal abscess is suspected (Fig. 73–5). Significant fluid collections should be drained, preferably under CT or ultrasound guidance via a percutaneous route, and an indwelling catheter left in the cavity. This then permits subsequent examination of the cavity under fluoroscopy with water-soluble contrast to assist in delineation of the fistula tract. Although the site of perforation may not be identified on initial injection because of inflammation, subsequent examinations after several days of drainage will often show the site of the fistula. CT scanning is highly recommended for suspected duodenal perforations; no other imaging modality is currently better at demonstrating gas in the retroperitoneum surrounding the duodenum, which is a diagnostic sign of perforation. An elevated serum amylase level may accompany duodenal perforation after ERCP and give the impression of pancreatitis, thus leading to a delay in diagnosis with an increase in the mortality rate.[22]

Intravenous pyelography and retrograde pyelography may be helpful in defining a nephroenteric fistula, whereas cystoscopy is usually a more accurate method for determining the presence of an enterovesical fistula. In general, CT is the most sensitive study for identifying a colovesical or enterovesical fistula. ^{99m}Tc-labeled hepatoiminodiacetic acid (HIDA) scanning or ^{111}In-labeled leukocyte scintigraphy may have an advantage over conventional radiography in certain proximal enterocutaneous or biliary-enteric fistulas.

Endoscopic evaluation, including colonoscopy, esophagogastroduodenoscopy, and ERCP, may be helpful in certain specific clinical situations. However, endoscopy is not usually advisable if an acute perforation is suspected and should generally be delayed until the acute inflammatory process has resolved. Endoscopic examination of the stomach and duodenum may occasionally be used to identify a fistulous source and to take biopsy samples of adjacent tissue for exclusion of malignancy. Billroth II anatomy will usually preclude duodenal examination, although enteroscopy through the afferent jejunal limb is possible by highly skilled endoscopists. ERCP will allow the diagnosis of fistulas connecting the gallbladder or biliary tract to the duodenum or stomach. For suspected gastrocolic or duodenocolic fistulas, colonoscopy may identify the involved site and enable a biopsy to be performed to diagnose inflammatory bowel disease or malignancy. The fistulous output may be analyzed for electrolytes and cultured to determine drug sensitivities, as well as assayed for bilirubin and amylase for comparison with serum values.

In the rare circumstance when perforation has not been excluded by noninvasive tests and the patient's condition is not improving or is worsening, diagnostic laparotomy should be considered. Morbidity and mortality rates are only increased by a delay under these circumstances. Diagnostic laparoscopy may be useful to rule out perforation after a previous laparoscopic procedure or after an endoscopic procedure. It is not usually appropriate in a septic, hypotensive patient and does not enable a satisfactory examination of the retroperitoneal duodenum. As mentioned previously, early laparoscopy for tachycardia or unexplained fever is essential to prevent mortality from an anastomotic leak after gastric bypass surgery.

Computed tomography scans obtained in the patient whose fistulogram is demonstrated in Figure 73–4B. **A,** Intra-abdominal air-fluid collection containing contrast just below the abdominal wall in the midline. **B,** Lower cuts showing the inflammatory response and subcutaneous air representing the early stages of fistula development. **C,** Computed tomography scan demonstrating resolution of an intra-abdominal abscess after percutaneous catheter drainage.

Decision

The next step in fistula management is a decision on management and the timing of such management. When one is making these decisions, the likelihood of spontaneous closure must be determined. The likelihood of closure depends on several factors. The first is anatomic location. In general, anatomic locations that are favorable for closure are the oropharynx, esophagus, duodenal stump, pancreas, biliary tree, and jejunum. Alternatively, unfavorable locations include the stomach, lateral duodenum, ligament of Treitz, and the ileum. As mentioned previously, nutritional status is very important. Patients with poor nutritional status, as measured by overall assessment, albumin, short-turnover proteins (serum transferrin, thyroxin-binding prealbumin, retinol-binding protein), injected skin antigens, and other factors, are much less likely to close a fistula no matter what the anatomic location.[41] More importantly, if a patient's nutritional status is poor, the mortality rate is higher. Another important factor is the presence or absence of sepsis. The absence of sepsis has a positive predictive value for closure, whereas the converse is true in the presence of sepsis. Elimination of sepsis should be considered a necessity for spontaneous closure. The cause of the fistula is also predictive of closure. Postoperative fistulas and fistulas secondary to appendicitis or diverticulitis are likely to close. Fistulas associated with active Crohn's disease are unlikely to close until the Crohn's disease is quiescent. Fistulas associated with cancer will usually require excision of the tumor along with the fistula. In addition, the presence of a foreign body will prevent closure of the fistula without operative intervention.

After sepsis has been controlled and diagnostic studies have been completed, management of a fistula should follow a conservative course. An opportunity for spontaneous healing should be permitted. It is important to provide adequate nutritional support and to aggressively investigate any new onset of signs of sepsis during this convalescent period. The duration of conservative treatment must be individualized. If a positive nitrogen balance is maintained, fistula output decreases, and no septic complications develop, nonoperative manage-

ment may be continued. The spontaneous closure rate of enterocutaneous fistulas in several large series ranged from 32% to 80%.[27,28] Reber and associates reported that more than 90% of small intestinal fistulas that closed did so within a month.[28] Less than 10% closed after 2 months, and none closed spontaneously after 3 months. Thus, a reasonable management plan may consist of at least 1 month of nonoperative management, with reasonable extensions should the fistula show signs of slow but continued healing. Delaying surgery allows peritoneal reaction and inflammation to subside, thus making a definitive surgical procedure easier and safer. Delaying repair also permits nutritional optimization, thereby decreasing the likelihood of postoperative wound complications. A postoperative enterocutaneous fistula usually extends hospitalization by 2 to 3 months, but this period may shorten somewhat with refinements in TPN, administration of somatostatin analogue, and wider availability of outpatient nursing care. In fact, many patients are candidates for discharge home or to a skilled nursing facility during the convalescent period because of the availability of these agents in such settings.

The condition of the bowel or other organ involved in the fistula is also important. Healthy adjacent tissue is a favorable factor. Other favorable factors include a small fistula, quiescent disease, and the absence of an abscess. On the other hand, total disruption of the bowel negates closure, as does distal obstruction, abscess, malignancy or irradiation (or both), epithelialization of the fistula tract, and active disease. Typically, a long fistula tract (longer than 2 cm) is more likely to close than a short fistula tract. Similarly, a thin, narrow tract is a favorable prognostic indicator (i.e., less than 1 cm^2). Therefore, short, wide tracts are unlikely to close spontaneously.[31,32] Nutrition has been mentioned as an important factor in stabilization and spontaneous closure. The short-turnover proteins can provide prognostic information. Specifically, a serum transferrin level less than 200 mg/dl predicts a low likelihood of spontaneous closure.[41]

Failure of an enterocutaneous fistula to close spontaneously is associated with a number of factors (represented by the acronym *FRIENDS*): the presence of a *foreign body* within the tract or adjacent to it, previous *radiation* exposure of the site, ongoing *inflammation* (most commonly from Crohn's disease) *or infection* that contributes to a catabolic state, *epithelialization* of the fistula tract (particularly if the fistula tract is less than 2 cm long), *neoplasm, distal intestinal obstruction,* and pharmacologic doses of *steroids.* Fistulas associated with a concurrent pancreatic fistula also have a low rate of spontaneous closure, as do those occurring in the presence of malnutrition or adjacent infection. As mentioned, the loss of intestinal continuity or the presence of abdominal wall defects makes operative correction more likely. Vigorous attempts to identify each of these confounding factors and to modify their influence may increase the success of nonoperative strategies, but operative intervention is generally necessary when they are present.

Campos et al. analyzed prognostic factors for closure of external duodenal fistulas and found that the odds of spontaneous closure were (1) three times greater with low-output fistulas than with high-output fistulas, (2) five times greater with postoperative fistulas than with fistulas associated with inflammatory bowel disease or trauma, and (3) two times greater with duodenal fistulas than with jejunoileal fistulas.[60] For duodenal fistulas, spontaneous closure was observed in 33%, with an overall mortality rate of 36%. Williams et al. found that even high-output lateral duodenal fistulas spontaneously closed in 63% with TPN and eradication of sepsis.[61] Their median output was 1480 ml/day, with a median time to closure of 29 days and an overall mortality rate of 15%. Kuvshinoff et al. found that seven of eight gastric fistulas closed spontaneously but only one of four duodenal fistulas did so; approximately 50 days was required for closure.[41]

After considering all the aforementioned factors, one determines whether to observe the fistula for spontaneous closure or plan early surgery after stabilization. When one determines that the fistula is likely to close and does not operate, if the fistula has not closed after 4 to 5 weeks without sepsis, an operation will probably be required. General wisdom holds that a fistula that has not closed by 4 to 6 weeks is unlikely to do so and surgery is indicated. The decision to operate is tempered by the patient's condition and the state of the abdomen. In particular, when faced with a firm, indurated abdomen, it is better to stabilize the infection, nutrition, and fluid balance in this circumstance and wait until the abdomen is soft, without significant induration, to maximize the chance for operative success and minimize the risk of creating new enterocutaneous fistulas. In certain cases then, the period of waiting may be greater than 6 weeks.

Definitive Therapy

The next important decision is to determine whether definitive operative therapy is necessary and the timing of such therapy. In situations that are favorable, between 80% and 90% of fistulas that are going to close spontaneously will close within 4 to 5 weeks. When spontaneous closure is unlikely or has not occurred within 4 to 5 weeks, an operation will be required. When operative therapy has been chosen, the operation must be carefully planned. Whenever possible, the operation should not take place until the patient is stable, not septic, and in an adequate nutritional state. The most favorable time to reoperate on patients is either within 10 days of diagnosis or after 4 months.[32]

Gastric and Duodenal Perforations and Fistulas

Endoscopically produced gastroduodenal perforations are appropriately referred for surgical management when a free perforation is recognized by the presence of intra-abdominal air on radiographic films. However, retroperitoneal duodenal perforations that occur during ERCP and sphincterotomy have been treated both medically and surgically, depending on the size of the perforation and the patient's response. Loperfido et al. reported 12 retroperitoneal perforations in a series of 2769 ERCP procedures; 6 were treated nonoperatively,

with one death.[21] From a surgical standpoint, Bell et al.[22] warned that patients with perforations diagnosed within 24 hours of surgery had a mortality rate of 13% whereas delay beyond 24 hours increased mortality rates to 43% because of sepsis or multiorgan failure. If medical therapy is undertaken for a small, contained perforation, close monitoring should be performed, with surgical exploration initiated within 24 hours for perforations that do not improve or that worsen.

Acute intraoperative gastric or duodenal perforations should be repaired during the course of the operation. This simple principle presupposes both that the perforation is recognized and its repair is possible. In particular, laparoscopic surgical procedures may produce perforations that are not recognized at that time. Frequently, if recognized, such injuries can be repaired with laparoscopic suturing techniques. However, in some situations laparoscopic repair of gastric or duodenal lacerations may be quite difficult to perform, particularly if the surgeon is not expert in advanced laparoscopic maneuvers. Conversion to laparotomy in these circumstances to ensure a safe repair reflects good surgical judgment rather than failure. Initial complications tend to breed subsequent complications, which are minimized by prompt and thorough treatment of the initial problem.

Gastric perforation occurring during a surgical procedure can usually be primarily repaired with an inner layer of continuous absorbable suture and an outer layer of interrupted silk suture. Alternatively, a stapler may be used if the anatomy is appropriate and the tissues are not inflamed or markedly edematous. During laparoscopic procedures, serosal lacerations are often visible; methylene blue instillation via a nasogastric tube will reveal extravasation. Intraoperative endoscopy with air insufflation and distal occlusion under saline irrigation may be even more accurate in identifying a leak. Manual distal occlusion and removal of the insufflated air by suction at the conclusion of the test are essential because air insufflation of the intestine can make the remainder of the procedure very difficult. Serosal lacerations may be sutured laparoscopically if amenable, but laparotomy is appropriate for difficult anatomy or poor exposure.

Usually, patients with perforations that are recognized in the immediate postoperative period should be returned to the operating room for repair. For initial laparoscopic procedures, repeat laparoscopy may be appropriate to diagnose the perforation and to close it, if possible. Laparotomy will often be required for satisfactory identification, washout, and closure. With both laparoscopic and open procedures, anastomotic leaks will frequently occur later, about 1 week after surgery. The decision to operate will be influenced by the ability to drain associated abscesses percutaneously and the presence of peritonitis. Focal collections that are adequately drained, with a good systemic response and only local tenderness, may continue to be observed for eventual closure. Ongoing sepsis, poorly drained collections, or generalized peritoneal signs should mandate reexploration, débridement, drainage, and management of the perforation.

Surgical options for gastric perforation include simple closure, partial gastric excision with reclosure, or partial gastrectomy. An indurated stomach with extensive inflammation will make resection hazardous; in this situation, an omental patch of the perforation should be considered. Placement of a drain or sump in the area may convert the perforation to a controlled fistula if the repair or patch leaks again. Placement of a gastrostomy tube, if possible, will permit gastric decompression and avoid the prolonged use of a nasogastric tube with its risk for sinusitis. Placement of the gastrostomy tube through the area of perforation may be optional if closure or excision cannot be safely accomplished. Consideration should be given to placement of a feeding jejunostomy tube (or a combined gastrostomy-jejunostomy tube). A leaking gastroduodenostomy may be treated by distal gastric resection with conversion to a Billroth II gastrojejunostomy.

Perforations that are recognized in the first several days postoperatively should usually be treated by reoperation and closure or by anastomotic revision. More typically, nearly 1 week after surgery, the onset of fever, tachycardia, respiratory failure, and acidosis with ileus and pain will suggest a leak or abscess. After CT-guided percutaneous drainage, with appropriate antibiotic therapy, the perforation will often heal. Failure to resolve shifts the focus to management of a fistula. An early leak after gastric bypass surgery should be recognized and repaired as soon as possible to prevent significant morbidity and mortality. This complication usually requires revision of the anastomosis and drainage.

Repair of ERCP-induced duodenal perforations should be performed as soon as possible after diagnosis and hemodynamic and respiratory stabilization. Delay increases the friability and edema of the duodenum and increases retroperitoneal contamination and the possibility of damage to the small and large intestine and mesentery. A midline laparotomy is advised to allow access to all of the small bowel and mesentery. Wide kocherization of the second portion of the duodenum, with mobilization of the hepatic flexure if needed, allows close inspection of the second and third retroperitoneal portions. In most cases with an early diagnosis, local débridement of the wound edges with suture closure will close the duodenal defect. If the perforation occurred during sphincterotomy, the location of the bile duct must be determined before suture closure. If the duct location is uncertain, cholecystectomy may be performed, and a small catheter can be passed through the cystic duct stump into the distal common bile duct and duodenum. For a significant ampullary injury, proximal bile drainage with either a T-tube or a tube cholecystostomy should be considered. Proximal decompression is accomplished with a gastrostomy tube. Internal duodenal decompression can be achieved with either a retrograde tube duodenostomy (placed through the proximal jejunum) or a combination gastrostomy-jejunostomy tube, with the distal end cut short appropriate to a duodenal tip location. The duodenal repair is reinforced with omentum, if possible, and a local closed suction drain will, in many cases, facilitate evacuation of the fluid. It also serves to convert any subsequent leakage to a controlled fistula. A

feeding jejunostomy should be created for postoperative enteral nutrition. With a delay in the diagnosis of duodenal perforation, there may be widespread inflammation or necrosis in the retroperitoneum that extends under the transverse mesocolon and small bowel mesentery. Much of this can be accessed by hepatic flexure mobilization, but a counterincision beside or below the small bowel mesentery may be needed to adequately débride and drain the areas of necrosis. Sump drain placement under the small bowel mesentery and near the duodenum generally permits good drainage; the sumps may be gradually withdrawn later after tube checks and CT scans demonstrate healing.

Pyloric exclusion has been used successfully in trauma patients with extensive duodenal injury, with diagnosis delayed more than 24 hours after injury, and after initial primary duodenal repair with subsequent breakdown and a high-output lateral fistula. Closure of the pylorus, gastrojejunostomy, gastrostomy, and feeding jejunostomy without vagotomy are performed in the expectation that the pylorus will reopen within 3 to 6 weeks, although subsequent intra-abdominal abscesses may require drainage. This technique may be most suitable for nontrauma patients with a delayed diagnosis of duodenal perforation in which the bowel wall is markedly thickened, friable, and inflamed and where other options, such as closure, serosal patching, or tube duodenostomy, are not thought to be adequate (see Chapter 53 on duodenal trauma).

Gastroduodenal fistulas that develop in association with necrotizing pancreatitis and necrosectomy may be treated during laparotomy or by subsequent percutaneous drainage. Tsiotos et al. treated two gastrocutaneous fistulas 1 month after necrosectomy by percutaneous drainage, with eventual closure.[19] Duodenal fistulas were treated by tube duodenostomy or Roux-en-Y duodenojejunostomy; late-developing duodenal fistulas were treated by percutaneous drainage. Ho and Frey used primary closure and delayed external drainage for gastric fistulas after necrosectomy and treated duodenal fistulas with pyloric exclusion or external drainage.[20]

If the gastric or duodenal defect is too large to allow primary closure or the fistula originates in conjunction with the ampulla and pancreatic duct, a Roux-en-Y gastrojejunostomy or duodenojejunostomy is a flexible and valuable technique for dealing with such difficult gastric or duodenal fistulas. It is best used in the absence of ongoing infection, when sufficient time has been allowed, and the jejunum is pliable and not edematous. Although mucosa-to-mucosa apposition is best, hand sewing the end of the Roux limb even with the chronically thickened tissue around a fistula usually results in healing. A feeding jejunostomy distal to the enteroenterostomy should always be considered.

Treatment of a duodenal stump fistula is based on the condition of the stump and surrounding tissue and the surgeon's judgment. Options include primary suture closure, mobilization of the stump with resuture or stapling, lateral tube duodenostomy for duodenal decompression, direct tube drainage through the fistula, a serosal patch, or the use of a Roux jejunal limb. Duodenal fistulas that are associated with recurrence of Crohn's disease at an ileocolic anastomosis are managed by resection of the recurrent disease with reanastomosis. The duodenal end of the fistula is débrided and primarily closed, and omentum is interposed to separate it from the new anastomosis. Difficult duodenal closure has been managed by either a jejunal serosal patch or duodenojejunostomy. Primary colonic Crohn's disease with either a gastric or duodenal fistula is similarly treated by resection of the primary source and closure of the fistula, with duodenojejunostomy reserved for large residual defects.

Internal gastrocolic or duodenocolic fistulas from colon carcinoma are generally managed by partial colon resection, as well as resection of the involved stomach or duodenum, along with primary closure. Large duodenal defects require a patch or duodenojejunostomy. A gastrojejunocolic fistula is treated by a partial gastrectomy that includes the anastomosis and by excision of the involved jejunum and colon. Reconstruction may be performed by either reanastomosis of the jejunum with a more distal loop gastrojejunostomy (to include truncal vagotomy if ulcer related) or conversion to a Roux-en-Y gastrojejunostomy. The colon may be anastomosed, or a proximal colostomy may be performed if extensive local inflammation is present.

For repair of both perforations and fistulas, the use of fibrin sealant as an adjunct should be considered. It has been used successfully in the transthoracic repair of esophageal perforations to anchor a pleural flap over the sutured repair. Bardaxoglou et al. also reported successful use of fibrin sealant for esophageal perforations, combined with absorbable mesh.[62] Lau et al. compared sutured repair and fibrin sealant with a gelatin sponge for the treatment of perforated ulcers and also compared laparoscopic and open techniques.[63] They did not find any significant differences between sutured and fibrin sealant repair. These results, combined with successful reports of nonoperative fistula closure with the use of fibrin sealant, suggest a broader role in operative management.

Enterocutaneous Fistulas

Many enterocutaneous fistulas close spontaneously if infection is controlled, nutrition is adequate, and distal obstruction is not present. Definitive operative correction remains the final step in the management of nonhealing small intestinal fistulas. As with the duration of medical management, the surgical procedure needs to be individualized. Direct suture closure of the fistula is associated with a high incidence of breakdown and fistula recurrence.[28] This operation is rarely useful except as a last resort in patients with dense abdominal adhesions from previous surgeries or in medically moribund patients. In most cases, the preferred operation is resection of the involved segment of intestine and primary end-to-end anastomosis. This technique was successful in 57 of 66 patients reported by Reber and colleagues.[28] In the setting of extensive sepsis, primary anastomosis may not be appropriate. In these circumstances, exteriorization of both the proximal and distal ends of the intestine

may be performed. It is critical that the proximal end be constructed as a standard everted Brooke stoma so that a proper appliance can be fitted and the subsequent effluent adequately managed.

If the fistula is not deemed appropriate for resection, such as when it develops as a complication of a deep pelvic procedure, staged approaches involving bypass should be considered. A simple side-to-side anastomosis proximal and distal to the fistula is inadequate, as is unilateral (proximal or distal) exclusion of the involved segment. Bilateral exclusion with isolation of *both* the proximal and distal portions of the involved intestine is necessary for effective defunctionalization of the fistula. In a staged procedure, the fistulous segment is left in situ, or the ends are exteriorized as mucous fistulas; the afferent and efferent bowel loops are anastomosed to restore intestinal continuity. Alternatively, if the efferent loop cannot be mobilized, the intestine proximal to a distal ileal fistula can be divided and anastomosed to the transverse colon. The fistulous segment is again returned to the pelvis or exteriorized as a mucous fistula. This technique is not as satisfactory as complete exclusion but works reasonably well if the ileocecal valve is competent. Optimally, the staged procedure is completed when the fistula segment is removed at a later date, although this is not always possible.

Gastrointestinal fistulas associated with large abdominal defects are not only the most difficult to manage surgically but also the most likely to result in mortality. The wound V.A.C. works well to keep these wounds smaller and easier to manage and frequently closes even large abdominal wall defects. Musculocutaneous flaps and the application of abdominal wall reconstruction techniques involving component separation and prosthetic materials may be required to obtain adequate coverage.

Enteroenteric Fistulas

An internal fistula refers to a communication between the small intestine and some other organ or structure within the peritoneal cavity. An enteroenteric fistula occurs when the small intestine joins with either another segment of small intestine or the colon. Most enteroenteric fistulas are caused by Crohn's disease, although colonic diverticulitis and colon cancer can also be antecedent events. Fistulas develop in direct proportion to the length of the involved intestine. Fistula formation in Crohn's disease begins with serosal cohesion of healthy small or large bowel to the diseased intestinal segment. The process is usually gradual and results in internal perforation and subsequent fistula formation as the ulcer penetrates through the newly formed common wall. Free perforation and generalized peritonitis are unusual. Ileocecal fistulas are most common because of the high percentage of patients with Crohn's disease who have chronic inflammation of the terminal ileum. The jejunum and duodenum are involved less frequently.

Careful evaluation is needed to diagnose an enteroenteric fistula because abnormalities may be subtle, reported as generalized complaints, or even absent. Symptoms such as diarrhea, abdominal pain, weight loss, and fever are not specific and are frequently caused by the underlying disease process, as well as the fistula. Abdominal tenderness or a mass may be noted on physical examination. In some patients there may be evidence of obstruction. Enteroenteric fistulas are often serendipitously diagnosed on a small bowel series or barium enema obtained for evaluating vague abdominal discomfort or dysfunction (Fig. 73–6). Sometimes the fistula is not discovered until laparotomy. In others with Crohn's disease, long-term parenteral nutrition, bowel rest, and the use of pharmacologic therapy that includes 6-mercaptopurine, cyclosporine, or infliximab has been successful in resolving certain types of fistulas.[51-57] This outcome contrasts greatly with the natural history of these fistulas before such pharmacologic innovation. For instance, a 1974 study involving 63 patients with Crohn's disease and enteroenteric fistulas found that 52 ultimately required surgery.[64] However, surgical intervention is still necessary in many patients because of refractory disease or intolerance to medications and their side effects.

Figure 73–6. Small bowel series demonstrating a complex "starburst" enteroenteric fistula.

When surgical intervention is warranted, the operative procedure of choice is en bloc resection of the diseased intestine in continuity with the fistula tract. If inflammation or an abscess is present, primary resection may be unwise. In such a situation, proximal diversion or percutaneous drainage of any associated abscess cavity is prudent. Resection of the diseased intestine and fistula should be delayed for 6 weeks, if possible, to allow the inflammatory process to subside. Nutritional support during this time is essential.

Any resection, whether primary or as part of a staged procedure, should be confined to the involved segment of intestine to conserve overall bowel length. Extensive resection does not appear to protect against further

Figure 73–7. Fistulogram demonstrating an enterovesical fistula in a patient with long-standing ileal Crohn's disease (the *arrow* indicates a fistula tract). (From Tassiopoulos AK, Baum G, Halverson ID: Small bowel fistulas. Surg Clin North Am 76:1175, 1996.)

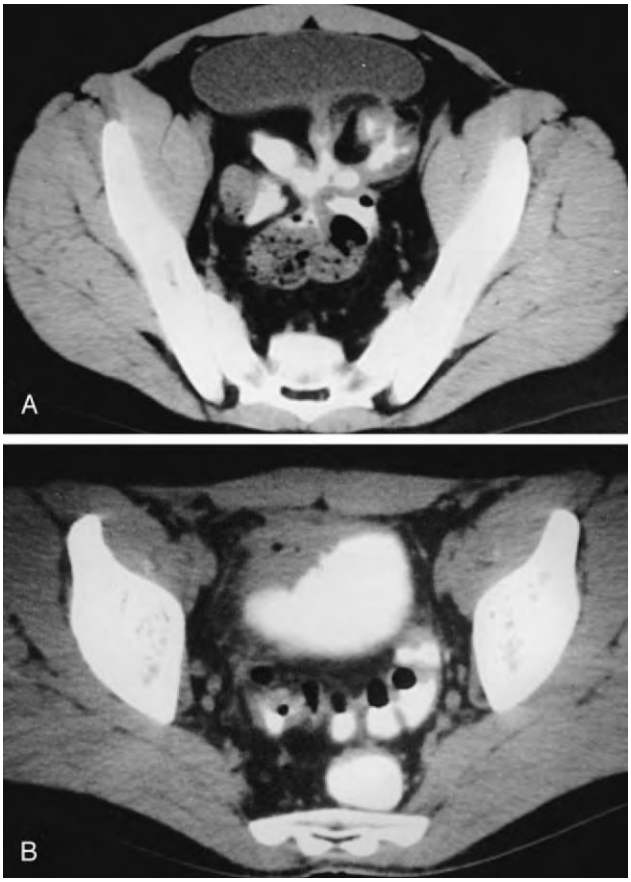

Figure 73–8. Computed tomographic scans in patients with enterovesical fistulas **A,** Complex enteroenteric and enterovesical fistula. **B,** A loop of small intestine is adherent and causing significant inflammation on the wall of the bladder with subsequent fistula formation.

complications and only increases the likelihood of subsequent malabsorption. This is particularly true in Crohn's disease, in which repeat laparotomy, intestinal resection, and subsequent absorptive loss are common and could result in short-gut syndrome.

Enterovesical Fistulas

Although a colonic communication with the urinary bladder caused by diverticulitis or colon cancer is seen with some frequency, fistula formation between the small intestine and the bladder is rare. More than half of all enterovesical fistulas occur as a complication of Crohn's disease; however, radiation injury to the small bowel can also result in their formation. An ileovesical fistula develops in 2% to 4% of patients with regional enteritis, usually as a late manifestation of their disease. Such fistulas tend to be long, narrow, and tortuous (Fig. 73–7). Many seem to maintain patency only intermittently. The fistula frequently tracks downward from the ileum in the right iliac fossa. The uterus does not function as an anatomic barrier to such fistula tracts as it does with the short, localized fistulas resulting from diverticulitis or rectosigmoid cancer. Thus, enterovesical fistulas have an even distribution among the sexes.

More than 80% of patients with enterovesical fistulas have urinary symptoms such as fecaluria or pneumaturia.[65] Evidence of bladder irritability and subsequent dysuria are common. In a few patients fulminant sepsis may develop because of contamination of the urine with intestinal organisms. The presence of an internal fistula involving the urinary tract can be confirmed by the appearance of charcoal or indigo carmine in the urine after administration. Cystoscopy is helpful in establishing or confirming the diagnosis. The most consistent finding is an area of bullous edema, usually on the posterior-lateral wall or the fundus of the bladder. In some patients, the fistula opening can be directly visualized. Biopsy should be performed to evaluate for unusual causal processes such as tuberculosis or cancer.

CT is the most accurate and efficient radiographic means for diagnosing an enterovesical fistula (Fig. 73–8). Barium contrast studies of the gastrointestinal tract often do not demonstrate the fistula but are invaluable in determining the nature of the underlying disease process and assessing its extent. Intravenous pyelography and cystography are rarely useful in evaluation of the fistula itself. They may be important as a means of demonstrat-

ing bilateral renal function and evaluating abnormalities of the upper urinary tract.

In the absence of obstruction, inflammation, or abscess, the preferred treatment of an enterovesical fistula is resection of the diseased intestine and involved portion of the bladder. Removal of the fistula is particularly important to prevent continued contamination of the urinary tract. A primary anastomosis is used to restore intestinal continuity, and the bladder wall is closed. As with other fistulas, if an inflamed intestine or mass makes resection unsafe, transection plus cutaneous diversion of the proximal and distal intestinal segments is recommended.

Nephroenteric Fistulas

Fistulas between the gastrointestinal system and the upper urinary tract are rare. Primary renal disease causes most nephrogenic fistulas. As with bladder fistulas, the colon is more frequently involved than the small intestine. When a small bowel fistula is present, anatomic proximity appears to be the prime determinant of the affected segment of intestine. Therefore, the duodenum is most often involved, whereas nephrojejunal fistulas are rare.

Bissada and associates analyzed a group of 43 patients with nephroenteric fistulas identified over a period of several decades. Before 1945, fulminant infections were responsible for fistula formation in 21 of 26 patients.[66] Renal tuberculosis and bacterial infections were equally responsible, whereas obstructing renal calculous disease was a rare finding. With the advent of effective antimicrobial agents, however, tuberculosis has become a rare cause of fistulization. Bacterial infections are still an important antecedent event but are now almost always associated with secondary staghorn calculi. Since 1945, renal trauma has become the second most common cause of nephroenteric fistulas, and it accounted for 35% of the cases reported in this series. Penetrating, blunt, and iatrogenic types of trauma have all been reported to result in the formation of a fistula. Rarely, fistulas arise spontaneously from the alimentary tract, primarily in association with diverticulitis.

The symptom complex associated with a nephroenteric fistula is determined by the nature of the underlying renal disease, the rapidity with which the fistula forms, and the presence of associated conditions such as diverticulitis or perinephric abscess. Often, development of the fistula is insidious. The patient appears chronically ill and debilitated. There are invariably manifestations of a chronic urinary tract infection with chills and fever, and fulminant sepsis is not uncommon. Flank pain, tenderness to palpation, or a mass may be present. Pneumaturia, fecaluria, nausea and vomiting, and watery purulent diarrhea are frequent symptoms. Dehydration and uremia develop in the more advanced stages of the disease. Hyperchloremic acidosis may occur as urine electrolytes are reabsorbed in the gastrointestinal tract.

As with enterovesical fistulas, oral administration of charcoal or indigo carmine can confirm a suspected fistula between the intestine and the urinary tract. Barium contrast studies are usually ineffective in demonstrating nephroenteric fistulas.[66] An intravenous pyelogram can be helpful, but only if the involved kidney remains functional, which is uncommon. Invasive pyelography, both retrograde and antegrade, is sensitive in diagnosing nephroenteric fistulas, with dye often passing into the intestine, especially if the fistula is large. Retrograde pyelography combined with cinefluorography is most commonly performed. When obstruction precludes a retrograde approach, percutaneous access to the renal pelvis followed by antegrade pyelography is useful. CT remains an important radiographic adjuvant to the evaluation and management of nephrogenic fistulas by diagnosing associated perinephric abscesses and thus should always be performed.

Treatment of a nephrogenic fistula is initiated by correcting fluid and electrolyte imbalances and anemia, along with administering broad-spectrum antibiotics. Nutritional support should begin by the parenteral route to help correct further debilitation. Urinary obstruction, if present, should be relieved either by retrograde placement of a ureteral catheter or by a temporary nephrostomy tube. A perinephric abscess must be drained if present.

Medical management alone rarely results in closure of the fistula. The involved kidney is often dysfunctional or nonfunctional and thus continues to be a nidus for ongoing infection and inflammation. The affected intestine generally has extensive inflammatory changes. In most cases, therefore, nephrectomy with intestinal resection is the procedure of choice. Primary intestinal anastomosis can be carried out, depending on the severity of disease.

Procedures conserving the involved renal parenchyma are reserved for nephrogenic fistulas detected before severe renal functional impairment has occurred. Conservation is more likely to be appropriate for fistulas of traumatic origin. If the contralateral kidney has adequate function, the outcomes associated with surgical intervention are good, with perioperative mortality occurring in less than 10% of patients.

Enterovaginal Fistulas

Fistulas from the small intestine to the vagina are rare. As with colovaginal fistulas, enterovaginal fistulas are more likely to occur in women who have undergone a hysterectomy. Enterovaginal fistulas are usually caused by regional enteritis, radiation enteritis, granulomatous disease, or rarely, malignant tumors.

Most patients have a purulent or feculent vaginal discharge. Gas may also be intermittently expelled from the vagina. Associated intra-abdominal sepsis is common and may cause fever, chills, and abdominal pain. Enterovaginal fistulas can lead to hypovolemia and severe fluid and electrolyte abnormalities, particularly when the drainage is profuse. Speculum examination generally confirms the diagnosis by revealing vaginal erosion and drainage of intestinal contents. CT scanning, as well as contrast studies of the small intestine or vagina, may also be diagnostic. In more subtle cases, a suspected fistula between the intestine and the vagina may be identified by placing

a tampon in the vagina before the oral administration of charcoal or indigo carmine.

Management of an enterovaginal fistula is similar to that for an enterocutaneous fistula. Local drainage through sump drains placed through the vagina may allow adequate control of sepsis and fistula output. If sepsis is eradicated, fistula output is low, and adequate nutrition is provided, an enterovaginal fistula may close without an operation. Spontaneous closure of a fistula associated with Crohn's disease, however, is rare. Resection of a cuff of vaginal tissue along with the fistula and involved intestine is the preferred surgical approach. A primary intestinal anastomosis should be performed if the surrounding inflammation permits. The vaginal defect may be left open to allow external drainage of the pelvis postoperatively.

Enterouterine, Enterocervical, and Enterofallopian Fistulas

On rare occasion, a fistula forms between the intestine and the uterus, cervix, or fallopian tube. Enterouterine fistulas have been reported to occur secondary to various pelvic malignancies or as an unusual sequela to a long-standing ectopic pregnancy. The thick muscular wall of the uterus makes the development of such fistulas unusual. Appropriate treatment of the underlying disease together with a hysterectomy is usually indicated.

Fistulas to the cervix generally develop secondary to radiation therapy to the cervical stump and occur only when a previous supracervical hysterectomy has been performed. Fistulas from the intestine to the fallopian tube can result from endometriosis, tuberculosis, and lymphogranuloma venereum. Rarely, an ectopic pregnancy can rupture into the intestine and cause lower gastrointestinal bleeding.[67]

Aortoenteric Fistulas

The most common fistula between the arterial tree and the small intestine arises from the aorta. Complications of aortic aneurysms and their repair are by far the most frequent cause of this entity, although such fistulas have occurred after other abdominal procedures. Spontaneous or primary aortoenteric fistulas usually occur when the plaque of an atherosclerotic aortic aneurysm ruptures into the intestine. On rare occasion, mycotic, tubercular, or traumatic aneurysms may also rupture into the small bowel. The duodenum is most often involved when a spontaneous fistula develops. Reckless and associates reviewed 131 spontaneous aortoenteric fistulas and found that rupture into the third portion of the duodenum occurred in 57.6% of cases whereas the remainder of the small intestine was involved in only 8%.[68]

Secondary aortoenteric fistulas complicate 2% to 4% of all aortic reconstructions and generally involve aortoiliac or aortofemoral prosthetic grafts. The fistulas usually occur at the level of the proximal aortic anastomosis, and most rupture into the duodenum. If the fistula occurs at the anastomosis between the prosthesis and the iliac arteries, the ileum is the most commonly involved segment of intestine.

Two processes can cause secondary aortoenteric fistulas and result in different clinical manifestations. A direct communication between the intestine and the arterial lumen ultimately leads to massive gastrointestinal hemorrhage. Initially, bleeding is intermittent and is rarely exsanguinating. Such episodic bleeding, known as *herald* or *sentinel* bleeding, is generally painless and may cause chronic anemia. Melena or hematemesis in any patient with an aortic prosthesis should be assumed to be from an aortoenteric fistula until proved otherwise. Several months may elapse between the initial bleeding episode and the inevitable massive hemorrhage. The second form of secondary fistula is known as a *paraprosthetic-enteric* fistula. In this type of aortoenteric fistula, the intestine communicates with a perigraft abscess or aneurysm and not directly with the arterial lumen. Most of these patients have manifestations of sepsis. In a group of 21 patients with such fistulas, O'Mara and Imbembo noted 14 with sepsis, 4 with gastrointestinal hemorrhage, and 3 with abdominal pain.[69] Although a distinct clinical entity, a paraprosthetic fistula ultimately leads to a direct communication with the arterial lumen and subsequent hemorrhage if untreated.

The mechanism by which aortoenteric fistulas develop is controversial. A combination of mechanical and infectious factors probably contributes in most instances. Mechanical injury to the intestine can occur from the trauma of the adjacent arterial pulsation. This is more apt to transpire when the intestine has become fixed to the area of anastomosis, which may be avoided by separating the intestine from the aorta with interposed omentum or surrounding tissues. After the intestine has been sufficiently traumatized, leakage of intestinal contents occurs, with subsequent infection and enzymatic digestion at the suture line. The localized septic process ultimately leads to suture line disruption. Other methods of fistula formation have been hypothesized, including aneurysmal degeneration of the graft with subsequent mechanical erosion into the intestinal wall. Occasionally, a false aneurysm develops at the suture line and ultimately ruptures into the intestine. False aneurysms are usually a consequence of technical errors during the graft anastomosis, but they can also result from infected grafts.

Although the presence of an aortoenteric fistula may be suspected clinically, extensive evaluation and confirmation may not be possible if severe hemorrhage is present. In such instances, immediate laparotomy and proximal control of the aorta are priorities. Fortunately, most aortoenteric fistulas are associated with multiple episodes of limited gastrointestinal bleeding. These patients should be prepared for an urgent operation, but there is generally enough time to perform further diagnostic investigation. Upper gastrointestinal endoscopy should be performed initially to exclude common causes of hemorrhage, such as peptic ulcer disease or esophageal varices. The actual erosion into the intestinal wall can often be seen if the endoscopist is instructed to examine the distal end of the duodenum. Biopsy of such an erosion is absolutely contraindicated. CT is sensitive in evaluating the retroperitoneum for suspected aortoenteric fistulas. CT has the advantages of rapid imaging

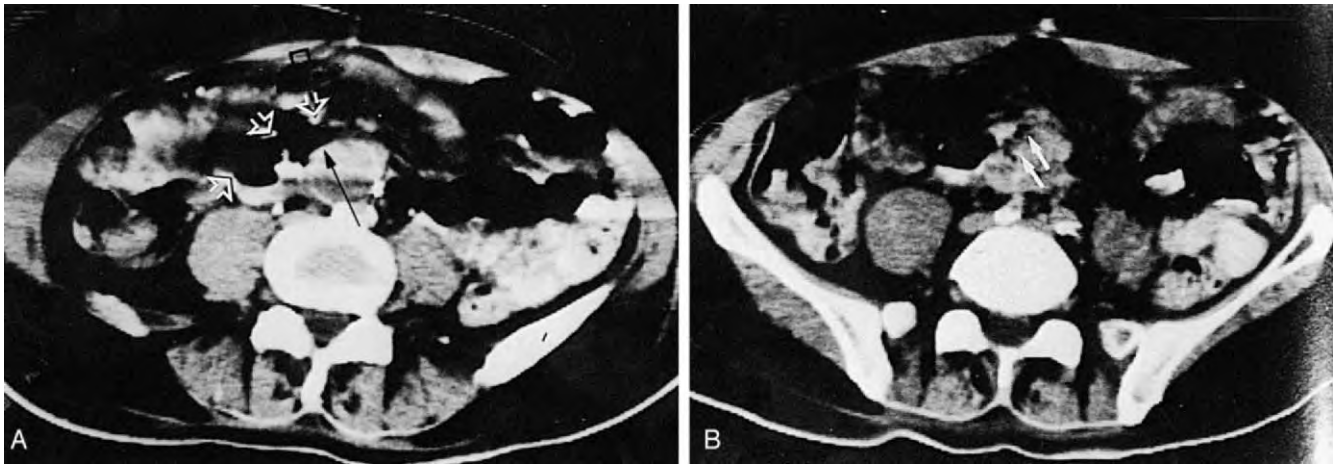

Figure 73–9. Computed tomographic scan of aortoenteric erosion. **A,** Apparent erosion of an aortic graft *(black arrow)* into the overlying duodenum *(open arrows).* **B,** Perigraft air *(arrows).* (From Bernhard VM: Aortoenteric fistulas. In Rutherford RB [ed]: Vascular Surgery. Philadelphia, WB Saunders, 1989, p 530.)

and wide availability (Fig. 73–9). Because it is a noninvasive study, CT does not require technical expertise and does not cause patient discomfort, thereby avoiding the potentially disastrous consequences of raising the patient's blood pressure. CT may demonstrate loss of the normal fatty plane between the aortic graft and the duodenum, a finding indicative of a probable fistula. It may also reveal a false aneurysm at the anastomosis or the presence of a periaortic gas or fluid collection.

When the diagnosis remains elusive, aortography should be performed. Aortography is particularly useful if there is active hemorrhage or if a false aneurysm is suspected. Extravasation of contrast material into the intestine or retroperitoneum confirms the diagnosis. If endoscopy, CT, and aortography fail to find the suspected fistula, upper and lower gastrointestinal barium contrast studies can be performed. Barium evaluation should be postponed until after endoscopy, CT, and aortography, however, because residual barium decreases the sensitivity of these procedures. Barium studies may demonstrate a sinus tract from the intestine. The presence of an intestinal diverticulum or ulcer may result in a false-negative evaluation. If the patient is febrile or a perigraft infection is suspected, blood for culture should be drawn from both upper and lower extremity veins. Positive blood cultures, particularly if limited to the lower extremities, are predictive of a poor clinical outcome.[70]

Management of an aortoenteric fistula, once confirmed, consists of early and aggressive operative intervention. Removal of the prosthesis and extra-anatomic bypass should be coupled with broad-spectrum antibiotics appropriate for the multiple enteric organisms usually present. Conventional wisdom holds that the presence of infection at the prosthetic site precludes less involved procedures such as local closure of the fistula or replacement of the prosthesis. In a series reported by O'Mara and associates, a recurrent aortoenteric fistula developed in all four of the patients treated by initial repair of the fistula, but without extra-anatomic bypass.[71] By contrast, five of the seven patients who had the prosthesis removed, followed by an axillobifemoral bypass, lived and did well. However, there have been successful reports of in situ repair of the aorta with prosthetic grafts or cryopreserved aortic homografts. Walker and colleagues reported excellent overall results with in situ replacement of the abdominal graft and primary closure of the duodenal fistula in 20 patients. Of the 18 survivors, 15 had no further complications.[72] Vogt and associates reported a similar low operative mortality rate and no complications of reinfection when in situ cryopreserved aortic homografts were used to replace the infected aortic prosthesis.[73] The intestinal defect can be débrided and primarily closed in most cases, but bowel resection and end-to-end anastomosis may be necessary or technically easier in some patients.

The survival rate in patients with aortoenteric fistulas is poor, often because of exsanguinating hemorrhage or associated cardiovascular or renal impairment. The mortality rate has been reported to be as high as 50%. A multicenter retrospective study of 98 patients found an improved mortality rate of 24% in patients with aortoenteric fistula or infection treated by axillobifemoral bypass and aortic exclusion. Bypass patency rates at 2 and 5 years were reported to be 82% and 65%, respectively, and limb salvage was achieved in 90% and 82% of patients, respectively, over the same time course.[74]

General Considerations

When planning the operation for fistula patients, the surgeon should allow adequate time for a difficult and prolonged procedure. Depending on the complexity of the abdominal wound, component release and other reconstructive maneuvers may be required to achieve closure of the abdominal wall. It is frequently helpful to enlist the expertise of a plastic surgeon for closure of the abdominal wound (Fig. 73–10A). The component separation release technique is useful for the reconstruction

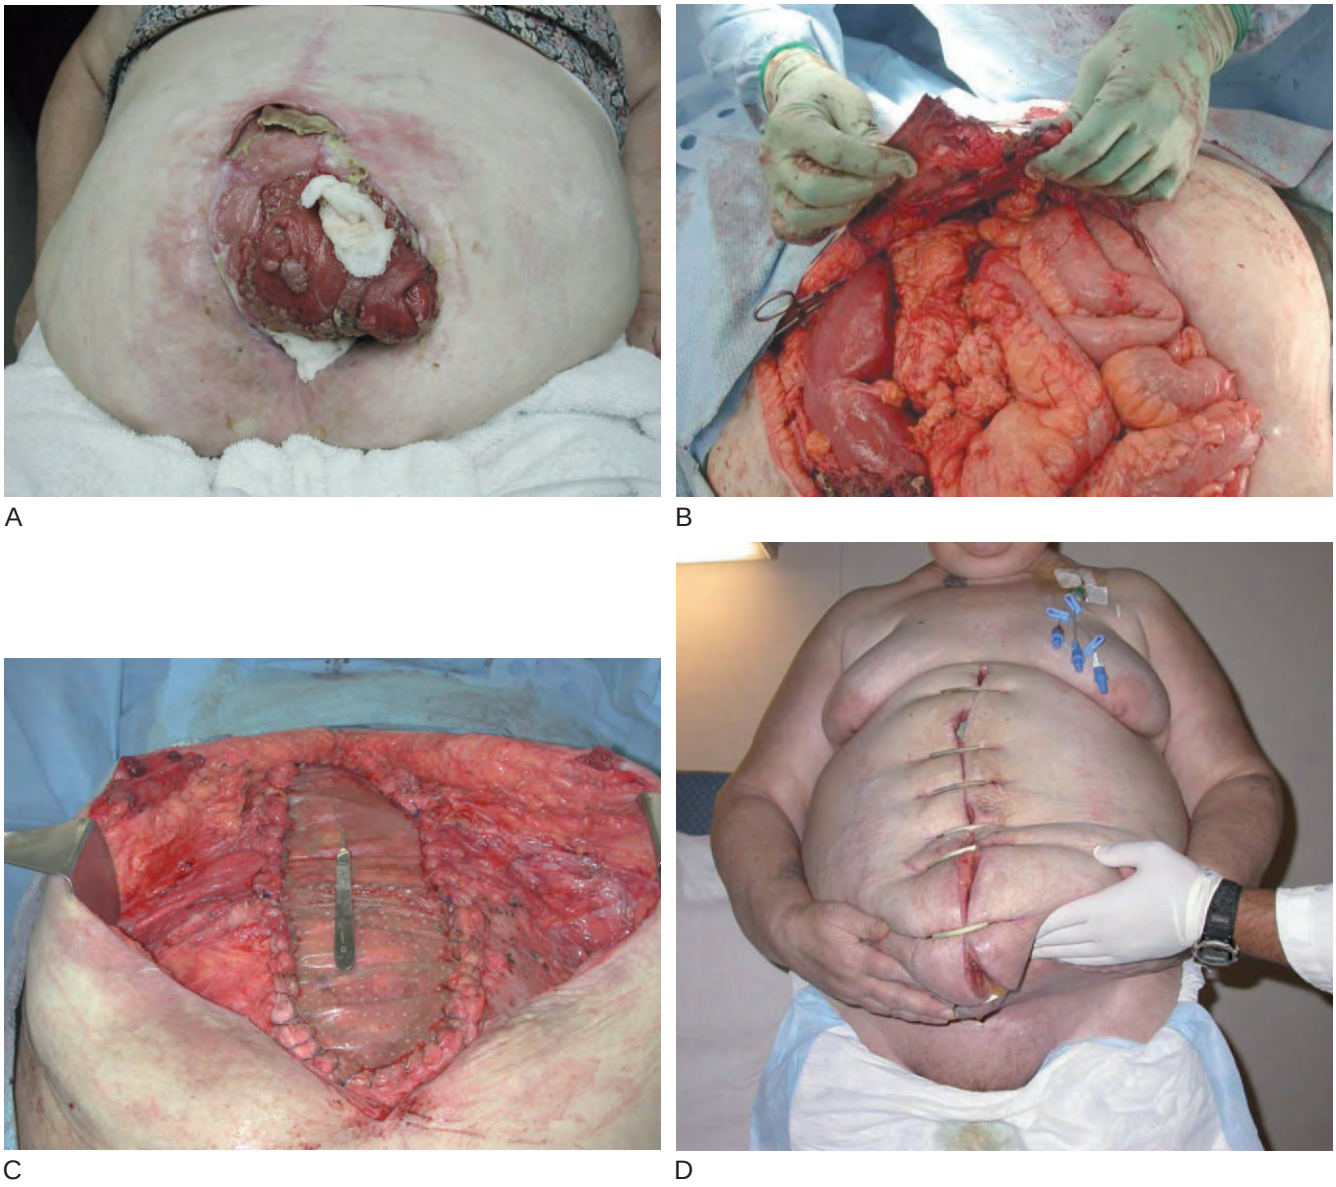

Figure 73–10. **A,** Enterocutaneous fistula with epithelialization of the tract and a large abdominal wall defect. **B,** The entire intestinal tract has been mobilized and complete enterolysis performed. **C,** The large abdominal wall defect is closed with a combination of abdominal wall and small intestinal submucosa (Surgisis Gold). **D,** Completed resection of the fistula and abdominal wall closure with loose closure of the skin and the use of retention sutures.

of large abdominal wall defects, especially when contaminated conditions exist in which the use of prosthetic material may be contraindicated. Thus, preoperative consultation and evaluation by the plastic and reconstructive surgery team should be considered. Preoperative preparation should include a mechanical bowel preparation whenever feasible, preoperative abdominal wall preparation with antiseptic (e.g., chlorhexidine) scrubs beginning at least 24 hours in advance, and perioperative antibiotics directed toward bowel and skin flora, as well as any specific organisms identified by recent culture and sensitivity information.

Whenever possible, a new incision or extension of the previous incision over "virgin" abdominal wall will make reentry into the abdominal cavity easier and safer. Once the peritoneal cavity is entered, the entire intestinal tract should be mobilized, and complete enterolysis should be performed if possible, especially is there is any question of distal obstruction (see Fig. 73–10B). A useful adjunct during this portion of the operation is to use laparotomy pads soaked in saline solution to "rehydrate" the adhesions before attempting adhesiolysis. By using a combination of gentle compression and palpation with one hand and sharp dissection with either scissors or a scalpel in conjunction with the use of copious amounts of saline-soaked sponges, one can usually carry out complete mobilization of the involved intestine. In general, an intestinal fistula cannot be repaired primarily; such repair usually

results in recurrence. Fistulas require complete resection back to healthy tissue with enteroenterostomy. If the anastomosis is performed on healthy bowel, the choice between a stapled or hand-sewn anastomosis does not matter. More importantly, the anastomosis should be under no tension, there must be adequate blood supply, and distal obstruction cannot be present. A feeding jejunostomy or nasoentric tube should be placed. Ongoing nutritional repletion is an extremely important constituent of a successful outcome, and most patients will not be able to take enough calories by mouth during the postoperative recovery period. A gastrostomy tube may also be a useful adjunct in the postoperative period. Depending on the state of the intestinal tract, the extent of enterolysis required, and the underlying process that led to fistula formation, prolonged postoperative ileus will commonly occur, and decompression via a gastrostomy tube, while downstream enteral nutrition is given, may be very beneficial. Because of the usual extensive nature of the dissection during such operations, the formation of intra-abdominal adhesions is likely. Methods for decreasing intra-abdominal adhesions, such as the use of hyaluronic acid–carboxymethylcellulose membrane (Seprafilm), may be beneficial in preventing postoperative complications.[75] Finally, abdominal wall closure is extremely important to allow the best chance for success and to prevent recurrent fistulization. It is essential that the abdominal wall be closed with autologous tissue (using component separation or musculocutaneous flaps) or an absorbable prosthesis consisting of either small intestinal submucosa (Surgisis Gold) (see Fig. 73–10C) or dermis (AlloDerm) or with a permanent prosthesis that is resistant to infection such as titanium mesh (TiMesh). Assistance by surgeons with specific skills in abdominal reconstruction (plastic and reconstructive surgery) is often quite helpful in these situations, and their advice and consultation should be readily sought (see Fig. 73–10D).

Healing

Most postoperative fistula patients are in a profoundly catabolic state in the early postoperative period and are at risk for nutritional complications. Again, optimal nutrition is as important postoperatively as preoperatively. Supplemental nutrition via enteral, parenteral, or a combination is frequently required, and with time, the patient can be transitioned to complete intake by mouth. Even when a patient cannot tolerate full caloric intake via the enteral route, providing a portion of the nutrition enterally remains an important objective. It may be useful to cycle tube feeding at night once the patient is eating in an attempt to stimulate appetite. Meals from home also occasionally help with appetite stimulation. A dietitian consultation can be very helpful as well. A period of home tube feeding or, if necessary, home parenteral nutrition is not unreasonable in these patients because re-establishing normal eating habits may be a long process. The final phase of the treatment of fistulas, then, is healing, and this phase is highly dependent on good nutrition after a well-performed operation. If the patient cannot tolerate at least 1500 kcal/day enterally, parenteral nutrition should be continued until this goal is achieved. Once enteral intake approaches this range, the parenteral nutrition can be weaned.

The overall mortality rate if one includes all fistulas is approximately 20%. Mortality with a postoperative fistula is not as high. Postoperative fistulas are associated with less than 2% mortality and approximately 12% morbidity. Delayed complications may include short-bowel syndrome, depending on the extent of the intestinal resection, previous resections, and the underlying disease state (i.e., Crohn's disease). In patients with a marginal amount of bowel remaining, some intestinal adaptation may occur, and with time, weaning of parenteral nutrition may be possible. As a general guide, approximately 90 cm of small intestine with an intact ileocecal valve may be adequate to prevent short-bowel syndrome, whereas 150 cm may be necessary when the ileocecal valve has been resected. The surgeon must be vigilant for recurrent fistulas postoperatively. These patients are also highly susceptible to adhesive small bowel obstruction. It is generally prudent to manage early postoperative small bowel obstruction in these patients with long-tube decompression and TPN rather than risk further complications with another operation in the early postoperative period.

SUMMARY

Management of intestinal fistulas provides a surgeon with multiple challenges. Careful attention must be paid to the physiologic, metabolic, and immunologic derangements in these patients. An organized and tolerant approach to the stabilization, investigation, planning and implementation of medical and surgical therapy, and healing phase should allow for a successful outcome in the majority of patients.

Internal Hernias—Congenital and Acquired

Mohammad K. Jamal · Eric J. DeMaria

Small bowel obstruction (SBO) is a common surgical emergency that accounts for nearly 20% of acute surgical admissions and often requires definitive operative treatment. The diagnosis of SBO is relatively straightforward in most instances and is based on a history of nausea, vomiting, and abdominal pain. Physical examination in most cases reveals vital signs suggestive of hypovolemia and a distended abdomen with high-pitched bowel sounds. The diagnosis of SBO is confirmed with plain radiographic films and in some instances computed tomography (CT) scans of the abdomen, which typically show air- and fluid-filled distended small bowel loops with or without a transition zone—denoting a complete or partial bowel obstruction.

Initial treatment of SBO involves nasogastric tube decompression, aggressive replacement of fluids, and correction of electrolyte imbalance. Surgical exploration should not be delayed because bowel incarceration or strangulation can occur. Strangulated obstructions are surgical emergencies and, if not diagnosed and properly treated, lead to vascular compromise resulting in bowel ischemia and further morbidity and mortality. Because as many as 40% of patients have strangulated obstructions, differentiating the characteristics and causes of obstruction is critical to proper patient treatment. The leading causes of SBO include adhesive disease (50% to 75%), malignancies (20%), abdominal wall hernias (10%), and inflammatory bowel disease (10%).

Internal hernias, either congenital or acquired, account for a small percentage of SBO cases (0.6% to 5.8%).[1-5] This condition involves herniation of a viscus, usually small bowel, through a normal or abnormal aperture within the peritoneal cavity. This herniation may be intermittent or persistent and may pose a diagnostic challenge given the rare nature of its occurrence. Only rarely is an internal hernia accurately diagnosed preoperatively. Because of the risk for strangulation of the hernia contents, even small internal hernias are dangerous and may be lethal. However, as a result of their rarity, discovery of an internal hernia at laparotomy may be confusing to an unsuspecting surgeon who is not familiar with this abnormality, and thus appropriate management may be compromised.

CONGENITAL INTERNAL HERNIAS

Congenital internal hernias are the result of malformation of the peritoneum and, in some instances, malrotation of the midgut during the embryonic period. A paraduodenal hernia (PDH) is the most common variety of congenital internal hernia, followed by the transmesenteric and transomental varieties. Others, including Foramen of Winslow and paracecal hernias, are extremely rare and are briefly discussed at the end of the section.

Paraduodenal Hernia

Also known as a paramesocolic hernia, PDH accounts for nearly 53% of the 500 published series of all internal hernias and was first described by Neubaur in 1786.[6-10] One hundred years later, Treitz and Waldeyer additionally described *hernia retroperitonealis*—several peritoneal folds and fossae through which small bowel could potentially herniate. The pathogenesis of PDH is controversial, but two theories regarding its origin appear to be most popular.[11] In a report by Moynihan in 1889, it was proposed that paraduodenal fossae were congenital and the hernia was acquired by gradual enlargement of an existing fossa. In 1923, Andrews disputed this theory and proposed that PDH forms as a result of a congenital anomaly in development of the peritoneum that arises during midgut rotation. As a consequence, small bowel becomes invaginated into an avascular, and therefore unsupported, segment of the left mesocolon. The resulting small bowel thus becomes trapped between the posterior abdominal wall, with the mesocolon and inferior

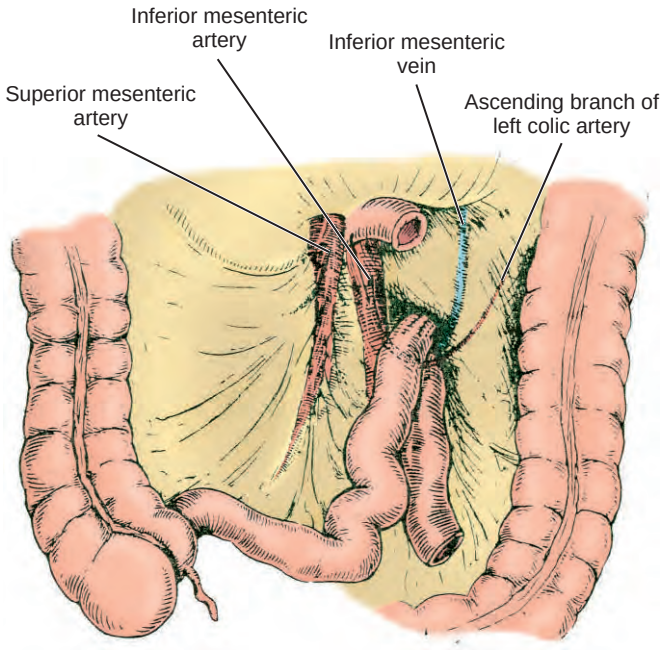

Figure 74–1. Left paraduodenal hernia. The opening of the hernia sac lies above the ascending branch of the left colic artery and the inferior mesenteric vein. The sac lies behind the left mesocolon. (From Newsom BD, Kukora JS: Congenital and acquired internal hernias: Unusual causes of small bowel obstruction. Am J Surg 152:279-285, 1986.)

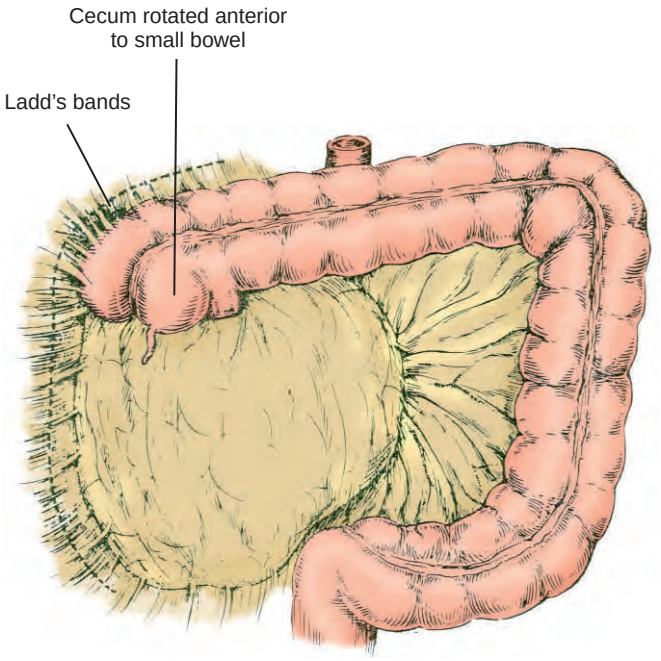

Figure 74–2. Right paraduodenal hernia. This hernia is caused by failure of the small bowel to rotate to the left with the right colon continuing to rotate anterior to it. This results in trapping of the small bowel behind the right mesocolon when fusion with the retroperitoneum occurs. The *dotted line* represents the plane opened to mobilize the right colon and reduce the hernia. (From Newsom BD, Kukora JS: Congenital and acquired internal hernias: Unusual causes of small bowel obstruction. Am J Surg 152:279-285, 1986.)

mesenteric vein (IMV) forming the anterior wall of the hernia sac.

Of the published cases of PDH, nearly 75% were left sided with a male-to-female ratio of 3:1.[11] The average age at diagnosis is reported to be between the third and fourth decades of life. A left PDH contains most of the small bowel, with the afferent limb being the fourth part of the duodenum and the efferent limb being the terminal ileum (Fig. 74–1). The small bowel invaginates into the fossa of Landzert, which lies to the left of the fourth portion of the duodenum. After formation of the hernia, the colon usually retains its normal position. Several other possibilities exist—the colon can undergo malrotation, the left colon can lie on the right side of the hernia, or if it is on a long mesentery, there is the potential for colonic volvulus.[12-14]

A right PDH similarly originates from abnormalities arising during the second phase of embryonic intestinal rotation; it results in arrest of further rotation of the pre-arterial segment of the gut in the right side of the abdomen (Fig. 74–2). Continued rotation of the postarterial segment leads to entrapment of small bowel behind the right colonic mesentery, with the superior mesenteric artery forming the anterior edge of the hernia sac.[15]

Clinical Findings

PDH may be asymptomatic and be discovered incidentally at laparotomy, at autopsy, or during radiologic studies for other unrelated causes.[11,16,17] More commonly, PDH is manifested as acute SBO on a background of recurrent chronic, vague abdominal pain. The abdominal pain associated with a left PDH is typically left sided but can be variable in location and sometimes even right sided.[18] The pain is often exacerbated by eating and postural changes and relieved by lying supine. It is postulated that the pain arises from recurrent incarceration of the hernia contents and is relieved by spontaneous reduction of the hernia.[5] Weight loss is variable and may be severe if symptoms are present for a long time. In its most malignant form, PDH may be associated with bowel strangulation with a resultant increase in death. On occasion, a tender left-sided abdominal mass may be palpable during an acute episode.

Diagnosis

The diagnosis of PDH generally requires a high index of suspicion and is usually made by upper gastrointestinal barium contrast study. The small bowel is found clustered to the left of the midline with a well-circumscribed edge that corresponds to the hernia sac.[5,11,19-21] Passage of contrast may be delayed with a change in position of the patient. There is usually a mass effect causing

displacement of the posterior wall of the stomach, duodenojejunal flexure, and transverse colon. In some instances, a CT scan may detect a PDH by showing a similar clustering of small bowel loops in the retroperitoneum.[8,22] Upward displacement of the IMV by the hernia contents may also be noted on intravenously enhanced CT scans or arteriography.[5,22] A barium enema may be performed in stable patients to rule out colonic malrotation.

However, all radiologic studies may be normal, especially in chronic intermittent cases because the hernia may reduce spontaneously. These investigations are most often diagnostic during an acute episode. In a literature review of nearly 32 cases reported by Tong and colleagues,[22] a preoperative diagnosis through either small bowel follow-through or CT scan was made in 23 (72%) of the 32 patients, but 14 (61%) had an acute manifestation. Given the rarity of symptoms, an incidental diagnosis of PDH is relatively infrequent and usually made at the time of abdominal exploration.

Treatment

The lifetime risk for bowel incarceration associated with PDH is around 50%. Incarceration can result in increased morbidity and mortality, and therefore these hernias should be treated if found incidentally.[11,15,20,23] Treatment of PDH follows the basic principles of hernia surgery—reduction of the contents, resection of the hernia sac, restoration of normal bowel anatomy, and repair of the hernia defect. Initial exploration of the abdomen will often reveal the classic empty abdomen sign, with only a segment of the ileum present in the abdominal cavity and the remainder encased in the hernia sac to the left of the midline. The small bowel may be manually reduced if the hernia orifice is large enough and the defect can be closed with nonabsorbable suture.[11,23] If the small bowel is edematous, the hernia orifice is tight, or adhesions within the sac prevent manual reduction of the contents, the hernia orifice can be widened by excising the avascular plane to the right of the IMV. Care should be taken to avoid damage to this structure and the left colic artery, both of which lie in close proximity to the anterior edge of the orifice.[24]

If the hernia orifice cannot be widened, the sac should be opened along the anterior wall and the contents reduced. A decompressive enterotomy is sometimes beneficial to evacuate the contents of the incarcerated bowel, thus allowing easy reduction. The sac should then be excised from the left of the IMV toward the left colon while taking care to preserve the marginal artery of Drummond. In cases of obvious bowel strangulation, the appropriate length of small bowel should be resected and a decision made regarding reanastomosis or creation of an end ostomy, depending on the hemodynamic stability of the patient and the overall condition of the involved bowel segments.

More recently, several authors have reported laparoscopic repair of both right and left PDH.[19,25,26] However, the role of laparoscopy in the diagnosis and treatment of PDH is relatively recent, and to date, experience with this modality is limited.

Transmesenteric Hernia

A transmesenteric hernia (TMH) is an intraperitoneal hernia that may be either congenital or acquired. As the name suggests, TMH consists of protrusion of a loop of bowel through an aperture in the mesentery (Fig. 74–3). It accounts for nearly 5% to 10% of all cases of congenital internal hernia and occurs more commonly in the pediatric age group. When found in children, TMH is often associated with intestinal atresia or mesenteric ischemia and occurs near the ligament of Treitz or the ileocecal valve.[15,27] In contrast, most TMHs in adults are related to predisposing factors, including previous surgery, abdominal trauma, and peritonitis. A common type of TMH occurs after an iatrogenically created mesenteric defect, such as after gastrectomy or Roux-en-Y gastric bypass (RYGBP). These hernias are discussed in more detail in the section on acquired internal hernias.

TMH was first reported by Rokitansky in 1836 as an autopsy finding in which the cecum alone herniated through a hole near the ileocolic angle. Several others, including Loebl in 1844 and then Turel in 1932, described variations of TMH through the transverse mesocolon and sigmoid colon, respectively.[28] Several etiologic hypotheses for the occurrence of idiopathic mesenteric defects causing TMH have been proposed in the surgical literature, three of which have gained relative acceptance. Federschmidt in 1920 stated that these defects represented partial regression of the dorsal mesentery in humans. Menegaux, on the other hand, postulated the presence of fenestrations during developmental enlargement of an inadequately vascularized

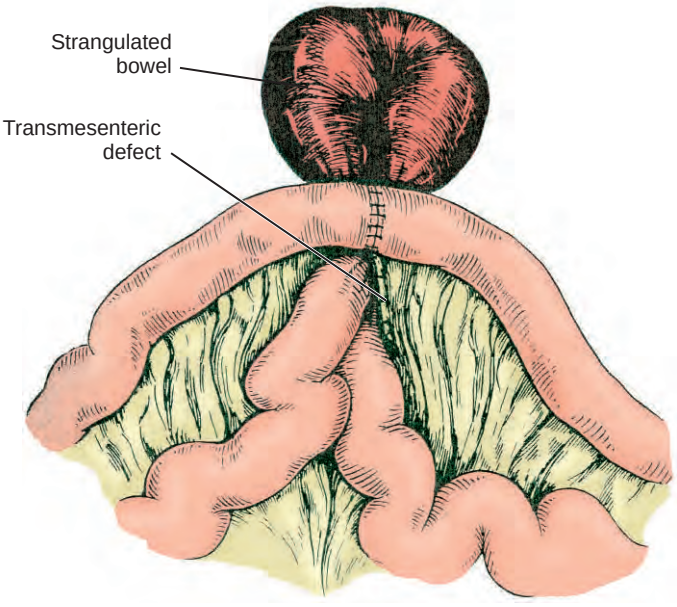

Figure 74–3. Transmesenteric hernia caused by herniation of a loop of small bowel through an unclosed mesenteric defect after small bowel resection. (From Newsom BD, Kukora JS: Congenital and acquired internal hernias: Unusual causes of small bowel obstruction. Am J Surg 152:279-285, 1986.)

area as a cause of TMH. Judd, Kiebel, and Mall believed that because the greater part of the gut is displaced from the abdominal cavity into the umbilical cord in fetal life, considerable pressure might displace the colon along the path of least resistance and gradually force it through the delicate mesentery. Another theory by Macklin assumes that when two epithelial layers are apposed with a deficient intervening supportive stroma of connective tissue, coalescence inevitably takes place, with development of a space or defect.

There is no sex and age predominance in the occurrence of TMH. In a collective review by Janin et al., nearly 70% of reported TMHs occurred through defects in the small bowel mesentery.[28] Ileocecal defects accounted for 53% of these and 37% of the entire group of TMHs. These ileocolic defects are typically circular or oval, lie in the area of the mesentery between the ileocolic artery and the last ileal branch of the superior mesenteric artery, and range in size from 2 to 3 cm. Transverse mesocolic defects, on the other hand, are bound by the vascular arch formed by the middle and left colic arteries, whereas defects of the sigmoid mesocolon are usually circular and lie immediately above the superior rectal vessels.

Clinical Findings

The clinical manifestations of TMH are similar to those of any other case of SBO—crampy abdominal pain, nausea, vomiting, and abdominal distention. These patients most frequently have right-sided abdominal tenderness but, occasionally, diffuse pain accompanied by various degrees of abdominal distention is noted. Patients typically appear to be severely ill and may rapidly progress to a shock-like state concurrent with mesenteric ischemia and bowel necrosis. A palpable abdominal mass is sometimes present, usually sausage shaped and tympanitic, and a localized succession splash may be elicited over it.

Because most mesenteric defects are small and there is no limiting hernia sac, a large portion of the small bowel can herniate through a tight opening. The resulting pressure of the herniated bowel and its thickened mesentery compresses the vessels in the free margins of the mesenteric defect and results in early incarceration and strangulation of the loop forming the margin of the defect. This may explain why the latter may be found to be gangrenous whereas the herniated bowel may not even be strangulated. Furthermore, the herniated segment of bowel or a redundant sigmoid can freely undergo volvulus, a condition more commonly seen in TMH than in other types of internal hernias.

Diagnosis

TMHs are more difficult to diagnose than other internal hernias. Based on a history of bowel obstruction, a CT scan may show a cluster of small bowel loops, SBO, and central or posterior displacement of the colon. Mesenteric vessels may be stretched, crowded, and engorged and have a *whorl sign*. Furthermore, the major mesenteric trunk may be displaced by herniated small bowel loops. Signs of volvulus or mesenteric ischemia, including bowel wall thickening, twisting of the mesenteric vessels (the whorl sign), engorged blood vessels, and mesenteric ascites, may be the predominant CT findings and denote a delayed diagnosis.[29,30] In patients with acquired TMH after gastrectomy or RYGBP, a retro-anastomotic TMH can be detected on CT scan as an abnormal position of an efferent loop of the gastrojejunostomy, an obstructed afferent or efferent loop (or both), or clumped and fixed jejunal loops in the left upper portion of the abdomen. Rarely, small bowel herniation occurs through a peritoneal defect in the pouch of Douglas as a result of previous hysterectomy.[29]

Treatment

Nasogastric decompression, aggressive preoperative fluid replacement, and correction of electrolyte disturbances are essential before surgical exploration. Laparotomy is mandated in all cases of TMH given the high incidence of incarceration and strangulation. Treatment is dependent on viability of the bowel—if the herniated loops are gangrenous, resection is mandatory, with or without primary anastomosis. If the bowel is viable, reduction of the incarcerated loops plus repair of the defect with interrupted nonabsorbable suture is recommended. Furthermore, if a mesenteric defect is discovered during laparotomy for an unrelated cause, it is imperative that it be closed with a similar technique.

Transomental Hernia

Transomental hernias typically represent less than 5% of all internal hernias. Only a handful of cases have been reported in the surgical literature.[15] As the name suggests, internal herniation of a viscus, typically small bowel, occurs through an opening in the gastrocolic omentum (Fig. 74–4). The actual cause of the omental rent is unknown, but inflammatory, traumatic, circulatory, and congenital mechanisms have all been implicated. A variant of this hernia, the *internal double omental hernia,* has been reported by some authors and denotes herniation of the small bowel through an opening in the gastrocolic omentum and exit through the gastrohepatic omentum.[31,32]

Management consists of simply releasing the constricting ring of omentum, which typically tends to be stiff and fibrous, and resecting or reducing the bowel, depending on its viability.[33,34]

Miscellaneous Congenital Internal Hernias

Foramen of Winslow hernias are rarely encountered. Only 117 cases have been reported in the world literature through 1977[35] (Fig. 74–5). In cases reported since 1966, the cecum was the most commonly herniated viscus, followed by the small bowel.[36] Preoperative diagnosis of a Foramen of Winslow hernia is generally established in less than 10% of cases. In some instances, an epigastric mass and radiographic evidence of a retrogastric mass containing air are suggestive of this entity.[9] Management involves manual reduction of the hernia

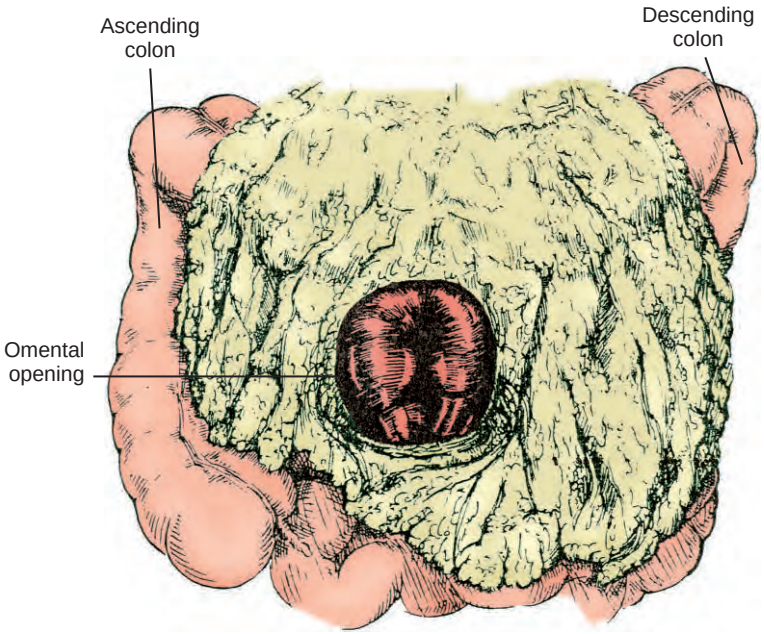

Figure 74–4. Transomental hernia with strangulation of a loop of bowel through the transomental hernia defect. Management consists of simply cutting the constricting ring around the bowel and resection of involved bowel. (From Newsom BD, Kukora JS: Congenital and acquired internal hernias: Unusual causes of small bowel obstruction. Am J Surg 152:279-285, 1986.)

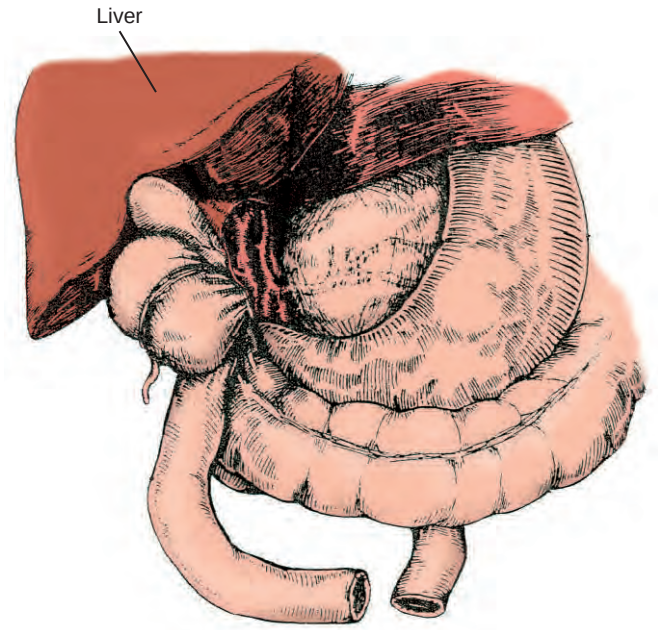

Figure 74–5. Foramen of Winslow hernia. The mobile right colon has been shown to be incarcerated through the opening into the lesser sac. The neck of the sac contains vital structures that must be preserved when repairing these hernias. (From Newsom BD, Kukora JS: Congenital and acquired internal hernias: Unusual causes of small bowel obstruction. Am J Surg 152:279-285, 1986.)

contents, which sometimes requires opening of the lesser sac for counterpressure or decompressive enterotomy. A wide Kocher maneuver may at times be necessary to enlarge the hernia opening. Attempts at closure of the opening are not generally recommended, although fixation of a mobile cecum is advised.[35,37-39]

Paracecal hernias, as well as herniation into fossae of the sigmoid mesentery, account for a small percentage of internal hernias. Others, including herniation through fossae or defects in the broad ligament and foramina in the falciform ligament, are extremely rare varieties of internal hernia.[40-43]

ACQUIRED INTERNAL HERNIAS

Acquired internal hernia (AIH) refers to herniation of a viscus, most commonly small intestine, through iatrogenically created defects in the peritoneum after major abdominal surgery, including Roux-en-Y reconstructions after gastrectomy, gastric bypass, esophageal replacement, and pancreatic and hepatobiliary surgery. With the recent increase in the number of certain bariatric surgical procedures performed in the United States, especially RYGBP, the incidence of AIH has risen in recent years. Therefore, herniation after gastric bypass will be discussed in this section as a representative AIH.

Nearly 150,000 bariatric surgical procedures are performed in the United States each year, the majority of which involve RYGBP. With the advent of minimally invasive techniques, the associated morbidity with this relatively high-risk procedure has decreased somewhat. When compared with the open procedure, there has been a reduction in incision-related complications such as wound infections and incisional hernias after laparoscopic gastric bypass; other complications, including the risk for anastomotic leak and SBO, have remained essentially unchanged or have increased in certain series. SBO is a known complication of gastric bypass surgery, with an incidence varying anywhere from 1.3% to 5% in several series of experienced bariatric surgeons using the open technique.[44-48] The incidence of bowel obstruction

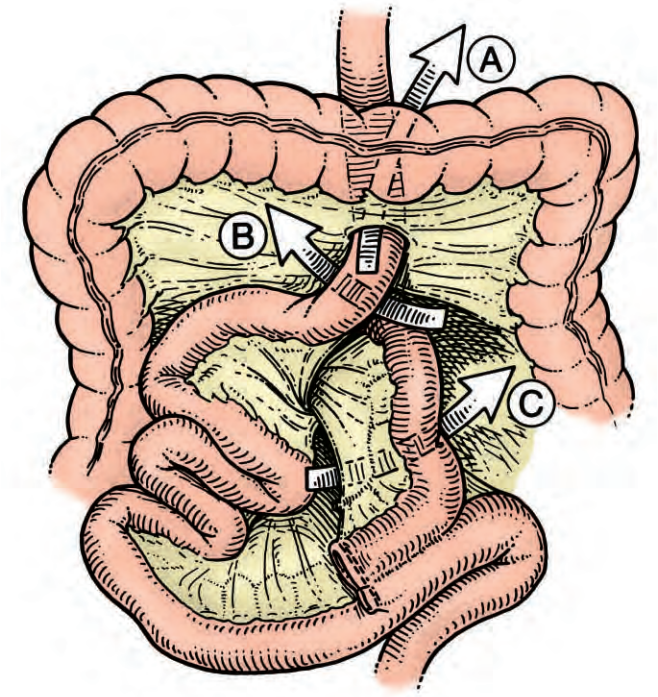

Figure 74–6. Internal hernia after a retrocolic Roux-en-Y gastric bypass. Potential sites of internal herniation of small bowel include the mesocolic mesenteric defect (A), the Petersen defect (B), and the jejunojejunostomy mesenteric defect (C). (From Schweitzer MA, DeMaria EJ, Broderick TH, Sugerman HJ: Laparoscopic closure of mesenteric defects after Roux-en-Y gastric bypass. J Laparoendosc Adv Surg Tech A 10:173-175, 2000.)

appears to be similar in earlier series of laparoscopic gastric bypass—anywhere from 1.5% to 3.5%, with most obstructions caused by internal hernias.[49,50] Other unrelated causes of SBO in gastric bypass patients include adhesions, incarcerated ventral hernias, and rarely, intussusception of the jejunojejunostomy.

The technique of laparoscopic gastric bypass has not been standardized, and there are several variations in the technique. The laparoscopic approach may involve the use of a circular stapler, linear stapler, or a hand-sewn technique for the two anastomoses; the Roux limb may be placed in antecolic or retrocolic fashion, with or without closure of the mesenteric defect; the enterotomies may be closed by suture or staples; and finally, the trocar sites may or may not be closed. It is closure of the several different mesenteric defects that may prevent internal herniation of small bowel in these patients. Internal herniation in gastric bypass patients can occur through any of the two mesenteric defects when an antecolic approach is used and through any of the three defects when a retrocolic approach is used. These potential hernia defects occur at the jejunojejunostomy, the mesocolic window, and Petersen's space (Fig. 74–6).

An enteroenterostomy mesenteric defect is created as a standard step in essentially all variations of gastric bypass, and in our practice, it is closed with a running absorbable suture. If an antecolic approach is used, an opening is created in the gastrocolic omentum, and the Roux limb is brought over in an antecolic and antegastric fashion. If the greater omentum is especially thin, the Roux limb can be passed anterior to it without a window. In the retrocolic approach, a window is created in the transverse mesocolon, and the Roux limb is brought through the lesser sac in retrogastric fashion to the transected pouch. Mesenteric defects are again routinely closed in our practice with running absorbable suture, beginning at the medial edge of the mesocolic window and running superiorly over the Roux limb, with incorporation of the bowel serosa and closure of the base of the Petersen defect.

The debate between proponents of antecolic and retrocolic gastric bypass continues among bariatric surgeons. Several authors have reported a higher incidence of internal hernia after laparoscopic RYGBP—this difference is probably explained by the absence of adhesion formation after a minimally invasive approach.[51-53] In the series reported by Champion and Williams, the incidence of SBO from all causes was 4.5% in the retrocolic group and 0.43% in the antecolic group.[51] Seventy-one percent of the obstructions in this group of 711 patients were caused by internal hernias. Furthermore, the incidence of bowel obstruction in the group with sutured mesenteric defects was slightly lower (4.1%) than in those with an unsutured mesenteric defect (4.5%). In another report by Higa et al., the incidence of SBO from an internal hernia was 3.1% in a group of 63 patients undergoing retrocolic RYGBP.[52] The site of internal hernias varied—they occurred at the mesocolon (70%), jejunal mesentery (22%), and Petersen's space (8%) in that order. Although most patients were symptomatic, 5% of internal hernias were incidental findings at the time of another surgical procedure.

Clinical Findings

The diagnosis of AIH is difficult, and radiologic evaluation is often nondiagnostic. The presence of colicky, postprandial left upper quadrant abdominal pain after gastric bypass should raise suspicion of an obstruction. The location of the abdominal pain generally correlates with the side of internal herniation, with left upper quadrant pain occurring when the small bowel herniates through the defect to the patient's left side and right upper quadrant pain typically being seen when the small bowel herniates to the right side of the defect. Other symptoms may include nausea, emesis, and abdominal distention. Although similar symptoms may be seen in other pathologic conditions, including a marginal ulcer or SBO from other causes, persistence of such symptoms, even in the absence of radiologic findings, generally mandates exploration.

Diagnosis

Patients with acute intermittent abdominal pain should be evaluated initially with plain films. An obstructed bowel gas pattern with air-fluid levels is sometimes

enough evidence of an internal hernia that urgent exploration is required. Others with vague abdominal pain can be investigated with contrast-enhanced upper gastrointestinal series with small bowel follow-through or CT, or with both. A high index of suspicion is required for proper diagnosis and management of these patients. In a series reported by Blachar et al., 463 patients were investigated for complications after RYGBP.[54] The incidence of internal hernia after gastric bypass was 3%, whereas SBO from other causes developed in nine patients.

Several important features diagnostic of internal hernia that are found on upper gastrointestinal series include a cluster of small bowel loops seen in the mid or left upper portion of the abdomen.[54] This cluster is relatively fixed and remains high on erect radiographs, which reveal stasis and delay in passage of contrast material. The CT appearance of internal hernias often depends on their location, although clustering of dilated small bowel loops with crowding and congestion of the mesenteric vessels is seen in all instances. In cases of herniation through the transverse mesocolon, the herniated cluster of bowel is located posterior relative to the stomach and may exert a mass effect on its posterior wall. Furthermore, herniations through the small bowel mesentery cause the clustered bowel to press against the abdominal wall with no overlying omental fat and thereby result in central displacement of the colon. A Peterson-type hernia is difficult to diagnose because it has neither a confining sac nor a characteristic location, and the only clues to its presence may be engorgement and crowding of the mesenteric vessels and evidence of SBO.

Treatment

On diagnosis of AIH, exploration is mandatory and can be performed laparoscopically by experienced surgeons with minimal morbidity and complications.[51,52,55,56] The biliopancreatic limb and the common channel should be run from the ligament of Treitz to the ileocecal valve. The Roux limb should be identified and the entire length run from the gastrojejunostomy to the enteric anastomosis. Any herniated segment of small bowel should be reduced, and any mesocolic and jejunojejunostomy mesenteric defects should be closed with nonabsorbable running suture. Controversy exists regarding closure of Petersen's defect, with some authors recommending interrupted closure of this mesenteric defect to prevent internal herniation postoperatively.

Mesenteric Arterial Trauma

Rao R. Ivatury

EPIDEMIOLOGY

Injuries to the mesenteric arteries are rare and occur in less than 1% of all trauma admissions. No mesenteric arterial injuries were found in a collective review of 3705 arterial injuries from World War II, the Korean War, and the Vietnam War, as reported by DeBakey and Simeone, Hughes, and Rich and associates.[1-3] This rarity is also substantiated by civilian series reported by several authors.[4-16] In a recent multi-institutional study, Asensio and colleagues[16] could collect only 250 patients with these injuries over a period of 10 years from 34 participating trauma centers. It is evident that even an established trauma surgeon may not have a large experience dealing with these difficult lesions.

SURGICAL ANATOMY

The superior mesenteric artery (SMA) originates about 1.5 cm below the celiac axis and is the second branch of the abdominal aorta; it is located at approximately the level of L1. Surrounded by the portal vein, pancreas, and duodenum, the SMA soon disappears under the neck of the pancreas. The zones of the artery as described by Fullen and associates[7] in 1972 were based on the collateral circulation and the extent of ischemia resulting from injury or ligation of the different portions of the artery (Fig. 75–1). Zone I extends from the origin of the artery at the aorta to the first major branch (inferior pancreaticoduodenal artery). Loss of this portion of the artery leads to maximal ischemia. Zone II extends from the inferior pancreaticoduodenal artery to the origin of the middle colic artery. Injuries in this area lead to severe ischemia. Zone III extends distal to the origin of the middle colic artery to the origin of the segmental branches. Zone IV is the region of the artery termed by segmental names: ileocolic, right colic, and so forth. The collateral circulation of the SMA is not as well developed as that of the celiac axis and the inferior mesenteric artery (IMA). Superior and inferior pancreaticoduodenal branches of the celiac axis and the SMA and the marginal artery of Drummond between the SMA and IMA are the usual collateral channels. These vessels, however, are inconstant and variable, thus making the SMA essentially an end artery.

OPERATIVE EXPOSURE AND MANAGEMENT DECISIONS

Operative exposure of the SMA is very difficult because of its high location and a dense celiac plexus and lymphatics around the origin of the artery. Active bleeding from the region behind the pancreas may be an indication of SMA injury in zone I. This zone is best approached by dividing the pancreas at its neck anterior to the mesenteric vessels. Further exposure is facilitated by medial visceral rotation (Figs. 75–2 and 75–3). Rotation is commenced by incising the avascular line of Toldt on the left colon, dividing the lienosplenic ligament, and rotating the left colon, spleen, tail and body of the pancreas, and stomach toward the midline. The left kidney may also be mobilized and reflected medially (Mattox maneuver) to gain access to the proximal infradiaphragmatic aorta and its first two branches (the celiac axis and SMA). Transection of the dense celiac and peripancreatic venous plexus is also required. This medial visceral rotation, especially when the left kidney is included, does take time and experience to perform. Potential pitfalls are damage to the spleen, kidney, and renal pedicle during the maneuver. In addition, the resulting altered anatomy may prove confusing to an inexperienced operator.

Injuries with hematoma below the transverse mesocolon can be approached by several methods. Dividing the mesocolon and performing an extended Kocher maneuver with extension along the third portion of the duodenum allow one to palpate the SMA. The Cattell-Braasch maneuver, in which the root of the small bowel mesentery is dissected in a diagonal line to the junction of the third and fourth portions of the duodenum and reflected cephalad, also exposes the SMA pulsations for dissection and isolation. Injuries to the distal zones of the

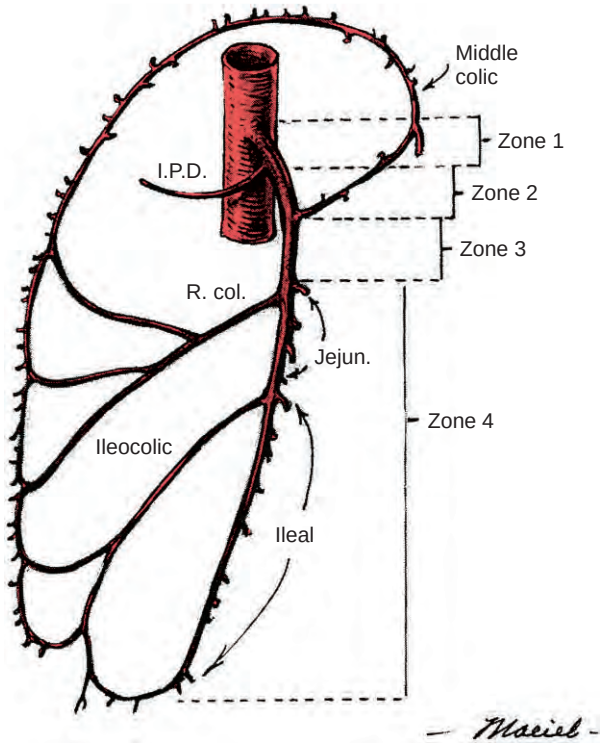

Figure 75–1. Fullen's anatomic classification of injuries to the superior mesenteric artery based on the location of the injury in relation to the main arterial branches. I.P.D., inferior pancreaticoduodenal artery; R. col., right colic artery. (From Fullen WD, Hunt J, Altemeier WA: The clinical spectrum of penetrating injury to the superior mesenteric arterial circulation. J Trauma 12:656-663, 1972.)

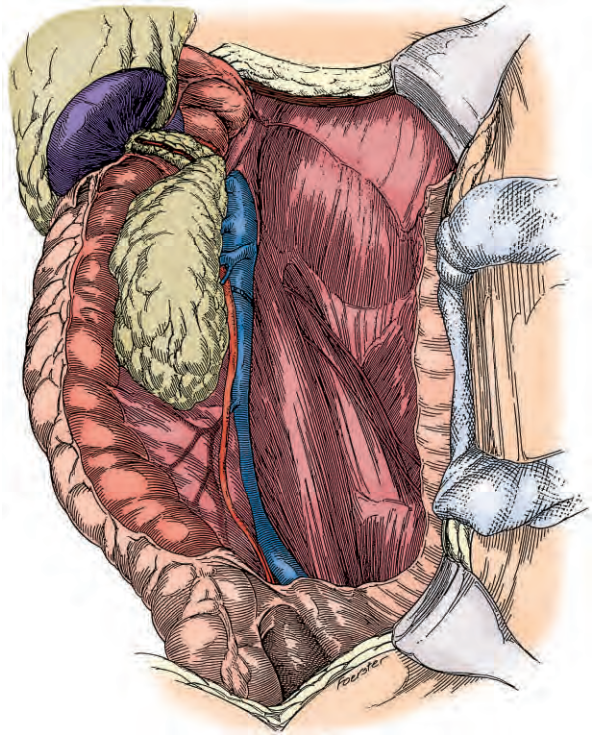

Figure 75–2. Left medial visceral rotation. The descending colon, left kidney, spleen, and distal pancreas are mobilized en bloc to expose the suprarenal aorta in the retroperitoneum. (From Rutherford RB: Atlas of Vascular Surgery—Basic Techniques and Exposures. Philadelphia, WB Saunders, 1993.)

SMA can be approached directly. The frequent presence of associated injuries to other abdominal vessels and intra-abdominal organs and the severe associated hypotension may make it necessary to compress the aorta under the diaphragm while the patient is resuscitated with transfusions. Aortic compression can be performed initially with a sponge stick or the assistant's fingers. Longer periods of compression may necessitate enlargement of the aortic isthmus in the diaphragm, mobilization of the aorta, and the application of a Satinsky clamp (Fig. 75–4). The dense celiac plexus of nerves and lymphatics and the long hiatal fibers of the diaphragm make the dissection difficult and time-consuming. One useful technique is to divide the left crus of the diaphragm at the 2-o'clock position, widen the aortic isthmus, bluntly dissect the distal portion of the thoracic aorta, and then apply a clamp on the suprarenal aorta.[5] A left anterolateral thoracotomy and occlusion of the descending aorta may be faster and easier.

Frequently, these patients will have major associated injuries causing extensive blood loss and hemodynamic instability. Onset of the critical "triad of death," namely, hypothermia, acidosis, and coagulopathy, is often the rule rather than the exception and is precipitated by associated abdominal injuries, multiple transfusions, the need for aortic compression, and dilutional coagulopathy. In these circumstances, it is prudent to institute "damage control" principles.[17] Rapid termination of the laparotomy is the goal. Ligation of the SMA is usually reserved as a means to control life-threatening hemorrhage or exsanguination in these circumstances. The morbidity associated with SMA ligation is high, but because the patient may not tolerate a prolonged vascular replacement at this time of physiologic exhaustion, placement of a temporary arterial shunt between the ends of the divided SMA is the preferred approach.[18] Javed shunts or any vascular shunt available in the operating room will serve the purpose. If none is immediately available, intravenous infusion tubing will be a good substitute. This will maintain SMA flow distally and avoid mesenteric ischemia. These shunts are well tolerated for at least 24 hours. A heparin-bonded shunt, if available, is another option. Control of contamination is achieved by rapid closure of bowel perforations. In these patients the abdomen is usually left "open" by the placement of a "Vac-Pac" dressing. The patient is transferred to the intensive care unit (ICU) for resuscitation. This ICU phase of "damage control" will focus on correction of the hypothermia, acidosis, and coagulopathy. Acidosis is reversed by aggressive blood and fluid resuscitation. It must be remembered that ligation of the SMA and superior mesenteric vein (SMV) may cause profound bowel

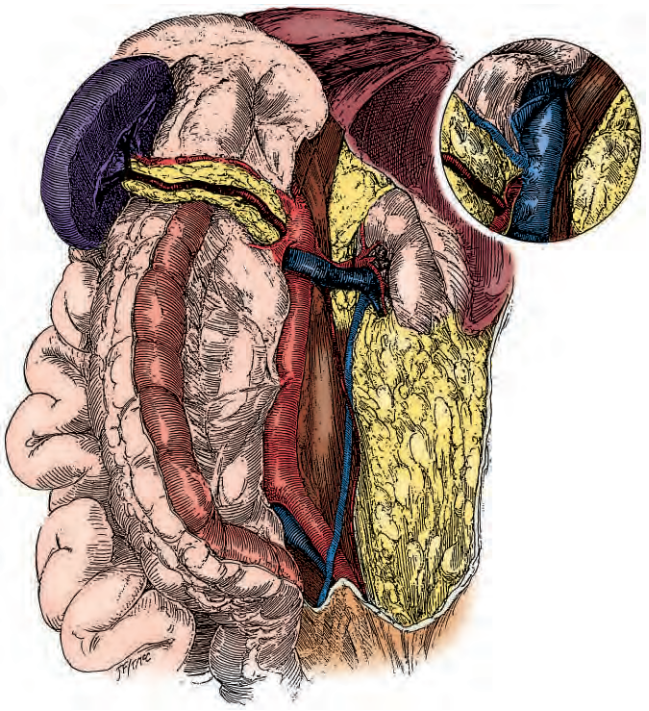

Figure 75–3. Modified left medial visceral rotation. The left kidney is left in situ in the retroperitoneum while the rest of the viscera are mobilized. With division of the left crus of the diaphragm *(inset),* this maneuver gives better exposure of the proximal celiac axis and superior mesenteric artery. (From Rutherford RB: Atlas of Vascular Surgery—Basic Techniques and Exposures. Philadelphia, WB Saunders, 1993.)

Table 75–1 Survival After Superior Mesenteric Artery Injury

Author	No. of Patients	No. of Survivors (%)
Fullen, 1972	8	5 (62.5%)
Graham, 1978	45	27 (60.6%)
Lucas, 1981	15	10 (66.7%)
Kashuk, 1982	6	4 (66.7%)
Sirinek, 1983	20	14 (70%)
Accola, 1986	22	7 (31.8%)

edema and increase the need for massive volume replenishment. Intra-abdominal hypertension and abdominal compartment syndrome are common complications in these circumstances and must be carefully watched for by frequent measurement of bladder pressure as a surrogate for intra-abdominal pressure.[19] It is our practice to perform decompressive laparotomy if bladder pressure is greater than 20 mm Hg with organ dysfunction.

More definitive SMA repair is usually undertaken at the second laparotomy, when the patient is in a better physiologic state. Injuries to zone III and beyond the middle colic branch and those at the origin of zone IV before the origin of the enteric branches should be repaired primarily. Distal zone IV injuries involving segmental branches to the small and large bowel may be ligated. Only occasionally it is possible to perform lateral arteriorrhaphy of the SMA. Bypass grafting to the proximal SMA is ideally performed as a short graft taken directly off the infrarenal aorta. SMA bypass may be performed safely with a synthetic graft, even in the face of a contaminated field,[5] unless the injury involves a high-velocity missile. This graft is routed through the root of the mesentery of the small bowel to anastomose with the mid or distal part of the SMA.[5] It is imperative that the aortic suture line be protected from adjacent bowel by omentum or a retroperitoneal flap to prevent an aortoenteric fistula in the future.[5] After successful mesenteric revascularization, bowel viability must be critically assessed. There is no single good test to determine bowel viability after revascularization. Ballard and associates[20] found that in patients who were revascularized for acute mesenteric ischemia, the overall accuracy of clinical judgment, intravenous fluorescein, and intraoperative Doppler was 50%, 56%, and 0%, respectively. Bulkley and colleagues[21] also found fluorescein to be the best tool to assess viability. A recent study reported that clinical judgment alone had an overall accuracy of 87% and a predictive value of only 69% versus 100% overall accuracy, sensitivity, and predictive value for laser Doppler flow measurements of the bowel mucosa.[22] There should be a low threshold for second-look or third-look laparotomy, especially if the patient fails to improve in the early postoperative period.

RESULTS

As indicated earlier, SMA injury is rare and the majority of series in the literature included less than 25 patients per report (Table 75–1). A recent study of these injuries, conducted under the auspices of the multi-institutional trials committee of the American Association for the Surgery of Trauma, was published by Asensio and coauthors. This is the largest series yet reported, and 250 patients were analyzed during a 10-year period from 34 participating centers. The majority of SMA injuries occurred as a result of penetrating trauma (52%) and were predominantly in Fullen zone IV (112). Zone I, II, and III injuries totaled 51, 35, and 42, respectively. Twenty-two percent of patients underwent primary repair, and 16 (7%) underwent interposition grafts consisting of 10 (4%) autogenous reverse saphenous vein grafts and 6 (2%) polytetrafluroethylene grafts. Forty-four of 206 patients (21%) underwent planned second-look procedures, and 9 died during their hospitalization.

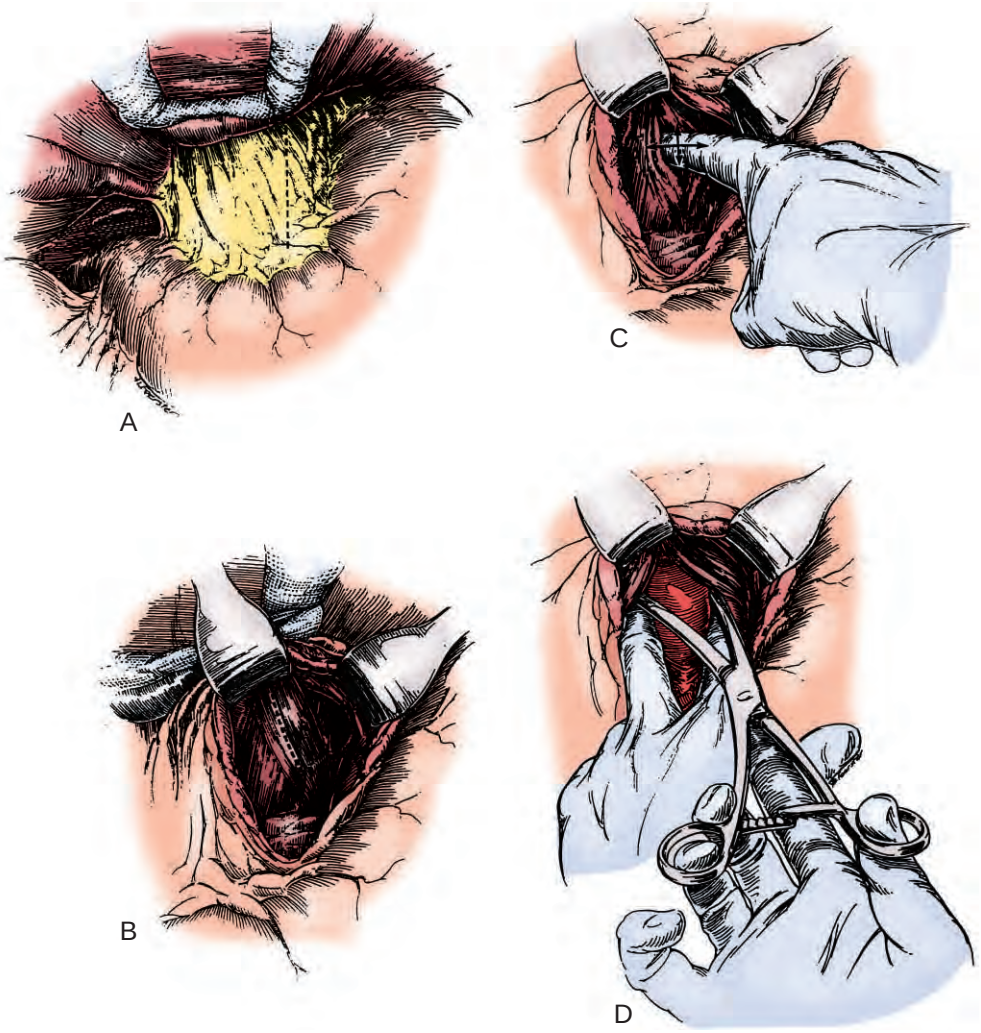

Figure 75–4. Sequential maneuvers for rapid exposure of the supraceliac aorta. **A,** Longitudinal opening in the lesser omentum. **B,** Blunt dissection of the left crural fibers. **C,** Freeing of the aorta from the surrounding loose areolar tissue with a finger. **D,** Guiding the occluding vascular clamp in over two fingers until its tips "touch bottom" on the vertebral body behind the aorta. (From Rutherford RB: Atlas of Vascular Surgery—Basic Techniques and Exposures. Philadelphia, WB Saunders, 1993.)

Overall mortality was 39% (97 of 250); of these patients, 69 (71%) died in the operating room or within the first 24 hours of admission, either from exsanguination or injury-related causes; the other 28 patients (29%) succumbed as a result of complications in the postoperative period. As might be expected, Fullen zone I injuries had the highest mortality (76.5%). This report should be carefully studied for its detailed account of the outcome after these injuries.

Interesting case reports describe some sequelae from injury to the superior mesenteric vessels.[23-28] Radonic et al.[23] described two cases of SMA-SMV fistula from penetrating trauma that were diagnosed by angiography and treated operatively. Deitrick et al.[26] reported a proximal SMA–portal vein fistula that was embolized by angiographic methods. Miglietta et al.[27] presented a case of traumatic SMA–duodenal fistula from a gunshot wound of the abdomen. At the initial laparotomy a hematoma around the SMA was not explored. One month later the patient experienced massive upper gastrointestinal hemorrhage. Immediate exploratory laparotomy revealed a large fistula between the SMA and the duodenum, but the patient could not be resuscitated after an intraoperative cardiac arrest. These cases illustrate the importance of careful exploration of the SMA and its surrounding hematoma at the initial laparotomy.

In summary, injuries to the mesenteric arteries are associated with high mortality. Most result from penetrating trauma, but blunt injury, usually to the SMA, does occur. Proximal injuries to the celiac artery or SMA are manifested as intraperitoneal bleeding or a central retroperitoneal hematoma. All central retroperitoneal hematomas should be explored so that major vascular injuries are not missed. In cases of extreme blood loss with accompanying coagulopathy, acidosis, and hypothermia, damage control principles yield the best results, with temporary intravascular shunting of the SMA being the preferred approach. Planned second- and

third-look laparotomy is crucial for early detection of bowel nonviability. Interventional techniques, combined with improved abdominal imaging, can also be effective in avoiding laparotomy entirely and dealing with delayed complications such as arteriovenous fistulas and pseudoaneurysms.

Reoperative Surgery of the Stomach and Duodenum

Bruce Schirmer ▪ C. Joe Northup

Reoperative surgery of any type is always more difficult than operating on virgin tissue. Scarring from previous surgery means, at best, additional time and dissection to establish appropriate tissue planes to perform the operation. At worst, it predisposes the patient to more serious consequences, including significant intraoperative bleeding, leading to transfusion and increasing the risk of postoperative infection. Damage to organs in the dissection process through such scar tissue may leave the patient with unrecognized perforations or organ injury that may result in disastrous postoperative complications, such as leak, abscess, fistulas, sepsis, and death.

Although clinical circumstances may force the performance of a reoperation on an emergent or urgent basis, when reoperative surgery is elective, the surgeon must take into consideration the need to avoid severe intraoperative scarring as much as possible. The most important rule to follow to minimize the consequences of scarring from previous surgery is *waiting an adequate period of time* since the last laparotomy to perform further abdominal surgery.

This chapter examines the aspects of reoperative surgery of the stomach and duodenum that the authors believe are particularly important for optimizing the outcomes of such procedures. In some situations, the procedures are performed only as a last resort when medical therapy has failed. In other situations, reoperative surgery has a stronger and more effective track record for success. This chapter focuses on elective reoperative surgery or surgery for longer term complications or failures of previous upper digestive system operations. Emergent reoperation of the stomach and duodenum may be required for immediate complications of recently performed surgery. These types of operations are not dealt with for the most part in this chapter because they essentially constitute immediate complications and treatment of complications of the initial operation. These complications are discussed in most circumstances in the various chapters covering the index operation. The focus in the present chapter is on reoperations that are done at a later date after the original operation. For the most part, these are elective procedures, but semiurgent ones for commonly occurring late problems of previous gastroduodenal surgery also are discussed as appropriate.

The types of reoperations are grouped according to the disease type for which they are being performed. These categories include peptic disease, gastroparesis and motility disorders, gastroesophageal reflux disease, bile reflux gastritis, cancer, bariatric surgery, and obstructive processes of the distal duodenum or segments of intestine draining a gastrojejunostomy.

GENERAL PRINCIPLES OF REOPERATIVE SURGERY

Although the individual operation planned as a reoperative procedure has varying degrees of success, and indications are based on previous outcomes data, the success of most reoperative operations depends on adhering to certain basic principles (Box 76–1). Most reoperative procedures are performed based on background knowledge of the likelihood of success of a repeat operative procedure achieving the intended goal. As with any operative procedure, reoperations have a higher degree of success the more severe the symptoms and the more likely the cause of the symptoms can be correlated with a clearly definable anatomic abnormality or pathology. Procedures that have variable success, particularly when the goal is eradication of nonspecific symptoms, should be avoided or performed only when a good benefit-to-risk ratio can be established.

Information Acquisition and Preparation

Preparation for reoperative surgery should always include obtaining as complete as possible records from

Box 76–1 Basic Principles of Reoperative Surgery

- Potential benefits must outweigh risks or likely outcome without intervention.
- Confirm that there is an anatomic and not a functional problem.
- Obtain all possible information regarding previous operations.
- Define the anatomy by radiographic, functional, and endoscopic studies as indicated.
- Allow an adequate amount of time to pass to minimize previous operative scarring, which can prevent ease of operation and increase complications.
- Be certain of blood supply to remaining tissues, especially anastomoses.
- Do not leave sections of the upper gastrointestinal tract without adequate drainage of luminal contents.
- Provide for a fail-safe mechanism of nutrition should postoperative complications occur.
- Assess the success of a reoperative procedure constantly as it is in progress. Do not hesitate to stop if more harm than good is being done. Do not leave the patient worse off than before.
- Anticipate that complications, such as leaks, may occur, and prepare for their possibility intraoperatively.

earlier operative procedures. Recent complete nonsurgical medical records also must be obtained. Attention to the details of which, if any, major blood vessels were divided during previous surgery may prove helpful in planning the appropriate reoperative approach. Knowledge of the relative location of Roux limbs and afferent and efferent intestinal limbs relative to other abdominal organs enables the initial dissection process to proceed with confidence based on such information.

Preoperative assessment of the current gastroduodenal anatomy is essential before embarking on any reoperative procedure of the upper gastrointestinal system. Such assessment often requires radiographic studies, endoscopy, or both. The surgeon should be certain he or she has a firm grasp on the existing anatomy of the stomach and duodenum, to as great an extent as possible, before embarking on an elective reoperation.

Assessment and Counseling

The patient and his or her current condition must be assessed carefully by a thorough history, physical examination, and review of the records and imaging studies. It is important for the surgeon to make a recommendation for reoperative surgery when there is a clear anatomic indication for the operation. In several areas of reoperative upper digestive surgery, such as bariatric surgery and antireflux surgery (see later), relying solely on symptoms or a patient's desire for further improvement of their symptoms as a basis for performing reoperative surgery may lead to a poor ultimate outcome from the reoperation. If a previously well-constructed operation remains intact, there is little reason to think that revising it would likely improve the situation.

After a thorough review of all pertinent information, the surgeon must make an assessment and recommendation as to whether reoperation is indicated. A thorough counseling session by the surgeon with the patient is necessary to discuss the relative merits or lack of merits of reoperative surgery. Such counseling sessions can be multiple if the initial encounter occurs at a time when appropriate and needed imaging studies or other laboratory evaluations are still pending.

Because reoperative surgery carries increased risks for complications, it must be entered into with significant planning and with careful contemplation on the part of the surgeon as to the risks and potential benefits of the procedure. The potential benefits are often less likely to be as good as the original procedure, if a revision is planned. Similarly, the risks are almost always increased. This combination puts the burden of proof on the surgeon to counsel the patient appropriately as to these parameters and to advise reoperation only when the likelihood of success is clear, and the danger of life-threatening complications is mitigated as much as possible.

Technical Aspects of Performing Reoperative Surgery

Open Surgery

The multiply-operated abdomen presents a challenge for all surgeons. Adhesion formation and subsequent obstruction is a frequent indication for surgical intervention. A careful approach must be undertaken to enter a previously operated abdomen. The typical approach is first to identify an area that would tend to have fewer adhesions or an unoperated area. Typically, the most superior aspect of the midline adhesion is often the best place to approach the adhesions associated with a previous scar. Inadvertent injury to the liver is generally less of a problem than injury to a piece of small intestine or colon. We advocate the use of sharply entering the abdomen to avoid any risk of thermal injury from cautery. When the fascia has been identified, Kocher clamps can be placed on the fascia with gentle traction by an assistant. The surgeon should apply gentle countertraction on the bowel and sharply take down adhesions from the abdominal wall. Adhesiolysis should be completed to the point where the operative goals can be accomplished. There is no benefit in taking down unnecessary adhesions.

Historically, attempts have been made to reduce the development of obstruction from intraoperative adhesions, including bowel plication and long intestinal tubes. Careful surgical technique remains the most effective method of adhesion prevention. Removal of foreign material, careful handling of tissues, adequate hemostasis, and avoidance of unnecessary dissection are the most efficient methods to prevent adhesions.[1,2]

Newer, bioresorbable materials have been shown to provide some benefit in reducing the severity or formation of adhesions. Cohen et al.[3] prospectively showed a reduction in adhesion formation and a decrease in severity using a hyaluronate-based barrier. In another prospective trial, Becker et al.[4] also showed a significant decrease in incidence, extent, and severity of postoperative adhesions with a similar product. Pharmacologic agents, such as anticoagulants and anti-inflammatory agents, have not reliably decreased adhesion formation.

When a surgeon performs an operation in which there is a high likelihood of returning, consideration must be given to adhesion prevention. Surgeons may want to consider using a hyaluronate-based barrier in these situations. Future advances in bioresorbable materials may improve their benefit in adhesion prevention further and possibly result in a decrease in the risk of postoperative bowel obstruction.

Laparoscopic Surgery

Since the advent of the laparoscopic era of performing general surgery operations, there is no question that a laparoscopic approach results in considerably less intra-abdominal adhesions than a celiotomy. Laparoscopy is currently the best approach a gastrointestinal surgeon can use to prevent significant and difficult postoperative adhesion formation. Not all operations described in this chapter are amenable to a laparoscopic approach, however, unless the surgeon has considerable expertise in laparoscopic surgery. Each individual operation must be assessed for the potential to apply a laparoscopic technique if possible, and such a decision must be based on the patient's previous operations, reports of the intra-abdominal condition at the time of those procedures, and the skill of the surgeon in performing laparoscopic surgery. Although most primary upper gastrointestinal operations are routinely performed laparoscopically by skilled laparoscopic gastrointestinal surgeons, reoperative surgery is approached more often using a celiotomy because of the time element and extreme technical difficulty encountered in using laparoscopy for revisional surgery of the foregut. Nevertheless, for bariatric and antireflux operations, there is a considerable body of published experience with successful use of a laparoscopic approach for revisional operations.

Laparoscopic Technique With the increasing use of laparoscopy, one of the most challenging barriers remains the previously operated abdomen. The initial difficulty is the approach to obtaining intra-abdominal access. The surgeon may choose a closed (Veress needle) or open (Hasson trocar) approach. An open versus closed approach has not shown any significant differences in the ease of use or the complication rate when entering the abdomen.[5,6] The open approach to laparoscopy is often thought to be safer with better visualization of the tissues. The open approach tends to be more complicated, however, when a trocar is inserted away from the midline. Also, in an overweight or morbidly obese patient, the open approach results in several technical problems, including the fact that the incision needs to be larger to allow for safe entry into the peritoneal cavity. The larger incision is subsequently more prone to leak gas from the pneumoperitoneum.

Our approach of choice is to use the Veress needle in an unoperated field or area of the abdomen. Optimal areas for safe entry to the reoperated abdomen are the right or left upper quadrants, 1 to 2 cm below the costal margin. Through a small incision, a tracheotomy hook is used to elevate the fascia, and the Veress needle is inserted. Initial aspiration should be performed to evaluate for any potential organ violation. Aspiration of gross blood or enteric contents should prompt a change in entry location or a conversion to an open procedure, and the damaged organ should be repaired. Structures underlying any site of attempted peritoneal access always must be given special attention on reentering the abdomen.

When adequate pneumoperitoneum has been achieved, a bladeless trocar is inserted. After the initial trocar is placed, a telescope is inserted to confirm intra-abdominal placement. The bowel should be carefully inspected directly below and surrounding the initial entry site to identify any possible injury.

After entry, the extent of adhesion formation must be assessed. The first priority is the placement of an additional operating port. An area of the anterior abdominal wall must be identified that is free of adhesions and safe for placement of an operating trocar. If no space is readily apparent, consideration must be given to converting to an open procedure. After a second operating port is placed, a careful adhesiolysis is begun. We prefer first to free enough space to be able to place a third trochar an adequate distance from the first operating port, preferably on the opposite side of the abdomen. This allows for a grasper to apply gentle, downward traction, while bluntly and sharply dividing adhesions to the anterior abdominal wall.

We use 5-mm ports and a 5-mm 30- to 45-degree angled laparoscope. An angled scope allows for visualization of the adhesions at different perspectives and decreases the chance of injury to adherent intestine. Additionally, using a 5-mm telescope allows for movement of the camera from port to port to inspect adhesions and organs from a different viewpoint.

Adhesiolysis should be continued until the surgical objective can be accomplished. Excessive adhesiolysis places the patient at greater risk for a bowel injury. Little benefit is gained by doing a total abdominal adhesiolysis, and this only lengthens the procedure time. Omental adhesions to the anterior abdominal wall are common-

place in the previously operated abdomen and relatively easy to divide. Bowel adhesions may be more difficult, and care should be taken to avoid an enterotomy at all costs because recognition of enterotomy with a laparoscopic approach may be more difficult than with open surgery. We sometimes divide the peritoneum to dissect the bowel down off the abdominal wall still densely adherent to the peritoneum if this would prevent injury. Small bowel interloop adhesions also are a technical challenge and must be divided carefully. Probably the most difficult situation technically in reoperative laparoscopic enterolysis involves an area of the abdominal wall where previously placed mesh exists that was used to repair an incisional or ventral hernia. In such situations, bowel can be so tightly stuck to the mesh as to preclude its safe enterolysis using a laparoscopic approach, and conversion to an open approach is necessary.

Bowel Injury During Laparoscopic Enterolysis Management of a bowel injury during laparoscopy varies depending on the procedure being performed. Any enterotomy that occurs can be repaired with primary repair with interrupted sutures. Any large tear in the intestine must be evaluated carefully for resection. Typically, an enterotomy of greater than or equal to 50% of the lumen should be resected. A colon injury also can be managed with primary closure with laparoscopy.

In patients undergoing laparoscopy with multiple previous operations, we require patients to have a bowel preparation before surgery. Bowel preparation allows for decreased contamination if an injury occurs and decreases bowel "bulk" to allow for increased intraoperative space.

A missed bowel or gastric injury during laparoscopic enterolysis is a major complication that usually results in significant morbidity for the patient. The patient often presents with severe abdominal pain and peritonitis. Sepsis also may be a complicating accompanying problem. The patient should be re-explored immediately and undergo resection or primary repair of the injury, placement of drains if indicated by tissue quality, and diversion of the gastrointestinal stream if needed for severe injuries.

Nutritional Issues and Access

A final note is needed for reoperative surgery of the upper gastrointestinal system. Because nutritional intake is based on food or nutrients passing through these organs if an oral route of postoperative nutrition is expected (as it usually is), the operation must be highly likely to guarantee that eventuality in the relatively immediate postoperative period. If there is a significant likelihood that oral feeding may be precluded by a typical and common postoperative complication resulting from the reoperation, the burden is also on the surgeon to make provisions for a reliable enteral feeding access to be placed at the time of the operation for postoperative use. This access is usually an operatively placed gastrostomy or jejunostomy tube, depending on the operation performed.

PEPTIC DISEASE

Gastric Outlet Obstruction After Pyloric or Duodenal Ulcer Surgery

Gastric outlet obstruction after a previous operation for obstructing peptic ulcer may occur as a result of technical problems with the anastomosis, postoperative scarring, recurrence of the peptic disease with ulceration resulting in anastomotic scarring, or functional disorders of gastric emptying, the most common of which is postvagotomy syndrome with poor gastric emptying. Patients typically present with nausea, vomiting, early satiety, and postprandial pain. Patients can be extremely miserable if the nausea and vomiting are severe. Secondary dehydration and abnormalities in electrolytes, such as hypokalemia, also may develop. Malnutrition may be present. Gastric outlet obstruction at the level of the anastomosis may present as vomiting of clear gastric juice with undigested food contents. Obstruction at a level beyond the anastomosis, or of the efferent limb of a gastrojejunostomy, manifests more typically as bilious vomiting.

The diagnosis is strongly suggested by the clinical picture and secondarily reinforced by plain radiographs showing a distended gastric remnant. Definitive diagnosis is confirmed by contrast upper gastrointestinal series. Unless perforation is suspected, barium is the oral contrast medium of choice for improved visualization in perhaps a large reservoir of gastric secretions and as a less dangerous material if any aspiration of vomitus were to occur. Upper endoscopy may be helpful in determining the degree and level of obstruction of an anastomosis, although it often can be inaccurate in determining emptying ability of the anastomosis.

For more chronic situations, in which poor gastric emptying is intermittent and of varying severity, solid and liquid radionuclide gastric emptying studies should be performed to assess the emptying capacity of the stomach. Patients who present with delayed gastric emptying by radionuclide studies, but who have a patent anastomosis confirmed by upper gastrointestinal series, must be presumed to have primarily a functional gastric emptying disorder rather than an anatomic outlet obstruction. These patients should be managed medically whenever possible, with prokinetic agents being the mainstay of therapy. The reader is directed to the subsequent section on gastroparesis for further details.

In a situation in which a pyloroplasty or Billroth I procedure has been performed, and in which the pyloric channel has become re-obstructed, conservative measures of eliminating any potential causes of recurrent ulcer, such as smoking, nonsteroidal anti-inflammatory drugs, and steroids, and treatment for existing *Helicobacter pylori* in the stomach, must precede reoperation and be given an adequate trial to determine if they alone may provide adequate relief of the obstructive process. Balloon dilation of a scarred pylorus may provide satisfactory relief in some situations, particularly when the recurrent ulcer disease or cause has been eliminated or successfully treated. Balloon dilation may be done endoscopically or fluoroscopically.

When conservative measures at reopening the pyloric region have failed, the operative procedure of choice for relieving this obstruction is a gastrojejunostomy. *Trying to resect the stenotic and scarred pylorus is difficult, dangerous, and contraindicated for benign disease.* Adding a vagotomy is indicated only if recurrent peptic ulceration has occurred at the pyloric channel area, contributing to the re-stenosis. Often, adding a vagotomy is detrimental to the overall result of the operation because it greatly inhibits gastric emptying through the newly created gastrojejunostomy. Patients should be tested and treated for the presence of *H. pylori* before undergoing reoperation, even if other causes for the recurrent ulcer exist. Eradication of the bacteria must be confirmed by hydrogen breath testing.

Operative Technique

Gastrojejunostomy for an obstructed pyloric outflow must emphasize several principles:

1. The anastomosis must be adequately large. We prefer to use a 60-cm length linear stapler to perform the anastomosis or duplicate sequential firings of a 45-cm length stapler. This creates an anastomosis of at least 4 to 5 cm in length.
2. The location of the anastomosis should be dependent to allow maximum gravitational drainage. This means creation of the gastrojejunostomy on the posterior surface of the stomach, with a retrocolic location of the jejunal limb (Fig. 76–1).

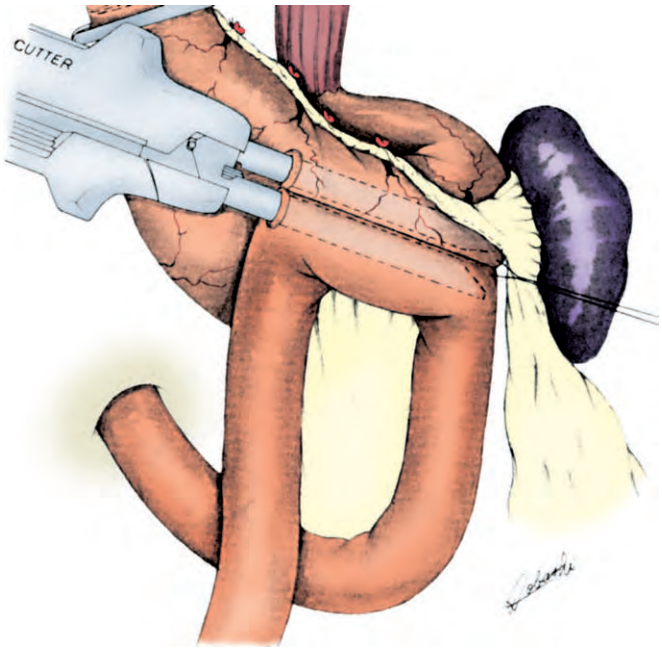

Figure 76–1. Stapled gastrojejunostomy. Creation of a stapled Billroth II anastomosis. Note the preferred method of placing the staple line in a posterior position to improve gastric emptying. (From Feil W, Lippert H, Lozac'H P, et al [eds]: Atlas of Surgical Stapling, New York, Thieme Medical Publisher, 2000, p 132.)

3. The critical outflow to the stomach is not the anastomosis size itself, but the patency of the efferent limb of a gastrojejunostomy. To ensure that the lumen of the efferent limb is open to drainage, the bowel should be tacked to the posterior surface of the stomach 1 to 2 cm beyond the anastomosis to prevent kinking downward of the efferent limb and limiting the surface area for drainage. The tacking stitches should serve to stent open the lumen of the efferent limb.
4. A smooth and unobstructed passageway of the afferent and efferent limbs of the gastrojejunostomy through the mesentery of the transverse colon should be assured. Similarly, the mesenteric opening needs to be sutured to the sides of the bowel to prevent herniation of other loops of bowel superior to the level of the colon mesentery.

Gastric Outlet Obstruction at the Site of a Surgical Gastrojejunostomy

In a patient with a previous antrectomy or subtotal gastrectomy of some portion and a gastrojejunostomy, reobstruction at the site of the anastomosis may occur immediately after surgery or later. Immediate postoperative issues involve technical problems, anastomotic edema, distal efferent loop obstruction, or other kinking or obstruction of the efferent limb of intestine draining the stomach. These complications are discussed elsewhere. Chronic causes of gastric outlet obstruction after a previous gastrojejunostomy include efferent limb obstruction, marginal ulcer at the anastomosis with scarring, and simply stenosis of the anastomosis.

Patient presentation with this anatomic problem is similar to that of gastric outlet obstruction after stenotic pyloroplasty, but vomitus is bilious if the anastomosis is patent to the afferent limb of the gastrojejunostomy. This most often is true. Diagnosis is by upper gastrointestinal series or by endoscopy. The upper gastrointestinal series gives a better anatomic picture of the situation and a better analysis of gastric emptying. Passage of an endoscope through an anastomosis may suggest patency, but functional emptying may be seriously compromised despite the ability to pass an endoscope through the anastomosis. This is especially true if there is an element of obstruction of the efferent intestinal drainage limb, not appreciated by endoscoping the anastomotic area alone.

Initial measures to improve stenotic gastrojejunostomy involve medical therapy to treat and eliminate any marginal ulcer present. Endoscopy with anastomotic dilation is often helpful to relieve symptoms while medical therapy has a chance to reverse the obstructing ulcer process. Eradication of *H. pylori* also is important in this situation, as are other measures to eliminate causes of recurrent ulcer of the stomach (mentioned previously).

Stenosis of the anastomosis is unusual without accompanying reulceration. It may occur on the basis of foreign body reaction to anastomotic staples or sutures, however, or on the basis of chronic ischemia. These causes can

produce a progressive stenosis of the anastomosis, which is usually amenable to treatment with multiple dilations.

Marginal ulcer may cause obstruction at the site of a previous gastrojejunostomy. Diagnosis is usually by endoscopy because contrast studies often do not clearly identify the presence of a marginal ulcer. The site of the ulcer is normally at or just beyond the anastomosis, and this must be confirmed on endoscopy as well. Endoscopic dilation and fluoroscopic dilation may prove successful in treating these obstructions.[7] The presence of a marginal ulcer and a more chronic pattern of stenosis are factors that decrease the likelihood of success using balloon dilation alone. If dilations have failed, and a marginal ulcer persists, a barium radiograph should be performed before reoperation to confirm the marginal ulcer has not fistulized to surrounding structures, such as the transverse colon. This situation is rare, but important to determine if present preoperatively. At times, such a fistula is small and difficult to visualize on the contrast study. Severe scarring in the area of the anastomosis and adherence of an adjacent organ to the area may suggest the presence of such a fistula, even if it is not seen clearly on the contrast study. Such fistulas represent an indication for reoperation because conservative measures are not likely to result in healing.[8]

A minimally invasive approach that has been used in treating fistulas elsewhere in the gastrointestinal tract, but that is currently little proved as a definitive treatment for marginal ulcer fistulas at a gastrojejunostomy site, is fibrin glue injection of the fistula tract to produce occlusion of it. Fibrin glue has been shown to be effective in closing some enterocutaneous fistulas,[9] but its role in treating marginal ulcer fistulas is as yet unproven.

Confirmatory determination of the obstruction site to be at the area of the anastomosis is done with the upper gastrointestinal series, but also may be accomplished with endoscopy. Obstruction of the efferent limb of the gastrojejunostomy may result from stenosis and kinking of the bowel as it exits through the transverse colon mesentery or may be on the basis of postoperative intra-abdominal adhesions, internal hernia, or other less common causes that produce bowel obstruction. Operative treatment of this condition is much more likely, and balloon dilation usually has little role if the obstruction is much beyond the anastomosis.

Operative Technique

Operative treatment of an obstruction at a previous gastrojejunostomy site includes adherence to the following general principles:

1. If a vagotomy was not performed at the initial gastrojejunostomy, a completion vagotomy is indicated in the setting of marginal ulceration. Most incomplete vagotomies result from inaccurate identification of the posterior vagus nerve, which may lie considerably away from the posterior esophageal surface, coursing over the top of the diaphragmatic crura. Dissection further up the right side of the esophagus in the mediastinum often allows the surgeon to find, identify clearly, and follow the posterior vagus trunk. Intraoperative frozen section confirming neural tissue and skeletonization of the distal 5 cm of esophagus are crucial components of completion vagotomy.
2. The area of the previous anastomosis is usually best resected, to eliminate the scarred and obstructed portion of the stomach containing the previous anastomosis. The more proximal stomach is used for creation of the gastrojejunostomy. If resection is substantial, the surgeon may wish to perform a Roux-en-Y drainage of the stomach because this allows a greater length of intestine to reach the more proximal stomach. In addition, resection that includes the jejunal portion of the gastrojejunostomy predisposes to the use of a Roux limb for drainage because the bowel already is divided. Another factor in favor of using a Roux limb for any resection beyond the mid body of the stomach is to prevent potential bile reflux esophagitis.
3. Either the Roux limb or the gastrojejunostomy must be created without any tension on the anastomosis.
4. The efferent limb of the gastrojejunostomy or the Roux limb itself must lie in a position such that the outlet pathway of the bowel is not kinked or in any way obstructed.
5. Orienting the gastrojejunostomy in an isoperistaltic fashion is favorable, but not essential, to good emptying. Either retroperistaltic or isoperistaltic orientation to the stomach functions as long as the efferent limb is widely patent.
6. The bowel must be sutured to the transverse colon mesentery as it passes through it, to prevent postoperative internal hernias of other loops of bowel through the defect. Excessive suturing, especially running permanent suture lengths, may result in stenosis at this site, however.

Postgastrectomy Dumping and Diarrhea

Postgastrectomy dumping is a manifestation of the loss of pyloric control of gastric emptying and is present, to a greater or lesser extent, after any gastric resection with gastrojejunostomy or pyloroplasty. Rapid emptying of food into the jejunum results in the release of vasoactive amines and peptides, including insulin.[10] The vasoactive amines cause early dumping, which occurs within 30 to 60 minutes of eating and consists of physical manifestations including tachycardia, mild hypotension, and symptoms of nausea, abdominal pain and fullness, weakness, dizziness, and a sick feeling after meals with a high osmotic content. The major offending types of foods are calorically dense ones, such as sweets. Eating and drinking at the same time exacerbates symptoms. Late dumping occurs 2 to 4 hours after eating and is characterized by diaphoresis, tachycardia, light-headedness, and confusion. Hypoglycemia often, but not always, is present. Glucagon-like polypeptide (GLP-1) has been implicated as a vasoactive amine contributing to early and late dumping syndrome.[11]

Treatment for postgastrectomy dumping is nonoperative. In almost all situations, the patient can adjust food

intake and speed to ameliorate symptoms. Separating eating from drinking, avoiding high-calorie foods and concentrated sweets, and eating slowly prevent most severe symptoms of dumping. If dumping proves still refractory even with these measures, subcutaneous octreotide is effective in reversing the symptoms of dumping.[12] Longer acting intramuscular dosing of the drug has been shown to prevent the need for subcutaneous injections three to four times a day[13] with equal efficacy. Usually patients experience a decrease in dumping severity as time passes after surgery. Similarly, patients usually can be tapered off octreotide after a several-month course of treatment. For severe cases, the drug is effective long-term, but side effects, which often lead to its discontinuation, include diarrhea and gallstone formation.[14]

Postgastrectomy diarrhea is a sequela of the postprandial dumping that follows the loss of pyloric-controlled gastric emptying after gastric resection. It may be exacerbated further by vagotomy. Diarrhea typically follows mild to more severe dumping symptoms by about 30 minutes and can be as debilitating as the dumping. Following the same approach of alteration of eating pattern that is used to treat dumping often improves the diarrhea as well. Octreotide is less useful for diarrhea alone, whereas antidiarrheal agents are usually of some symptomatic benefit. Adaptation and time usually also are helpful for this condition.

Operative treatments of reversing short segments (10 to 15 cm) of intestine, previously advocated in past decades as a treatment for postprandial dumping (proximal segment of bowel reversal) or diarrhea (more distal small bowel reversal), are no longer generally advocated for the treatment of these conditions and are now rarely used by surgeons working on the upper gastrointestinal tract.[15] Nonoperative therapy usually results in enough improvement of symptoms to satisfy most patients. The conditions usually improve with time, and the ability to obtain an adequate experience in such procedures is so rare as to preclude most surgeons from obtaining expertise in them. Despite the occasional reports of success with such operations, many surgeons have found that these operations often are associated with a high incidence of bowel obstruction, stenosis, and not appreciably greater improvement in symptoms than less aggressive nonoperative measures. One relatively recent report described elimination of dumping when an isoperistaltic 10- to 12-cm segment of jejunum was placed as an interposition graft as an alternative to Billroth I reconstruction after distal gastrectomy for gastric cancer.[16]

The amount of nonbariatric gastric surgery that is done for benign gastric disease, such as peptic disease, has decreased greatly over the past several decades. Medical therapy is often adequate to relieve many of the symptoms of peptic ulcer and cure the disease without surgical therapy. Patients who still require surgery for benign gastric disease, although less numerous, still may manifest the same severe complications and symptoms that made gastric surgery difficult in the past. For those patients, appreciating the experience of past decades helps in planning any needed reoperative surgery.

GASTROPARESIS AND GASTRIC EMPTYING OR MOTILITY PROBLEMS

Gastroparesis

Gastroparesis is defined as poor intrinsic gastric emptying resulting from a lack of peristaltic activity. Most patients with gastroparesis have this condition secondary to another medical condition, such as diabetes, vagotomy, collagen vascular disease, viral illness, medications, Parkinson's disease, hypothyroidism, or amyloidosis. Rarely, patients have primary gastroparesis, and this is part of an overall neural or smooth muscle disease of the gut that manifests itself as overall pseudo-obstruction or ileus, rather than isolated gastroparesis. Gastroparesis is often idiopathic as well.

Patients with gastroparesis present with early satiety, vomiting of undigested food, abdominal pain, nausea, and food intolerance and aversion. Patients with idiopathic cases, believed sometimes to result from a viral illness, may develop sudden severe symptoms. Other secondary causes are usually more insidious in onset except for postvagotomy patients. These patients have perhaps the most profound symptoms and are perhaps the one subgroup of patients with gastroparesis for whom reoperative surgery may be indicated for severe symptoms.

The diagnosis of gastroparesis is made by the clinical syndrome and symptoms accompanied by a documentation of solid food and liquid food delayed emptying using radionuclide gastric emptying studies. Such studies are considered the gold standard for confirming the presence of delayed gastric emptying of solids and liquids. Gastroparesis can be mistaken for rapid gastric emptying, and gastric emptying studies are necessary sometimes to define clearly the cause of patient symptoms.[17]

Gastroparesis is mentioned here largely as a warning to surgeons that the primary and best therapy for such patients is *medical*. Prokinetic agents, either erythromycin or metoclopramide, are the medications of choice for treating gastroparesis. Erythromycin, a macrolide antibiotic, has a chemical structure similar to the gastrointestinal regulatory peptide motilin. Erythromycin exerts gastric-specific contractile stimulation and assists in gastric emptying. It has been shown to be effective for short-term and long-term use. Side effects include cramping. Metoclopramide is a procainamide derivative that acts to stimulate the entire gastrointestinal tract by antagonism of peripheral dopamine receptors and increasing acetylcholine release from the myenteric plexus. It is the most commonly prescribed prokinetic agent available in the United States today and is effective for gastroparesis. The side effects of long-term metaclopramide use are its major detraction; these include extrapyramidal side effects and nightmares particularly in elderly patients, dystonic reactions in young patients, and hyperprolactinemia.

Reoperative surgery for causes of gastroparesis is uncommon and generally limited to cases of severe postvagotomy gastroparesis.[18] Diabetic gastroparesis is usually treated adequately with medical therapy. Nutritional

compromise occasionally may occur, however, secondary to the disease. In such situations, placement of enteral access is needed for management of the disease. Such enteral access must be a *jejunal* feeding tube, not a gastrostomy. Placement of nutrients directly into the stomach not only does not guarantee they will reach the intestine before being vomited but also exacerbates symptoms of the gastroparesis. Surgeons are urged to use a conservative approach to patients with idiopathic gastroparesis because these individuals may resolve their disease spontaneously over months to years and should not be subjected to irreversible gastric resection, which could compound subsequent upper gastrointestinal symptoms.

Patients with severe persistent symptoms of gastroparesis, who have had the disease for a long time, who have a known cause for the disease, who have experienced nutritional compromise, and who have a poor quality of life secondary to the problem occasionally may be considered candidates for surgical therapy. Most individuals who fit this description have postvagotomy gastroparesis, and so reoperative surgery is the norm. In such patients, removal of most of the stomach, leaving only a small gastric reservoir that cannot serve as a large atonic pouch to store food, is indicated. The operation resembles the Roux-en-Y gastric bypass (RYGB) that currently is the most frequent operation performed for morbid obesity except that the distal stomach is resected. Near-total gastrectomy with Roux-en-Y gastric drainage is relatively successful in relieving symptoms in this patient population. One study by Echauser et al.[19] showed nearly 80% relief of symptoms for patients undergoing near-total gastrectomy for postvagotomy motor disorders of the stomach. Even this radical surgical approach to gastroparesis is not guaranteed to restore a good quality of life to the patient, but it remains the only surgical option for the most severely affected patients.

Reports have arisen regarding the use of gastric electrical stimulation for the treatment of gastroparesis. Although symptomatic relief has been achieved in patients, data showing pacing produces an increase in gastric emptying by radionuclide testing are still lacking.[20] This treatment modality still must be considered an experimental procedure.

Roux Limb Syndrome

The Roux limb syndrome, described previously in the surgical literature, is manifested by symptoms of early satiety, bloating, upper abdominal pain, and vomiting after eating. Patients who have this syndrome have had previous gastric resection with vagotomy and often had a second operation to convert the gastric drainage from a loop gastrojejunostomy to a Roux-en-Y drainage. The cause of the Roux syndrome was attributed to a primary motor disorder of the Roux limb by some authorities. Other authors, including us, believe the vagotomy itself was the primary reason for the symptoms and the dysfunction.[21] Evidence to support this position derives from the fact that patients who did have Roux syndrome, and who underwent subsequent near-total gastrectomy with Roux-en-Y drainage, usually were relieved of symptoms with the same frequency as patients with gastroparesis. As a result of improvements in medical treatment for peptic ulcer disease, the performance of gastric resection with vagotomy has decreased markedly over the past 3 decades, and this situation is now rarely encountered in clinical practice. The numerous morbidly obese patients who have undergone RYGB, without vagotomy, without producing a large number of patients with the Roux syndrome, lends further evidence to the fact that the vagotomy and gastroparesis were likely the underlying cause of the symptoms experienced in the past by patients given the diagnosis of the Roux limb syndrome. If such patients are encountered today, they should be managed in a similar fashion as patients with gastroparesis, reserving surgical therapy for patients refractory to medical management, and using near-total gastrectomy as the surgical procedure of choice if reoperation is performed.

GASTROINTESTINAL NEOPLASMS

Adenocarcinoma of a Gastric Remnant

Patients who have undergone previous distal gastrectomy for benign peptic ulcer disease are at risk for cancer of the remaining gastric remnant. This risk has been well documented in the surgical literature.[22] The occurrence of tumors is on average several decades after the original operation, however. Routine screening endoscopy for all such patients is recommended starting 20 years after surgery. Should a suspicious lesion be found on gastroscopy in this setting, multiple biopsy specimens of the lesion should be obtained. The highest likelihood for yield of a correct diagnosis is when biopsy specimens are taken at the edge of the ulcerated lesion, not in the often necrotic central portion of a tumor ulcer. Completion gastrectomy is the surgical treatment of choice and is curative in nearly all cases that are diagnosed by endoscopic screening.

Patients who have had previous gastric resection for adenocarcinoma are at risk for local recurrence. Surveillance endoscopy in this patient population is performed on a 6- to 12-month basis, until several years of disease-free interval have passed. Then endoscopic frequency is decreased. If a recurrent cancer is diagnosed, reoperative surgery with total gastrectomy and en bloc radical resection including an R2 nodal dissection as indicated is the procedure of choice. Achievement of an R0 status is the goal of resection. Roux-en-Y esophagojejunostomy is indicated for reconstruction, and a feeding jejunostomy is placed for assurance of enteral access and feeding capability should any problems arise at the esophagojejunostomy anastomosis. Results of resection for recurrent gastric adenocarcinoma show a high incidence of ultimate death from recurrent cancer.[23] If recurrent gastric cancer has progressed beyond the realm of feasible curative re-resection, options for palliation of the problem include laparoscopic gastrojejunostomy[24] and endoscopic placement of metallic stents.[25]

Recurrent Stromal Cell Tumor

Gastrointestinal stromal cell tumors, known in the past as leiomyomas of the gastrointestinal tract, have variable malignant potential. Their tumor biology behavior mimics sarcomas, in the sense that local recurrence is the most common manifestation of recurrent neoplastic disease. If such a situation occurs for a previously resected gastric stromal tumor, radical re-resection is indicated to cure the condition. A 5-cm proximal and distal margin of resection is optimal, if possible. Intraoperative frozen section of the margins of the resected specimen is appropriate to help confirm the adequacy of surgical excision of the recurrent tumor. Neither radiation nor chemotherapy has much efficacy in this disease; surgery remains the only chance for complete cure. If the tumor has extended into surrounding structures, en bloc resection including the spleen, distal pancreas, and colon or wedge resection of the left hepatic lobe may be necessary. Reconstruction usually is achieved with a Roux-en-Y gastrojejunostomy or esophagojejunostomy. Recurrent stromal cell tumors have a penchant for repeat recurrence, and the potential for cure is markedly diminished over that of initial resection.[26]

Recurrent Desmoid Tumors

Desmoid tumors, which are commonly associated with patients with familial colon polyposis and Gardner's syndrome, are a difficult surgical problem. They are generally slow-growing tumors and manifest themselves by creating symptoms of obstruction or pain. They tend to occur in the mesentery of the small bowel.

Diagnosis is usually by suggestive clinical picture and computed tomography. A mass in the mesentery of the small bowel is diagnostic. Desmoids most commonly involve the bowel distal to the duodenum, but may occur in the area of the celiac axis or duodenum. In such cases, they tend to be difficult tumors to remove completely because they often present at a stage where perivascular invasion of major mesenteric arteries, such as the superior mesenteric artery or branches of the celiac axis, is involved. Radical excision with vascular reconstruction is occasionally possible, but often tumor extent and invasion preclude this option as well. Debulking of the tumor has some benefit, but offers only palliative therapy.[27] Because desmoid tumors are so difficult to cure, a high index of suspicion for their presence must be maintained in patients at risk for the disease.

GASTROESOPHAGEAL REFLUX DISEASE

Reoperation for failed antireflux surgery is becoming increasingly commonplace, especially at major referral centers for complex gastrointestinal problems. During the mid-1990s, the incidence of fundoplication performed in the United States dramatically increased with the availability of a laparoscopic option for the procedure. The number of procedures increased by approximately 800% between 1989 and 1999.[28] Foregut surgeons now are seeing an increasing number of patients who have developed problems from their initial operation and present as potential candidates for revisional surgery. Patients who develop recurrent symptoms after previous antireflux surgery do so because the operation may have failed for the following reasons:

1. Recurrent diaphragmatic herniation with migration of the wrap to an intrathoracic location
2. Slippage of the wrap with recurrent gastroesophageal reflux
3. Inadequacy of the wrap or disruption of the wrap with recurrent gastroesophageal reflux
4. Inadequate length of abdominal esophagus at the original operation, with the wrap placed around the proximal stomach, preventing adequate increase in lower esophageal sphincter pressure and resulting in subsequent recurrence of gastroesophageal reflux
5. Stenosis of the wrap area with persistent postoperative dysphagia

The symptoms that generally occur after failure of antireflux surgery differ. Symptoms should be a guide to suspicion of one of the above-listed failures of the previous fundoplication. Symptoms alone are notoriously unreliable for confirming the presence of a failed previous fundoplication, however, and the surgeon must confirm the presence of recurrent disease and the anatomic problem with the fundoplication before offering reoperation to the patient. Only with such information can a rational plan for reoperation be constructed and the appropriate counseling occur regarding the likelihood of success of the revisional operation.

Recurrent and persistent epigastric pain after a previous fundoplication should raise the suspicion that recurrent herniation of the wrap through the diaphragm and into the mediastinum has occurred. This is the classic symptom of recurrent diaphragmatic herniation. An upper gastrointestinal series is usually diagnostic and may be the only test needed in this setting before reoperation is recommended. Recurrent herniation of the wrap into the chest does not always manifest with significant symptoms. Hashemi et al.[29] reviewed the University of Southern California series of repairs of large paraesophageal hernias by obtaining a routine upper gastrointestinal series an average of 27 months postoperatively for patients undergoing repair of type III hiatal hernias with fundoplication. Patients who had a previous laparoscopic repair had a 42% incidence of recurrent hernia, and more than half had few, if any, symptoms.

Reoperation for recurrent diaphragmatic herniation can be performed through the abdomen or through the chest. If multiple previous upper abdominal operations have been performed, the latter approach may allow a technically easier repair. Left thoracotomy, reduction of the herniated wrap back into the abdomen, and crural diaphragm repair are indicated in this setting. Use of reinforcing mesh is still controversial, but may be considered if the diaphragm tissue is of poor quality. Mesh must be placed so as to avoid potential erosion into the esophagus. Materials that have a smooth surface (e.g., Gore-Tex or composite meshes) are preferred to

materials with an open weave configuration (e.g., Prolene or Marlex).

Repair of the reherniation also can be accomplished with high likelihood of success through the abdomen. Our experience has been that performance of this recurrent surgery may require an open incision, depending on the severity of scarring at the diaphragmatic hiatus. A previous operation done via celiotomy usually requires another open approach. If the previous antireflux operation was done laparoscopically, however, and scarring in the area of the diaphragm is not excessive, we have repaired the recurrent herniation successfully with a laparoscopic approach. The same consideration must be entertained for the use of a nonadherent mesh material to reinforce the crural repair through the abdomen and when a laparoscopic approach is used. Mesh should be securely fixed with sutures, not stapled or tacked to the diaphragm.

Patients who present with symptoms resembling recurrent gastroesophageal reflux after a previous fundoplication should be assessed carefully to determine that recurrent reflux is present. Patients are often restarted on proton pump inhibitor therapy for presumed recurrent reflux after surgery when vague or nonspecific symptoms that could be reflux are voiced to the patient's internist or gastroenterologist. Lord et al.[30] showed that at a mean time of 28 months after fundoplication, 43% of symptomatic patients were taking acid suppression medications, and only 24% of patients taking acid suppression medications had abnormal 24-hour pH studies.

If a patient complains of symptoms of recurrent reflux, full evaluation of the patient and the previous operation is indicated. Minimum tests include an upper gastrointestinal series to assess for potential disruption of the wrap, herniation of the wrap into the chest, or gross reflux on contrast agent ingestion. If the upper gastrointestinal study shows a clear problem with the wrap, some surgeons proceed to reoperation. A pH test is the gold standard for documenting recurrent reflux in this setting. Upper endoscopy should be liberally performed, especially if considerable time has passed since the first operation, or if there is any concern that Barrett's esophagitis may have developed in the interim. Upper endoscopy also gives good information regarding the current position of the wrap and further enhancing information regarding diaphragmatic herniation. Lord et al.[30] reported that endoscopic assessment of the fundoplication was the most significant factor associated with an abnormal pH test, documenting the accuracy of endoscopy to assess a disrupted wrap.

Our general recommended approach to the reevaluation of patients with a failed antireflux operation is to obtain an upper gastrointestinal series and upper endoscopy and proceed with pH testing if those studies do not show gross herniation of the wrap into the chest. Adding a repeat esophageal manometry in this setting is controversial and should be based on the patient's symptoms. Any symptoms that suggest atypical pain, esophageal spasm, or dysphagia are indications for a preoperative manometry study before reoperative surgery.

The outcomes of reoperation for failed antireflux operations are generally good. The largest series in the literature was reported by the group from Emory.[31] In their series of 1892 patients who underwent fundoplication at Emory, 2.8% required reoperation. Most reoperations occurred within 2 years of the initial procedure. Transdiaphragmatic wrap herniation was the most common reason (61% of cases) for reoperation in that group. A group of 231 patients had fundoplication done elsewhere, and in that group transdiaphragmatic herniation was the problem in 47% of cases. Slipped or disrupted wraps were found in 19% and 18% of the two groups and were the second most common reason for failure. Most of the reoperations were done laparoscopically (70%). Mortality for the series was 0.3%. Intraoperative perforation occurred in 17% of the laparoscopic cases and 29% of the open cases. Postoperative complication rates were 11.7% for the laparoscopic cases and 40.3% for the open cases. Relief of postoperative symptoms to the mild or absent category was achieved in 73% to 89% of patients. Failure of the reoperations requiring a second reoperation was reported in 8% of patients, with transdiaphragmatic herniation again being the leading cause of failure.

Other reports of reoperative surgery for failed fundoplication also have shown relatively good results, although never as good as the initial operation. Neuhauser and Hinder[32] reported results of 100 consecutive patients undergoing reoperative surgery for failed fundoplication. Only 52% of the patients had a previous laparoscopic operation. These authors performed reoperative laparoscopic fundoplication in 83% of cases. There was a 30% perioperative or postoperative complication rate, however, and the authors cautioned that such reoperative surgery is a major surgical technical challenge. Byrne et al.[33] described their experience with 118 patients undergoing reoperative antireflux surgery, with 101 of the 118 being able to be done laparoscopically. Heartburn was relieved or minimal in 84%, and regurgitation was relieved or minimal in 87% of patients. Patients having preoperative dysphagia were improved in 25 of 32 cases. Rosemurgy et al.[34] reoperated on 64 patients: 28% owing to hiatal failure, 19% owing to wrap failure, and 33% owing to failure of both. Most (76%) reoperations were done laparoscopically. Improvement in dysphagia was observed in 100% of symptomatic patients, improvement of reflux was seen in 79%, and improvement of both when both were present was seen in 74% of patients. Heniford et al.[35] reoperated on 55 patients. They did 37 of the procedures laparoscopically and had a 12.7% complication rate and an average hospitalization of 4.6 days; greater than 90% of patients experienced good to excellent symptom relief. Dutta et al.[36] reported a series of 28 redo fundoplications, most for symptoms of gastroesophageal reflux disease. All but two were done laparoscopically, with an average operating room time of less than 1 hour. Three patients required reoperation for reherniation of the wrap.

Reoperation for failed fundoplication can be performed with good symptomatic and overall outcomes. Patients must be cautioned that the reoperations have a higher complication rate and a slightly lower symptomatic improvement rate than the initial operation.

Success at performing reoperations laparoscopically depends on the severity of previous scarring and the surgeon's skill and persistence. These reoperations should be performed by surgeons with extensive laparoscopic and antireflux surgical experience.

Technical Aspects of Revisional Antireflux Surgery

Revisional antireflux surgery poses a significant technical challenge. The following are recommendations for successful laparoscopic performance of the operation:

1. The initial approach should be as for all previously operated abdomens, with care being taken to avoid organ injury on accessing the abdomen.
2. The most difficult initial organ dissection plane is the one between the inferior surface of the left lobe of the liver and the anterior proximal stomach. Dissection of the liver off the stomach without excessive violation of Glisson's capsule and significant bleeding is important. If liver parenchymal violation occurs, often the liver retractor can be positioned to place direct pressure on the area of the injury, tamponading any bleeding and achieving hemostasis as the operation progresses. Significant liver laceration warrants the placement of a closed-suction drain in the area at the completion of the operation to drain any potential bile leak. Liver surface hemostasis, if difficult, can be enhanced by high-energy electrocautery applied 1 to 2 mm off the surface of the liver to seal the tissue. The argon beam coagulator is even more effective if significant areas of capsular disruption have occurred. If one uses this instrument during laparoscopic surgery, the abdomen must be vented while the energy source is turned on.
3. The fundoplication position and the relationship to the diaphragmatic crura must be assessed. Usually is it evident if the problem is wrap herniation through the diaphragm, wrap disruption, or wrap misplacement.
4. Sutures used to create the wrap should be identified and cut, loosening the wrap.
5. The fundoplication should be taken down carefully and completely. Tissue planes should be confirmed. If any question exists as to the location and edge of the esophagus, an intraoperative endoscope or lighted bougie can facilitate location of its borders. Nonlighted bougies also are helpful if neither an intraoperative endoscope nor lighted bougie is available.
6. Conversion to an open incision should be performed if the tissue planes of the gastric fundus, the borders of the esophagus, or the borders of the diaphragmatic crura are not clearly seen. It is hoped that this decreases the incidence of intraoperative organ injury.
7. The fundus must be redissected to achieve good mobilization, and the retroesophageal area must be maximized for adequate room to pass the wrap.
8. Abdominal esophageal length must be 2 cm at rest. Mobilization of the esophagus to achieve this length must be performed. An esophageal lengthening procedure rarely is necessary. If so, we have successfully used a circular then linear stapler laparoscopically, similar to a laparoscopic vertical banded gastroplasty (VBG) being done for morbid obesity.
9. Re-repair of the crura is almost always necessary. Poor tissue quality of the crura should raise the consideration of placement of a soft mesh across the lower crura, not in contact with the esophagus, for reinforcement of the closure.
10. The wrap must be constructed over a dilator, preferably one No. 54 to 60 French size.
11. Any concerns for injury to the esophagus or stomach should be tested by air insufflation using an endoscope intraoperatively.
12. The wrap, when reconstructed, should be placed as high as possible on the esophagus and fixed to the crura of the diaphragm in revisional surgery. This placement should help prevent a second hiatal failure.
13. If a hiatal failure is still of concern, anterior gastropexy may help prevent gastric migration upward into the mediastinum.

The most important of these principles are summarized in Box 76–2.

BARIATRIC SURGERY

Revisional bariatric surgery should be performed only by an experienced bariatric surgeon. Laparoscopic revisional bariatric surgery requires extremely advanced laparoscopic skills, significant bariatric surgical experience and skill, and an efficient and supportive operating room team that is well equipped for such a surgically challenging operation. A skilled laparoscopic first assistant is a necessity for all bariatric surgery, but particularly revisional surgery.

Box 76–2 Major Principles of Reoperative Antireflux Surgery

Expect the plane between the undersurface of the left lobe of the liver and the stomach to be difficult to dissect cleanly.

Identify the source of the failure—wrap slippage, disruption, diaphragmatic hernia, or combination.

Clearly identify the esophagus.

Take down the wrap.

Confirm adequate length of abdominal esophagus.

Reconstruct the operation, and test for leaks or organ injury.

Patient Selection

Based on supply, demand, and public health concerns, one can make a strong case that revisional bariatric surgery is rarely indicated. Currently more than 23 million people in the United States are candidates for bariatric surgery, and less than 1% of them receive surgical therapy annually. There is a shortage of well-trained bariatric surgeons, especially those who perform the operation laparoscopically, for the patient demand. Use of surgeon time and medical facility resources for revisional bariatric surgery is, in light of these facts, of debatable merit. The practice of medicine and surgery holds care of the individual patient as the paramount concern, however, and as such, revisional surgery may be appropriate at times.

All bariatric operations have some failures. A figure of approximately 10% is often used in discussions regarding the "failure rate" of various well-established bariatric operations. The reasons for failure may vary. These reasons must be assessed carefully and understood before reoperative surgery is entertained or offered. If the failure is *primarily of the operation,* consideration for reoperation is appropriate. If the failure is *primarily of the patient and the patient's eating habits and compliance,* reoperation has little likelihood of succeeding any more than the initial failed operation. Surgical ego, compassion for a noncompliant patient who is upset with his or her current condition, and the incentive to perform a technically challenging operation all should be avoided in such situations and should not lead the surgeon to offer reoperation to a patient who has failed a previous bariatric operation because of behavioral and eating issues.

Reoperation should be considered in a situation where the operation has failed. The surgeon must define this anatomic failure. Reoperation is based on correcting the previous failure or safely revising the first operation to another bariatric procedure appropriate for the patient and his or her needs, expectations, and eating patterns. It is wise to have several counseling sessions with patients who request reoperative surgery. A dietary history not only from the patient, but also from the patient's family is appropriate in this setting. The patient needs to have demonstrated the appropriate behavior after the initial failed operation.

Any patient who is a candidate for reoperative surgery, if the surgery is to produce further weight loss, must meet the National Institutes of Health criteria for qualifying for weight loss surgery. The patient must have a body mass index (BMI) of greater than 40 kg/m^2 without weight-related comorbid medical problems or a BMI greater than 35 kg/m^2 with a comorbid problem. Psychological stability, motivation, documentation of previous appropriate behavior after the initial operation, and no medical conditions making the reoperation of excessively high risk are criteria that we mandate before reoperative bariatric surgery.

Failed Vertical Banded Gastroplasty

The VBG was the most popular bariatric operation performed in the 1980s. By 1990, it had fallen out of favor largely because of the poor long-term weight loss record of the operation[37] and because a considerable percentage of patients also develop progressive stenosis of the gastric outlet,[38] prompting conversion to a high-calorie liquid diet.[39] Multiple reports exist in the bariatric surgical literature documenting the ability to convert patients with previously failed VBG operations successfully to RYGB. Jones[40] reported only a 13% complication rate for a series of 141 patients undergoing reoperative surgery to convert from failed bariatric procedures to RYGB. Sugerman et al.[41] performed conversion of 53 VBG procedures with complications to RYGB, achieving 67% excess weight loss. The complication rate was high—about 50% for the series, including 20 marginal ulcers. Cariani et al.[42] also reported a high incidence of complications after reoperative surgery for VBG or failed RYGB, totaling greater than 55% between early and late complications. Reoperative surgery, especially bariatric surgery, carries increased risk for infection, wound complications, pulmonary complications, and intra-abdominal crises from leaks above that seen for initial operations.

Most reoperative surgery for failed VBG has been done using a celiotomy approach. Some surgeons have performed this operation laparoscopically, however. Gagner et al.[43] reported laparoscopically converting 27 patients with failed open or laparoscopic gastroplasty, adjustable gastric banding, or RYGB to a new or revised RYGB. The average BMI for these patients decreased from 43 kg/m^2 to 36 kg/m^2, and the complication rate was 22%. There are increasing reports of small experiences in the bariatric surgical literature where surgeons have used a laparoscopic approach successfully to convert a failed previous bariatric operation to a RYGB. These failed procedures are most often VBG or laparoscopic adjustable gastric banding (LAGB). Technical considerations when performing a conversion of a VBG to a RYGB, whether laparoscopic or open, are as follows:

1. Dissection of the left lobe of the liver off the area of the band, on the lesser curvature of the stomach, is usually the most difficult tissue plane encountered.
2. The proximal gastric pouch must be clearly identified.
3. The new gastric pouch must be made above the level of the band. This is not usually difficult because the existing pouch above the band is usually distended and of more than adequate size to divide and still have an adequate proximal gastric pouch.
4. A decision to resect or leave the distal portion of the existing proximal pouch above the band must be made. If it is left in place, the opening through the band must be adequate to drain this isolated gastric segment. If it is resected, the band and the section must be completely resected, with the distal resection line below any previous staple lines.

The failed fixed banding procedure of the VBG also has been successfully revised to placement of an adjustable gastric band. The adjustable gastric banding

procedure is the most common bariatric operation performed throughout the world outside the United States and is gaining popularity in this country. O'Brien et al.[44] placed an adjustable band to revise failed gastroplasty and other procedures for 50 patients. The 3-year weight loss was 47% of excess weight. The early complication rate of placement of these bands, done via a celiotomy, was considerably increased versus band placement as a primary operation (17% versus 1.1%), always done laparoscopically. Late (2% versus 18%) complication rates were lower for the revision series than for initial LAGB.

Failed Laparoscopic Adjustable Gastric Banding

Reports in the literature that have described reoperation for failed LAGB have usually taken the approach of using only one other alternative operation for this problem. Conversion of a failed LAGB to a laparoscopic RYGB was performed by Mognol et al.[45] for 70 patients. They reported a conversion rate of only 4.3%, an operative time of 4 hours, hospital stay of 7 days, complication rate of 14.3% early and 8.6% late, and no deaths. Excess weight loss averaged 70%, and more than 60% of patients achieved a BMI less than 33 kg/m^2. These results are excellent and are similar to the results reported by Calmes et al.[46] for a series of 49 patients converted from LAGB or VBG to laparoscopic RYGB. They had no conversions, operating room time was 3.25 hours, morbidity was 20%, and nearly 75% of patients achieved a BMI less than 35 kg/m^2.

The use of a laparoscopic biliopancreatic diversion to treat patients with failed weight loss after LAGB was reported by Fielding.[47] Having performed a large series of LAGB procedures, surgeons reoperated on 5.4% of the initial LAGB group who had their bands removed for a variety of reasons. They performed the biliopancreatic diversion 38 times laparoscopically and 20 times via celiotomy. They also performed a laparoscopic duodenal switch procedure for 21 patients. In this entire group, excellent weight loss of 40% excess weight was achieved with only a 6.3% complication rate and no mortality.

Failed Roux-en-Y Gastric Bypass

RYGB may fail for several reasons. If the surgeon does not divide the stomach in creating the proximal gastric pouch, there is a significant incidence of disruption of the gastric staple line with regain of weight and associated development of marginal ulceration at the site of the gastrojejunostomy. MacLean et al.[48] reported the incidence of such staple line disruption in 29% of cases followed up to 8 years. Our own experience with not dividing the stomach in the first few years of performing RYGB was a 5% incidence of staple breakdown per year, which accumulated to 25% by 5 years' follow-up. It is now commonly accepted in bariatric surgery that dividing the stomach to create the proximal gastric pouch results in fewer long-term complications from staple line breakdown.

If staple line breakdown is the reason for the failure of the RYGB, reoperation is indicated to redivide the stomach at or above the original staple line. Care must be taken by the surgeon not to leave an isolated undrained closed section of stomach between staple lines. If staple line identification intraoperatively is difficult, we have used upper endoscopy to help define the proximal edge of the staple line. If confirmation of a preexisting staple line can be done only from the distal stomach, we have no concerns about creating a small gastrotomy in the distal stomach during revisional gastric surgery to identify with absolute certainty the level of the previous staple line. This maneuver is useful for all types of reoperative gastric surgery, not just bariatric. The gastrotomy is easily closed later.

Failed RYGB has been treated by adding a malabsorptive component to the original procedure by Fobi et al.[49] and Sugerman et al.[50] Fobi's group[49] performed a distal RYGB, decreasing the absorptive length of the alimentary tract in half. They reported an excessive protein malnutrition incidence of 23% in the 65 patients for whom this was done. Weight loss was from a BMI of 42 kg/m^2 to 35 kg/m^2. Sugerman's group[50] similarly found adding malabsorption to significant restriction can be problematic when they created a distal RYGB with only a 50-cm common channel after failed gastric bypass. All five reported patients developed protein-calorie malnutrition, and two died of hepatic failure. Creation of a 150-cm common channel in 22 patients resulted in only 3 developing protein-calorie malnutrition and reoperation to lengthen the common channel. Bariatric surgeons must be aware of the *significant* potential morbidity that may result from adding a malabsorptive operation on to an already present restrictive one.

There is a trend in the bariatric field, especially by bariatric surgeons or their colleagues who perform advanced intraluminal endoscopic surgery, to consider reoperating on patients after RYGB who have regained weight or failed to lose adequate weight and who have a larger than 1-cm gastrojejunostomy. The reasoning is that the enlarged anastomosis has allowed excess food intake and weight regain. Initiatives of performing endoscopic intraluminal suturing to narrow the gastrojejunostomy anastomotic opening have begun in several centers.[51] Endoscopists use the same endoscopic tissue suturing device that has been used to treat gastroesophageal reflux disease endoscopically for several years in some centers. The latter experience has been less than satisfying and does not compare in efficacy with laparoscopic antireflux surgery. The major concern with this reoperative procedure is that to date there is *no direct evidence* anywhere in the bariatric literature that a smaller anastomosis produces improved weight loss after RYGB. The experience with failed VBG should have taught bariatric surgeons that a small anastomosis does not guarantee good prolonged weight loss. Similarly, no study has been published showing that reoperation to narrow the anastomosis has any efficacy. Endoscopists who venture into this arena should be aware of the lack of evidence substantiating these procedures. Until proved effective (including lack of placebo and associated diet and

exercise effects), these procedures must be considered experimental.

Failed Malabsorptive Procedure

Few reports of reoperative surgery for biliopancreatic diversion or duodenal switch operations exist. This is largely because the operation usually produces satisfactory weight loss. The reoperations that do occur usually are due to the consequence of protein-calorie malnutrition and the need for repeated episodes of parenteral nutrition and persistent hypoalbuminemia. This situation is corrected by revision to increase the length of the common channel. Surgeons usually revise the operation to make a considerably longer common channel, but there are no clear guidelines for the amount or percentage that the surgeon must increase the common channel to avoid residual protein-calorie malnutrition and still preserve some degree of weight loss. Cases must be individualized, and the surgeon does well to err on the side of safety in restoring adequate digestive function in these situations.

All bariatric operations may fail for a variety of reasons. The success with reoperation, as noted earlier for many of the reported series, is usually only modest. It is typical for the reoperative candidate to have a BMI in the low to mid 40s and to have some additional weight loss to achieve a BMI near 35 kg/m^2. Achieving a BMI less than 30 kg/m^2 is unusual based on most reported experiences. Many reoperations are done via an open celiotomy approach. Performance of laparoscopic reoperation should be restricted to only surgeons with significant advanced laparoscopic experience in bariatric surgery. Overall, the complication rates of reoperative bariatric surgery are considerably higher than the rates reported for initial procedures. Because of this combination of facts, the bariatric surgeon is cautioned to be particularly selective in offering reoperative surgery for failed previous bariatric operations. The concerns elaborated earlier regarding patient rather than operation failure always must be heeded when assessing a patient for reoperative bariatric surgery.

BILE REFLUX GASTRITIS

Enterogastric reflux is within the normal pattern of gastrointestinal physiology. The gastric mucosa is relatively resistant to modest amounts of bile, and gastritis normally does not occur with such quantities of bile. If bile reflux is excessive, however, bile gastritis may occur. Patients with this problem typically have epigastric abdominal pain, nausea, and bilious vomiting. The diagnosis of bile reflux gastritis requires first that no concurrent obstructive process is present. Such problems include afferent limb syndrome, efferent limb obstruction after gastrojejunostomy, more distal bowel obstruction, and gastroparesis, particularly postvagotomy gastroparesis. Upper gastrointestinal series, endoscopy with careful examination and biopsy of the gastric mucosa, gastric emptying studies, and quantitative assessment of the amount of enterogastric reflux all should be performed in patients suspected to have bile reflux gastritis. Radionuclide scintigraphy of the biliary tree is helpful in quantitating the amount of bile reflux. In most cases, an underlying cause for the patient's symptoms can be found after such a battery of tests. Often the problem is not true bile reflux. The surgeon must *avoid* operating on patients for this condition without a complete evaluation. Performing reoperative surgery for presumptive bile reflux when the true cause of the problem is gastroparesis leads to poor outcomes and persistently symptomatic patients.

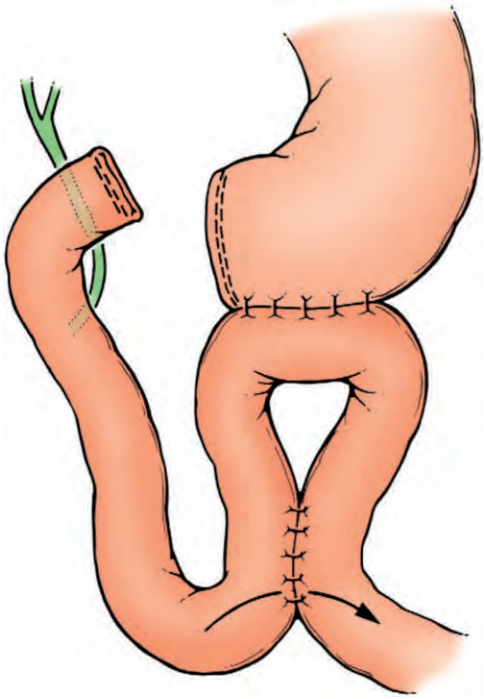

Figure 76–2. Braun's enteroenterostomy. Anastomosis between afferent and efferent limbs for surgical management of bile reflux gastritis. (From Madura JA: Postgastrectomy problems: Remedial operations and therapy. In Cameron JL [ed]: Current Surgical Therapy, 7th ed. Philadelphia, Mosby, 2001, p 92.)

Treatment of a patient with true bile reflux gastritis is based on the existing anatomy. If the patient has a gastrojejunostomy, the options include conversion to a Roux-en-Y drainage or creation of a Braun enteroenterostomy between the afferent and efferent limbs of bowel. This is performed by simply creating a side-to-side anastomosis between the afferent and efferent limbs draining the stomach (Fig. 76–2). Typically, the distance is 30 cm away from the gastrojejunostomy. Vogel et al.[52] reported excellent reversal of alkaline reflux gastritis by use of the Braun enteroenterostomy in a group of 30 patients.

The duodenal switch operation, first described by DeMeester et al.[53] for the treatment of this condition, treats bile reflux gastritis when there is no gastrojejunostomy or previous gastric resection. The duodenal switch is performed by dividing the duodenum 2 to 3 cm distal to the pylorus, then performing an anastomosis of the duodenal stump to a Roux-en-Y loop of jejunum (Fig.

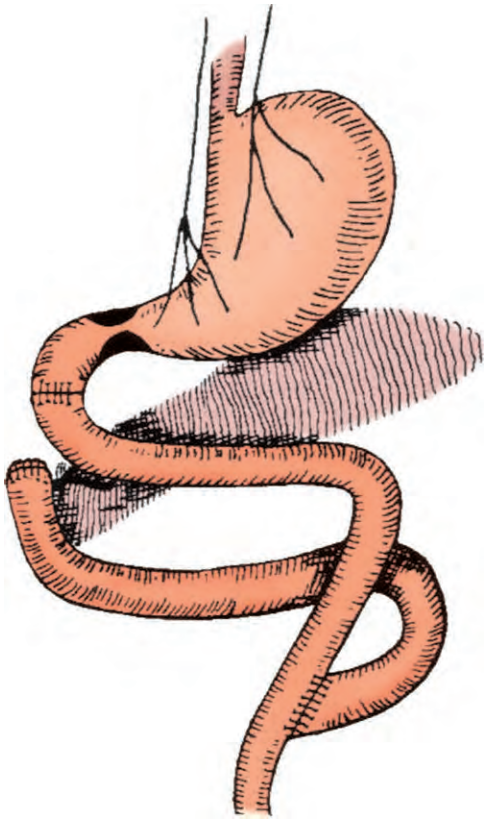

Figure 76–3. Duodenal switch procedure. The duodenum is transected 2 to 3 cm distal to the pylorus and anastomosed to a Roux-en-Y limb.

76–3). The enteroenterostomy of the Roux limb is typically at least 75 cm downstream to avoid any potential for bile reflux under normal circumstances. Marginal ulceration is a common problem after this operation, and consideration should be given to long-term proton pump inhibitor therapy postoperatively.

AFFERENT LIMB SYNDROME

Afferent limb syndrome is the term used to describe the partial obstruction of the afferent limb of a gastrojejunostomy after previous gastric resection and Billroth II gastrojejunostomy. The afferent limb contains the biliary and pancreatic secretions carried from the duodenum. Obstruction to drainage of the afferent limb may arise as a result of any obstructive process, benign or neoplastic. Early obstruction after a recent operation is usually the result of technical error in creating the gastrojejunostomy, with resulting kinking of the efferent limb. More chronic obstruction may result from progressive scarring of the afferent limb as it passes through the transverse colon mesentery; adhesion formation with stricture, chronic volvulus, or internal hernia; or any other chronic obstructive process.

Symptoms of the afferent limb syndrome commonly include postprandial epigastric and right upper quadrant pain, followed by bilious vomiting with simultaneous relief of the pain. The pain occurs as a result of the increased biliary secretions causing distention of the duodenum and afferent limb. When the limb pressure is sufficient to decompress into the stomach, bilious vomiting results. Because the syndrome is usually slowly progressive, it may cause enough partial obstruction of the drainage of the bile and pancreatic juice to elevate bilirubin and amylase. Chronic obstruction in the afferent limb also may result in a chronic diarrhea syndrome from bacterial overgrowth. Pancreatitis also has been reported.[54] Diagnosis of the afferent limb syndrome is often a clinical one. Radiographic studies, including upper gastrointestinal series or computed tomography with oral contrast administraton, often clearly delineate the problem and are usually diagnostic.

Treatment of afferent limb syndrome is reoperative, and the operative findings should dictate the procedure performed. If simple adhesiolysis resolves the problem, and the intestine is not chronically scarred and narrowed, that is all that is indicated. If the afferent limb is chronically scarred near the gastrojejunostomy, however, which is usually the case, surgical treatment is division of the bowel just proximal to the obstruction point and creation of a Roux-en-Y drainage of the stomach by reanastomosing the proximal end of the divided afferent limb to the jejunum 50 to 75 cm beyond the gastrojejunostomy. Closure of the mesenteric defect completes the procedure.

HOSTILE ABDOMEN

A taxing challenge a surgeon faces is the *hostile abdomen*. This term is used to describe an abdomen in which tissue planes are obscured, and bowel mobility is limited or absent. Severe scarring and carcinomatosis are the most common reasons for such an abdomen. Bowel obstruction is a common occurrence with abdominal or pelvic cancer. Patients develop an obstruction with a prevalence of 5.5% to 42% with ovarian cancer and 10% to 28.4% with colorectal cancer.[55] A complete obstruction requires operative intervention regardless of the patient's history. Most operative management of this situation would not involve reoperation on the stomach or duodenum, but often a gastrostomy tube is placed at the time of such procedures to help decompress the stomach; this may be the only option for patient palliation in the presence of an abdomen filled with carcinomatosis. Indications for placement of a gastrostomy tube are listed in Box 76–3. This is not a comprehensive list, but includes the most frequent indications for gastrostomy.

Gastrostomy tube placement is generally a straightforward procedure. Care must be taken to choose an area of the stomach that most easily reaches the anterior abdominal wall; this is usually the greater curvature area in the proximal body area of the stomach. The traditional Stamm gastrostomy serves adequately in almost all cases. Janeway gastrostomies, created from a greater curvature tube of stomach anastomosed to the skin, are indicated only as a permanent feeding access.

When encountering diffuse carcinomatosis in the setting of an obstructed gastrointestinal tract, the surgeon is wise to do as little as necessary and feasible to

Box 76–3 Indications for Gastrostomy

- As an alternative to nasogastric intubation during operations in which a prolonged postoperative ileus is expected
- As a means of long-term enteral access for patients who cannot eat without assistance
- For patients with obstructing lesions of the hypopharynx or esophagus
- As a reliable means of decompressing the stomach and giving enteral nutrition after esophageal and bariatric surgery
- Palliative decompression for distal obstructing lesions in which resection or bypass is not technically feasible or medically indicated

improve the patient's remaining time. Bowel obstruction in patients with metastatic cancer is often considered a relatively terminal event, with median survival following being 3 months.[56] Patients with terminal cancer who are unfit for an operation may benefit from nonoperative management of a malignant obstruction. Analgesics, antiemetics, and antisecretory medications have been shown to provide an alternative management of a chronic obstruction.[57] Surgery is an appropriate option in low-risk to moderate-risk patients. Only 30% of patients with malignant bowel obstruction have prolonged postoperative symptom relief after surgical intervention.[58]

When a lysis of adhesions is attempted in a patient with multiple previous operations, the patient is at great risk for multiple enterotomies. In contrast to an enterotomy during a standard dissection, an enterotomy in a "frozen abdomen" is much more hazardous. The bowel injury may be extremely difficult to close if the intestine cannot be safely mobilized to allow for adequate closure. Also, there is a slightly greater risk for luminal narrowing from a repair of a bowel injury that is poorly visualized and mobilized. When multiple enterotomies have been made, or no progress is being safely made, consideration must be given to backing out of the operation. This is a difficult decision for any surgeon to make. Although the original operative goals may not have been accomplished, consideration must be given to avoiding causing further morbidity to the patient.

Radiation Enteritis

Rainer K. Saetzler · Thomas Wiegel · Doris Henne-Bruns

Radiation therapy or combined chemoradiation therapy is a widely accepted adjuvant or neoadjuvant treatment modality for various tumors. Despite steady technical improvements in irradiation techniques, the major drawback is the unnecessary irradiation of normal tissue in close vicinity to the tumor, which can result in radiation toxicity such as radiation enteritis, an entity that can occur in an acute or chronic form.

This chapter attempts to shed some light on the pathogenesis of radiation-induced toxicities or complications and discusses possible future treatments for patients suffering from this condition. Moreover, new technical developments in radiation oncology and radiochemotherapy that will improve the protection of nonmalignant tissue and hence decrease the complication rate of radiation therapy without compromising the tumor-killing activity of these methods are discussed as well.

BACKGROUND

Radiation is a common adjuvant and, more recently, a neoadjuvant therapy in the multimodality approach to the treatment of various abdominal and pelvic cancers and has been proved in multiple studies to be an important tool for destroying cancer cells. Besides these beneficial effects, radiation also affects normal and healthy tissue surrounding the targeted tumor, such as the small and large intestine, liver, kidney, and lung.[1-9]

Radiation enteritis is one of the most feared complications of abdominal and pelvic irradiation. The mucosa and submucosal vasculature of the intestine are most sensitive to radiation and might sustain severe acute or chronic damage leading to malabsorption, strictures, and fistulas, with considerable impact on the patient's quality of life.[10]

The amount of radiation required to produce clinical signs of enteritis varies with the treatment regimen and from patient to patient. Because of the current trend of combined chemotherapy and radiation therapy, the incidence of radiation enteritis is increasing.[11]

Clinicians are usually confronted with the sequelae of early and late complications of radiation enteritis and therefore need a detailed understanding of the mechanisms leading to early and late radiation enteritis.

INCIDENCE

Radiation enteritis is a relentless disease process reflecting widespread bowel involvement. The first patient with radiation-induced enteropathy was described by Walsh in 1897, only 2 years after Roentgen's description of ionizing radiation.[12,13]

According to the literature, the exact incidence of radiation enteropathy is not known. However, since the 1980s, the incidence of acute enteritis appears to have increased because more than 50% of patients with cancer receive radiotherapy as a component of their treatment.[14-18]

The incidence of *acute* radiation enteritis shows great variation and has been reported in the literature as being between 20% and 80%.[19,20]

The exact incidence of *chronic* radiation enteritis remains controversial and ranges from 0.5% to 36% with an average of 5%.[16,21-23] However, the prevalence seems to be underestimated in the literature because of losing track of patients, patient death as a result of malignancies, and differences in treatment regimens.[12,15,22] Moreover, one has to bear in mind that this wide variation is also due to different factors such as radiation dose per fraction and total dose of radiation and to patient-related predisposing factors such as location and size of the treatment volume, hypertension, diabetes mellitus, and preexisting vascular or pelvic inflammatory disease.[16,24]

A total radiation dose of less than 4000 cGy (4000 rad) rarely causes deleterious effects on bowel mucosa and hence radiation enteritis (1 Gy is equivalent to 100 cGy or 100 rad).[15,16] If the dose does exceed 5000 cGy, the complication rate increases significantly. Doses of radiation producing clinical damage in up to 5% or in up to 50% of patients within 5 years are termed $TD_{5/5}$ or $TD_{50/5}$, respectively, depending on the volume of irradiated tissue. The range is 60 to 75 Gy for the esophagus, 45 to 50 Gy for the stomach, 45 to 65 Gy for the small bowel and colon, and 55 to 80 Gy for the rectum.[25]

In addition, the use of certain adjuvant chemotherapeutic agents such as 5-fluorouracil (5-FU), doxorubicin, actinomycin D, and methotrexate increase the likelihood of enteritis secondary to radiation therapy. A history of laparotomy and previous abdominal operations also increases the risk for enteritis, probably because of adhesions that tether portions of the small bowel into the irradiated field.

ETIOLOGY

Roentgen rays have their most destructive effect on rapidly dividing cells such as bowel epithelium, and as a consequence many of these epithelial cells die during radiotherapy. Cells in other tissues are sublethally damaged and die off later when entering the mitosis phase.

The pathophysiologic effect behind radiation-induced cell death is the deposition of energy in the anatomic structure of the chemical constituents of cells.[16] Disruption of the DNA helix or abnormal reconstitution of the genetic code will result in cell death or cell dysfunction. Radiation injury will subsequently occur in the mucosa, submucosa, muscularis propria, and serosa as a function of cell turnover in these tissue layers.

Therefore, three distinct phases of radiation effects have been identified:

1. *Acute phase:* primarily affecting the mucosa
2. *Subacute phase:* predominantly affecting the submucosa
3. *Chronic phase:* affecting all layers of the bowel wall

During radiation therapy, adjacent healthy tissues are invariably located within the irradiated field and therefore represent the main dose-limiting factor of radiation therapy. The small bowel appears to be one of the most radiosensitive organs of the abdomen because of the high number of proliferating cells, the extensive vascular network, and important metabolic activities.[16] However, its mobility seems to be somewhat protective. The most sensitive cells of the bowel wall are those of the crypt of Langerhans in the small intestine.

Late radiation injuries more frequently involve the immobile and fixed terminal ileum. Because the jejunum, except for its upper portion and the proximal ileum, is relatively protected by its mobility, repeated exposure of selected small bowel segment is avoided.[16,22]

Predisposing Risk Factors

Many factors are thought to predispose to radiation injury. Dose-escalating techniques in radiation oncology, combined with chemotherapy and thin-built patients, are associated with a higher risk of sustaining small bowel injury.[26,27] Thin patients, especially females, and the elderly have an increased amount of small bowel in the pelvic cul-de-sac.[12,26,28,29] They also have a decreased amount of subcutaneous tissue, which would allow greater depth of penetration of ionizing radiation.

Any previous operation or pelvic infection may cause intra-abdominal fixation of the small bowel and thereby expose the same segment of bowel to the radiation field. This situation is predominantly seen after rectal surgery because of the development of more adhesions as a result of a high level of physical injury to the gut serosa and increasing microbial leakage through the intestinal wall into the peritoneum, unsuccessful reperitonealization, and the impaired vasculature of small bowel loops in the sacral cavity.[30] Low splanchnic blood flow as seen in congestive heart failure or conditions associated with vascular occlusion or narrowing predisposes to radiation-induced injury. Moreover, DeCosse et al. demonstrated a significant association between hypertension, diabetes, and cardiovascular disease and the subsequent development of radiation enteritis.[31,32]

PATHOPHYSIOLOGY AND HISTOPATHOLOGIC FEATURES

The gut wall is damaged by ionizing radiation either directly or indirectly. The direct effect of intestinal irradiation is loss of regenerating cells within the crypts of the intestinal epithelium.[16,22,30,33] Indirectly, damage to the fine vasculature of the intestine may progress to obliterative vasculitis and cause ischemia of the bowel many years after radiation therapy.

Early Histologic Findings

The first 2 weeks after radiation therapy is characterized by four early histologic findings. The first is *mucosal ulceration*. In early stages these ulcers are small and shallow but get bigger and deeper in the later stages and thereby lead to perforation and fistulization. The second histologic feature consists of *epithelial atypia*. Radiation-induced fine mutation is the single important factor involved in malignant transformation of intestinal epithelium in humans. The third finding is termed *ileitis cystica profunda*, which is defined by the presence of cystic glandular structures in the intestinal wall below the muscularis mucosae. Its mechanism remains controversial, but it has been suggested that fragmentation of the muscularis mucosae leads to herniation of epithelium into deeper layers of the intestinal wall. Moreover, mucosal trapping during the re-epithelialization phase of deep ulcers has been proposed as a potential explanation. The fourth characteristic is *serosal thickening*. This finding reflects an increased amount of fibrous connective tissue and edema. Its pathogenesis, however, is controversial. It is believed that radiation-induced vascular permeability is followed by edema, intestinal protein deposition, and subsequent fibrosis. These histopathologic findings decrease gradually and remain constant for 20 weeks on. Other features such as vascular sclerosis, intestinal fibrosis, and lymph congestion are virtually absent at 2 weeks but with time increase and reach a constant level 8 to 14 weeks after irradiation.

Late Histologic Findings

Late histologic features include three distinct entities. The first is characterized by vascular sclerosis. The struc-

tural and functional alterations in blood vessels consist of three stages: *early* (hours to days after irradiation), *intermediate* (4 weeks after irradiation), and *late* (4 to 6 months after irradiation). During the *early stage* an inflammatory reaction takes place with deletion of capillaries secondary to substances released by the damaged endothelial cells. The *intermediate phase* is characterized by destruction and obliteration of capillaries, sloughing of endothelial cells, and the formation of focal thrombi. Plasma proteins accumulate in the extravascular space and possibly lead to hyalinization, which is also seen histologically. In the *late phase* several histologic entities are observed, such as necrosis of the vessel wall, ulcerations, and thrombosis. Thickening of the vessels and media necrosis induce total vascular occlusion and disruption. The second late histologic finding is *intestinal wall fibrosis* as a result of deposition of collagen in the intestinal wall. Several pathophysiologic mechanisms have been discussed and are briefly outlined. Radiation has a direct effect on collagen and components of the extracellular matrix such as glycosaminoglycans. Cell injury or cell death involved in the production or degradation of collagen leads to fibrosis. Moreover, vascular and lymphatic damage contributes to the ongoing fibrosis. Some authors suspect nonspecific inflammatory or autoimmune processes. The third characteristic is *lymph congestion*. Loss of the epithelial barrier of the bowel leads to exposure of deeper layers of the bowel wall to intraluminal contents, which induces a severe inflammatory reaction. In late radiation enteropathy, fibrotic constriction of lymph vessels, rather than their direct damage, is the cause of obstructed lymph flow and consequent dilation.

MOLECULAR BIOLOGY OF RADIATION ENTERITIS AND MICROCIRCULATION

Recent progress in molecular biology has led to new concepts of the pathogenesis of radiation enteritis. The first concept involves *apoptosis,* which is defined as an active mode of cell death characterized by chromatin and cytoplasmic condensation as a result of the activation of DNA endonucleases and transglutaminases. It is controlled by regulatory genes such as *p53, bcl-2, ced-3, ced-4,* and *ced-9.* Under normal physiologic conditions, both small intestinal and colonic epithelia undergo a low rate of spontaneous apoptosis.

Animal experiments have shown that exposure to low-dose radiation leads to an increase in the rate of apoptosis of intestinal crypt cells, especially stem cells of the crypts. The rate of apoptosis was dose dependent and depended on the expression of tumor suppressor genes in stem cells.[34-36]

Paris et al. demonstrated in mouse models that microvascular endothelial cell apoptosis is the primary lesion leading to stem cell dysfunction.[37]

Garcia-Barros et al. provided evidence that tissue and tumor response to radiation is also determined by microvascular sensitivity to radiation. Their studies indicated that microvascular damage in response to radiation occurs at clinically relevant dose ranges.[27] Another concept comprises the pathogenesis of fibrosis. Herskind et al. investigated the role of cytokines in radiation enteritis.[38] They found that transforming growth factor β (TGF-β) is of particular importance in extracellular matrix deposition and development of tissue fibrosis.

Ionizing radiation activates translation of the gene coding for TGF-β. Radiation induces the formation of hydroxyl radicals that stimulate the production of TGF-β_1. This cytokine remains elevated even at 26 weeks after radiation, especially in vascular endothelial cells, fibroblasts, and smooth muscle cells and is mainly implicated in the pathogenesis of fibrosis.[39,40] Immunohistochemical studies of bowel mucosa showed that TGF-β_1 is primarily located in intestinal villi or at the top of colonic crypts.[41-43] Animal experiments demonstrated increased TGF-β immunoreactivity in the small intestine. It acts as a potent fibrogenic and proinflammatory cytokine that leads to connective tissue hyperplasia and increased leukocyte migration and activation in the intestinal wall.[44] The molecular or chemical inhibition of TGF-β_1 caused less structural injury and significantly decreased intestinal wall fibrosis when exposed to high doses of radiation.[44] Further studies have demonstrated a prominent role of TGF-β in the pathogenesis of not only radiation-induced enteritis but also radiation-induced organ dysfunction and fibrosis.[1-9] These radiation-induced processes are strikingly similar to the pathogenesis of known clinical entities characterized by an excess of fibrosis, such as scleroderma,[45-47] idiopathic pulmonary fibrosis,[48-50] diabetic nephropathy,[51] and membranous glomerulonephritis.[52]

RADIATION AND THE MICROCIRCULATION

Recent evidence showed that radiation is leading to significant microcirculatory perturbations, eventually causing microvascular dysfunction and organ damage. It was demonstrated that irradiation causes an increase in leukocyte–endothelium interaction and vascular permeability, a similar process seen during inflammation or ischemia/reperfusion injury. [45,53-62] This finding was also substantiated in histologic studies in which irradiated intestinal tissue showed a significant interstitial accumulation of polymorphonuclear leukocytes.[63] The inhibition of leukocyte adhesion to endothelial cells through the administration of antibodies directed toward specific adhesion molecules resulted in a significant reduction in radiation-induced tissue damage.[45,53-58,62,64] This radiation-induced intestinal inflammatory process at the microcirculatory level was also inhibited by the application of oxygen–free radical scavengers such as SOD.[65]

NATURAL HISTORY AND CLINICAL FEATURES

According to the aforementioned pathologic changes, radiation enteritis is manifested as acute radiation enteritis or late radiation enteropathy with early and late symptoms, respectively.

The *acute phase* occurs during the course of irradiation and results from direct radiation-induced depletion of the actively proliferating intestinal crypt cells with concomitant inflammation of the lamina propria. The clinical symptoms of acute radiation enteritis consist mainly of diarrhea, abdominal pain, anorexia, malaise, and vomiting, all of which are usually self-limited. These symptoms disappear after 2 to 6 weeks and require only symptomatic treatment. They are dependent on the rate and duration of time over which radiation is applied rather than on the total dose. This stage frequently remains subclinical despite marked mucosal damage.

The symptoms of *late radiation enteropathy* occur after a variable latency period averaging 2 to 3 years with a range of 6 months to 20 years. The symptoms are the result of progressive occlusive vasculitis and diffuse collagen deposition and fibrosis.

Symptoms of late radiation enteritis consist of abdominal pain as a result of obstruction secondary to radiation-induced strictures or perforation and necrosis. The onset of symptoms is often insidious, and they are mostly due to changes in intestinal transit and include intermittent diarrhea and constipation. Fistulization between the bowel and pelvic organs, such as the bladder, vagina, or other bowel segments, causes pneumaturia, feculent vaginal discharge, and rapid passage of undigested food in stool, respectively. Moreover, intestinal malabsorption, bile salt malabsorption, anemia, and hypoalbuminemia have been observed. Multiple segments of small bowel can be involved simultaneously.[14]

Abscesses can occur as well, usually in the pelvis, and may cause signs of sepsis. Intestinal perforation may cause acute peritonitis, but this complication is uncommon. Significant intestinal bleeding occurs rarely as a result of ileal ulcerations, but rectal bleeding from radiation proctitis is relatively common.[66]

A four-point injury scale from 0 to 4 has been introduced by O'Brian et al.[30] for the classification of radiation-induced bowel injury: *0,* no complaints; *1,* mild diarrhea (controlled by diet and reassurance); *2,* marked diarrhea and rectal pain, which are relieved by antidiarrheal pain medications or antibiotics; and *3,* severe complications, including fistula formation, perforation, or stricture. The Radiation Therapy Oncology Group (RTOG) introduced a gastrointestinal morbidity scoring system with five grades: *0,* no symptoms; *1,* mild diarrhea, cramping, bowel movements five times daily, slight rectal discharge; *2,* moderate diarrhea and colic, bowel movements more than five times daily, excessive rectal mucus or intermittent bleeding; *3,* obstruction or bleeding requiring surgery; and *4,* necrosis, fistula, or perforation.

It is important to stress that radiation can lead to the development of secondary radiation-induced malignancies, synchronous radiation lesions, or recurrent malignant disease.[67-77] The pathophysiologic mechanisms of radiation-related carcinogenesis and malignant transformation have been studied intensively.[78,79] In a series of 51 patients, Galland and Spencer reported that 47% remained symptom-free at a median follow-up of 1 year. In the remainder, new radiation-related GI problems developed. In none of the patients who were initially seen with bleeding did new problems develop. In comparison, 33% of the patients with strictures and 89% of those with perforation or fistula formation went on to manifest new lesions. Patients whose initial manifestation was fistulas also appeared to be at increased risk of having synchronous radiation lesions at the time of diagnosis. These patients were at increased risk of dying as a result of recurrent malignant disease within a relatively short period.[26-29,80]

Associated collateral radiation damage, frequently underestimated, has been described in the urinary tract system, specifically in the bladder. Other injuries include radiation myelitis, osteitis pubis, pathologic fractures, and atheromatous changes in blood vessels within the radiation field.[32]

Most deaths are due to recurrent disease or the effects of radiation on the gut. Galland and Spencer reported in their study that radiation enteritis was responsible either directly or indirectly for the death of 23 of the 37 patients who died. Nine of these patients died with no evidence of their original tumor.[26,27]

DIAGNOSIS

Establishing the diagnosis of radiation enteritis can be challenging and should include a detailed history and physical examination, followed by laboratory tests and radiologic imaging studies.

The clinical findings in a patient suffering from radiation enteritis can range from subtle symptoms to malabsorption and bowel perforation, as described earlier in the section on natural history. The physician should be guided by a high index of suspicion and eliminate all possible differential diagnoses.

A complete blood count should be obtained when patients are bleeding or suffering from malabsorption. Moreover, a metabolic panel is essential for patients with vomiting or diarrhea. To establish the cause of diarrhea, stool cultures should be obtained, as well as stool volume and stool fat studies. Measurement of bile acid absorption by synthetic gamma-labeled bile acid might be useful.[81] Its absorption and enterohepatic circulation are identical with that of taurine-conjugated bile acids; however, it cannot be deconjugated. Therefore, its absorption is sensitive and specific for terminal ileal function. However, this test is cumbersome to perform and not usually available for clinical use on a routine basis. Measurements of changes in intestinal permeability may be useful in the diagnosis of chronic intestinal damage. Intestinal permeability to large molecules such as chromium-ethylenediaminetetraacetic acid is increased in acute radiation enteritis, but there have been no reports on chronic radiation enteritis.[82]

An acute abdominal series is needed to evaluate for obstruction and ileus. Barium contrast studies provide better mucosal detail and can identify areas of stricture, as well as fistulas. Mendelson and Nolan and Sellink and Miller described the radiologic findings after a single-contrast barium infusion technique, enteroclysis.[83,84] This method seems to be more sensitive and specific for radiation-induced changes and has been shown to be superior to the conventional follow-through examination in demonstrating stenotic segments and mucosal pathol-

ogy because of optimal bowel distention.[20,83] In addition, information regarding GI motility can be obtained. However, with the advancement of modern technology, these small bowel imaging studies have been partially replaced by MRI-enteroclysis, multislice CT-enteroclysis, and sono-enteroclysis.[63,85-87]

Abdominal and pelvic CT scans are the best studies to confirm obstruction and perforation and to exclude extraintestinal processes, including possible abscesses.

Endoscopy allows mucosal biopsy, which can reveal classic histologic changes consistent with radiation injury, as described earlier.

Many studies have addressed the radiologic features of chronic radiation enteritis in an attempt to identify specific radiologic signs.[19,88,89] Many of them used barium follow-through techniques, whereas others used enteroclysis as the preferred method.

A pathologic fold pattern in the ileum as a result of submucosal edema was observed in 71% of patients.[19] Approximately 50% of patients had no fold pattern at all because of mucosal atrophy. Mural thickening and stenosis were also found. More than 70% of patients showed delayed intestinal transit with dilatation of the jejunum and proximal ileum. These findings were associated with hypoperistalsis of the affected ileal loops. More than half of the patients showed dilatation of the proximal ileum with a maximum diameter of 60 mm. In more than two thirds of all cases an associated dilatation of the jejunum was noted. Radiologic features reflecting the presence of adhesions are known as fixed bowel loops that can be displaced only by deep palpation or as mucosal tacking associated with focal adhesions.

Puddling of barium in the terminal ileum or a segmental saw-toothed appearance of the small bowel is commonly seen. Kinking of bowel loops was attributed to by some authors to mesenteric shortening or adhesions and wall thickening.[83,88,89]

Multiple studies, however, have shown that the extent of the disease is clearly underestimated by radiologic methods when the radiographic results are compared with data obtained during laparotomy. Nonetheless, there is good correlation between intraoperative and radiologic findings with regard to the presence and site of strictures and adhesions.[83] Poor correlation was observed for peritoneal metastases extrinsic to the bowel wall.[20]

PROGNOSIS

It is generally believed that radiation enteritis is a progressive disease. The median latent period between radiation therapy and intestinal symptoms is usually 6 to 24 months with a range between 1 month and 37 years.[27-29,45,90]

Gilinsky et al. reviewed patients with radiation-induced proctosigmoiditis and found that those who had not received blood transfusions had a higher rate of spontaneous remission. In contrast, patients whose symptoms were so severe that transfusions were required rarely experienced remissions and were more likely to undergo surgery.[91] Galland and Spencer reported new radiation-induced GI problems in 39% of patients (20 of 51). Ten patients underwent surgery, 5 of whom died.[16]

No new problems developed in patients whose initial manifestation was bleeding, as opposed to 33% of patients with strictures and 89% of patients with perforation or fistula formation as their initial symptom.[27] Harling and Balslev found cumulative 10-year survival rates of 37% and 64% in patients with perforation or fistula versus bleeding or stricture.[27]

Hatcher et al. made similar observations that patients whose initial manifestation was fistulas appear to be at increased risk of having synchronous radiation lesions at the time of diagnosis, as well as at increased risk of dying.[80] They estimated that additional complications become apparent in about half of those surviving the initial lesion. Harling and Balslev found in their study that during an observation period of 14 years (from 1972 to 1986), 23% of all deaths (13 of a total of 75 deaths) were related to radiation complications and 47% were due to recurrent malignant disease.[90] The cumulative 10-year survival rates were 58% for the entire series of 136 patients, not including those who died from radiation enteritis.[90] However, the 10-year survival rate of patients presenting with bowel perforation or fistulae compared to those presenting with bleeding or stricture was 37% and 64%, respectively.[90]

All investigative groups have confirmed that the risk for new radiation-induced lesions is greater in patients who initially have perforation or fistula than in patients with initial bleeding or stricture. Moreover, life expectancy was poorer in patients with fistulas. The presence of a fistula seems to imply wider dissemination of the destructive process and an excessive rate of recurrent disease.[26,80] However, Perez et al. did not support this finding.[92]

Galland and Spencer and Harling and Balslev reported a 40% to 60% 5-year survival rate.[26,90] Galland and Spencer showed that radiation enteritis was responsible either directly or indirectly for the death of 23 of 37 patients. Nine of these patients had no evidence of their original tumor.[26] It has also been reported that small bowel injuries carry more than four times the mortality than colorectal injuries do[93]; however, this observation was not confirmed by others.[94]

Regimbeau et al. estimated that approximately one third of all patients suffering from chronic radiation enteritis will need to undergo surgery at one point.[23] Furthermore, they found that reoperation was more common in the conservative surgical group of patients who did not undergo bowel resection (50%) compared to those patients who underwent bowel resection (34%).[23] Reoperations were associated with a higher mortality rate overall.[23]

Libotte et al. reviewed the clinical and survival data of 108 patients with radiation enteritis at a median follow-up of 11 years. The median time of occurrence of severe radiation-induced lesions (obstruction, perforation) after radiotherapy was 18 months, 9 months for rectal bleeding and 10.5 months for mild symptoms.[95] They showed that patients with rectal bleeding had a poorer prognosis than did those with mild symptoms but an equivalent prognosis to patients with severe complications.[95]

The development of radiation-induced malignancy is a pivotal factor in the patient's prognosis. It has been shown experimentally that colonic adenocarcinoma will

develop in 47% of rats after having been exposed to 4500 rad.[96] Galland and his group examined colonic resection specimens from 26 patients with radiation-induced colitis and found a significant increase in the prevalence of dysplasia and other premalignant changes.[27,97] The relative risk for the development of colonic carcinoma after radiotherapy has been calculated as being 2 to 3.6 in women who undergo irradiation for gynecologic cancer.[98]

MANAGEMENT OF RADIATION ENTERITIS

Methods of Prevention

Prophylactic measures that help reduce the incidence of radiation enteritis include methods to exclude the small bowel from the pelvis, such as reperitonealization, omental transposition, or placement of absorbable mesh slings.[99-101] The small bowel is a mobile structure that can be altered by a variety of positions and techniques, including the prone, Trendelenburg, and decubitus positions.[14] Das et al. studied the efficacy of a belly board device that resulted in a 70% reduction in small bowel volume within the irradiated pelvic field.[102] Ferguson described the use of omental pedicle grafts.[103]

The use of radioprotectant chemicals during radiotherapy is an evolving strategy of clinical importance. Amifostine was the first cytoprotectant approved by the Food and Drug Administration for ovarian cancer patients receiving cisplatin-based chemotherapy and for the prevention of xerostomia in patients undergoing radiation therapy for head and neck cancer.[104-106] The protection of normal cells is believed to occur predominantly by scavenging of free radicals. Active metabolites of amifostine react with free radicals in competition with oxygen.[107] Pretreatment with amifostine in clinical trials reduced the frequency of cyclophosphamide-induced neutropenia and nephrotoxicity and the neurotoxicity of platin compounds.[108] Halberg et al. reported that the intraluminal administration of amifostine during intraoperative radiation therapy produced localized radioprotection and reduced duodenal damage.[109] Despite all these promising results, there is still controversy regarding the selectivity of amifostine because some studies have shown variable degrees of tumor protection as well.[110,111] A few phase I and II studies suggest that amifostine could be beneficial in limiting the radiation damage.[112] Superoxide dismutase, a free radical scavenger, has been used successfully to reduce radiation-induced complications.[65]

Numerous pharmacologic interventions have been reported to reduce the symptoms of radiation enteritis. Diarrhea associated with abdominal irradiation has been positively affected by sucralfate. A randomized, placebo-controlled trial of 70 patients who were treated by pelvic irradiation for bladder and prostate cancer showed that patients who received sucralfate during radiation therapy had statistically significant reductions in both the acute and chronic symptoms of radiation enteritis when compared with patients who received placebo.[113,114]

Glutamine-enriched enteral formulas, as well as hormones such as bombesin, growth hormone, glucagon-like peptide 2, and insulin-like growth factor 1, have proved useful in preventing symptoms of acute radiation enteritis.[115-117]

Novel Techniques in Radiotherapy and Combined Radiotherapy/Chemotherapy

The goal of all new technologic changes in the field of radiation oncology is to allow safe administration of greater radiation doses to the tumor and achieve an increased rate of cure with acceptable normal tissue toxicity. The irradiation technique must prevent unnecessary irradiation of tissues outside the tumor-containing areas.

Radiation enteritis can be minimized by using special ports to deliver optimal treatment specifically to the tumor and not to the surrounding tissues. Radiopaque markers such as titanium clips could be placed during laparotomy to further delineate and identify the area of interest for future, more targeted radiation therapy.

Frykholm et al. have found that technically, a two-field radiation approach cannot spare the surrounding tissues to the same extent as three or four fields can,[118] and hence two types of conformal radiation therapy have evolved and been introduced into clinical practice*: three-dimensional conformal radiation (3DCRT)* and *intensity-modulated radiation therapy (IMRT).*

Traditional radiation therapy techniques, including 3DCRT with uniform radiation intensity or with simple beam fluence–modifying devices such as wedges, do not provide a method for sparing critical structures that push into the target or that are partially or fully surrounded by a target or combination of targets. True 3DCRT dose distributions are now possible, in large part because of continuing advances in computer technology that have led to the development of sophisticated *three-dimensional radiation treatment planning (3DRTP)* systems with inverse planning capabilities and computer-controlled radiation therapy delivery systems equipped with a multileaf collimator. Such planning and delivery systems have made the implementation of 3DCRT with modulated radiation fluence practical. The ultimate goal of 3DCRT is to conform the spatial distribution of the prescribed dose to the three-dimensional target volume (cancerous cells plus a margin for spatial uncertainties) while at the same time minimizing the dose to surrounding normal structures (RTOG, The National Cancer Institute Guidelines for the Use of Intensity-Modulated Radiation Therapy in Clinical Trials).

IMRT represents a new paradigm in radiation therapy that requires knowledge of patient immobilization, multimodality imaging, setup uncertainties and internal organ motion, tumor control probabilities, normal tissue complication probabilities, three-dimensional dose calculation and optimization, and dynamic beam delivery of nonuniform beam intensities. This new process of planning and treatment delivery shows significant potential for further improving the therapeutic ratio and reducing toxicity. The radiation beam is broken into beamlets for which the intensity can be adjusted individually. Up to now, however, it is not clear whether IMRT will fulfill the expectations that it has raised,[119,120] and hence further studies need to be conducted and evaluated.

Adjuvant (postoperative) and *neoadjuvant* (preoperative) radiotherapy for resectable rectal cancer, for example, has been studied extensively.[17,121-125] In terms of neoadjuvant therapy, a meta-analysis of 4000 patients found that both a *short-term course* (25 Gy in 5 fractions, common approach in Europe) and a *long-term course* (45 Gy in 25 fractions, commonly applied in the United States) of radiation therapy were equally effective in reducing local recurrence.[126,127] Neoadjuvant radiation therapy using 25 Gy with daily fractions of 5 Gy, administered within 1 week followed by surgery the next week, is a widely used treatment for patients with resectable rectal cancer.[18,121,128,129] Nevertheless, the high dose per daily fraction (5 Gy) led to significant impairment of bowel function.[130]

This regimen was changed to 2.5 Gy per fraction twice daily for 5 days preoperatively and provided excellent results in terms of local tumor control without marked late morbidity. This modification was called non–down-staging *hyperfractionation* and was thought to be safe for the treatment of selected patients. Hypofractionation with greater doses per fraction led to an increase in the occurrence of radiation-induced damage.[131]

Kupelian et al. reported a clinical trial of 166 patients with early-stage prostate cancer who were treated with hypofractionated intensity–modulated radiotherapy delivering 2.5 Gy/fraction (total of 70 Gy) in comparison to 116 patients who were treated with 3DCRT delivering 2.0 Gy/fraction (total of 78 Gy). Rectal toxicity was observed in only 5% of patients treated with IMRT as compared with 12% in a group of patients treated with 3DCRT.[132]

The German Rectal Cancer Study Group trial published by Sauer et al. provided evidence that preoperative or neoadjuvant chemoradiation has numerous potential advantages over postoperative chemoradiation, such as less toxicity, a lower incidence of radiation enteritis, a lower rate of local recurrence, and a lower rate of anastomotic stricture after surgery.[17,133] It was suggested that this should be the preferred treatment for patients with locally advanced and low-lying rectal cancer. The theoretical background for the advantage of preoperative radiotherapy in comparison to postoperative treatment has been discussed in various publications.[121,122] Despite all positive aspects of preoperative chemoradiotherapy in the treatment of rectal cancer, Sauer et al., for example, pointed out the possibility of overtreating early-stage tumors (TNM stage I). Despite the use of endorectal ultrasound, approximately 18% of the patients (stage I) had been over-staged during the initial evaluation and received unnecessary postoperative chemoradiotherapy.[17,134] The percentage of unnecessary postoperative chemoradiation was even higher if those patients with stage IV disease (7%) and those with unknown TNM stage (6%) were included. This important issue illustrates the importance of correct preoperative clinical staging, which might improve with the additional use of MRI, leading to better patient selection.[135]

Preoperative combined-modality treatment with conventional radiation doses and fractionation plus concurrent 5-FU–based chemotherapy has yielded better results than preoperative radiation therapy has alone.[17,18,133] Patients with clinical T3 rectal tumors or positive lymph nodes, or both, are commonly treated with combined-modality treatment, followed by surgery and four cycles of postoperative chemotherapy.[136,137] This concept, however, is not completely accepted and is being currently investigated as part of the European Organization for Research and Treatment of Cancer (EORTC) trial.[104,138-140]

Other studies have investigated the effect of conventional fractionation, hypofractionation, accelerated and hyperfractionated regimens, and radiation dose escalation techniques and found that with concurrent chemoradiotherapy, either the dose of the chemotherapeutic drug or the radiation dose needs to be reduced to avoid significant GI complications such as ulceration or hemorrhage without affecting the tumoricidal effects of both radiation therapy and chemotherapy.[119,141-145]

New drug-radiation combinations with such drugs as *capecitabine, raltitrexed, oxaliplatin,* and *irinotecan* are currently being investigated in several trials.[145,146] In addition to these cytotoxic drugs, novel targeted biologic agents, including *epidermal growth factor inhibitors* and *vascular endothelial growth factor inhibitors,* have been shown to enhance the antitumor effect of both radiation therapy and chemotherapy.[146]

The time interval between the completion of radiation therapy and definitive surgery turned out to be a pivotal factor for achieving maximal tumor response to radiation in order to achieve R0 resections or perform sphincter-sparing operations.[147,148] Grann et al. recommended a minimum of 4 weeks.[147] This was supported by the Lyon R90-01 randomized trial.[149] Beets-Tan and coworkers determined the applicability of MRI in predicting tumor-free resectability of the primary lesion.[150]

Because pancreatic cancer is only moderately sensitive to radiation, doses of 50 to 50.4 Gy can be applied safely in combination with chemotherapy. Early experimental trials initially stated that doses of 70 Gy and higher can be administered to patients with pancreatic cancer when given without chemotherapy.[145,151] However, at these high doses, the radiosensitivity of adjacent organs considerably limited the option of percutaneous radiation therapy. A significant number of radiation-induced toxicities occurred.[151] Moreover, radiotherapy alone did not improve the overall survival rate. *Intraoperative radiation therapy (IORT)* using fast electrons allows the application of high radiation doses to the tumor and tumor bed while protecting adjacent organs and tissues.[152] However, such treatment did not translate into improved overall survival rates. Nevertheless, IORT might help reduce the percutaneous radiation dose to 40 to 50 Gy, thereby significantly reducing the frequency of radiation-induced toxicity.[152]

Treatment Options

Conservative/Symptomatic Management

Treatment of acute radiation enteritis is directed toward controlling the symptoms.[81] Antispasmodics and analgesics, including opiates, may alleviate the abdominal pain and cramping. The use of steroids is of uncertain value. Conservative measures such as the administration of intravenous fluids, bowel rest, and antidiarrheal drugs are indicated.[30,153] Dietary manipulation, including oral

elemental diets, has been advocated to ameliorate the symptoms of radiation enteritis. Diets low in milk, fat, and lactose had beneficial effects in patients with acute radiation enteritis.[12] Loiudice and Lang showed that administration of total parenteral nutrition (TPN) to patients with chronic small bowel problems was superior to a low-residue diet in clinical improvement and immunologic and radiologic parameters.[154] The addition of methylprednisolone appeared to enhance the effects of TPN.[12,154-156] In contrast, Silvain and co-workers found that TPN alone was not superior to surgical management, with clinical radiation enteritis recurrence rates of 34% and 47% at 1 and 2 years, respectively.[157] Although TPN corrected nutritional deficits effectively and deferred surgery in some patients, radiation enteritis remains an unpredictable progressive disease.[157]

Acute enterocolitis may be mediated by prostaglandin, at least in part. In a small prospective study, Mennie et al. found that aspirin as an inhibitor of prostaglandin E synthesis caused a significant decrease in diarrhea and abdominal pain.[158] Cholestyramine (4 to 12 g/day), which binds bile salts, has also been found to be effective.[159] Kilic et al. reported that sulfasalazine (2 g/day) was effective in reducing the symptoms of acute radiation enteritis.[160] Probiotics have been found to be effective in preventing various gastrointestinal diseases, especially radiation-induced enteritis.[161]

In the acute phase of radiation proctitis, hydrophilic stool softeners may help control mucous diarrhea, whereas sitz baths and perineal compresses have been used in an attempt to ease tenesmus if analgesics fail. Steroid retention enemas are helpful for both acute and chronic radiation proctitis. Jacobs et al. found that the administration of oral or rectal Salazopyrin alleviated the symptoms of acute and chronic radiation proctitis in 37 of 40 patients.[162] Moreover, hemorrhagic radiation proctitis can be alleviated by the topical application of formalin. If the bleeding is refractory to local formalin treatment, argon plasma coagulation has been shown to be an effective and safe treatment.[163-165] In addition, bipolar electrocoagulation or endoscopic laser coagulation has been described for the management of hemorrhagic radiation injury or radiation-induced mucosal vascular lesions.[166,167]

Surgical Management

Before definitive surgical treatment is considered, it is important that the extent of both the original malignancy and the radiation damage be established and any sepsis, malnutrition, or biochemical abnormalities be corrected.[35]

Radiation enteritis is one of the most challenging problems in GI surgery. The operations are complex and prone to complications.[168]

Operative interventions may be required in only a subgroup of patients with chronic effects of radiation enteritis. This subgroup of patients represents just a small percentage (2% to 3%) of the total number of patients who have undergone abdominal or pelvic irradiation.[153]

Indications for surgery include obstruction, fistula formation, perforation, and bleeding. Complete bowel obstruction as a result of strictures is the most common indication for surgery. Surgeons are frequently confronted with dense adhesions, unexpected problems, and fragile irradiated tissues that are difficult to handle and poor to heal.[153]

Caution must be exercised when operating on patients with previously irradiated bowel because the vascular injury may be widespread and not readily recognizable by gross inspection of the intestine. The risk for dehiscence of the anastomosis, however, is not negligible. Extensive adhesiolysis should be avoided if possible. Perforation should be treated by resection and anastomosis. When the anastomosis is thought to be unsafe, ostomies should be created. The utility of frozen section or laser Doppler flowmetry for assessment of blood flow at the anastomosis site is of limited value.[169]

Bowel perfusion at the resection borders is usually assessed by gross examination, color, capillary refill, and bleeding tendency, depending on the surgeon's experience.

If resection and anastomosis are planned, at least one end of the anastomosis should be from intestine outside the irradiated field. An incidence of anastomotic breakdown as high as 50% has been reported after resection and anastomosis involving diseased segments of bowel because of the poor healing properties of irradiated tissue.[28,29]

In a retrospective analysis from 1970 to 1982, Wobbes et al. showed 27 patients who were operated on for stenosis, perforation, fistulization, and chronic blood loss of the small bowel after radiotherapy for malignant disease.[170] Bypass procedures in the form of ileotransversostomies were performed on 20 patients who presented with either obstruction or fistulization. Two patients died postoperatively. In contrast, 4 of 7 patients who underwent bowel resection for perforation, fistulization, or obstruction died of intra-abdominal sepsis. The researchers concluded that a bypass procedure should be performed if possible. In case of resection, the anastomosis should be done during a second operation. Obstruction caused by rigid and fixed pelvis incorporating small intestinal loops is best treated by bypass procedures.

Regimbeau et al. retrospectively studied 109 patients, from 1984 to 1994, who were operated on for radiation enteritis. Of these patients, 68% had been irradiated for gynecologic carcinoma, 28% for digestive cancer (24 colorectal cancer and 4 anal cancer), 7% for urologic carcinoma, and 4% for Hodgkin's disease, cutaneous neoplasia, and soft tissue carcinoma.[23] The operative mortality was approximately 5%. Thirty-three patients (30%) experienced postoperative complications, including anastomotic leak in 11 patients. Overall survival, after a mean follow-up of 40 months in patients without cancer recurrence, was 85% at 1 year and 69% at 5 years after surgery. Overall survival was influenced by the nature of the treatment, with 51% and 71% 5-year survival after conservative and resection treatment, respectively. Despite high initial mortality and morbidity rates, life expectancy in patients who underwent bowel resection was superior to conservative surgical treatment.[23] They and other investigators said that bypass procedures are associated with a higher relative risk of radiation-induced cancer in the irradiated bowel that is not resected but left in place.[27,98] However, the bypass operation is a valid surgical alternative for patients with high risk of short-gut

syndrome and poor medical condition.[23] Regimbeau et al. mentioned in their publication that reoperation after the first surgical procedure was mandatory for approximately 40% of their patients because of recurrence of gastrointestinal symptoms. The mortality and morbidity rate was higher for those patients. They also found a higher reoperation rate among patients who were treated conservatively without resection of small bowel.[23] Onodera et al. retrospectively analyzed 48 patients who underwent small bowel resection for intestinal obstruction and pull-through reconstruction for proctitis. They postulated that generous small bowel resection of affected bowel is a safe procedure for small bowel injury, whereas rectal resection is best dealt with by restorative proctectomy.[171]

Multiple resections and bypass of large segments of intestine will eventually place the patient at risk for short-bowel syndrome, as well as dependence on TPN. The use of TPN has been described as a life-prolonging measure; however, the long-term outcome of patients who have radiation enteritis and receive home TPN is dismal, with 5-year survival rates of only 36%.[157] Most of these patients died because of complications due to radiation therapy. The others had cancer recurrences.

In a retrospective study, Scolapio et al. reviewed 225 patients requiring home TPN for various diseases; 32 patients suffered from radiation enteritis. The overall 5-year survival probability was 60%, irrespective of age and underlying disease. The 5-year survival of patients with home TPN suffering from radiation enteritis was only 54%.[172] Therefore, efforts to preserve the remaining intestinal length may be warranted in an attempt to avoid the metabolic and nutritional consequences of further major resections or bypass procedures. Dietz and co-workers presented the use of strictureplasty for the management of patients with obstructing complications of radiation enteritis.[172] Three patients presented with small bowel obstruction and enterocutaneous fistula, two patients with chronic small bowel obstruction and rectovaginal fistula. Four patients required home TPN. Strictureplasty was successfully performed on all patients. All patients who were dependent on home TPN were eventually weaned from TPN. The authors pointed out that strictureplasty procedures should not be recommended as a primary surgical procedure for the treatment of perforation, hemorrhage, or fistula. It may be considered a useful option if resection would be likely to induce short-bowel syndrome.[173]

SUMMARY

Radiation enteritis is a serious complication of abdominal or pelvic irradiation and should be understood as a progressive and chronic disease with early and late clinical symptoms. The clinical manifestations range from mild diarrhea to severe complications such as bowel obstruction, fistula formation, and hollow viscus perforation. Management of this relentless disease varies from supportive care to surgical intervention, depending on the initial clinical symptoms. New molecular and microcirculatory insights into the pathomechanism of radiation enteritis can lead to novel therapeutic concepts for preventing rather than treating this relentless disease.

Improved long-term survival after radiotherapy should be achieved primarily by better tumor control. The use of novel techniques in radiation oncology, such as IMRT combined with new cytotoxic and biologic agents, might lead to improved protection of nonmalignant tissue without compromising the tumor-killing activity of these methods. Other methods such as hypofractionation, accelerated and hyperfractionated regimens, concurrent chemoradiotherapy, and neoadjuvant and adjuvant chemotherapy might help reduce GI complications without affecting the tumoricidal effects of the therapy.

Short-Bowel Syndrome

Jon S. Thompson ▪ Alan N. Langnas

Intestinal failure refers to a condition that results in inadequate digestion or absorption of nutrients, or both, so that an individual becomes malnourished and requires specialized medical and nutritional support.[1] Short-bowel syndrome is a type of intestinal failure caused by a shortened remnant after intestinal resection. The pathophysiologic changes that occur in short-bowel syndrome relate primarily to the loss of intestinal absorptive surface and more rapid intestinal transit (Box 78–1). The consequences of malabsorption of nutrients include malnutrition, diarrhea, steatorrhea, specific nutrient deficiencies, and fluid and electrolyte abnormalities. These patients are at risk for other specific complications, including an increased incidence of nephrolithiasis, cholelithiasis, and gastric hypersecretion. The clinical manifestations of short-bowel syndrome vary greatly among patients and depend on intestinal remnant length, location, and function; the status of the remaining digestive organs; the presence or absence of the ileocecal valve; and the adaptive capacity of the intestinal remnant. Thus, short-bowel syndrome is not entirely dependent on a given length of remaining intestine.

The prevalence of short-bowel syndrome is 3 to 4 per million, and thousands of patients are now surviving with short-bowel syndrome.[1] This condition occurs in about 15% of adult patients who undergo intestinal resection, with three fourths of these cases resulting from massive intestinal resection and one fourth from multiple sequential resections.[2] Massive intestinal resection continues to be associated with significant morbidity and mortality, primarily related to the underlying diseases necessitating resection.[2,3] About 70% of patients in whom short-bowel syndrome develops are discharged from the hospital, and a similar percentage are alive 1 year later.[4] This improved survival rate has been achieved primarily by the ability to deliver long-term nutritional support. The long-term outcome of these patients is often determined not only by their age and underlying disease but also by complications related to the management of short-bowel syndrome.

FACTORS INFLUENCING OUTCOME

Intestinal remnant length is the primary determinant of outcome in patients with short-bowel syndrome. The length of the small intestine in adults varies between 12 and 20 ft (360 to 600 cm), depending on how it is measured and the height and sex of the individual. The duodenum measures 10 to 12 inches (25 to 30 cm). The length of the small intestine from the ligament of Treitz to the ileocecal junction is about 16 ft (480 cm), with the proximal two fifths being jejunum and the distal three fifths being ileum. Resection of up to half of the small intestine is generally well tolerated. Although short-bowel syndrome may develop in patients with less than 180 cm of small intestine, or about a third the normal length, permanent parenteral nutrition (PN) support is likely to be needed in patients with less than 120 cm of intestine remaining without colon in continuity and less than 60 cm remaining with colonic continuity (Table 78–1).[4,5]

The site of resection is also an important factor. Patients with an ileal remnant generally fare better than those with a jejunal remnant. The ileum has specialized absorptive properties for bile salts and vitamin B_{12}, unique motor properties, a hormone profile different from that of the jejunum, and a greater capacity for intestinal adaptation.[6,7] The presence of the ileocecal junction improves the functional capacity of the intestinal remnant.[7] Although previously this had been attributed to a barrier function and transit-prolonging property of the ileocecal valve, this advantage may actually be related to the specialized property of the terminal ileum itself.

The status of the other digestive organs also contributes to outcome. The stomach influences oral intake, mixing of nutrients, transit time, pancreatic secretion, and protein absorption. Pancreatic enzymes are important in the digestive process and particularly influence fat absorption. The colon absorbs fluid and electrolytes, slows transit, and participates in the absorption of energy from malabsorbed carbohydrates. When compared with

Box 78–1 Pathophysiologic Consequences of Massive Resection

General

Table 78–1 Intestinal Length and Nutritional Prognosis

Intestinal Anatomy	Intestinal Length to Avoid Permanent Parenteral Nutrition
End-jejunostomy (type 1)	100 cm
Jejunocolic anastomosis (type 2)	65 cm
Jejunoileocolic anastomosis (type 3)	30 cm

Adapted from Messing B, Crenn P, Beau P, et al: Long term survival and parenteral nutrition dependence in adult patients with the short bowel syndrome. Gastroenterology 117:1043, 1999.

an end-jejunostomy (type 1 anatomy), a jejunoileal anastomosis with an intact colon (type 3 anatomy) is equivalent to 60 cm of additional small intestine, and a jejunocolic anastomosis (type 2 anatomy) is equivalent to about 30 cm of small intestine.[5]

A variety of conditions requiring intestinal resection lead to short-bowel syndrome (Table 78–2).[8] Patients with underlying inflammatory disease may have impaired intestinal function. The cause of resection will also influence the outcome because of the effect on other digestive organs. Long-term treatment and survival are influenced by the patient's age and other morbid conditions. Underlying disease will also influence these parameters.

INTESTINAL ADAPTATION

The small intestine is able to adapt to compensate for the reduction in absorptive surface area caused by intestinal resection.[9-11] This process occurs within the first year or two after resection and improves intestinal absorptive capacity (Fig. 78–1).[11] Whether the adaptive response can be significantly accelerated or augmented is not clear. The overall intestinal adaptive response results from changes in intestinal structure, function, and motility.

Structural adaptation after intestinal resection involves all layers of the intestine.[9,10] Mucosal DNA and protein synthesis and crypt cell proliferation are increased within hours after resection. Both the total number of cells and the proportion of proliferating cells are increased in the crypt. Enterocytes migrate at a faster rate along the villus. Villus lengthening occurs by an overall increased number of cells. Rates of apoptosis, or programmed cell death, increase in both crypt and villus enterocytes after resection. However, the proliferative stimulus dominates, so adaptation occurs. The ratio of crypts to villi may also increase. Microvilli along the epithelial surface increase as well. Overall, mucosal weight increases.

The thickness and length of the muscle layers also increase after resection, primarily as a result of hyperplasia rather than hypertrophy of the muscle cells.[9] Muscle adaptation, however, occurs at a later time than mucosal adaptation and only after more extensive resection. These changes in the components of the intestinal wall result in marked thickening of the intestinal wall, as well as increased intestinal circumference and length. Thus, there is an overall increase in mucosal surface area because of both villus hypertrophy and the increases in length and circumference of the remnant.

Intestinal motor activity is also altered by intestinal resection.[6] The canine small intestine demonstrates a biphasic motor response to varying degrees of distal resection. There is initial disruption of motor activity, followed by adaptation. In the distal segment of the intestinal remnant after limited resection and more generally after 75% resection, motility recordings are initially dominated by recurring bursts of clustered contractions.[12] With extensive resection, these clusters are prolonged and associated with baseline tonic changes. With limited resection, there is evidence of progressive motor adaptation with eventual slowing of transit and return of migrating motor complex (MMC) cycling. This adaptation is less apparent after massive resection. Motor adaptation

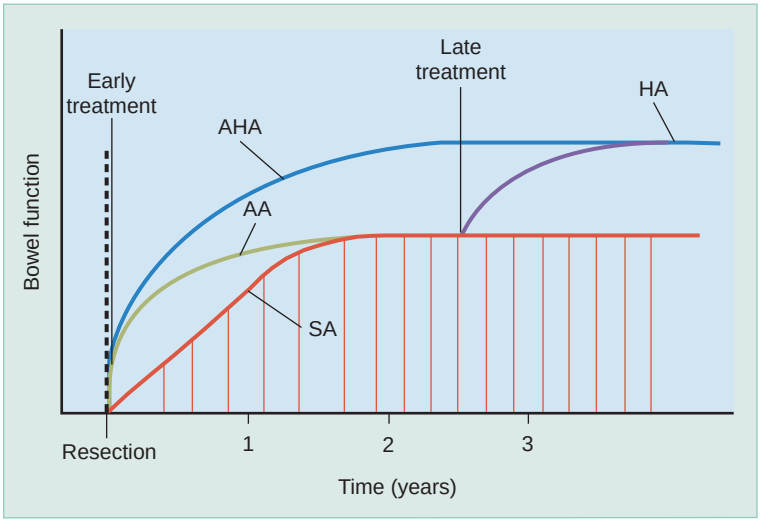

Figure 78–1. Schematic presentation of intestinal adaptation. AA, accelerated adaptation; AHA, accelerated hyperadaptation; HA, hyperadaptation; SA, spontaneous adaptation. (From Jeppesen PB: Clinical significance of GLP-2 in short bowel syndrome. J Nutr 133:3721, 2003.)

is more prominent in the jejunum than in the ileum. These changes are accompanied by modest alterations in smooth muscle contractility. Clinical reports also demonstrate a biphasic adaptive motor response during the first year after resection. There is disrupted motor activity in the first few months after resection, but these changes occur only after extensive resection (remnant shorter than 100 cm). Long-term human studies demonstrate a shorter duration of the MMC cycle and fed pattern after resection.[13]

Functional adaptation has been well documented after resection,[1,5,14,15] and structural adaptation increases intestinal absorptive surface area. Both structural adaptation and motor adaptation lead to prolonged transit time. Although the formerly accepted theory of improved absorption by individual enterocytes was discounted, more recent studies suggest that certain transport capabilities do improve. Within months of resection, diarrhea diminishes and nutritional status improves.

The mechanism of intestinal adaptation has been studied extensively but is still not entirely understood. The degree of structural adaptation is related to the extent and site of resection.[9,10] Adaptation is greater with more extensive resection, and the ileum has a greater adaptive capacity than the jejunum does. Subsequent resection elicits a further adaptive response. Luminal nutrients and secretions and growth factors are important for achieving the maximal response but are not essential for adaptation to occur (Box 78–2).[9,10] The early molecular events associated with this hyperplastic response are being investigated.[16,17] Intestinal resection results in increased levels of a variety of gene products in enterocytes within hours. There is an immediate increase in genes that encode transcription factors, not only genes that influence cell proliferation but also those that augment nutrient trafficking, as well as heat shock genes, which maintain normal cellular function. Many of these are novel genes not normally present in intestinal epithelium. The specific triggers for these events are not clear, and there are obviously many candidates. Currently, there is clinical interest in manipulating the adaptive response pharmacologically.

MEDICAL MANAGEMENT

The early management of a patient with short-bowel syndrome is that of a critically ill surgical patient who has recently undergone intestinal resection and other concomitant procedures. Thus, control of sepsis, maintenance of fluid and electrolyte balance, and initiation of nutritional support are important in the early management of these patients. For patients who have survived this early phase, the primary goals of management are to maintain adequate nutritional status, maximize the absorptive capacity of the remaining intestine, and prevent the development of complications related to both the underlying pathophysiology and the nutritional therapy.

Maintain Nutritional Status

The most important therapeutic objective in the management of short-bowel syndrome is to maintain the patient's nutritional status. This usually requires PN support in the early period after surgery. Fluid and electrolyte losses from the gastrointestinal tract may be great during the early postoperative period and must be monitored and replaced as soon as possible. Enteral nutritional support should be started as soon as possible when the ileus has resolved. With time, an increasing amount of nutrients are absorbed by the enteral route. This is important for maximizing intestinal adaptation and preventing complications related to PN. As their condition improves and intestinal adaptation occurs, many patients can absorb the necessary nutrients entirely by the enteral route. The length of the intestinal remnant and the status of the colon have important prognostic implications in this regard (see Table 78–1).

The ability of patients with short-bowel syndrome to maintain adequate caloric intake enterally is determined by a variety of factors, including intestinal remnant length and location, any underlying intestinal disease, and the status of the remaining digestive organs.[15,18] Whether there is continuity in the intestinal tract or a stoma is also an important consideration. Diarrhea and perianal complications may markedly diminish oral intake. Patients with stomas are more likely to have a greater percentage of their calories taken enterally. Hyperphagia develops in many patients with short-bowel syndrome to overcome inefficient absorption.[19]

Many patients with short-bowel syndrome require long-term PN for survival, and this therapy has considerable expense and morbidity. Patients without malignancy have 1-, 3-, and 5-year survival rates of about 90%, 70%, and 60%, respectively.[4] One third of deaths are related to the underlying disease, 50% to other supervening disease, and 10% to 15% to PN therapy. Sepsis and liver disease related to PN are important factors in long-term survival.

The incidence of sepsis varies from 0.1 to 0.3 episodes per patient year of PN. Sepsis may be associated with catheter thrombosis. The need for prolonged therapy makes vascular access a long-term problem, and catheters may eventually need to be placed in the azygos, hepatic, or inferior vena cava veins.

End-stage liver disease develops in about 15% of long-term adult PN patients and is associated with a survival time of about 1 year without liver transplantation.[20,21] Although the etiology of the liver disease is not completely understood, it appears to be a multifactorial process that is initially reversible but ultimately leads to severe steatosis, cholestasis, and cirrhosis. Liver disease occurs more frequently in children than adults. Provision of enteral nutrients may prevent this problem, but overfeeding is a predisposing factor. Control of sepsis and bacterial overgrowth is important to minimize this liver disease. Patients with abnormal liver function test results while receiving PN should undergo abdominal ultrasound for evaluation of the gallbladder and bile ducts and should have a liver biopsy performed as appropriate.

Maximize Enteral Nutrient Absorption

Because the morbidity associated with nutritional support in patients with short-bowel syndrome is related primarily to PN, maximizing enteral absorption of nutrients is important for long-term survival. Furthermore, diarrhea and stomal fluid losses can also be important clinical problems that affect the patient's quality of life. Thus, it is beneficial to ensure that the patient's intestinal remnant is functioning optimally and absorbing nutrients and fluid.

The optimal diet for patients with short-bowel syndrome remains controversial. Provision of nutrients in their simplest form to minimize digestion has been one strategic approach. Simple sugars and dipeptides and tripeptides are rapidly absorbed from the intestinal tract. However, partially hydrolyzed diets appear to be just as effective and are less expensive. Complex carbohydrates reduce the osmotic load, but concentrated sugars, such as fruit juices, should be avoided because they generate a high osmotic load. Whether the diet should have a high-fat or low-fat content is another issue. There appears to be increasing agreement that patients with colon should have a low-fat (20% to 30% of calories), high-carbohydrate (50% to 60% of calories) diet but that patients with an end-enterostomy do not require fat restriction (30% to 40% of calories). Fat absorption obviously requires more digestion unless the fat is supplied in the form of medium-chain triglycerides. The ability to absorb these nutrients improves with time, so the diet may need to be continually modified. Specific problems such as lactase deficiency are often present, and the diet should be altered appropriately. Ingestion of a glucose-electrolyte oral rehydration solution with a sodium concentration of at least 90 mmol/L will optimize water and sodium absorption in the proximal jejunum and prevent secretion into the lumen.

Minimizing gastrointestinal secretions and controlling diarrhea are also important goals for maximizing absorption. Both histamine H_2 receptor antagonists and proton pump inhibitors are effective in controlling gastric hypersecretion, correcting malabsorption, and improving nutritional status in patients with short-bowel syndrome. Furthermore, cimetidine may also increase intestinal adaptation. Somatostatin and its long-acting analogue octreotide have been investigated for the management of severe refractory diarrhea in short-bowel syndrome. They improve diarrhea by prolonging small intestinal transit time and reducing salt and water excretion. Part of the beneficial effect may also be related to a reduction in gastric hypersecretion. Although these therapeutic agents are beneficial in the short term, it is not clear whether they continue to be effective after a few months, and they may have some potential deleterious effects. Somatostatin may exacerbate steatorrhea because of impaired pancreatic exocrine function. Other potential adverse effects of octreotide are inhibition of intestinal adaptation and the development of cholelithiasis. Recent evidence supports the use of ox bile and cholylsarcosine, a synthetic conjugated bile acid, as replacement therapy because they improve fat absorption without exacerbating diarrhea.

Box 78–3 Restoration of Intestinal Continuity

Advantages

- Absorptive capacity increased
- Energy absorbed from short-chain fatty acids
- Infectious complications reduced
- Transit time prolonged
- Stoma avoided

Disadvantages

- Bile acid diarrhea
- Dietary restrictions
- Nephrolithiasis increased
- Perianal complications

From Thompson JS: Intestinal resection and the short bowel syndrome. In Quigley EMM, Sorrell MF (eds): Medical Management of the Gastrointestinal Surgery Patient. Baltimore, Williams & Wilkins, 1994, p 327.

Another important aspect of dietary management is to provide a diet that will maximize the intestinal adaptive response.[9,10,18] Provision of fat and dietary fiber may be particularly important in this regard. Long-chain and short-chain fatty acids appear to have a greater trophic effect on the intestine than medium-chain fatty acids do. Although these nutrients directly stimulate intestinal adaptation, nutrients also stimulate intestinal adaptation through endocrine and paracrine effects.

Pharmacologic therapy for short-bowel syndrome is a rapidly expanding area of investigation. Recent evidence suggests that provision of the appropriate diet, nutritional supplements such as glutamine, and growth factors such as growth hormone improves intestinal absorption and perhaps modifies the adaptive response in patients with established short-bowel syndrome.[22] However, which of these components is actually responsible for improved absorption is controversial. Growth hormone and glutamine do not have a consistent beneficial effect.[23,24] Currently, glucagon-like peptide-2 appears to have the most promise for promoting absorption and adaptation.[11] Epidermal growth factor also stimulates intestinal adaptation and may soon be studied in clinical trials.[25]

An important clinical issue is whether to establish intestinal continuity in patients who have a colonic remnant. There are both advantages and disadvantages to restoring continuity (Box 78–3). The colon may improve intestinal absorption by increasing the absorptive surface area, deriving energy from short-chain fatty acids, and prolonging transit time, particularly if the ileocecal valve is intact. Avoiding a stoma also improves quality of life. However, the response of the colon to luminal contents is somewhat unpredictable. Bile acids may cause a secretory diarrhea. Perianal problems can be quite disabling and decrease the patient's oral intake. Oxalate is absorbed primarily in the colon, and restoring continuity places the patient at increased risk for the formation of calcium oxalate stones. Serum and intestinal fluid markers have been investigated as a means of predicting the response of the individual patient to restoring continuity, but none is generally available and useful. Distal reinfusion of enteral contents into a mucus fistula to assess the functional outcome has some usefulness, but it is cumbersome. Not all patients who initially have a stoma created eventually have continuity restored with a satisfactory outcome.[26] This decision should be considered on an individual basis and depends on the length of the intestinal remnant, the status of the ileocecal valve and the colon, and the patient's overall condition. Generally, at least 3 ft of small intestine is required to prevent severe diarrhea and perianal complications. Restoring continuity, however, should always be given strong consideration because of possible improvement in absorption.

Prevent Complications

Metabolic complications are common in patients with short-bowel syndrome because of their tremendous fluid and electrolyte losses and the need to replace these losses with specialized solutions. Intravascular volume has to be maintained to prevent dehydration and renal dysfunction. Hypocalcemia is a common problem related to poor absorption and binding by intraluminal fat. Maintaining adequate calcium and magnesium levels and vitamin D supplementation are important to minimize bone disease. Hyperglycemia and hypoglycemia are frequent complications of patients receiving a large amount of their calories parenterally. Both metabolic acidosis and metabolic alkalosis can occur. A specific problem is D-lactic acidosis, which results from bacterial fermentation of unabsorbed nutrients, particularly simple sugars. Lactate reduces colon pH, thereby permitting the growth of acid-resistant anaerobes capable of producing D-lactate. Impaired metabolism of D-lactic acid may also contribute to elevated serum D-lactic acid levels. This diagnosis is suggested by an unexplained metabolic acidosis and associated neurologic symptoms, such as confusion and somnolence. D-Lactic acid is not measured by standard laboratory techniques for lactic acid determination. Thus, an increased anion gap but normal lactate level in the appropriate clinical setting mandates measurement of D-lactic acid. D-Lactic acidosis is treated by minimizing overall caloric intake or by instituting a low-carbohydrate diet. Administration of intestinal antibiotics may be appropriate, but the optimal duration of such treatment is unclear, and recurrence rates are significant.

Specific nutrient deficiencies need to be prevented and monitored closely, including iron and vitamin deficiencies, as well as deficiencies in micronutrients such as selenium, zinc, and copper. Because fat is poorly absorbed, fatty acid deficiency can also occur. Although medium-chain fatty acids can supplement the diet enterally, parenteral lipids are required in patients who

depend primarily on that route. Serum free fatty acid levels and triene-to-tetraene ratios may need to be monitored periodically to determine the need for supplementation and response to treatment. In general, enteral intake must greatly exceed the absorptive needs to ensure that these needs are being met.

Catheter-related sepsis is an important problem that often necessitates rehospitalization and replacement of catheters. Attention to technique and meticulous patient education are important to prevent this complication. Most infections are due to *Staphylococcus* species, but gram-negative bacteria and fungi are also associated with line sepsis. An attempt at line sterilization before removal is appropriate when infections are caused by coagulase-negative staphylococci and gram-negative bacteria. Repeated placement of catheters can lead to catheter thrombosis, which is the other common problem. In patients who require PN permanently, this may become an important factor in the patient's survival because vascular access may not be achievable indefinitely.

PN-induced liver disease is another potential long-term problem.[20,21] It can be minimized by providing as large a portion of the calories as possible enterally, avoiding overfeeding, using mixed fuels (less than 30% fat), and preventing specific nutrient deficiencies. Treating bacterial growth and preventing recurrent sepsis are also important. Ursodeoxycholic acid administration may likewise be beneficial.

Bacterial overgrowth is another long-term complication associated with both intestinal disease and resection. It may result from impaired motility or stasis caused by obstructive lesions (Fig. 78–2). Achlorhydria is also a contributing factor. Bacterial deconjugation of luminal bile salts impairs bile salt reabsorption. Bacteria also metabolize intraluminal vitamin B_{12}. Depending on the bacterial species present, secretory diarrhea may occur as well. Bacterial overgrowth requires a high degree of suspicion to make the diagnosis. This complication should be suspected when a patient's absorptive capacity and stool habits change acutely. It may result from a mechanical obstruction or a blind loop, which can be relieved by surgery. However, it is often a primary motor abnormality and requires intermittent therapy with antibiotics. Colonization of the lumen with acidophilus or other nonpathogenic organisms is another potential therapy.[27]

Cholelithiasis occurs in 30% to 40% of patients with intestinal insufficiency.[28,29] Factors that predispose these patients to gallstone formation include altered hepatic bile metabolism and secretion, gallbladder stasis, and malabsorption of bile acids. Depending on the dominant mechanism, either mixed pigment stones or cholesterol stones may occur. Long-term PN is an important contributing factor causing altered hepatic bile metabolism and gallbladder stasis. Patients receiving PN are susceptible to the development of cholelithiasis and hepatocellular dysfunction and thus require careful clinical evaluation.[28,29] Biliary sludge forms within a few weeks of initiating PN if there is no enteral intake, but it rapidly disappears when enteral nutrition is resumed. Intestinal mucosal disease and resection, particularly of the ileum, cause bile acid malabsorption, which leads to lithogenic bile and the formation of cholesterol stones. The risk for cholelithiasis is significantly increased if less than 120 cm of intestine remains after resection, the terminal ileum has been resected, and PN is required. The incidence of cholelithiasis can be minimized by providing nutrients enterally whenever possible. Patients totally dependent on PN may be treated with intermittent cholecystokinin injections to prevent stasis and the formation of sludge. Administration of intravenous lipids also stimulates gallbladder emptying. Cholelithiasis may lead to complications in a higher number of patients with short-bowel syndrome than in the general population and also requires more complicated surgical treatment. Thus, several authors now recommend prophylactic cholecystectomy in these patients when laparotomy is being undertaken for other reasons.[29]

Nephrolithiasis also occurs with some frequency. Calcium oxalate stones form as a result of increased oxalate absorption from the colon.[29] Oxalate is normally bound to calcium in the intestinal lumen and is not absorbed. Decreased availability of calcium secondary to reduced intake or binding by intraluminal fat leaves free oxalate in the lumen. Thus, the oxalate is absorbed in the colon and forms calcium oxalate in the urine. Nephrolithiasis is unusual in patients after intestinal resection and jejunostomy but occurred in a fourth of such patients with an intact colon within 2 years of

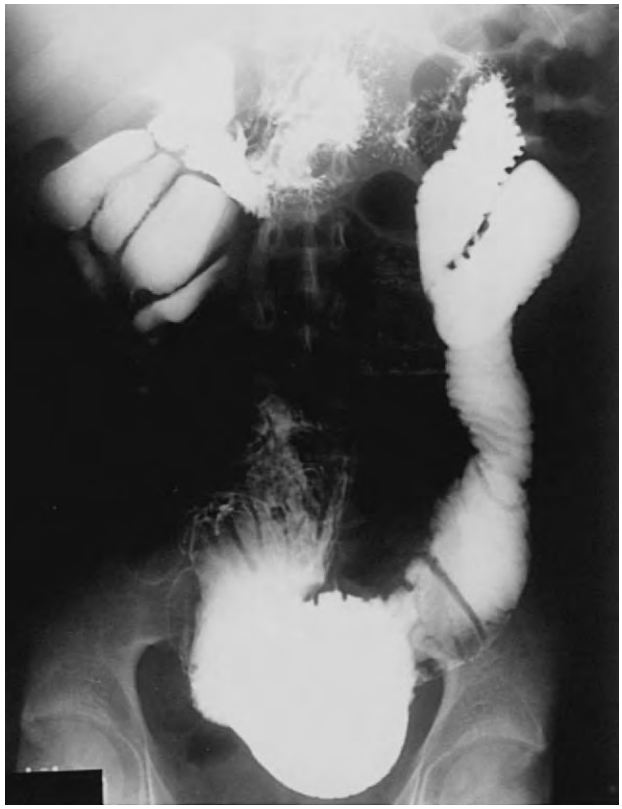

Figure 78–2. Contrast study of a patient with short-bowel syndrome. The shortened remnant lies primarily in the left side of the abdomen with a large dilated segment in the pelvis. Contrast has passed into the right colon beyond this area.

resection. Nephrolithiasis can be prevented by maintaining a diet low in oxalate, minimizing intraluminal fat, supplementing the diet with calcium orally, and maintaining a high urinary volume. Foods with high oxalate content include chocolate, tea, cola, spinach, celery, carrots, and other fruits and vegetables. Cholestyramine, which binds oxalic acid in the colon, is another potential treatment.

Gastric hypersecretion is a potential problem in patients with short-bowel syndrome. Massive intestinal resection can cause gastric hypersecretion as a result of parietal cell hyperplasia and hypergastrinemia. This phenomenon is usually transient and lasts several months. The etiology has not been elucidated but may involve loss of an inhibitor from the resected intestine. The associated hyperacidity exacerbates malabsorption and diarrhea. Clinical development of peptic ulcer disease may also occur and is seen in about a fourth of patients undergoing massive resection.[26] Treatment of gastric acid secretion may improve absorption but also prevents peptic ulcer disease. Control of acid secretion by H_2 receptor antagonists or proton pump inhibitors should be initiated in the perioperative period after resection and maintained until the increased acid production resolves. Some patients, however, continue to have symptoms of peptic ulcer disease that eventually require surgical intervention. Gastric resection therapy should be avoided when possible. A highly selective vagotomy may be the most desirable procedure if feasible.

SURGICAL MANAGEMENT

The primary goal of surgical therapy for short-bowel syndrome is to increase intestinal absorptive capacity, which can be achieved either by improving absorption by existing intestine or by increasing the area of absorption (Box 78–4). Recruiting additional intestine into continuity, relieving obstruction, or slowing intestinal transit will often improve absorption. The intestinal lengthening procedure is feasible in selected patients. The most significant increase in length, however, is potentially achieved by intestinal transplantation. The choice of surgical therapy for short-bowel syndrome is influenced by intestinal remnant length and caliber and the clinical condition of the patient (Table 78–3).[3]

Preserve and Maximize the Intestinal Remnant

An abdominal reoperation is required in about half the patients with short-bowel syndrome after discharge from the hospital.[26] Intestinal problems are the most common indication. An important goal with any reoperation in patients with short-bowel syndrome is to preserve the length of the intestinal remnant. Several strategies can be used when further intestinal disease requires surgery.[30] Resection can often be avoided by intestinal tapering to improve the function of dilated segments, performing stricturoplasty for benign strictures, and using serosal patching for certain strictures and chronic

Box 78–4 Surgical Strategies for Short-Bowel Syndrome

- Preserve and maximize remnant
  - Avoid resection
  - Restore continuity
  - Recruit additional intestine
- Improve intestinal function
  - Relieve obstruction
  - Taper dilated bowel
  - Slow intestinal transit
- Increase absorptive area
  - Intestinal lengthening
  - Intestinal transplantation

Table 78–3 Surgical Approach to Short-Bowel Syndrome

Intestinal Remnant	Clinical Condition	Surgical Options
Adequate length with normal diameter	Enteral nutrition (remnant >120 cm in adults, >60 cm in children)	Optimize intestinal function, recruit additional length
Adequate length with dilated bowel	Bacterial overgrowth, stasis	Treat obstruction, intestinal tapering
Marginal length with normal diameter (remnant 60-120 cm in adults, 30-60 cm in children)	Rapid transit, need for parenteral nutrition	Recruit additional length, reversed intestinal segment, artificial valve, colon interposition
Short length with normal diameter (remnant <60 cm in adults, <30 cm in children)	Need for parenteral nutrition	Optimize intestinal function
Short length with dilated bowel	Need for parenteral nutrition	Intestinal lengthening
Short length	Complications of parenteral nutrition	Intestinal transplantation

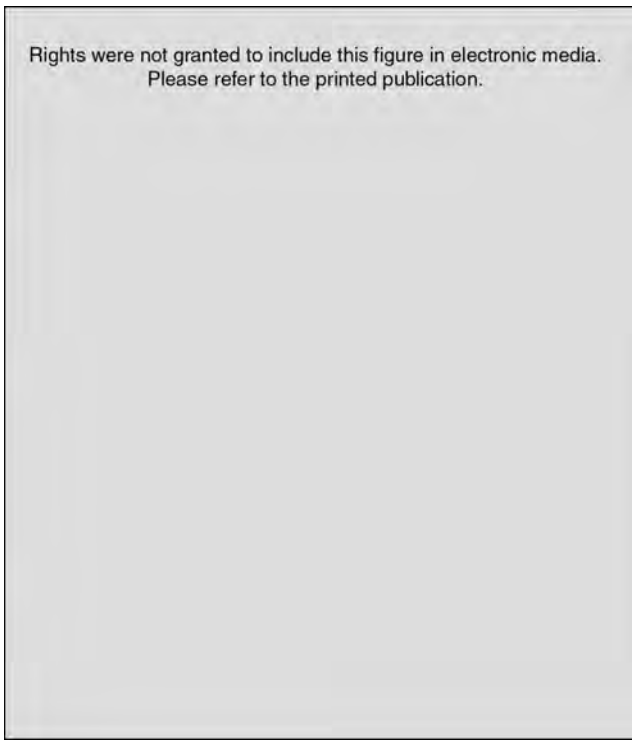

Figure 78–3. Techniques for preserving intestinal length include tapering of dilated segments rather than resection **(A)**, stricturoplasty for strictures **(B)**, and serosal patches for strictures and perforation **(C)**. (From Thompson JS: Recent advances in the surgical treatment of the short bowel syndrome. Surg Ann 22:110, 1990.)

perforations (Fig. 78–3). Resections should be limited in extent when they cannot be avoided. An end-to-end anastomosis is favored both to prevent blind loops and to maximize functional length of the intestine. Depending on the previous operations performed, patients occasionally have intestinal segments that can be recruited into continuity at the time of reoperation. This should always be given careful consideration. The length, location, and characteristics of the remnant should be carefully documented at the time of any operation.

Stricturoplasty is most often performed in the fashion of a Heineke-Mikulicz pyloroplasty. The stricture is incised longitudinally and closed transversely. The incision extends at least 1 cm proximal and distal to the stricture, but larger incisions may be required to achieve a satisfactory orifice. The enterotomy can be repaired with either a single-layer or a two-layer anastomosis. Longer strictures or multiple closely associated strictures can be opened with a side-to-side stapled anastomosis. Blind loops should be avoided, however.

Serosal patching is performed by apposition of an adjacent serosal surface, usually either small intestine or colon, to a nonhealing fistula, stricture, or other focal defect. A single-layer seromuscular-to-seromuscular anastomosis is created in either an interrupted or continuous fashion. The serosal patch becomes covered by normal mucosa from adjacent tissue. This technique is most applicable to smaller defects because contraction of the patch does occur and could lead to a stenotic segment.

Improve Intestinal Function

Improve Motility

Patients with short-bowel syndrome have a propensity for the development of dilated intestine secondary to chronic obstruction or intestinal adaptation. Dilated intestine may lead to stasis and bacterial overgrowth, which can further aggravate the malabsorption associated with the short remnant. Mechanical obstruction at an anastomosis or from adhesions or strictures related to the underlying disease process should always be sought in these patients and corrected with the techniques mentioned previously. These dilated segments, however, are often not associated with distal obstruction. Tapering dilated segments improves motility by permitting closure of the lumen during contraction of the wall, which improves peristalsis. Simple imbrication of the redundant bowel is the preferred method, although longitudinal transection plus removal of intestine along the antimesenteric border has also been performed. A continuous nonabsorbable suture line is usually most expeditious, particularly for lengthy segments. Excisional techniques are easily performed with stapling devices but can also be performed with bowel clamps. Tapering enteroplasty improves intestinal function in patients with short-bowel syndrome.[3] Blind loops should be sought and eliminated, preferably by revision of the anastomosis rather than resection.

Prolong Intestinal Transit

Procedures designed to prolong intestinal transit time have been evaluated experimentally and performed clinically, but their efficacy remains questionable (Fig. 78–4).[31,32] Most of the reports are anecdotal. These adjunctive procedures are often performed during the adaptive phase; hence, it is difficult to determine whether the improvement in nutritional status and absorption was due to the surgical procedure or the normal adaptive process. Three procedures have been attempted in sufficient numbers to be considered, including reversed intestinal segments, colon interposition, and artificial sphincters (Table 78–4).

Reversed Intestinal Segments Reversing segments of intestine to slow intestinal transit is the surgical procedure that has been reported most extensively. The antiperistaltic segment functions by inducing retrograde peristalsis distally and disrupting the motility of the proximal part of the intestine. In addition, disruption of the intrinsic nerve plexus slows myoelectrical activity in the distal remnant. Reversed segments also alter the hormonal milieu after resection.

Most experimental studies of antiperistaltic segments demonstrate slowed intestinal transit, improved absorption, reduced weight loss, and prolonged survival after intestinal resection, but some reports do not show a

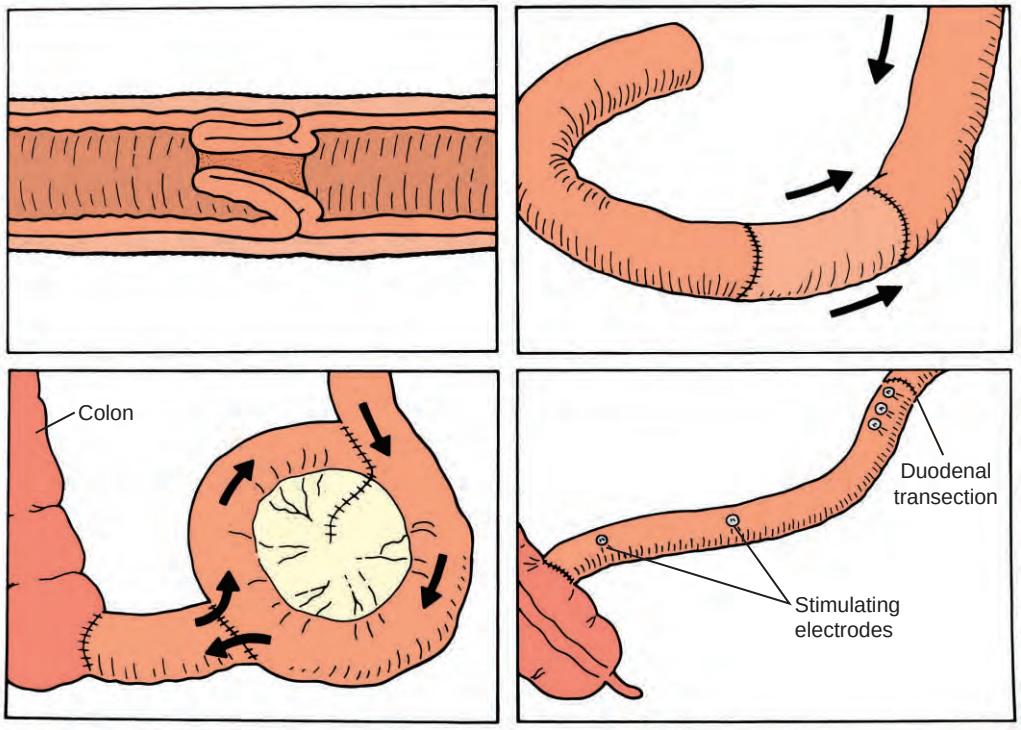

Figure 78–4. Techniques for slowing intestinal transit: intestinal valve *(upper left)*, antiperistaltic segment *(upper right)*, recirculating loop *(lower left)*, and intestinal pacing *(lower right)*. (From Thompson JS, Rikkers JS: Surgical alternatives for the short bowel syndrome. Am J Gastroenterol 82:97, 1987.)

Table 78–4 Clinical Experience with Procedures to Prolong Transit for Short-Bowel Syndrome

Procedure	Number of Patients	Number of Children (%)	Number of Patients with Clinical Improvement (%)
Reversed segment	55	6 (11)	45 (81)
Intestinal valve	12 (6)*	1 (16)	4 (67)
Colon interposition	12	11 (92)	6 (50)
Pouch or loop	4	1 (25)	1 (25)
Intestinal pacing	1	0 (0)	0 (0)

*Six procedures performed as a staged approach for intestinal lengthening.
From Thompson JS: Surgical approach to the short bowel syndrome: Procedures to slow intestinal transit. Eur J Pediatr Surg 9:263, 1999.

beneficial effect.[33,34] The variable outcomes may be explained by several factors, including variation in the extent of resection, timing of the procedure, and the use of different lengths of antiperistaltic segments. Reversed segments performed simultaneously with 75% resection in canines blunted the normal adaptive response, which may be related to the altered hormonal response.[35]

The ideal antiperistaltic segment slows transit without causing complete obstruction. Several technical details are important. The optimal length of the reversed segment would appear to be about 10 cm or less in adults and 3 cm in children. The reversed segment should be created as distal in the small intestinal remnant as feasible. Care must be taken to avoid complete rotation of the mesentery to prevent intestinal ischemia.

Antiperistaltic segments have been reported clinically in more than 50 patients, about 90% of whom were adults.[31] In these anecdotal reports, clinical improvement with slowed intestinal transit and increased absorption has been reported in 80% of patients. Transient obstructive symptoms and anastomotic leak are potential problems. The length of the segment has varied from 5 to 15 cm in these reports. Performance of this procedure in patients with Crohn's disease does not appear to

influence recurrence rates. Long-term function has been demonstrated.

Intestinal Valves The effect of valves and sphincters on intestinal motility involves several different mechanisms. They create a partial mechanical obstruction, disrupt the normal motor pattern of the small intestine, and prevent retrograde reflux of colonic contents.[31] In experimental studies, intestinal valves and sphincters have been shown to prolong transit time, increase absorptive capacity, and extend survival, although the results have been inconsistent. Effective valves usually result in some dilation of the proximal part of the intestine and may cause, at least transiently, obstructive symptoms. Potential complications include necrosis of the valve, complete obstruction, and intussusception. Durability of the sphincter function of valves has been questioned.

Several different techniques for creating intestinal valves and sphincters to replace the ileocecal valve have been reported, including external constriction of the intestine, segmental denervation, and intussusception of intestinal segments to increase intraluminal pressure, with the latter being used most frequently. Intussuscepted valves should be 2 cm in length if retrograde and 4 cm if the intussuscepted valve is prolapsed antegrade. We have generally created a retrograde sphincter similar to that used in the continent ileostomy procedure, but it is only 2 cm in length.[3]

The reported clinical experience with intestinal valves and sphincters is less extensive than that with reversed segments. Nipple valves were recently used in six infants to cause dilation of the intestine so that subsequent intestinal lengthening could be performed.[33] Intussuscepted valves were reported as primary treatment in five adults and one infant with short-bowel syndrome.[31] Four patients improved markedly, one had questionable benefit, and takedown of the valve was required in the other. Ileocolic nipple valves were lost in a third of patients monitored for more than 5 years in one study, again raising the issue of durability.

Colon Interposition Interposing a colonic segment in the small intestinal remnant in either an isoperistaltic or antiperistaltic fashion retards intestinal transit. Isoperistaltic interposition is performed proximally and functions by slowing down the rate at which nutrients are delivered to the distal portion of the small intestine.[31] The antiperistaltic colon interposition is placed distally, similar to the reversed small intestinal segment. Interposed colonic segments absorb water, electrolytes, and nutrients, in addition to their effect on intestinal transit. Although it has been suggested that interposed colon might develop structural and functional similarities to the small intestine, this has not been substantiated.

In experimental studies, isoperistaltic colon interposition generally resulted in slower transit time, less weight loss, and improved survival after resection. Results with antiperistaltic colon interposition, however, have been less consistent. The length of colon interposed seems to be less critical than with reversed segments.

The use of colon interposition has been reported in 12 patients, 11 of whom underwent isoperistaltic interposition.[32] All but one of the patients were infants younger than 1 year. The interposed colon segment varied between 8 and 24 cm in length. All patients were PN dependent preoperatively. Six (50%) patients demonstrated sustained clinical improvement; the other six, including the one with the antiperistaltic colon, did not improve and subsequently died of sepsis or hepatic failure. Colonic stasis with bacterial overgrowth may have contributed. This experience suggests that isoperistaltic colon interposition may have some merit.

Other Approaches Intestinal pouches and recirculating loops would theoretically prolong transit time by permitting prolonged exposure of luminal nutrients to the intestinal absorptive surface. In experimental studies, however, these procedures have not improved absorption or survival rates after massive resection. Four clinical reports involving recirculating loops have been disappointing as well.

Intestinal pacing in a retrograde fashion has also been investigated as a means of prolonging transit time. Retrograde electrical pacing promotes peristalsis in a reverse direction but also alters proximal intestinal motility, possibly through a hormonal mechanism. Postprandial retrograde pacing in canines improved absorption and intestinal status. In the one reported attempt to achieve retrograde pacing in a patient with short-bowel syndrome, the pacemaker failed to stimulate the intestine.

Choice of Procedure Procedures designed to slow intestinal transit should be applied cautiously in patients with nearly adequate remnant length and demonstrated rapid transit. They should be considered only after maximal adaptation has occurred. Reversed intestinal segments and artificial valves have the greatest appeal as procedures to slow intestinal transit. Antiperistaltic segments should be used in patients with longer remnants. The 10-cm segment still leaves sufficient remnant for absorption. Valves should be considered in patients with shorter remnants because less bowel is used. In one experimental study, an intestinal valve was more effective than an antiperistaltic segment in prolonging transit time after resection. The efficacy of these procedures remains questionable, however, and other approaches have been even less encouraging. Furthermore, these procedures are applicable to only a small proportion of patients with short-bowel syndrome.

Increase Absorptive Area

Dilated intestinal segments may be amenable to an intestinal tapering and lengthening procedure. Theoretically, such a procedure has the advantage of not only improving motility and reducing stasis but also improving intestinal absorption by the increased absorptive area. The primary technique was initially described by Bianchi[34] (Fig. 78–5). More recently, an alternative technique called serial transverse enteroplasty (STEP) has been reported[36,37] (Fig. 78–6). In these approaches the

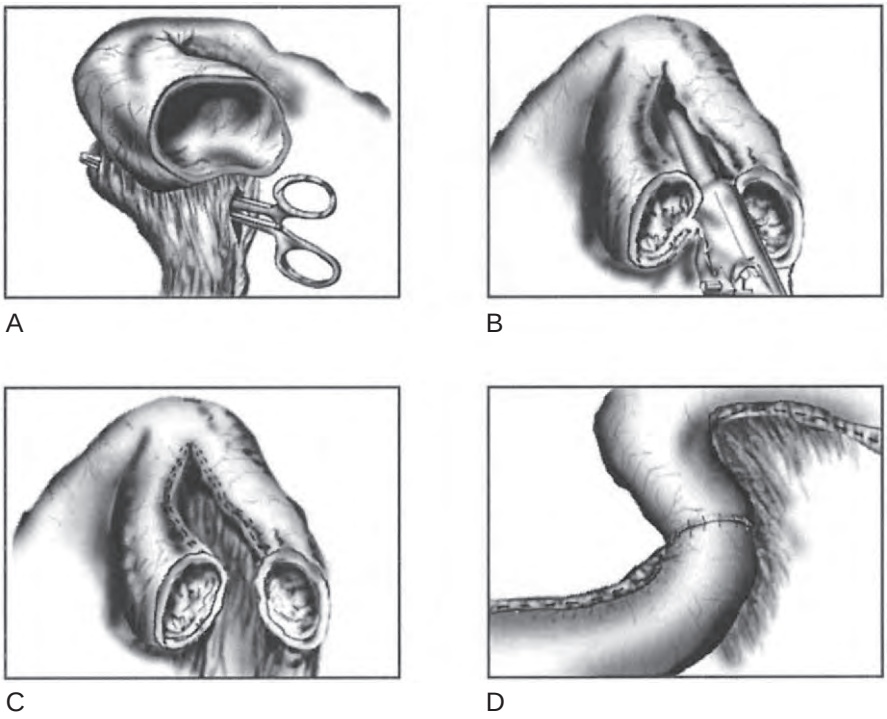

Figure 78–5. The Bianchi procedure. Longitudinal dissection between the blood vessels on the mesenteric border **(A)** permits the use of staples to divide the intestine longitudinally **(B** and **C)**. The two parallel segments are then anastomosed end to end **(D)**. (From Thompson JS: Surgical rehabilitation of the intestine in short bowel syndrome. Surgery 135:465, 2004.)

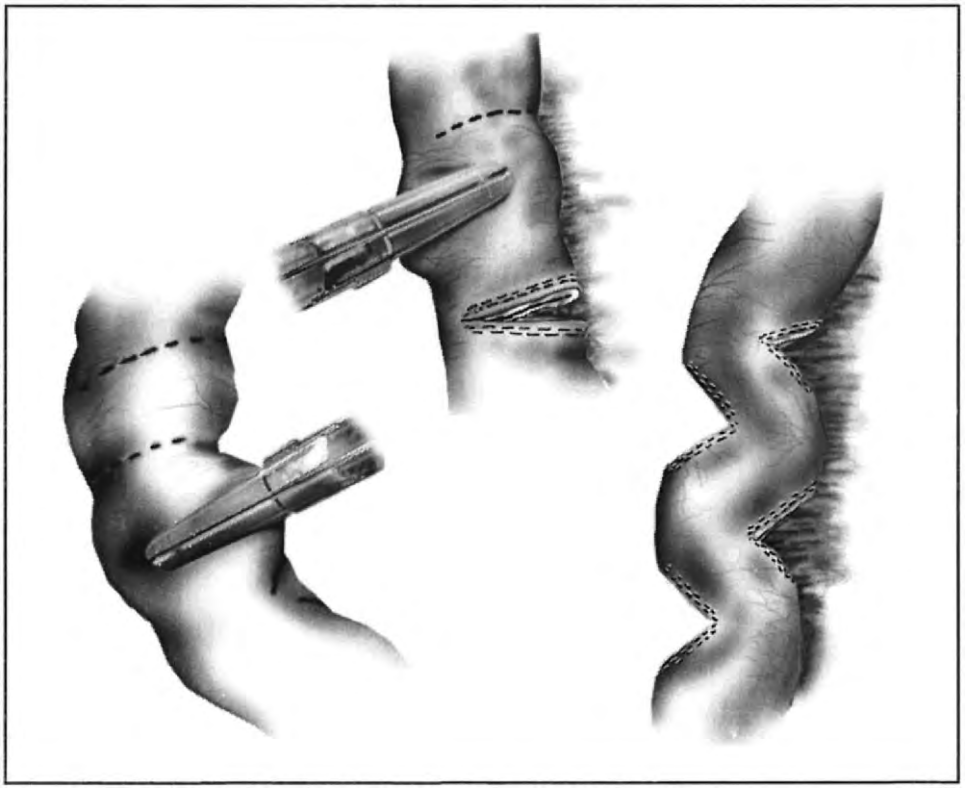

Figure 78–6. The STEP procedure. Several transverse applications of a linear stapler from opposite directions on the bowel wall allow the intestine to lengthen with reduced diameter. (From Thompson JS: Surgical rehabilitation of the intestine in short bowel syndrome. Surgery 135:465, 2004.)

dilated segments are tapered, and the redundant intestine is preserved and restored into continuity for additional length.

In experimental studies, intestinal lengthening by the Bianchi procedure prolongs transit time but does not clearly improve absorption in the short term.[38] Intestinal lengthening causes motor disruption in the proximal portion of the intestine and alters the hormonal response to resection. The jejunum may yield better results than lengthening of ileum. Improved nutrition

has been demonstrated in an animal model after the STEP procedure.[36]

The Bianchi procedure is performed by transecting distal to the dilated segment to be tapered. Dissection is performed longitudinally for about 5 cm on the mesenteric edge of the bowel between the terminal branching vessels to create a space that permits longitudinal division of the bowel with a stapler. A hand-sewn anastomosis can also be used. If the diameter of the bowel permits, the staple line can be imbricated as well. This procedure is repeated until the desired length is achieved. The two parallel longitudinal segments can then be anastomosed end to end to halve the diameter and double the length of the segment. Intestinal lengthening of segments from 5 to 90 cm has been reported. Obviously, longer segments are at greater risk for complications.

The STEP procedure involves serial transverse applications of a linear stapler from alternating directions to divide the bowel perpendicular to the long axis of the intestine. The length and spacing of the transverse division are determined by the diameter of the intestine. Multiple stapler applications are required. The net result is an increase in length and a reduction in diameter. This procedure is less complicated than the Bianchi procedure because it avoids the extensive mesenteric dissection and the additional anastomosis. It is feasible for very short segments and those near the ligament of Treitz.

Intestinal lengthening, primarily the Bianchi procedure, has now been reported in more than 100 patients.[34,37,39,40] After an initial prolonged ileus, significant improvement in absorptive capacity and nutritional status has been reported in 90% of these patients in the short term. Potential complications, however, such as necrosis of divided segments, anastomotic leak, and obstruction develop in up to 20% of patients. Gastrostomy tubes are often placed because of the prolonged dysmotility that occurs. Although short-term results have been encouraging, emerging long-term results suggest that about half the patients undergoing this procedure have a sustained benefit for up to 10 years.[39] The initial experience with the STEP procedure has been favorable.[37,40] Initial short-term results in 10 patients have demonstrated the feasibility and safety of the technique in the clinical setting. The outcome of these procedures is heavily influenced by patient selection in terms of age, remnant length, hepatic function, and requirement for PN. Thus, these procedures should be applied cautiously.

One of the limitations of lengthening procedures is that they can be applied only to a fairly select group of patients. Obviously, the procedures should be considered only if bacterial overgrowth or other signs of malabsorption are identified that appear to be related to the dilated segment. The intestinal diameter should be at least 4 cm to provide an adequate lumen size after tapering. Sequential operations, first using a procedure such as an artificial valve to produce intestinal dilation and then performing the lengthening at a later time, have been used to expand the applicability of this technique. The vascular anatomy must be favorable for the Bianchi procedure. Effort is also being directed at recruiting additional vascular supply to permit further lengthening. The STEP procedure should markedly increase the applicability of intestinal lengthening.

INTESTINAL TRANSPLANTATION

The development of intestinal transplantation must be placed in the context of patients and physicians faced with catastrophic clinical circumstances in the absence of reliable alternatives. The mortality rate of patients requiring PN for benign disease has been estimated at 5% to 25% per year, or about 15% at 3 years.[41] For infants, the risk for PN-induced liver disease is especially great. It is estimated that half the deaths in children receiving PN are due to liver failure.[42] Currently, intestinal transplantation is applied as rescue therapy for patients with life-threatening complications of intestinal failure. In 2001 the U.S. federal government through the Centers for Medicare and Medicaid Services (CMS) approved payment for intestinal transplantation at select centers.

Indications

Indications for intestinal transplantation are restricted to life-threatening complications of intestinal failure, with the most common complication being the development of liver disease. It is important to determine whether the liver disease is reversible. If the liver disease is found to be irreversible, based on either biopsy findings or clinical features such as massive splenomegaly, ascites, encephalopathy, or gastrointestinal bleeding, the patient should undergo combined liver–small bowel transplantation. Greater emphasis has recently been placed on considering isolated small bowel transplantation for patients with potentially reversible PN-induced liver disease. Regardless of the type of transplant required, early referral and listing are important to ensure the patient the greatest opportunity to obtain a transplant.

The other common indications for intestinal transplantation are an irreversible permanent PN requirement along with episodes of sepsis or loss of venous access. Septic episodes that would prompt consideration for intestinal transplantation are typically catheter related. Patients who have undergone multiple hospitalizations related to catheter sepsis, often requiring intensive unit care with the need for vasopressors, fall in this category. Other indications for intestinal transplantation are multiantibiotic-resistant bacteremia or metastatic infection in sites such as the tricuspid valve or brain. Loss of venous access typically implies an inability to place a catheter in the subclavian or intrajugular veins and the use of extemporaneous sites such as the hepatic veins or the inferior vena cava. A transplant evaluation is strongly recommended in patients with known poor survival on PN, such as those with microvillus inclusion disease, intestinal aganglionosis, or desmoid tumors that have previously been eviscerated. Today, with improved outcomes and large numbers of patients dying on the waiting list, greater responsibility is being placed on the treating physician to make earlier referral to a transplant center.

The transplantation evaluation process for patients with intestinal failure requires a multidisciplinary group of health care professionals, including surgeons, gastroenterologists, dietitians, social workers, and nurse specialists. The evaluation process also incorporates an assessment of the feeding program that the patient is currently receiving. Contrast studies of the small and large bowel are frequently performed. A liver biopsy is performed in patients with evidence of liver dysfunction to help select the appropriate type of transplantation procedure. During the evaluation process, other problems are addressed, including worsening liver failure, sepsis, difficult vascular access, and septic episodes. After being identified as a potential candidate, the patient is placed on an active transplantation waiting list.

Operative Procedure

The donor operation begins similarly regardless of the organs being removed. Potential organ donors are matched with recipients according to blood type, size, and medical necessity. Most patients with short-bowel syndrome have a loss of peritoneal domain, thus requiring the donor to be about 50% smaller than the potential recipient. Recent success with reduced-size intestinal transplants has challenged these donor size guidelines. Donors should be ABO blood group identical, although exceptions to this rule have been reported.[43] Human leukocyte antigen matching and a negative T-cell crossmatch may be beneficial, particularly for recipients of isolated small bowel allograft. Donor logistics often prevent this type of testing from being performed prospectively.

Removal of the intestine for isolated small bowel transplantation involves removal of the liver and small bowel together, after which they are separated on the back table.[44] The donor operation for a future liver–small bowel transplantation is relatively similar, but no hilar dissection is performed. The colon and stomach are mobilized out of the field, and the liver–small bowel composite is removed en bloc, with care taken to remove as much aorta proximal to the celiac axis as possible.[44]

Back-table preparation for an isolated small bowel graft involves removing the duodenum–head of the pancreas from the portal vein and superior mesenteric artery. For liver and small bowel grafting procedures, the preparation involves removal of the distal pancreas and spleen. The numerous intercostal arteries are ligated, and the distal end of the aorta is oversewn. Critical for a liver–small bowel graft is that no hepatic hilar dissection take place so that the hepatobiliary-duodenal complex remains undisturbed.[44]

The recipient operation typically makes use of previous incisions. For isolated small bowel transplantation, the infrarenal aorta is isolated, and the arterial anastomosis for the small bowel graft is typically performed between the donor superior mesenteric artery and the infrarenal aorta.[44] Venous drainage can be systemic or portal, but systemic drainage is preferred whenever liver disease is present. An enterostomy is created to decompress the small bowel and to facilitate biopsy. A loop ileostomy is the most common type of stoma created for both liver–small bowel and isolated small bowel transplantation.

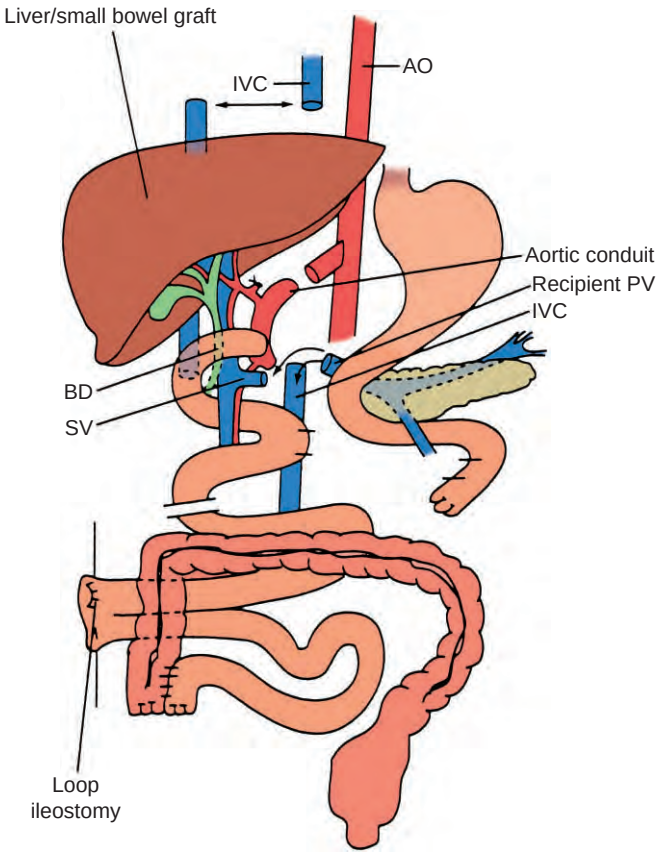

Figure 78–7. Diagram of a liver–small bowel allograft. This diagram demonstrates the intact hepatobiliary duodenal complex. AO, aorta; BD, bile duct; IVC, inferior vena cava; PV, portal vein; SV, splenic vein. (From Deroover A, Langnas A: Surgical methods of small bowel transplantation and liver-bowel transplantation. Curr Opin Organ Transplant 4:335, 1999.)

The liver–small bowel transplantation surgical technique leaves the donor hepatic hilar structures undisturbed and the hepatic-duodenal-biliary system intact (Fig. 78–7). The advantage of this approach is that it limits the necessary back-table dissection, prevents any torsion around the portal vein after implantation, and virtually eliminates any possible biliary tract complications after transplantation. The liver–small bowel composite allograft is implanted orthotopically. Arterial inflow is through the donor aortic conduit, and a native portacaval shunt is created to decompress the recipient's viscera. Under certain circumstances, particularly when the native foregut is diseased or dysfunctional, complete abdominal evisceration is performed before implantation of the donor organs. With evisceration of the native foregut the operation is often referred to as a multivisceral transplant. The proximal gastrointestinal anastomosis is frequently performed between the remnant proximal part of the stomach and the donor jejunum.

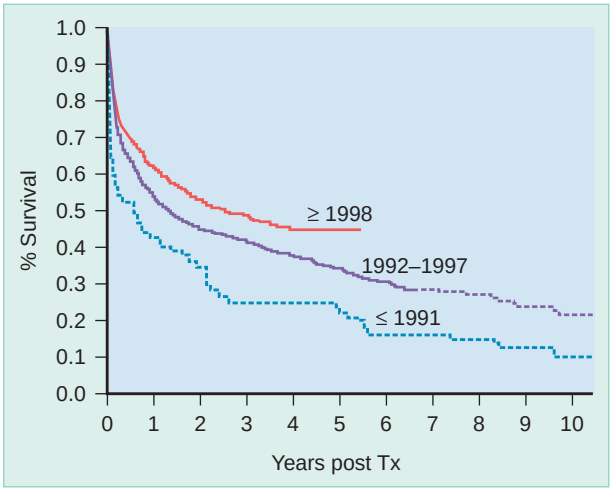

Figure 78–8. Graft survival rates after intestinal transplantation have improved over time. (From Grant D, Abu-Elmagd K, Reyes J, et al: 2003 Report of the intestine transplant registry: A new era has dawned. Ann Surg 241:607, 2005.)

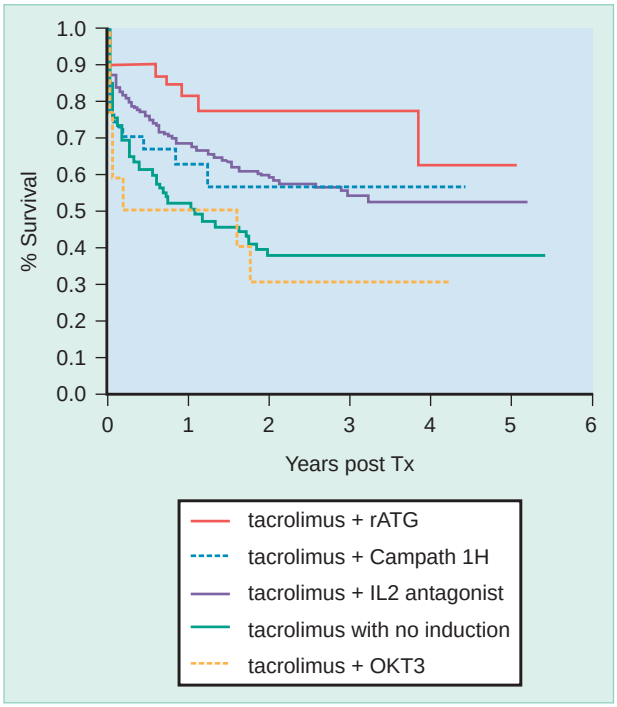

Figure 78–9. Graft-survival rates plotted according to the type of immunosuppressive protocol with particular reference to induction therapy. ATG, antithymocyte globulin; IL2, interleukin-2. (From Grant D, Abu-Elmagd K, Reyes J, et al: 2003 Report of the intestine transplant registry: A new era has dawned. Ann Surgery 241:607, 2005.)

After transplantation, the cornerstone of immunosuppressive management is the administration of tacrolimus and steroids. The majority of intestinal transplant programs now make use of some form of induction therapy, either with biologic agents such as Thymoglobulin or with interleukin-2 receptor blocking agents.[45-47] Reports have been made of other drugs being administered, including sirolimus, alemtuzumab (Campath 1H), and mycophenolate.[48] Numerous other agents are given as prophylaxis for infection, in particular, broad-spectrum antibiotics, antifungal agents, and antiviral drugs.

Outcome

Worldwide, based on published data from the 2003 Intestinal Transplant Registry (ITR) contributed by 61 programs in 10 countries, 989 transplants have been performed in 923 patients.[49] According to ITR data, isolated intestinal transplantation was performed 433 times and an intestinal allograft transplanted with a liver 556 times. Thirty-two grafts were obtained from living donors, including an identical twin and a triplet. In 2001 the CMS approved intestinal transplantation as therapy for patients with life-threatening complications of intestinal failure.

A total of 484 of the 923 patients reported in the ITR who underwent any type of intestinal transplantation are alive. The longest survivor has been on an enteral diet for over 14 years. Patient and graft survival has also steadily increased over time (Fig. 78–8). The ITR results also demonstrated factors important in improving patient and graft survival.[49] In a log-logistic model, factors associated with improved patient and graft survival included transplantation of a patient coming from home and the use of induction therapy (Fig. 78–9). As expected, programs that have performed at least 10 transplantations have better patient survival rates than do programs that have performed less than 10 transplantations. Patients who are called in from home have much higher survival rates, which should encourage physicians to refer patients earlier. Clinical experience remains confined to a small number of programs, with 83% of the cases performed at 10 institutions. The most common causes of death after intestinal transplantation included sepsis, multiorgan system failure, graft thrombosis, rejection, and post-transplantation lymphoma.

Rejection episodes continue to be a major problem in small bowel transplantation, even with tacrolimus-based immunosuppression combined with some form of induction therapy. The incidence of transplant rejection remains variable. According to the ITR, graft rejection rates were 57% for intestine grafts, 39% for combined intestine and liver grafts, and 48% for multivisceral grafts.[49] Contemporary single-center reports demonstrate even further reductions in rejection rates. At the University of Pittsburgh, Thymoglobulin induction combined with tacrolimus has resulted in a 44% rejection rate in the first month, whereas patients receiving interleukin-2 receptor blocking agents combined with tacrolimus at the University of Nebraska had a rate of about 5%.[45,47] These rates of rejection are now similar to those seen in recipients of heart, liver, and kidney transplants. The diagnosis of rejection is based on histologic findings. Mild rejection is diagnosed by the findings of

mild cryptitis, increased inflammatory infiltrated lamina propria, and apoptosis of crypt cells (Fig. 78–10). A diagnosis of moderate rejection is made when villus blunting develops in addition to the findings associated with mild rejection. Serious rejection is diagnosed when there is not only severe blunting but also complete loss of mucosal lining and severe crypt cell destruction. Biopsy of the small bowel allograft is performed either on a protocol basis or when changes in clinical findings occur. Clinical findings that could be associated with rejection include diarrhea, increased stoma output, bloody diarrhea, abdominal pain, or an intolerance to feedings. Unfortunately, a noninvasive marker for the diagnosis of rejection episodes is not available.

Infections after organ transplantation are generally frequent as a result of two important factors in these patients: increased levels of immunosuppression and an allograft colonized with enteric organisms. Common sites of bacterial infection include the central line, surgical wound, and intraperitoneum. Bacteremia or fungemia may also develop as a consequence of allograft rejection, infectious enteritis, or preservation injury. With any of these bowel injuries, there can be loss of mucosa with eventual translocation of enteric organisms.

The primary viruses that cause infections after intestinal transplantation include herpesviruses such as cytomegalovirus (CMV) and Epstein-Barr virus (EBV). A variety of strategies have been proposed to either prevent or diagnose both CMV and EBV infection. Molecular monitoring for both EBV and CMV DNA in blood is now routine in most transplant programs. Prophylactic measures include infusions of pooled immunoglobulins and antiviral drugs such as ganciclovir. The intestinal graft is the most common site of CMV infection. Treatment is based on the use of antiviral drugs such as ganciclovir or foscarnet.

Post-transplant lymphoproliferative disease (PTLD) is an EBV-associated process that occurs after all solid organ transplantations. Intestinal transplant recipients appear to be at higher risk for PTLD than do recipients of other organ transplants, probably in part because of the high level of immunosuppression needed to control rejection, as well as the relatively young age of recipients. The reported incidence of PTLD after intestinal transplantation is between 7% and 29%.[45-47,49] Treatment of PTLD often involves lowering of immunosuppression and the use of antiviral agents as a first line of therapy. Newer treatments being proposed include the use of a low-dose cyclophosphamide (Cytoxan) regimen to control PTLD without the side effects of more traditional chemotherapeutic regimens.[50] Rituximab, a monoclonal antibody directed at CD20-positive B cells, is now being used to treat PTLD. Recently, the use of blood tests to measure qualitative and quantitative amounts of EBV DNA in the peripheral blood of transplant recipients has been advocated.[51] Measurements of EBV DNA are used

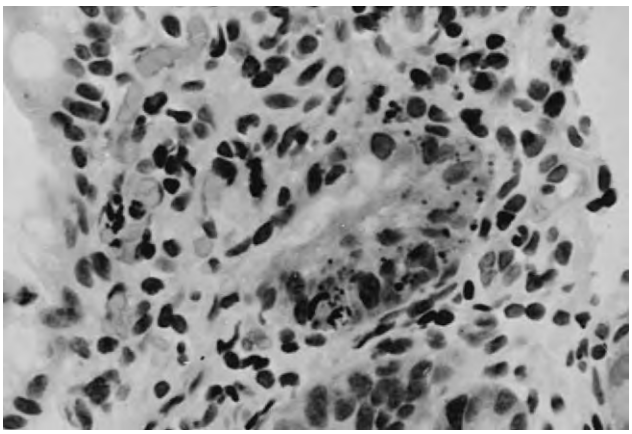

Figure 78–10. Photomicrograph of intestinal rejection in a transplanted intestinal graft. Apoptosis is a prominent feature. A single crypt is seen in the center with multiple apoptotic cells.

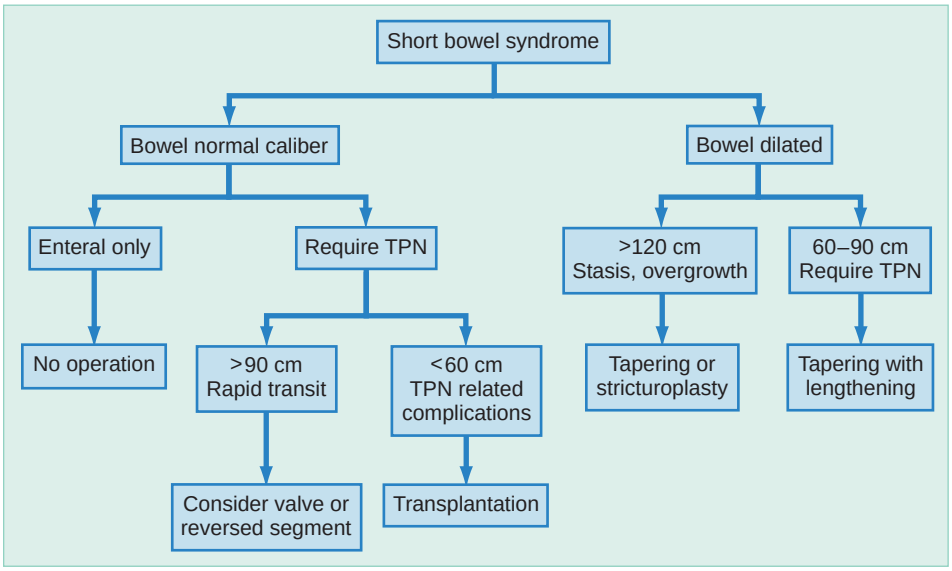

Figure 78–11. Surgical management of short-bowel syndrome. TPN, total parenteral nutrition. (From Thompson JS, Langnas AN, Pinch LW, et al: Surgical approach to the short bowel syndrome: Experience in a population of 160 patients. Ann Surg 22:600, 1995.)

in the hope of identifying PTLD before it becomes clinically evident so that less toxic preemptive therapy can be administered.

Graft-versus-host disease has been a relatively uncommon clinical event after intestinal transplantation. Its incidence was 7% in one series.[45] The diagnosis is based on traditional histopathologic criteria of skin, native gastrointestinal tract, or mucosa. Treatment of graft-versus-host disease is based primarily on increases in immunosuppression.

The functional status of the small bowel allograft is the foremost factor in determining the long-term quality of life for recipients. According to the ITR, enteral autonomy develops in 81% of recipients. Data also demonstrate that intestinal transplantation becomes cost-effective in comparison to PN at 2 years.[52]

The increasing experience and improved outcome of intestinal transplantation support the clinical use of this treatment modality. Although the potential morbidity of transplantation is greater than that of nontransplant surgical procedures, so too is the benefit. Intestinal transplantation is potentially applicable to a greater number of patients with short-bowel syndrome than nontransplant procedures are. All these procedures should be performed only in carefully selected patients (Fig. 78–11).

Gastrointestinal Carcinoid Tumors

Cletus A. Arciero ▪ Elin R. Sigurdson

Lubarsch first described carcinoid tumors in 1888.[1] Oberndorfer used the term "karzinoide" in 1907 to describe a tumor that was more indolent behaving than adenocarcinoma.[2] Since these early discoveries, carcinoid neoplasms have been described in most organs in the body. Carcinoid neoplasms are neuroendocrine tumors that span the realm from benign to malignant. They are derived from enterochromaffin cells, or secretory cells found within respiratory and gastrointestinal epithelial tissues. These cells, which belong to the amine precursor uptake decarboxylase (APUD) system, are often argentaffinic (silver staining), are usually argyrophilic (silver staining only with the addition of a reducing agent), and produce a wide array of biogenic amines, neuropeptides, and peptide hormones. Although gastrointestinal neuroendocrine tumors are rare, carcinoid tumors are the most common of them.

INCIDENCE AND EPIDEMIOLOGY

The incidence of gastrointestinal carcinoids in the United States is estimated to be 2.47 to 2.58 per 100,000, with similar rates noted in Europe and Japan.[3] The incidence of carcinoid tumors is higher in African Americans, who have rates of 3.98 to 4.48 per 100,000. Necroscopy studies have shown that upward of 0.65% to 1.2% of all patients examined exhibit evidence of a small intestine carcinoid.[4] However, because of their often indolent course, far fewer diagnoses are made. The tumor occurs most commonly in the fifth to sixth decade of life with a slight predilection for females (55 : 44 female-to-male ratio). Sixty-seven percent of all carcinoids arise in the gastrointestinal tract, with the majority (25.3%) of the remaining occurring in the tracheobronchial tree.[3]

Gastrointestinal carcinoids are distributed via embryologic origins: foregut, midgut, and hindgut. Foregut carcinoids account for approximately 7% of all carcinoids, whereas midgut and hindgut carcinoids represent 62% and 30% of all carcinoids, respectively. Because of the preponderance of APUD cells within the ileum and appendix, the most common sites are the appendix (35%) and small intestine (23%), followed by the rectosigmoid (12%) and colon (6%). The majority of the small intestine carcinoids occur within 2 ft of the ileocecal valve. Both foregut and midgut carcinoids are associated with a second, synchronous primary carcinoid tumor of similar embryologic origin in 25% of cases. Non-neuroendocrine, synchronous cancers are discovered in 17% to 53% of patients with carcinoid tumors.[5]

Some patients have a genetic predisposition to carcinoid tumors. First-degree relatives of patients with carcinoid have an increased relative risk (RR = 3.6) for development of a carcinoid tumor.[5] There is also a notably increased risk for carcinoid tumors in those who have a well-educated social background (RR = 2.8) and reside in a major metropolitan region (RR = 1.39).[5]

PATHOLOGY

Carcinoid tumors are composed of enterochromaffin cells (which are cells that stain with chromaffin). Grossly, these tumors are well-circumscribed, round, submucosal lesions that reveal a yellow coloration when sectioned because of the high lipid content of the tumors (Fig. 79–1). They are typically small (<2 cm) and multicentric. Microscopically, carcinoid tumors are pathologically categorized by the presence of small, uniform cells in orderly bands or ribbons (Fig. 79–2). They have benign cytologic features with rare mitotic figures. The cytoplasm is marked by the abundant presence of neurosecretory granules, and immunohistochemical staining reveals numerous peptides. The exact microscopic features of carcinoid neoplasms vary according to their origin. Foregut tumors are mostly argyrophilic, whereas midgut tumors are mostly argentaffinic. Hindgut tumors appear to be a mix, with 60% to 70% being argyrophilic, 8% to 16% being argentaffinic, and the rest having no

evidence of any silver staining. Carcinoid tumors have five histologic patterns: insular, trabecular, glandular, undifferentiated, and mixed.[6]

Although pathologic examination of the primary tumor cannot clearly define malignant versus benign without evidence of metastasis, certain features indicate increased aggressiveness. These more aggressive-appearing carcinoids are termed atypical/anaplastic carcinoid and have features of increased cellular atypia, high mitotic rate/activity, or necrosis. Immunohistochemical staining to detect increased levels of p21 or MIB-1, or both, can aid in determining the increased aggressiveness of a tumor.[7,8]

CLINICAL FEATURES

Carcinoid tumors are marked by their relatively slow growth and often dearth of symptoms. The median

duration of symptoms is 2 years before diagnosis. Eighty percent to 90% of patients who do have symptoms at initial evaluation are found to have metastatic or advanced disease.

The behavior of carcinoid neoplasms is dependent on the embryologic origin of the tumor. Foregut carcinoids consist of gastric and duodenal tumors. Duodenal carcinoids may cause gastrointestinal obstruction, biliary obstruction, or duodenal ulcers, although they are often discovered incidentally during endoscopy. Gastric carcinoids, 0.3% of all stomach neoplasms, can be associated with a myriad of symptoms, including abdominal pain, bleeding, and rarely, atypical carcinoid syndrome. Gastric carcinoids arise from enterochromaffin-like cells and are classified into three groups. Type I consists of gastric carcinoids associated with chronic atrophic gastritis type A. This group represents 75% of all gastric carcinoids and is marked by a lack of parietal cells, achlorhydria, and hypergastrinemia. The tumors are often less than 1 cm in diameter, diffusely involve the stomach, and metastasize in 10% of all cases, with an overall 5-year survival rate approaching 100%. The present theory is that these carcinoid tumors arise secondary to chronic stimulation by high gastrin levels and possibly mutations of the RegI alpha gene.[9] Animal models have shown a direct relationship between hypergastrinemia and carcinoid tumor formation, therefore raising the issue of the safety of using chronic proton pump inhibitors and whether antrectomy might lead to tumor regression. Patients with type I gastric carcinoid are often 70 to 80 years of age and female with symptoms of abdominal pain. Carcinoid syndrome is not seen, and these tumors usually follow an indolent course.

Type II gastric carcinoid tumors are associated with Zollinger-Ellison syndrome and familial multiple endocrine neoplasia type I syndrome. Patients in this group, 5% of those with gastric carcinoids, are younger (in their sixth decade of life), exhibit no evidence of carcinoid syndrome, and have a tumor size less than 1.5 cm with an equal gender distribution. Although metastases develop in up to 25%, the clinical course is usually indolent.

The last group of gastric carcinoids (type III) consists of sporadic carcinoid tumors. Patients in this group have larger tumors, and hepatic metastases develop in more than 65%. This group of patients (15% to 25% of those with gastric carcinoids) is associated with the development of an atypical carcinoid syndrome and have a 5-year survival rate near 50%. Indicators of tumor aggressiveness include angiolymphatic invasion, clinicopathologic type, mitotic index, Ki-67 grade, and tumor size.[10]

Midgut carcinoid tumors are the most common and include neoplasms arising from the ileum, jejunum, appendix, and proximal part of the colon. The tumors can lead to obstruction, abdominal pain, diarrhea, and gastrointestinal bleeding. Small intestinal carcinoids are also well known to cause intense fibrosing reactions leading to obstruction, ischemia, and strangulation of the small bowel and ureters (Fig. 79–3). Although carcinoid syndrome develops in only 5% to 7% of patients with midgut carcinoid, these patients represent 90% of all patients in whom carcinoid syndrome develops.

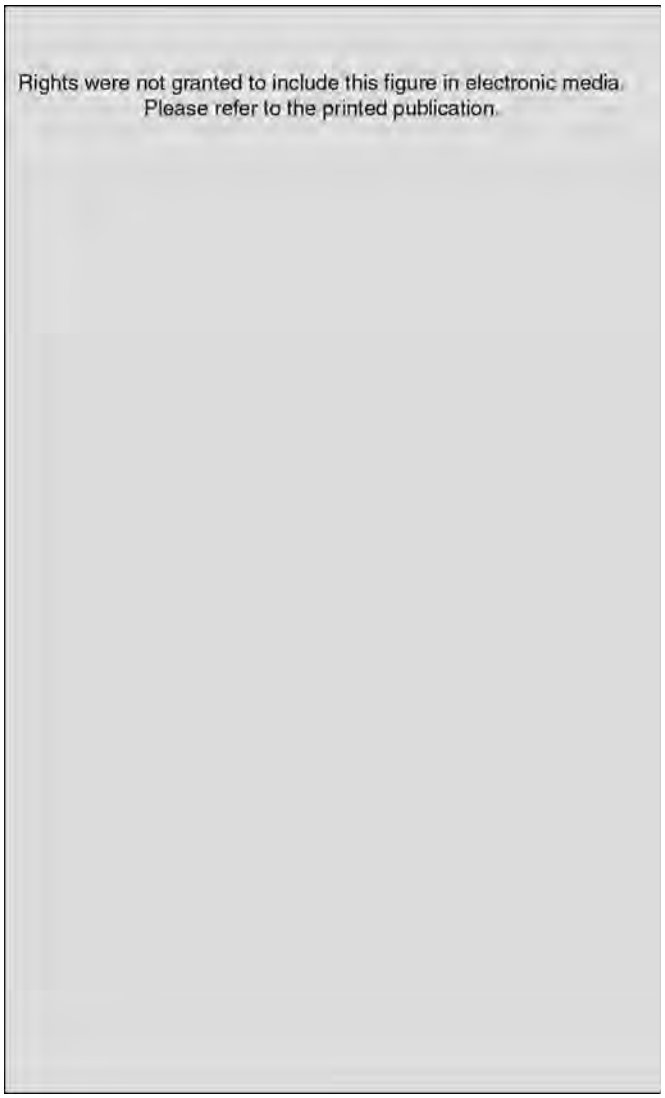

Figure 79–3. Gross pathologic characteristics of carcinoid tumor. **A,** Carcinoid tumor of the distal ileum demonstrating intense desmoplastic reaction and fibrosis of the bowel wall. **B,** Mesenteric metastases from a carcinoid tumor of the small bowel. (Adapted from Evers BM, Townsend CM Jr, Thompson JC: Small intestine. In Schwartz SI [ed]: Principles of Surgery, 7th ed. New York, McGraw-Hill, 1999, p 1245, with permission of The McGraw-Hill Companies.)

Abdominal pain is the initial complaint in 40% of patients with midgut carcinoid. This pain can be multifactorial and be due to bulky lymphadenopathy, mesenteric vascular invasion/occlusion, microvascular metastasis, hepatic metastases, or the vasoactive effects of serotonin. Patients can also have obstruction as a result of mesenteric kinking from the desmoplastic response. The fibrosis associated with midgut carcinoids can be quite extensive. Not only can intestinal obstruction occur, but retroperitoneal fibrosis can also develop and lead to ureteral obstruction and even Peyronie's disease (inflammation and scarring of the tunica albuginea).

Appendiceal carcinoid tumor is one of the most common forms of carcinoid disease and accounts for 50% of all diagnosed carcinoids. Ninety percent of appendiceal carcinoids are found via pathologic examination in patients undergoing incidental appendectomy. Another 10% undergo appendectomy for appendicitis, with two thirds of these patients having an incidental finding of a carcinoid tumor, usually located at the tip of the appendix. In general, less than 1% of all appendiceal carcinoid tumors have carcinoid syndrome as the initial clinical manifestation.

Hindgut carcinoids arise from the distal end of the colon and rectum. These nonsecretory carcinoid tumors are most often asymptomatic and discovered during colonoscopy for screening or evaluation of unrelated complaints. If symptoms are present, they are usually due to the increased size of the tumor, and these patients will often have symptoms similar to those with colorectal adenocarcinoma (bleeding, changes in bowel habits, or obstruction).

Carcinoid Syndrome

Malignant carcinoid syndrome is a clinical entity marked by flushing, diarrhea, abdominal cramping, wheezing, heart valve dysfunction, and pellagra. Although classically described as the hallmark of a carcinoid tumor, carcinoid syndrome occurs relatively infrequently. It is found in 10% to 18% of all patients with carcinoid tumors, but the incidence increases to 40% to 50% in patients with advanced disease.[11]

Carcinoid syndrome is based on the biochemical behavior of the tumors involved. Carcinoid tumors are neoplasms of peptide- and amine-producing cells, the enterochromaffin or Kulchitsky cells. These cells produce a large number of substances, including serotonin, tachykinins, and histamine. Ultimately, it is the metabolism of tryptophan that leads to the development of carcinoid syndrome. In carcinoid tumors that produce large amounts of serotonin, dietary tryptophan is diverted for this purpose. It is the actions of serotonin that lead to many of the manifestations of carcinoid syndrome. The syndrome develops in the presence of hepatic metastasis, which precludes hepatic inactivation of the active metabolites of serotonin.

The development of carcinoid syndrome is related to the embryologic origin of the original tumor. Midgut carcinoids are the most common source of carcinoid syndrome because these tumors produce high levels of serotonin. More than 90% of all patients suffering from carcinoid syndrome have a midgut primary. Foregut carcinoids, on the other hand, lack the aromatic amino acid decarboxylase required to convert 5-hydroxytryptamine (5-HT) to serotonin and therefore cannot produce the classic carcinoid syndrome. Hindgut carcinoids also lack the ability to convert tryptophan to serotonin, and thus even if metastatic lesions are present, carcinoid syndrome will not develop.

The symptoms associated with carcinoid syndrome include cutaneous flushing, which occurs in 85% of affected patients. This flushing, which has diverse patterns, including diffuse erythematous, violaceous, prolonged, and bright red patches, is possibly caused by the release of various kinins. The flushing lasts 2 to 10 minutes in patients with facial flushing and can last 2 to 3 days in those whose flushing occurs throughout their body. There may also be an associated tachycardia and hypotension. This rash can increase in duration as the disease progresses. Onset of the rash has been linked to eating, alcohol intake, defecation, emotion, palpation of the liver, and induction of anesthesia. General anesthesia can induce a carcinoid crisis marked by the sudden release of catecholamines from the tumor, acute hypotension, flushing, and bronchospasm. Pretreatment with octreotide can help avoid this anesthetic complication.

The diarrhea associated with carcinoid syndrome is directly related to serum serotonin levels; serotonin stimulates secretin release, which results in an increase in intestinal motility and decreased intestinal absorption. This watery, nonbloody diarrhea affects 80% of patients with carcinoid syndrome and is the symptom described by patients as the most debilitating. It is associated with abdominal cramping, and the number of daily bowel movements ranges from a few to more than 30.

Bronchospasm develops in 10% to 20% of patients with carcinoid syndrome. This wheezing/dyspnea often occurs during flushing episodes. However, treatment with β-adrenergic agonists can worsen the situation by triggering an intense, prolonged symptomatic vasodilation.

The valvular disease associated with carcinoid syndrome is a result of valvular fibrosis secondary to high concentrations of circulating amines. Serotonin is thought to be a major cause of the fibrosing reaction via stimulation of fibroblasts and fibrogenesis. Fibrous plaques develop on the endocardium of the valvular cusps, cardiac chambers, and occasionally, the intima of the pulmonary arteries or aorta (or both). The right side of the heart is the most commonly affected because of pulmonary inactivation of the humoral substances before exposure to the left side of the heart.

Other symptoms that can develop include venous telangiectasia, pellagra as a result of diversion of dietary tryptophan, and muscle wasting secondary to protein malnutrition.

Atypical or variant carcinoid syndrome is a syndrome that occurs in patients with gastric carcinoid tumors. These patients experience cutaneous flushes that are patchy and highly pruritic. Diarrhea, bronchospasm, and cardiac lesions are rare. It is thought that the syndrome is secondary to large release of histamine from the tumor rather than serotonin.

DIAGNOSIS

Laboratory Studies

Biochemical testing can often be the cornerstone of diagnosing a carcinoid tumor preoperatively. The 24-hour urinary excretion of 5-hydroxyindoleacetic acid (5-HIAA) is a helpful laboratory study. This test has a

sensitivity of 75% to 100%, with the greatest sensitivity in patients with midgut carcinoids. Consumption of a large amount of tryptophan-containing food before urine specimen collection can confound the test results. Therefore, dietary intake must be controlled for accurate measurements. The sensitivity is decreased somewhat in patients with foregut and hindgut tumors. Foregut tumors generally lack aromatic amino acid decarboxylase; therefore 5-HIAA secretion is relatively unhelpful. However, 5-HT urinary secretion is increased and, with foregut tumor, has a sensitivity of 60%.[12,13]

The serum chromogranin level is another biochemical assay that parallels urinary 5-HIAA. Although the sensitivity and specificity are not well supported for all gastrointestinal carcinoids, studies indicate that chromogranin A is 100%, chromogranin B is 85%, and chromogranin C is 5% specific for carcinoid tumor.[14] Chromogranin A and an associated protein neurokinin A have also been used as a prognostic indicator, with increasing levels correlating with decreased survival.[13]

Although serum serotonin levels are increased in patients with carcinoid tumors, its specificity is low. Other markers such as substance P, neurotensin, human chorionic gonadotropin, and neuropeptides K and PP have not been useful.

Several provocative tests have historically been used to aid in the diagnosis of carcinoid. An epinephrine provocation test involves the use of escalating doses of epinephrine to produce carcinoid syndrome. A pentagastrin provocation test similarly involves the use of pentagastrin to stimulate a flushing response. Neither of the tests is commonly used.

Imaging Studies

Radiographic imaging of primary carcinoid tumors is difficult because of the small size of most tumors and their common submucosal location. A large proportion of these tumors are also located within the small bowel, which is historically difficult to image. Common approaches to the diagnosis of carcinoid tumors are based on the features of the tumors themselves. Gastric and rectal carcinoids are often asymptomatic and are thus most commonly imaged on screening or diagnostic endoscopy. The advent of endoscopic ultrasound has aided in the characterization of these tumors.

Barium studies, including small bowel series and enteroclysis, have shown good success in the diagnosis of larger carcinoid tumors of the small bowel (Fig. 79–4). The submucosal location of carcinoid tumors actually lends itself to more accurate localization with contrast studies, especially enteroclysis, than with conventional sectional imaging, such as computed tomography (CT).[15] Barium studies can also display the characteristics of a carcinoid tumor, including target signs of ulcerated tumors and angulation or narrowing from fibrosis. These characteristics, however, are shared by many other small bowel tumors, thus decreasing the specificity of barium studies.

The most commonly used radiologic examination in patients with a carcinoid neoplasm is CT. Primary tumor localization is rare with CT because of its submucosal location and often small size. CT is effective at identifying the mesenteric stranding/fibrosis that often accompanies carcinoid tumors, as well as mesenteric nodal involvement. The desmoplastic response can also cause changes in the mesenteric vasculature that can be identified with CT-angiography. The advent of three-dimensional CT imaging/reconstruction has likewise aided in the radiographic identification of small bowel tumors, including carcinoids.[16] CT is most effective for identifying hepatic metastasis, with sensitivity greater than 85%.[17,18] Metastatic carcinoid tumors are highly vascular and hence display bright enhancement during arterial-phase imaging.

The role of magnetic resonance imaging (MRI) in the diagnosis of a primary carcinoid tumor is limited, and it

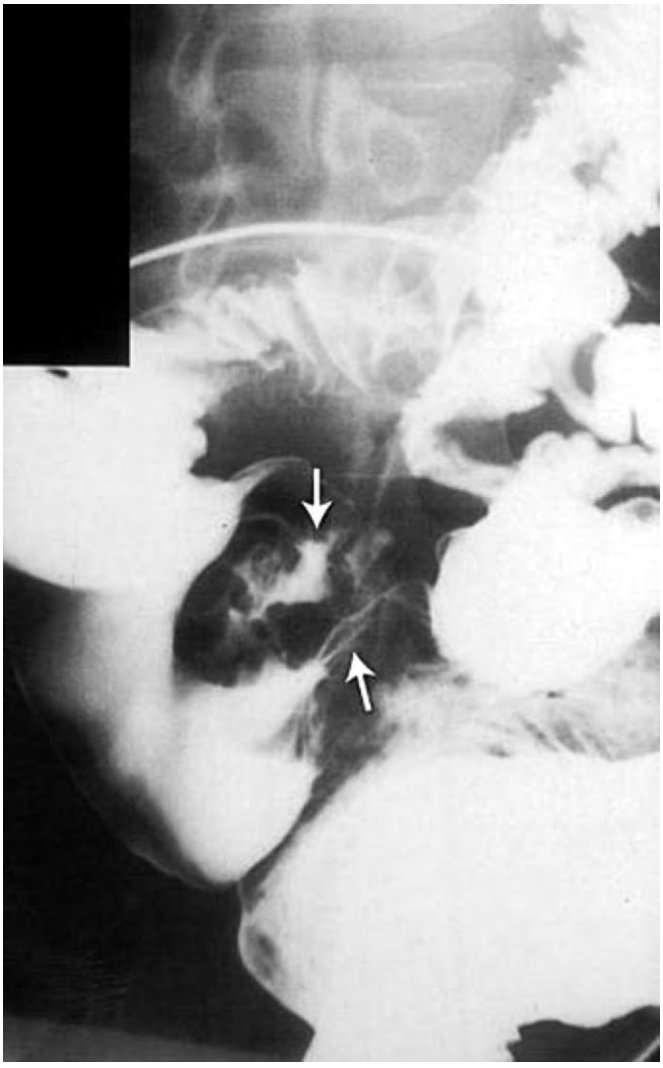

Figure 79–4. A barium radiograph of a carcinoid tumor of the terminal ileum demonstrates fibrosis with multiple filling defects and high-grade partial obstruction *(arrows).* (Courtesy of Melvyn H. Schreiber, M.D., The University of Texas Medical Branch.)

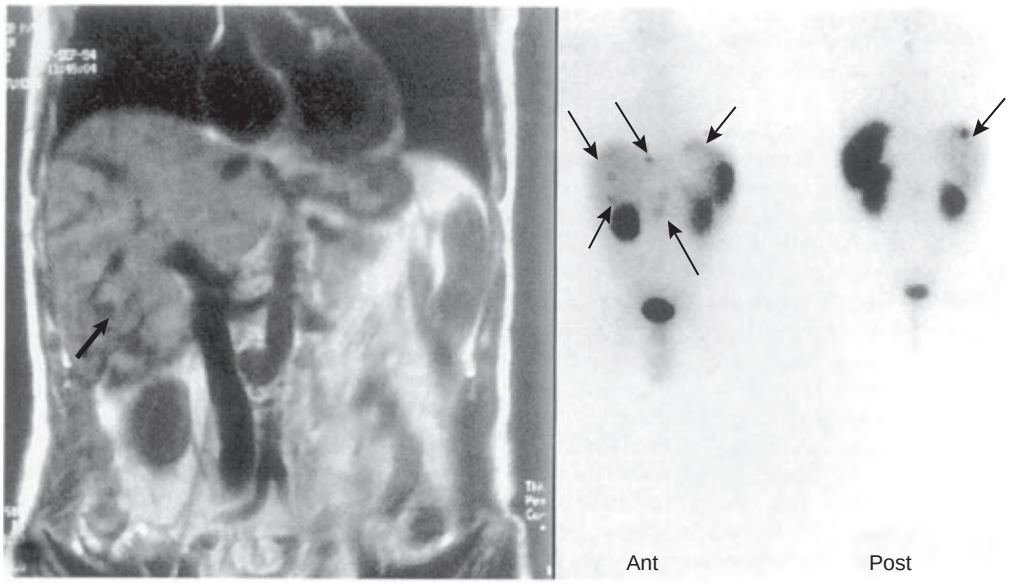

Figure 79–5. **A,** Magnetic resonance image showing a single focus of metastatic disease *(arrow)* in the right lobe of the liver in a patient with a carcinoid tumor and elevated 5-hydroxyindoleacetic acid. **B,** A ^{111}In-labeled pentetreotide scan of the same patient shows multiple hepatic lesions and two involved para-aortic lymph nodes. These findings were confirmed at laparotomy. Radionuclide activity in the kidneys, spleen, and bladder is evident. (From Anthony T, Kim L: Gastrointestinal carcinoid tumors and the carcinoid syndrome. In Feldman M, Friedman LS, Sleisenger MH [eds]: Sleisenger & Fordtran's Gastrointestinal and Liver Disease, 7th ed. Philadelphia, WB Saunders, 2002, p 2160.)

adds little or no information above that provided by CT. In the assessment of hepatic metastases, MRI has recently been shown to be more effective than either CT or somatostatin receptor–based scintigraphy (SRS) (Fig. 79–5).[19]

SRS has been used to image carcinoid tumors. Based on ^{111}In-labeled diethylenetriamine pentaacetic acid (DPTA)-D-Phe1-octreotide, Octreoscan uses a somatostatin analogue to obtain 80% to 90% sensitivity and specificity in identifying carcinoid neoplasms (see Fig. 79–5).[20] Various ligands have been used, including octreotide, pentetreotide, and lanreotide, with octreotide showing the greatest sensitivity for carcinoid tumors.[21] The technology is most effective in somatostatin receptor–positive carcinoid tumors, thus limiting its use in tumors that are nonfunctional. The technology is also limited in patients who do not exhibit carcinoid syndrome, for whom the sensitivity is only 60% for identification of the primary tumor.[22] The addition of single-photon emission computed tomography (SPECT) has increased the sensitivity of SRS in the detection of abdominal carcinoid.[23,24] SRS technology is also well suited to monitor response to treatment and progression of disease.

Positron emission tomography (PET) has had mixed results in imaging carcinoid tumors.[25] 2-Deoxy-2-[^{18}F]fluoro-D-glucose (FDG)-PET appears to be sensitive and specific in identifying carcinoid tumors that exhibit high proliferative activity or are poorly differentiated. However, for tumors that have low proliferative activity and are well differentiated, somatostatin-based imaging is much more sensitive and specific.[26] FDG-PET has shown some utility in identifying the retroperitoneal fibrosis that may develop in patients with carcinoid neoplasms.[27] FDG-PET should be used in patients with suspected or known carcinoid who have negative somatostatin receptor imaging.[21,28] A newer modality that has found improved success with PET technology is 5-HT–PET. 5-HT–PET has shown improved accuracy in comparison to both FDG-PET and conventional CT.[29] In a direct comparison of FDG-PET, 5-HT–PET, Octreoscan, and conventional imaging (CT/MRI), researchers report that conventional imaging is the most sensitive technique.

Another modality that has been tested for the evaluation of patients with carcinoid tumors is ^{131}I-metaiodobenzylguanidine (MIBG) scans. Limited studies have shown results roughly equivalent to those of CT, with a sensitivity of 55% to 70% and a specificity of 95%.[22,30] This scan may be especially helpful in patients who are being maintained on long-term octreotide therapy or who have had previously unrevealing Octreoscan findings.

TREATMENT AND OUTCOME

Surgery is the only cure currently available for patients with carcinoid tumors. The extent of resection is based on the location of the tumor within the gastrointestinal tract, the size of the tumor, the presence/absence of metastatic disease, and the presence/absence of

symptoms. The embryologic origin also determines not only the surgical approach but also the overall prognosis. Patients with foregut carcinoids can expect 5-year survival rates of 74%, 40%, and 18% for locoregional, nodal, and metastatic disease, respectively. The 5-year survival rates with midgut (80%, 75%, 35%) and hindgut carcinoids (76%, 46%, 19%) reveal the differences.[3]

Locoregional Disease

Duodenal carcinoid tumors are extremely rare, and therefore there is no standard surgical approach. Duodenal carcinoid tumors smaller than 1 cm should be treated by endoscopic or local resection. Although tumors 1 to 2 cm in diameter can be removed endoscopically, it is recommended that transduodenal resection be performed.[31] In tumors larger than 2 cm, more aggressive resection should be undertaken, which may entail segmental resection or pancreaticoduodenectomy with en bloc lymph node dissection. The overall 5-year survival rate for patients with duodenal carcinoids is 60%, but patients with tumors larger than 2 cm have a much higher rate of recurrence and lower survival than those with smaller tumors.[31,32]

Resection of gastric carcinoids is based on the type of tumor. Type I and II gastric carcinoids small than 1 cm in diameter can be treated by local excision or endoscopic removal, followed by endoscopic surveillance every 6 to 12 months. Therapy for lesions 1 to 2 cm in diameter is variable. Some report using antrectomy to remove gastrin stimulation along with local excision of the tumor or tumors, whereas others approach all tumors larger than 1 cm in diameter with resection via gastrectomy, partial or total.[22,33,34] However, the success of this approach is still unknown. Tumors 2 cm or larger in diameter should be resected via partial or total gastrectomy, depending on their location. The prognosis for patients with type I and II gastric carcinoids is excellent, with a nearly 100% 5-year survival rate.

Type III gastric carcinoids are much more aggressive. These tumors should be treated by partial/total gastrectomy and lymph node dissection.[22,33] Despite this aggressive surgical approach, 5-year survival rates are closer to 50%, in part because of the large percentage of patients initially seen with metastatic disease.

Carcinoid tumors of the jejunum and ileum should be treated by segmental resection and en bloc lymphadenectomy. This approach should be undertaken even in patients with metastatic disease in an attempt to avoid the fibrotic complications that are often associated with primary small bowel carcinoids.[35] Patients with localized disease have a 5-year survival rate of 75%, which drops to 59% to 65% for nodal disease and to less than 36% for metastatic disease.[34] Patients with recurrent disease may live many years.

Treatment of carcinoid tumor of the appendix is largely based on its excellent prognosis and the likelihood of metastatic disease. Tumors that are smaller than 2 cm and do not involve the base can be safely removed via appendectomy alone. If the base is involved in an otherwise low-risk tumor, cecectomy can be performed. Tumors that are 2 cm or larger in diameter or have mesoappendiceal invasion should be treated by right colectomy.[36] Overall, the rate of lymphatic spread of appendiceal carcinoid is very low, and such spread is rare in tumors smaller than 2 cm in diameter.[36] Five-year survival rates are 94% for patients with localized disease, 85% for nodal disease, and 34% for metastatic disease.[3,37]

Carcinoid tumors of the colon should be managed in the same manner as colonic adenocarcinoma. Therefore, all tumors of the colon should be treated by segmental colectomy and resection of the accompanying lymph nodes.[38] Five-year survival rates for colonic carcinoid range from 71% in patients with locoregional disease to 20% in those with metastatic disease.[3]

Rectal carcinoids that are smaller than 1 cm in diameter can be treated by local excision, often endoscopically. Tumors larger than 2 cm in diameter should be treated by radical resection, either low anterior resection or abdominoperineal resection. The role of the more radical resection has been questioned because of the lack of a survival benefit over local excision.[39] Overall, 5-year survival rates are 81% for patients with locoregional disease, 47% for nodal disease, and 18% for metastatic disease.[3] Management of rectal carcinoid tumors that are 1 to 2 cm in diameter is more controversial. Researchers have proposed that poor prognostic markers such as muscular invasion, ulceration, or symptoms at diagnosis should lead to radical resection rather than local excision.[34]

These guidelines for resection of carcinoid tumors are not absolute; individual clinical scenarios must be considered when deciding on the treatment plan and extent of resection.

Metastatic Disease

Surgical Therapy

The approach to the treatment of patients with metastatic disease is based on symptoms. Patients whose only symptoms are mild diarrhea may be successfully treated with oral codeine. However, the role of surgical intervention for metastatic disease has increased in modern times. The biologic activity of carcinoid neoplasms lends itself to aggressive treatment of metastatic disease.

Most patients with carcinoid tumors should undergo resection of the primary tumor regardless of metastasis. Such resection aids in avoiding complications from growth of the primary tumor in terms of bleeding, obstruction, and abdominal pain, especially with midgut carcinoids because of their propensity to cause intense fibrosing reactions. Even large tumors that are locally advanced with nodal disease are usually amenable to surgical resection.[40]

Patients with hepatic metastases may also benefit from surgical intervention. By using a resection or ablative approach to hepatic metastases, the patient can be palliated and even enjoy a long-term survival benefit. Surgical therapy for metastatic carcinoid tumors is aimed at removing more than 90% of the tumor burden via either anatomic or wedge resections, with acceptable morbidity

and mortality rates of 15% and 1.2%, respectively.[40] By using this cytoreductive approach, symptoms from metastatic carcinoid are reduced in 95% of patients, with a median symptom-free duration of 45 months. Five-year survival rates improve from 40% to 50% in patients who do not undergo surgery to 60% to 82% in patients after hepatic resection of their metastatic disease.[41,42]

Patients whose tumor is unresectable or in whom reduction of greater than 90% of the tumor burden is not feasible may be palliated with techniques of hepatic therapy. Palliation methods include radiofrequency ablation (RFA), cryotherapy, hepatic arterial occlusion, embolization, and chemoembolization.

RFA has found success as an ablative technique for colorectal metastases. Its application to metastatic carcinoid has also been shown to be effective in patients with unresectable hepatic disease or as an adjunct to resection. In one study, the use of RFA for metastatic carcinoid provided symptomatic relief in greater than 80% of patients, and 41% showed no progression of disease during a short follow-up period.[43] Cryotherapy has also provided good symptomatic relief for up to 100% of patients with metastatic carcinoid.[44] Both modalities have relatively short-term response rates, but they can be successfully used on multiple occasions in patients with recurrent disease.

Ablative techniques that are based on vascular occlusion or embolization have also been studied. Their ability to induce tumor necrosis has largely been unsuccessful because of the rich collateral circulation within the liver. Hepatic arterial vascular occlusive therapy produces biochemical and tumor response rates of 37%. Embolization, often with gelatin, has shown slightly better results. Chemoembolization combines inflow disruption with the local administration of chemotherapeutic agents. This technique has led to a reduction of symptoms in 60% to 100% of patients with carcinoid syndrome and a biochemical response in 57% to 91%.[45] However, the results of these therapies have been mostly symptomatic and short lived. Patients undergoing either of these therapies are also subject to complications after occlusion/embolization, including abdominal pain, fever, fatigue, and even carcinoid crises as a result of the sudden release of hormones from the targeted lesion or lesions.

Orthotopic liver transplantation has also been performed in patients with metastatic carcinoid; however, its true role in the treatment of patients with metastatic carcinoid remains unclear. There have been limited attempts at liver transplantation in this patient population, but with significant morbidity and mortality and high rates of recurrence. Recently, researchers have attempted to define a more select group of patients for transplantation. Patients who appear to have the greatest survival rates are those with well-differentiated tumors that exhibit low proliferative activity. In this select group, orthotopic liver transplantation can yield a 5-year survival rate of up to 69%.[46]

Medical Therapy

Systemic treatment of patients with advanced carcinoid tumors has focused mainly on relief of the symptoms of carcinoid syndrome. The most commonly used therapy for such patients is somatostatin receptor–mediated hormonal therapy. The somatostatin receptors are blocked with a somatostatin analogue, thereby relieving the flushing, diarrhea, and other symptoms of carcinoid syndrome. The most commonly prescribed agent has been octreotide. Octreotide administration leads to resolution or a reduction in symptoms, including flushing (53% complete response, 32% partial response) and diarrhea (25% complete response, 49% partial response). However, the short half-life (2 to 4 minutes) of octreotide necessitates continuous infusion or twice-daily subcutaneous injections.

Newer analogues with longer half-lives have recently been developed with similar response rates. Lanreotide is administered every 10 to 14 days, whereas depot octreotide is given just once monthly. Side effects of the treatment include sinus bradycardia, arrhythmias, gallbladder stones, steatorrhea, hypothyroidism, and hypoglycemia.

Although designed to reduce the symptoms of carcinoid syndrome, there has been some objective tumor responses noted with somatostatin analogues. A biochemical response is seen in 27% to 72% of patients with carcinoid treated with somatostatin analogues; however, the actual tumor response is only 2%. Tumor stabilization has been noted in nearly 50%, but over a relatively short follow-up period of 5 months.[22]

Systemic treatment with interferon has been examined as possible systemic therapy for patients with advanced carcinoid disease. The mechanism that has been proposed is interferon's ability to inhibit cellular proliferation, inhibit angiogenesis, and enhance immune cell–mediated cytotoxicity. Trials including interferon alfa and gamma and human leukocyte interferon have been performed. Treatment with either human leukocyte interferon or interferon alfa has resulted in biochemical responses but little tumor response. The results were less favorable for combination therapy consisting of interferon alfa and gamma, for which no response was noted. The combination of interferon alfa and octreotide led to a reduced risk for tumor progression, without any survival benefit.[47]

Various studies have examined the effects of systemic chemotherapy, both single agent and combination, in patients with metastatic carcinoid with little success. A more recent phase II trial examined docetaxel as a potential therapeutic agent.[48] Although the therapy was well tolerated, there was minimal tumor response, and only a small proportion of patients experienced even a biochemical response. To date, systemic chemotherapy has failed to have a role in the treatment of metastatic carcinoid disease.

Biologic therapies are currently being examined for a potential role in the treatment of metastatic carcinoid tumors. Epidermal growth factor receptor (EGFR)-based therapy has shown success in solid tumors such as lung, breast, colon, and head and neck cancers. Recent basic science research has shown that gefitinib, which targets EGFR, induces apoptosis, growth inhibition, and cell cycle arrest.[49] These findings indicate that EGFR-based treatments may be an effective therapy in the future.

Case reports and small series have reported the use of hormone receptor–mediated radiation therapy for metastatic carcinoid tumors. Peptide-targeted therapies include ^{131}I-MIBG–octreotide; ^{177}Lu-, ^{111}In-, and ^{90}Y-labeled somatostatin analogues; and more recently, bombesin and neuropeptide Y (Y1) analogues. Research to date has shown some success with these therapies, although the success is often noted to be equivalent to that of treatment with nonradiolabeled somatostatin analogues. Most reports show short-term stabilization of disease, with greater than half of all treated patients reporting some symptomatic relief.[50,51] However, tumor response rates (complete and/or partial) have been low, 23% to 30%. Combined peptide approaches are being used in an attempt to improve tumor and patient response to therapy.[51]

External beam radiotherapy has had some limited role in the treatment of advanced carcinoid disease. As a palliative procedure for bulky disease, brain metastasis, spinal cord compression, and bony metastasis, radiation therapy has shown some benefit.

FUTURE DIRECTIONS

Gastrointestinal carcinoid tumors have varied manifestations and clinical courses. Advances in molecular biology will continue to aid the clinician in determining what clinical course a particular tumor will take. The application of high-throughput genomic and proteomic analysis to the pathologic examination of tumors, as well as the application of this technology to the serum of patients with carcinoid disease, will possibly enable a more accurate prognosis.

Advances in peptide receptor–aided imaging will enable more accurate and earlier diagnosis of carcinoid tumors. Possibly, the use of multiple markers in a single radionuclide-based scan will permit the localization of small carcinoid tumors that currently remain unrecognized and undiagnosed.

The emerging field of biologic therapies may also aid in the treatment of patients with advanced or metastatic disease, or both. Phase III trials of EGFR-targeted therapies are hoped to produce exciting results. There are numerous other potential biologic therapies that have yet to be discovered and examined.

Overall, gastrointestinal carcinoid is a variable disease process because of its varied embryologic origin. Surgical resection is the only chance for cure. As the expansion of molecular biology and biologic therapy continues, treatment options for this disease will improve.

Gastrointestinal Stromal Tumors

Burton L. Eisenberg ▪ Kari M. Rosenkranz

Although rare, gastrointestinal stromal tumors (GISTs) are the most common mesenchymal neoplasms of the gastrointestinal (GI) tract. Understanding and treatment of these tumors have improved dramatically over the last several years. Enhanced diagnostic specificity and recognition of the pathophysiology and natural history of this previously poorly defined clinical entity have resulted in novel treatment approaches. Initially managed as a surgical disease with a relatively poor prognosis, a greater understanding of GIST pathobiology has transformed therapeutic options and led to an improved prognosis for patients with advanced disease. The present management of this GI tumor could potentially serve as a paradigm for the combined surgical management of a solid tumor with molecularly specific, targeted therapeutics enhanced by optimal pharmacologic and pharmacodynamic properties.

HISTORICAL PERSPECTIVE AND NATURAL HISTORY

The true incidence of GIST has been somewhat obscured by the fact that until recently this clinical entity was ill defined. It is now recognized as the most common mesenchymal tumor of the GI tract, with an estimated annual incidence of approximately 6000 cases per year. Previous reported series of GI sarcomas, particularly those compiled before the year 2000, were dominated by the defining nomenclature of smooth muscle tumors (leiomyosarcoma and leiomyoblastoma). It is now recognized that many of these tumors that were previously reported as smooth muscle neoplasms have distinctive pathologic features and could be retrospectively reclassified as GIST. As suggested by Mazur and Clark, who first introduced the term stromal tumor,[1] these neoplasms are probably not derived from a direct smooth muscle cell lineage. Further advances in the defining pathology of GIST indicated that GIST cells originate from the same precursor cell as the interstitial cells of Cajal (ICC), the GI myenteric plexus pacemaker cell, and therefore have characteristics of both smooth muscle and neural differentiation, as evidenced by morphology and immunophenotype.[2]

Strict criteria for recognition of GIST have now enabled retrospective studies to be performed to evaluate the prognosis and natural history relevant to clinical care. A variety of different tumor-related variables have been assessed by both univariate and multivariate analysis to determine their importance in outcome prediction, as well as malignant potential. The most significant prognostic features of the primary tumor are size and mitotic index (Table 80–1).[3] These two primary tumor categories allow reliable risk assessment, although other tumor features that are surrogates of proliferation, such as Ki67 expression, have also been found to be helpful in risk modeling. These patient risk profiles suggest that greater than 50% of high-risk tumors will recur within 10 years after initial diagnosis, the majority within 3 years. In contrast, low-risk/very-low-risk tumors have a less than 5% probability of recurrence, with the intermediate-risk category being less predictable and therefore necessitating very close follow-up. At the time of diagnosis approximately a third to a half of all clinically detected GISTs are either overtly malignant by virtue of demonstrated metastatic disease or high risk for malignant behavior, and approximately two thirds will have pathologic features suggestive of potential malignant behavior, such as larger size or increased mitotic index.[4,5] For this reason, classification of GIST into benign versus malignant is often problematic, and therefore GIST in aggregate represents a biologic continuum, with even small contained tumors historically noted to recur 15 to 20 years after initial diagnosis. Obviously, this risk stratification strategy provides important guidelines for the necessity of

Table 80–1 Gastrointestinal Stromal Tumor Risk Assessment

Risk of Recurrence	Tumor Size (cm)	Mitotic Index (50 HPF)
Very low	<2	<5
Low	2-5	<5
Intermediate	<5	10-16
	5-10	<5
High	>5	>5
	>10	Any
	Any	>10

HPF, high-power field.

long-term patient follow-up and radiologic surveillance, as well as consideration of more aggressive primary tumor management directed toward high- and intermediate-risk groups.

Tumor location has also been linked to prognosis, with primary gastric GISTs seeming to fare better than those of small bowel or rectal origin.[6] The rare GIST of the retroperitoneum, mesentery, or omentum will similarly generally display a malignant aggressive course when compared with those of primary gastric origin.

PATHOLOGY

Elucidation of the pathology of GIST has been closely paralleled by therapeutic advancements. As the specific diagnosis of GIST has been defined by morphology, ultrastructure, and immunohistochemistry, the true incidence and prevalence of this tumor are now more accurately reflected in population studies.[7] The annual incidence of GIST is approximately 5000 to 6000 cases in the United States yearly. The incidence statistics are more reliable at this time because in the past many of these tumors were reported as GI smooth muscle tumors. It is now evident that through ultrastructural studies and lineage-specific immunomarkers, GIST cells have features in common with ICC, with both GIST and ICC staining positive for KIT (CD117).[8] Although approximately 95% of GIST cells stain positive for KIT, a variety of other immunomarkers can also be demonstrated, including BCL-2 (80%), CD34 (70%), muscle-specific actin (50%), smooth muscle actin (35%), S-100 (10%), and desmin (5%).[9] The differential diagnosis of GIST includes a number of different mesenchymal tumors such as schwannomas, leiomyomas, and leiomyosarcomas; however, morphology and KIT staining will generally establish the diagnosis.

The majority of GISTs are composed of a uniform population of spindle cells (approximately 70% of cases), with epithelioid cells (20% of cases) and a mixed variety (10% of cases) accounting for the rest (Figs. 80–1 to 80–3). The spindle cells are generally arranged in short fascicles but can align in a schwannian pattern. Most

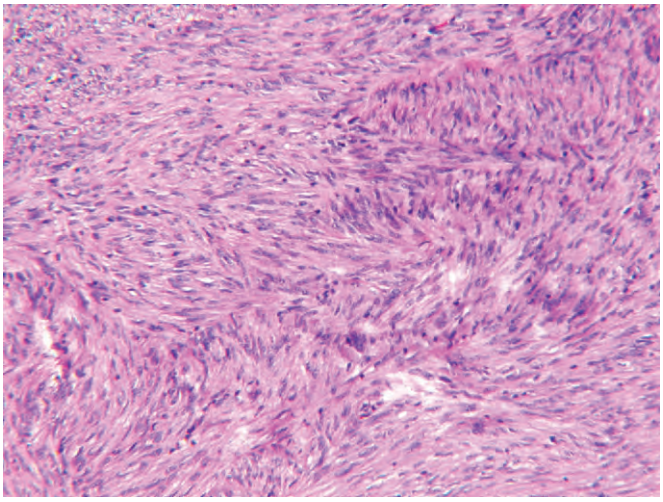

Figure 80–1. Spindled GIST. Although the histologic patterns of GIST vary, many demonstrate short interlacing fascicles of spindled cells with indistinct cytoplasm, uniform nuclei, and a variable degree of matrix production.

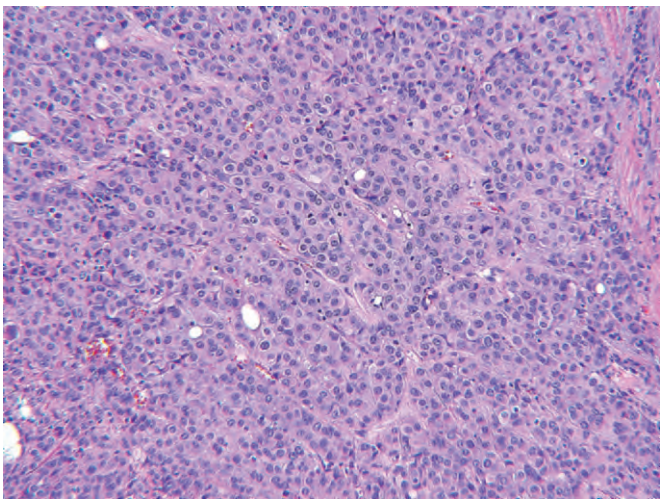

Figure 80–2. Epithelioid GIST. In contrast to spindle cell GIST, the epithelioid variant is composed of polygonal cells with abundant eosinophilic cytoplasm and well-defined cytoplasmic borders.

GISTs have a uniform cytology, and marked cytologic pleomorphism is uncommon. Approximately 5% of cases can have a prominent myxoid stroma. Nuclear atypia is more common in epithelioid GISTs and often represents a malignant phenotype. The use of KIT immunostaining has been helpful in the diagnosis of GIST; however, it is possible that because of technical issues, such as overstaining with inappropriately titered KIT antibodies, there may be instances of false-positive reporting. The possibility of overstaining is important to consider because KIT-negative, desmin-positive tumors, such as desmoid tumors or leiomyosarcoma, may have similar

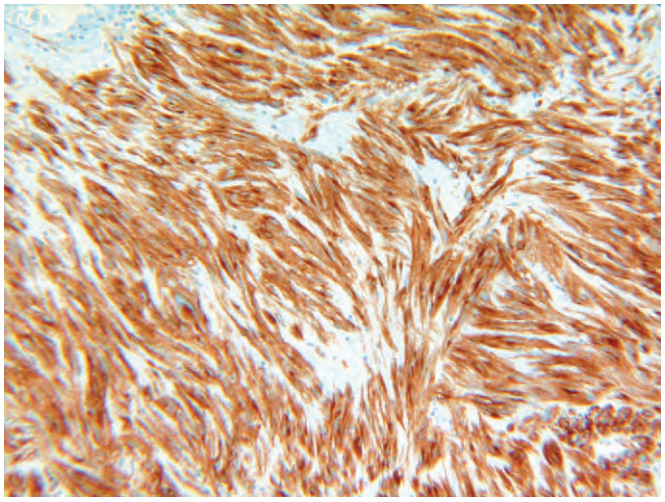

Figure 80–3. CD117 immunohistochemistry. GIST stains uniformly with CD117.

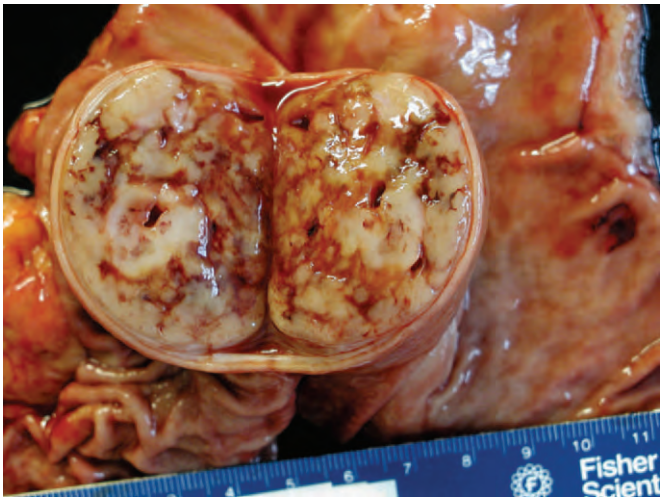

Figure 80–4. Photograph of a small submucosal gastric GIST after partial gastric resection.

spindle cell morphology. It is also important to note that the overall intensity of KIT staining, which may be cytoplasmic, membranous, or paranuclear, is not related to either prognosis or response to therapeutic KIT-specific inhibition.

As with most spindle cell neoplasms, adequate tissue is essential for making an accurate diagnosis. In the case of a primary GIST that is surgically resectable, it is not recommended that an immediate transabdominal tissue biopsy be performed because tumor cell exfoliation after biopsy manipulation can lead to tumor recurrence. Tissue can, however, be safely obtained by endoscopic core biopsy when necessary.

When assessing malignant potential, the pathology of GIST is somewhat unreliable in that malignant potential is more closely related to risk stratification (see the section on natural history and Table 80–1), which is based mainly on mitotic index and tumor size rather than tumor morphology and pleomorphism. However, cytogenetic analyses of GIST have provided some clues with regard to the malignant phenotype. Karyotypes from two thirds of GISTs demonstrate either monosomy 14 or partial loss of 14q, with at least two regions of 14q deletions appearing to be hot spots and representing probable areas of tumor suppressor genes.[10] In addition, loss of the long arm of chromosome 22 is present in 50% of GISTs and is often associated with progression to a borderline or malignant lesion. Losses on chromosomes 1p, 9p, and 11p are more significantly found in malignant GISTs. Common pathways for the genetic changes that have been observed in the development and progression of GIST are KIT or platelet-derived growth factor receptor-α (PDGFR-α) mutation → 14q deletion → 22q deletion → 1p deletion → 8p gain → 11p deletion → 9p deletion → 17q gain.[10]

Approximately 5% of GISTs will be KIT negative by immunostaining, yet by all other morphologic/clinical criteria these tumors can be classified as GISTs. They are generally a rather heterogeneous group of tumors consisting mostly of tumors containing mutations in PDGFR. This small subset of GISTs characterized by negative KIT staining is more likely to be of epithelioid histology, be nongastric in location, and have activating PDGFR-α mutations. A few of these weakly positive or non–KIT-staining GISTs will have evidence of KIT mutations on genotyping, and in rare instances there will be no discernible mutations in either PDGFR-α or KIT, thus suggesting that a KIT-negative GIST can arise through alternative oncogenic mechanisms.[11] An adequate tumor sample in the clinical instance of KIT negativity should be evaluated by genotyping because a mutation in KIT or PDGFR-α can be diagnostic and has important therapeutic implications. In addition, new tumor markers of GIST, such as DOG1 (discovered on GIST-1) and protein kinase C-θ, can be helpful in the differential diagnosis in difficult cases.[12,13]

CLINICAL EVALUATION

GIST is most commonly diagnosed in adults 50 to 80 years of age, with a mean age of 60. The male-to-female ratio is approximately 1:1. The majority of patients with GIST are symptomatic, with the most common symptoms being abdominal pain, early satiety, and bloating related to the presence of a space-occupying mass. GI bleeding and anemia are frequently noted and are due to erosion of mucosa by the tumor, even though GISTs originate within the muscular layer of the bowel wall and are often manifested by evidence of an extrinsic mass. The most common location is the stomach (60% to 70%), followed by the small bowel (20% to 25%), colorectum (5%), and esophagus (5%). Rarely, cases of GIST originating within the retroperitoneum, omentum, appendix, gallbladder, pancreas, and mesentery have been described. Approximately 20% of GISTs are asymptomatic and discovered incidentally by radiographic imaging or endoscopy, or

they may be an unexpected surgical finding (Fig. 80–4). These incidental tumors are often asymptomatic, noncystic submucosal masses most commonly found during endoscopy. Recommendations for management of an asymptomatic incidental GIST with regard to biopsy or resection are not based on large cohort follow-up studies. However, in general, even a subcentimeter, submucosal suspected GIST should undergo biopsy or be removed, or both, if the clinical situation allows because of the necessity for long-term observation and the potential for malignant clinical progression based on the defined risk profile.

The clinical work-up for a suspected GIST should follow the pattern for evaluation of any patient with an undiagnosed intra-abdominal mass. Although some GISTs are small submucosal solid tumors found incidentally, the majority are larger than 5 cm and are symptomatic because they are a space-occupying abdominal mass. GI bleeding and the insidious anemia of chronic blood loss are not uncommon with large necrotic GISTs. The initial work-up should consist of a history and physical examination, which may reveal the presence of a palpable abdominal mass, followed by a cross-sectional abdominal imaging study, usually a contrast-enhanced computed tomography (CT) scan. Routine chest radiographs and blood work, including liver function tests, are indicated. Endoscopy, endoscopic ultrasound, and possibly endoscopic biopsy can be recommended if the clinical situation warrants because the majority of GISTs are of gastric origin. Early surgical involvement should address the potential for complete resection, and in patients with locally advanced or metastatic disease, consultation with medical oncology, evaluation for systemic therapy with imatinib mesylate, and close surgical follow-up should be considered. Close surgical follow-up is especially important for patients with large GISTs involving bowel mucosa, which may subsequently bleed either intra-abdominally or intraluminally as a manifestation of rapid tumor response after the initiation of systemic therapy.

Percutaneous core or intraoperative biopsy of a suspected GIST that is localized and presumed to be resectable is not necessary. These tumors tend to be soft, well vascularized, and friable, and tumor spill or spontaneous rupture portends a poor prognosis and compounds the difficulty of treatment decisions. Conversely, it is relatively safe to biopsy the tumor by endoscopic means, either by direct visualization of a mucosal component or by endoscopic ultrasound guidance. Image-guided percutaneous tumor biopsy is considered as part of the work-up, however, for a metastatic tumor or a primary tumor that is marginally resectable. Additionally, careful biopsy and tissue diagnosis can be considered when immediate tumor resection could lead to considerable morbidity or functional disability. In this instance the possibility of tumor down-staging with a preoperative neoadjuvant targeted therapy regimen should be considered. Although data regarding the efficacy of this combined neoadjuvant approach are insufficient, it has the theoretical benefit of organ preservation and function-sparing management of some GISTs, such as those originating in the rectum or the pancreas.

MOLECULAR BIOLOGY OF GASTROINTESTINAL STROMAL TUMORS

Greater insight into the pathogenesis and subsequently the pathobiology of GIST has altered the diagnostic parameters and therapeutic implications for this mesenchymal tumor. These tumors are nearly universally characterized by the expression of KIT, a transmembrane receptor tyrosine kinase encoded by the c-kit proto-oncogene and recognized by the immunohistochemical stain for CD117, an antigen to an epitope on the extramembranous portion of the KIT molecule (Fig. 80–5).[14]

The c-kit gene is a cellular homologue of the v-kit oncogene found in the genome of the feline sarcoma virus.[15] Stem cell factor is the natural ligand for KIT, and under normal physiologic conditions, two molecules of KIT form a dimer by binding to two molecules of the ligand, with the resulting dimerization leading to activation of the intracellular tyrosine kinase. Ligand-independent activation of the KIT kinase leads to signal transduction abnormalities favoring proliferation and enhancement of cell survival mechanisms.[16] Structurally,

the KIT molecule has an extracellular domain of five immunoglobulin-like repeats and a tyrosine kinase domain split by a variable kinase insert that separates the adenosine triphosphate binding site and the phosphotransferase regions, thus placing this receptor kinase in the same category as similar type 3 tyrosine kinase receptors such as macrophage colony-stimulating factor and PDGF.[17]

A seminal event in the definition of GIST initially reported by Hirota et al. and subsequently verified by a number of investigators was identification of a c-kit gain-of-function mutation by gene sequencing in the majority of these tumors.[18] These in-frame mutations are noted early in GIST tumorigenesis and are important drivers of the malignant phenotype. The gain-of-function kinase activity results in ligand-independent KIT autophosphorylation and constitutive activation and is probably a hyperproliferative transforming event. The mutations are often physically located within 11 amino acids (Lys-550 to Val-560) in the juxtamembrane domain (exon 11) and can be characterized as either deletions, point mutations, or insertions. In the unusual event that these mutations occur in a germ cell line, the family lineage is characterized by instances of multiple GISTs.[19] Further compelling evidence for KIT mutation in the pathogenesis of GIST has been substantiated by transfection experiments of mutated KIT leading to cellular clonal transformation of the transfectant.[20] In addition, there is a transgenic mouse model of a KIT mutation leading to spontaneous GISTs that are morphologically similar to the human counterpart.[21]

The reported frequency of KIT mutations in GIST is variable and depends on the methodology used, but a mutational event probably occurs in 85% to 90% of malignant GISTs.[22] In addition, these mutations generally occur in exonic hot spots: 11 (intracellular juxtamembrane region), 9 (extracellular domain), and rarely 13 or 17 (both found in the intracellular portion of the receptor).[23] It is also notable that KIT mutations were found in 85% of a series of morphologically benign GISTs found incidentally, and these tumors ranged in size from 4 to 10 mm.[24] This suggests that mutated KIT is an early sign of genomic instability and may not be prognostically important in predicting the extent of malignant behavior. KIT mutations are distinctive, however, and have not been found in morphologically similar tumors, such as leiomyomas or leiomyosarcomas, thus making this mutation pathognomonic for GIST.[25]

TARGETED THERAPY

Enhanced appreciation of the pathobiology of this mesenchymal tumor, particularly with regard to autonomous kinase activation, has prompted clinical trials involving pharmacologic exploitation of the dysregulated KIT receptor tyrosine kinase.[26] Imatinib mesylate (Gleevec), a rationally designed small-molecule oral drug that is a selective inhibitor of type 3 tyrosine kinases, showed remarkable efficacy in preclinical studies against the KIT oncoprotein. This activity was manifested by antiproliferative effects and a measurable decrease in the tyrosine phosphorylation of KIT in KIT-expressing malignant cell lines.[27] These compelling preclinical data fostered interest in conducting the first clinical application of imatinib mesylate in a solid tumor, which resulted in a dramatic response in a patient with inoperable bulky metastatic GIST.[28] This report was followed by multi-institutional proof of the principal trial of imatinib mesylate in previously treated, unresectable patients with confirmed and measurable recurrent metastatic GIST. The study resulted in 147 patients being treated; 54%, 28%, and 14% demonstrated partial and durable responses, stable disease, and progressive disease, respectively.[29] It is important to note that all these patients had KIT expression confirmed by CD117 staining, thus emphasizing the important selectivity of this drug.[30] This clinical benefit has continued to be durable after a median follow-up of 3 years, with approximately 85% of patients still taking the drug. This study served as the basis for a registration study leading to Food and Drug Administration approval of imatinib mesylate for GIST patients with metastatic or recurrent disease.

Because the GIST clinical trial experience serves as a paradigm as one of the first in human trials to demonstrate efficacy for a designed small-molecule molecularly targeted therapeutic agent, evaluation of its pharmacodynamics and resistance patterns has potential applicability to other drugs of this classification. One interesting and clinically relevant response factor resides within the c-kit gene itself. The majority of GISTs sampled from patients in the initial metastatic disease trials with imatinib mesylate were found to harbor KIT mutations, with exon 11 being the most common site detected. The response to imatinib mesylate, as well as event-free and overall survival, was adversely affected by the presence of either an exon 9 mutation (extracellular portion of KIT) or wild-type KIT (Fig. 80–6).[31] The presence of wild-type KIT in approximately 10% of the patients in this series of KIT genomic mutational analyses was perplexing because the dysregulated KIT oncoprotein was initially thought to be the sole kinase driver of the transformed proliferative phenotype. A partial explanation for the GIST malignant phenotype without KIT mutant protein may be found in the recent identification of PDGFR-α gain-of-function mutations in GIST samples.[32] It appears that PDGFR-α mutations and KIT mutations are mutually exclusive, and in a series of GIST genotyping, 4.7% of patient samples were noted to have PDGFR-α mutations involving domains homologous to those often mutated in KIT (Fig. 80–7).[31] The uncommon patient with a PDGFR-α mutation can have a GIST that is morphologically and clinically identical to those with a KIT mutation. Some of these patients have a documented response to imatinib mesylate, thus implying that this drug can be clinically useful in inhibiting two different kinases. A small percentage of GISTs do not demonstrate a mutation in either KIT or PDGFR. The mechanism of malignant transformation and expression of the malignant phenotype is probably multifactorial in these GISTs and may be related to increased kinase activity downstream of the KIT receptor or amplification of the KIT gene or the KIT gene product. Knowledge of the GIST genotype can also have therapeutic implications because

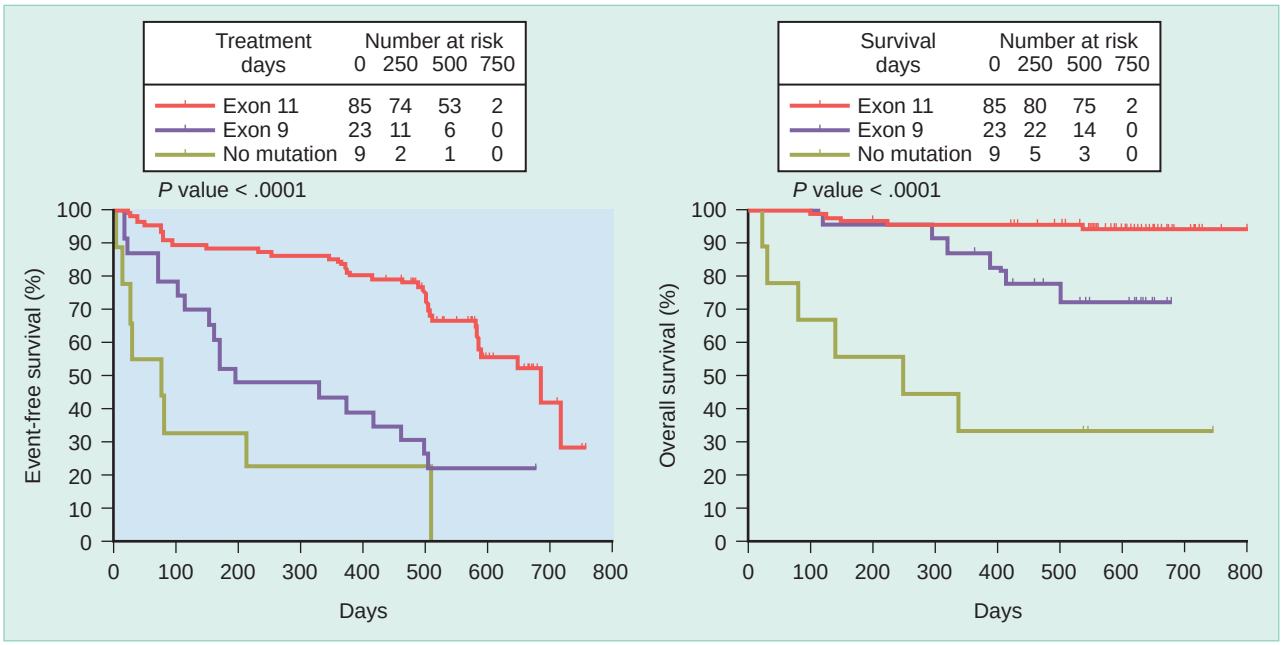

Figure 80–6. The GIST kinase genotype correlates with event-free and overall survival, as demonstrated by the Kaplan-Meier estimate of the probability of event-free and overall survival for patients with KIT exon 11 mutation, KIT exon 9 mutation, or no mutation of KIT or PDGFR. (From Heinrich M, Corless C, Demetri G, et al: Kinase mutations and imatinib response in patients with metastatic gastrointestinal stromal tumors. J Clin Oncol 21:4347, 2003.)

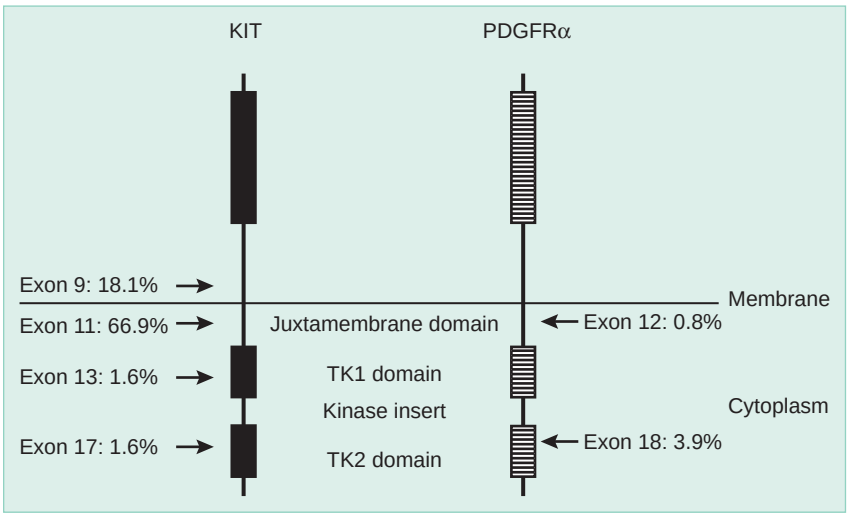

Figure 80–7. Structure of KIT and PDGFR-α. The locations of GIST kinase mutations are shown in relationship to the structural features of the proteins. GIST from 9 (7.1%) of 127 patients had no detectable KIT or PDGFR-α mutation. (From Heinrich M, Corless C, Demetri G, et al: Kinase mutations and imatinib response in patients with metastatic gastrointestinal stromal tumors. J Clin Oncol 21:4343, 2003.)

GIST patients harboring a KIT mutation outside of exon 11 are less likely to respond to imatinib mesylate. They may therefore be candidates for alternative therapies as they become available. It is especially important, however, to emphasize that approximately 5% of GISTs will be KIT "negative" by CD117 immunostaining. These KIT-negative GISTs, when compared with KIT-positive GISTs, are more likely to have epithelioid morphology, arise in the omentum/peritoneal surface, and contain PDGFR mutations. These GISTs may contain imatinib mesylate–sensitive clones, and therefore patients with morphologically and clinically confirmed KIT-negative GIST should not be denied a trial of imatinib mesylate therapy.[5,11] Because of the success of imatinib mesylate therapy in the management of GIST, the present recommendations in the work-up of a KIT-negative GI mesenchymal tumor with histopathology suggesting a spindle, epithelioid, or mixed variant of GIST are to evaluate tumor tissue for KIT or PDGFR-α mutations. Thus, genotype screening in this particular patient population may provide clinically actionable information.[33] Investigations into the molecular mechanisms of GIST response are ongoing with broad-based implications for specific targeted therapeutics in other solid tumor models. Data

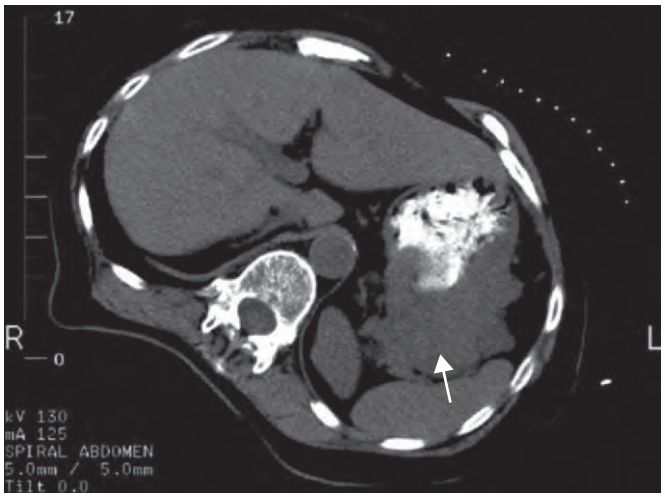

Figure 80–8. Computed tomographic scan of a primary gastric GIST (*arrow*). Note the extrinsic mass effect on the stomach.

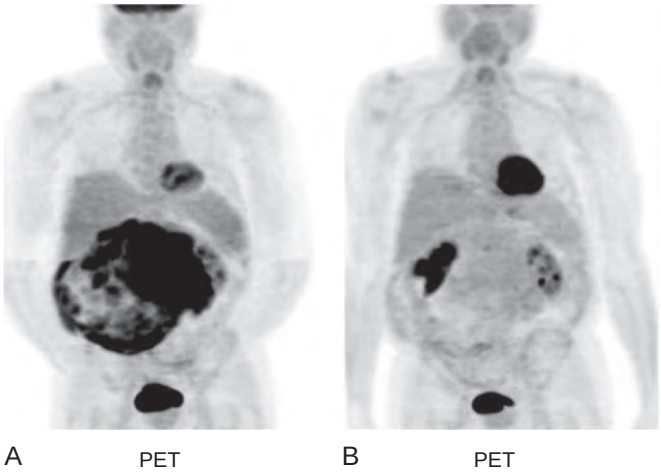

Figure 80–9. ^{18}F-fluorodeoxyglucose (FDG)–positron emission tomographic (PET) scan indicating a large bulky primary GIST before **(A)** and after **(B)** imatinib mesylate administration. The decreased FDG concentration in the tumor was noted within several weeks after initiation of drug therapy.

generated from evaluation of downstream signal transduction pathways suggest differential expression of signaling intermediates depending on the type of KIT mutation, and robust genomic-based platform arrays have identified differential-response gene expression signatures associated with GIST cells sensitive to imatinib mesylate. It is conceivable that future evaluations will provide enough data so that GIST patients can be phenotyped by tumor biopsy before and just after administration of imatinib mesylate to determine whether they will respond to single-drug therapy or whether alternative or combination therapies will be necessary to optimize their outcome.

IMAGING

Cross-sectional imaging, particularly in the initial workup of a patient with suspected primary or recurrent GIST, is the diagnostic procedure of choice. A contrast-enhanced (oral and intravenous) CT scan is recommended and generally allows assessment of the extent of the primary, as well as the potential presence of metastatic disease. The typical primary GIST will be manifested as an intestinal-based mass with the bulk of the tumor extrinsic to the bowel, thus often providing an opportunity for complete resection, even in patients with a large primary tumor (Fig. 80–8). In many instances the primary tumor, although large, may be pedunculated, particularly if originating from the stomach. Guidelines for follow-up after successful GIST surgical resection, as recommended by the National Comprehensive Cancer Network, are as follows: CT of the abdomen/pelvis performed every 3 to 6 months for 3 to 5 years and annually thereafter, except in patients with very-low-risk primary GIST, in which case less frequent follow-up is required.[33] The frequency of metastasis of GIST to the lung is quite low, and therefore routine screening chest CT is not necessary.

Standard image-based response criteria are being reevaluated in light of the information available for GIST patients treated with imatinib mesylate. These characteristic CT scan changes in GIST, consistent with a favorable response to a molecularly targeted agent, include a change in density of the measurable tumor to a more myxoid or hypodense appearance rather than a definitive decrease in size. This response can take place within a month of initiation of therapy and can be quantitated by measurement of Hounsfield units. Within 2 months of therapy a decrease in tumor size, usually confirmed by comparing the sum of the longest diameters of all target measurable lesions or a 15% decrease in density, can be considered predictive of a beneficial response, although a maximal decrease in tumor size may take 6 months or longer. Conversely, drug resistance may be manifested as the appearance of a small intratumoral nodule without a change in overall density or size of the tumor mass. Lessons learned about the clinical usefulness of these measurable response criteria may have more universal applicability to assessment of specific targeted therapy for other solid tumors as increasing numbers of these agents become clinically available.

Functional imaging with ^{18}F-fluorodeoxyglucose (FDG)–positron emission tomography (PET) can be an important adjunct to standard CT by assessing early changes in metabolic activity in GIST. FDG-PET can provide an immediate and sensitive measure of response in GISTs, which are generally PET avid tumors.[34] Imatinib mesylate may have a dramatic effect on abrogation of GIST cell glycolysis, and these measurable decreases in glucose uptake by the tumor can be visualized within hours of initiation of therapy and can be predictive of long-term response by comparison to the standard uptake value. This may be particularly helpful in the assessment of neoadjuvant treatment (Fig. 80–9). If FDG-PET is being considered as a diagnostic modality to

monitor continued response, detect recurrence, or complement an ambiguous CT scan, a baseline PET scan should be obtained before initiation of therapy.

SURGICAL MANAGEMENT

Surgical management of GIST is based on sound oncologic principles, and before the introduction of imatinib mesylate as an effective systemic therapy, surgical resection was the only viable therapeutic option. However, approximately 50% of all GIST patients will have evidence of overt malignant disease at initial evaluation, and survival after surgical management of these patients has historically been quite poor. Because of the low incidence of GIST there is a paucity of information regarding the results of surgical resection from retrospective data. In several reported series, optimal patients with primary tumors predominantly gastric in origin and treated by complete tumor resection still had a relatively poor reported 5-year survival rate of approximately 50%.[35,36] Tumor size is a predominant factor in surgical resection series for primary GIST, and patients with tumors larger than 10 cm have reported survival rates in the 20% range at 5 years. There continues to be attrition in resected GISTs during prospective follow-up, with one series reporting only 10% of resected patients being free of disease after a median follow-up of 68 months.[37] The median time to recurrence after resection of a primary GIST is 2 years, but in subsets with small tumor size or slowly proliferating GIST, metastases can develop more than 10 years after diagnosis, and therefore all these patients require life-long follow-up.

Of patients with primary disease at initial diagnosis, approximately 75% will undergo complete resection. The most common sites of disease failure after complete resection are the peritoneal cavity and the liver. The finding of an extra-abdominal site is quite uncommon. Approximately half to two thirds of GIST primaries will have disease failure within the liver, and nearly 40% of patients will have the liver as the only site of failure. Generally, hepatic involvement is multifocal; however, one series of 34 patients reported a 5-year survival rate of 30% after hepatic resection.[38] Surgical resection for recurrent GIST has found limited use with rare long-term success, even after complete tumor removal or ablation. Palliative surgery for bleeding or obstruction can be entertained as a viable alternative in a patient with limited disease and a good performance status.

The goal of surgery in the management of primary GIST is complete gross resection with an intact pseudocapsule. At laparotomy the abdomen should be carefully explored for any evidence of metastatic disease on the peritoneal surfaces or in the liver. GISTs should be handled gently and with care to avoid rupture. GISTs are generally exophytic, tend to displace adjacent structures, and despite the CT appearance, can often be lifted away from surrounding organs. En bloc resection is infrequently necessary and only when there is evidence of dense adherence to adjacent organs. Segmental resection of the stomach or intestine can be performed with the intent of negative margins. Partial or wedge gastrectomy is a viable option because GIST cells do not manifest submucosal spread, as is common with adenocarcinoma. Lymphadenectomy is unnecessary because lymph node metastases are rare. The value of microscopically negative resection margins, especially in a large tumor, is questionable since margin status does not appear to be a prognostic indicator for recurrence when it has been evaluated as a meaningful risk factor. This may be because these large extrinsic tumors tend to shed cells into the peritoneal cavity, so local/regional recurrence is predicted more by tumor size than by resection margin. The value of reoperative surgery for microscopically positive margins is unproven and should depend on many factors, such as tumor size, potential morbidity, and the availability of adjuvant therapy. Laparoscopic wedge resection may be used for small GISTs (<2 cm) when the risk for rupture is minimal, but data on this approach are lacking.

Surgical considerations for the management of GIST have recently undergone considerable change. Although surgical resection remains the standard form of treatment of primary GIST, the efficacy of the KIT-targeted oral agent imatinib mesylate has transformed therapeutic considerations into a multimodality paradigm. There is increasing awareness that GIST needs to be managed with the combined expertise of pathology, surgery, medical oncology, and imaging in the initial evaluation and subsequent management. It is reasonable, then, to evaluate surgical considerations and outcomes with respect to pre–imatinib mesylate and post–imatinib mesylate time frames. Traditional sarcoma-based polychemotherapy and irradiation have historically been ineffective in the treatment of GIST, and surgical management in general has been associated with disappointing results in terms of recurrence-free and overall survival for high-risk GIST patients, particularly for large and highly proliferative tumors. Imatinib mesylate is a rationally based therapeutic agent that was developed as an antagonist to the KIT receptor on GIST cells and has shown remarkable effectiveness against metastatic and unresectable GIST.[39] Addition of this drug to surgical management decisions in GIST leads to the possibility of effective adjuvant therapy for improving long-term outcomes. Furthermore, surgical debulking of slowly responding, stable, or partially responding large primary or recurrent GISTs after "neoadjuvant" administration and assessment of response to imatinib mesylate may enhance long-term disease control in GIST patients with large tumor burdens. Advantages of this combined approach could also lead to organ preservation, an important consideration for GIST patients with primary tumor location in the proximal stomach, rectum, or duodenum. The results of ongoing clinical trials will probably provide more concrete recommendations for the surgical management of GIST and become part of the care standard in the future.

ADJUVANT THERAPY

Surgery is the primary initial treatment of resectable GIST, but it is seldom curative in patients with a high risk for recurrent disease. Surgery is even less effective in

patients with locally recurrent or metastatic disease. Before the availability of imatinib mesylate the only treatment of GIST, other than surgical resection, was conventional chemotherapy and radiotherapy. However, lack of efficacy has been a constant in studies evaluating these modalities in the management of GIST patients.[40] The recent availability of an effective systemic therapy raises the issue of its potential use as adjuvant or neoadjuvant treatment in conjunction with surgical tumor resection with the objective of either cytoreduction of disease before surgery or improvement in long-term survival after successful resection. Other than anecdotal experience, data on the combined use of imatinib mesylate and surgical resection are lacking. Clearly, patient selection factors for adjuvant trial design are critical. Patients typically at high risk for recurrence, such as those with tumors larger than 10 cm or tumors with greater than five mitoses per 50 high-powered fields, are obvious candidates for such a trial. Patients with other risk factors, such as tumor perforation or rupture or a known specific drug-sensitive genotype, might also be considered for clinical trial participation. Presently, three national cooperative group trials are evaluating imatinib mesylate as adjuvant or neoadjuvant therapy.[39] One is already completed with the results pending for a phase II trial design of postoperative imatinib mesylate in high-risk patients, another is an ongoing phase II randomized postoperative trial for high- and intermediate-risk patients with comparison to placebo, and the third is an ongoing neoadjuvant design for patients with bulky primary or resectable recurrent/metastatic GIST. The possibility of pharmacologic debulking with imatinib mesylate, followed by surgical resection, may be a rational strategy for organ preservation, in vivo drug sensitivity testing, optimization of therapy for focal metastatic disease, and abrogation of emerging drug-resistant clones. Short follow-up clinical experience has suggested the usefulness of limited surgery in some patients with multiple-site recurrent disease whose tumor demonstrated a mixed pattern of response to imatinib mesylate and in whom resection or ablation was successful in removing unresponsive sites while the bulk quiescent residual disease was managed successfully with continued imatinib mesylate therapy. At this time the optimal dose plus duration of imatinib in the surgical adjuvant or neoadjuvant strategy has not been defined, and this combination in treating GIST in standard actual practice awaits elucidation in clinical trials.

Gastrointestinal Lymphomas

Lindsey N. Jackson • B. Mark Evers

Despite recent advances in the diagnosis and treatment of non-Hodgkin's lymphoma (NHL), this disease remains the sixth leading cause of cancer-related deaths in the United States, with an approximate 5-year survival rate of 56%.[1] An estimated 56,000 cases of NHL will occur in the United States in 2005, and approximately 19,000 will die of the disease.[1] The incidence of NHL has increased rapidly, almost doubling, since the early 1970s, probably because of an increased incidence of human immunodeficiency virus (HIV) infection and environmental and toxic exposure.[1,2] However, the incidence stabilized in the 1990s, primarily as a result of a decline in acquired immunodeficiency syndrome–related malignancy.[1]

NHL classically originates in lymph node basins, but it may occur as extranodal lymphoma or lymphoma arising within a solid organ in up to 30% of cases.[3] The gastrointestinal (GI) tract is the most common site of extranodal disease and accounts for approximately 20% of all NHL and approximately half of extranodal NHL.[2,4] Requirements for the diagnosis of primary GI lymphoma include absence of palpable lymphadenopathy, normal bone marrow biopsy and peripheral blood smear, absence of mediastinal lymphadenopathy on chest radiographs, disease grossly confined to the affected viscus, and absence of hepatic or splenic involvement unless via direct extension of the primary tumor.[5] This chapter focuses on lymphomas occurring in the stomach and small intestine, the two most commonly affected organs of the digestive tract worldwide.

INCIDENCE AND EPIDEMIOLOGY

GI tract lymphomas may occur in any part of the digestive tract from the oral cavity to the rectum, and the incidence appears to depend on geographic location.[2] In Western and Middle Eastern regions, the stomach is the most commonly affected site, followed by the small intestine, colon, pancreas, and all other sites; however, in other parts of the world such as India, Africa, and the South Pacific, intestinal lymphoma is the predominant form, followed by the stomach, colon, and other organs (Table 81–1).[2,6]

Gastric Lymphoma

In the United States the stomach is the most common site of GI lymphoma and accounts for more than half of the lymphomas of the GI tract. Yet it is relatively uncommon and accounts for less than 15% of primary gastric neoplasms and 2% of all lymphomas.[6-8] Gastric lymphomas tend to occur in patients older than 50 years, with a peak incidence in the sixth and seventh decades, and they are two to three times more common in men.[6,7] However, recent studies have demonstrated that the disease is occurring more commonly in an increasingly younger age group, predominantly because of increased incidence in HIV-infected patients.[6] Gastric lymphomas most frequently occur in the gastric antrum or distal body, but they may arise from any portion of the stomach.[7,9]

Small Intestinal Lymphoma

Lymphoma of the small intestine is the second most common extranodal lymphoma of the GI tract in the United States. It is the third most common primary neoplasm of the small bowel and accounts for 15% to 20% of malignant small bowel tumors, 5% of all lymphomas, 4% to 12% of all NHLs, and 20% to 30% of primary GI lymphomas.[7,10,11] Small intestinal lymphomas, like gastric lymphomas, tend to occur in patients older than 50 years; however, it is the most common intestinal neoplasm in children younger than 10 years, thus resulting in a bimodal distribution.[7,11] Small bowel lymphoma is most commonly located in the ileum, the site of the highest concentration of gut-associated lymphoid tissue.[7]

CLINICAL FEATURES

The typical signs and symptoms of GI lymphoma are often nonspecific and commonly mimic other abdomi-

nal pathologies, such as gastritis, peptic ulcer disease, and pancreatic or gallbladder disorders, as well as other neoplasms.[6] The most common initial symptom of both gastric and intestinal lymphomas is abdominal pain; additional symptoms may include early satiety or abdominal fullness, fatigue, diarrhea, nausea, vomiting, and indigestion (Table 81–2).[8,12] Lymphoma of the small intestine is more likely to cause intussusception, obstruction, or perforation than gastric lymphoma is. In fact, approximately 30% to 50% of patients will have an abdominal emergency, with perforation present in up to 25% of cases.[2,5] Over half of patients with GI lymphoma will exhibit anemia secondary to chronic occult blood loss; overt bleeding is uncommon.[7] Constitutional B symptoms, which include fever, weight loss, and night sweats, are rare (less than 12% of patients) unless systemic disease is present.[8] Because of the insidious onset and nonspecific nature of many of these symptoms, it is often months or years before the diagnosis is made.[4] Physical examination is normal in approximately 55% to 60% of patients, with abdominal tenderness encountered in 20% to 35% and a palpable mass in 17% to 25%.[6] Other physical findings may include fever, lymphadenopathy, jaundice, hepatomegaly, and splenomegaly.[6]

PATHOLOGY

Appropriate management of GI lymphomas requires determination of the stage and subtype of the lymphoma, as well as consideration of morphology, genetic alterations, and immunophenotype.[2] There are several classification systems for GI lymphomas (Table 81–3). In the World Health Organization (WHO) classification, the most common NHL arising in the GI tract is diffuse large B-cell lymphoma (DLBCL) (55%), followed in frequency by extranodal marginal cell lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma) (40%), Burkitt's lymphoma (3%), and follicular, mantle cell, and enteropathy-type T-cell lymphomas (<1% each) (Table 81–4).[2]

Diffuse Large B-Cell Lymphoma

DLBCL is the most common type of NHL, extranodal lymphoma, and GI lymphoma. It may occur as de novo disease, but it may also arise from or coexist in a background of low-grade MALT lymphoma, chronic lymphocytic leukemia, small lymphocytic lymphoma, or follicular lymphoma (Fig. 81–1).[2,13] DLBCL is often manifested as a tumor mass replacing the normal architecture of its tissue of origin and is most commonly located in the stomach or ileocecal region (Fig. 81–2).[2] There are several morphologic variants of DLBCL that are distinguished by histologic, cytogenetic, and molecular genetic features; patterns of gene expression dictate the prognosis.[14,15] A Bcl-2 gene mutation, commonly involved in a (14;18)(q32;q21) translocation, is present in 10% to 40% of DLBCLs, and a Bcl-6 gene mutation with a (14;3)(q32;q27) rearrangement may occur in

approximately 30% to 40% of cases; variabilities in survivin expression and p53 mutations have also been described.[14-16] The Bcl-2 protein is involved in the prevention of apoptosis, and recent evidence suggests that overexpression of it is associated with decreased overall, disease-free, and relapse-free survival.[15] In contrast, overexpression of the Bcl-6 protein, which normally regulates T-cell–dependent antigen responses, is associated with increased overall survival.[14]

MALT Lymphoma

MALT lymphomas were first described in 1983 and have since been reclassified as extranodal marginal zone lymphomas of the MALT type.[17] The stomach, which is paradoxically devoid of organized lymphoid tissue, is the site most frequently affected by MALT lymphomas.[18] These gastric tumors are thought to arise from MALT acquired as a result of chronic inflammation, most commonly gastritis associated with *Helicobacter pylori* because more than 90% of patients with gastric MALT lymphoma are infected with this bacterium.[4] Chronic activation of tumor-infiltrating T-cells is responsible for B-cell activation, with subsequent oligoclonal and monoclonal proliferation in an *H. pylori* strain–specific manner.[17] Once an active, proliferating monoclonal B-cell population develops, reactive oxygen species released at the site of inflammation contribute to an accumulation of oxidative stress and resultant genetic abnormalities.[9]

Genetically, two predominant translocations, t(11;18)(q21;q21) and t(1;14)(p22;q32), are implicated in the development of MALT lymphoma.[19] The t(11;18)(q21;q21) translocation, which fuses the inhibitor of apoptosis *(IAP2)* gene to the MALT 1 *(MLT)* gene, is detected in approximately 21% to 60% of gastric MALT lymphomas.[20] The resultant IAP2-MLT fusion protein is associated with nuclear localization of Bcl-10, a protein with transforming and proapoptotic functions

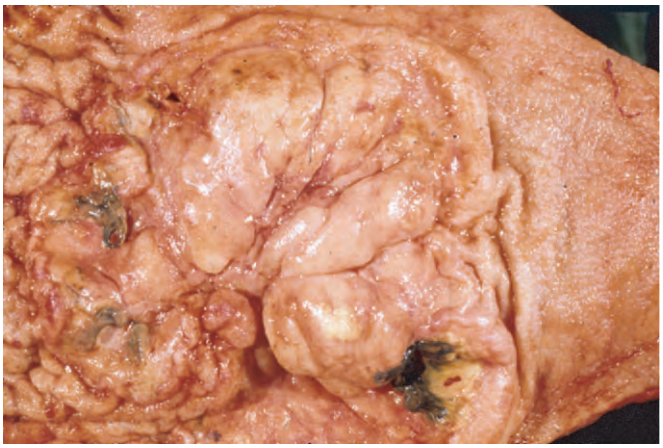

Figure 81–4. Gastric MALT lymphoma, gross photograph. (Courtesy of Mary R. Schwartz, M.D., Baylor College of Medicine.)

normally localized in the cytoplasm, as well as activation of the nuclear factor kappa B (NF-κB) pathway, which results in antigen-independent growth and disease dissemination.[17] This translocation is associated with resistance to *H. pylori* eradication, lymphoma regression, and more aggressive, advanced stages of disease.[7,17] The t(1;14)(p22;q32) translocation, which occurs in less than 5% of gastric MALT lymphomas, transfers the Bcl-10 gene to the immunoglobulin heavy chain promoter region and thereby results in a similar pattern of Bcl-10 overexpression and nuclear localization, activation of the NF-κB pathway, and an association with more advanced stages of disease.[20] Mutations leading to the formation of MALT lymphoma are summarized in Figure 81–3.

Gastric MALT lymphoma is often multifocal, with most tumors located in the antrum or distal body of the stomach (Fig. 81–4).[9] Histologically, there is diffuse

Figure 81–5. Schwartz, M.D., Baylor College of Medicine.)

permeation of the lamina propria with germinal centers; neoplastic cells infiltrate the marginal zone around reactive lymphoid follicles and invade gastric glands, with the formation of characteristic lymphoepithelial lesions (Fig. 81–5).[9,13] The neoplastic MALT lymphoma cells generally express B-cell markers, including CD20, CD22, and CD79a, but they lack markers expressed by other B-cell neoplasms, such as CD5, CD10, CD23, and Bcl-6.[13,19]

Burkitt's Lymphoma

Burkitt's lymphoma is an aggressive lymphoma that may occur as endemic (in equatorial Africa) or sporadic disease.[2] It has a well-established association with Epstein-Barr virus infection.[7] Burkitt's lymphoma generally

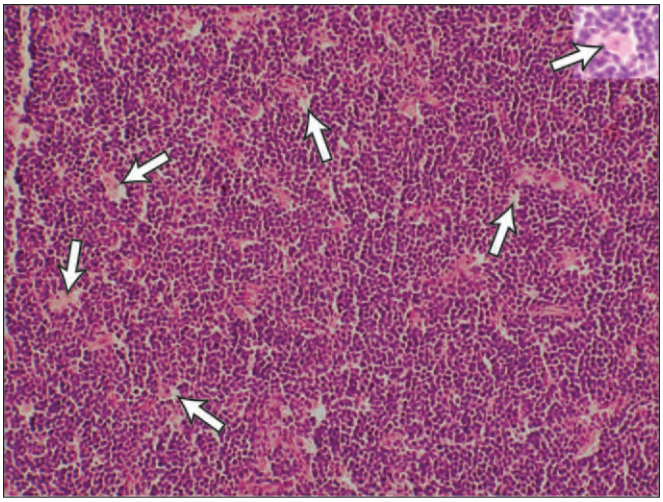

Figure 81–6. Low-power view of Burkitt's lymphoma with monotonous lymphocytic infiltrate and scattered clear spaces (starry sky appearance) *(arrows).* Clear spaces are actually large histiocytes *(inset).* (Courtesy of Suimin Qiu, M.D., The University of Texas Medical Branch.)

affects younger populations than other types of gastric lymphoma do and is typically located in the cardia or body of the stomach or the terminal ileum.[7,13] Apoptosis and mitosis are common within the tumor, which attracts circulating macrophages and thereby results in the classic "starry sky" appearance (Fig. 81–6).[13] Burkitt's lymphoma generally expresses CD10, CD20, CD79a, and Bcl-6 but lacks Bcl-2. Rearrangement of the *c-myc* oncogene is typical of this lymphoma.[21]

Follicular Lymphoma

Follicular lymphoma is most commonly a systemic disease, but it may rarely be manifested as localized GI tract involvement.[13] There is an apparent predilection for the duodenum, and differentiation from MALT lymphoma is often difficult because of the lymphoepithelial lesions common to both.[13] Transformation of follicular lymphoma to diffuse large B-cell disease may occur in as many as 32% of patients and carries a poor prognosis.[22] The most useful markers for the diagnosis of follicular lymphoma are CD10, Bcl-6, and Bcl-12.[13] Additionally, up to 85% of tumors will demonstrate a t(14;18)(q32;q21) translocation leading to Bcl-2 overexpression.[23]

Mantle Cell Lymphoma

Mantle cell lymphoma, in contrast to other forms of GI lymphoma, tends to be manifested as polyposis predominantly involving the small bowel (Fig. 81–7).[24] There is an infiltrate of small or medium-sized cells with irregular nuclei and little cytoplasm, and lymphoepithelial lesions are rare (Fig. 81–8).[13] Unlike other lymphomas, the tumor cells tend to compress rather than infiltrate.[13] Typical tumor markers include CD5, CD20, CD79a, and cyclin D1.[13,24]

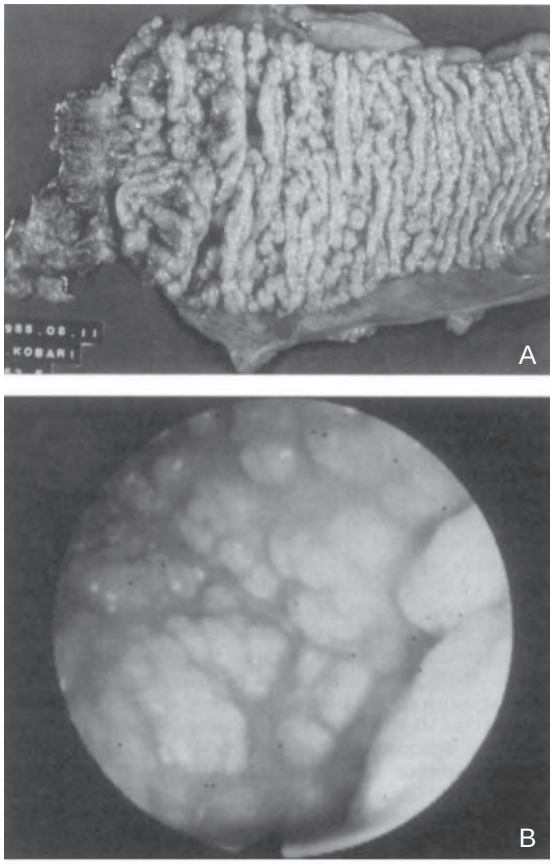

Figure 81–7. Growth manifestations of multiple lymphomatous polyposis. **A,** A surgically resected rectum shows a myriad of confluent polyps and the formation of giant folds. **B,** Endoscopic examination of the duodenum shows numerous polyps that were densely present with the same lesions extending throughout from the esophagus to the rectum. (From Hashimoto S, Nakamura N, Kuze T, et al: Multiple lymphomatous polyposis of the gastrointestinal tract is a heterogenous group that includes mantle cell lymphoma and follicular lymphoma: Analysis of somatic mutation of immunoglobulin heavy chain gene variable region. Hum Pathol 30:581-587, 1999.)

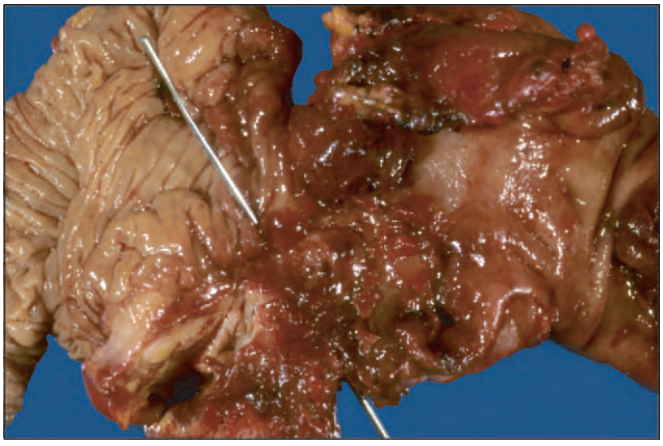

Figure 81–9. Duodenal T-cell lymphoma with circumferential ulceration extending from the pylorus to the ampulla. (Courtesy of Mary R. Schwartz, M.D., Baylor College of Medicine.)

Enteropathy-Type T-Cell Lymphoma

Enteropathy-type T-cell lymphoma (ETL) is an unusual lymphoma variant most commonly localized to the jejunum and ileum.[25,26] A well-defined relationship exists between celiac disease and the development of ETL, and compliance with a gluten-free diet reduces the risk for lymphoma in these patients.[25,27] Perforation is a frequent complication of ETL.[28] Circumferential ulceration of the mucosa is common with this lymphoma, and a heavy eosinophilic and histiocytic infiltrate may obscure tumor cells, which are generally blastic with prominent nucleoli (Fig. 81–9).[29] Adjacent normal bowel generally demonstrates villus atrophy and crypt hyperplasia.[30] ETL exhibits variable tumor markers, which may include CD3, CD4, CD8, and TIA-1.[29] A summary of the immunophenotypes characteristic of various GI lymphomas is shown in Table 81–5.

GRADING

Grading GI lymphomas is important for determination of the prognosis and proper treatment strategy for the disease. GI lymphomas are considered to be low-grade, indolent NHL or high-grade, aggressive NHL by the new WHO classification.[8] Low-grade lymphomas are almost always a derivative of MALT and are thus termed low-grade MALT lymphomas. High-grade lymphomas contain low-grade MALT components in about a third of cases and represent progression of disease; in the remaining two thirds of high-grade tumors, the disease may have progressed from low-grade lesions or may have arisen as a de novo high-grade tumor.[8] Low-grade lymphomas are generally composed of a diffuse infiltrate of small- to medium-sized lymphocytes demonstrating monoclonality. In contrast, high-grade lymphomas appear histologically as large numbers of transformed blasts that

may coalesce in clusters or sheets, ultimately effacing the residual low-grade elements.[8]

STAGING

No consensus has been reached on the optimal system for staging GI lymphoma, but the TNM staging system (as proposed for gastric carcinoma, Box 81–1) is commonly used in surgical applications.[7] The Ann Arbor classification system (Box 81–2) was modified by Musshoff[5] for staging of GI lymphomas (Box 81–3), and both are still commonly applied. Accurate staging often requires evaluation by endoscopy, ultrasonography, chest radiography, bone marrow biopsy, and computed tomography (CT).[6]

DIAGNOSIS

A high index of suspicion is required to make the diagnosis of GI lymphoma because the clinical and radiologic

Box 81–3 **Musshoff's Criteria for Staging of Gastric Lymphomas**

Stage	Definition
IE	Lymphoma restricted to the GI tract on one side of the diaphragm
IE_1	Infiltration limited to the mucosa and submucosa

features are often vague. A careful physical examination should include palpation of all lymph node regions and evaluation of the abdomen for palpable masses or hepatosplenomegaly.[8] Laboratory evaluation should include a complete blood count with differential, routine biochemical assays, lactate dehydrogenase level, and serum protein electrophoresis.[8] Once the diagnosis of GI lymphoma is established, evidence of metastatic disease should be sought by performing an upper airway examination, bone marrow biopsy, and CT of the chest and abdomen to evaluate for lymphadenopathy; any enlarged lymph nodes should be biopsied.[7]

Gastric Lymphoma

The diagnosis of gastric lymphoma is generally made by upper endoscopy and biopsy, with a diagnostic yield of approximately 90%.[31] The most frequent endoscopic finding is ulceration in both low-grade and high-grade lesions (Fig. 81–10). Diffuse infiltration and polypoid masses are also common findings (Fig. 81–11).[31] Such appearances are mistaken for benign conditions such as gastritis or peptic ulcer disease in approximately 50% of patients with low-grade disease and 25% of patients with high-grade disease, thus reinforcing the importance of

biopsy for tissue diagnosis.[31,32] Endoscopic ultrasound is an important adjunct for detecting intramural tumor infiltration and determining tumor stage and is considered to be more reliable than routine CT scanning (Fig. 81–12). The sensitivity of lymph node detection is more variable, with 45% to 90% accuracy.[31] *H. pylori* testing should be performed on biopsy samples and, if negative, confirmed by serology.[7]

Intestinal Lymphoma

In approximately 30% to 50% of patients, the initial manifestation of small bowel lymphoma is an abdominal emergency.[2] As many as 90% of small bowel lymphomas are diagnosed intraoperatively, either as part of a treatment plan or to establish a diagnosis.[33] Commonly used preoperative imaging modalities include CT of the abdomen and pelvis, lymphangiography, gallium scanning, upper GI series, barium enema, upper endoscopy, and colonoscopy; the appropriate work-up depends on the suspected location of the tumor, and decisions should be made on an individual basis (Fig. 81–13).[33]

TREATMENT

Initial treatment of both gastric and intestinal lymphomas should take into account *H. pylori* status because approximately 70% to 80% of MALT lymphomas and a variable

Table 81–6 *Helicobacter pylori* Treatment

Regimen 1	Regimen 2	Regimen 3
Omeprazole (20 mg, twice a day) Amoxicillin (1 g, twice a day) Clarithromycin (500 mg, twice a day)	Omeprazole (20 mg, twice a day) Metronidazole (500 mg, twice a day) Clarithromycin (500 mg, twice a day)	Omeprazole (20 mg, twice a day) Tetracycline (500 mg, 4 times a day) Metronidazole (500 mg, 4 times a day) Bismuth (525 mg, 4 times a day)

Treatment duration is 10 to 14 days. Regimen 1 is the treatment of choice. Regimen 2 is for penicillin-allergic patients. Other proton pump inhibitors may be substituted at equivalent dosages. Eradication rates exceed 85% with all three regimens.
From Kahl BS: Update: Gastric MALT lymphoma. Curr Opin Oncol 15: 347-352, 2003.

number of DLBCLs regress after *H. pylori* eradication in patients harboring the bacterium.[34] Currently, management of gastric lymphoma takes a predominantly conservative, nonsurgical approach, whereas treatment of many intestinal lymphomas involves a multidisciplinary approach with surgical management being a key component of therapy.

Gastric Lymphoma

Optimal treatment of gastric lymphoma depends on *H. pylori* status, disease stage, degree of large cell transformation, and the presence of genetic mutations such as t(1;14), t(11;18), or Bcl-10 overexpression.[16] The indolent nature of low-grade MALT lymphomas lends itself to conservative treatment, with antibiotic therapy being the sole initial agent, given that the patient can be monitored closely.[35] Approximately 77% of patients with gastric MALT lymphoma will experience complete remission after *H. pylori* eradication.[9] Remission is generally achieved within 12 months of therapy, but a latent period of up to 45 months may occur, with a relapse rate of less than 10%.[9] Current *H. pylori* eradication therapy should include a 2-week regimen of either (1) omeprazole or lansoprazole, clarithromycin, and amoxicillin; (2) omeprazole or lansoprazole, metronidazole, and clarithromycin; or (3) omeprazole or lansoprazole, bismuth, metronidazole, and tetracycline (Table 81–6). Strict endoscopic surveillance with biopsy is recommended 2 months after treatment and at least twice per year for 2 years to monitor for regression.[35] Indicators of possible failure of *H. pylori* eradication include lymphomas of stage IIE and above, stage IE_2 cases that involve the muscularis propria or serosa, lymphomas demonstrating t(11;18)(q21;q21) or t(1;14)(p22;q32) translocations or nuclear expression of Bcl-10, or lymphomas associated with underlying autoimmune disorders.[9] However, eradication should still be pursued in these patients. An algorithm for the management of MALT lymphoma is presented in Figure 81–14.

There are no treatment guidelines for the management of patients who experience antibiotic failure. Surgical therapy is highly curative for localized tumors, but many gastric lymphomas disseminate widely within the mucosa, with frequent tumor relapse in the gastric stump and eventual need for total gastrectomy, which has a significant impact on quality of life.[9] Thus, a multimodal approach consisting of any combination of chemotherapy, radiation therapy, and surgery is common.[4] Chemotherapy with a single alkylating agent, such as cyclophosphamide or chlorambucil, is useful either alone or as an adjunct to surgical resection for *H. pylori* eradication–resistant MALT lymphomas.[9,35] Combination chemotherapy with CHOP (cyclophosphamide, hydroxydaunomycin, Oncovin [vincristine], and prednisone), with the possible addition of rituximab (a chimeric monoclonal antibody against the CD20 B-cell antigen), is preferred for the treatment of high-grade MALT lymphoma or DLBCL.[35-37] MALT lymphomas are also highly radiosensitive, and the use of low-dose localized radiation alone is highly effective in the management of lymphomas unresponsive to *H. pylori* eradication, with a 5-year survival rate of greater than 90%.[9] The combination of surgery and radiotherapy has been advocated for management of low-grade disease, with the addition of chemotherapy for high-grade disease, but no consensus has been reached.[4,36]

Intestinal Lymphoma

Patients with lymphoma of the intestine who are *H. pylori* positive benefit from eradication therapy, as with gastric lymphoma.[11] Initial management of stage I or II small bowel lymphoma should otherwise include segmental surgical resection with regional lymph node excision, regardless of patient age or lymphoma type, given the increased risk for perforation and obstruction associated with these tumors (Fig. 81–15).[2] An aggressive multimodal therapeutic approach combining both surgical resection and polychemotherapy can improve the outcome in patients with all intestinal lymphoma variants, but decisions on the appropriate course of therapy must be made on an individual basis.[11,38] The most commonly applied chemotherapy regimen for patients with intestinal DLBCL or MALT lymphoma is CHOP, with the addition of rituximab in those with mantle cell or follicular variants.[2,11] Treatment of Burkitt's lymphoma is similar to CHOP, with the substitution of methotrexate for prednisone.[2] T-cell lymphomas are notoriously chemotherapy resistant; the best chance for cure in this patient population is achieved by enrollment in clinical trials.[2] Radiotherapy is infrequently used in the treatment of intestinal lymphomas because of a high risk of late complications.[38]

PROGNOSIS

Factors affecting prognosis in patients with GI lymphoma include lymphoma type, grade, stage, location, molecular markers, genetic rearrangements, and age of the patient. MALT and MALT-derived lymphomas have the best overall prognosis, regardless of location.[2,11] Gastric lymphomas have a better overall prognosis than intestinal lymphomas do; 5-year survival rates for tumors localized to the stomach are approximately 91% for low-grade, 73% for secondary high-grade, and 56% for primary high-grade tumors, whereas the 5-year survival rate for aggressive small intestinal lymphomas is approximately 25% to 30%.[5,6,39] Intestinal B-cell lymphomas are associated with a better prognosis than those of T-cell origin, with average 5-year survival rates of 75% and 25%, respectively.[5,40]

SUMMARY

GI lymphomas are a diverse group of neoplasms that are often associated with vague symptoms that imitate common intra-abdominal pathologies; a high degree of suspicion is frequently required to make the diagnosis. Many advances have been made in the diagnosis and management of GI lymphomas over the past decade. The importance of *H. pylori* infection to the development of lymphomas has only recently been realized, and this realization has revolutionized treatment of the disease. Gastric lymphoma, once a surgical disease, is now managed conservatively, with *H. pylori* eradication being central to treatment. Although surgery remains the mainstay of treatment of small intestinal lymphoma, *H. pylori* eradication has proved to be a useful adjunct in its management as well.

Surgical Conditions of the Small Intestine in Infants and Children

Marshall Z. Schwartz ▪ Ahmed Mami

Conditions of the small intestine in infants and children can be categorized into congenital abnormalities and acquired abnormalities. These two categories combined represent the majority of abdominal surgical emergencies in infants and young children. They are also the major cause of mortality. The advent of new and better imagining technologies has led to more precise and earlier diagnosis. For example, detailed fetal ultrasonography and fetal magnetic resonance imaging are more precise than they were 5 to 10 years ago. In addition, new minimally invasive surgical approaches have allowed for more rapid recovery.

Congenital abnormalities refer to developmental anomalies such as malrotation. Acquired abnormalities are entities that evolve after birth.

Congenital abnormalities covered in this chapter include malrotation, intestinal atresia, duplications, meconium obstruction, and omphalomesenteric duct remnants. Acquired lesions include necrotizing enterocolitis and intussusception.

Over the past 8 to 10 years two significant changes have occurred in the evaluation and treatment of many of the conditions discussed in this chapter. Imaging technology and techniques have continued to improve, which allows for more precise diagnosis. Although it could be stated that the usual approach to surgical problems in children is minimally invasive (i.e., through very small incisions), the use of laparoscopic techniques with very small ports (3 mm) and instruments has become common in pediatric surgery.

MALROTATION

The term *malrotation* refers to incomplete midgut rotation and fixation during in utero development. Thus, a more appropriate term would be *incomplete rotation*. The midgut, which is supplied by the superior mesenteric vessels and extends from the duodenojejunal junction to the midtransverse colon, remains unfixed and suspended on a narrow mesentery. This abnormal anatomy predisposes the midgut to life-threatening volvulus. Although this condition was first described by Mall in 1898,[1] it was William Ladd who described the currently used principles of malrotation repair in 1936.[2]

The primitive gut is recognized as a straight tube in the fourth week of embryologic development (Fig. 82–1). Rapid growth plus elongation of the midgut starting in the fifth week leads to herniation of the midgut with the superior mesenteric vessels as its stalk. This results in the formation of a physiologic umbilical hernia at the base of the umbilical cord. The midgut undergoes 270-degree counterclockwise rotation around the superior mesenteric vessels. This initial rotation results in the normal position of the duodenojejunal flexure in the left upper quadrant at the level of the gastric antrum. The duodenojejunal flexure becomes fixed to the posterior abdominal wall by the ligament of Treitz. As a result of this rotation and fixation, the third portion of the duodenum lies posterior to the superior mesenteric artery (SMA). In the 10th week the herniated intestinal loop begins to return to the abdominal cavity. The cecocolic loop undergoes another 270-degree counterclockwise rotation around the SMA, which leads to the normal position of the cecum in the right lower quadrant. Subsequently, the ascending colon and descending colon become fixed to the posterior abdominal wall. During the fourth and fifth weeks of gestation, the small intestine mesentery attaches itself to the posterior abdominal wall in a broad base extending diagonally from the duodenojejunal flexure to the cecum.

There are several degrees of rotational abnormality. Nonrotation is characterized by failure of counterclockwise rotation after return of the midgut to the

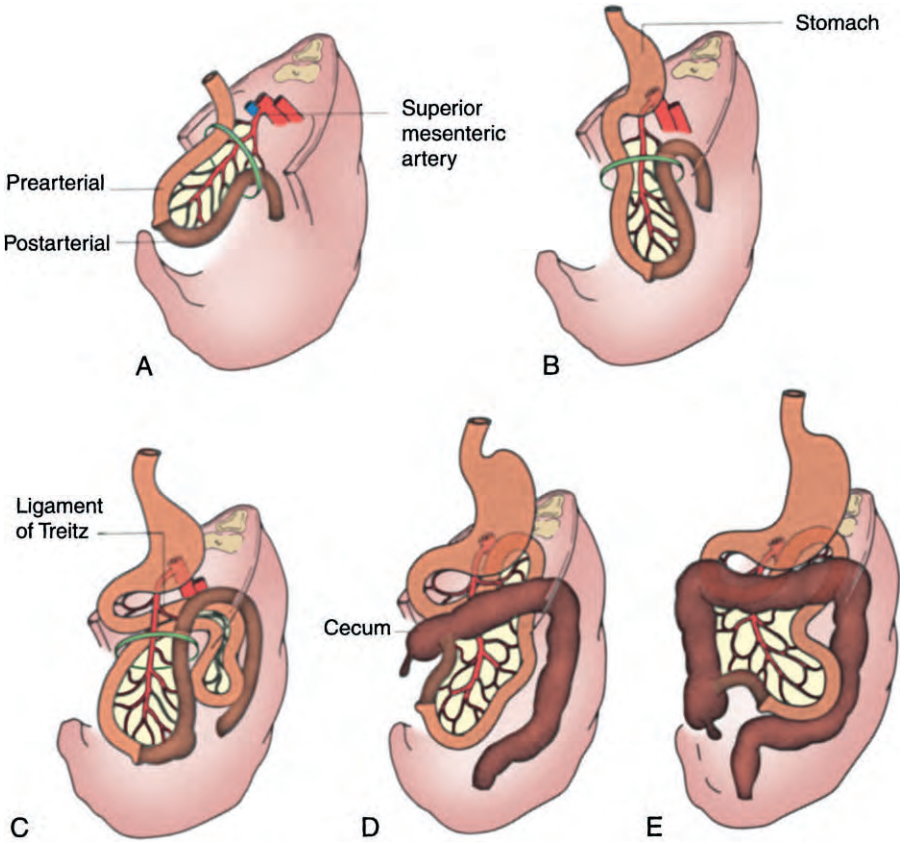

Figure 82–1. Normal midgut rotation is shown beginning in the 5th gestational week **(A)** through completion of the process in the 12th week **(E)**. (From Ashcraft KW, Holder TM [eds]: Pediatric Surgery. Philadelphia, WB Saunders, 1999.)

abdominal cavity (Fig. 82–2A). In incomplete rotation, the counterclockwise rotation is arrested at around 180 degrees. These are the most common forms of malrotation. The small intestine lies on the right side with the duodenojejunal flexure to the right of the vertebral column, and the duodenum has a corkscrew configuration. The large intestine lies on the left side with the cecum at abnormal locations, usually in the midline. Other forms of fixation anomalies may be due to failure of fixation of the ascending colon in the right hypochondrium. Associated with this abnormal fixation is a narrow intestinal mesentery and Ladd's bands. Ladd's bands represent the retroperitoneal attachments that normally fix the cecum and ascending colon to the posterior abdominal wall. Because the right colon is more medial, the bands extend across the duodenum from the right upper quadrant to the cecum and ascending colon. In reverse rotation, part of the rotation occurs in a clockwise direction around the SMA (see Fig. 82–2D). The duodenum assumes an anterior position and the colon lies posterior to the duodenum and the SMA. If the counterclockwise rotation extends beyond 270 degrees, the cecum comes to rest in the left hypochondrium position (see Fig. 82–2E). This rare form is called hyper-rotation. Other forms of fixation anomalies may be due to failure of fixation of the ascending or descending colon to the posterior abdominal wall. In this condition, the small intestine is at risk of entrapment in the potential space between the mesocolon and the posterior abdominal wall and is referred to as a mesocolic or paraduodenal hernia (see Fig. 82–2F). Lesser degrees of malrotation may affect only the cecocolic loop. Although the duodenum may lie in a normal position, the cecum remains unfixed and in an abnormal position with Ladd's bands. These patients are at risk for duodenal obstruction and cecal volvulus.

Patients with malrotation have a 30% to 62% risk of having associated anomalies, and most involve the gastrointestinal tract.[3] Five percent to 26% are associated with duodenal or other small intestinal atresias. Other less common anomalies include imperforate anus, cardiac anomalies, duodenal web, Meckel's diverticulum, and trisomy 21. Rare associations include biliary atresia, esophageal atresia, mesenteric cyst, Hirschsprung's disease, and craniosynostosis. Malrotation is always present in infants with congenital diaphragmatic hernia, omphalocele, and gastroschisis.

Malrotation is documented in 0.5% of autopsy studies,[4] although the incidence of clinically symptomatic malrotation is estimated to be 1 in 6000 live births.[5] Malrotation may initially be recognized at any age, but in approximately 90% of patients symptoms develop before 1 year of age, with 50% to 75% appearing within the first month of life.[6-8]

Malrotation can be totally asymptomatic and discovered only during work-up for an unrelated condition or during an autopsy examination. The initial symptoms depend on the cause. Neonates typically have bilious emesis, which may be the only initial symptom of midgut volvulus. If the diagnosis is delayed and the bowel

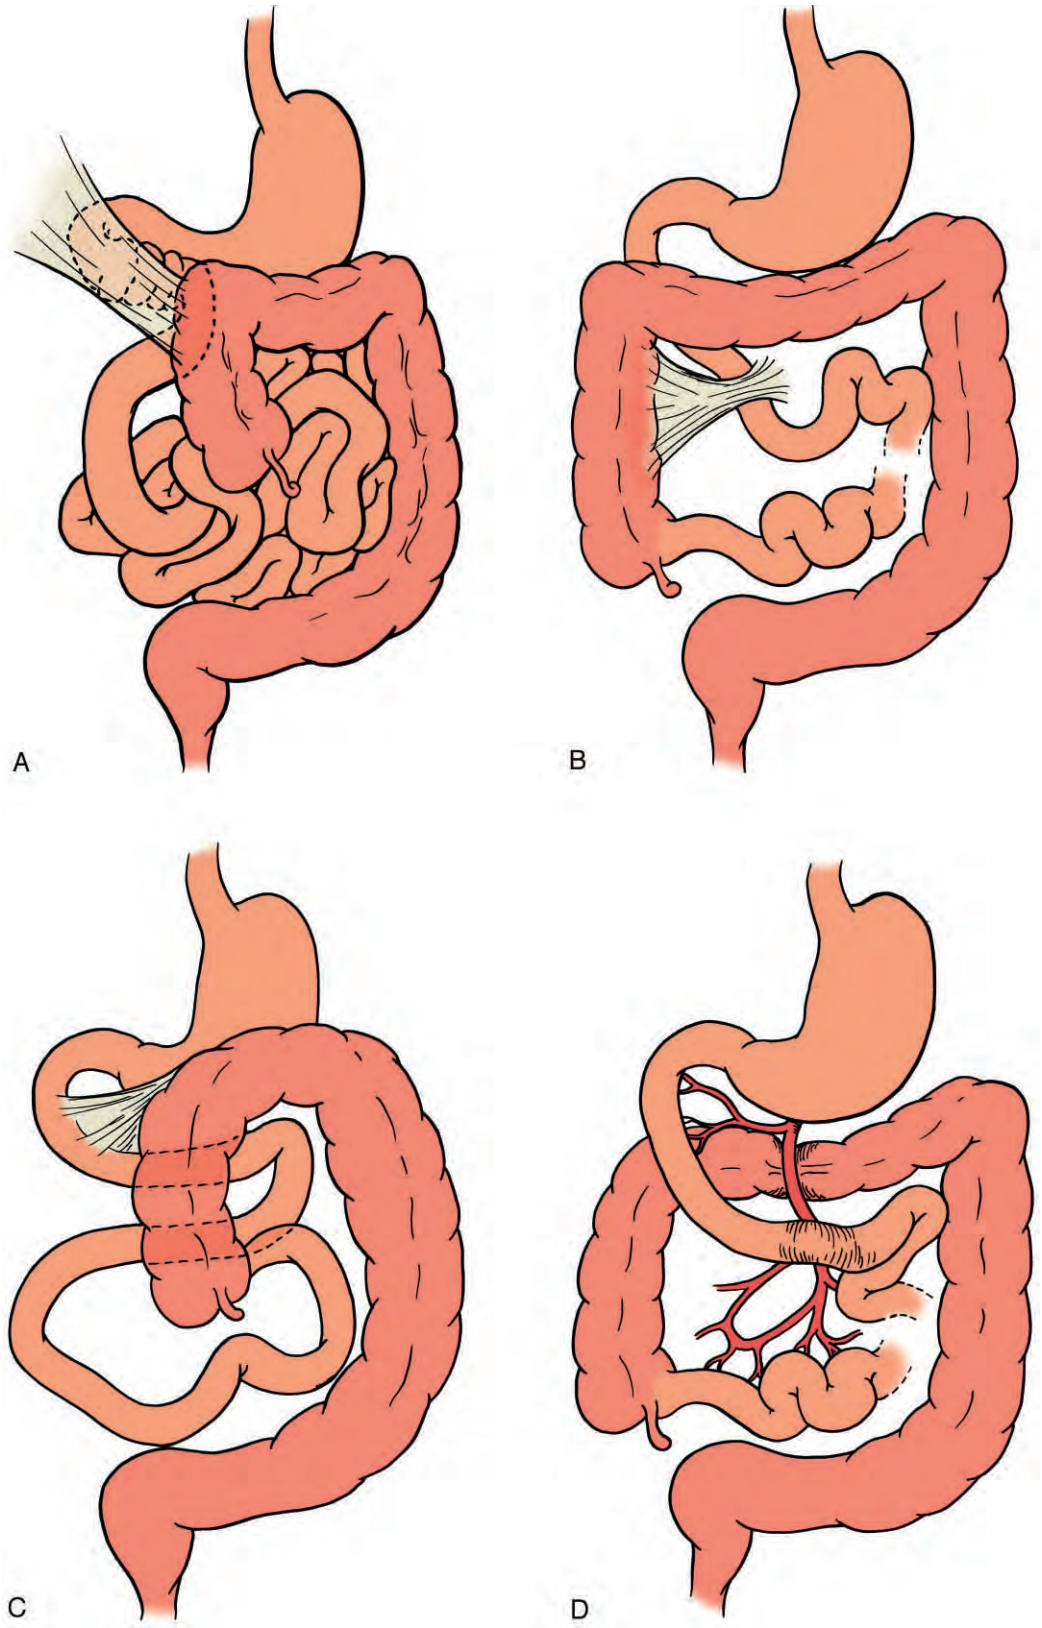

Figure 82–2. **A,** Complete nonrotation of the midgut. Neither the duodenojejunal junction nor the cecum has rotated around the superior mesenteric artery (SMA). All of the small bowel lies to the right of the SMA, and all of the colon lies to the left. This anomaly is the most frequent type of malrotation, and the risk for midgut volvulus is ever present. **B,** Nonrotation of the duodenojejunal junction with normal rotation of the cecum. This abnormality may be manifested clinically as duodenal obstruction as a result of abnormal mesenteric (Ladd's) bands from the colon across the anterior duodenum. **C,** Normal rotation of the duodenojejunal junction with nonrotation of the cecum. These patients are at risk for midgut volvulus. **D,** Reverse rotation of the duodenojejunal junction passing ventral rather than dorsal to the SMA, followed by reverse rotation of the colon (the cecum rotating dorsal rather than ventral to the SMA). This abnormality may be manifested clinically as obstruction of the transverse colon.

Continued

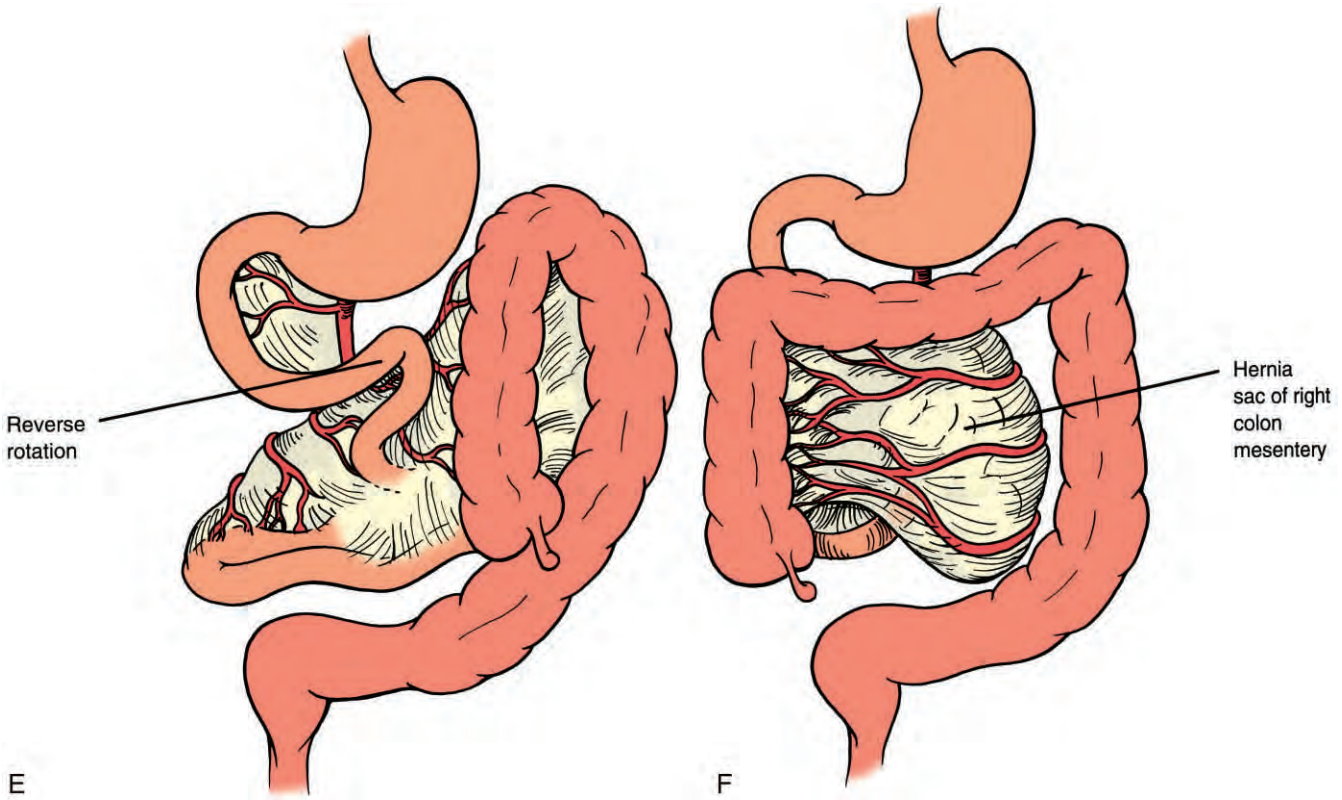

Figure 82–2, cont'd. **E,** Reverse rotation of the duodenojejunal junction (passing ventral rather than dorsal to the SMA), followed by normal rotation of the colon. **F,** A paraduodenal hernia sac is created by the mesentery of the colon as the cecum passes over the small intestine to lie in the right lower quadrant. (From Oldham KT, Colombani PM, Foglia RP [eds]: Surgery of Infants and Children: Scientific Principles and Practice. Philadelphia, Lippincott-Raven, 1997.)

becomes ischemic, the infant will demonstrate systemic signs such as increasing lethargy with poor perfusion, temperature instability, cardiopulmonary compromise, and low urine output. The patient may deteriorate to septic shock and multiorgan failure with other signs such as melena, hematemesis, and peritonitis. Hematologic studies may show metabolic acidosis, thrombocytopenia, and leukopenia. Malrotation without volvulus may be manifested as chronic, vague abdominal pain, with or without intermittent bilious emesis, and failure to thrive.

Successful treatment of malrotation depends on early diagnosis. The acute onset of bilious vomiting in a neonate is a sign of malrotation until proved otherwise. It demands immediate radiologic evaluation. The gold standard test for the diagnosis of malrotation is an upper gastrointestinal contrast study. Malrotation is diagnosed by an abnormal position of the ligament of Treitz. The normal location is typically to the left of the vertebral column and posterior to the stomach. In the absence of a ligament of Treitz, the duodenum remains to the right of the spine. Another possibility is that the duodenojejunal flexure crosses to the left of the vertebral column but lies below the level of the gastric antrum. Volvulus can be diagnosed by contrast-enhanced upper gastrointestinal series showing a corkscrew configuration of the upper portion of the small intestine (Fig. 82–3) or a "bird's beak" appearance at the third portion of the duodenum (Fig. 82–4). It must be emphasized that plain abdominal radiographs are not helpful in ruling in or out midgut volvulus.[4] The abdominal radiograph may show a wide range of abnormalities, including a dilated stomach and proximal duodenum, similar to a "double-bubble" sign, a paucity of abdominal gas, or dilated bowel loops with multiple air-fluid levels, or the radiograph may appear normal. A contrast enema study is not part of the work-up for malrotation. The presence of a normally located cecum in the right lower quadrant does not rule out malrotation. Abdominal ultrasonography may be used to study the position of the superior mesenteric vein (SMV) in relation to the SMA. Normally, the SMV lies to the right of the SMA. An abnormal position of the SMV in relation to the SMA may indicate the presence of malrotation with volvulus.

Children who are acutely ill with peritonitis need emergency surgery without radiologic studies. Patients who are symptomatic from volvulus as a result of malrotation should undergo nasogastric decompression, be resuscitated with intravenous fluid, and receive broad-spectrum antibiotics. Blood samples should be sent for laboratory analysis, including a complete blood count and type and crossmatching. The patient should be taken to the operating room urgently. Unnecessary delay may further compromise the bowel and lead to infarction.

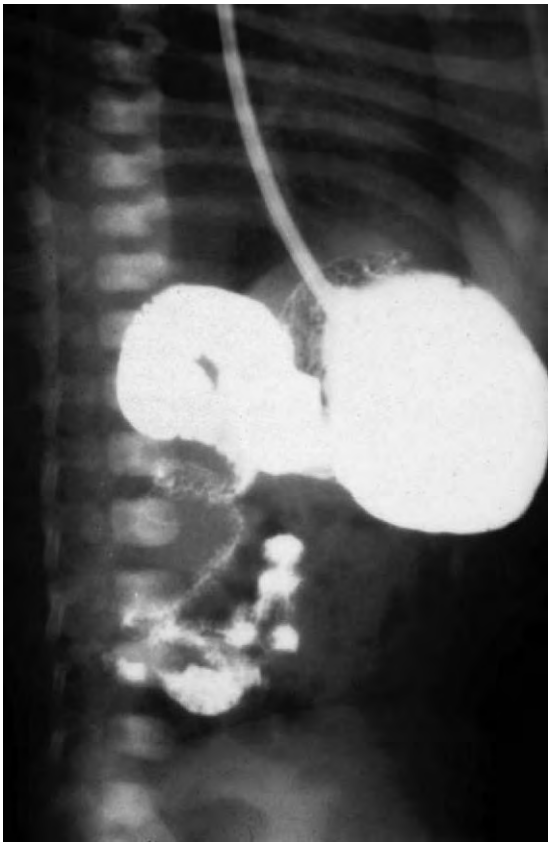

Figure 82–3. Midgut volvulus. A spot film from an upper gastrointestinal series demonstrates a distended, contrast-filled stomach with corkscrew configuration of the proximal part of the small bowel. (Courtesy of A. B. Campbell, MD, St. Christopher's Hospital for Children.)

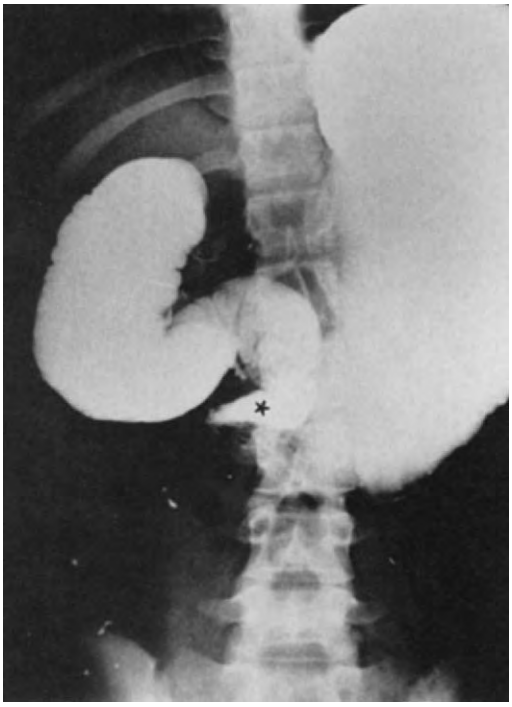

Figure 82–4. This upper gastrointestinal contrast study shows malrotation with volvulus. The "beak" is illustrated by the *asterisk*. Note the malposition of the distal duodenum as well. (From Oldham KT: Pediatric abdomen. In Greenfield LJ, Mulholland M, Oldham KT, et al [eds]: Surgery: Scientific Principles and Practice. Philadelphia, Lippincott-Raven, 1997.)

Children with vague chronic symptoms or children who are symptom-free should undergo elective correction.

The standard approach to correction of malrotation has been via a right upper quadrant transverse incision. However, a Ladd procedure in the absence of volvulus can be performed laparoscopically as long as there is no question of bowel compromise. The entire small intestine is eviscerated and carefully examined for the presence of volvulus (Fig. 82–5). If volvulus is present, it should be reduced by counterclockwise rotation as necessary because volvulus usually occurs in a clockwise direction. The bowel is assessed for viability. Mild to moderately ischemic bowel resumes its normal color after reduction of the volvulus. Bowel with uncertain viability should be wrapped with warm moist gauze sponges for at least 15 minutes. Frankly gangrenous bowel should be resected and a stoma or stomas fashioned. Bowel with marginal viability should be left in continuity if possible with a view to perform a second-look operation 24 to 36 hours later. At the second operation any necrotic bowel should become obvious, and further resections may be necessary. After reducing the volvulus if it is present, Ladd's bands, which represent the posterior peritoneal attachments of the right colon that cross over the duodenum, should be divided on the lateral aspect of the duodenum (Fig. 82–6). Widening of the mesenteric base is necessary, and the duodenum is mobilized and straightened by dividing the abnormal ligament of Treitz and Ladd's bands. The duodenum is carefully examined for intrinsic obstruction. If there is any doubt, a balloon catheter can be passed transorally and manipulated into the upper jejunum. An inability to pass the catheter or to pull the catheter back with the balloon inflated indicates the presence of intrinsic obstruction. Incidental appendectomy should be performed to avoid diagnostic confusion in the future because the cecum will be placed in the left lower quadrant. The intestine is returned to the abdominal cavity, starting with the duodenum and proximal jejunum, which are placed on the right side, and ending with the terminal ileum and cecum, which are placed in the left hypochondrium.

Postoperative care of these patients includes nasogastric decompression and intravenous fluid until return of bowel function. Prolonged ileus is not unusual postoperatively, especially if volvulus was present. Postoperative complications include bleeding and recurrent volvulus. The latter is rare if the initial operation is technically complete. The most serious complication is short-gut syndrome as a result of volvulus and bowel necrosis requiring extensive small bowel resection.

The operative mortality of Ladd's procedure ranges from 3% to 9%,[3] with the higher mortality being

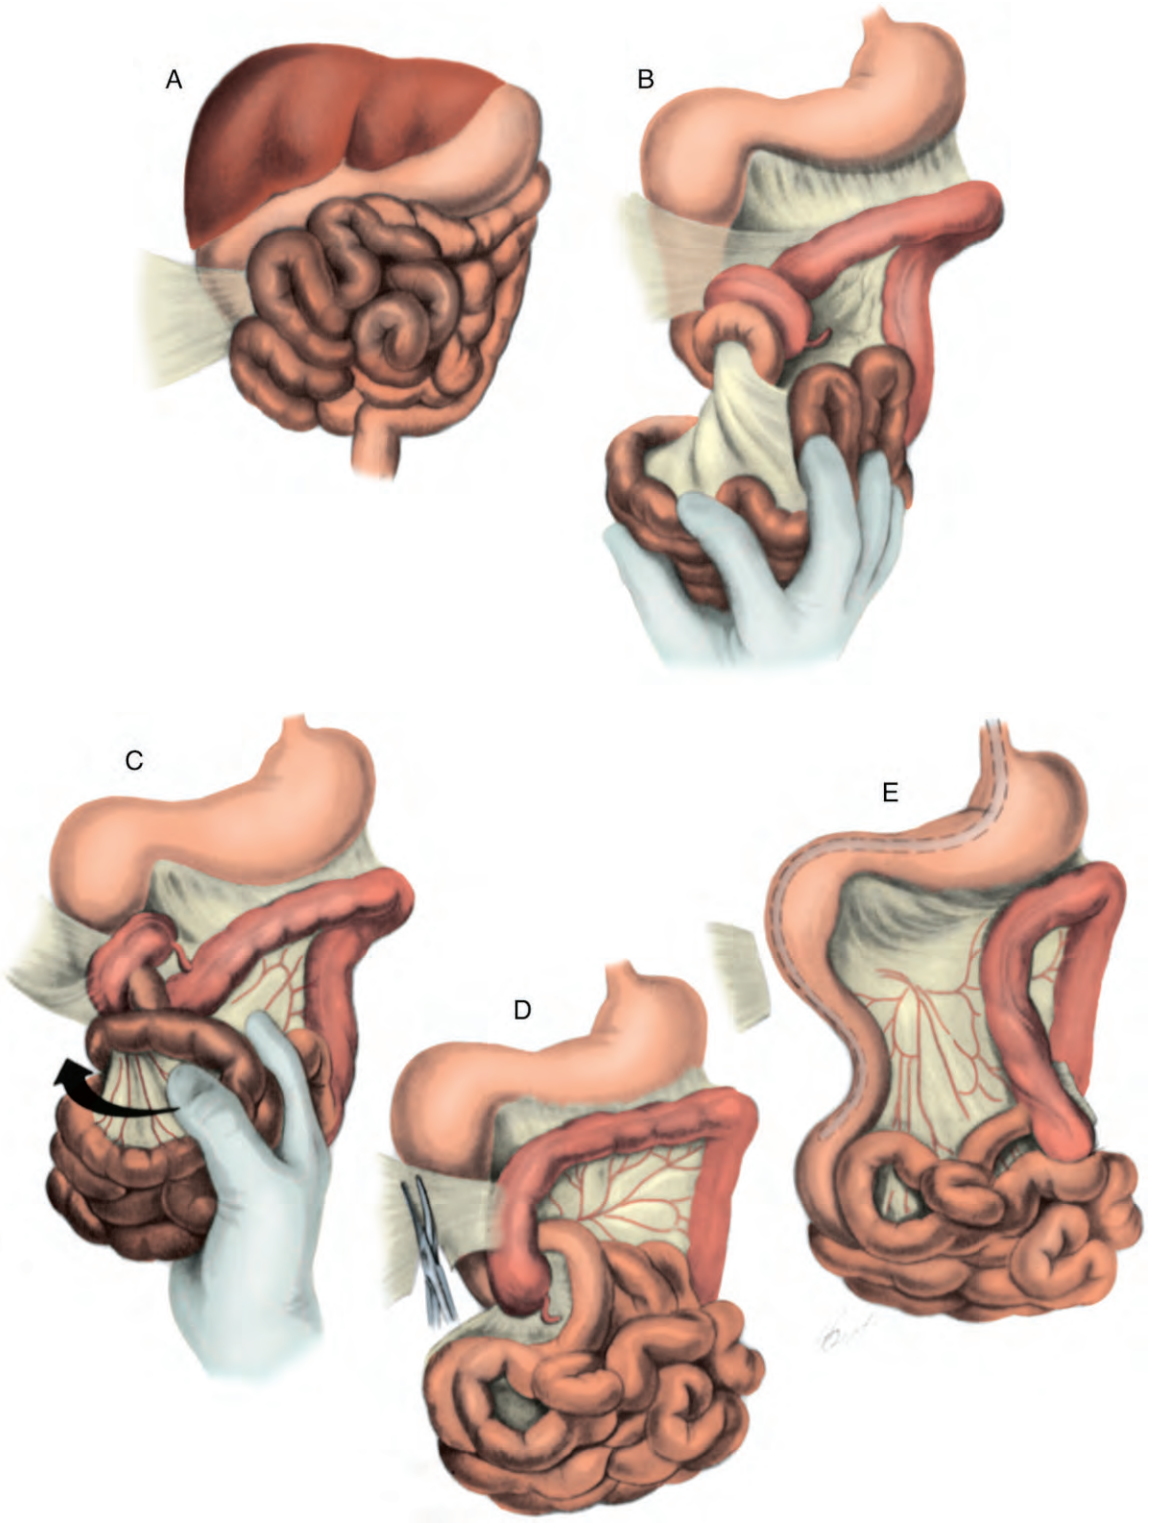

Figure 82–5. Malrotation of the intestine. **A,** Appearance of the viscera as the abdominal cavity is opened. The small intestines are seen at once and seem to hide the colon. Vascular compromise of the intestine may be obvious. **B,** The entire intestinal mass is delivered out of the wound and drawn downward to reveal the base of the mesentery. Coils of intestine or ascending colon are wrapped around the root of an incompletely anchored mesentery. The volvulus has taken place in a clockwise direction. The descending duodenum is dilated because of extrinsic pressure from Ladd's bands or peritoneal folds that cross it. **C,** The volvulus is reduced by taking the entire intestinal mass in the hand and rotating it counterclockwise (in most cases). **D,** With reduction of the volvulus, the cecum lies in the right paravertebral gutter. The peritoneal folds from the cecum obstruct the duodenum. The folds are incised close to the lateral serosal border of the duodenum. The underlying superior mesenteric pedicle is identified and carefully preserved. **E,** Appearance of the intestines and ascending colon at the end of surgery. The duodenum descends along the right gutter. The small intestines lie on the right side of the abdomen, and the cecum and ascending colon are in the midline or left side of the abdomen. The superior mesenteric artery and its branches are left exposed as shown. A nasogastric tube has been passed into the jejunum to exclude intrinsic obstruction. (From O'Neill JA Jr, Rowe MI, Grosfeld JL, et al [eds]: Pediatric Surgery. St Louis, Mosby–Year Book, 1998.)

associated with complete small intestinal necrosis, prematurity, or other serious congenital abnormalities.[9]

ATRESIA AND STENOSIS

Atresia and stenosis are among the most common causes of neonatal intestinal obstruction.[10] The reported incidence of jejunoileal atresia is about 1 in 1000 live births with a range of 1 in 300 to 1500 live births.[11-15] The most widely accepted cause of these defects is a localized intrauterine vascular accident leading to necrosis and resorption of the affected segments.[13] The vascular event can be thrombosis, embolism, intussusception, or volvulus. The general acceptance of this etiology is based in part on animal studies in which in utero occlusion of mesenteric vessels led to atresia.[13,16] The association of atresia with certain disease states such as gastroschisis and midgut volvulus adds weight to the ischemia/necrosis theory.[17]

The gender ratio is equal. Jejunal atresia is slightly more common than ileal atresia. In 80% to 90% of cases the atresia is isolated. However, in up to 20% of cases atresias are multiple.[10,18] Hence, it is important to evaluate the whole intestine for other atresias. In one study, about a third of patients had associated anomalies, predominantly gastrointestinal.[19] An important comorbid condition that can be overlooked in infants with jejunoileal atresia is cystic fibrosis. The reported incidence is 10% to 20%.[18-21] White infants with jejunoileal atresia have more than 210 times the risk for cystic fibrosis than white infants in the general population do.[22] These children should be screened routinely for cystic fibrosis.[20,23]

Small intestine atresias have been classified into four types (Fig. 82–7), and the outcome can vary significantly depending on the type. Intestinal atresia is being diagnosed more frequently with prenatal ultrasonography.[19] The more proximal small bowel atresias can be associated with maternal polyhydramnios as a result of decreased fetal intestinal absorption of amniotic fluid.[24] Ultrasonography may show dilated, fluid-filled intestinal loops. Antenatal diagnosis permits earlier recognition, which allows for more effective parental counseling and appropriate preparation for surgical intervention postnatally.[25] At the time of delivery, bile staining of amniotic fluid is associated with intestinal obstruction.[26]

Infants with atresia or stenosis usually have bilious vomiting on the first day of life. However, in about 20% of cases, the vomiting may be delayed for 24 hours.[13,27] The higher the obstruction, the earlier the vomiting. Abdominal distention is more pronounced with distal obstruction. More than 60% of these infants fail to pass meconium in the first day of life.[10,13] They may have grayish mucoid contents in the rectal vault. Other associated symptoms and signs include fever, dehydration, aspiration pneumonia, and unconjugated hyperbilirubinemia. The latter may be due to impairment of the enterohepatic circulation.[18] Examination of the abdomen may also reveal signs of peritonitis or ischemia, such as tenderness, edema, and erythema of the abdominal wall. The clinical manifestations of intestinal stenosis are more subtle, with intermittent partial bowel obstruction, malnutrition, and failure to thrive. The initial findings in infants with intestinal stenosis may be unremarkable, but higher-grade bowel obstruction ultimately develops and requires surgical intervention.

Abdominal radiographs show gas- and fluid-filled bowel loops with absence of gas distally (Fig. 82–8A). In proximal obstruction, there are fewer distended bowel loops. Distal ileal atresia may be difficult to differentiate from meconium ileus or colonic obstruction. In patients with atresia or meconium ileus, a contrast enema will show a microcolon and small, unused distal ileum (see Fig. 82–8B). In meconium ileus, some of the contrast may outline the impacted stool and thus make the diagnosis. In colonic atresia, contrast will not demonstrate the cecum or ileocecal valve. Ten percent of patients with atresia have meconium peritonitis from in utero bowel perforation.[10,18]

Management of infants with atresia includes intravenous fluid, decompression of the stomach, withholding of enteral feeding, and administration of antibiotics. After resuscitation the infant is taken to the operating room for exploratory laparotomy. The goals of the operation are to restore intestinal continuity after resection of the atretic segment while preserving intestinal length. Through a right upper or lower quadrant transverse incision, the small bowel is eviscerated. A transition point is usually identified. Normal saline is injected distal to the transition point and milked more distally to rule out other obstructions. If the proximal dilated bowel appears ischemic and nonviable, it should be resected. Resection of massively dilated proximal bowel may expedite bowel recovery postoperatively. A tapering procedure may be performed in the proximal bowel segment. It is important to note that in atresia the proximal blind end is dilated and hypertrophied with ineffective peristaltic activity.[28] It is also deficient in mucosal enzymes and muscular adenosine triphosphate.[29] Although dysmotility resolves after removal of the obstruction, recovery may take longer in patients with very dilated bowel loops. The

tapering procedure can be performed by resecting a part of the antimesenteric side of the bowel with a stapling device. Another technique to reduce the caliber of the proximal part of the bowel is imbrication of the antimesenteric side with running suture. Studies suggest that bowel plication may prevent disturbed intestinal transit postoperatively.[30] Continuity of the bowel is achieved by an end-to-oblique anastomosis after opening the distal part of the bowel and making a longitudinal antimesenteric incision to accommodate the difference in size between the proximal and distal bowel loops. Simple atresias of the small intestine can be managed with "laparoscopic assistance" by identifying the anatomy laparoscopically, bringing the atretic ends out through an enlarged umbilical port incision, performing the anastomosis extraperitoneally, and replacing it back through the umbilicus.

Infants with gastroschisis and intestinal atresia present a special problem. Atresia may be missed initially because of thick peel obscuring the bowel. It is preferred that the gastroschisis defect be repaired initially and the atresias be addressed after a period of bowel decompression and parenteral nutrition to give the peritoneal and bowel inflammation time to resolve. However, early enterostomy may be needed, especially in patients with complicated distal atresia.[31,32]

Postoperatively, parenteral nutrition is started pending return of bowel function. Proximal atresias tend

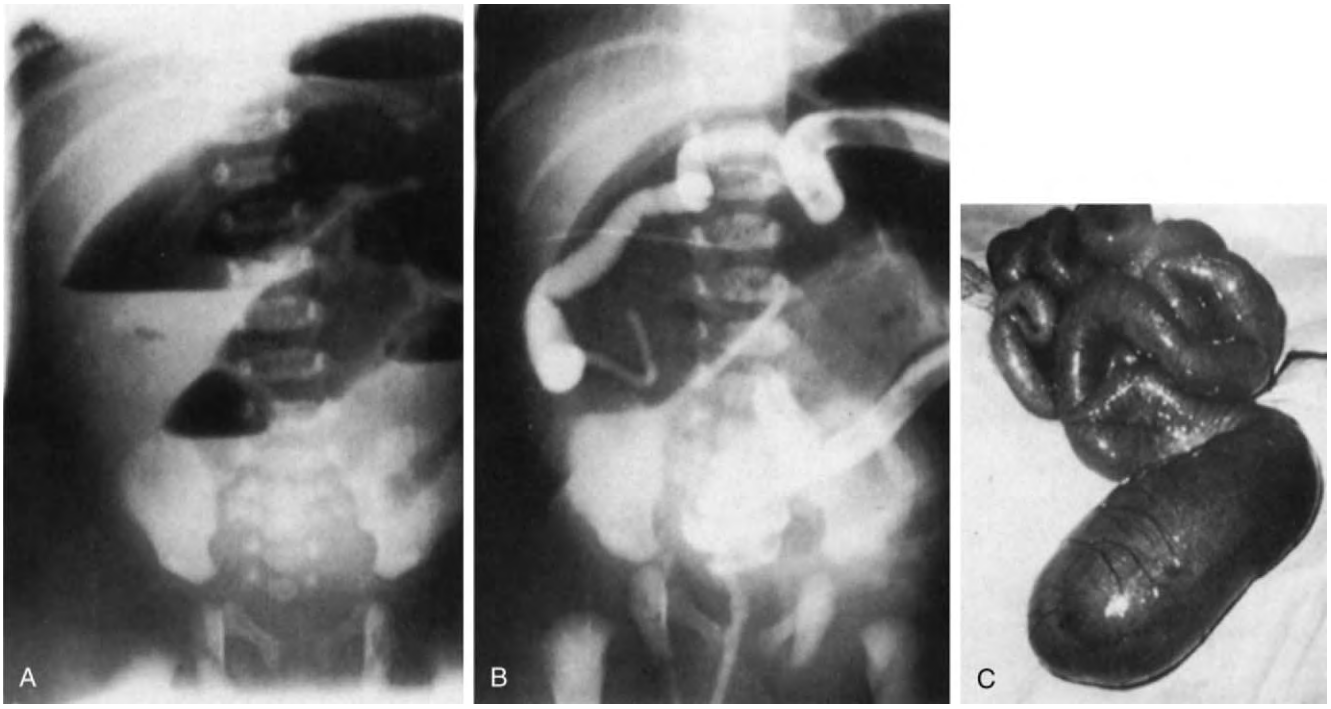

Figure 82–8. Ileal atresia. **A,** Erect abdominal radiograph showing distended intestinal loops with air-fluid levels. **B,** Contrast enema demonstrating a microcolon (unused), suggestive of small bowel obstruction. **C,** Atresia of the ileum (type IIIa) at laparotomy. to take a longer time before return of bowel motility. Enteral feeding is started when the infant shows signs of return of bowel function. Passing of gas and stool together with decreasing and clearing of the gastric aspirate is a good indicator of return of bowel function.

The prognosis in these patients is excellent, with survival rates of 90%, as opposed to a mortality rate of 90% before 1952.[13] The reduction in mortality is probably due to improvements in neonatal care, nutrition, and surgical techniques. Anastomotic leak or stricture requiring surgical intervention develops in 10% to 15% of infants.[33] These patients are also at risk for adhesive bowel obstruction and necrotizing enterocolitis (NEC); however, these complications are infrequent. Extensive resection of the bowel can lead to short-bowel syndrome. Adaptation and recovery of bowel motility take 12 to 24 months in these patients.

DUPLICATIONS AND CYSTS OF THE SMALL INTESTINE

Three forms of cystic structures can be associated with the small intestine. Abnormalities that are in direct contact with the small intestinal wall are referred to as duplications because they contain all three layers of bowel. Two forms of duplication can occur. The most common is a spherical structure referred to as a *cystic duplication* (Fig. 82–9). These lesions do not have communication with the lumen of the normal small intestine. Another form of duplication is a *tubular duplication* (Fig. 82–10).

These duplications parallel the normal bowel lumen and share a common wall and blood supply with the adjacent bowel. They have a higher incidence of communication with the existing lumen of the small intestine and have a significant incidence of ectopic gastric mucosa.[34]

The second category of cystic structures consists of cysts that arise in the mesentery of the bowel, whereas the third category includes cysts that involve the omentum. Several theories have been proposed to explain the origin of these structures, but because of the numerous types of cysts in and around the small intestine, there is no common theory that best explains all of them.

The small intestine is the most common location for enteric duplications and accounts for more than half of such anomalies.[35] Twenty percent of the remaining duplications occur in the thorax and 5% are found at the junction of the thorax and abdomen. Seventy-five percent of enteric cysts do not communicate with the lumen of the bowel.[36] It is important to emphasize that both tubular and cystic duplications of the bowel share a common wall and a common blood supply with the adjacent normal intestine. It is also relevant that 25% of duplications contain ectopic tissue.[37] The most common ectopic tissue is gastric mucosa.

The clinical findings vary significantly, depending on the size and site of the duplication or cyst. Cystic duplications of the bowel are typically manifested as partial small bowel obstruction as a result of the cyst gradually

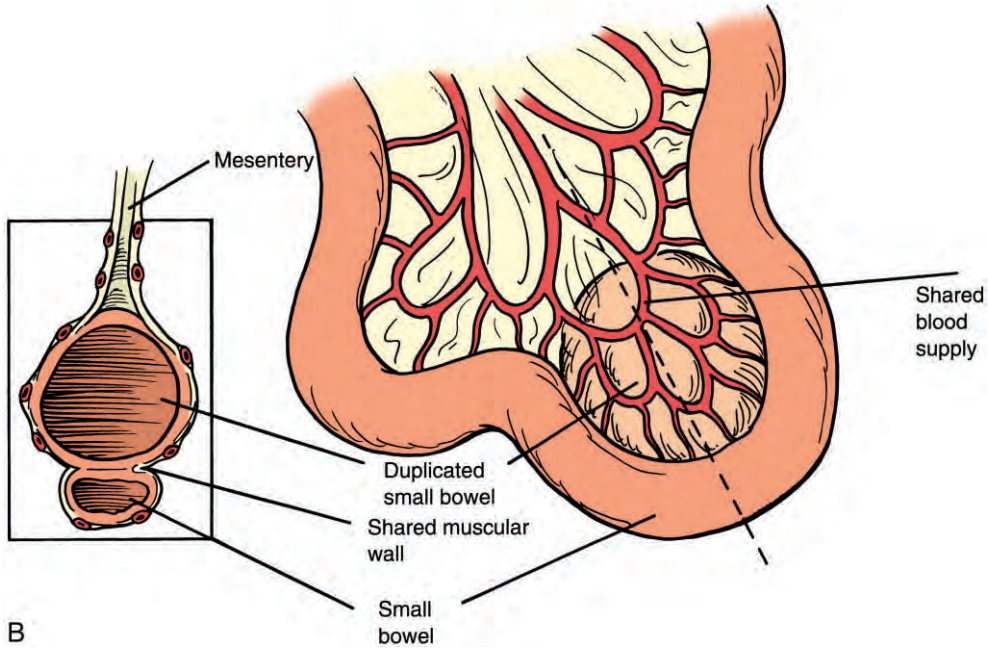

Figure 82–9. **A,** Large cystic duplication of the small intestine. (From Ashcraft KW, Holder TM [eds]: Pediatric Surgery. Philadelphia, WB Saunders, 1999.) **B,** Small bowel duplication in cross section demonstrating the common wall, shared blood supply, and intramesenteric location. enlarging and compressing the adjacent lumen. Tubular duplications of the bowel may likewise cause bowel obstruction. However, bleeding is also a common manifestation because of the high incidence of ectopic gastric mucosa with secondary ulcer formation. Very large mesenteric or omental cysts can be manifested as a palpable mass producing vague abdominal symptoms or pain.

Treatment of duplications of the small intestine depends on the specific findings and circumstances. Cystic duplications of the small intestine usually require resection of the adjacent bowel because of the shared common wall and blood supply. Tubular duplications that are relatively short (under 20 cm) can be resected along with the adjacent intestine. If the tubular duplication is extensive, which would result in major loss of

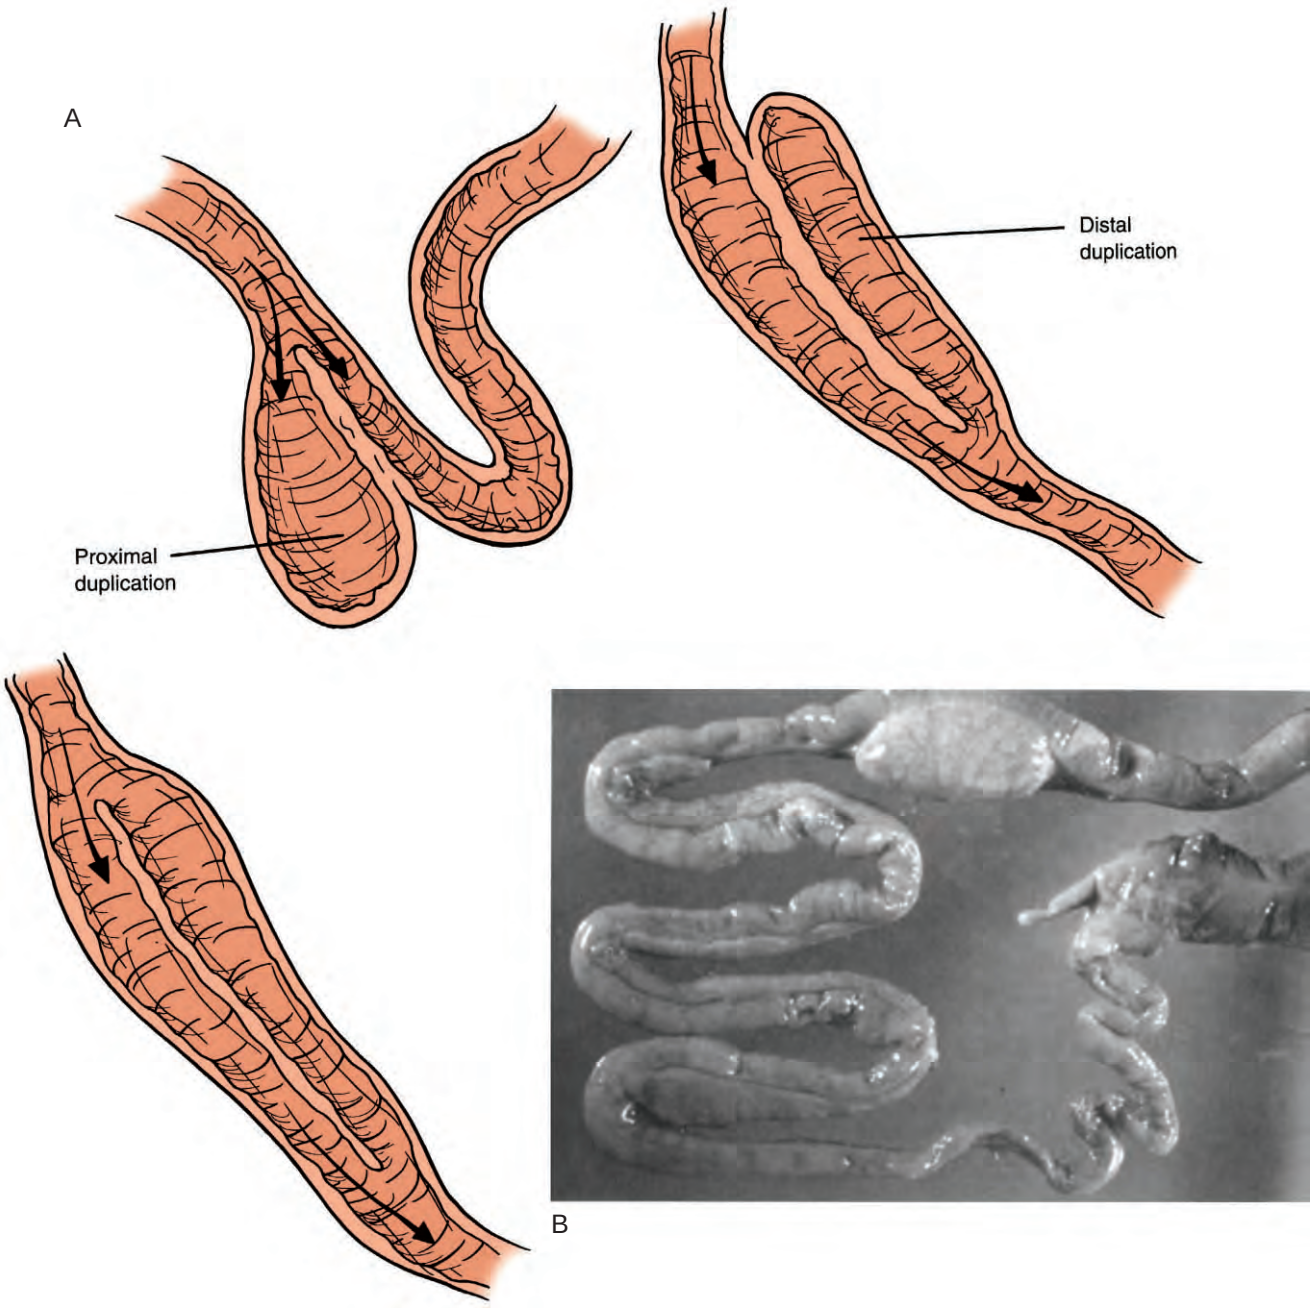

Figure 82–10. **A,** Schematic depiction of the various forms of communicating tubular duplications: duplication communicating proximally and forming a bulbous mass, duplication communicating distally and remaining clinically asymptomatic, and duplication communicating proximally and distally. **B,** Autopsy specimen showing a tubular small bowel duplication involving a portion of the ileum and much of the jejunum. normal small intestine, the duplication can be opened along its longitudinal direction and the mucosa of the duplication excised. Any communication with the adjacent normal small intestine would have to be closed.

Omental cysts can readily be removed by excising the adjacent omentum. Very large cysts can be decompressed by aspiration of fluid and therefore require less of an abdominal incision for removal. Treatment of cysts within the mesentery of the small intestine can be difficult if they are extensive and large. Every effort should be made to carefully dissect a mesenteric cyst to achieve complete removal. However, such dissection may not be safe because of extensive involvement of the blood supply to the small bowel. In these circumstances it may be necessary to leave some of the cyst behind.

The overall outcome of treatment of these cysts should be excellent. Recurrence is likely only in large mesenteric cysts, where complete excision might compromise the blood supply to the normal small intestine, and extensive tubular small intestinal duplications.

MECONIUM SYNDROMES

Intestinal obstruction secondary to meconium impaction occurs frequently. In a newborn infant, entities such as meconium plug syndrome and small left colon syndrome can develop. These conditions involve meconium impaction in the descending and rectosigmoid colon. A water-soluble contrast enema is performed for diagnosis and treatment (Fig. 82–11). Passage of the meconium plug generally resolves the problem, with recurrence being uncommon.

Meconium ileus is a much more complicated entity characterized by meconium impaction beginning at the terminal ileum and extending proximally for various distances (Fig. 82–12). It can involve up to a third to half of the small intestine. Almost all infants with meconium ileus have cystic fibrosis with secondary pancreatic exocrine enzyme deficiency, which leads to thick, tenacious meconium. Cystic fibrosis, an autosomal recessive disease, results in chloride transport abnormalities produced by a defect in chromosome 7. The thickened secretions also affect the biliary tract, pancreas, and most commonly, the respiratory tract. Approximately 10% to 20% of cystic fibrosis patients will have meconium ileus.[38]

Meconium ileus is usually manifested at birth as abdominal distention and bilious vomiting. Plain abdominal radiographs demonstrate dilated bowel loops with a "ground glass" appearance in the right lower quadrant (Fig. 82–13).[39] These infants require resuscitation with intravenous fluids, bowel decompression, and broad-spectrum antibiotics. If there is no evidence of complicated meconium ileus, a water-soluble contrast enema should be performed. This study may be therapeutic as well as diagnostic. If meconium ileus is present, the goal of the study is to reflux the contrast past the obstructing

meconium and free it from adherence to the mucosa. A more hypertonic solution or a mucolytic substance (e.g., 4% Mucomyst) may enhance the effectiveness of the procedure. The success rate is 50%, but it is dependent on the length of bowel impacted with meconium.[40] Failure to relieve the obstruction after a few attempts is an indication for exploratory laparotomy.

A subset of these patients have complicated meconium ileus, which refers to evidence of perforation with free air, a meconium cyst, or atresia secondary to in utero perforation. The findings on the first day of life are indicative of bowel perforation, meconium peritonitis, volvulus, or atresia. Abdominal radiographs may show free air, free fluid, or calcifications in addition to bowel obstruction. A contrast study may be contraindicated in patients with complicated meconium ileus, or it may be performed for diagnosis only. If laparotomy is necessary, the usual approach is to irrigate the obstructing meconium with 4% acetylcysteine solution, which can be performed via a proximal enterotomy. The inspissated meconium may be gently milked out through the enterotomy or into the colon. Only a small subset of patients may require bowel resection and primary anastomosis. It would be unusual, but if the distal part of the bowel cannot be cleared of the obstructing meconium, an ostomy and mucous fistula should be created. The mucous fistula can be used to irrigate the bowel distally. Infants with complicated meconium ileus are managed operatively, with resection of atretic or necrotic bowel and exteriorization enterostomies possibly being required. The most complicated form is a meconium cyst secondary to in utero perforation (Fig. 82–14). In this situation the perforation does not close, and a large cyst that often fills the entire peritoneal cavity can develop. In such circumstances, finding the two ends of the bowel in the setting of generalized inflammation may be difficult.

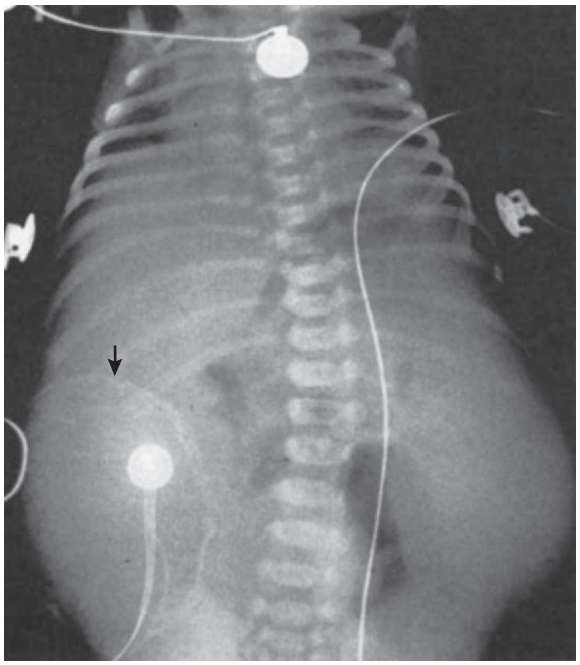

Figure 82–14. Abdominal radiograph of meconium peritonitis with a giant pseudocyst demonstrating calcification *(arrow)* in the cyst wall. (From Ashcraft KW, Holder TM [eds]: Pediatric Surgery. Philadelphia, WB Saunders, 1999.)

Spontaneous prenatal bowel perforation may lead to a condition known as meconium peritonitis. Postnatally, an abdominal radiograph may show scattered areas of calcification in the peritoneal cavity. In many cases the perforation seals and heals in utero and does not result in any postnatal bowel sequelae. The presence of pneumoperitoneum, intestinal obstruction, or clinical deterioration mandates surgical intervention, which usually involves resection of atretic or necrotic bowel with exteriorization.

MECKEL'S DIVERTICULUM AND OTHER OMPHALOMESENTERIC DUCT REMNANTS

The omphalomesenteric, or vitelline, duct is a remnant of the embryonic yolk sac. Remnants of these structures are the most common postnatal anomalies of the gastrointestinal tract (Fig. 82–15). The most frequently occurring residual of the yolk sac is a diverticulum arising from the antimesenteric border of the distal ileum, which has come to be known as *Meckel's diverticulum.* Knowledge of these omphalomesenteric duct remnants is important because complications related to these structures are numerous and may be life-threatening. It is estimated that a remnant of an embryonic yolk sac is present in 1% to 4% of all infants.[41] Although the incidence of omphalomesenteric duct remnants (especially Meckel's diverticulum) is high, the risk for development of symptoms from these anomalies is relatively low. The apparent risk of a complication developing as a result of Meckel's diverticulum is approximately 4%, with 80% of these patients initially being seen at younger than 10 years of age.[42]

Partial or complete failure of involution of the omphalomesenteric duct results in various residual structures, depending on the stage in which this process fails to progress.[41] The portion of the omphalomesenteric duct that does not become atretic will persist and develop along with the remainder of the gastrointestinal tract. Persistent patency of the omphalomesenteric duct can be determined by the 10th week of gestation.

There are many abnormalities that result from remnants of the embryonic yolk sac, and the various abnormalities can generally be categorized as either a patent omphalomesenteric (vitelline) duct, Meckel's diverticulum, omphalomesenteric cyst, omphalomesenteric duct remnants at the umbilicus, omphalomesenteric band, or vitelline blood vessel remnants.

Patent Omphalomesenteric (Vitelline) Duct

This structure represents a persistent connection between the distal ileum and the umbilicus and accounts for approximately 2.5% to 6% of the spectrum of

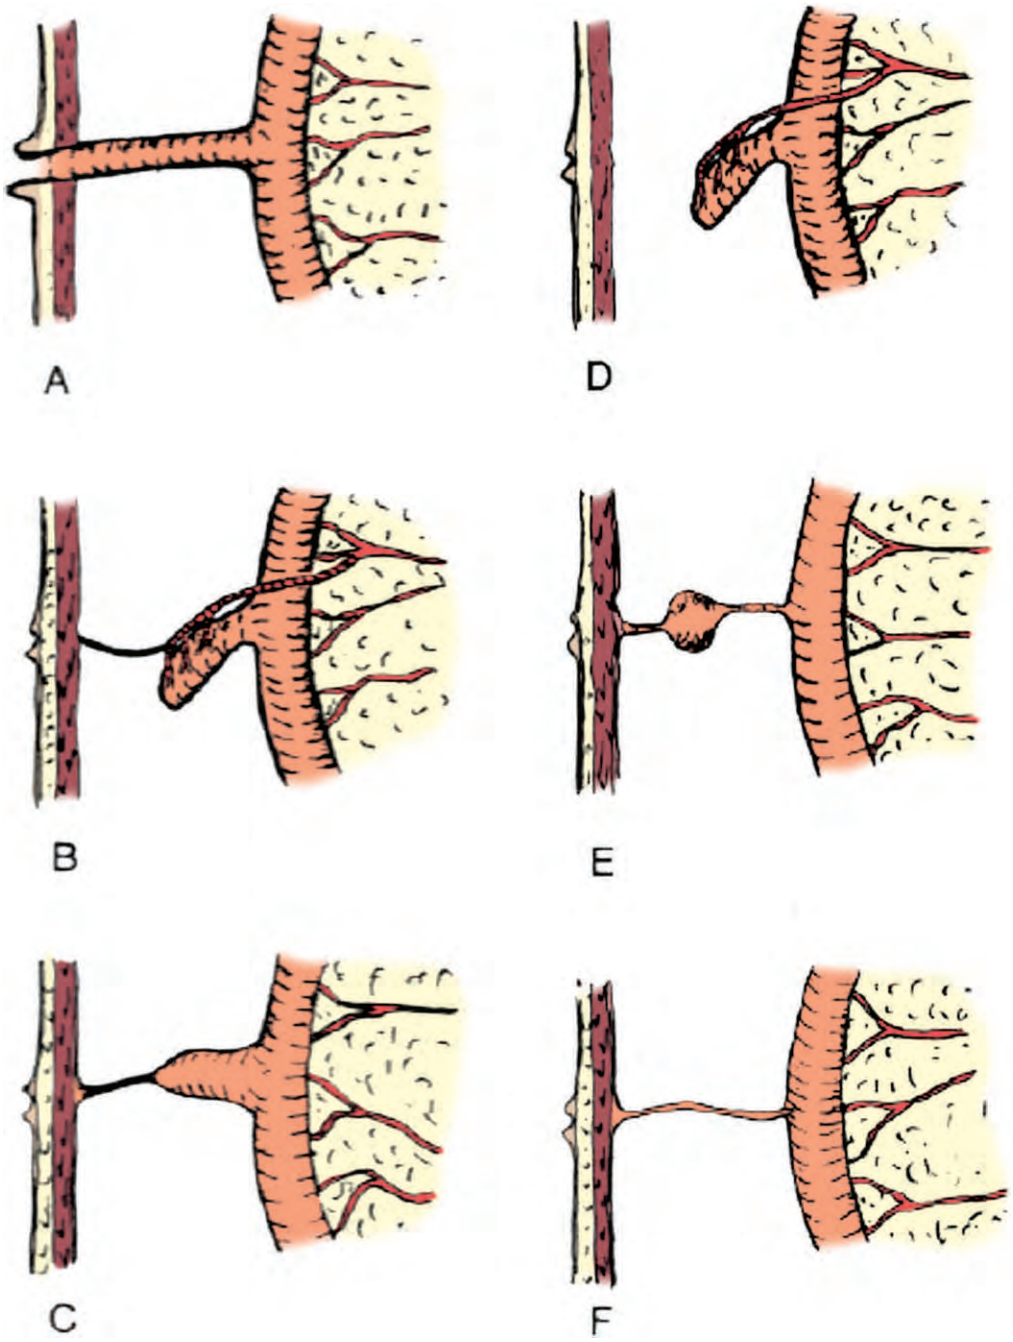

Figure 82–15. Illustrated are some of the more common residual congenital abnormalities that result from the embryonic yolk sac. **A,** Patent omphalomesenteric duct representing a communication from the terminal ileum to the umbilicus. **B,** Meckel's diverticulum with a patent right vitelline artery illustrated as a cord to the undersurface of the umbilicus. **C,** Meckel's diverticulum with a cord connecting the tip of the diverticulum to the undersurface of the umbilicus. (From Wyllie R, Hyams J [eds]: Pediatric Gastrointestinal Disease. Philadelphia, WB Saunders, 1999.)

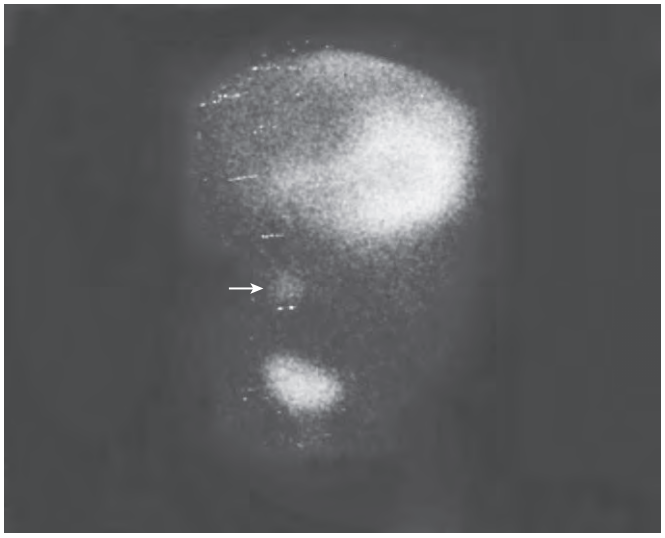

Figure 82–16. Typical appearance of a positive Meckel scan with an area of increased uptake above the area of the bladder in the lower midportion of the abdomen *(arrow)*.

omphalomesenteric duct remnants. Of interest is that males predominate by a ratio of 5 to 1.[43] Ectopic gastric mucosa is identified in approximately a third of patients with a complete fistula. Clinical manifestations of the anomaly usually appear in the first 2 weeks of life. After separation of the umbilical cord, drainage from the umbilicus (which has the appearance of intestinal contents) occurs. Once a diagnosis is made, resection of the entire omphalomesenteric duct is indicated.

Meckel's Diverticulum

This congenital abnormality is the most common of the embryonic yolk sac remnants and represents at least 80% of all of these anomalies. Meckel's diverticulum contains all three layers of the intestinal wall and is typically located within 40 to 50 cm of the ileocecal valve. However, this distance is related to age. The diverticulum originates from the antimesenteric border and is typically 3 to 6 cm in length. Of considerable significance is the presence of ectopic tissue within Meckel's diverticulum. This tissue can include gastric, duodenal, or colonic mucosa, as well as pancreatic tissue.[44] In the majority of patients who become symptomatic as a result of Meckel's diverticulum, the symptoms are caused by this ectopic tissue. A bleeding Meckel's diverticulum is diagnosed with a technetium 99 pertechnetate uptake scan ("Meckel's scan"), which identifies gastric mucosa (Fig. 82–16).

Treatment of Meckel's diverticulum depends on symptoms or anatomic findings at the time of incidental identification. Patients who have symptoms from Meckel's diverticulum such as bleeding or obstruction require resection of the diverticulum. With the presence of gastric mucosa or other ectopic mucosa or tissue, complete resection may require a sleeve resection of the attached small intestine. If the ectopic tissue is contained in the tip of the Meckel diverticulum, amputation at the antimesenteric border of the bowel will result in complete resection. In patients who are asymptomatic or in whom Meckel's diverticulum is incidentally identified at the time of abdominal exploration, removal is indicated if ectopic tissue can be palpated within the diverticulum or if there is a very narrow base, which would be associated with a high potential for obstruction.

Omphalomesenteric Cyst

Involution of the omphalomesenteric duct at the umbilicus and at the ileal end of the duct results in a mucosa-lined cyst. The cyst can be located in the intraperitoneal or preperitoneal space and may become quite large. Most often they are associated with secondary infection, which requires initial drainage and subsequent excision.

Omphalomesenteric Duct Remnants at the Umbilicus

These remnants are uncommon but, when present, are identified within the first 1 to 2 weeks of life. Identification occurs when the umbilical stalk falls off and a polypoid mass covered by mucosa is present at the umbilicus. If an omphalomesenteric duct remnant is identified at the umbilicus, it should be excised.

Omphalomesenteric Band

This abnormality results from involution of the omphalomesenteric duct without disappearance of the tissue. As a result, a solid cord connecting the ileum to the undersurface of the umbilicus is present. This abnormality generally becomes evident as the cause of intestinal obstruction.

Vitelline Blood Vessel Remnants

Occlusion but failure of involution of this structure also results in a fibrous cord within the peritoneal cavity. This remnant becomes clinically evident by producing intestinal obstruction as a result of twisting of a segment of small intestine around the band.

In general, treatment of symptomatic omphalomesenteric duct remnants is resection; however, symptoms from these remnants can be vague and difficult to diagnosis. Radiographic and clinical evidence of bowel obstruction in the absence of previous surgery or other clear-cut etiology suggests the presence of remnants of the omphalomesenteric duct as the cause of the bowel obstruction. If a symptomatic Meckel's diverticulum is identified and there is no evidence of perforation, the current approach is to remove the diverticulum laparoscopically.

NECROTIZING ENTEROCOLITIS

NEC is the most common and the most lethal surgical emergency affecting the gastrointestinal tract in premature infants. This entity was first described in 1967[45] and became more common as neonatal intensive care units

(NICUs) became more advanced in supporting premature infants. NEC produces various degrees of ischemic necrosis affecting the large and small intestine and usually involves the watershed areas of the bowel, namely, the terminal ileum and the cecum. The degree of involvement may be limited to the mucosa, or it can be more extensive and lead to total intestinal necrosis. NEC tends to be patchy and can affect both the large and small intestine in 44% of cases.[46] The most severe form of the disease leading to pan-necrosis develops in 20% of patients. The mortality rate of this disease is 13 per 100,000 live births, with a case fatality rate ranging from 20% to 40%.[47] Although more than 90% of affected patients are born prematurely, the disease can also affect full-term infants. It is estimated that NEC develops in up to 10% of premature infants weighing less than 1500 g.[48] Despite the high incidence of this disease, the pathogenesis remains elusive. Prematurity, low birth weight, and excessive feeding are known risk factors. These infants are usually stressed and may have had poor intestinal perfusion as a result of a number of causes, such as asphyxia, patent ductus arteriosus, exchange transfusion, catheterization of the umbilical artery or vein, anemia, systemic infection, and cardiac anomalies. Premature infants have an immature intestinal mucosal barrier that predisposes them to bacterial translocation.[49] In addition, they have an immature immune system with a reduction in both specific and nonspecific immune defense mechanisms.[50] Premature infants also have impaired gut motility and higher gastric pH, which puts them at risk for bacterial colonization.[51] Moreover, many of them are colonized with nosocomial bacteria from their stay in the NICU. Enteral feeding also provides the substrate for bacterial overgrowth. Formulas increase the risk for development of NEC 20-fold in comparison to breast milk. Formulas lack immunoglobulins, lactoferrin, macrophages or platelet-activating factor, acetylhydrolase, and numerous other peptides that are present in breast milk.[52] However, studies have shown the efficacy of hypocaloric feeding in reducing the risk for NEC in premature infants by "conditioning" the immature gut.[53]

Patients usually have nonspecific signs such as apnea, bradycardia, hemodynamic and temperature instability, hypoglycemia, and lethargy.[54] Initial gastrointestinal signs include abdominal distention, increased gastric residuals, vomiting, and Hemoccult-positive stools, which may become frank blood as the disease progresses. In infants with more advanced disease, signs of peritonitis develop as a result of bowel necrosis and perforation. There may be discoloration, edema, and tenderness of the abdominal wall, and a mass may be palpable. Multiorgan failure with hypotension, poor urinary output, and worsening respiratory status may develop. Metabolic acidosis and falling platelet counts are ominous signs. Abdominal radiographs may demonstrate pneumatosis intestinalis (Fig. 82–17), which is the hallmark of NEC.[55] However, absence of pneumatosis intestinalis does not rule out the diagnosis because it is usually a transient finding.

Other radiologic findings include dilated bowel loops, which may be persistent and fixed, diminished bowel gas, portal venous gas, and ascites. Fixed, dilated bowel loops and ascites may be signs of intestinal necrosis. Abdominal radiographs may show free intraperitoneal air, indicative of bowel perforation (Fig. 82–18). This sign is best demonstrated on a left lateral decubitus radiograph as air between the liver and the lateral abdominal wall.

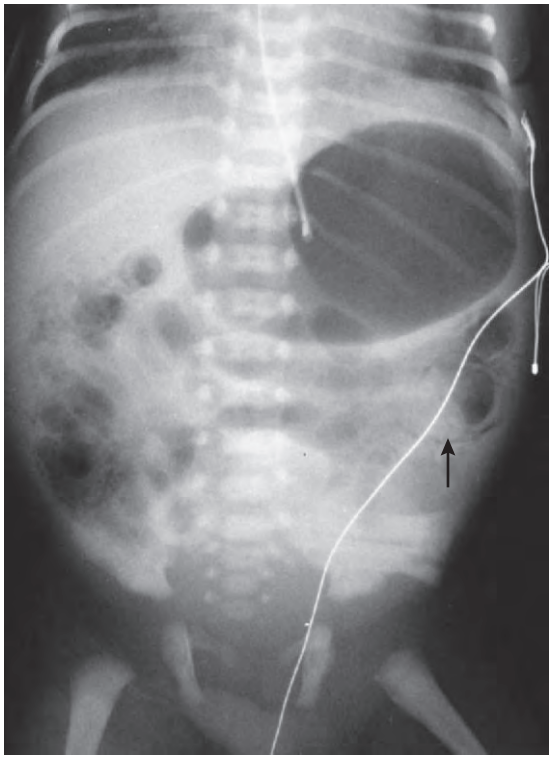

Figure 82–17. Patterns of intestinal pneumatosis. A supine abdominal radiograph in a neonate with necrotizing enterocolitis demonstrates submucosal (right hemiabdomen) and linear intramural pneumatosis *(arrow)*. (Courtesy of A. B. Campbell, MD, St. Christopher's Hospital for Children.)

When NEC is diagnosed or suspected, medical therapy is initiated and includes discontinuation of enteral feeding, placement of an orogastric tube for intestinal decompression, intravenous fluids, and broad-spectrum antibiotics. It is necessary to obtain serial abdominal radiographs, a complete blood count, and platelet counts (typically every 6 to 8 hours) to monitor the infant's status and look for free intra-abdominal air as an indicator for surgical intervention. Sixty percent to 70% of infants improve with medical management. However, infants who fail to improve with maximal medical management or continue to deteriorate with persistent metabolic acidosis, significant thrombocytopenia, and hemodynamic instability may need surgical exploration. Currently, the only absolute indication for surgical intervention is free intra-abdominal air as an indication of bowel perforation. Other "relative" indications are persistent metabolic acidosis, profound thrombocytopenia, a palpable abdominal mass, abdominal wall erythema, and portal venous gas. However, none of these signs, by themselves, are indications for surgery. The objectives of surgery are to resect nonviable bowel while preserving as much viable bowel as possible to avoid

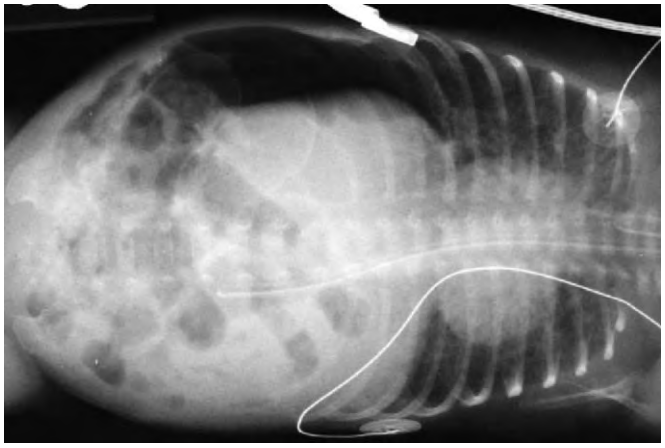

Figure 82–18. Pneumoperitoneum in necrotizing enterocolitis. An abdominal radiograph in the left lateral decubitus position demonstrates a large amount of free intraperitoneal air and extensive intestinal pneumatosis. (Courtesy of A. B. Campbell, MD, St. Christopher's Hospital for Children.)

creating short-bowel syndrome. Exploratory laparotomy is generally performed through a right supraumbilical or infraumbilical transverse incision. The entire gastrointestinal tract is inspected. Infants with the most severe form of the disease have their entire bowel affected (NEC totalis), which may result in an "open and close" procedure. If more than one area of nonviable bowel is present, multiple resections with primary anastomosis and proximal diversion at the point of the first bowel resection may be required. If multiple affected areas are of questionable viability but not frankly necrotic, a proximal diverting enterostomy may be indicated, followed by a "second look" 24 to 48 hours later. A technique described by Lessin et al. to treat multiple bowel involvement involves multiple resections of nonviable segments and lining up the remaining viable segments of the intestine over a feeding tube without anastomosis.[56] Contrast studies have shown that the segments undergo autoanastomosis. This technique avoids multiple stoma-related complications and further loss of intestinal length with closure and may help avoid a reoperation.[56] If only a single bowel segment is affected, this area is resected with the formation of a proximal ostomy and distal mucus fistula. The ostomy is usually brought through the lateral aspect of the incision. Another important technique is placement of peritoneal drains, which was first reported in 1975.[57] Although this technique was originally described as a temporizing procedure for very-low-birth-weight premature infants, subsequent reports have described it as the primary and sole operative intervention.[58,59] With more experience in using this approach, it appears to be more beneficial in infants with pneumoperitoneum who weigh less than 1000 g. It involves placing one or two Penrose drains at the bedside through a small incision in the lower abdominal quadrants. Bowel continuity is evaluated later with contrast studies. Azarow et al. compared the survival rate of neonates with NEC who weighed less than 1000 g and were treated by either laparotomy or percutaneous peritoneal drains. The survival rate in the peritoneal drainage group was 69% as opposed to only 22% in the laparotomy group.[60] Placement of peritoneal drains for increasing ventilatory requirements because of severe abdominal distention in the absence of free peritoneal air offers rapid stabilization. However, the mortality remains high in this group of critically ill patients.[61] A major sequela of NEC is the formation of stenosis or strictures of the small and large bowel. Strictures develop in 29% to 35% of infants after NEC. After recovery from NEC, all infants require a contrast enema or a distal colostogram before stoma take-down. Strictures are resected at the time of reversal of the ostomy. Recurrence of NEC is seen in less than 6% of patients.[62] The mortality associated with NEC has improved because of advances in neonatal and surgical care. It is estimated that 50% of premature infants weighing less than 1000 g and 75% weighing less than 1500 g survive an episode of NEC.[63] The long-term outcome after NEC treated at one tertiary NICU was favorable, with 83% of infants subsequently attending school full-time and only 14.3% suffering from developmental delay.[64]

INTUSSUSCEPTION

Intussusception is a process whereby the intestine telescopes into itself. The telescoping bowel segment is referred to as the intussusceptum. Although it was first described by Paul Barbette of Amsterdam in 1674,[65] it was not until nearly 200 years later that the first successful operation for intussusception (in a toddler) was performed.[66] The incidence of intussusception is highest between 4 and 10 months of age, and 80% to 90% of cases occur between 3 and 36 months.[67] Nearly all intussusceptions in infants and toddlers are idiopathic. That is, there is no clear etiology. In addition, most are ileocolic or ileoileocolic. Upper respiratory tract infections or gastroenteritis (adenovirus and rotavirus have been implicated) have been thought to be contributory to the development of "idiopathic" intussusception.[68] Hypertrophy of Peyer's patches can be seen at surgery, but no single etiologic factor predominates. Approximately 5% to 10% of cases have a true pathologic lead point.[69] The older the toddler, the more likely there will be a lead point.[70] The most common lead point is Meckel's diverticulum. Other lead points include polyps, the appendix, intestinal duplication, foreign bodies, and tumors such as hamartomas associated with Peutz-Jeghers syndrome. Children with Henoch-Schönlein purpura may have intussusception with submucosal hemorrhage acting as a lead point. Patients with cystic fibrosis may be at risk for recurrent intussusception, and these children tend to be older than the usual age at which it occurs.[68]

The typical history is that of sudden, short-duration, cyclic crampy abdominal pain. During these episodes the infant cries inconsolably with the knees drawn up. Between episodes the infant is asymptomatic. After the development of intussusception, lymphatic and venous obstruction of the intussusceptum occurs and leads to congestion (Fig. 82–19). Subsequently, swelling develops

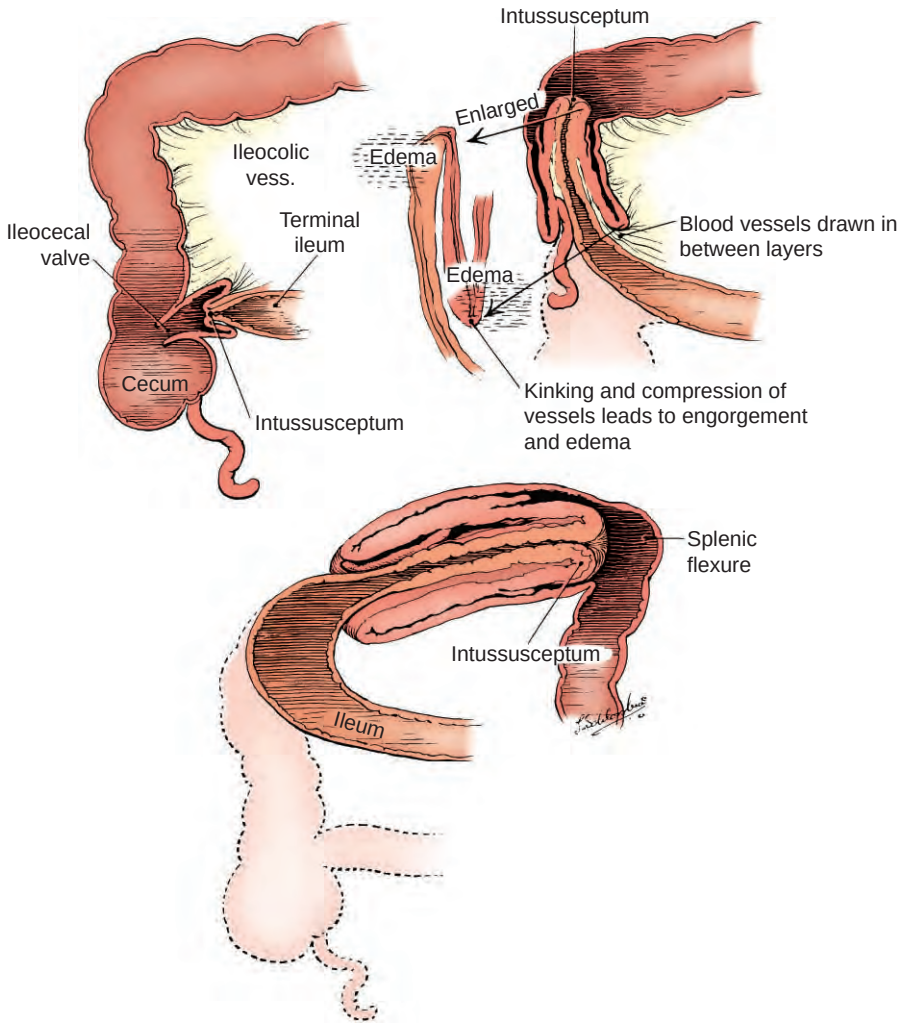

Figure 82–19. Development of an intussusception. Most intussusceptions in infants and children are of the kind shown here. The intussusception begins at or near the ileocecal valve without an obvious local anatomic lesion to cause it. From the first moment there is simultaneous interference with patency of the alimentary canal and with the vascular supply of the intussusceptum. The drawings indicate the manner in which the mesenteric vessels are drawn between the layers of the intussusception and compressed. The slight interference with lymphatic and venous drainage that occurs almost immediately results in edema and an increase in tissue pressure. This further increases resistance to the return of venous blood, the venules and capillaries become enormously engorged, and bloody edema fluid drips into the lumen. The mucosal cells swell into goblet cells and discharge mucus, which after mixing in the lumen with the bloody transudate, forms a "currant jelly" stool. Edema increases until venous inflow is completely obstructed. As arterial blood continues to pump in, tissue pressure rises until it is higher than arterial pressure, and gangrene ensues. The drawings indicate the sharp U-shaped turns of the intestine and mesenteric vessels at either end of the intussusceptum. The outer coat of the intussusceptum (middle layer of the intussusception) is isolated between the two sharp bends and understandably is the first to become gangrenous. Gangrene appears in this coat near the tip of the intussusception and progresses back toward the neck of the intussusceptum. Rarely, the intussuscipiens is damaged. (From Ravitch MM, Welch KJ, Benson CD, et al [eds]: Pediatric Surgery, 3rd ed. Chicago, Year Book, 1979.)

and results in impairment of arterial flow and mucosal necrosis. This produces the classic "currant jelly" stool. On examination the child may show signs of dehydration or lethargy, depending on the length of time that has passed and whether bowel necrosis is present. A sausage-shaped mass may be palpable in the right upper quadrant. The presence of peritoneal signs is ominous and mandates operative intervention. In 60% to 90% of cases, rectal examination demonstrates either occult or gross blood.[71]

Abdominal radiographs may be normal or show a paucity of gas in the colon and dilated small bowel loops (Fig. 82–20). Ultrasonography has been used more frequently to diagnose intussusception. It may show a kidney-shaped mass in the longitudinal view or a target sign in the transverse view (Fig. 82–21). A barium contrast enema was the "gold standard" for diagnosis, and in over 50% of cases, hydrostatic pressure was successful in reducing the intussusception (Fig. 82–22). However, this treatment strategy changed in 1990 as a result of a report

Figure 82–20. Ileocolic intussusception. A scout film for a contrast enema demonstrates a rounded soft tissue mass in the right upper quadrant with central radiolucency along the inferior margin of the liver. This pseudotumor suggests the presence of intussusception. (Courtesy of A. B. Campbell, MD, St. Christopher's Hospital for Children.)

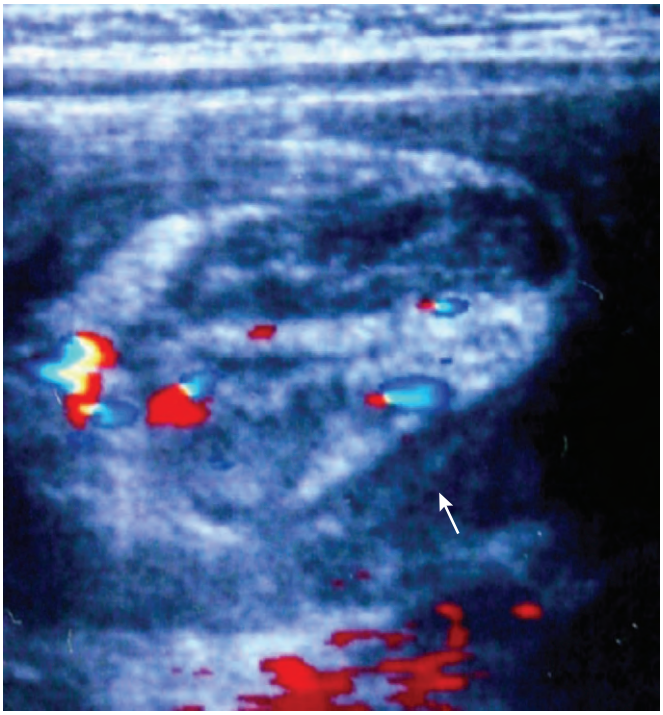

Figure 82–21. Intussusception, color Doppler imaging. A cross-sectional color Doppler ultrasound image of intussusception demonstrates the typical target appearance with compression of an eccentric small bowel segment, a hypoechoic peripheral colon wall *(arrow)*, echogenic mesenteric fat, and incidental mesenteric lymph nodes. Brisk flow is noted within the mesenteric vessels centrally. (Courtesy of A. B. Campbell, MD, St. Christopher's Hospital for Children.)

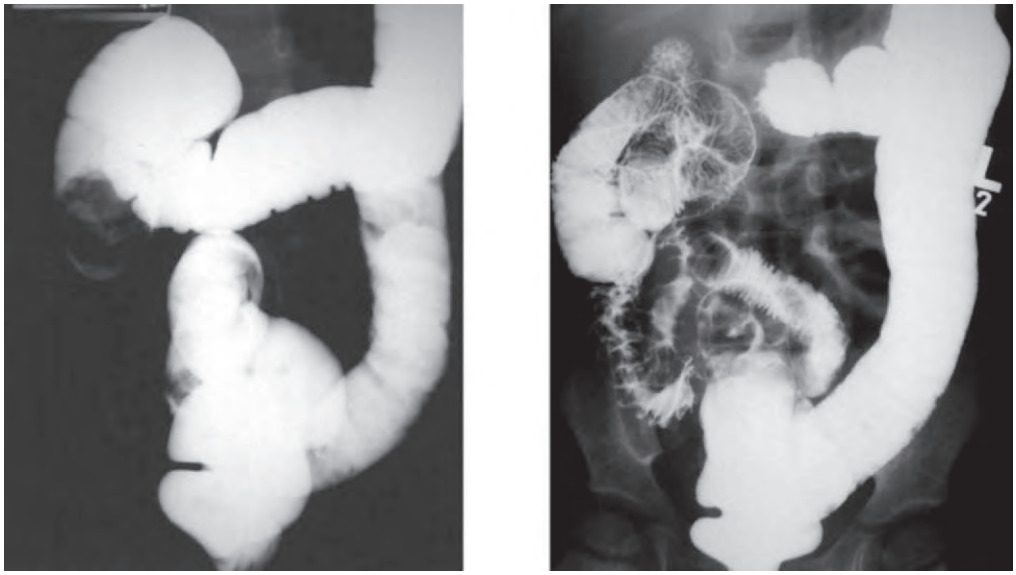

A B

Figure 82–22. Barium enema reduction of intussusception. **A,** A filling defect in the ascending colon is shown. **B,** The intussusception is successfully reduced with reflux of contrast into the small bowel. (Courtesy of A. B. Campbell, MD, St. Christopher's Hospital for Children.)

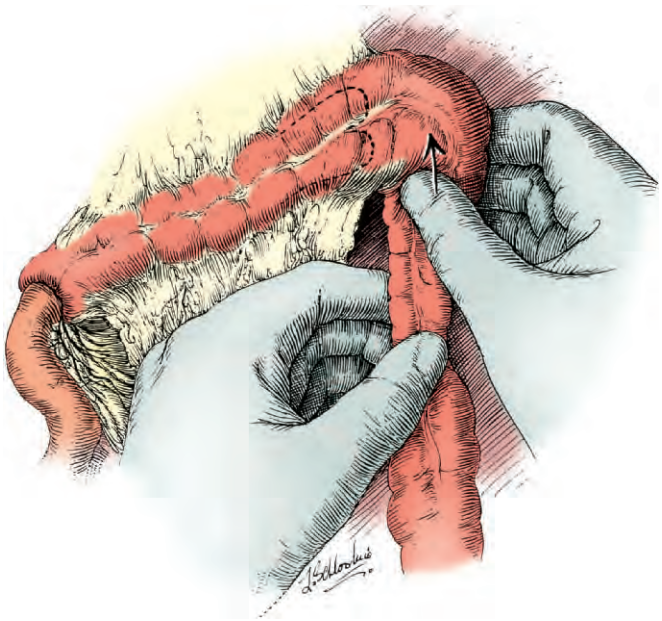

Figure 82–23. Manual reduction of intussusception. If a barium enema fails or intussusception is encountered during laparotomy for intestinal obstruction, manual reduction is required. The intestine is occluded immediately distal to the intussusception with the fingers of one hand and stripped proximally with the fingers of the other. In effect, this maneuver increases intraluminal pressure just as an enema does. The intestine should not be pulled. If reduction is not readily achieved, resection and anastomosis should be performed. (From Ravitch MM, Welch KJ, Benson CD, et al [eds]: Pediatric Surgery, 3rd ed. Chicago, Year Book, 1979.)

from a Chinese group describing air-contrast enema as a diagnostic and therapeutic tool.[72] The intussusception is reduced under fluoroscopic guidance. The patient receives intravenous fluid and antibiotics before the procedure. Successful reduction is confirmed by reflux of air (or barium) into the small bowel. The success rate with air or barium reduction should exceed 70%. Failure of reduction or the presence of peritonitis mandates operative intervention, which can be performed laparoscopically or by a standard approach. If done laparoscopically, reduction is accomplished by gently pulling the intussusceptum from the intussuscipiens. In the open approach an infraumbilical transverse incision is made. The intussusception is reduced by applying gentle pressure retrogradely in a distal-to-proximal direction and milking the intussusceptum out of the intussuscipiens (Fig. 82–23). After operative reduction the bowel is carefully inspected for viability and the presence of a "lead point." The intussuscepted bowel may be congested and edematous. Observation over a 10- to 20-minute period may be necessary to assess viability. If the lead point was Meckel's diverticulum or a polyp, it should be resected. Intussusception may recur in 5% to 10% of cases after successful hydrostatic reduction.[68] In contrast, the reported recurrence rate after operative reduction is 1% to 4%.[68,73] Recurrence is usually managed by hydrostatic reduction. Repeated episodes of intussusception mandate operative intervention to look for a lead point. Bowel perforation is a serious complication that occurs in 0.2% of cases treated by hydrostatic reduction and requires emergency surgery. If there is necrosis of the intussuscepted bowel or operative reduction is impossible, resection is necessary. Usually, an end-to-end anastomosis can be safely performed.

Anatomy and Physiology of the Mesenteric Circulation

Steven B. Goldin ▪ Alexander Rosemurgy

This chapter discusses the anatomy of the mesenteric arterial circulation, including common normal arterial variations.[1] Collateral pathways between the major arterial vessels and their clinical significance are also discussed. Reviewing embryonic developmental anatomy[2] simplifies understanding of the arterial anatomy. Venous anatomy is detailed elsewhere in this text. The intestine serves a variety of functions, including digestion, absorption of fluids and nutrients, secretion of fluids and hormones, and propulsion of enteric contents, and it forms a barrier that contributes to host defense mechanisms. This chapter also concentrates on regulation of mesenteric blood flow. Detailed understanding of the physiologic factors that augment blood flow to and from the intestinal circulation requires a closer look at the arteriolar, capillary, venule, and venous anatomy. For purposes of this discussion, the mesenteric circulation designates blood flow only to the intestinal circulation, and the splanchnic circulation refers to blood flow to any of the gastrointestinal organs or structures within the peritoneal cavity as seen in Figure 83–1.

EMBRYOLOGY

The foregut structures of the digestive tract, including the esophagus, stomach, duodenum, liver, gallbladder, and pancreas, develop when the embryo is approximately 4 weeks old. These structures receive blood flow from the celiac artery, which begins at the proximal ends of the vitelline arteries near the seventh cervical vertebra. With growth of the embryo, the celiac artery migrates caudally to T12. The midgut begins just distal to the entrance of the ampulla of Vater and extends to the proximal two thirds of the transverse colon. The midgut's vascular supply is from the superior mesenteric artery (SMA). The midgut develops from two limbs called the cephalic and caudal limbs. During development of the midgut, there is rapid elongation of these limbs and its mesentery, as well as counterclockwise rotation of approximately 270 degrees around the SMA, as seen in Figure 83–2A. This rotation occurs just after the SMA has given off its duodenal branches. Therefore, the proximal SMA branches to the small bowel originate on the right side of the SMA, whereas distally, branches to the small bowel originate on the left side of the SMA. Likewise, the colonic branches of the SMA, which branch off distally from the SMA, originate from the right side of the SMA, as shown in Figure 83–2B. The hindgut gives rise to the distal third of the transverse colon, extends to the upper part of the anal canal, and terminates in the cloaca. The blood supply to the hindgut is via the inferior mesenteric artery (IMA). The cloaca is divided into an anterior portion, called the primitive urogenital sinus, and a posterior portion, called the anorectal canal, by the urorectal septum, as seen in Figure 83–3. Descent of the urorectal septum to the cloacal membrane results in formation of the perineum, as well as a posterior anal membrane and an anterior urogenital membrane. The anal membrane contacts the anal pit, or proctodeum, which has an ectodermal origin. Therefore, the upper portion of the anal canal has an endodermal origin, whereas the lower portion is of ectodermal origin. Accordingly, the upper portion of the anal canal is supplied by the IMA, with the lower portion being supplied by the systemic circulation.

ANATOMY

The small intestine, or small bowel, extends from the pylorus in the right upper quadrant to the cecum in the right lower quadrant. A large fold of peritoneum that extends from the posterior abdominal wall suspends the small bowel within the peritoneal cavity and prevents significant rotation. This fold of peritoneum is called the mesentery and contains arteries, veins, nerves, lymphatic vessels, lymph nodes, and fat. The small bowel mesentery begins at its base, just to the left of the second lumbar vertebral body, and extends inferiorly and obliquely to

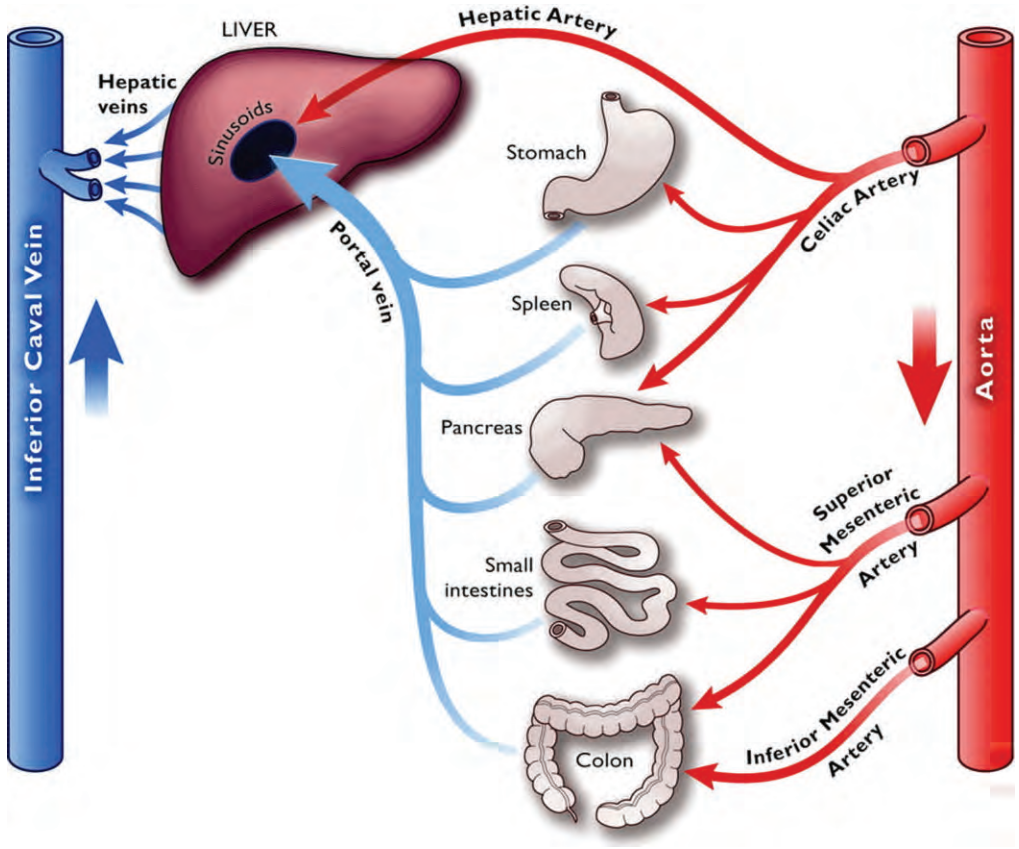

Figure 83–1. Schematic representation of the splanchnic circulation. (From Gelmen S, Mushlin PS: Catecholamine-induced changes in the splanchnic circulation affecting systemic hemodynamics. Anesthesiology 100:434-439, 2004.)

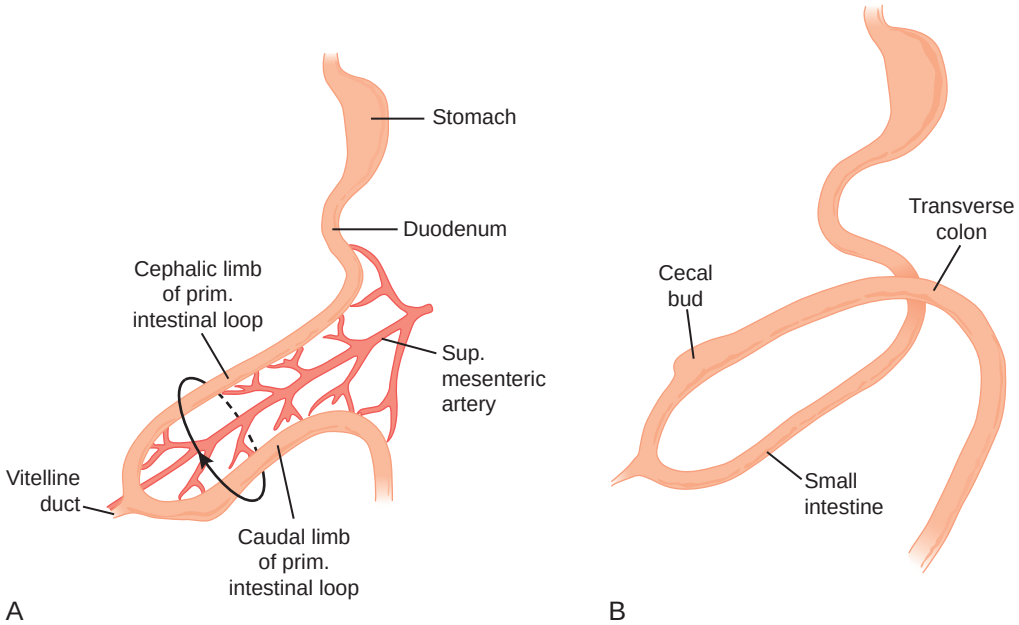

Figure 83–2. **A,** Schematic drawing of the primitive intestinal loop before rotation (lateral view). The superior mesenteric artery forms the axis of the loop. The *arrow* indicates the direction of the counterclockwise rotation. **B,** Similar view as in **A,** but showing the primitive intestinal loop after 180-degree counterclockwise rotation. Note that the transverse colon passes in front of the duodenum. (From Sadler TW: Langman's Medical Embryology, 7th ed. Baltimore, Williams & Wilkins, 1995.)

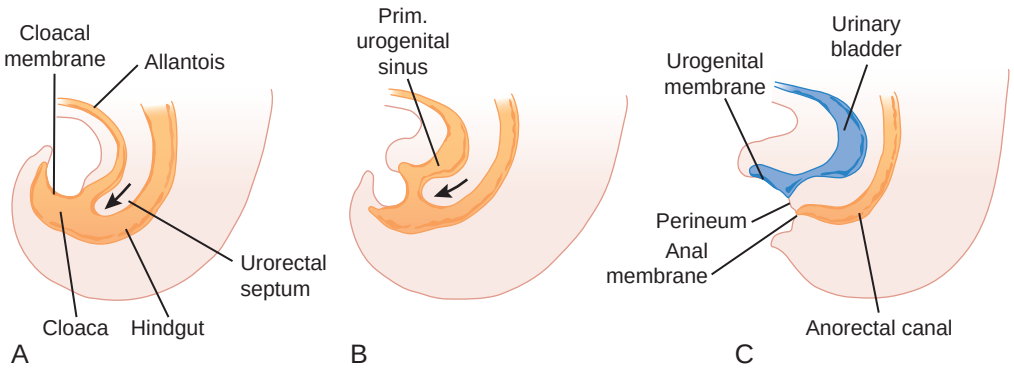

Figure 83–3. **A-C,** Drawings of the cloacal region in embryos at successive stages of development. The *arrows* indicate the route of descent followed by the urorectal septum. Note the anorectal canal and perineum. (From Sadler TW: Langman's Medical Embryology, 7th ed. Baltimore, Williams & Wilkins, 1995.)

the right toward the iliac fossa. The mesentery attaches in a fan-like pattern to the entire length of the small bowel along one side termed the *mesenteric border of the small bowel*. In humans, the total length of the duodenum is approximately 20 cm, and that of the jejunum and ileum is 260 cm. The duodenum begins at the pylorus and extends in a C-loop fashion to the duodenojejunal junction, which is located just to the left of the second lumbar vertebra and is supported by the ligament of Treitz. The jejunum makes up approximately two fifths of the length of the small bowel, with the remaining three fifths constituting the ileum. There is no clear anatomic demarcation between the jejunum and ileum.

The colon, which begins in the right lower quadrant and extends in a question mark pattern throughout the abdominal cavity to reach the rectum, also has mesenteric attachments composed of similar elements. The length of the human colon is approximately 110 cm. The cecum is the first portion of the colon and begins at the ileocecal valve. It is approximately 6.3 to 7.5 cm long and 7.5 cm wide. Like the small bowel, it is completely covered by peritoneum, but it differs from the small intestine by not having a mesentery. The vermiform appendix is attached to the cecum 2.5 cm below the ileocecal valve and may vary in length from 2.5 to 23 cm. The appendix may be located in a variety of locations, including the pelvis and retrocecal area, or it may be directed superiorly and to the left. The appendix is completely covered with peritoneum and has a mesentery, which furnishes its blood supply. The ascending colon is continuous with the cecum and located on the right side of the abdomen. It ascends toward the inferior surface of the liver, where it turns medially to make the hepatic flexure. The ascending colon and hepatic flexure are retroperitoneal structures. The transverse colon begins at the hepatic flexure and crosses the peritoneal cavity. It is an intraperitoneal structure and has a mesentery, which makes its location and relationship to other structures variable. The transverse colon ends at the splenic flexure, which is usually higher than the hepatic flexure. It is also a retroperitoneal structure. The descending colon begins at the distal end of the splenic flexure, where it courses retroperitoneally and inferiorly on the left side of the abdomen until it reaches the left iliac fossa and becomes the sigmoid colon. The sigmoid colon is intraperitoneal and has a mesentery. It is S-shaped, starts in the left iliac fossa, and continues to the rectum. The

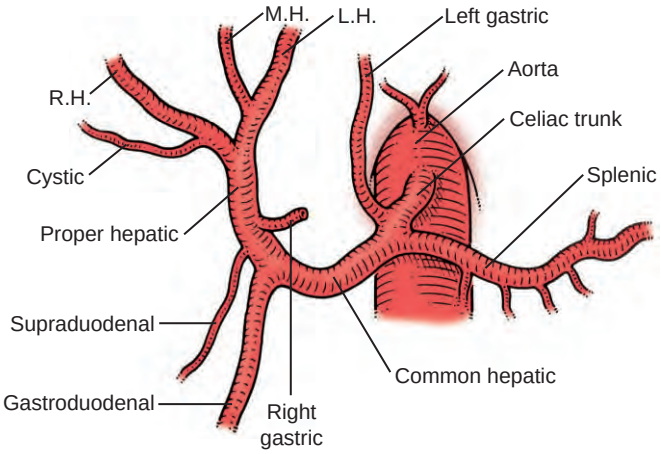

Figure 83–4. Major branches of the celiac trunk. L.H., left hepatic artery; M.H., middle hepatic artery; R.H., right hepatic artery. (From Blumgart LH, Hann LE: Surgery of the liver and biliary tract. In Blumgart LH, Fong Y [eds]: Surgical and Radiologic Anatomy of the Liver and Biliary Tract, 3rd ed. London, WB Saunders, 2000.)

rectum is approximately 15 cm long and begins at the midsacral area. It then follows the curve of the sacrum and coccyx into the pelvic cavity.

Mesenteric attachments, as mentioned, contain all the blood vessels going to the viscera. Clinically understanding the relationship of the vasculature, mesentery, and bowel is extremely important. Resectional strategies are based entirely on the blood supply. The mesentery contains a large number of collateral blood flow pathways, which also have extremely important clinical implications that will be described in subsequent sections.

Celiac Axis

The celiac artery is the largest branch of the abdominal aorta and it supplies the embryologic foregut. It leaves the aorta at a 90-degree angle between T12 and L1 just after the aorta has penetrated the diaphragm. There is considerable variability in both the celiac artery and the SMA, as described later. Classically, the celiac artery trifurcates into the left gastric, splenic, and common hepatic arteries, as seen in Figure 83–4. Multiple

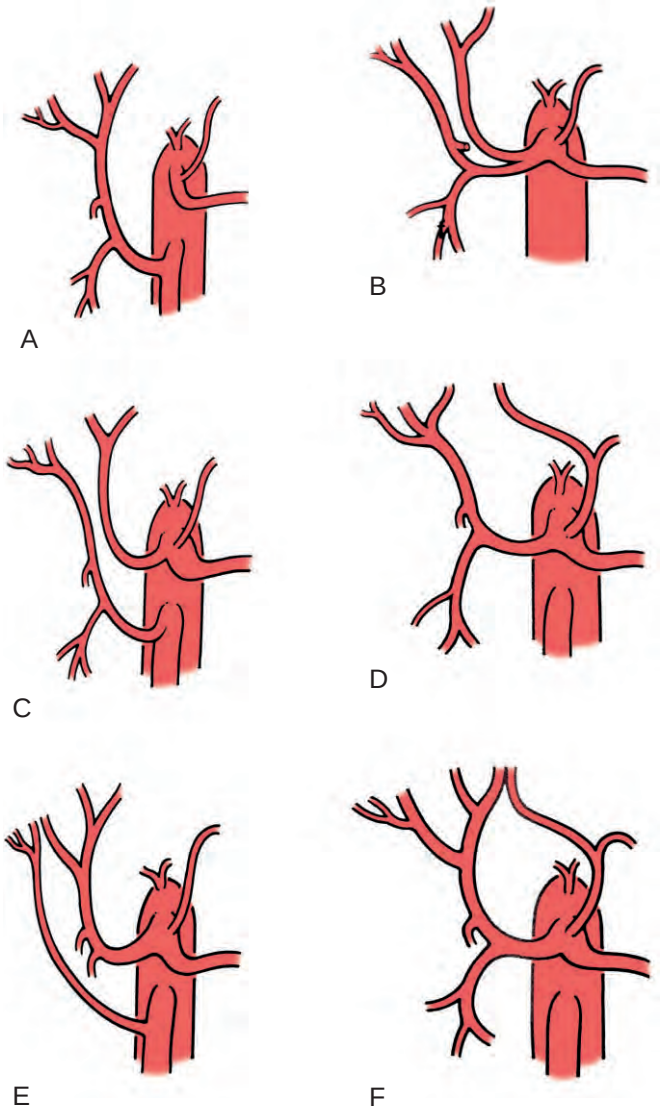

Figure 83–5. Hepatic artery variation. In 25%, the right hepatic artery arises partially or completely from the superior mesenteric as seen in **A, C,** and **E.** A similar proportion of individuals have a variation in the left hepatic artery, with flow arising from the left gastric artery as seen in **D** and **F.** Rarely, the right or left hepatic arteries originate independently from the celiac trunk or a branch after a very short common hepatic artery origin from the celiac as seen in **B** and **C.** The gastroduodenal artery may originate from the right hepatic artery as seen in **B** and **C.** (From Blumgart LH, Hann LE: Surgery of the liver and biliary tract. In Blumgart LH, Fong Y [eds]: Surgical and Radiologic Anatomy of the Liver and Biliary Tract, 3rd ed. London, WB Saunders, 2000.)

anatomic variations of the celiac artery and SMA branches are common and are shown in Figure 83–5. Within the lesser omentum, the left gastric artery first sends branches to supply the distal portion of the esophagus. It then follows a course along the lesser curvature of the stomach and anastomoses with the right gastric artery, which is a branch off the common hepatic artery. The common hepatic artery is also visualized and first gives off a variable number of branches to the pancreas before the branching of the right gastric artery and the gastroduodenal artery. The common hepatic artery then becomes the proper hepatic artery, which subsequently divides into the right and left hepatic arteries supplying the liver. Before dividing, the proper hepatic artery often gives off branches to the duodenum, including a retroduodenal artery that follows the common bile duct. In approximately 75% of individuals, the cystic artery originates from the right hepatic artery. In approximately 20%, the right hepatic artery may not originate from the proper hepatic artery or is lacking. In the majority of these individuals, the blood supply to the right lobe of the liver originates from the SMA and is called a *replaced right hepatic artery.* If both a right hepatic artery and a supply vessel from the SMA are present, the latter vessel is termed a *recurrent* or *accessory right hepatic artery.* The replaced and accessory right hepatic arteries usually run just posterior, inferior, and lateral to the bile duct and can be injured during pancreaticoduodenectomy and other procedures that involve the porta hepatis if care is not taken to assess their presence. Another 20% of individuals will also have an aberrant left hepatic artery. In this case, some of the blood supply to the left lobe of the liver originates from the left gastric artery and runs with the hepatic branch of the vagus nerve through the lesser omentum to the left lobe of the liver. Rarely, the entire arterial supply to the liver originates from the SMA. The right gastric artery, as mentioned, courses on the lesser curvature of the stomach to anastomose with the left gastric artery. The gastroduodenal artery courses posterior to the duodenum and usually divides into the superior pancreaticoduodenal and right gastroepiploic arteries. The superior pancreaticoduodenal artery divides into duodenal and pancreatic branches. The duodenal branch courses between the pancreas and duodenum anteriorly and continues caudally to anastomose with a branch of the inferior pancreaticoduodenal artery. The superior pancreaticoduodenal artery runs on the posterior surface of the head of the pancreas. The right gastroepiploic artery runs along the greater curvature of the stomach in the greater omentum and eventually communicates with the left gastroepiploic artery. The last branch of the celiac artery is the splenic artery. It courses toward the spleen and lies on the cephalad boarder of the pancreas, which it also supplies. Just before reaching the spleen, the splenic artery gives off multiple short gastric branches to supply the stomach, as well as the left gastroepiploic artery, which courses along the greater curvature of the stomach inferiorly to anastomose with the right gastroepiploic artery.

Superior Mesenteric Artery

The SMA supplies the entire embryologic midgut and is the second largest intra-abdominal branch of the aorta. It branches off the aorta 0.5 to 1.5 cm caudal to the celiac artery. In approximately 1% of individuals, the SMA and celiac arteries arise from a common trunk. The SMA and celiac vessels may also communicate by the artery of Buhler if this embryologic remnant has not been

obliterated. The SMA leaves the aorta at a 20- to 30-degree angle posterior to the body of the pancreas at L1. The artery then passes inferiorly and just medial and anterior to a small portion of the uncinate process of the pancreas, where it gives off its first branch, the inferior pancreaticoduodenal artery, as seen in Figure 83–6. This vessel usually arises on the right side because of a relative lack of rotation of this part of the vessel during development. The artery then passes anterior to the third portion of the duodenum, where it divides into anterior and posterior branches that anastomose with pancreaticoduodenal branches of the superior pancreaticoduodenal artery previously described. After passing the duodenum, the SMA enters the root of the mesentery. Other major SMA branches seen in the majority of patients include multiple jejunal and ileal branches and the ileocolic, right colic, and middle colic vessels. There are approximately 12 to 20 jejunal and ileal branches. They run in the mesentery and form a series of arcades before reaching the intestines. The mesentery is longer in the ileum, and there are more arcades in this area. The last ileal artery also forms arcades with the branch supplying the cecum and thus forms a collateral circulation with the ileocolic artery. The ileocolic artery often has a common takeoff with the right colic artery and sends branches to the ascending colon and the ileum. The branch to the ileum supplies the cecum and appendix, with the appendiceal artery usually passing posterior to the ileum and entering the mesoappendix, or the mesentery of the appendix. The ascending branches of the ileocolic artery join the right colic artery, which again divides into ascending and descending branches that anastomose with the ileocolic vessels as mentioned and the middle colic artery. The middle colic artery is usually the second branch of the SMA and supplies the transverse colon. It forms collateral anastomoses to the right and left colic arteries. The right colic artery, as mentioned, is a branch of the SMA, but the left colic branches are derived from the IMA. The middle colic artery arises as a common right-middle colic vessel in approximately 50% of people. In approximately 40%, the right colic comes directly off the SMA. The ileocolic artery may originate directly from the SMA or arise as a common vessel with the right colic artery.

Inferior Mesenteric Artery

The IMA, like the celiac artery and SMA, arises from the anterior surface of the aorta; it is located approximately 3.8 cm proximal to the bifurcation of the aorta into the common iliac arteries at L3. The IMA supplies the embryologic hindgut. It courses approximately 3.5 cm before branching and is approximately 0.5 cm in diameter. It supplies the distal third of the transverse colon, the splenic flexure, the descending colon, the sigmoid colon, and the proximal part of the rectum. Its branches include the left colic, three or four vessels to the sigmoid colon, and the superior rectal vessels. The left colic artery branches ascend on the descending colon and anastomose with branches of the middle colic artery from the SMA at the splenic flexure. The sigmoidal branches form arcades that anastomose with the left colic artery and the superior rectal artery. The superior rectal artery supplies blood to the wall of the upper two thirds of the rectum and to the mucosa of the lower third of the rectum.

Celiac Axis–Superior Mesenteric Arterial Communications/Collaterals

Approximately 20% of individuals will have greater than 50% stenosis of the celiac artery at the time of death.[3] The majority of these patients are asymptomatic[4] because of the presence of rich collateral vessels from the SMA. The network of collaterals between the celiac artery, SMA, and IMA is demonstrated in Figure 83–7. The most common collateral pathways surrounding the duodenum and pancreas are shown in Figure 83–6 and involve the pancreaticoduodenal vessels and the dorsal pancreatic artery.[5] The pancreaticoduodenal arcades course anterior and posterior through the head of the pancreas, which they supply along with the duodenum.[6,7] Both the anterior and the posterior pancreaticoduodenal arcades are fed by the gastroduodenal artery from the cephalad direction. These arcades communicate with the SMA via separate inferior pancreaticoduodenal arteries from the

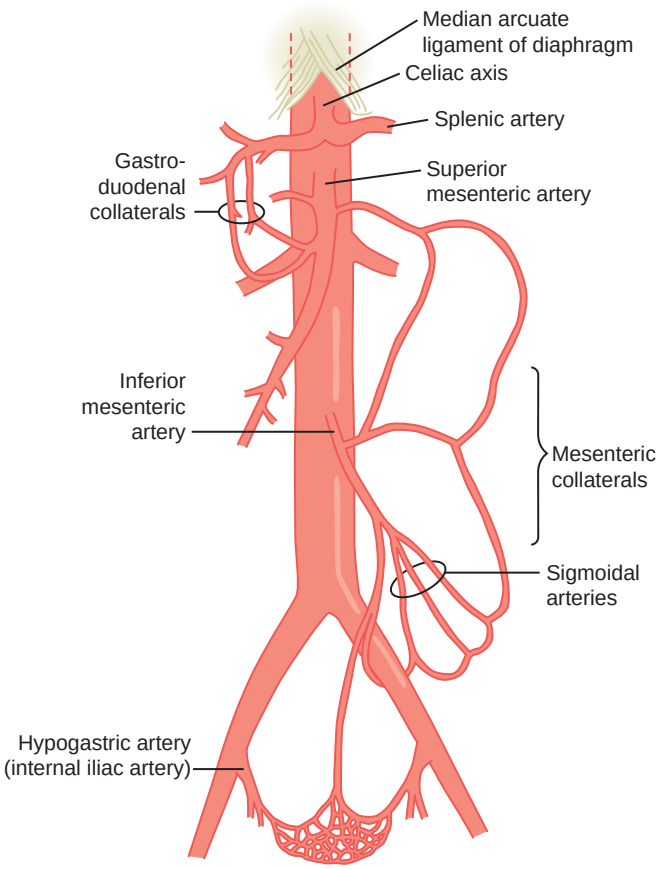

Figure 83–7. Schematic depiction of the major visceral vessels and collateral pathways. (Adapted from Hanson KJ: Mesenteric ischemia syndromes. In Dean RH, Yao JST, Brewster DC [eds]: Current Diagnosis and Treatment in Vascular Surgery. Englewood Cliffs, NJ, Appleton & Lange/ Prentice Hall, 1995, p 264.)

SMA. The dorsal pancreatic artery may arise from a variety of sites, including the splenic artery (39%), the right hepatic artery (12%), the SMA (14%), the celiac artery (22%), or another vessel (13%).[8] This artery has numerous connections between the celiac artery and SMA. The dorsal pancreatic artery also divides into two right and one left branch, with one of the right branches joining the pancreaticoduodenal arcades. The other right branch supplies the uncinate process of the pancreas. The left branch becomes the transverse pancreatic artery, which communicates with caudal pancreatic vessels supplied by the splenic artery. A fourth branch of the dorsal pancreatic artery runs below the inferior border of the pancreas and communicates with the SMA or with branches from the SMA. The collaterals that form may be extensive and a variety of unusual pathways may exist in light of the large variety of hepatic arterial anatomic variants that exist.[5]

Superior Mesenteric–Inferior Mesenteric Arterial Communications

As for the celiac axis, it is not uncommon for the SMA (30%) and IMA (30%) to be stenotic at the time of death.[3,9] Collateral circulation therefore plays a large role in maintaining visceral health. Besides the communicating arcades just described for these vessels, there are a variety of other important vascular communications between the SMA and IMA. The marginal artery of Drummond is located peripherally in the mesentery of the colon. It is usually a continuous arterial pathway along the colon. An anastomosis between the middle and left colic arteries is present in 95% of people and occurs at the splenic flexure of the colon. The location of these anastomoses is designated Griffiths' point. This artery may also be lacking in the proximal portion of the descending colon just beyond the splenic flexure in 5%, in the sigmoid colon in 20%, and at the rectosigmoid junction in an even larger number. Likewise, there is a critical point of Sudeck that occurs between the last sigmoidal branch and the superior rectal artery. When undertaking colonic resection, it is important to ensure adequate blood supply to both ends of the bowel, and rectal resections should include a portion of the sigmoid colon taken above this potential critical point to ensure adequate vascular supply at the anastomosis. Other important vascular communications include the meandering mesenteric artery (MMA), which is its preferred name. The MMA is present in approximately two thirds of the population. It has also been called the central anastomotic artery of the colon, the accessory middle colic artery, the mesomesenteric artery, the middle-left colic collateral, the arch of Riolan, the arch of Treves, and the artery of Drummond (not the marginal artery of Drummond). The MMA is a communication between a branch leaving the SMA just proximal to the middle colic artery and a branch of the ascending left colic artery.

Inferior Mesenteric–Hypogastric Communications

The rectum receives three main sources of blood flow. The superior rectal arteries arise from the IMA and have been described. The two other vessels are the middle and inferior rectal vessels, as seen in Figure 83–8. The superior rectal artery is largely responsible for supplying the upper two thirds of the rectum, but its branches course submucosally and anastomose with branches from the inferior rectal artery in the anal columns. The middle rectal arteries are branches of the internal iliac arteries and supply the muscular layer of the lower third of the rectum. The inferior rectal arteries are branches of the internal pudendal arteries and supply the lower end of the anal canal, where they anastomose with the superior rectal vessels. The mesenteric circulation is therefore in communication with the systemic circulation via these vessels, which can provide a route of collateral circulation.

Rare Communicating Vessels

Occasionally, other collateral pathways also play significant roles. The splenic artery may supply a branch to the left colic artery, and the iliolumbar branches and superior and inferior epigastric vessels may provide important collaterals via the circumflex iliac and femoral arteries. Parietovisceral communications may also exist.

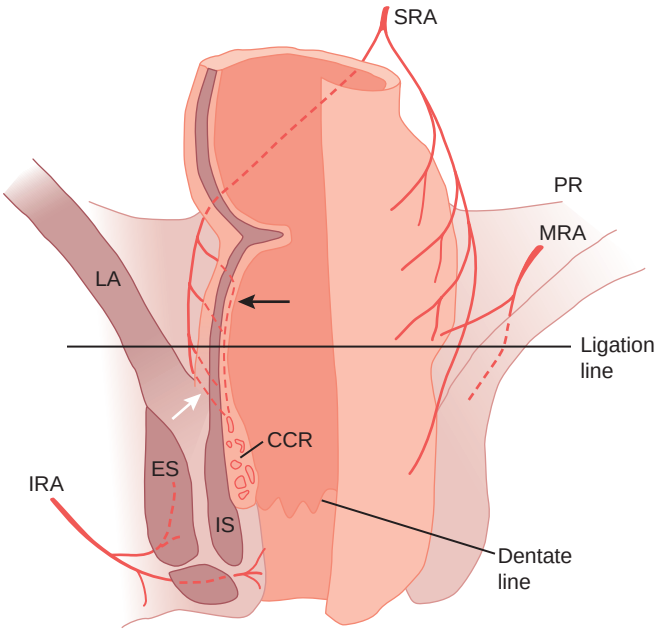

Figure 83–8. Schematic illustration of the rectum and anal canal. The rectal wall has been removed on the right side to demonstrate the transmural course of the branches of the superior rectal artery (SRA). The middle rectal artery (MRA), inferior rectal artery (IRA), corpus cavernosum recti (CCR), levator ani muscle (LA), internal sphincter muscle (IS), external sphincter muscle (ES), and peritoneal reflection (PR) are shown. The *black arrow* indicates longitudinal submucosal branches; the *white arrow* indicates transmural "piercing" branches of the SRA. (From Aigner F, Bodner G, Conrad F, et al: The superior rectal artery and its branching pattern with regard to its clinical influence on ligation techniques for internal hemorrhoids. Am J Surg 187:102-108, 2004.)

CLINICAL CORRELATIONS

Understanding the mesenteric collateral circulation is fundamental to comprehending a variety of disease processes and the compensatory issues that occur in individuals. Chronic blockage of any single mesenteric vessel is usually inconsequential if the collateral pathways are functional. Blockage of the celiac artery usually results in blood flow being routed through the SMA via the pancreaticoduodenal arcades and the dorsal pancreatic vessels that communicate with the gastroduodenal and left gastroepiploic arteries to supply the liver, stomach, pancreas, duodenum, and spleen. Likewise, blockage of the SMA will usually result in blood being routed via the same vessels, as well as the MMA and IMA, to supply the small bowel and right colon. Blockage of the IMA is usually compensated for by blood flow through the MMA, marginal artery of Drummond, and collateral vessels from the inferior and superior rectal arteries.

Acutely, the hypogastric or internal iliac arterial collateral circulation plays an insignificant role. Critical ischemia from acute occlusion can result from single-vessel disease in the absence of adequate collateral circulation or when multiple vessels are involved. The individual is also much more apt to compensate appropriately when the blood flow disturbance occurs slowly or chronically than when blood flow through a major mesenteric vessel is abruptly or acutely stopped. Likewise, it is important for an operating surgeon to be cognizant of the locations of the anastomosing systems. As mentioned, these communicating systems may be lacking and compounded by disease processes in the native vessels. Segmental colectomy may interrupt critical anastomotic networks between the SMA and IMA and result in acute ischemia in patients with severe mesenteric occlusive disease. Similarly, a Whipple operation in a patient with chronic celiac occlusion can cause hepatic ischemia by interrupting collateral arterial flow from the SMA through the pancreaticoduodenal arcades.

The mesenteric artery most frequently occluded by chronic vascular disease is the IMA. Abdominal aortic aneurysm repair usually results in sacrifice of the IMA. Understanding the collateral circulation is imperative to prevent the development of ischemic colitis in these patients. Likewise, if the SMA is severely diseased and the midgut is receiving a large proportion of blood from the MMA, sacrificing this vessel during aneurysm repair can result in infarction of the small bowel and right colon.

PHYSIOLOGY OF THE MESENTERIC CIRCULATION

The major arterial vessels to the splanchnic system include the celiac axis, SMA, and IMA. In the resting or unfed state, these vessels receive approximately 20% to 25% of cardiac output.[10,11] Approximately 25% of the splanchnic circulation flows directly to the liver, with the remaining 75% of blood flow reaching the liver via the portal system. The splanchnic circulation contains approximately a third of the total blood volume, which makes it the circulatory system's largest reservoir. Branches of the celiac artery, SMA, and IMA penetrate the bowel wall and continue to divide into smaller vessels that result in a vascular plexus within the submucosa.[12] At rest, approximately 70% to 80% of the blood flow is distributed to the mucosa, 15% to 25% is directed to the muscular and serosal layers, and the remaining 5% is distributed to the submucosal layer.[13,14] Sixty percent of the blood flow to the mucosa supplies the epithelial cells in the terminal villi, with the remaining 40% supplying the crypts and goblet cells.[13]

Arterioles are arteries approximately 25 μm in diameter. They are the main resistance vessels to the intestine and are composed of three layers, including an outer tunica adventitia, the tunica media, and an inner tunica intima. The adventitia contains nerve cells that are capable of augmenting the tone of the media, which is composed of a thick layer of smooth muscle. This muscle responds to a variety of neurohumoral stimulatory signals, as described later in this chapter. The intima contains endothelial cells.

Arterioles continue to divide, and at approximately the third-order division they become vessels that supply the tips of the mucosal villi and feed a capillary system.

The capillaries, or exchange vessels, allow for the transfer of particles less than 3 nm in size, such as fluid, electrolytes, nutrients, and oxygen, between cells and the bloodstream. A valve-like mechanism located between arterioles and capillaries controls the entry of blood into capillaries. These valves control blood flow into nutrient beds where exchange takes place, but they have no significant effect on vascular resistance. These valves are, however, responsible for physiologic shunting whereby blood flow is redistributed between nutrient beds. The capillaries coalesce to form venules located in the center of each villus and course along the arterial pathways in reverse.

Venules and veins serve as capacitance vessels and contain the majority of blood in the mesenteric circulation. The small bowel venous system contains approximately 300 to 400 ml of blood that can be readily diverted into the systemic circulation. The walls of capacitance vessels are much thinner than the walls of resistance vessels. These walls, however, do contain smooth muscle, which can significantly affect vessel tone and blood volume within these vessels.

Resistance vessels (arterioles) and capacitance vessels (venules) have different sensitivities to various stimuli, including sympathetic, baroreceptor, and chemoreceptor stimulation.[15-17] These vessels are also innervated by entirely separate sympathetic neurons, which allows for differential control.[18] An increase in venous sympathetic activity results in increased tone within this system and the shifting of a large quantity of blood from the mesenteric circulation to the general circulation. This increased venous tone is also reflected on the capillary bed and results in increased hydrostatic pressure causing an influx of fluid from the capillaries into the bowel, which may be manifested as bowel wall edema.

CONTROL MECHANISMS

Multiple control mechanisms of splanchnic blood flow exist, with some degree of interdependency between them. Control mechanisms may be either extrinsic or intrinsic. Extrinsic mechanisms are systemic, whereas intrinsic mechanism function locally. Both mechanisms affect mesenteric blood flow by altering arteriolar smooth muscle vascular tone.[19]

Extrinsic Control of Splanchnic Blood Flow

Extrinsic control begins with hemodynamic parameters, including cardiac output, blood pressure, and blood volume. Inadequate perfusion results in reduction of blood flow to the intestine. Extrinsic mechanisms may also be neuronal, humoral, or combinations of both. Neuronal control mechanisms include the autonomic reflexes. The intestine is directly innervated by both the sympathetic and parasympathetic nervous systems. Stimulation of the sympathetic and parasympathetic nervous systems results in vasoconstriction and vasodilatation, respectively. Sympathetic activity is the most important single determinant of intestinal blood flow and consists of both adrenergic fibers and nonadrenergic, noncholinergic fibers that result in vasoconstriction and vasodilatation, respectively. These fibers originate in the brainstem or medulla. Afferent fibers also arise in the intestine and regulate blood flow by releasing neurohumoral substances. These substances are released by a variety of stimuli, including heat, ischemia, and hypoxia. These fibers also connect to the medulla via the vagus nerve and provide feedback to the sympathetic nervous system.[20]

The sympathetic nervous system tonically innervates small arteries, submucosal arterioles, and the myenteric and submucosal plexuses in the small intestine. Norepinephrine, adenosine triphosphate, and neuropeptide Y are the neurotransmitters released from synaptic vesicles in these nerves. Activation of nicotinic or muscarinic receptors by various drugs augments or diminishes the release of norepinephrine.

Functionally, the parasympathetic nervous system does not play a significant role in augmenting blood flow, although three types of parasympathetic nerves exist and travel with the vagus nerves. The parasympathetic nervous system's main role involves intestinal motility. The neurotransmitter in all three parasympathetic pathways is acetylcholine,[21] which does causes vasodilation. The receptors are located on the endothelium, and activation of these receptors results in the release of nitric oxide from the endothelium. Nitric oxide then diffuses to the vascular smooth muscle, where it results in vasodilation. Vasoactive intestinal polypeptide (VIP) may also play a role as a second messenger to acetylcholine.

Intrinsic Control of Splanchnic Blood Flow

Intrinsic regulation involves the intramural nervous system, endothelial signal transduction, and paracrine secretion of vasoactive substances. The response depends on the receptor status of the tissue in the region of the vasoactive material. Mucosal perfusion is largely regulated by products of the endothelium, mainly the vasodilators prostaglandin I_2 and nitric oxide and the vasoconstrictor endothelin. The intrinsic sympathetic tone is mediated by norepinephrine.[22] The resultant blood flow is determined by contributions from the aforementioned factors.

Intrinsic control involves both metabolic and myogenic mechanisms. Metabolic control links the available blood supply to the nutritional needs of the tissue. Cellular by-products and oxygen depletion result in vasodilation and an increase in tissue perfusion. Myogenic control mechanisms are related to transmural pressure. Increased vascular transmural pressure results in diminished blood flow because of increased vascular resistance and arteriolar vasoconstriction, whereas decreased vascular transmural pressure results in increased blood flow because of diminished vascular resistance and arteriolar vasodilation. The metabolic and myogenic control mechanisms therefore exist to ensure autoregulation of blood flow to the intestine, which remains constant between perfusion pressures of 30 and 100 mm Hg.

Direct intraluminal contact of a variety of agents and intramural neurotransmitters (Box 83–1) also affects

Box 83–1 Agents That Alter or Possibly Alter Mesenteric Blood Flow*

Vasoconstriction

Increased sympathetic tone (adrenergic), decreased parasympathetic tone (cholinergic), catecholamines (except in liver and muscle), angiotensin I, II, and III, antidiuretic hormones, calcium, dopamine (high dose), endothelin-1, epinephrine, leukotrienes, motilin, neuromedin U, neuropeptide Y, norepinephrine (high dose), oxytocin, peptide YY, vasopressin, phenylephrine, potassium, prostaglandin B_2, D, F_1, $F_{2\alpha}$, H_2, serotonin (high dose), somatostatin, thromboxane A_2, vasopressin, methoxamine, metaraminol, propranolol, digoxin, ergotamine, platelet-activating factor, increased P_{O_2}, decreased P_{CO_2}, increased pH, decreased metabolites (K^+, lactate, adenosine, etc.)

Vasodilation

Decreased sympathetic tone, increased parasympathetic tone, acetylcholine, adenosine, adenosine diphosphate, adenosine triphosphate, bradykinin, calcitonin gene–related peptide, carbon dioxide, cholecystokinin, dopamine (low dose), gastric inhibitory peptide, gastrin, glucagon, glucocorticoids, glucose-dependent insulinotropic peptide, histamine, hydrogen, insulin, kallikrein, magnesium, neuromedin N, neurotensin, endothelium-derived relaxing factor, nitric oxide, endothelium-derived hyperpolarizing factor, nitroglycerin, norepinephrine (low dose), catecholamines (only in liver and muscle), opiates (enkephalins), pituitary adenylate cyclase–activating polypeptide, prostacyclin, prostaglandin E and I, secretin, serotonin (low dose), substance P, thrombin, thyrotropin-releasing hormone, uridine triphosphate, vasoactive intestinal polypeptide, xenin, adrenomedullin, xenopsin, phentolamine, isoproterenol, pentagastrin, tolazoline (Priscoline), papaverine, nitroprusside, caffeine, sodium nitrite, aminophylline, decreased P_{O_2}, increased P_{CO_2}, decreased pH, increased metabolites

Unknown or Variable Effects

Bombesin, chromogranin A, chromogranin B, cryptins, cholecystokinin, duodenal cholecystokinin-releasing peptide, duodenal secretin-releasing peptide, enteroglucagon, galanin, gastrin-releasing polypeptide, glucagon, glucagon-like peptides, guanylin, incretins, monitor peptides, neuromedin B, neuromedin C, pancreastatin, pancreatic polypeptide, sorbin, trefoil peptides

*Vasoconstriction diminishes blood flow, whereas vasodilation increases blood flow.

mucosal blood flow.[23,24] The actual role that these agents have in vivo in the local regulation of blood flow is largely uncertain. Increased blood flow occurs with local vasodilation in the submucosal vascular network and can be triggered by a variety of substances that work through both cholinergic and noncholinergic pathways.[25] The observed vasodilation is a result of inhibition of sympathetic activity by VIP-containing sensory neurons.

RESTING STATE

Vascular tone is mediated by a variety of mechanisms, including neural mediators, circulating humoral mediators, paracrine and autocrine mediators, and metabolic vasodilators. Neural and humoral mediators have their largest effect on the heart and large vessels and less effect on the microvasculature in the intestine. Paracrine and metabolic mediators have their greatest effect on the microvasculature and significantly less effect on larger vessels. Metabolic autoregulation plays a significant role in modulating vascular tone in the resting state.

DIGESTION

During digestion, blood flow to the gastrointestinal organs increases and is called postprandial intestinal hyperemia. This increased flow is probably required to maintain intestinal function and integrity.[26-28] The intestinal response to a meal includes an increase in blood flow to the submucosal arterioles.[29] This increase in flow may be up to 200% of the resting state flow.

There are two phases of the response to food: the anticipatory phase and the postprandial phase.[10,26] During the anticipatory phase, mesenteric vascular resistance is increased in response to higher sympathetic activity.[30,31] The increased sympathetic activity causes an increase in cardiac output, blood pressure, heart rate, and splanchnic and renal vascular resistance. The postprandial phase begins as the stomach fills with food.

Postprandially, the mesenteric vasculature dilates and blood flow in the SMA increases within 5 minutes by as much as 60%.[32,33] This increase in mesenteric blood flow occurs as a result of redistribution from the extremities.[34] Peak flow occurs 30 to 90 minutes after ingestion and then declines over a period of 2 to 3 hours.[35] The major increase in blood flow is largely to the mucosal layer and is determined by both neurohumoral and paracrine agents released secondary to chemical and mechanical stimuli,[10,25,26,36-38] as well as digested food (protein, lipid, carbohydrates), bile, and chime.[25] Lipids in combination with bile salts produce the greatest net increase in blood flow, whereas the response to carbohydrates occurs quickest.[35] Distention of the bowel lumen does not affect blood flow.[38,39] Various peptides and hormones, including cholecystokinin, secretin, gastrin, serotonin, and bradykinin, may also contribute to postprandial hyperemia.

Postprandial hyperemia cannot occur simultaneously in the entire gastrointestinal tract. Vasodilation of the entire mesenteric circulation would result in the capacity to accommodate a blood flow of 4 to 5 L/min

(majority of cardiac output). Therefore, blood flow to the mesentery increases in a sequential manner, with areas containing food receiving the majority of flow.[38,40] According to some reports, hyperemia occurs in the segment containing food,[25,41,42] and once the chyme passes a particular region in the intestinal tract, blood flow returns to baseline.[30,43]

AUTOREGULATORY ESCAPE

Blood flow is maintained at normal levels during a variety of physiologic conditions, including those with elevated sympathetic activity and catecholamine levels. This process is called splanchnic autoregulation and acts via multiple mechanisms as described earlier. As long as mean blood pressure remains higher than 70 mm Hg, intestinal blood flow is not dependent on blood pressure. Blood flow may initially decrease under the vasoconstrictor effects, but then it gradually returns toward normal. Resumption of blood flow is most likely a result of local metabolic factors that result in vasodilation, including ischemia. Blood flow, under such circumstances, is preferentially increased to the submucosa over the mucosa, which probably explains why the mucosa may sustain ischemic damage with the bowel still remaining viable if flow is restored. When blood pressure drops below 70 mm Hg, intestinal perfusion will have a linear relationship to blood pressure. Below a pressure of 40 mm Hg, the bowel will become ischemic and sustain injury.[44]

DOPAMINE

Administration of low-dose dopamine (<5 μg/kg/min) produces preferential dopaminergic and β-adrenergic effects over α-adrenergic effects. Activation of these receptors results in dilation of the splanchnic circulation and a net increase in splanchnic blood flow.[45,46] This blood flow, however, is redistributed away from the gut mucosa,[47] and although net splanchnic flow increases, mucosal ischemia worsens. Mucosal ischemia results in increased translocation of microorganisms and endotoxins into the portal circulation. Dopamine also increases hepatic ischemia, which results in decreased clearance of proinflammatory cytokines. To conclude, low-dose dopamine probably worsens mesenteric ischemia.[48-50] Besides being harmful to the gastrointestinal tract, recent evidence also suggests that dopamine is not useful in the treatment or prevention of renal dysfunction and is harmful to the endocrine, immunologic, and respiratory systems in critically ill patients.[51] The long upheld practice of administering low-dose dopamine to improve renal function and mesenteric perfusion should be abandoned.

CATECHOLAMINES

Sympathetic stimulation is a major determinant of tone in both the arterial resistance vessels and venous capacitance vessels. Table 83–1 lists some commonly used intravenous agents, including catecholamines, that augment mesenteric vascular blood flow. Vascular tone is largely dependent on the type of receptors stimulated. Receptor stimulation depends on the type of catecholamine and its concentration at the receptors. Understanding the effects of catecholamines on mesenteric blood flow

Table 83–1 Commonly Used Intravenous Agents That Augment Mesenteric Vascular Blood Flow*

Agent	Mechanism of Action in Normovolemic Patients
Amrinone	Direct inhibition of phosphodiesterase results in increased cAMP and vasodilation
Dobutamine	Mild β_2 stimulation
Dopamine	Dopaminergic effects at 1 μg/kg/min†
	Predominately β effects between 3 and 10 μg/kg/min
	Combined α and β between 10 and 20 μg/kg/min
	Predominately α at >20 μg/kg/min
Epinephrine	Renal vasoconstriction at less than 1 μg/min
	Cardiac β stimulation between 1 and 4 μg/min
	Increasing α stimulation between 5 and 20 μg/min
	Predominantly α at >20 μg/min
Isoproterenol	Pure β-agonist
Nitroglycerin	Directly relaxes arteries and veins
	Venodilation predominates at doses <50 μg/min
	Arterial vasodilation predominates at doses >200 μg/min
Nitroprusside	Directly dilates arteries and veins
Norepinephrine	Predominately α effects
Papaverine	Blocks angiotensin II– and vasopressin-mediated vasoconstriction
Phenylephrine	Pure α-agonist

*Generally, vasoconstriction occurs with stimulation of α-receptors, which diminishes mesenteric blood flow, whereas vasodilation occurs with stimulation of β-receptors, which increases mesenteric blood flow. These effects, however, are dependent on the location of the receptors, which is shown in Figure 83–9; the density of receptors in the mesenteric arterial and venous circulation, which is shown in Table 83–2; the affinity of the agent for the receptor subtype; the plasma concentration of other agents; the preexisting tone of the mesenteric vessels; and the volume of blood in the circulation. The effects of catecholamines administered during hypovolemia depend on the blood volume in the splanchnic reservoir.

†See text specific to dopamine action on mesenteric vascular flow.

cAMP, cyclic adenosine monophosphate.

requires a full understanding of catecholamine actions on the entire splanchnic circulation.[11] The receptors located on various splanchnic beds are detailed in Table 83–2 and shown in Figure 83–9. The hepatic arterial vascular bed contains mainly α_1-, a smaller quantity of α_2-, and an intermediate number of β_2-receptors.[52] The hepatic capacitance vessels, including the sinusoids, have α-adrenergic receptors, and the hepatic veins have both α- and β_2-adrenergic receptors. Activation of α-receptors results in vasoconstriction, whereas activation of β_2-receptors results in vasodilation. The intestinal resistance (arterial) vessels have roughly equal numbers of α_1- and β_2-receptors and a lesser number of α_2-receptors. The mesenteric venous system contains largely α_1-, a smaller number of α_2-, and a questionable number of β_2-receptors. Activation of α-receptors results in venoconstriction and a decrease in venous capacitance, whereas activation of β_2-receptors results in venodilation and an increase in venous capacitance.

Sympathetic activity causes a variety of hemodynamic consequences, including an increase in cardiac output. This increased output is dependent on an increase in blood volume, which largely comes from the splanchnic circulation. When arterial flow decreases, pressure within the venous capacitance vessels also decreases. The decrease in venous pressure is minimized by elastic recoil in the veins, which maintains a pressure adequate to force the splanchnic vascular volume into the systemic circulation. This phenomenon of elastic recoil can function even as arterial inflow is decreased. These two methods of venoconstriction are also responsible for the decreased splanchnic flow and shift of blood volume from the splanchnic circulation to the systemic circulation with exercise or hemorrhage. With mild exercise, there is a 35% decrease in splanchnic blood volume. In cases of moderate hemorrhage, approximately 65% of the total splanchnic blood volume can be directed into the systemic circulation.[53]

Table 83–2 Vascular Bed Receptor Subtypes

	Receptor Subtype		
Vascular Bed	α_1	α_2	β_2
Mesenteric arterial	+++	++	−−−
Hepatic arterial	+++	+	−−

SUMMARY

Nature has developed a mesenteric circulatory system that is rich in collateral circulation. A significant survival advantage is probably held by animals and people who foster a rich blood supply to their mesenteric circulation. Understanding the blood supply to the mesenteric circulation is critical for clinicians and especially surgeons, for all resectional and other procedures performed within the abdomen have the potential to result in

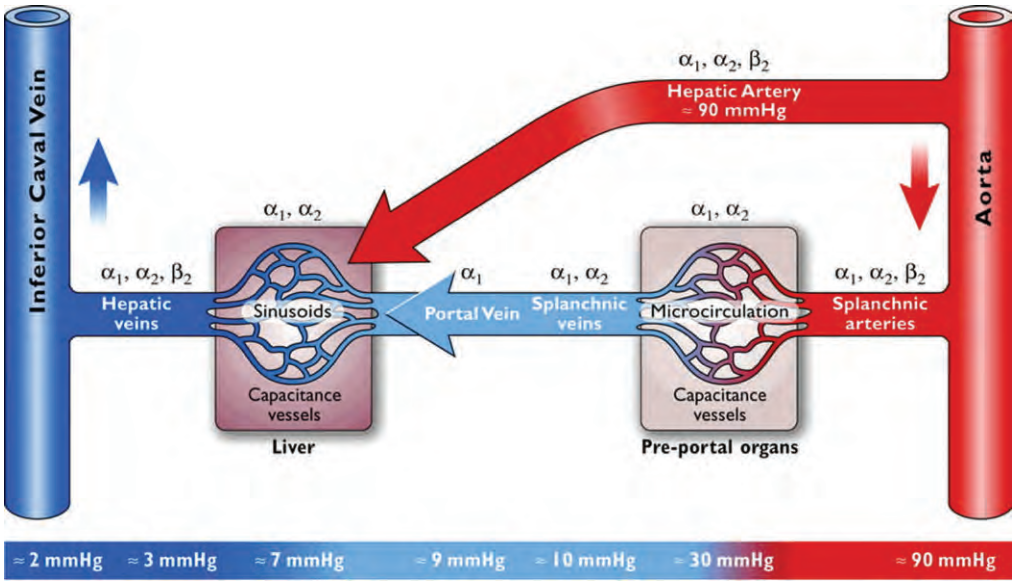

Figure 83–9. Diagrammatic representation of the splanchnic vasculature. Splanchnic arteries represent all arterial vessels of the preportal organs; splanchnic veins represent the pooled venous blood from all these organs. The distribution of adrenoceptor subtypes (α_2, β_2) and approximate intravascular pressures are shown for corresponding segments of the splanchnic vasculature. (From Gelmen S, Mushlin PS: Catecholamine-induced changes in the splanchnic circulation affecting systemic hemodynamics. Anesthesiology 100:434-439, 2004.)

ischemia of the mesenteric organs if done without attention to their vascular supply. The complexity of the situation grows exponentially when dealing with the multitude of pathologic states that can affect vessel patency, as well as the variety of anatomic variations, including the presence of collateral vessels.

Regulation of mesenteric blood flow is an extremely complex process that involves a variety of control mechanisms operating at multiple levels. Adding to the complexity, these control mechanisms directly influence and augment each other. Changes that occur within humans after ingestion of a meal further complicates the scenario. Clinically, it is essential to understand where various receptors are located and their function when stimulated. It is also crucial to understand the effects of various pressor agents on both the systemic and mesenteric systems and realize that progress is still being made in understanding the effects of these agents. The best example of this continues to be dopamine. Low-dose dopamine was once touted as being a drug that improves both renal and mucosal blood flow. Recent studies have now shown that it is actually harmful and should not be used for this indication. With the extremely large number of chemicals and hormones that directly affect the mesenteric circulation and the large number of disease states that affect patients, there will probably be further important changes in the manner in which we practice medicine in the future.

Chapter

84

Mesenteric Ischemia

Anthony J. Comerota ▪ Matthew Todd Miller

Mesenteric ischemia is a frequently lethal condition resulting from critically reduced perfusion to the gastrointestinal tract. It has acute and chronic forms that involve both the arterial and venous sides of the circulation. Common to all forms of mesenteric ischemia are the diagnostic difficulties and challenging management decisions accompanying these patients. First described in the 1500s, diagnosis and management of mesenteric ischemia consisted of abdominal exploration with resection of the involved bowel, but the diagnosis was often made too late to save the patient. In 1950, using the newly delineated principles of vascular surgery, Klass[1] performed an early abdominal exploration with superior mesenteric artery (SMA) embolectomy in a patient with acute mesenteric ischemia. Although the patient died of acute heart failure during the postoperative period, the significant advance of visceral revascularization was apparent when normal bowel was observed at autopsy. In the years that followed, numerous cases of successful mesenteric embolectomy with patient survival were reported, and operations were developed for revascularization of patients with acute and chronic mesenteric ischemia.[2] It is conceptually important that physicians involved in the care of patients with mesenteric ischemia, especially acute mesenteric ischemia, recognize that the major advances in care and the improved survival of these patients have been achieved as a result of revascularization of the ischemic bowel.

Despite the remarkable advances in vascular surgical technique, vascular imaging, percutaneous intervention, and surgical critical care, mesenteric ischemia remains a complex and often disheartening disease. Acute mesenteric ischemia is a life-threatening vascular emergency that requires a high degree of clinical suspicion and early intervention to avoid a poor outcome. Unfortunately, recent reports indicate that its incidence is on the rise.[3,4] Mesenteric ischemia accounts for 0.1% of hospital admissions and 1% to 2% of admissions for abdominal pain.[5] One population-based study showed the incidence of mesenteric ischemia to be 9 per 100,000 person-years; however, as anticipated, the incidence increases substantially with age.[6] The reported mortality ranges from 24% to a high of 96%, with an average of 69%.[7]

The mesenteric arterial circulation comprises three major aortic branches with multiple collaterals: the celiac axis, the SMA, and the inferior mesenteric artery (IMA). The celiac axis consists of three major branch vessels to the foregut: the common hepatic, left gastric, and splenic arteries. The SMA supplies blood flow to the majority of the small intestine and the right colon and a portion of the transverse colon. Finally, the IMA is responsible for blood flow to the remaining transverse, descending, and sigmoid colon. The arterial collaterals with their anastomotic arcades often allow for compensatory intestinal blood flow when one or more of the major visceral arteries becomes diseased or occluded, most commonly as a result of chronic disease. Therefore, patients with acute or, more often, chronic disease may be protected from intestinal ischemia because of their collateral circulation (Fig. 84–1). It is commonly observed that in patients with chronic mesenteric ischemia, two of the three major visceral arteries are diseased, and these patients have symptoms of intestinal ischemia. However, patients with acute arterial occlusion of one major artery, usually the SMA, experience severe symptoms because the compensatory collateral circulation is inadequate.

The splanchnic circulation receives approximately 25% of the resting and 35% of the postprandial cardiac output.[8-10] Seventy percent of the mesenteric blood flow is directed to the mucosal and submucosal layers of the bowel, with the remainder supplying the muscularis and serosal layers.

Not surprisingly, the mucosal layer of the bowel wall is the most severely affected by acute mesenteric ischemia, and abnormalities have been observed as early as 10 minutes after arterial occlusion in experimental models.[11] Mucosal integrity is compromised early, and bowel wall edema, loss of capillary integrity leading to bacterial translocation and endotoxemia, and exudation of fluid into the bowel lumen ensue. The mucosa sloughs, with ulcerations left in the bowel wall. Up to this point the intestine remains viable; however, if the

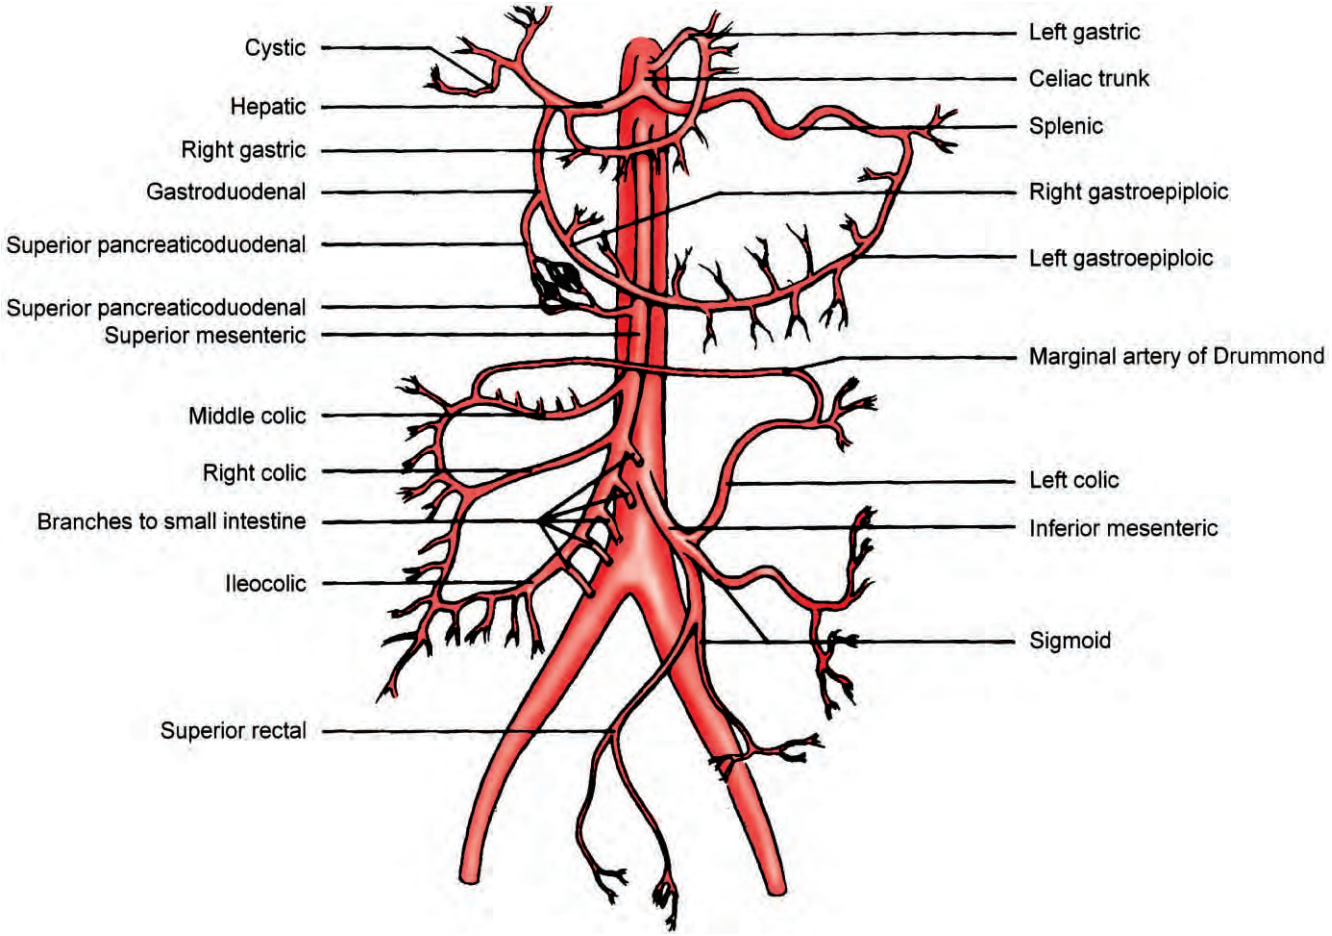

Figure 84–1. The mesenteric circulation. (From Schwartz LB, Davis RD Jr, Heinle JS, et al: The vascular system. In Lyerly HK, Gaynor JW Jr [eds]: The Handbook of Surgical Intensive Care, 3rd ed. St Louis: Mosby–Year Book, 1992, p 287.)

ischemia progresses, there is ongoing necrosis of the muscularis and serosal layers of the bowel wall, at which point the involved segment is no longer salvageable.

Although acute mesenteric ischemia results in profound illness, correcting the ischemia and reperfusing the ischemic bowel can cause further deterioration because of myocardial depression and a generalized systemic inflammatory response. Escape of oxygen free radicals, myocardial depressant factor, and other products of tissue injury into the circulation contributes to the reperfusion phenomenon, which can lead to disseminated intravascular coagulation and multiorgan system dysfunction. This is mentioned not to discourage mesenteric revascularization, but to emphasize the importance of expedient diagnosis and reversal of the ischemia. Hypoxia disrupts bowel wall metabolism and thereby causes cellular damage leading to profound vasoconstriction, which further compromises tissue perfusion, even after large-vessel revascularization. Early intra-arterial infusion of vasodilators has improved mesenteric revascularization and resulted in more favorable outcomes.[2,8,12,13] A limited experience with infusion of superoxide free radical scavengers has shown benefit in reducing mesenteric reperfusion complications[14]; however, the benefit of superoxide free radical scavengers remains under investigation.

ACUTE ARTERIAL MESENTERIC ISCHEMIA

Unfortunately, the prognosis of patients with acute mesenteric ischemia is poor and, in most communities, has not changed during the past 30 or more years. This is true despite the surgical, technical, endovascular, and pharmacologic advances that have occurred during the same time frame. This state of affairs should cause one to reflect on the disease process, appreciate the benefit of revascularization, and recognize that delay in diagnosis is costly and that traditional approaches to these difficult patients require modifications to improve outcomes.

Insight can be gained by reviewing advances in the management of mesenteric ischemia and putting them into the perspective of personal and clinical experience. Personal observation has revealed that patients who undergo emergency exploratory laparotomy without a definitive diagnosis preoperatively have a prohibitively

high mortality rate. A common scenario in these patients is resection of ischemic bowel without mesenteric revascularization. Absent a preoperative diagnosis and knowledge of patients' underlying anatomy and pathophysiologic contributors to their mesenteric ischemia, attempts at revascularization are often unsuccessful and are generally ill advised. On the other hand, in patients in whom the diagnosis is made preoperatively and who undergo hemodynamically guided aggressive resuscitation with appropriately planned revascularization that addresses the anatomic and pathophysiologic causes of the mesenteric ischemia, the likelihood of survival is maximized.

These clinical observations are supported by a number of animal experiments performed by Boley and colleagues.[15-17] They demonstrated that when mesenteric blood flow is reduced, either from a systemic cause or from mesenteric obstruction, vascular resistance increases within several hours as a result of mesenteric vasoconstriction. If normal mesenteric blood flow could be promptly restored, the vasoconstriction was immediately reversible. If, however, vasoconstriction was present for several hours, it remained even after large-artery mesenteric occlusion was corrected because of the profound vasospasm. These experiments were followed by others demonstrating that small-vessel mesenteric vasoconstriction was relieved by the intra-arterial infusion of papaverine into the SMA; therefore, a method of treating the vasoconstriction was proposed.

These experimental observations ultimately led to an aggressive diagnostic and revascularization approach to acute mesenteric ischemia. The improved outcomes with precise diagnosis and revascularization and the recent literature demonstrating the benefit of percutaneous techniques form the basis for the recommendations outlined in Figure 84–2. Early diagnosis is essential and is most often achieved by having a low threshold for arteriography and placement of a catheter for the infusion of papaverine. Using this approach of early arteriographic diagnosis with catheter-directed papaverine infusion, Boley et al.[2] and Clark and Gallant[18] reduced the mortality to less than 50% in patients with acute intestinal ischemia. Even in the subset of patients with acute SMA embolism in whom the diagnosis was made promptly (≤12 hours), Boley et al.[19] reported a 33% mortality rate. Though high, this is considered a substantial improvement over what had traditionally been reported.

Embolic Occlusion

Embolic occlusion of the SMA accounts for 40% to 50% of cases of acute mesenteric ischemia.[3,12] Most emboli originate in the heart and are secondary to myocardial infarction, cardiac arrhythmia, endocarditis, cardiomyopathy, ventricular aneurysm, valvular disorders, or depressed left ventricular function as a result of ischemic heart disease (Box 84–1). Rarely, a paradoxical embolus traveling through a patent foramen ovale from a thrombus in the venous system is the cause. Most mesenteric emboli lodge in the SMA because it branches from the aorta at an oblique angle, as opposed to the celiac artery, which is nearly perpendicular to the axis of the aorta. More than 50% of emboli lodge in the mid to distal segment of the SMA. The SMA tapers after major branch points, and emboli are commonly found distal to the middle colic artery. Less than 15% of emboli occlude the SMA at its origin.

The point of occlusion affects the magnitude and distribution of the ischemia that it produces. Occlusion at the origin of the SMA causes intestinal ischemia extending from the ligament of Treitz to the transverse colon, whereas occlusion distal to the middle colic artery preserves the right colon and proximal part of the small bowel. As emphasized earlier, the key to successful management of patients with acute mesenteric ischemia is a high index of suspicion leading to early diagnosis, aggressive resuscitation, and early mesenteric revascularization.

Patients with acute SMA embolism usually have sudden and dramatic symptoms that reflect the abruptness of the occlusion and the severity of ischemia distal to the embolus because of the absence of collateral

Box 84–1 Etiology and Distribution of Mesenteric Ischemia

Acute Mesenteric Ischemia

- Emboli (50%)
  - Arrhythmia
  - Valvular disease
  - Myocardial infarction
  - Hypokinetic ventricular wall
  - Cardiac aneurysm
  - Aortic atherosclerotic disease
  - Iatrogenic

  - Renal failure
  - Medications
- Venous occlusion
  - Hypercoagulable state
  - Sepsis
  - Compression
  - Pregnancy
  - Portal hypertension
  - Malignancy

Chronic Mesenteric Ischemia

- Atherosclerotic disease
- Arterial hyperplasia/dysplasia
- Inflammatory disease

circulation. As with all forms of acute mesenteric ischemia in patients who are evaluated early after the onset of occlusion, their complaints of severe abdominal pain contrast markedly with the absence of physical findings. Rectal examination is not generally helpful because the presence of occult blood is typically a late occurrence. Early on the pain may be colicky in nature, but it then becomes constant. Nausea and vomiting may occur in some patients and, less commonly, diarrhea, which may lead to diagnostic confusion.

Thrombotic Occlusion

Acute thrombotic occlusion generally occurs in conjunction with chronically diseased vessels and may have a somewhat more insidious onset because of previously developed collateral circulation. These patients account for 25% to 35% of cases of acute mesenteric ischemia. A history of general abdominal discomfort, anorexia, and perhaps symptoms of postprandial abdominal pain, weight loss, and food aversion before their acute episode assists an astute clinician in differentiating between acute thrombotic versus acute embolic occlusion in some patients. Unfortunately, such a history is not found consistently because many patients with acute thrombotic occlusion have no symptoms until the occlusive event. This may be due to rupture of a previously noncritical atherosclerotic plaque that abruptly occludes the vessel, a pathophysiologic catastrophe similar to embolic occlusion because the patient may not have had significant stenosis before the acute event.

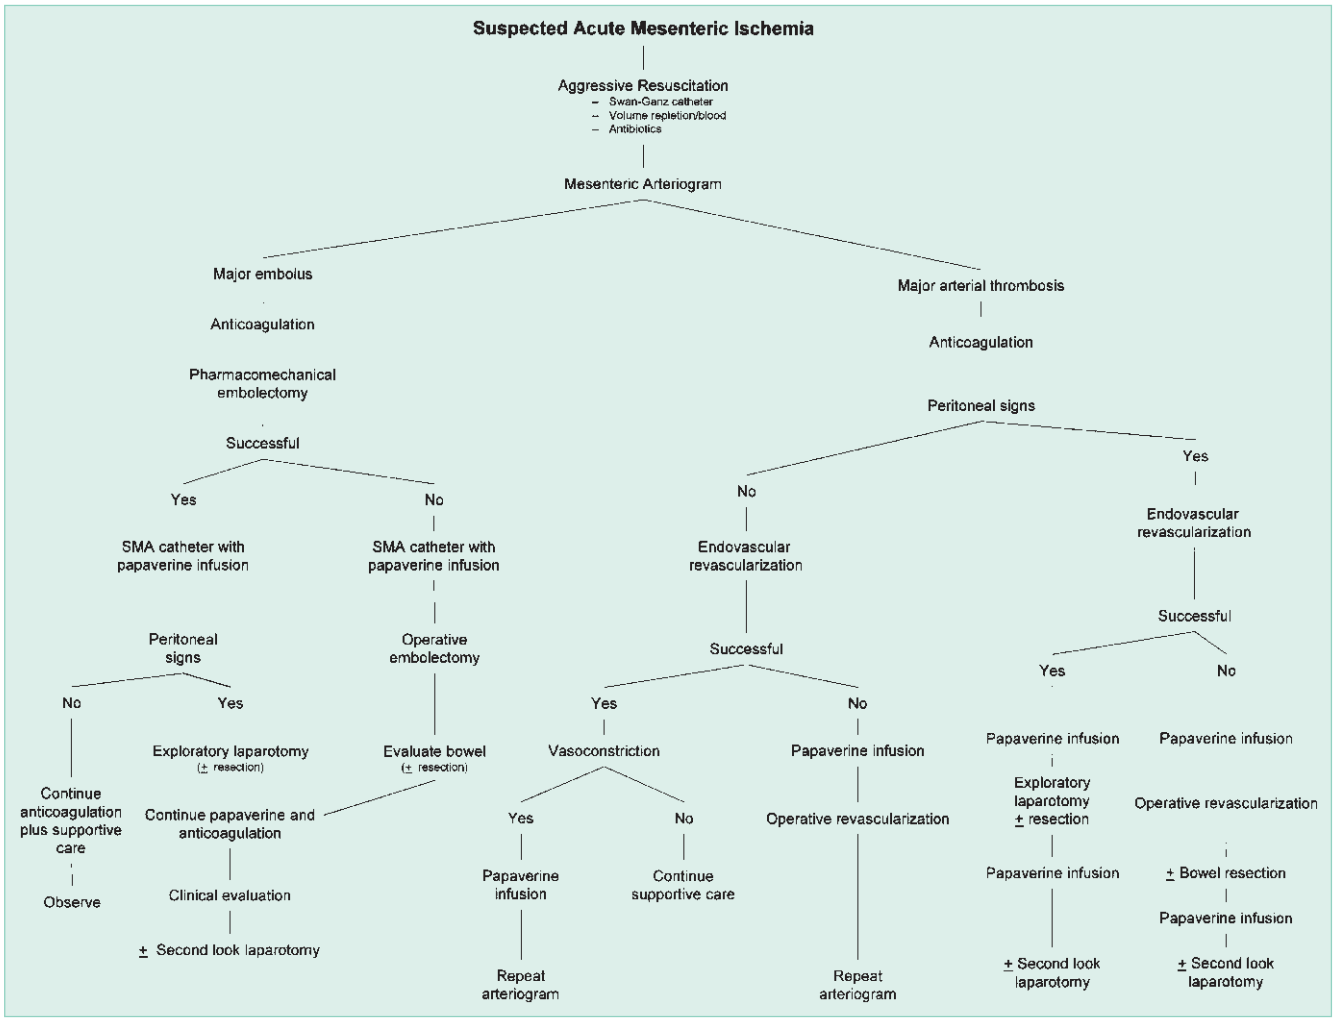
Figure 84–2. **A** and **B,** Recommended treatment of acute mesenteric ischemia. R/O, rule out; SMA, superior mesenteric artery.



B

Figure 84–2, cont'd.

Nonocclusive Mesenteric Ischemia

Nonocclusive mesenteric ischemia, which accounts for approximately 20% of all cases of acute mesenteric ischemia, has manifestations similar to those of mesenteric arterial thrombosis, but it occurs with patent mesenteric arteries. Splanchnic vasoconstriction is the underlying pathophysiologic process and is precipitated by hypoperfusion from medications, depressed cardiac output, or renal or hepatic disease.[13] When blood pressure in the bowel falls below a critical pressure of 40 mm Hg, ischemia develops and eventually leads to infarction and bowel necrosis.

Diagnosis of nonocclusive mesenteric ischemia can be especially difficult in hospitalized patients, who are often critically ill and unable to complain because of either ongoing sedation or intubation. The diagnosis is often delayed because their clinical manifestations may be wrongfully attributed to their underlying critical illness. Older patients who have acute myocardial infarction, congestive heart failure, dysrhythmia, sepsis, or hypovolemia or use splanchnic vasoconstrictors are at increased risk for nonocclusive mesenteric ischemia. Other patient populations at particularly high risk are hemodialysis patients and those with a recent history of cardiopulmonary bypass, major abdominal surgery, pancreatitis, aortic dissection, or burns.[20,21]

Diagnosis

Early diagnosis is the key to successful management of most diseases and is especially true for acute mesenteric ischemia. Acute arterial mesenteric ischemia results from a number of causes (see Box 84–1), which if uncorrected often lead to intestinal infarction. Recognition of acute mesenteric ischemia can be difficult because most patients have nonspecific symptoms of abdominal pain. *Abdominal pain out of proportion to the findings on physical examination and persisting beyond 2 to 3 hours* is the classic picture. Diarrhea, nausea, vomiting, and anorexia can also be part of the initial symptom complex. Fifteen

percent of patients report melena or hematochezia, and occult fecal blood is found in at least half the patients.[22] Leukocytosis is common. However, with delay in diagnosis and progression of ischemia to full-thickness bowel wall injury, the manifestation is one of an acute abdomen, with findings of distention, guarding, rigidity, and hypotension, consistent with overt peritonitis and its septic consequences.

The patient should have intravenous access established with blood drawn and sent for a complete blood count with differential, electrolytes, evaluation of renal and hepatic function, blood urea nitrogen, creatinine, amylase, lipase, prothrombin time, activated partial thromboplastin time, and cardiac enzymes. Frequently, the laboratory findings are consistent with hemoconcentration resulting from the patient's hypovolemia and dehydration. The white blood cell count is often elevated and metabolic acidosis is present. Hyperamylasemia and elevations in lactate dehydrogenase, aspartate aminotransferase, and creatine phosphokinase levels are common. If hyperkalemia and hyperphosphatemia are present, bowel infarction should be suspected.[23] An electrocardiogram is performed and the patient placed on a monitor to evaluate cardiac rhythm. Depending on the history and physical findings, a nasogastric tube can reduce further abdominal distention and vomiting. Patients with cardiac disease who are hypovolemic should have a Swan-Ganz catheter placed to assist in monitoring their resuscitation.

Plain Films

Plain films of the abdomen (supine, upright) and the chest (anteroposterior) are obtained, predominantly to exclude other processes such as bowel obstruction or free air as a result of perforation. Up to 25% are normal in appearance. Portal venous gas is an advanced finding that suggests intestinal necrosis. Suspicious findings on plain films include a nonspecific ileus pattern with dilated, fluid-filled loops of bowel, thumbprinting, separation of bowel loops (edematous mesentery), intramural gas, and free air. In the majority of cases, however, plain films are nondiagnostic.[24,25]

Ultrasonography

Although duplex ultrasonography can be helpful in patients with chronic mesenteric ischemia, its utility in patients with acute mesenteric ischemia is limited. Even when requested for elective evaluation of patients with chronic ischemia, up to 40% cannot be adequately assessed because of body habitus or bowel gas.[26] These limitations are magnified when ultrasonography is attempted in patients with acute mesenteric ischemia. Abnormalities such as calcification, thrombus, and arterial stenosis or occlusion can occasionally be identified in the acute setting, assuming that the patient can cooperate, does not have dilated bowel that interferes with sound wave penetration, and has a favorable body habitus. Though able to evaluate the proximal mesenteric circulation, duplex evaluation of peripheral mesenteric perfusion is indirect and based on the velocity profile of the proximal artery.[27] Duplex sonography may have its greatest utility after revascularization[28] because patients with persistent abnormalities face high mortality with graft failure; therefore, planned reintervention to preserve mesenteric perfusion is prudent.

Computed Tomography

Computed tomography (CT) has rapidly become the initial diagnostic test for most patients with abdominal disease. It is a quick (approximately 19 seconds to scan the abdomen and pelvis), noninvasive, easily tolerated test that can show the indirect findings of arterial bowel ischemia and may show the arterial occlusion or mesenteric venous thrombus. Moreover, it is available in most institutions.

Findings on CT scans associated with bowel ischemia include dilation of the bowel lumen, bowel wall thickening, abnormal bowel wall enhancement, arterial occlusion, venous thrombosis, and intramural or portal venous gas. Dilation of an ischemic bowel segment suggests interruption of normal peristaltic activity. Symmetrical bowel wall thickening greater than 3 mm in a distended segment of bowel suggests ischemia. Greater degrees of bowel wall thickening should raise suspicion of mesenteric venous thrombosis (MVT). Oral contrast should be avoided in patients with suspected mesenteric ischemia because it may obscure subsequent arteriographic imaging of the mesenteric vasculature, which usually leads to the definitive diagnosis. Intravenous contrast is useful in demonstrating the heterogeneity of the ischemic bowel wall (lack of bowel wall enhancement)[29] and may show occlusion of mesenteric arteries if given by rapid bolus administration. Correlation between ischemia and CT scan findings is delineated in Table 84–1.[30]

Taourel et al.[31] reported a sensitivity of 64% and specificity of 92% for the CT diagnosis of acute arterial mesenteric ischemia. However, CT is the diagnostic technique

Table 84–1 Correlation Between Pathologic Damage and Computed Tomography Findings

Pathologic Damage	CT Findings
Vasoconstriction	Wall hyperdensity Absence of wall enhancement
Increased capillary permeability	Wall thickening Bowel dilation
Mucosal cellular necrosis	Pneumatosis Gas in mesenteric vein branches Gas in portal vein branches
Transmural bowel necrosis	Pneumoperitoneum Retropneumoperitoneum Ascites

From Angelelli G, Scardapane A, Memeo M, et al: Acute bowel ischemia: CT findings. Eur J Radiol 50:37-47, 2004.

of choice for acute MVT, with a sensitivity exceeding 90%.[32,33] As CT scan technology has advanced, three-dimensional reconstructions of the aorta and its branches show additional detail, which has improved the sensitivity and specificity to 94% to 96%.[31,34] As the technology continues to evolve, newer-generation scanners will further improve diagnostic capability. The limitations and risks of CT angiography center around patients with renal insufficiency or contrast allergies, limitations of contrast volume, and metal artifacts obscuring the area of interest.

Magnetic Resonance Angiography

When compared with catheter arteriography, current contrast-enhanced (gadolinium) three-dimensional magnetic resonance angiography (MRA) performs favorably in the common and proper hepatic arteries, the splenic artery, the SMA, and the portal, superior mesenteric, and splenic veins. Agreement is poor, however, for evaluation of the intrahepatic arteries, the SMA branches, and frequently the IMA, and catheter-directed arteriography remains necessary for detailed evaluation of these branch vessels.[35] However, because of the compromised clinical status of many patients and the need for urgent diagnosis, MRA is not often the procedure of choice.

MRA is frequently used for the evaluation of patients suspected of having chronic mesenteric ischemia since it can provide both anatomic and functional information regarding mesenteric perfusion. Because deoxyhemoglobin is paramagnetic and oxyhemoglobin is not, an increase in deoxyhemoglobin reduces the T2 of blood. By using this effect, patients with chronic mesenteric ischemia have been shown to have a decrease in the percentage of oxygenated blood in the superior mesenteric vein.[36] MRA spares patients the side effects of ionizing radiation and contrast toxicity.[27]

Arteriography

Catheter-directed contrast arteriography has been and remains the method of definitive diagnosis for acute and chronic mesenteric ischemia. Through the arteriographic access, catheter-based interventions are being performed with increased frequency in both patients with acute disease and those with chronic disease. Arteriograms establish the diagnosis; assist in differentiating between acute embolic, thrombotic, or nonocclusive mesenteric ischemia as the cause; and allow proper planning of the revascularization procedure. Anteroposterior (AP) and lateral views of the aorta and the mesenteric branches are required for proper arteriographic evaluation. The lateral view is particularly important to examine the proximal celiac artery and SMA, which overlap the aortic contrast column on AP views.

Acute embolic occlusion of the SMA is characterized arteriographically by abrupt occlusion of the artery, usually at a branch point where the vessel tends to narrow (Fig. 84–3). If imaged acutely, a meniscus sign (crescent) is often observed. If secondary thrombosis occurs proximal to the embolus, the classic meniscus sign of embolic occlusion will be obscured. The specific location of the occlusion depends on the size of the embolus, with the most common location being just distal to the middle colic artery, at which point the SMA rapidly narrows. Because these patients generally have a cardiac source for the embolus and peripheral atherosclerosis is not etiologically related to their mesenteric ischemia, the aorta and other arteries may show little atherosclerotic disease. Emboli rarely lodge in the proximal SMA (<15%).

Figure 84–3. Acute embolus (*arrow*) occluding the superior mesenteric artery. (From Hladík P, Raupach J, Lojík M, et al: Treatment of acute mesenteric thrombosis/ischemia by transcatheter thromboaspiration. Surgery 137:122-123, 2005.)

Acute thrombotic occlusion usually occurs in an artery with significant underlying atherosclerosis. Atherosclerotic plaque most frequently develops at branch points of arteries from the aorta, most commonly at the origin of the celiac artery, SMA, and IMA. When segmental occlusion occurs as the result of chronic disease, the chronicity of the process is suggested by the development of collateral circulation to the distal branches. Delayed arteriographic imaging is often required to properly opacify the distal vessels. Patients with mesenteric arterial thrombosis frequently have more advanced atherosclerotic disease in their abdominal aorta and its branches than do those with acute embolic occlusion.

The diagnosis of nonocclusive mesenteric ischemia is typified by diffuse spasm of the SMA branches with intermittent areas of narrowing and dilation. Perfusion is markedly compromised because the intense distal vasospasm causes high peripheral resistance, with frequent reflux of contrast into the aorta. The distal mesenteric arterial arcades are not usually visualized. Patients with acute critical illness, those taking vasopressors, and those who are hypovolemic can demonstrate these arteriographic findings as a result of the body's physiologic response to hypovolemia. Additionally, acute proximal mesenteric arterial occlusion is often followed by distal

A B

vasospasm, thus compounding the severity of the intestinal ischemia. This underscores the need for rapid and effective resuscitation of these patients, performed most efficiently while monitoring their cardiopulmonary hemodynamics. Aggressive rehydration reduces the compensatory mesenteric vasoconstriction and decreases the nephrotoxic effects of the contrast agent.

Patient Management

Effective management of patients with mesenteric ischemia is linked to (1) early diagnosis, (2) aggressive resuscitation, (3) early revascularization, and (4) ongoing supportive care. Resuscitative efforts should begin immediately on suspicion of the diagnosis because these patients often have multiple medical comorbid conditions and associated cardiac disease. Early and aggressive resuscitation is aimed at correcting the patient's hypovolemia and low cardiac output. A Swan-Ganz catheter is frequently required to gauge the patient's response. Because the mucosal layer of the bowel wall is the most sensitive to ischemia, bacterial translocation should be anticipated and intravenous antibiotics used to treat the associated bacteremia. Catheter-directed papaverine to reverse the often severe mesenteric vasospasm is initiated early after arteriography. Anticoagulation is given to prevent propagation of mesenteric thrombus. The most expedient evaluation of patients with acute arterial mesenteric ischemia is mesenteric arteriography. Further delay caused by relatively insensitive or nonspecific diagnostic testing puts the patient at greater risk for a poor outcome. Once the nature of the mesenteric ischemia is delineated, a specific plan for revascularization can be initiated. A treatment-specific algorithm is summarized in Figure 84–2.

A normal arteriogram should include its venous phase and be followed by a CT scan, if not already performed, to exclude the diagnosis of MVT. If the diagnosis of MVT is excluded, the patient should be aggressively supported and observed. If peritoneal signs are present, exploratory laparotomy should be performed.

Approximately 20% of patients with acute mesenteric ischemia will have a nonocclusive mesenteric vasospastic phenomenon alone. This is generally associated with low cardiac output or a history or present condition of congestive heart failure and treatment with a digitalis preparation. Associated hypovolemia in patients receiving vasopressors and those undergoing operative coronary revascularization who were on cardiopulmonary bypass round out this clinical scenario. The arteriogram generally shows diffuse vasospasm with marked narrowing of the major branches of the SMA (Fig. 84–4), often with the "string of lakes" appearance. Because of the high outflow resistance in the SMA, reflux of contrast into the aorta is common. In addition to aggressively correcting the low cardiac output, terminating vasoconstrictor use, and discontinuing digitalis preparations, intra-arterial papaverine infusion at 30 to 60 mg/hr is the treatment of choice. In the absence of peritonitis, supportive care with anticoagulation and continued papaverine infusion is recommended. The arteriogram is repeated at 12- to 24-hour intervals, and the papaverine infusion is discontinued once the vasospasm has resolved.

Ideally, patients who demonstrate evidence of peritonitis should undergo exploratory laparotomy, with appropriately conservative resection of necrotic bowel

during the papaverine infusion. Postoperatively, the infusion is continued and repeat arteriography is performed. Depending on the patient's clinical evaluation, a second-look laparotomy is considered. In the event that abdominal surgery has been performed without arteriography, clearly necrotic bowel is expeditiously resected, and then arteriography with papaverine infusion is performed. Second-look laparotomy is considered.

Patients who have embolic occlusion of a small branch are also treated with anticoagulation to avoid additional thromboemboli. Associated vasoconstriction is treated with catheter-directed papaverine. In the absence of peritonitis, patients can be observed. In the presence of peritoneal signs, exploratory laparotomy is performed.

During the past several years, remarkable technologic advances have been made with percutaneous interventions. Patients who have major embolic occlusion or major thrombotic occlusion of their visceral vessels can often be approached with a percutaneous, pharmacomechanical method to dissolve or extract the embolus or thrombus and correct an underlying stenosis, if found.[37-41] Combining plasminogen activators with mechanical thrombus disruption and suction extraction can often restore perfusion more quickly and potentially with less morbidity than is the case with standard operative techniques. Because vasospasm is frequently associated with acute mesenteric occlusion, SMA catheter infusion of papaverine should be used to relieve the vasospasm. In the presence of peritonitis, exploratory laparotomy with appropriate resection is performed. The papaverine infusion is continued to relieve ongoing vasospasm and improve bowel perfusion, and anticoagulation is continued to avoid additional embolic or thrombotic events. A second-look laparotomy is planned if the condition of the bowel wall is tenuous at the time that the abdomen is closed. If a second-look laparotomy has been planned and the patient is clinically improving, the repeat laparotomy should be delayed to allow maximal improvement.

If catheter-based pharmacomechanical techniques are unsuccessful in the management of an acute SMA embolus, the catheter should be left in the proximal SMA and papaverine infusion initiated, followed by an expedient operative thromboembolectomy. After perfusion is restored to the bowel, it should be carefully examined for areas of irreversible ischemia. Areas of necrosis should be resected. If there is no irreversible ischemia and blood flow is restored, it can be anticipated that bowel wall perfusion will improve, with good prospects for ultimate bowel viability. Papaverine infusion is continued postoperatively and a repeat arteriogram performed to assess reperfusion and the degree of ongoing vasospasm.

In patients with major arterial thrombosis, anticoagulation should be initiated to minimize progressive thrombotic occlusion of branch vessels. Endovascular revascularization is recommended, including balloon angioplasty and stenting (if necessary) of the celiac artery, SMA, or IMA, or any combination of these arteries. Intra-arterial lytic therapy can be used to clear the acute thrombus[37,38] and unmask an underlying lesion, which should be corrected with adjunctive angioplasty and stenting.[39,42] If the endovascular approach is successful, the completion arteriogram is evaluated for mesenteric vasoconstriction. If present, a catheter is left in place and papaverine infusion continued with subsequent repeat arteriography. In the absence of vasoconstriction, continued supportive care is offered. If endovascular revascularization is unsuccessful, the catheter is left in the SMA for intra-arterial papaverine infusion if a portion of the artery is available for catheter positioning. The patient is then taken to the operating room for operative revascularization. A repeat arteriogram is performed postoperatively and the catheter appropriately repositioned if continued papaverine infusion is indicated.

Patients with peritoneal signs require exploratory laparotomy. Before operating, however, endovascular reconstruction is attempted. If successful, a papaverine infusion is initiated before exploratory laparotomy. Postoperatively, the papaverine infusion is continued and a second-look laparotomy performed, if appropriate.

In the absence of successful endovascular reconstruction, the patient is taken to the operating room for operative revascularization while papaverine is being infused into the SMA. Bowel infarction is often more extensive with arterial thrombosis than with embolic occlusion and has been observed from the duodenum to the transverse colon. Performing an adequate thrombectomy of a diseased visceral artery is difficult and not usually successful as an isolated procedure. Antegrade or retrograde bypass of the diseased artery is generally warranted to restore perfusion. Autologous vein grafts are preferred if bowel resection is required; however, synthetic grafts have fewer problems with compression and kinking,[43] although their use is discouraged in patients with questionable bowel viability. McMillan et al.[44] reported 3-year patency rates of 93% for antegrade grafts, 95% for retrograde grafts, 95% for saphenous vein grafts, and 89% for synthetic grafts. Outcomes were not as favorable in the experience of Cho et al.,[45] who reported 5- and 10-year patency rates of 57% and 46%, respectively, for all grafts. When the SMA beyond an occlusion is an adequate target for revascularization, it appears that a single bypass is all that is required in the majority of cases.[46] After operative revascularization, the bowel is inspected for areas of necrosis and appropriate resection performed. The papaverine infusion should be continued through the new conduit, with subsequent arteriography and a second-look laparotomy performed if indicated.

ACUTE MESENTERIC VENOUS THROMBOSIS

MVT accounts for 5% to 15% of patients with mesenteric ischemia.[47] The superior mesenteric vein is most commonly involved, frequently with extension of thrombus into the portal vein. Interestingly, the inferior mesenteric vein is most often spared.[48] The patient's clinical findings depend largely on the extent of thrombosis, the mesenteric veins involved, and the degree of bowel wall ischemia. Unfortunately, the mortality rate in these patients remains high, up to 50% in some reports.

Although patients with acute MVT have a more abrupt symptom onset than do patients with subacute and chronic mesenteric venous occlusion, the diagnosis remains difficult. Most commonly, patients complain of midabdominal colicky pain, which suggests small bowel involvement. Because of the diffuse and nondescript nature of their symptoms, most patients delay seeking medical care for 2 or more days after symptom onset.[49] Nausea, vomiting, diarrhea, and anorexia frequently accompany their abdominal discomfort. Although findings of occult blood in the stool are present in half of the patients,[50] gross bleeding such as hematemesis, hematochezia, or melena occurs in approximately 15%.[51]

Because of the generalized nature of the patient's symptoms and the relative infrequency of MVT, the definitive diagnosis is often delayed. The past medical history or family history is often informative because venous thromboembolism is part of the history in half of the patients.[48-50]

Physical findings are frequently similar to those in patients with early arterial mesenteric ischemia. Their abdomen is soft, without tenderness or peritoneal signs, and in the early stage the abdominal examination is often unimpressive save for some abdominal distention. Fever, muscular guarding, and rebound tenderness are indicators of more advanced disease progression and bowel infarction leading to peritonitis. Bowel infarction ultimately develops in 30% to 60% of patients with acute MVT.

Because of fluid sequestration within the bowel wall and lumen and the development of ascites, hypotension with hemodynamic instability is often part of the clinical picture. Patients first seen in this advanced clinical condition have a poor prognosis.[51,52]

Blood tests are obtained but are not generally helpful. Elevation of the white blood count with a shift toward immature white cells can be found in 50% to 65% of patients.[51] Serum amylase is usually normal, and serum lactate is elevated only in patients with advanced bowel ischemia and suggests necrosis.

Plain abdominal films are often the initial diagnostic test and are generally of little value. Although abnormalities can be found in 50% of patients,[47] the findings are nonspecific. Thumbprinting, when seen, is indicative of the mucosal edema resulting from venous congestion. Pneumatosis intestinalis, portal vein gas, and free air in the abdomen usually represent bowel infarction.[52]

CT of the abdomen with intravenous contrast is the diagnostic test of choice for patients with suspected acute MVT. A definitive diagnosis can be made in more than 90% of patients. Harward et al.[50] reported 90% sensitivity of abdominal CT with observation of a luminal venous thrombus. However, if one includes other characteristic findings of the bowel wall, such as thickening, pneumatosis, or streaking of the mesentery, CT sensitivity increases to nearly 100%.[33,52] Magnetic resonance venography is used less commonly, but when properly performed, it is highly sensitive.

Depending on the timing of the examination, color duplex ultrasound of the mesenteric veins can be helpful. If performed early, before significant bowel distention, a sensitivity of 80% or greater can be anticipated.[53]

Figure 84–5. Computed tomographic scan of a patient with mesenteric venous thrombosis showing a thrombosed superior mesenteric vein at the splenic vein junction *(arrow),* streaking of the mesentery, and bowel wall thickening.

Selective mesenteric arteriography is not frequently used to establish the diagnosis of MVT, although it may be helpful in the management of these patients. Findings such as incomplete filling of the mesenteric veins, prolonged opacification of the arterial arcades, and the presence of thrombus or nonfilling of the superior mesenteric, splenic, or portal vein (Fig. 84–5) are seen in these patients. Most report a sensitivity of 70% to 80%.[54,55]

Treatment is generally directed at limiting progressive venous thrombosis, reducing the risk for bowel necrosis, and performing timely resection in those with irreversible bowel ischemia. Unfortunately, because of delay in diagnosis, the diffuse nature of the thrombosis, and the rarity of this condition, treatment directed at restoring patency to the thrombosed veins is unusual. In light of the rapid technologic advances in percutaneous interventions, which incorporate pharmacologic and mechanical methods of thrombus dissolution/extraction, it appears reasonable, if not advisable to initiate a strategy of thrombus dissolution/extraction to restore venous drainage because with the traditional care of anticoagulation alone, these patients continue to face a mortality rate ranging from 15% to 50%.[48,50,55,56] The diagnosis of MVT should trigger a search for an underlying thrombophilia. Such an evaluation includes factor V Leiden, prothrombin gene mutation, antiphospholipid/anticardiolipin antibodies, antithrombin III, protein C, protein S, factor VIII levels, hyperhomocysteinemia, paroxysmal nocturnal hemoglobinuria, and assessment for an underlying myeloproliferative disorder.

Rapid initiation of systemic anticoagulation is important. In patients with localized or diffuse peritoneal irritation, exploratory laparotomy is indicated. Laparoscopy

should be avoided in these patients because the increased abdominal pressure associated with the pneumoperitoneum further diminishes mesenteric blood flow.

On entering the abdomen, the superior mesenteric and portal veins should be assessed to determine the relative age of the thrombus. If the large veins appear to have an acute thrombus within them, thrombectomy is recommended, followed by bolus infusion of a recombinant tissue plasminogen activator (rt-PA) solution. The authors use a high-volume, low-dose solution of rt-PA, typically diluting 2 mg in 50 ml and infusing the entire 2-mg dose. Necrotic bowel is conservatively resected with preservation of viable intestine. The patient is treated with heparin intraoperatively and anticoagulation is continued postoperatively.

Associated arterial vasospasm should be evaluated by arteriography and treated with catheter-directed papaverine into the SMA, which improves perfusion to the ischemic bowel and reduces the necessity for additional resection. Patients treated for MVT have a high risk of recurrence (35% to 70%),[49] most frequently within 30 days, thus emphasizing the need for early and persistent anticoagulation.

Patients surviving the acute episode of MVT face chronic mesenteric venous hypertension with a subsequent risk for varices. This post-thrombotic venous hypertension occurs most commonly in patients with persistent large-vein mesenteric thrombosis, which further supports a strategy to remove the thrombus in patients with acute large-vein MVT. Some have reported success with transhepatic portography and instillation of a plasminogen activator directly into the thrombus.[57,58] Unfortunately, thrombolytic agents have been used infrequently in these patients because of the perceived risk for hemorrhage. The success of thrombolysis is often compromised by the delay in diagnosis. Intrathrombus thrombolytic therapy and, alternatively, intra-arterial thrombolytic therapy via the SMA should be considered in patients with thrombosis of large mesenteric veins when the potential benefit outweighs the risk of bleeding.

CHRONIC MESENTERIC ISCHEMIA

Chronic mesenteric ischemia is most commonly the result of advanced atherosclerotic disease of multiple mesenteric arteries. Because of the good collateral circulatory network that exists between the mesenteric vessels, symptomatic chronic mesenteric ischemia is rare. Risk factors for its development are the same as those for atherosclerotic disease in general: a positive family history, smoking, hypertension, and hypercholesterolemia. Generally, when symptomatic disease does occur, there is a female preponderance. Nonatherosclerotic causes of chronic mesenteric ischemia are less frequent and include inflammatory arterial disease, middle aortic syndrome, celiac artery compression (median arcuate ligament syndrome), chronic aortic dissection, aortic coarctation, fibromuscular dysplasia, and neurofibromatosis.

The finding of mesenteric artery atherosclerotic disease does not necessarily indicate intestinal ischemia. Significant atherosclerotic obstruction of the mesenteric arteries has been observed in 6% to 10% of individuals at autopsy.[59] In patients who undergo abdominal aortography, which is a select group of patients who are more likely to have occlusive disease, obliterative disease of the celiac or mesenteric artery has been found in 14% to 24%.[60] Although visceral artery stenosis is frequent, symptoms resulting from visceral arterial occlusive disease are uncommon because of the extensive collateral circulation.

As imaging techniques are becoming more common and stenosed visceral arteries detected more frequently, a temptation exists to correct "asymptomatic" visceral arterial stenosis. This approach is not prudent in light of the natural history study of asymptomatic intestinal arterial occlusive disease performed by Thomas and colleagues.[61] They identified 60 patients with significant mesenteric artery occlusive disease and monitored these patients for a mean of 2.6 years. In none of the 45 patients with one- or two-vessel mesenteric arterial occlusive disease did signs or symptoms of intestinal ischemia develop. Fifteen patients had severe three-vessel disease. During follow-up, fatal intestinal infarction developed in one patient and symptoms of intestinal angina in three.

The natural history of asymptomatic mesenteric occlusive disease appears to be reasonably documented. It has been our experience, which is supported by the literature, that few if any of these patients require mesenteric revascularization.

Clinical Features and Diagnosis

The classic picture of patients with chronic mesenteric ischemia is postprandial abdominal pain leading to an aversion to food and resulting in weight loss. The pain has been characterized as intestinal angina or, in the authors' parlance, intestinal claudication. The pain is characteristically diffuse and often midabdominal, midepigastric, and crampy in nature. The pain generally develops within 15 to 45 minutes after eating, with the severity frequently related to the size of the meal ingested. The authors have observed early-onset pain with foregut (celiac artery distribution) ischemia, with later-onset pain occurring with more diffuse ischemic disease. Because of the association of abdominal pain with food ingestion, fear of eating develops and leads to the characteristic weight loss and subsequent malnutrition.

Other symptoms of nausea, vomiting, and diarrhea have accompanied chronic mesenteric ischemia. Bloating has also been observed. Symptoms of constipation and findings of occult blood in the stool and ischemic colitis represent hindgut ischemia. Because none of these symptoms or signs is specific for chronic mesenteric ischemia, the majority of these patients will have been subjected to an extensive diagnostic evaluation before referral to a vascular surgeon. If a complete evaluation has not been performed, conditions that produce

abdominal pain and weight loss more commonly than visceral ischemic disease does should be excluded before plans for revascularization.

Evaluation of the mesenteric arteries frequently begins with a noninvasive mesenteric duplex scan. This should be performed with the patient in a fasted state because mesenteric outflow resistance changes with food intake and increases in bowel gas.

The most frequent criterion used to identify celiac artery stenosis is a peak systolic velocity of 200 cm/sec or higher, which has been reported to have a sensitivity of 75% and a specificity of 89%.[62] The same investigators reported that a peak systolic velocity of 275 cm/sec or higher predicted 70% to 99% stenosis of the SMA with a sensitivity of 89% and a specificity of 92%. The absence of a Doppler signal in the SMA represents occlusion. Others have reported an end-diastolic velocity of 45 cm/sec or higher to be the best indicator of 50% or greater stenosis of the SMA, with a sensitivity of 100% and specificity of 92%.[63] Retrograde flow in the common hepatic artery is a reliable indicator of severe proximal celiac artery occlusive disease.[64]

Aortography with AP and lateral views has been the diagnostic technique of choice. Lateral aortograms are important for evaluation of the origin of the mesenteric vessels. CT angiography is rapidly becoming the preferred technique for contrast visualization of the aorta and its branches. Contrast-enhanced (gadolinium) MRA is useful in patients with dye allergy and renal compromise.

Laboratory tests to evaluate the malabsorption that may accompany intestinal ischemia, such as stool fat content, D-xylose tolerance, and vitamin B_{12} absorption, may yield positive results; however, they are nonspecific and not generally useful in the overall management of these patients.

Mesenteric Revascularization

Although it is generally true that patients with symptomatic chronic mesenteric ischemia have at least two, if not three intestinal vessels diseased, this is not always the case. Patients with single-vessel occlusive disease who do not have adequate collateral circulation from other mesenteric arteries will suffer chronic mesenteric ischemia. The authors have successfully revascularized a single celiac artery, and others have reported similar findings.[65]

As with all vascular reconstruction, patient selection and the physician's judgment, combined with operative skill, play an important role in overall success. Dogma should be replaced by intelligent decision making based on knowledge of the disease process, awareness of the current options for revascularization, both endovascularly and operatively, and the patient's inherent risk.

Surgical Revascularization

Because chronic symptomatic mesenteric ischemia is relatively unusual in the majority of vascular practices, few physicians have broad-based experience with surgical mesenteric revascularization. There is a wide range of operative techniques, and the one chosen should be based on the patient's anatomy, disease distribution, and associated comorbid conditions and the surgeon's comfort and expertise with the available technique.

Mesenteric Artery Endarterectomy

Endarterectomy of the SMA and the celiac artery was initially performed in retrograde fashion, often attempting a "blind endarterectomy" through a distal arteriotomy.[66] The technique served its purpose during the formative years of vascular surgery. Though occasionally successful, this approach is often complicated by failure, and blind endarterectomy is no longer acceptable in any area of the vascular tree. An improved technique popularized by Wylie et al.[67] advocates complete exposure of the aorta from below the renal arteries to the supraceliac aorta. Such exposure is most reliably accomplished through an extended retroperitoneal approach. A "trapdoor" aortic incision is made from above the celiac artery and extended laterally and then medially below the SMA. The atherosclerotic plaque of the aorta and the orifices of the celiac artery and SMA is then removed by the technique of endarterectomy. Because the plaque in the SMA often extends beyond the orifice of this vessel, subsequent SMA arteriotomy, endarterectomy, and patch angioplasty are frequently required (Fig. 84–6). Although good results are reported by those experienced in this technique, most vascular surgeons are not comfortable with this exposure and extensive dissection and are more likely to encounter complications. The risks associated with suprarenal aortic clamping during visceral endarterectomy include cholesterol embolization, renal failure, and paraplegia, as well as higher pulmonary and cardiac risk.

Aortomesenteric Bypass

On the basis of previous reports, many vascular surgeons favor multivessel revascularization for chronic mesenteric ischemia.[67-71] There seems to be an intuitive advantage to multivessel revascularization; however, others have convincingly argued that the single most important artery is the SMA and that successful bypass to the SMA will provide durable relief with outcomes equivalent to those of multivessel repair.[46,72] Furthermore, the controversy regarding antegrade versus retrograde bypass continues. The correct answer to these important questions for any given patient lies in the judgment of the treating physician. Success is likely for those who make appropriate judgments based on the distribution of disease, the patient's anatomy, and other clinical factors. For example, isolated revascularization of the IMA has been shown to be successful in properly selected patients. The degree of benefit from single-vessel revascularization is related to the number and quality of collateral channels to other portions of the ischemic gut.

Even the proponents of isolated SMA bypass recommend multivessel revascularization in patients in whom (1) the SMA is diffusely diseased, (2) there is a question of durability with a single bypass, and (3) a previous

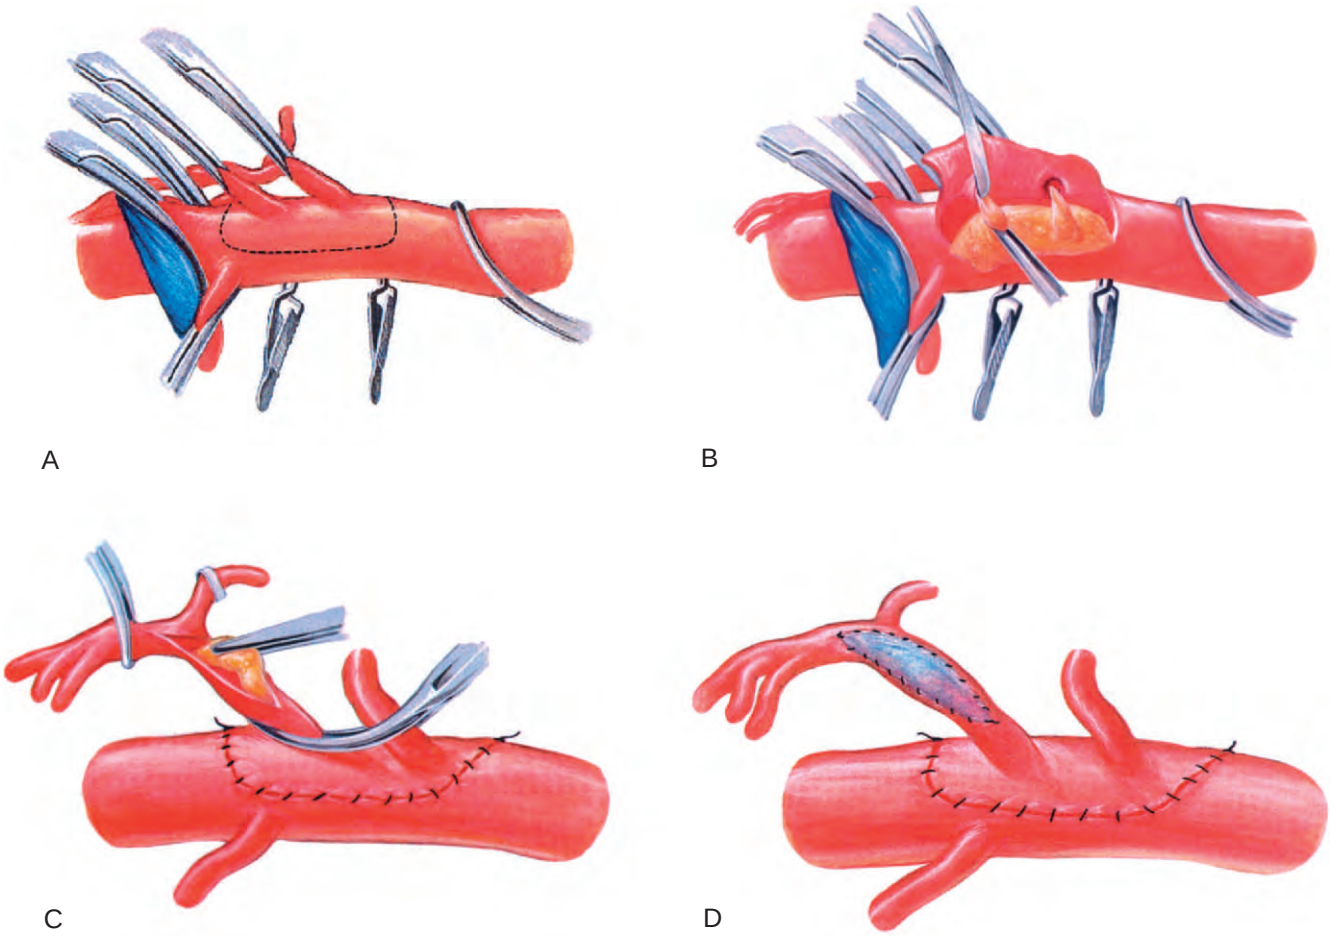

Figure 84–6. Transaortic endarterectomy for celiac and superior mesenteric stenosis. Exposure is obtained through a left thoracoabdominal retroperitoneal approach. **A,** Trapdoor aortotomy. **B,** Removal of orifice lesions from branches. **C,** After completion of transaortic endarterectomy, superior mesenteric artery (SMA) endarterectomy is completed through a separate incision (if needed). **D,** Vein patch closure of SMA. (From Wylie EJ, Stoney RJ, Ehrenfeld WK: Manual of Vascular Surgery, vol 1. New York, Springer-Verlag, 1980, pp 215-217.)

abdominal operation (especially gastrectomy and colectomy) has potentially interrupted the normal collateral connections between the superior mesenteric and celiac vascular beds.[65]

The antegrade aorta-to-celiac or aorta-to-SMA bypass is usually performed through a transperitoneal approach. The supraceliac aorta is generally soft and has much less atherosclerotic disease than the infrarenal aorta does. It is exposed by retracting the left lobe of the liver to the right after division of the triangular ligament. The gastrohepatic ligament is divided, and after entry into the lesser sac, the esophagus (which has a nasogastric tube coursing through it) is mobilized, encircled with a 1-inch Penrose drain, and retracted to the left. The diaphragmatic crura and median arcuate ligament are divided to expose a generous portion of the supraceliac aorta. The proximal celiac artery is also exposed during the course of this dissection, usually during transection of the median arcuate ligament.

The SMA is exposed through an incision at the base of the transverse mesocolon. Occasionally, the duodenum can be mobilized to aid exposure as the SMA exits from beneath the pancreas. A variety of techniques have been used, including anastomosing a 12×6 or 14×7 aortic bifurcation graft. The celiac and SMA anastomoses have been variously performed in an end-to-end or end-to-side fashion. Most frequently, the celiac revascularization is accomplished with an end-to-side anastomosis to the right hepatic artery and the SMA revascularization with an end-to-side anastomosis to the infrapancreatic SMA. Many surgeons tunnel the SMA bypass behind the pancreas, but anterior to the renal vein. A useful technique is sequential mesenteric revascularization with a single 8-mm graft, which revascularizes the celiac artery with a side-to-side anastomosis and the SMA with an end-to-side anastomosis.[69]

Mesenteric bypass from the mid infrarenal aorta to the SMA (Fig. 84–7) should be avoided because of the likelihood of kinking once the viscera are replaced after the procedure. The concept of the shortest graft being the best does not necessarily hold for mesenteric bypasses. The choice of graft material is often debated among

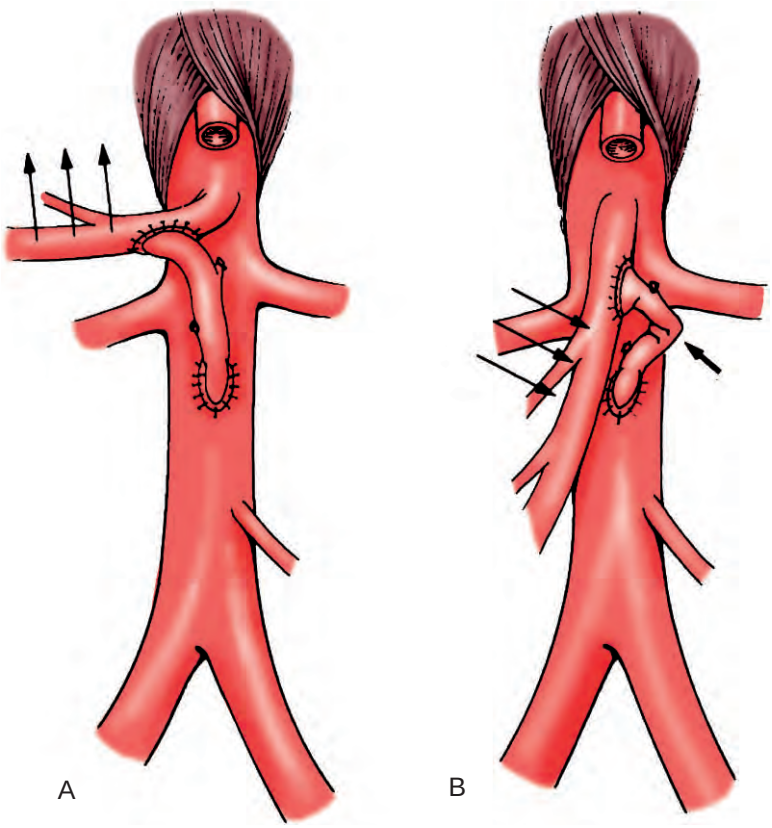

Figure 84–7. Illustration of the potential for kinking when using short saphenous vein grafts from the infrarenal aorta to the superior mesenteric artery. (From Taylor LM, Moneta GL, Porter JM: Treatment of chronic visceral ischemia. In Rutherford RB [ed]: Vascular Surgery, 5th ed. Philadelphia, WB Saunders, 2000, p 1536.)

surgeons. Although autogenous grafts are inherently more attractive from an infection and thrombogenicity perspective, they are subject to kinking and compression and may not be of adequate size to carry the blood flow required for the intestines. Normal SMA blood flow usually exceeds 750 ml/min,[73] and saphenous vein grafts of average size (<6 mm in diameter) rarely carry more than 500 ml/min.

Retrograde Bypass

Visceral bypass grafts originating from the distal infrarenal aorta or the iliac arteries offer the advantage of anatomic familiarity to all vascular surgeons and limit the amount of dissection required to achieve revascularization. Several authors have suggested that retrograde bypasses are not as durable as antegrade revascularization; however, avoidance of the common pitfalls leading to graft kinking and improvement in patient selection may eliminate many of these disadvantages.[74,75] Even proponents of antegrade bypass recognize that in certain clinical conditions retrograde bypasses are indicated: (1) emergency revascularization in patients undergoing laparotomy for acute mesenteric ischemia (an autogenous vein should be the conduit), (2) an inaccessible supraceliac aorta because of previous surgery or inflammation, (3) severe cardiac disease with contraindications to supraceliac aortic clamping, and (4) the need for simultaneous infrarenal aortic and mesenteric revascularization.[76]

Selection of the section of distal infrarenal aorta or iliac artery should be based on the distribution of atherosclerotic disease. If the infrarenal aorta and iliac artery are severely diseased, they should be replaced, with the mesenteric graft originating from the aortic prosthesis.

The most proximal suitable segment of the SMA as it passes from beneath the pancreas should be used. This maximizes the outflow bed and minimizes the likelihood of graft kinking.

The SMA anastomosis is performed first. If the conduit is autogenous vein, the viscera are returned to the abdomen and the graft placed under mild tension while constructing the aortic or iliac anastomosis (Fig. 84–8). If a prosthetic is used, it is configured in a gentle curve with the goal being to reduce the risk for graft kinking. The right hepatic artery is often a good target for celiac revascularization. Mobilization of the duodenum with a Kocher maneuver to expose the right hepatic artery or the use of a retropancreatic tunnel with the graft approaching the right hepatic artery from the left side of the abdomen provides a proper configuration that reduces the chance of graft kinking and maximizes technical success (Fig. 84–9).

Endovascular Revascularization

Operative reconstruction for mesenteric ischemia is a large operation that is usually performed on a patient with multiple risk factors who is often malnourished.

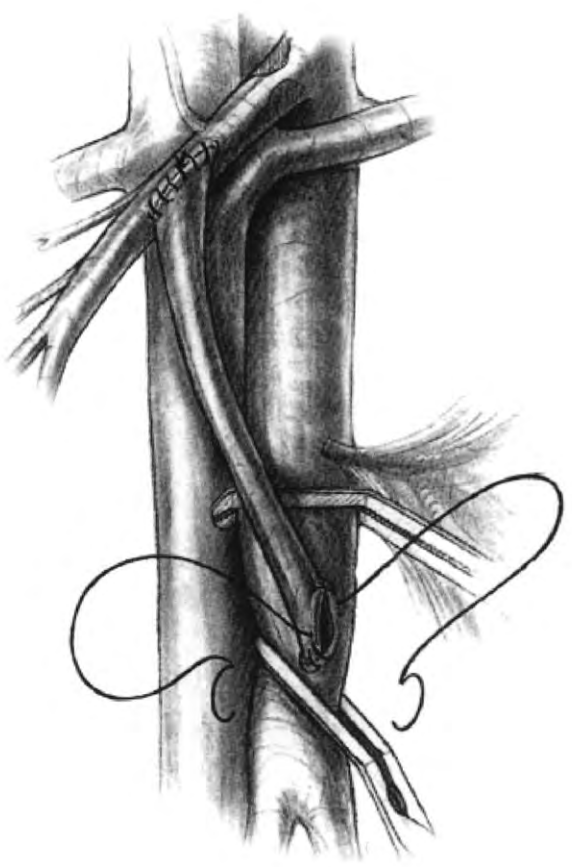

Figure 84–8. Retrograde infrarenal aorta–superior mesenteric artery bypass with autologous vein. (From Zarins CK, Gewertz BL: Atlas of Vascular Surgery. New York, Churchill Livingstone, 1989, p 107.)

Percutaneous techniques of mesenteric revascularization are intuitively attractive if they can be performed successfully with low complication rates. Tables 84–2 and 84–3 review operative and endovascular revascularization procedures for chronic mesenteric ischemia. In most operative reports, there appears to be nearly uniform early patency. However, early patency in operated patients is not usually based on objective imaging, but rather on operative observation and clinical follow-up. In contrast, endovascular procedures are always accompanied by completion arteriography, which offers more objective assessment of technical success and patency.

Procedure-related morbidity is considerably less with the endovascular approach, although it may not be readily apparent by a review of selected literature. This difference in significant morbidity may be hidden by the definition of procedure-related complications. As an example, the brachial artery approach is associated with a frequent need to repair the brachial puncture site, typically performed under local anesthesia. The authors plan to perform brachial artery repair in all patients undergoing this approach. However, when reviewing procedure-related complications, the need for a brachial artery repair is often considered numerically equivalent to renal failure, a respiratory complication, or acute myocardial infarction.

Balloon dilation of the SMA was first reported in 1980 by Furrer et al.[98] Early results have been encouraging, with technical success reported in up to 80% of patients along with symptomatic relief and improvement of nutritional status.[87,88,99,100] Current results of endovascular techniques have improved (see Table 84–3) as the technology has advanced and low-profile balloons and stents and better pharmacotherapy have become available. The high brachial approach is preferred by some because it offers a mechanical advantage in advancing balloon catheters and stents (if necessary) into the mesenteric arteries, especially the SMA. The celiac artery is externally surrounded by the dense fibers of the arcuate ligament and the crus of the diaphragm. Therefore, angioplasty alone is less likely to be effective and stenting is required more frequently. Generally, balloon angioplasty is all that is recommended, assuming that an arteriographically good result is observed. Indications for mesenteric artery stenting include (1) residual stenosis of 30% or greater, (2) an obstructing dissection or flap after percutaneous transluminal angioplasty, and (3) recurrent stenosis within 12 months of balloon dilation.[94] When these guidelines have been observed, technical success rates of 96% to 100% have been reported.[94,96] Procedure-related mortality is low and has been reported as 0% in most series. The hospital stay is short for most patients, and an increasing number are being treated as outpatients. Few, if any, require intensive care monitoring.

Figure 84–10A and B shows an arteriogram of a patient with postprandial abdominal pain and an associated 30-lb weight loss. High-grade celiac artery and SMA stenosis is apparent, and the IMA is occluded. The patient had minimal improvement of the celiac stenosis with angioplasty alone, but an excellent anatomic result of angioplasty and stenting of the SMA. The completion arteriogram in the AP view (see Fig. 84–10C and D) shows excellent collaterals to the celiac branches via the pancreatic duodenal and gastroduodenal arteries. After the procedure, the patient became asymptomatic.

The important end point is improvement in symptoms and long-term clinical success. This has been observed in approximately 85% with a mean follow-up of about 26 months (see Table 84–3). Repeat angioplasty and stenting (if necessary) for recurrent disease can generally be performed with equally low complication rates and has been associated with good technical and clinical success.

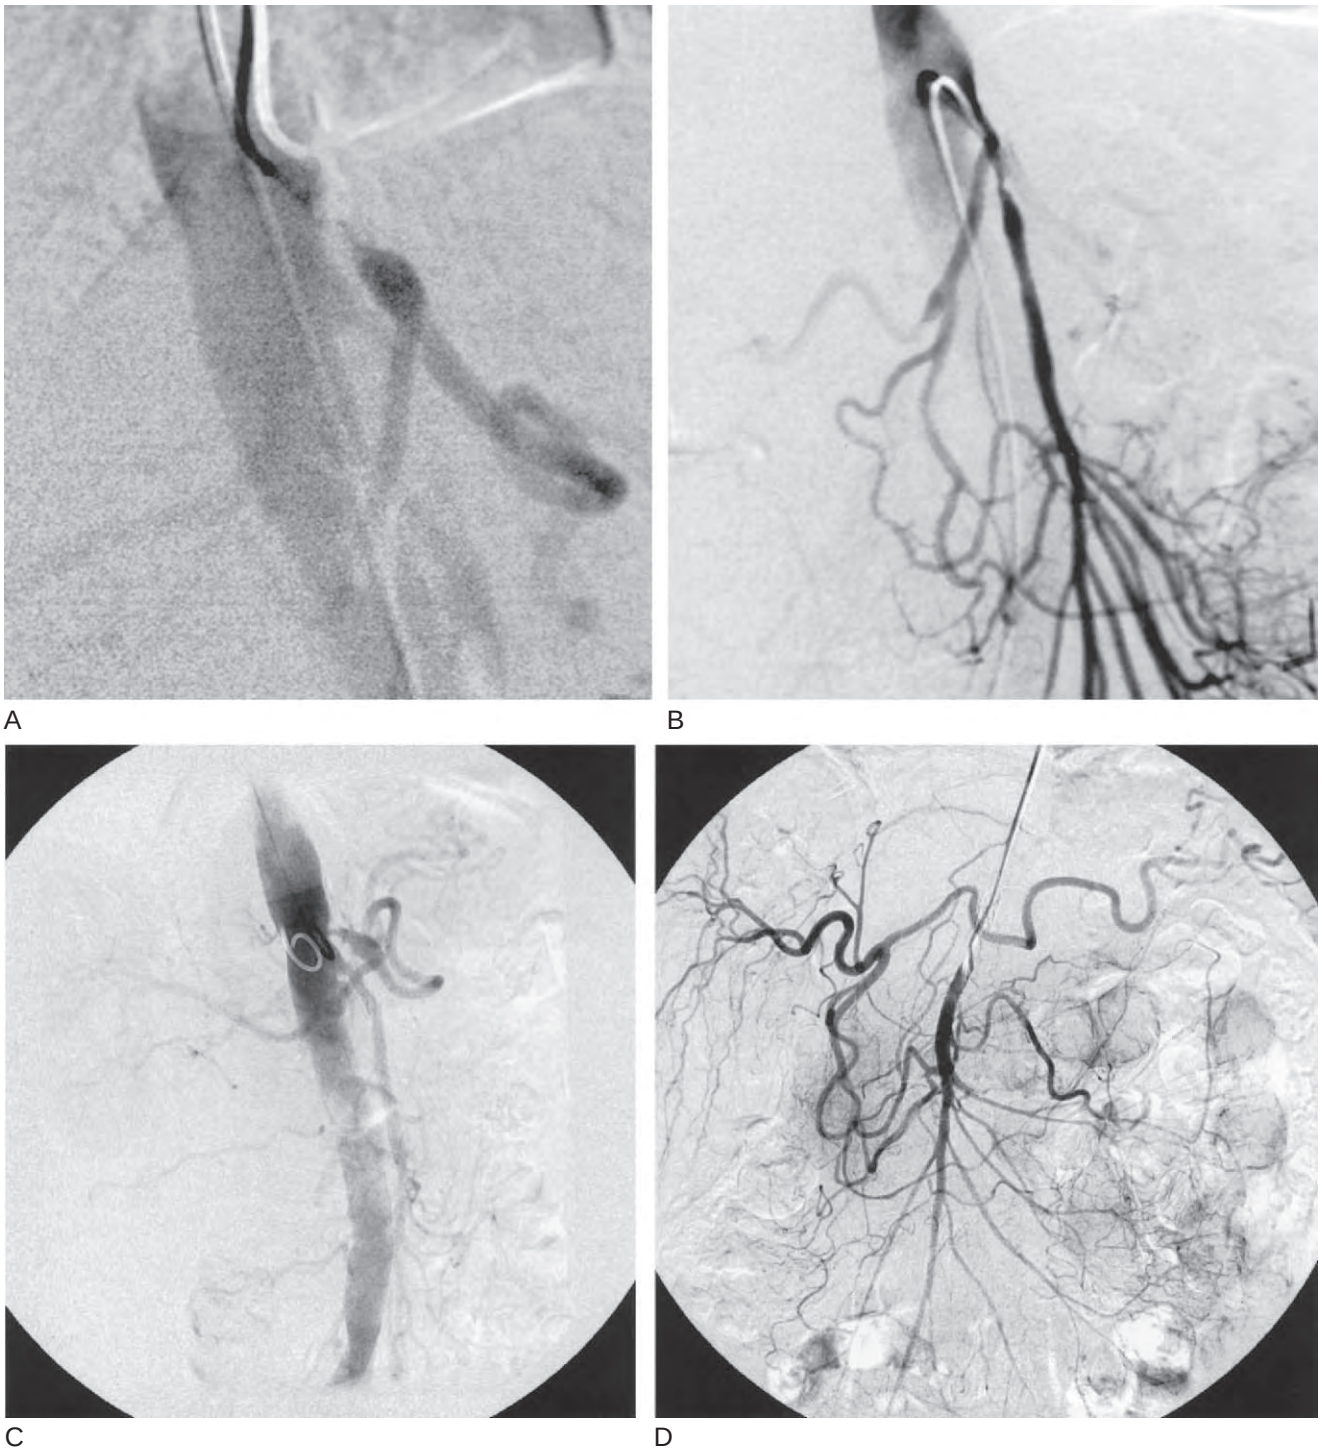

Figure 84–10. Abdominal aortograms of a woman with a 4-month history of postprandial abdominal pain, weight loss, and food avoidance. **A,** Lateral aortogram demonstrating high-grade stenosis of the origin of the celiac artery. **B,** Lateral aortogram demonstrating stenosis of the superior mesenteric artery (SMA) and no visualization of the inferior mesenteric artery. **C,** Lateral aortogram after percutaneous intervention with angioplasty of the celiac artery and angioplasty and stenting of the SMA. Note the residual stenosis of the celiac artery but good technical result of the SMA. **D,** Anteroposterior arteriogram after SMA angioplasty and stenting showing excellent filling of the celiac branches via collaterals (pancreaticoduodenal and gastroduodenal arteries). The patient remains asymptomatic 1 year after the procedure.

ACKNOWLEDGMENTS

The authors express their appreciation to Marilyn Gravett for her expert editorial assistance and to Victor Cantu for his graphics expertise during the writing of this manuscript.

Aortoenteric Fistula and Visceral Artery Aneurysms

John Blebea · Rashad Choudry

AORTOENTERIC FISTULA

Aortoenteric fistula (AEF) remains an uncommon, but potentially lethal problem that typically arises from the progressive growth of an abdominal aortic aneurysm (AAA) or, more commonly, as a complication of aortic reconstructive surgery. Early recognition and diagnosis rest on a high index of suspicion, although timely and accurate diagnosis remains difficult despite improvements in diagnostic technology. Prompt treatment can be lifesaving and prevents severe enteric hemorrhage, multisystem organ failure, or limb amputation. Recent advances in surgical and endovascular techniques, as well as perioperative care, continue to improve both the morbidity and mortality associated with AEF.

Classification

An AEF is an abnormal communication between the aorta and any gastrointestinal lumen. The classification of AEFs is based on the underlying pathophysiology, and they are categorized into either *primary* or *secondary* types. Primary AEF reflects erosion of an AAA or, in unusual circumstances, erosion of an atherosclerotic aorta into an overlying segment of intestine. Foregut, midgut, and hindgut fistulas have all been reported in the literature. The third and fourth segments of the duodenum are most commonly involved (70%) because of their close approximation to the infrarenal aorta and their fixed immobile position in the retroperitoneum.[1] Although the true incidence of primary AEF is not known, autopsy studies have found them to be present in 0.04% to 0.07% of specimens involving an atherosclerotic aorta, whereas 0.69% to 2.36% have been discovered in the presence of native aortic aneurysms.[2,3] *Secondary* AEFs are more frequently observed clinically, with an overall incidence of between 0.36% and 1.6%.[4] They typically occur after surgery on the aorta, particularly graft replacement for an AAA or atherosclerotic occlusive disease, endarterectomy, and renal or visceral artery bypass procedures. Two different types of *secondary* fistulas may develop. The first is a *graft-enteric fistula,* which originates from partial disruption of the proximal graft-aortic anastomosis. The other is a *graft-enteric erosion,* in which the bypass prosthesis directly erodes into the adjacent enteric wall. It is believed that despite a low overall incidence in the published literature, the actual occurrence of AEFs may be higher than reported. *Secondary* AEF is more commonly seen than *primary* types because of the number of aortic reconstructions performed. Recently, AEF has also been associated with endovascular aortic graft placement.[5]

Pathogenesis

Aortic wall pathology accounts for over three quarters of all *primary* fistulas and usually develops from the pulsatile enlargement of an AAA. In addition to atherosclerotic aneurysmal disease, enlargement secondary to an underlying aortic dissection can lead to AEF. More worrisome are inflammatory arteritides and infective mycotic aneurysms, tuberculosis, and syphilis, which can be initiating events of aorta-to-enteric fistulas.[2] The remainder of *primary* AEFs are thought to begin with gastrointestinal rather than aortic disease processes, including penetrating peptic ulcers, bowel wall ischemia, infection, foreign body erosion, trauma, operative injury, neoplasia, pancreatic pseudocyst, gallstones, and radiation therapy.[2,6,7]

Secondary AEFs involve a more complicated series of events ultimately leading to a similar result. Two specific mechanisms help explain the pathogenesis of these AEFs. The first involves degeneration of a proximal aortic suture line to a prosthetic graft. The etiology of such a breakdown of this anastomosis can be multifactorial, including a technical error with an insufficient amount of healthy tissue incorporated in the suture line, aneurysmal enlargement above the anastomosis when the original graft replacement was too distal from the

renal arteries, suture failure, although this is quite infrequent today, or pseudoaneurysm formation secondary to infection. All of these processes lead to localized arterial disruption and, with a progressive increase in size, can erode into nearby enteric structures and result in a *graft-enteric fistula,* which accounts for three quarters of all AEFs.[8] Because pseudoaneurysm formation after graft insertion may be the initiating event for AEF formation, yearly postoperative ultrasound scans of prosthetic aortic grafts is performed by many clinicians.

A second mechanism of AEF development involves postoperative direct erosion of a prosthetic graft into overlying adherent bowel. Long-standing contact between bowel and pulsatile prosthetic material eventually leads to thinning of the overlying bowel wall, ischemic degeneration, and enteric wall perforation and ultimately results in soilage of the underlying vascular graft. Gastrointestinal proteolytic and bacterial enzymes then erode more surface area along the graft with extension to the proximal suture line. Although the prosthetic graft itself is quite resistant to bacterial and lytic breakdown, the native aortic tissue at the anastomosis is not nearly as hardy. Eventually, a small disruption of the aorta at the anastomosis takes place and leads to bleeding from the aorta along the outside of the prosthesis and into the enteral opening with associated gastrointestinal bleeding. This process is known as *graft-enteric erosion*. The development of a *secondary* AEF without graft placement, for instance, after non–graft-related aortic reconstruction such as endarterectomy, is seen in only about 2% of patients.[8]

Surgical intervention for a ruptured AAA and for aortic atherosclerotic occlusive disease results in higher rates of secondary AEF development,[9] most likely because of the lack of an aneurysmal wall to cover the prosthetic graft in the latter circumstance and a large retroperitoneal hematoma and possible visceral wall ischemia in the former.

Several important principles can be used to prevent secondary AEF formation after aortic surgery. It is clear that direct contact between prosthetic grafts and enteric structures is key to the development of AEFs. Therefore, every effort should be made to place viable, healthy, autologous tissue between these two structures, and several options are available at the time of surgery to do so. Most commonly, in the case of AAA, the native aneurysmal wall is sufficient to cover the graft material, although this can be challenging at its most proximal point where the aortic anastomosis is located. This area, however, is usually just above the duodenum and the beginning portions of the jejunum. Although there may not be sufficient aneurysmal wall for coverage, this area should still be covered by reattaching the posterior layer of peritoneum. A greater challenge involves the placement of an aortofemoral or aortoiliac graft for occlusive disease when there is no aneurysmal wall at all to cover the prosthetic graft. This situation is especially problematic when a proximal end-to-side anastomosis is performed and more of the graft is extending anteriorly into the peritoneal cavity. In such circumstances, when insufficient retroperitoneal fat and posterior peritoneum are available to cover the graft, an omental flap can be mobilized and interposed between the graft and overlying bowel. It should cover all of the graft and be sutured in place to maintain its protective position. Correct length of the graft during insertion for any aortic procedure should be ensured so that there is no redundancy and angulation, which can also be associated with graft erosion.

Occasionally, in a hostile abdomen that has undergone previous laparotomies or has endured radiation therapy, incidental enterotomies may occur during aortic dissection. They characteristically involve the small bowel, and if they are small and without extensive spillage, aortic reconstruction can proceed safely. Similarly, associated open cholecystectomy can be performed for symptomatic cholelithiasis after the aortic procedure is completed.[10]

Perioperative administration of prophylactic antibiotics effective against gram-positive organisms, such as a first-generation cephalosporin, is routine clinical practice. Similarly, antibiotic irrigation of the abdominal cavity before closure is routinely performed. Although most primary graft infections are thought to result from prosthetic contamination at the time of placement, infection as a result of transient bacteremia from other sources may also develop, especially infection by anaerobic or gram-negative organisms.[11]

Clinical Findings

One of the most challenging aspects about AEFs is the difficulty of making a correct and timely diagnosis, which remains critical to effective resuscitation and successful treatment. Indeed, only a third of all AEFs are correctly diagnosed before surgical intervention.[4] The timing of the clinical manifestations of an AEF is quite variable and ranges from a few weeks to several years after the initial aortic reconstructive surgery.[12] Probably because of gender differences in the prevalence of AAAs, men with AEFs outnumber women by a ratio of 4:1.[13] The diagnosis of AEF is most often considered during evaluation for gastrointestinal bleeding because up to 64% of patients are seen in this manner.[2,14] Conversely, however, AEF is a rare cause of the bleeding inasmuch as less than 5% of patients with previous aortic surgery and gastrointestinal bleeding have an AEF as the underlying cause.[15] In those who do, an initial herald bleeding event is considered characteristic of AEF.[3] This may be manifested in a number of ways but commonly involves brisk upper and lower gastrointestinal bleeding. Rarely is this initial episode life-threatening, and some time is available to arrange for an endoscopic evaluation.[15] Although the initial event may be self-limited, subsequent uncontrolled fatal hemorrhage will occur if a correct diagnosis is not made and the cause left untreated.

More frequently seen is gastrointestinal hemorrhage with signs and symptoms of systemic infection. Hematemesis and fever are the two most common initial symptoms associated with a graft-enteric fistula, whereas melena and fever (sepsis) are more often seen with graft-enteric erosions.[8] Along with fever and leukocytosis, infection as an initial manifestation of AEF may be found

in 25% of patients. When present, sepsis with AEF is usually more severe than prosthetic graft infection alone. Seen less often than bleeding is abdominal pain. Primary AEF patients may complain of insidious abdominal pain, possibly related to an underlying cause such as peptic ulcer disease or neoplasia. Physical examination of patients with primary AEF reveals a palpable abdominal aneurysm in only 30%. Uncommonly, septic embolization to the lower extremities may occur and result in ischemic changes. Rarely do patients have the classic triad of gastrointestinal bleeding, abdominal pain, and a pulsatile abdominal mass.[16]

Aortoesophageal fistulas have been considered a separate pathologic entity. Like AEFs in other enteric sites, underlying aortic pathology and aortic surgery account for a large percentage of cases. Unique to esophageal fistulas, lesions of the esophagus and foreign body erosion constitute an equally prevalent number of cases. The typical site of aortic involvement in these circumstances is the thoracic aorta. Aortoesophageal fistulas remain rare, with a large proportion of cases being found at autopsy. The classic constellation of symptoms, or *Chiari's triad* (midthoracic pain, sentinel arterial hemorrhage, and subsequent exsanguination), is ascribed to this type of fistula. Like other types, upper gastrointestinal bleeding is the most common initial symptom, followed by chest pain and dysphagia.

Diagnosis

Diagnosis of an AEF may be difficult and depends on a high index of suspicion because the clinical findings may be subtle.[17] In any patient with a surgical history of bowel or aortic reconstruction and gastrointestinal hemorrhage, AEF should be considered. Attention to the patient's hemodynamic stability should take highest precedence, with unstable patients requiring immediate aggressive resuscitation followed by operative exploration of the abdomen. Patients with intermittent or self-limited bleeding can safely undergo a short preoperative work-up to assist in planning for corrective AEF surgery. Despite the spontaneous initial cessation of bleeding from many AEFs, early rebleeding occurs in 40% of patients, thus limiting the time available to arrive at an accurate diagnosis. It should be remembered that the only test that has 100% diagnostic accuracy is exploratory laparotomy.[8]

Esophagogastroduodenoscopy (EGD) remains the first and most frequently performed test in patients suspected of having an AEF.[18] EGD may best be conducted in the operating room with a qualified vascular surgeon present for patients with a high suspicion of AEF because manipulation of a quiescent AEF can lead to brisk and life-threatening bleeding. Essential to complete EGD is visualization of the fourth portion of the duodenum because it overlies the aorta and previously placed prosthetic grafts. Findings on EGD may range from mucosal surface changes to complete bowel perforation with visible prosthetic graft and active arterial bleeding. There are no therapeutic options during endoscopy to stop the bleeding. It serves only as a diagnostic procedure. Unless other definitive gastrointestinal pathology is found on EGD to explain the gastrointestinal bleeding, an indeterminate EGD cannot exclude an AEF in patients with prosthetic aortic grafts or those with aneurysmal aortas.

After EGD, computed tomography (CT) is the next most used tool (50%) in the work-up of AEF, and it has both high sensitivity (94%) and high specificity (85%).[18,19] CT scans are helpful because of their ability to image not only the aorta but also the entire retroperitoneum and bowel wall, as well as spatial relationships between the two. In patients who have previously undergone aortic reconstruction, abnormal perigraft findings may include air bubbles, fluid, obliteration of soft tissue planes, and a pseudoaneurysm. Considerable overlap does exist between CT findings in aortic infection and AEF.[19,20] Though pathognomonic, oral or intravenous contrast leak is a rare finding. Perigraft air or fluid more than a few weeks after an aortic operation is strong evidence of an AEF.[21]

Angiography is best used for preoperative planning before necessary vascular reconstruction. It rarely reveals a graft-enteric erosion or specific vascular defect, which is usually covered with thrombus, and is rarely diagnostic.[22] Angiography may document other graft characteristics that can cause overlying bowel erosion, such as a pseudoaneurysm or kink in the prosthesis.[23] The use of magnetic resonance imaging may be helpful for prosthetic graft infection; however, few convincing data have been published regarding its efficacy in the diagnosis of fistulas, and its utility in critically ill patients is also likely to be limited.

Nuclear imaging, including technetium 99m and indium 111 scans, offer high sensitivity for the diagnosis of AEF, but the associated false-positive rate may be unacceptably high for routine use (Fig. 85–1). Their applicability may be of benefit by using red blood cells to suggest the location of active gastrointestinal bleeding or in differentiating aortic graft infection with radiolabeled white blood cells.[24,25] Limited experience with ^{18}F-2-deoxy-D-glucose positron emission tomography (FDG-PET)

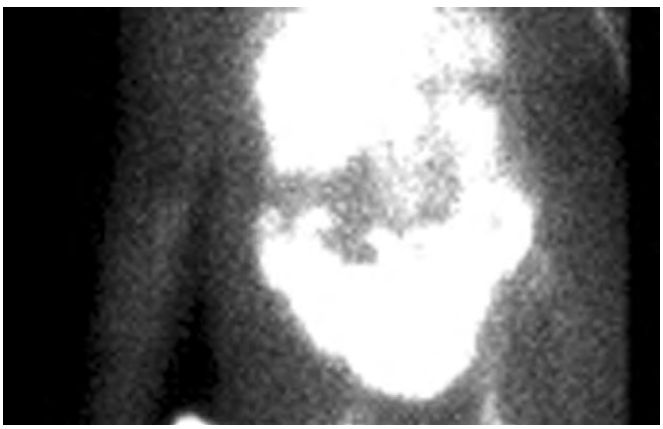

Figure 85–1. Red blood cell–labeled nuclear scan demonstrating diffuse blood in the small bowel without localization of the source of arterial bleeding.

scanning for AEF has been reported in patients with subtle signs of graft compromise.[26]

Ultrasound evaluation of the aorta and periaortic structures may be useful to screen for an aneurysm or pseudoaneurysm after surgery; however, its use in detection of AEFs is limited and therefore not recommended. Other modalities for bowel imaging, such as plain films and barium swallow, are seldom helpful for diagnosis or localization of fistulas and may interfere with other imaging because of barium artifacts.[11]

Surgical Treatment

The initial approach to patients suspected of having an AEF or those with an established diagnosis begins with an appreciation of the patient's cardiovascular status and underlying comorbid conditions. Central to planning of treatment is an appraisal of the survivability of these gravely ill patients after another major operation. Placement in an intensive care unit before and after surgery, central venous access, intra-arterial pressure monitoring, appropriate fluid resuscitation, correction of electrolyte abnormalities, and blood transfusions as needed should be undertaken. Antibiotic coverage is typically empirical until tissue culture results are available; however, appropriate coverage for gram-negative organisms, enteric bacterial species, and *Staphylococcus aureus* should be initiated.

The present standard of treatment of both primary and secondary AEFs remains surgery. Without surgery, a patient harboring an AEF will ultimately succumb to bleeding or sepsis. The primary aim of operative intervention is to stop active bleeding and prevent potential life-threatening hemorrhage. After successful vascular control, the surgeon can then address the enteric defect, infection control, and vascular reconstruction with preservation of distal blood flow.

Patients with any degree of hemodynamic instability should be resuscitated quickly and taken to the operating room without delay or extensive work-up. The initial approach should be through a midline laparotomy from the xiphoid to the pubis symphysis. Retroperitoneal exposure is an alternative approach to a diseased aorta and to avoid a hostile abdomen. However, limited visualization of the right iliac artery or graft limb and involved bowel make it a less than ideal choice for a patient in extremis. The first priority on abdominal entry should be proximal vascular control, which will in most cases best be accomplished through supraceliac aortic exposure and control. After proximal control, if the patient is hemodynamically stable, distal aortic or iliac artery control can be established. In unstable patients, distal control can be achieved through placement of occlusion balloon catheters, either through the open aorta or via a transfemoral approach. Once proximal and distal control is established, infrarenal dissection is undertaken and aortic cross-clamping performed in the infrarenal position to avoid prolonged mesenteric and renal ischemia. If hemostasis is present, systemic heparinization is induced before cross-clamping to prevent distal arterial thrombosis.

If there is no active bleeding, examination of the gastrointestinal tract should be performed. Beginning with the stomach and looking for evidence of peptic ulcer disease, a methodical running of the bowel should continue distally with particular attention paid to the area at the ligament of Treitz. Dissection of the bowel directly overlying the aorta should be performed sharply. Once the dense adhesions are freed, the AEF should be isolated and bowel repair or resection carried out as necessary. Because there is no definitive method of restoring bowel continuity, the operative anatomy should dictate the method selected. Enteric spillage into the operative field should be minimized by either clamping or oversewing any obvious defects. Small defects may be amenable to a transverse, two-layered repair, whereas segmental resection to healthy tissue is needed in other patients. Serosal patch placement and end-to-end, end-to-side, or Roux-en-Y anastomosis may be required for fistulated bowel.

Management of the aortic portion of the AEF should begin with extensive débridement of any infected retroperitoneal soft tissue. Intraoperative tissue Gram stain and culture will help in identifying the degree of infection and bacterial pathogens. Once clear tissue margins are ensured, full exposure through meticulous sharp dissection of the native aorta for primary AEF or the prosthetic graft for secondary AEF is performed. It is essential that dissection along the length of the aorta or graft be extended to well-incorporated healthy and uninfected tissue. The type of AEF will guide the manner in which the aorta is handled and the definitive reconstruction performed. If an AEF is not discovered at the usual location near the ligament of Treitz, the entire small bowel and colon should be assessed to look for other unsuspected pathology.

Primary Aortoenteric Fistula

Treatment of a primary AEF, once vascular and enteric control is established, rests on the degree of infection found at surgery. With more proximal AEFs involving structures such as the duodenum, it is possible for the bacterial inoculum to be lower than for AEFs involving more distal structures such as the colon. Nevertheless, historical studies report that up to 30% of primary AEFs may harbor infection.[27] In most cases, primary AEFs can be attributed to the progressive evolution of an aneurysmal aorta. Primary AEFs, as a result of either an aneurysmal or gastrointestinal etiology, may be repaired by either in situ graft placement or extra-anatomic bypass (EAB). Patients' medical comorbid conditions and cardiovascular instability usually dictate the use of a prosthetic graft. The use of antibiotic (rifampin)-impregnated grafts may lower the risk for infection. Alternatively, in stable patients, autologous aortoiliac bypass with superficial femoral veins is an available option.[28] In an operative field in which gross contamination or purulence is encountered, EAB is the safer alternative, although it prolongs the operative time. The key tenet in repair remains adequate débridement of all infected tissue and placement of healthy tissue between the aortic reconstruction and overlying bowel.

Secondary Aortoenteric Fistula

Of the *secondary* AEFs, aortoenteric erosions are the easier to treat. As in *primary* AEFs, the involved bowel is treated by either repair or resection. Because the aortic graft is only secondarily contaminated, excision of this segment of graft plus in situ replacement of it with another prosthetic graft is usually satisfactory. Treatment of *secondary* AEFs caused by associated aortic anastomotic disruption can be significantly more complicated because they generally involve more extensive prosthetic infection and less normal aortic tissue. Traditionally, a single operation addressing both graft excision and creation of an EAB has been associated with a high level of morbidity and mortality. In an effort to lower complications secondary to the long cross-clamp times required to perform both phases of the operation, a reversed staging approach has been adopted by some, with favorable results reported in the literature.[4] Reversed staging begins with placement of an EAB, followed by excision of the infected graft 1 to several days later.[4,9] Use of the reversed staging approach, however, depends on patient stability. Those with active bleeding or profound sepsis cannot undergo this sequence and require urgent graft excision. When possible, staging allows for decreased intraoperative blood loss, as well as avoidance of the metabolic and hemodynamic consequences of prolonged interruption of perfusion to the lower extremities. Though performed in two separate operations, each stage remains a challenging step in full reconstruction. The typical EAB includes an axillofemoral and femorofemoral bypass with preservation of pelvic blood flow in a retrograde manner from the common femoral arteries. Patients with previous bifemoral grafting and extension of infection into the groin present much more of a challenge because of the need to excise the existing anastomoses and then select new sites for distal graft placement, usually tunneled lateral to and downstream from the previous reconstruction. Once the EAB is completed, the patient is returned to the intensive care unit, where resuscitation and antibiotic coverage are continued. One to several days later, the patient is returned to the operating room for removal of the infected prosthetic graft and repair of the enteric defect.

Before graft excision, the enteric defect should be repaired or resected and gastrointestinal continuity reestablished. After complete exposure of the prosthetic graft and proximal and distal aorta, excision of the involved graft and radical débridement of infected perigraft tissue are performed. Complete removal of aortic tissue at the proximal suture line is required. If necessary to obtain viable aortic tissue because of infectious involvement extending to the renal arteries, separate revascularization with antegrade bypasses to the renal arteries can be performed. Fortunately, this is a rare occurrence. Insufficient débridement of the proximal aorta adjacent to the anastomosis has been associated with later aortic stump blowout and death from recurrent bleeding.[29] Recent studies, however, show a reduction in this complication with meticulous closure technique and the onlay of healthy autologous tissue. The stump and area of excised graft are optimally covered with an omental flap. The distal end of the aorta, after graft excision, is oversewn with monofilament polypropylene suture to prevent disruption. Thorough irrigation of the entire abdomen is required before abdominal closure. Specimens of all prosthetic and perigraft tissue should be taken for culture to help in tailoring the selection of postoperative antibiotics.

In situ reconstruction remains an important option for patients in whom EAB is not possible. Recent advances in replacement graft options have renewed interest in this type of repair, with a greater than 22% survival benefit over extra-anatomic repair.[2,30] The risk for aortic stump blowout after EAB is reported to be as high as 16% and can be avoided by using this approach.[2] Additionally, the amputation rate is 14% lower with in situ revascularization.[18] Currently, several choices of replacement conduit are available for reconstruction. Autologous tissue is ideal when reconstruction takes place in a known infected field. One useful type of autologous tissue is the superficial femoral vein used to reconstruct the aortoiliac system. An advantage over other venous tissue is its larger diameter. However, proper vein harvesting and construction of the bifurcation may be time-consuming and can lead to longer lower extremity ischemic times.[28] Saphenous vein, when sewn into a larger-diameter conduit through panel or spiral techniques, may be suitable, even for aortic replacement. Arterial allografts are seldom used because of the known risk for late aneurysmal degeneration. The use of cryopreserved homografts has been successfully reported in the literature, albeit with limited clinical experience. Authors using homografts as replacement conduits cite the inherent infection-fighting ability of this conduit, as well as its ability to function as a temporizing conduit, with definitive reconstruction performed in a delayed manner after the infection has cleared.[31] Rifampin-impregnated Dacron prosthetic grafts have demonstrated better protection against reinfection when used during in situ reconstruction.[32,33] Newer manufacturing techniques of antibiotic bonding with collagen or gelatin allow for longer antibiotic availability at the in situ site.[34]

Occasionally, in patients in whom aortic grafting was performed for occlusive disease or in patients with bilateral lower extremity amputations, graft excision without revascularization may be possible. In such circumstances, preoperative noninvasive vascular studies and arteriography can be helpful in determining the degree of available collateral circulation. Cases in which an end-to-side graft was initially placed may be handled by graft excision with aortic endarterectomy and patch closure, provided that thorough débridement of infected aortic tissue has been performed.

Endovascular Therapy

Endovascular therapies for AAA have not prevented the later development of an AEF. Such techniques, however, may also provide new options for interventions in the treatment of AEF. Despite the less invasive nature of endovascular surgery, AEF after stent deployment has been reported in the literature.[35-37] Specific aneurysmal

characteristics that may lend to the later development of an AEF after stent placement include the ongoing presence of an AAA under endotension, treatment of inflammatory aneurysms, the choice of stent, migration or kinking of endovascular devices, and unrecognized occult *primary* AEF.[37]

The therapeutic use of endovascular devices for AEF may be most helpful in the setting of acute, life-threatening hemorrhage, where timely operative control may be hindered by extensive adhesions and a hostile abdomen. Successful use of balloon control of aortic hemorrhage in a situation involving traumatic AEF has been reported.[38,39] Temporizing the bleeding from an AEF may also be accomplished through transcatheter coil embolization before operative intervention and open repair.[40] The use of endovascular repair in the presence of known aortic infection or AEF should be individualized to the patient because there is no current consensus on treatment in these circumstances. Successful stent placement in the presence of an AEF has been reported; however, recurrence of infection and fistula hemorrhage continue to be clear risks.[41-44] Stent repair of AEF is not definitive therapy because débridement and removal of associated retroperitoneal infection are not possible.[45] The use of more novel techniques, including the combined application of an aortic stent and endoscopic injection of fibrin sealant, has also been reported.[46,47] In the future, stent placement in patients with a known AEF may possibly be indicated as a bridge to definitive open repair once the acute, life-threatening circumstances are controlled or for palliative reasons.[48,49]

Results

The natural, untreated clinical course of *primary* AEF remains eventual death from gastrointestinal hemorrhage. Surgical approaches short of closure of the enteric defect, removal of infection, and vascular reconstruction, such as local patch repair or aneurysmorrhaphy, are complicated by reinfection and increased mortality.[50]

Secondary AEF follows a similar course if left untreated. Several options are currently available to handle this type of AEF, including the traditional method of fistula takedown and bowel repair, followed by graft excision, débridement, and EAB. The reversed staging technique still maintains these surgical principles but allows for reduced lower extremity ischemia times by EAB construction before intra-abdominal decontamination and repair. This method has produced improved results over the traditional technique, with an AEF cure rate of 70% (>3 years postoperatively) and 18% mortality.[4] Graft excision may be performed without revascularization, as potentially indicated for patients with occlusive disease, but it still carries a high mortality rate. More recently, renewed interest in in situ graft replacement has emerged, with investigators reporting improved surgical outcomes with appropriate patient selection and a range of bypass graft choices. A 20% reduction in mortality has been reported with in situ replacement versus EAB.[2]

Reinfection, graft occlusion, amputation, aortic stump blowout, and need for revision surgery are still seen. In a meta-analysis of *secondary* AEF by Pipinos et al., a third of patients undergoing AEF surgery suffered complications.[8] In another subset group, revision of graft placement was required in 40%, and recurrent *secondary* AEFs developed in 34%. Aortic stump rupture and anastomotic rupture occurred in 19% and 7%, respectively.[8] Amputation complicating AEF ranges from 6% after in situ repair, to 8% with lower extremity revascularization before graft excision, to 20% after EAB.[18]

Despite improvements in surgical technique and perioperative care, AEF remains a rare complication that is difficult to diagnose and treat. The majority of published data regarding AEF are in the form of small-volume, retrospective analyses or case reports, with multiple different practice standards applied. Definitive conclusions regarding any single method or technique are more difficult because of this lack of data. Death after AEF occurs in 30% to 40% of patients. Thirty-day survival rates after surgical treatment range from 13% to 86%, with an average of 33%. Overall, morbidity and mortality rates have been relatively unchanged and remain higher than seen with prosthetic graft infection. Quality of life after AEF and reconstruction has not been studied in the current literature.

VISCERAL ARTERY ANEURYSMS

Visceral artery aneurysms are relatively rare lesions. However, they are clinically important because of the potential for rupture and life-threatening hemorrhage. An increased frequency of abdominal imaging has brought to attention more visceral aneurysms than has previously been reported.[51,52] Although there is a paucity of prospective natural history data on which to base treatment recommendations, general guidelines for intervention have been developed. Newer techniques for treatment have expanded the available options for patients with visceral artery aneurysms.

Splenic Artery Aneurysms

Incidence

Splenic artery aneurysms (SAAs) are the most common visceral artery aneurysms found intra-abdominally. Only aortic and iliac artery aneurysms are more frequent. It is difficult to define the exact incidence of SAAs, with postmortem studies suggesting an incidence ranging from 0.1% to 10%. An average prevalence of 0.8% is suggested, with SAAs developing more commonly in multiparous women.[53,54] Improved and more frequently used radiographic imaging modalities are likely to increase the frequency of diagnosis of such aneurysms.

Pathogenesis

The exact etiology of SAA is not completely understood. Multiple underlying disorders are thought to be associated or directly responsible for SAA formation. Abbas et

al. reported the presence of hypertension (50%), obesity (28%), smoking (28%), and hypercholesterolemia (22%) in 217 patients with SAAs.[55] Historically, the most commonly implicated condition is arteriosclerosis. More recently, however, it has been suggested that the arteriosclerotic changes are secondary alterations in the composition of the vascular wall that are possibly associated with abnormal hemodynamic flow patterns.[56] Commonly seen in patients with SAAs is the presence of arterial fibrodysplasia, thus supporting a causative role of medial layer degeneration in the formation of these aneurysms.[54,57] Portal hypertension, cirrhosis, and splenomegaly are linked to the development of SAAs because of their contribution to elevated portal pressure and an increased diameter of the splenic artery. Accordingly, orthotopic liver transplantation has also resulted in an increased incidence of SAAs, probably because of the same mechanism. Other pathologic conditions that can lead to the development of SAAs include connective tissue disorders such as Marfan's syndrome, inflammatory states, and infection. Pseudoaneurysms can occur after traumatic injury to the abdomen, whereas chronic pancreatitis with pseudocysts leads to a 10% incidence of false aneurysms of the splenic artery.

A history of multiple pregnancies is common in women with SAAs. A recent analysis showed an average of 3.5 pregnancies in women with SAAs.[55] No single cause has explained the relationship between pregnancy and aneurysm development. Molecular and physiologic data suggest a predilection of the splenic artery to respond to changes of pregnancy, including hormonal effects and blood flow changes.[53]

Most SAAs appear saccular and may occur anywhere along the vessel. Typically, they are found along the main trunk or branch points, with multiple aneurysms occurring in up to 20% of patients. Smaller SAAs, such as those associated with systemic disease, may be found within the spleen itself. SAAs may vary in size considerably but largely fall between 2 and 3 cm. Calcification of the aneurysms occurs commonly and is found in up to 90% of splenic aneurysms.[55]

Clinical Findings

The majority of patients with SAAs are asymptomatic at the time of diagnosis. Those who do have symptoms at diagnosis are often found to have another cause for their complaints. Typical symptoms that may raise suspicion for SAA include vague, radiating left upper quadrant or epigastric pain that is exacerbated by positional changes. Episodic abdominal discomfort may be related to distal embolization of thrombus resulting in splenic infarction. SAAs are usually found incidentally by plain film radiography, CT, or arteriography for unrelated reasons. Calcification outlining the aneurysm sac tends to appear curvilinear and at the expected location of the splenic artery in the left upper quadrant.

The lifetime risk for SAA rupture may be as high as 10%, although some series have reported mortality rates as high as 25%.[58,59] Patients at increased risk for rupture include pregnant, multiparous women during the third trimester, cirrhotic patients, and those with connective tissue diseases. Symptomatic SAAs are typically due to intraperitoneal rupture. The phenomenon of *double rupture* refers to temporary lesser sac containment of a bleeding aneurysm resulting in transient symptoms, followed by breakthrough exsanguination into the rest of the abdominal cavity leading to hemodynamic collapse. SAAs may rarely rupture into adjacent structures such as the bowel, biliary tract, and splenic vein and result in occult bleeding. Symptomatic SAAs found in pregnant women have ruptured. The correct diagnosis, however, is difficult to make and can be confused with other obstetric, gynecologic, and general surgical conditions, thereby delaying emergency treatment. Mortality in pregnant women after ruptured SAAs has historically been reported to be as high as 70%, with fetal salvage being rare.[53,60]

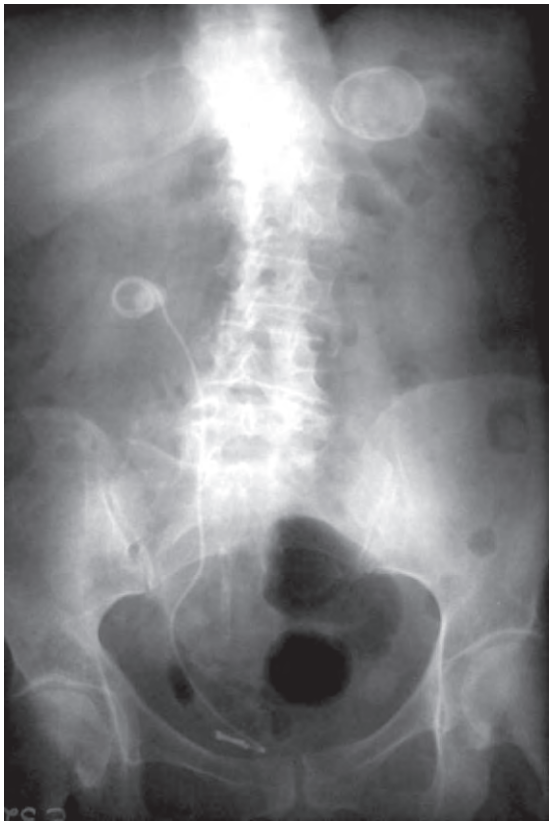
Diagnosis

Diagnosis of a symptomatic SAA rests on clinical suspicion. The initial clinical findings may lead to an evaluation for other intra-abdominal conditions first, with incidental identification of an SAA on radiographic studies. Plain abdominal radiographs may identify concentric calcifications in the left upper quadrant that suggest the presence of an aneurysm. CT scans, CT angiography, and duplex ultrasound will also be useful in the identification and diagnosis of an SAA (Fig. 85–2). Arteriography is not usually needed for identification of an aneurysm but can be helpful for operative planning before elective surgical repair. In patients in whom other modalities do not clearly define the precise vessel of origin, selective arteriography can provide the definitive diagnosis.

Treatment

The indications for treatment of an SAA have become better defined. Although definitive management of asymptomatic SAAs does not involve a fixed size cutoff for operative intervention, in good-risk patients, intervention is appropriate when the diameter of the aneurysm exceeds 2 cm. Lesions in young patients or women of childbearing age or aneurysms with progressive enlargement should be repaired electively. SAAs that are found during pregnancy are best treated at diagnosis because of the high mortality in the mother and fetus if rupture occurs. Symptomatic aneurysms should be repaired on an emergency basis.

Surgical treatment of SAAs may be individualized for each patient because several approaches are available for repair. Surgical techniques include aneurysm ligation, resection, and resection with splenectomy when the aneurysm is close to the hilum of the spleen. Because of the abundant collateral blood supply to the spleen via short gastric arteries, arterial reconstruction is not necessary. Aneurysm exclusion, accomplished through proximal and distal artery ligation, is all that is required and the preferred approach in most circumstances. Aneurysmorrhaphy, or opening of the aneurysm and oversewing the inflow and outflow vessel, is performed when adequate exposure of the proximal or distal splenic artery is



A

D

Figure 85–2. **A,** A plain abdominal radiograph shows a large calcified aneurysm in the left upper quadrant. **B,** Selective angiography of the celiac artery identifies signet-ring opacification of a splenic artery aneurysm. Thrombus on the inside of the aneurysm induces flow of contrast within the outer edges of the aneurysm. **C,** Coil embolization within the splenic aneurysm induces thrombosis of the aneurysm and occlusion of the mid and distal splenic artery. **D,** An abdominal roentgenogram illustrates the coils within the curvilinear structure of the splenic aneurysm.

not possible as a result of surrounding inflammation. Proximal ligation alone is not recommended because retrograde blood flow can potentially continue to enlarge an SAA. Splenectomy may be needed in cases in which an SAA is near the hilum or is encroaching on the parenchyma and might make exclusion hazardous. Splenectomy is not generally recommended, however, because of loss of splenic function and host resistance. A laparoscopic approach using any of these methods has been performed successfully.[61]

The characteristics of the SAA also define the manner in which exposure and subsequent aneurysm treatment are carried out. Ruptured aneurysms, patients with previous abdominal surgery and extensive adhesions, or those with severe inflammation from recent pancreatitis may make the operative approach technically challenging. SAAs are usually best approached surgically through the lesser sac with exposure and control of the proximal splenic artery. Patients with rupture and instability because of blood loss may benefit from proximal control of the splenic artery at its takeoff from the celiac trunk, after which evacuation of the contained hematoma in the lesser sac will allow easier dissection and identification of the aneurysm. Pregnancy can complicate surgery further, with the gravid uterus displacing the abdominal viscera superiorly. Cesarean delivery may be required before definitive therapy because the majority of SAAs rupture during the third trimester.

SAA embolization is an alternative endovascular technique for repair with a high reported success rate of 85%.[62] This method may be ideal for patients who are unfavorable candidates for either open or laparoscopic repair. Postembolization risks are real, however, and consist of incomplete aneurysm obliteration, coil migration, end-organ ischemia, and pain from splenic infarction.[63] Recently, stent graft exclusion of SAAs has been reported in carefully selected, high-risk patients who would benefit long-term from spleen salvage.[63-65] Endovascular stent graft placement requires sufficient normal proximal and distal splenic artery anatomy for graft anchoring. Additionally, feeding vessels to the aneurysm sac may not allow for complete endovascular exclusion and thus may contribute to a persistent endoleak.

The results of SAA treatment remain favorable, with low mortality rates in elective patients. Complications after surgery relate specifically to the performance of splenectomy when required. Recurrence after repair is rare and contingent on the technique used. Earlier diagnosis of SAA, continuing improvements in minimally invasive surgery, and endovascular stent graft placement should reduce the number and complexity of emergency aneurysm repairs in the future.

Hepatic Artery Aneurysms

Incidence

Hepatic artery aneurysms (HAAs) have historically been rare, with an incidence of approximately 0.4%.[66] They account for up to 20% of all splanchnic artery aneurysms.[67] The recent application of percutaneous procedures for biliary disease and the increased use of radiologic procedures performed for other reasons have increased the number of identified HAAs. Such aneurysms have the potential for rupture and continue to pose a threat for major hemorrhage and possible death.

Pathogenesis

Multiple different causes are responsible for the development of HAAs. Previously, an infectious cause was largely responsible for the formation of most HAAs. This incidence has decreased significantly, with only 10% presently related to infection, typically as a result of intravenous drug use or endocarditis.[68] Improvements in antimicrobial therapy have most likely also reduced this number. A significant number of HAAs found are false aneurysms, probably related to operative or percutaneous instrumentation and traumatic injury. Systemic inflammatory arterial diseases, infection, pancreatitis, liver transplantation, pregnancy, and portal hypertension have been associated with aneurysm formation. Medial degeneration and arteriosclerosis are factors in a significant number of HAAs.

Approximately 80% of HAAs are extrahepatic, with the common hepatic artery accounting for 63%. The remainder are most often seen to involve the intraparenchymal, right hepatic artery.[68] One third of HAAs are associated with aneurysms of other visceral arteries.[55] Hepatic aneurysms are usually solitary, with multiple aneurysms more frequently seen in patients with inflammatory arteriopathies, such as polyarteritis nodosa. Larger aneurysms tend to be saccular, whereas smaller ones are more fusiform in shape.

Clinical Findings

HAAs are seen twice as frequently in men as women. Both extremes of age are affected; however, patients average between 50 and 60 years of age at diagnosis. Traumatic causes may affect a younger population. Because a larger number of HAAs probably exist without being diagnosed, the majority of aneurysms are asymptomatic. Patients who do report complaints and are later found to have lesions typically have vague, right upper quadrant abdominal pain suggestive of other causes. The extreme manifestation of symptomatic HAA occurs after rupture, where peritonitis and hemodynamic compromise are usually seen. Other less common manifestations include jaundice and biliary colic secondary to extrahepatic biliary compression and obstruction. Aneurysms may also erode or rupture into adjacent organs or biliary ducts and cause massive gastrointestinal hemorrhage and hematobilia. Most often, hematobilia results from rupture of false aneurysms related to trauma. Fever is commonly seen with hematobilia. Physical examination rarely yields specific findings, and abdominal bruits are seldom found. Patients with long-standing fistulas from aneurysm rupture may have signs of chronic anemia. Quincke's triad of jaundice, abdominal pain, and hematobilia is not seen with any regularity.[69]

Diagnosis

Unless ruptured, most HAAs are not correctly diagnosed initially because other factors account for the symptoms and the HAA is an incidental finding. Some radiographic signs may indicate the presence of an HAA. Calcification of the aneurysm sac may be seen on plain films or CT. Compression of adjacent structures, such as bowel lumen or biliary ducts, can also be identified radiographically.

There are no accepted screening tests for HAA. Duplex ultrasonography and CT remain the primary methods of investigation when an aneurysm is suspected. Arteriography will effectively diagnose an HAA, but its role should most often be limited to preoperative evaluation of hepatic artery perfusion and surgical planning.

Treatment

Although aneurysm size has not been definitively correlated with the potential for rupture, HAAs carry the highest risk for rupture (44%) of any visceral aneurysm, and the mortality associated with rupture is greater than 35%.[70,71] Accordingly, aneurysm repair is recommended for all medically fit patients.

Operative planning is aided by arteriography in elective patients. Most importantly, the location of the aneurysm along the hepatic artery determines the approach. A subcostal incision or midline laparotomy is appropriate for most HAAs. Early proximal vascular control of the common hepatic artery should be carried out. Realizing the relationship of the foregut collateral vessels to an extraparenchymal aneurysm allows for determination of the need for revascularization of blood flow to the liver. Aneurysms proximal to the gastroduodenal artery takeoff may be treated by exclusionary ligation on both sides of the aneurysm with or without excision of the aneurysm.[66] An exception to this recommendation is the rare occluded superior mesenteric artery (SMA), which would limit collateral flow through the gastroduodenal artery.[66] HAAs found distal to the gastroduodenal artery involve more careful operative planning. The risk for liver necrosis after proper hepatic artery ligation can be avoided by arterial reconstruction. Arterial revascularization in such circumstances is required. A useful way to test for potential postligation liver ischemia is temporary intraoperative artery occlusion and parenchymal assessment. Multiple strategies to reconstruct the hepatic artery are available and include the use of primary end-to-end anastomosis with an autologous vein interposition graft, splenohepatic or aortohepatic bypass, and prosthetic graft placement.[71-73] Right or left hepatic artery aneurysm repair should be approached in a similar reconstructive manner. If ligation is required, adjunctive cholecystectomy is advocated to avoid postoperative necrosis of the gallbladder. Rarely, partial liver resection may be required to treat HAAs.

Advanced experience with endovascular stent graft placement makes it an attractive option in some patients. Its application may be particularly useful for intrahepatic aneurysms, small aneurysms, hostile abdomens, and patients who cannot tolerate open procedures. Percutaneous transcatheter embolization has also been used successfully in the management of HAAs but carries its own inherent risks, including parenchymal necrosis and hepatic abscess.[74] This option appears less appealing than graft placement.

Superior Mesenteric Artery Aneurysms

Incidence

Superior mesenteric artery aneurysms (SMAAs) are the third most frequent visceral aneurysms, after SAAs and HAAs. Aneurysms of the SMA and its branches have an incidence of less than 0.01%.[75] An increase in the number of reported aneurysms is likely to be seen as routine CT scans are increasingly being performed for a variety of other reasons. SMAAs are important because of their potential for rupture and the risk that they pose to small and large bowel supplied by the SMA.

Pathogenesis

Unlike other aneurysms, trauma and atherosclerosis do not account for the majority of SMAAs. Interestingly, the SMA is associated with an infectious etiology more frequently than any other muscular artery. Historically, an infectious cause was thought to be responsible for up to half of these aneurysms; however, recent reports do not support this high number of mycotic aneurysms. When infection is the underlying cause, *Streptococcus* is most commonly involved and may be related to left-sided bacterial endocarditis. Collagen vascular disorders and systemic syndromes affecting the arterial vasculature may also contribute to SMAA development in selected patients. Atherosclerosis has not been accepted as the primary cause of SMAA development; however, its presence is seen in a number of aneurysms.[76]

Clinical Findings

Similar to other visceral aneurysms, vague, intermittent abdominal pain is the leading complaint in patients found to have an SMAA. Unlike the silent nature of other abdominal aneurysms, SMAAs typically produce symptoms. Oftentimes, the symptoms may be similar to an episode of acute mesenteric ischemia. A pulsatile, mobile, epigastric mass may be found in a significant number of patients. The ability to displace the mass manually helps distinguish it from AAAs. A strong clinical suspicion should be present for patients with this type of manifestation and documented bacterial endocarditis. Ruptured SMAAs will probably cause cardiovascular collapse unless they are temporarily contained. Rupture into gastrointestinal structures does not occur routinely.

Diagnosis

Unlike other visceral aneurysms, calcification of SMAAs is not routinely seen and thus limits the usefulness of plain abdominal radiographs. Cross-sectional imaging is the preferred method of diagnosing these aneurysms, with CT scanning or duplex ultrasound yielding the most

accurate results. The role of arteriography is limited to preoperative planning and specific delineation of the celiac artery, inferior mesenteric artery, and surrounding collateral vessels.

Treatment

Operative repair of SMAAs is indicated in all patients because of the significant risk for rupture. Aneurysmorrhaphy and simple ligation are both acceptable surgical approaches. In cases in which appreciable collateral circulation has developed in response to a progressively diseased SMA, ligation proximal and distal to the aneurysm can be performed without enteric blood flow compromise. If, however, sufficient collateral flow has not developed because of stenosis in either the celiac or inferior mesenteric artery, reconstruction should be performed. Autologous vein and prosthetic routes are both acceptable and may be bypassed from the infrarenal or supraceliac aorta. In some cases, concomitant bowel resection may be required despite adequate resection and reconstruction.

Transcatheter embolization may be applied to a select group of patients who are at high risk for complications during open surgical repair. These patients should have excellent collateral flow on arteriography, and postprocedural clinical monitoring for bowel viability is warranted. Limited reports of successful embolization and stent graft placement in high-risk patients are available. There will probably be increased application of these techniques in the future.

Celiac Artery Aneurysms

Incidence

Celiac artery aneurysms (CAAs) are not well studied in the current literature, presumably because of a low overall incidence in the population. A prevalence of 5.9% has been reported, with two thirds of aneurysms found in men.[77] As with other visceral aneurysms, better and more frequent cross-sectional imaging should increase the radiographic identification of asymptomatic patients with CAAs. The importance of a CAA is related to its potential rupture and subsequent risk for death.

Pathogenesis

Unlike SAAs and HAAs, exposure to traumatic injury is uncommon in the development of CAAs. Historically, infection was thought to be a common cause of their development; however, atherosclerosis is currently the most common precursor. Other factors in the development of CAAs may include celiac axis instrumentation and medial degeneration. The frequency of associated aneurysms in other arteries may be as high as 38%.[78]

Clinical Findings

Demographically, CAAs are similar to other visceral artery aneurysms. Most aneurysms are asymptomatic before diagnosis, but epigastric pain seems to occur in a significant number of patients. Other common findings may include abdominal bruits or pulsatile masses.[79] Previously, a high incidence of CAA rupture was reported; however, a recent reappraisal does not seem to support this finding. Stone et al. reported a 6% rupture rate in a series of 18 patients, which is significantly lower than historical reports.[77] The risk for rupture has not been attributable to known risk factors. When ruptured, CAAs typically have symptoms similar to other visceral aneurysms. Intra-abdominal bleeding with hemodynamic compromise is likely to occur rapidly. The initial manifestation of a CAA may include acute mesenteric ischemia secondary to embolization of a mural thrombus within the aneurysm sac.[80]

Diagnosis

Incidental diagnosis during work-up for other disease most commonly identifies CAAs. Calcifications may be present in a small percentage of CAAs and helps in its diagnosis through plain roentgenographic studies. Ultrasound can also be useful for diagnosis. CT scanning was shown to identify 67% of CAAs in one series and is the preferred noninvasive imaging modality for CAAs.[77] Previously, arteriography was considered essential for work-up; however, its utility is effectively limited to preoperative planning.

Treatment

Not much data are available on which to base management recommendations for asymptomatic CAAs. The risk for rupture is difficult to measure in these patients, with recent reviews yielding a low overall rupture rate. The influence of aneurysm size on rupture is not clearly defined, but a size of 2 cm or greater in diameter has been recommended as a cutoff for operative treatment.[77] However, given the potential for mortality if rupture occurs (up to 40%), patients with CAAs should undergo operative intervention if they are medically fit.[78] A ruptured CAA is handled similar to other visceral aneurysms in the abdomen. Emergency surgery with early ligation of the CAA controls hemorrhage without significant ischemic threat to the liver or bowel. After proximal control is achieved, antegrade bypass revascularization from the aorta to the common hepatic and splenic artery should be attempted if the patient is hemodynamically stable.

Patients eligible for elective aneurysm resection should undergo revascularization. Reconstruction of the celiac trunk may be performed through several techniques. Either aortoceliac bypass after aneurysmectomy or aortohepatic/aortosplenic bypass should be performed. Autologous saphenous vein and prosthetic conduit are reasonable alternatives, especially with a short celiac artery. Some have suggested that prosthetic grafting may have better long-term patency than saphenous vein grafts.[77]

The use of endovascular stent grafts and embolization is currently not well reported. The short length of the celiac artery and acute angulation at its bifurcation may

limit the use of stent grafts in the near future for this indication.

Inferior Mesenteric Artery Aneurysms

Inferior mesenteric artery aneurysms are quite rare, and there are no recent reports of an increased incidence in the current literature. They will probably continue to be identified as incidental findings on cross-sectional imaging with CT or arteriography. Symptoms of these aneurysms are similar to those of other visceral aneurysms. Colonic ischemia as a result of embolization or rupture is possible, but rare. Aneurysmectomy with ligation of the inferior mesenteric artery is probably adequate treatment. The relative ease of access to this vessel would appear to make treatment recommended for all identified aneurysms. Future application of transcatheter embolization or stent grafting remains to be seen.

Mesenteric Artery Branch Aneurysms

Gastroduodenal, Pancreaticoduodenal, and Pancreatic Artery Aneurysms

Aneurysms of arteries providing collateral flow between the celiac and superior mesenteric systems are rare. Pancreaticoduodenal artery aneurysms account for only 2% to 3% of all splanchnic artery aneurysms.[81] When present, epidemiologic factors are similar to those for aneurysms found at other sites, including a gender propensity for development in men. The risk for rupture associated with these branch aneurysms is quite high (50% to 80%), and the resultant mortality exceeds 50%.[82,83]

Multiple causes exist for the development of these aneurysms; however, localized inflammation from pancreatitis is the most commonly theorized underlying cause. Pancreatitis is present in up to 60% of patients with gastroduodenal artery aneurysms and 30% of those with pancreaticoduodenal aneurysms.[79] The presence of a pancreatic pseudocyst may contribute to the arteriosclerosis leading to aneurysm formation.

The rarity and asymptomatic or nonspecific symptomatic nature of these aneurysms present a challenge for timely diagnosis and intervention. Most of them are small and nonpalpable. Physical examination alone is therefore rarely of diagnostic value before the aneurysm becomes quite large or has ruptured.[84] When calcified, the diagnosis may be suggested by its presence on an abdominal roentgenogram. Abdominal ultrasonography performed for ill-defined abdominal pain may identify the unsuspected vascular lesion (Fig. 85–3). Similarly, an abdominal CT scan can both identify these mesenteric branch aneurysms and provide an accurate measurement of their size (Fig. 85–4). In other circumstances, the diagnosis is mostly dependent on appropriate clinical suspicion and more objective subsequent evaluation. Mesenteric angiography is the definitive diagnostic modality because it not only confirms the diagnosis but also provides a necessary road map with which an appropriate therapeutic decision can be made. With

Figure 85–3. **A,** A longitudinal abdominal color duplex ultrasound demonstrates an aneurysm of the gastroduodenal artery (GDA) and an echogenic thrombus within it. **B,** Selective angiography of the celiac trunk shows the aneurysm with retained contrast in the distal portion of the gastroduodenal artery.

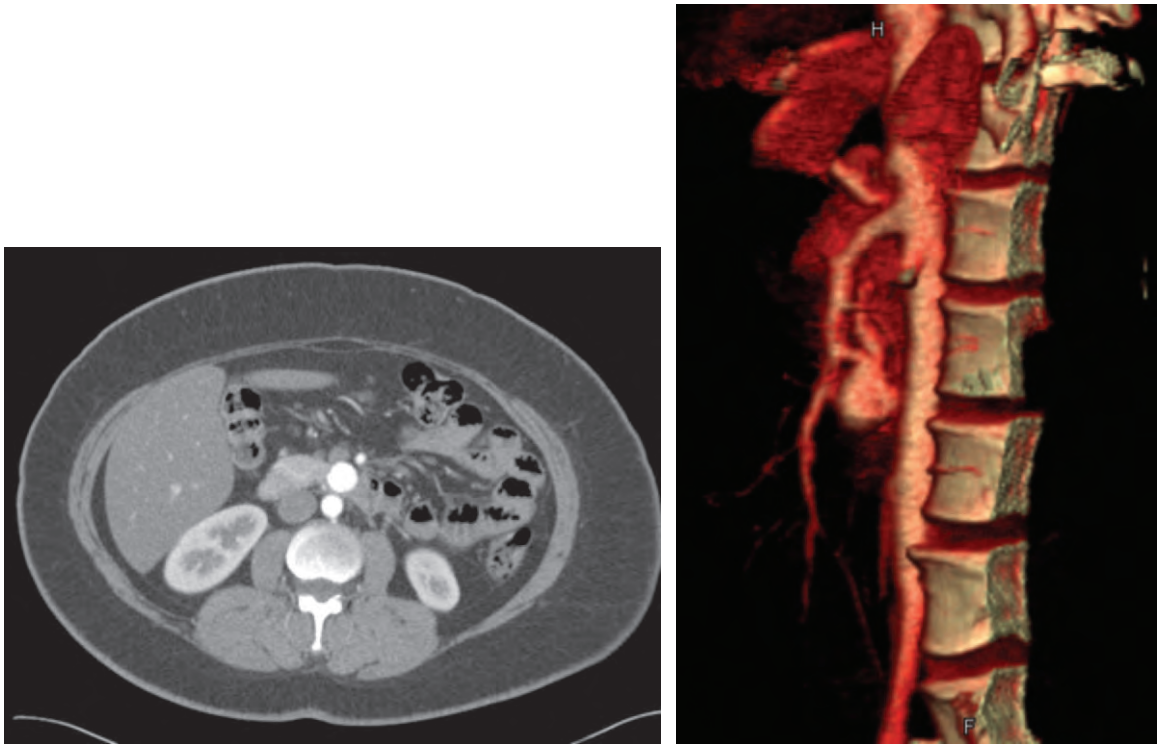

Figure 85–4. **A,** An abdominal computed tomography (CT) scan of the midabdomen with intravenous contrast identifies an aneurysm of the inferior pancreaticoduodenal artery lying between the underlying aorta and the smaller superior mesenteric artery above it. **B,** A sagittal three-dimensional reconstruction CT angiogram illustrates the inferior pancreaticoduodenal artery aneurysm arising posterior to the superior mesenteric artery.

improvements in technology, magnetic resonance angiography is also a useful noninvasive alternative to arteriography. Patients with hypotension and an evident surgical abdomen may require surgical intervention without the opportunity for a definitive preoperative diagnostic evaluation.

Most aneurysms are associated with nonspecific symptoms before the final correct diagnosis is made. Epigastric pain is the most common complaint, and it may initially appear clinically as pancreatitis. Rupture occurs with hemorrhage typically into the stomach or duodenum. Intra-abdominal cavity rupture is unusual. Rarely, obstructive jaundice may result from compression of the biliary ductal system by the expanding aneurysm. Preoperative diagnosis is rarely correctly made without a high index of suspicion. Typically, this group of ruptured aneurysms is identified at laparotomy for refractory gastrointestinal hemorrhage.

As with most visceral aneurysms, intervention is indicated when the risk for rupture and exsanguinating hemorrhage is thought to be greater than the potential risks associated with surgical or other interventional procedures. The risk for rupture of aneurysms is believed to be proportional to the size of the aneurysm.[81] Interestingly, Neville et al. found that 37% of ruptured pancreaticoduodenal aneurysms were less than 1.0 cm and there were no differences in size between ruptured and unruptured aneurysms.[85] Once such an aneurysm is diagnosed, surgical excision with or without vascular reconstruction or embolization is recommended because of the unpredictability of rupture of these aneurysms. Surgical excision is the treatment of choice. Surgical treatment of this group of aneurysms may be more difficult, however, because of the enteric erosion found in most cases and their location within the parenchyma of structures such as the pancreas. Additionally, the presence of pancreatic pathology, including pseudocysts, must be addressed at the time of surgery. A Kocher maneuver will usually be necessary for adequate exposure to ligate the aneurysm. Dissection of the aneurysm sac may be tedious and hazardous in the presence of pancreatitis. In such a situation, ligation of the feeding vessels to the aneurysm sac should suffice as treatment. In only rare cases will pancreatic resection be required. Surgical resection with revascularization is recommended in patients with significant celiac axis occlusion in order to prevent intestinal ischemia and death. If celiac or superior mesenteric artery stenosis is not an issue or if the collateral circulation is adequate, excision or ligation without vascular repair would be appropriate and is less technically demanding.

Transcatheter embolization can be used in unstable patients, those with high operative risk because of comorbid conditions, and those with unfavorable anatomy. The

presence of significant collateral circulation in this region may contribute to ineffective treatment with resultant rebleeding or rupture. The use of endovascular stent occlusion with embolization and thrombin injection has also been reported to be successful for these aneurysms.[86] Additional studies are needed to assess outcomes with these techniques.

Gastric and Gastroepiploic Artery Aneurysms

Aneurysms of these branch vessels occur with similar rarity as other branch aneurysms. Their origins may be related to a variety of initiating events, and no single cause is identified. Trauma, infection, congenital predisposition, medial degeneration, and other causes are plausible for their development.

Typical symptoms include epigastric pain and gastrointestinal complaints related to irritation or compression. Intraluminal rupture of an aneurysm may result in profound hematemesis in a significant number of patients.[87] Up to 30% of patients may have an abdominal rupture requiring laparotomy for control of bleeding.[88] Significant mortality is associated with rupture of these branch aneurysms.[83] Operative treatment includes ligation of the involved vessel and the aneurysm when technically possible. Aneurysms within the wall of the stomach may require partial gastric resection.

Jejunal, Ileal, and Colic Artery Aneurysms

This group of aneurysms is rare and typically seen as small, solitary lesions. Multiple lesions in a single patient may be found with systemic vasculitides, including polyarteritis nodosa.[89] There remains no single cause for the presence of these lesions, and congenital as well as degenerative arterial disease probably contributes to their progression. Most aneurysms remain relatively silent clinically and may be found initially at surgery for other disease. As with other aneurysms, cross-sectional imaging, including CT, duplex ultrasonography, and arteriography, can help in the diagnosis (Fig. 85–5). Arteriography may be particularly important in identifying the presence of multiple aneurysms before treatment. Rupture is difficult to predict; however, aneurysms of colic arteries are thought to rupture more commonly than those associated with the small bowel.[90,91]

Pancreas

Chapter

86

Anatomy, Physiology, and Embryology of the Pancreas

Dale E. Bockman

The healthy, mature pancreas functions silently to produce digestive enzymes and hormones. It usually comes to notice only when a pathologic alteration produces symptoms, frequently involving pain. Pancreatic access and pancreatic surgery are difficult because of the gland's retroperitoneal location in an area replete with major blood vessels and branches and multiple nerves, lymphatics, and ducts, interference with any of which can inhibit normal function.

The pancreas originates during early development of the gastrointestinal system, then differentiates and grows to produce a large gland stretching approximately 15 cm from the duodenum toward the spleen along the posterior body wall. It weighs approximately 90 g normally. Its size may decrease with diabetes or increase with chronic pancreatitis. The exocrine pancreas produces and releases digestive enzymes into the duodenum. Hormones, including insulin, are released from the endocrine portion into the blood vascular system.

Tracking the development of the pancreas from its first appearance in the primitive gut to the acquisition of its mature form can provide some understanding of its relationship with adjacent structures. Furthermore, examination of the developmental stages of the organ reveals cellular changes that are key to understanding regressive changes that may accompany pathologic alterations, which often are treated surgically.

EARLY ANATOMIC FORMATIONS

The pancreas and liver begin as epithelial buds from the primitive gut and reach their mature form through proliferation and differentiation of multiple cell types. Early in embryonic development the endoderm folds into a tube, the anterior part of which is the foregut. At the same time the precursors of major blood vessels form in the surrounding mesenchyme, which is important in early pancreatic development. The primitive aorta, paired anteriorly and fused into a single vessel in the region of the foregut, lies immediately dorsal to the gut. Primitive vitelline veins lie ventral to the gut. The primitive gut and the primitive vessels are, at this stage, tubes consisting solely of a single layer of epithelium. Interaction of the epithelium of the aorta with that of the gut induces proliferation of endodermal epithelium and the beginning of differentiation to form the dorsal primordium of the pancreas (Fig. 86–1). A similar inductive process occurs where vitelline vein endothelium touches gut endoderm to produce ventral buds. The proliferating pancreatic buds express the *Pdx1* gene,[1] providing an early marker of pancreatic differentiation.

The epithelium of the dorsal and ventral buds proliferates to form the growing dorsal and ventral pancreatic primordia (Fig. 86–2). The liver, gallbladder, and associated ducts also develop from the right ventral

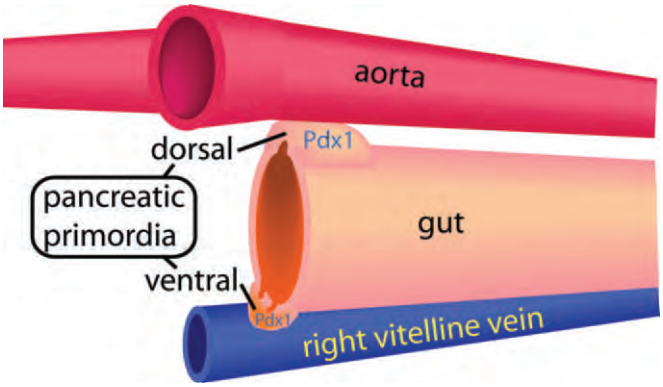

Figure 86–1. Induction of the pancreatic primordia. The epithelial interaction of aorta and gut has produced the dorsal pancreatic bud. The aorta, which originally is paired anteriorly, becomes single with development. Only the right vitelline vein is shown. The right vein persists to form the hepatic portal vein. Epithelial interaction between the vitelline veins and the gut produces primordia. The one associated with the right vitelline vein persists and develops as the ventral primordium.

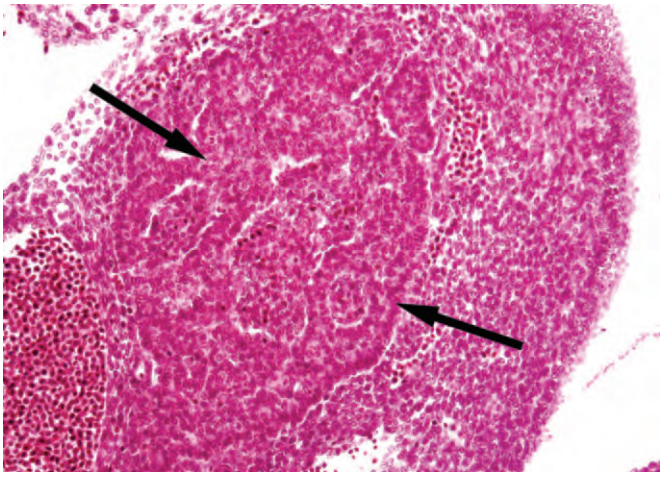

Figure 86–3. Histologic section of pancreatic primordium. The epithelium grows into surrounding mesenchyme as branching primitive tubules. The tubules anastomose in places, producing circular continuity (*arrows*).

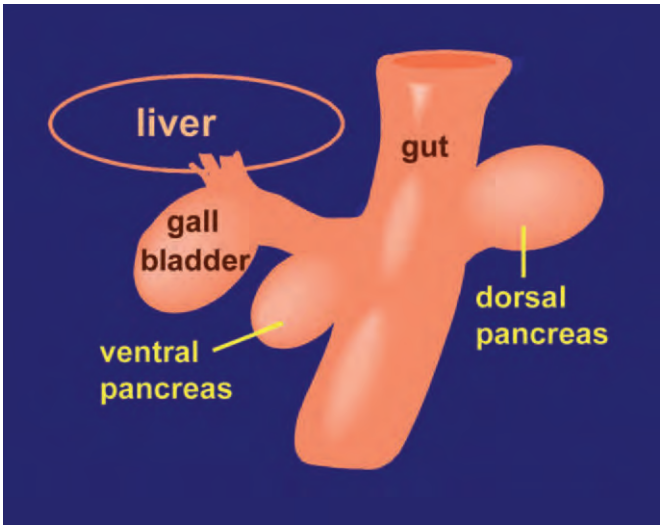

Figure 86–2. Early development of the pancreatic primordia. The dorsal and ventral primordia grow and begin the differentiation of different cell types. The liver, gallbladder, and bile duct also develop from the ventral primordium. (From Bockman DE, Freeny PC: Anatomy and anomalies of the biliary tree. Laparosc Surg 1:92-104, 1992.)

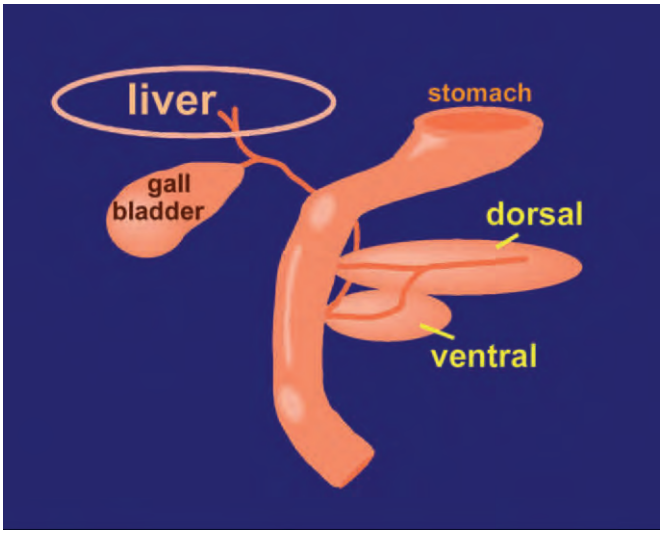

Figure 86–4. Diagram of later development of the pancreatic primordia. The ventral pancreatic primordium swings around to the same side as the dorsal. The primordia fuse, as do their ducts. The duct from the liver and gallbladder (primitive bile duct) maintains a close association with the duct of the ventral pancreatic primordium. (From Bockman DE, Freeny PC: Anatomy and anomalies of the biliary tree. Laparosc Surg 1:92-104, 1992.)

primordium. The epithelium expands as primordial tubules that branch as they grow into the surrounding mesenchyme. Mesenchyme is cellular at first. Adult connective tissue is derived from mesenchyme. Cells become more dispersed as differentiation toward adult extracellular matrix proceeds. Extracellular matrix plays a distinct role in the changes accompanying chronic pancreatitis and pancreatic cancer.[2]

Although some differentiation in genetic expression begins, the epithelial cells remain morphologically similar for some time. The branched primordial tubules, which appear as primitive ducts, may reunite within the primordium to form circular continuities (Fig. 86–3).

Further development of the gastrointestinal tract brings the embryonic ventral pancreas to the same side of the gut as the dorsal pancreas (Fig. 86–4). Fusion of

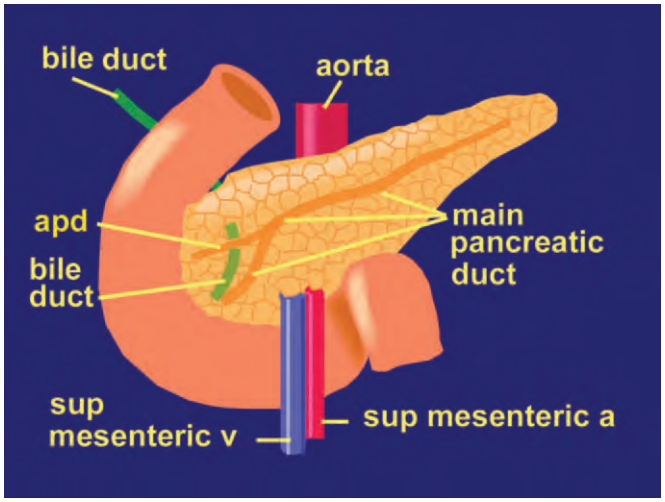

Figure 86–5. Basic associations of the mature pancreas. The head is tucked into the curvature of the duodenum. The previously separate dorsal and ventral primordia have fused completely. The main pancreatic duct develops from the duct of the ventral pancreas plus the distal part of the duct from the dorsal pancreas. The accessory pancreatic duct (apd) consists of the rest of the duct from the dorsal pancreas. The bile duct empties in common with the main pancreatic duct at the major papilla in the duodenum. If the accessory duct is patent, it empties into the duodenum at the minor papilla. The uncinate process laps around the superior mesenteric artery (sup mesenteric a) and vein (sup mesenteric v).

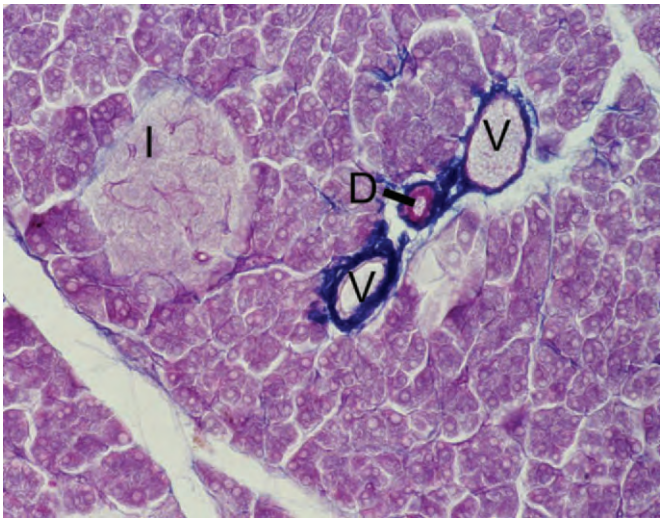

Figure 86–6. Histologic section through normal adult pancreas. Most of the figure is occupied by acinar tissue. One islet of Langerhans (I) is shown. Connective tissue is stained dark blue. It is present in moderate amounts around blood vessels (V) and a small duct (D). It is not prominent between acini and in the islet.

the two precursors takes place. Just as primitive ducts reunite within each primordium, the enlarging ducts that will drain the exocrine products of the pancreas into the duodenum anastomose with each other. The epithelial cells lining the main ductal pathways differentiate into mature duct cells. The duct of the ventral pancreas and the part of the duct of the dorsal pancreas that continues into the tail become the main pancreatic duct (Fig. 86–5). The bile duct retains its original association with the ventral primordium, entering into the duodenum with the main pancreatic duct at the major duodenal papilla. The part of the duct of the dorsal pancreas between the anastomosis and the gut becomes the definitive accessory pancreatic duct.

The pancreas initially grows within a free mesentery, but subsequent changes convert it into a retroperitoneal organ. Rotation of the gut moves the duodenum from the midline to the right side, its middle segment pressed against the dorsal abdominal wall. The pancreas, carried along in the duodenal mesentery, similarly acquires a retroperitoneal position as the mesenteric layers fuse.

Its location at the dorsal abdominal wall just posterior to the diaphragm places the pancreas into close association with a myriad of major vessels and nerves. The aorta gives off the celiac trunk on leaving the thoracic cavity and before passing along the dorsal surface of the pancreas. The superior mesenteric artery arises dorsal to the pancreas to pass ventrally over the duodenum. The superior mesenteric vein, paralleling the artery, passes to the dorsal surface of the pancreas where it is joined by the splenic vein to form the hepatic portal vein. The thinner part of the pancreas over the superior mesenteric–hepatic portal vein is its neck, separating the head from the body.

The endocrine and exocrine components of the pancreas derive from the same population of cells. Differentiation of the cells comprising the primitive ducts leads along three main pathways. At intervals cells bud off the primitive ducts, proliferate into spheroidal groups, lose their contact with the lumens, and become the islets of Langerhans. At the ends and along the sides of the primitive ducts, differentiating cells produce the spheroidal and elongate collections that constitute the acini. The remaining cells stay approximately in their original relationship to become the mature ducts.

In the mature pancreas, acinar tissue is most prominent (Fig. 86–6). Islets of Langerhans are interspersed among the acinar tissue, as are smaller (intralobular) ducts.

EARLY CELLULAR CHANGES

Early in embryonic development proliferation and differentiation of primitive duct cells produce the precursors of islets of Langerhans. The islet cells produced include those capable of expressing insulin, glucagon, somatostatin, or pancreatic polypeptide. Cells expressing each of these products are present by 14 weeks' gestational age.[3] During the early stages of islet formation, some of the cells express markers for duct cells at the same time they express insulin; that is, they represent an intermediate stage between duct cells and mature islet cells. The duct markers disappear with increased age.

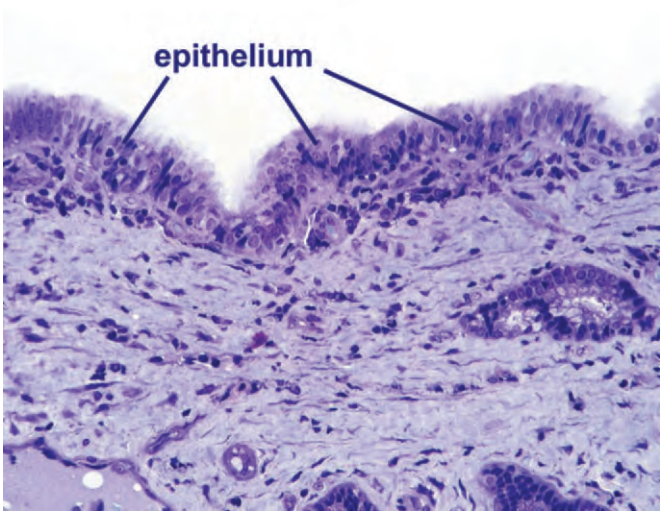

Figure 86–7. Light micrograph through a pancreatic duct. A continuous, single layer of epithelium separates the lumen (top) from the underlying connective tissue, which provides strength and substance for the wall. (From Bockman DE, Muller M, Buchler M, et al: Pathological changes in pancreatic ducts from patients with chronic pancreatitis. Int J Pancreatol 21:119-126, 1997.)

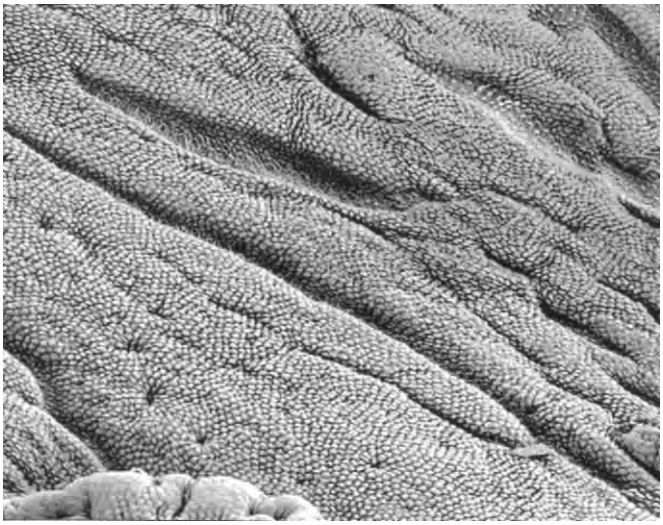

Figure 86–8. Scanning electron micrograph showing the luminal surface of a pancreatic duct. (From Bockman DE, Muller M, Buchler M, et al: Pathological changes in pancreatic ducts from patients with chronic pancreatitis. Int J Pancreatol 21:119-126, 1997.)

The rate of cellular proliferation of islet cells decreases with time.[3] Early islet cells proliferate more slowly than their primitive duct cell precursors, and proliferation becomes progressively slower with increasing gestational age. Islet cells maintain the ability to divide in the adult pancreas despite their low proliferative index.[4,5]

Distinct islets consisting of clumps of multiple cells are observed in the mesenchyme surrounding primitive ducts by 16 weeks' gestation.[3] A pattern is established that includes not only spheroidal accumulations of many islet cells (see Fig. 86–6) but also smaller numbers or single cells scattered within the pancreatic parenchyma. Single islet cells may be retained within ducts.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

Ductal Epithelial Cells

Mature ducts form a barrier between the secretion products they carry in their lumens and the surrounding extracellular matrix. The epithelium constitutes a continuous layer lining the ducts (Fig. 86–7). Ductal epithelial cells lie side-by-side with the apposing membranes at the luminal surface joined by tight junctions. Therefore interchange of fluid and ions between duct lumen and extracellular space must be a transcellular event regulated by the cells traversed. Larger ducts present a smooth, undulating surface toward the lumen (Fig. 86–8). Tightly joined ductal cells display microvilli projecting into the lumen between tight junctions (Fig. 86–9). In the absence of pancreatic disease, the ducts are surrounded by a connective tissue matrix with a small number of cells (see Fig. 86–7). With disease, however, such as chronic pancreatitis, the epithelial barrier may be missing in places,[6] with accumulation of inflammatory cells and proliferation of blood vessels exposed directly to the

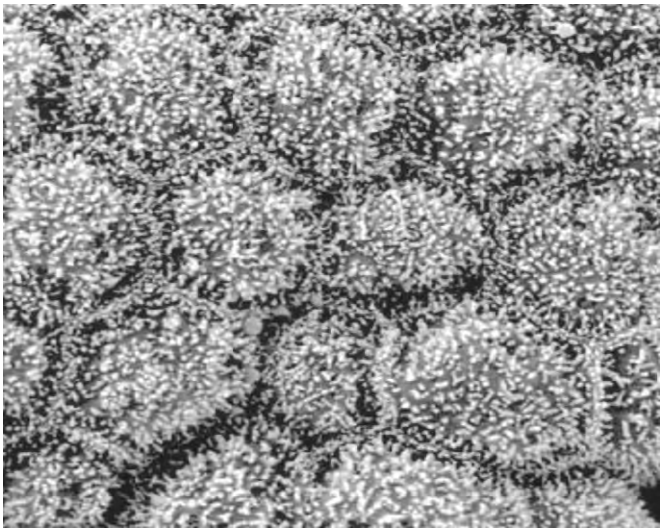

Figure 86–9. Scanning electron micrograph showing the luminal surface of a pancreatic duct at higher resolution than Figure 86–8. The epithelial cells are packed together in an approximately hexagonal array. The edges of the epithelial cells, joined by tight junctions, project slightly. The luminal surface of each cell displays short microvilli. (From Bockman DE, Muller M, Buchler M, et al: Pathological changes in pancreatic ducts from patients with chronic pancreatitis. Int J Pancreatol 21:119-126, 1997.)

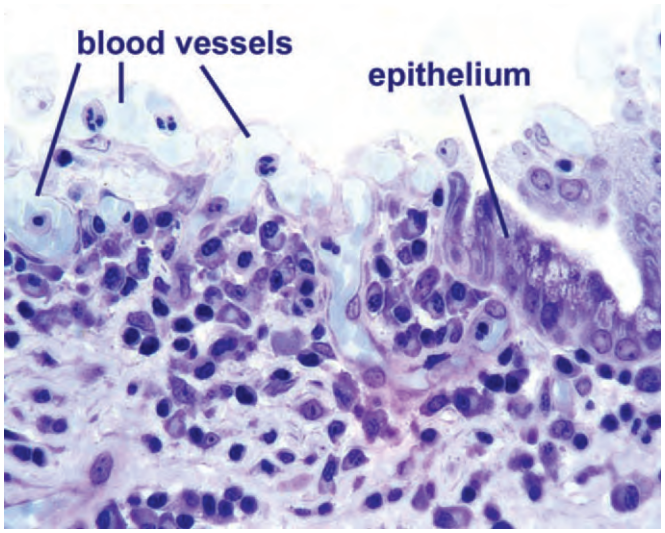

Figure 86–10. Histologic section of a pancreatic duct from a patient with chronic pancreatitis. The epithelium is not continuous; it has been breached. A large number of blood vessels are exposed directly to the lumen, and inflammatory cells are numerous. (From Bockman DE, Muller M, Buchler M, et al: Pathological changes in pancreatic ducts from patients with chronic pancreatitis. Int J Pancreatol 21:119-126, 1997.)

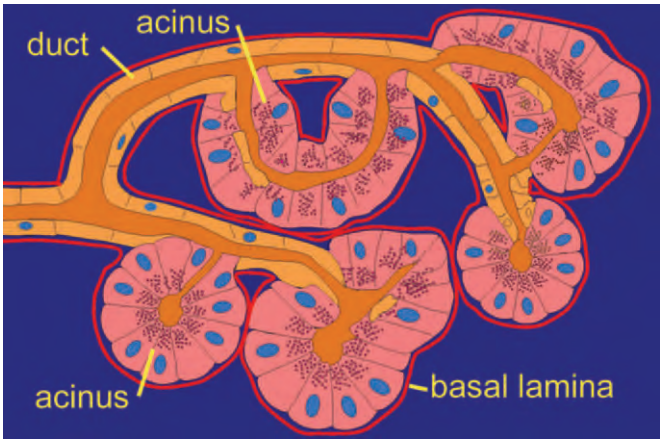

Figure 86–11. Diagram to show some of the relationships of acini to ducts. Acini may be simple spheroidal arrangements of acinar cells distributed along or at the termination of ducts. Acini also may be complex. Some may join a lumen at two ends, producing circular continuity. A continuous basal lamina is found at the base of the acinar cells. The basal lamina and tight junctions between acinar cells at the lumen provide a barrier between the lumen and the surrounding extracellular matrix. Digestive enzymes, stored as zymogen granules in the apex of acinar cells, are secreted into the lumen on stimulation. Centroacinar cells are duct cells within acini. (From Bockman DE: Histology and fine structure. In Beger HG, Warshaw AL, Büchler MW, et al [eds]: The Pancreas, Vol 1. Oxford, Blackwell, 1998, p 20.)

lumen (Fig. 86–10). In this condition interchange of substances and cells between lumen and the extracellular space of the pancreas can occur without the regulation normally provided by the ductal epithelium.

Acinar Cells

Acinar tissue constitutes the greatest proportion of the mature normal pancreas. Like islet cells, early acinar cells are derived from primitive ducts. Continued proliferation and differentiation produce the cells specialized to synthesize, store, and secrete digestive enzymes. Acinar cells are present by the 4th month of gestation. However, the relative proportions of enzymes change with time. At birth, trypsinogen levels are less than normal adult levels, lipase is only a fraction of adult levels, and amylase is almost absent.[7] Enzymes are synthesized in an abundant rough endoplasmic reticulum prominent in the base of acinar cells and packaged in the Golgi apparatus for storage. Many of the enzymes are stored in granules as precursor products (zymogens) mainly in the apex of acinar cells. Stimulation of the acinar cell releases zymogen granules at the cell membrane bordering on the acinar lumen. Activation of the enzymes occurs on entry into the duodenal lumen where enterokinase acts on the pancreatic juice conducted there through the pancreatic ductal system. Trypsin is activated, in turn activating other zymogens.

Pancreatic ducts branch and rebranch, producing progressively more and smaller ducts. The smallest ducts are intimately associated with acini. Some duct cells form tight junctions with adjacent acinar cells. The result is a continuous lumen, surrounded by a continuous epithelium, from the ductal system through the acinar system (Fig. 86–11). A duct may terminate on an acinus that is formed by a spheroidal accumulation of acinar cells. Alternately, a duct may contact one acinus, then continue on the other side to contact a second acinus.[8] Acini can be elongate, bifurcated, or multilobed. An acinus may contact a duct at two places, forming a looped lumen (see Fig. 86–11). Small ductal cells that are located within an acinus are referred to as *centroacinar cells.* Acini are grouped into microscopic lobules. Collections of these microscopic lobules are grouped together and surrounded by connective tissue septa to produce the lobulated pattern visible on the pancreatic surface with the naked eye. Once established, and in the absence of disease, the relative proportions of components are maintained in a steady state.

Dysfunctional Cellular Changes

Imposition of abnormal conditions on the pancreas leads to transdifferentiation, in which fully differentiated cells revert to another cell type. Relative proportions of components change when abnormal situations alter factors modulating cellular behavior. Some of the change can occur by necrosis and apoptosis. If, for example, acinar cells die while other cell types survive, their proportion decreases.

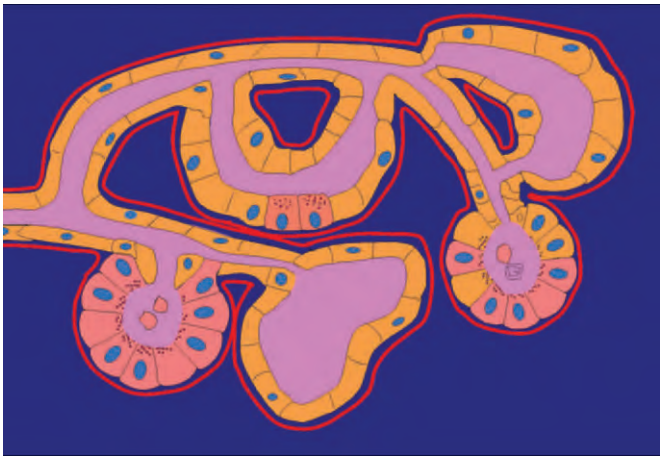

Figure 86–12. Diagram to illustrate the formation of a tubular complex by transdifferentiation of acinar cells to duct cells. Zymogen granules are sparse. Cells are lower and lumens are enlarged from the normal configuration. Cell loss occurs. The result is the appearance of collections of ducts. Compare with Figure 86–11. (From Bockman DE: Histology and fine structure. In Beger HG, Warshaw AL, Büchler MW, et al [eds]: The Pancreas, Vol 1. Oxford, Blackwell, 1998, p 20.)

A more complex change that occurs is the transition of cells backward along the path differentiation has taken. Acinar and islet cells transdifferentiate to ductal cells.[9,10] The result is clusters of small ducts, called *tubular complexes* (Fig. 86–12). Tubular complexes may be produced by obstruction of the ductal system or by genetic abnormalities. They are common in chronic pancreatitis and pancreatic cancer.

Cell markers and morphology change as acinar cells revert to a ductal phenotype,[11-13] signaling the expression of different sets of genes. Furthermore, the cells that have secondarily acquired the ductal phenotype exist in the population that is susceptible to malignant transformation.[14-16]

Cellular Membrane Function

Cell membranes regulate the transport of substances into and out of pancreatic cells, thereby controlling the physiology of the organ. The population of receptors contained in their membranes determines the response of the cells to relevant ligands. The integrity of cell membranes must be maintained to allow channels to function normally, providing precise levels of appropriate substances within the cells, at rest and during stimulation.

Pancreatic cells react to many hormones and neurotransmitters.[17] Among the variety of receptors contained in their membranes are receptors for cholecystokinin, secretin, and acetylcholine.

Release of secretin from the duodenum results in the secretion of bicarbonate-rich fluid into the ductal system. Secretin interacts with its receptor on the surface of ductal cells. Bicarbonate, generated within the cell through the action of carbonic anhydrase, is expelled into the duct lumen through the apical membrane via an exchange with chloride.[17] The channel that supplies the lumen with chloride ions is the cystic fibrosis transmembrane conductance regulator that is defective in cystic fibrosis.

Release of cholecystokinin results in secretion of digestive enzymes from acinar cells. Stimulation of secretion is accompanied by increased concentrations of intracellular calcium ions within acinar cells. The membranes of zymogen granules fuse with the apical membrane, releasing the contents of the granules into the acinar lumen. It is likely that the main interaction on the basolateral membrane of human acinar cells is not between cholecystokinin and its receptor but between acetylcholine and its receptor. Human acinar cells do not react to cholecystokinin the same as in some species.[18] Rather, it is likely that receptors for cholecystokinin on afferent fibers of the vagus nerve are activated, initiating stimulation of pancreatic secretion by vagal cholinergic pathways.[19]

Ligands and receptors normally interact within certain limits of concentration. In unusual situations the limits are exceeded. Supramaximal stimulation of acinar cells with the cholecystokinin analogue caerulein, a procedure that produces experimental acute pancreatitis, makes their cell membranes permeable to large molecules, suggesting a mechanism for the initiation of acute pancreatitis. Perhaps overstimulation via the vagus nerve damages acinar membranes, allowing early events characteristic of pancreatitis.[20]

Blood Supply

The abundant blood supply of the pancreas comes from branches of the aorta that also serve adjacent abdominal organs (Fig. 86–13). Arteries originating in the aorta branch to serve liver, stomach, spleen, and intestine in common with the pancreas. The celiac and superior mesenteric arteries constitute the primary arteries from which others are derived. The splenic and common hepatic arteries branch from the celiac. Dorsal and greater pancreatic arteries, in addition to smaller ones, branch from the splenic artery. The gastroduodenal artery branches from the common hepatic to form anterior and posterior superior branches that form loops by anastomosing with anterior and posterior pancreaticoduodenal branches of the inferior pancreaticoduodenal artery, a branch of the superior mesenteric artery (see Fig. 86–13). Arteries running in the region where the head of the pancreas apposes the duodenum supply both organs.

Abundant anastomoses of arteries provide alternate routes of circulation. The microcirculation within the pancreas is supplied by arteries that continue to branch. The arteries that penetrate the surface of the pancreas do not parallel the main ductal system. They derive from a peripheral location distinct from the ducts that originate in the duodenum and branch from central locations within the pancreas.[21] Part of the microcirculation supplies the ductal system. Vessels are numerous in the connective tissue surrounding ducts. A capillary plexus supplies the acinar tissue and drains into the venous system.

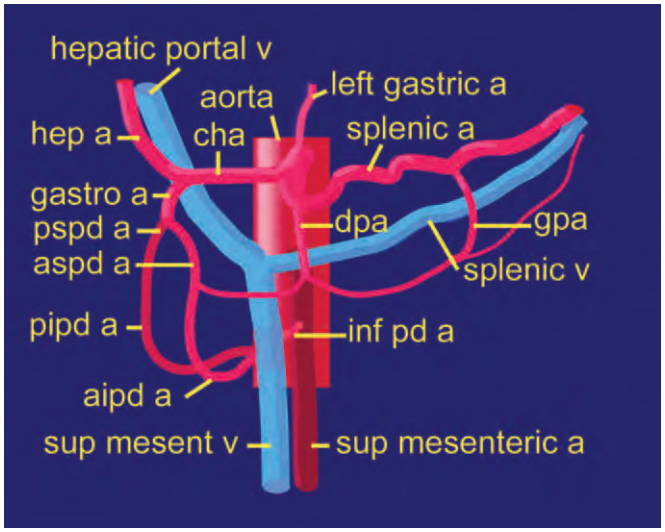

Figure 86–13. Diagram showing some of the major blood vessels associated with and supplying the pancreas. The dorsal pancreatic artery (dpa) and greater pancreatic artery (gpa) and smaller branches supply the pancreas from the splenic artery, which arises from the celiac trunk. The common hepatic artery (cha) also derives from the celiac trunk, giving rise to the gastroduodenal artery (gastro a). The anterior (aspd a) and posterior (pspd a) branches of the superior pancreaticoduodenal artery, from the gastroduodenal artery, anastomose with the anterior (aipd a) and posterior (pipd a) branches of the inferior pancreaticoduodenal a (inf pd a). These arcs and their branches supply the head region of the pancreas as well as the duodenum. The inferior pancreaticoduodenal artery branches from the superior mesenteric artery, a major branch of the aorta. The superior mesenteric vein (sup mesent v) unites with the splenic vein dorsal to the pancreas to form the hepatic portal vein.

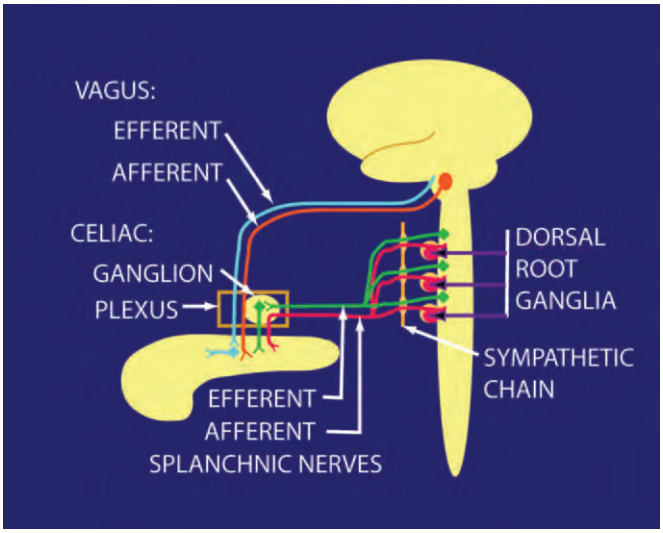

Figure 86–14. Stylized representation of the major nerves serving the pancreas. The vagus nerve carries parasympathetic (efferent) fibers and sensory (afferent) fibers to and from the brain directly. The fibers pass through the celiac plexus without synapse. Parasympathetic fibers synapse on nerve cell bodies within the pancreas. Splanchnic nerves carry sympathetic (efferent) fibers and sensory (afferent) fibers whose cell bodies are in dorsal root ganglia. Sympathetic fibers synapse on nerve cells bodies of secondary neurons in celiac ganglia, part of the celiac plexus. The sensory fibers can serve as the afferent arm of reflexes and under pathologic conditions as a route for pain impulses. The efferent fibers stimulate secretion and regulate blood flow.

The perfusion of the islets of Langerhans is much greater than that of acinar tissue.[22-23] One or more arterioles enter the islet to branch into a prominent capillary plexus (see Fig. 86–6). The fenestrated capillaries of the islets empty directly into the acinar capillary plexus.

Veins of the pancreas drain eventually into the hepatic portal system (see Fig. 86–6), so may become involved in the spread of pancreatic cancer to the liver. Cancer may invade the hepatic portal vein along its path dorsal to the pancreas.

Lymphatic System

The lymphatic system of the pancreas complements the drainage system provided by veins and serves as a route for cellular migration. Lymphatic vessels lie mostly in the connective tissue septa of the pancreas. They are not particularly numerous, they have thin walls, and they tend to collapse when not in situ, so they are difficult to observe. A few intralobular lymphatic vessels drain into the interlobular plexus. These, in turn, coalesce into larger vessels which tend to parallel the blood vessels serving the pancreas.[24] Lymphatic vessels emerge on the surface of the pancreas to enter lymph nodes. Efferent vessels from multiple nodes empty eventually into the thoracic duct.

In the normal situation the lymphatics carry mostly excess interstitial fluid so could be considered to serve as an overflow.[24] In pathologic situations, other things gain access and are conducted. Lymph-borne metastases of pancreatic cancer are found in primary and secondary lymph nodes interposed between the pancreas and the thoracic duct. Lymph nodes surround the pancreas and lie before and along the sides of the aorta and its branches. Many of the nodes are associated with blood vessels and may be described according to the vessel. Celiac, splenic, hepatic, gastroduodenal, pancreaticoduodenal, and superior mesenteric groups of nodes are described. Suprapancreatic and infrapancreatic groups lie immediately outside the pancreas.[24] Numeric designation and grouping are also used to describe nodes of importance to metastasis.[25]

Nervous System

Nerves control normal pancreatic function and serve as pain pathways and routes of cancer spread in the presence of disease. The principal nerve groups serving the pancreas are parts of the sympathetic and parasympathetic divisions along with their accompanying sensory fibers (Fig. 86–14). Sympathetic fibers carried primarily in the

splanchnic nerves originate in the intermediolateral cell column of the spinal cord. Accompanying sensory fibers have their cell bodies in the dorsal root ganglia. Parasympathetic fibers are carried with accompanying sensory fibers in the vagus nerve, which is attached to the brain. Sympathetic innervation affects pancreatic vasculature. Parasympathetic innervation modulates secretion. However, normal control of pancreatic function is complex and relies on simultaneous regulated activity of all mechanisms, so that a defect in one component can affect another. Physiologic control of and response by the pancreas is mediated in part by peptidergic innervation.[26,27] Among these neurotransmitters are substance P, neuropeptide Y, calcitonin gene-related peptide, and vasoactive intestinal polypeptide.

Splanchnic and vagus nerves pass through a plexus of nerve fibers and ganglia distributed around the base of the celiac artery. The sympathetic fibers synapse on secondary neurons in the celiac ganglia in addition to contributing to the celiac plexus. The parasympathetic fibers and sensory fibers pass through the celiac plexus without synapse. Parasympathetic fibers synapse on cell bodies of secondary neurons that form ganglia within the pancreas.

The pancreas is connected to the enteric neural system in addition to the brain and spinal cord. The enteric nervous system is an organized and interconnected network of nerve cell bodies and fibers found within and regulating the alimentary tract proper. Nerve cells in the lower stomach and duodenum extend fibers into the pancreas. A direct connection is thereby established between the enteric nervous system and that of the pancreas.[28]

Nerve fibers combine in the celiac plexus and are distributed to the substance of the pancreas as networks surrounding the arteries of supply.[29] The nerves that are distributed thus are mixed; that is, a nerve may contain sympathetic, parasympathetic, and sensory fibers. The nerves are mainly unmyelinated; that is, unlike the larger nerves supplying muscles in which nerve fibers are surrounded by layers of myelin, the nerve fibers in the pancreas are surrounded immediately by Schwann cells and contained in a protected environment[30,31] that is separated from the surrounding milieu by a perineurium (Fig. 86–15).

On direct intense stimulation of nerves, or because of damage to the perineurium and nerve fibers by invasion of pancreatic cancer or chronic inflammation accompanying chronic pancreatitis, pain may be induced and sustained. A logical approach to the treatment of unremitting pain is to interrupt the pathway conducting it. Common approaches have been to block the celiac plexus or to interrupt the splanchnic nerves since they are the principal pathways for pain conduction from the pancreas.[32]

The severity and breadth of pain generation may lead to incorporation, at least potentially, of other nerves that are less central to pain conduction from the pancreas.[33] It is possible that sensory nerves in the vagus may contribute to pain generation under appropriate circumstances. The pancreas lies on the posterior abdominal wall, and pancreatic cancer may extend from the pancreas proper to involve spinal nerves. Branches of the phrenic nerve could become involved in pain transmission.

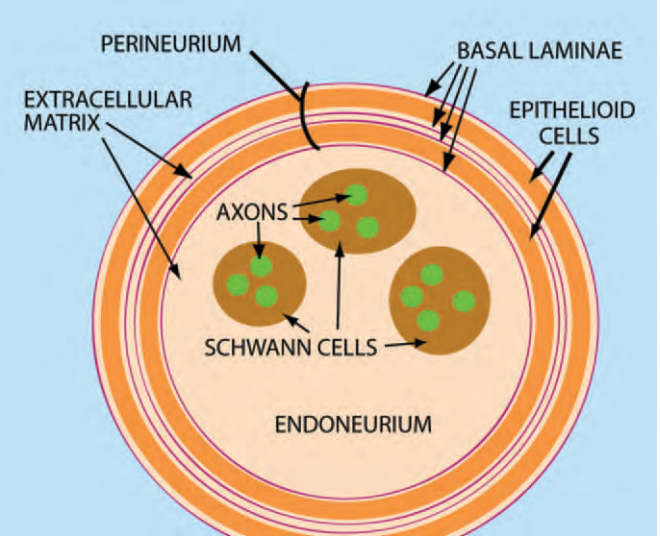

Figure 86–15. Stylized diagram of the components of a pancreatic nerve. Nerves in the pancreas are mainly unmyelinated. Afferent and efferent (sympathetic and parasympathetic) fibers may be included in the same nerve. Before the nerve ends are reached, the nerve bundles are surrounded by a multilayered perineurium that separates the inside (endoneurium) from the surrounding tissue. A specialized microenvironment is thereby maintained in the healthy nerve. The perineurium is composed of layers (here two) of epithelioid cells, basal laminae outside and inside each layer, and extracellular matrix between the layers. Individual nerve fibers are further supported and protected by surrounding Schwann cells. The interruption of the integrity of nerves by invasive cancer and chronic inflammatory cells is likely a cause of chronic pain.

After the nerve fibers carrying the impulses enter the spinal cord, they are carried to the brain where they are interpreted as pain. These are thought to travel primarily in the spinothalamic tract. There is some evidence, however, that fibers in the dorsal columns of the spinal cord may also carry chronic pain and that interruption of these fibers can provide relief.[34-36]

REGULATION OF THE PANCREAS

Development and physiology of the pancreas are tightly regulated. The normal situation is for a fully developed pancreas to respond to meals by aiding digestion and helping utilize or store glucose. To achieve this state, a long series of events, beginning in the embryo, depends on the serial expression and suppression of different genes. At the end of the differentiative process, normal function is controlled by a myriad of agents signaling among the participating components. Maintenance of normal function depends on the integrity of barriers

(individual cell membranes, epithelial layers, basal laminae) that make possible precise control.

Events that reach beyond these normal parameters lead to pancreatic disease. For the most part, the trigger for the diseases is not known. However, it is possible to recognize the deviations from normal: degeneration of acinar and islet cells and their transdifferentiation to ductal cells, alteration and expansion of the extracellular matrix, origin and extension of cancer, invasion of inflammatory cells, altered circulation, and damage to nerves. The possibility for improved treatment of pancreatic disease lies in the ability to determine what causes these deviations from normal.

Acute Pancreatitis

Scott F. Gallagher ▪ Colleen E. Jaffray ▪ Michel M. Murr

It is fascinating to conjecture how an inflammatory process in a retroperitoneal gland can produce abnormalities in so many organs.

Reginald Fitz 1889[1]

The first plausible explanations of the pathogenesis of acute pancreatitis were hypothesized by Halsted, Osler, and Opie, contemporaries at Johns Hopkins Hospital. In 1925, Sir Berkeley Moynihan declared that "acute pancreatitis is the most terrible of all the calamities occurring in conjunction with the abdominal viscera," which still holds true today.[2,3] Acute pancreatitis has widely variable clinical and systemic manifestations spanning the spectrum from a mild, self-limiting episode of epigastric pain to severe, life-threatening, multiorgan failure including sepsis, renal failure, acute respiratory distress syndrome, and death.

Despite decades of research and clinical trials, treatment remains essentially supportive as opposed to therapeutic that will treat or prevent pancreatic inflammation, the root of the problem. Improved outcomes are clearly linked to advancements in supportive care Currently, the only effective therapeutic interventions address the complications of acute pancreatitis, most commonly biliary sepsis, pancreatic necrosis, pseudocysts, infection, and sepsis; the latter account for mortality rates in excess of 50% to 80%.[4-6]

The advent and integration of minimally invasive surgery, including advanced endoscopic, radiologic, and interventional techniques, are changing the management of complicated, acute pancreatitis. Incorporation of these modalities has brought into question the use and timing of operative management for pancreatic necrosis, pseudocysts, and gallstones.

NOMENCLATURE (ATLANTA CLASSIFICATION)

Pancreatologists adapted a uniform nomenclature and classification for acute pancreatitis that became known as the *Atlanta Classification*. This was devised to establish a clinical classification system for interinstitutional comparisons and academic investigations.[4] In addition, this classification eliminates confusing, variable, local terminology and such terms as *phlegmon, infected pseudocyst, hemorrhagic pancreatitis,* and *persistent acute pancreatitis.* The definitions are as follows:

- *Acute pancreatitis* is an acute inflammatory process of the pancreas with variable involvement of other tissues or remote organ systems.
- *Mild acute pancreatitis* is associated with minimal organ dysfunction and an uneventful recovery (Fig. 87–1A).
- *Severe acute pancreatitis* is associated with distant organ failure and/or local complications such as necrosis, abscess, or pseudocyst.
- *Acute fluid collections* occur early in the course of acute pancreatitis, are located in proximity to the pancreas, and always lack a wall of granulation/fibrous tissue (see Fig. 87–1B).
- *Pancreatic necrosis* is a diffuse or focal area(s) of nonviable pancreatic parenchyma, which is typically associated with peripancreatic fat necrosis (see Fig. 87–1C).
- *Pancreatic abscess* is a circumscribed intra-abdominal collection of pus, usually near the pancreas, containing little or no pancreatic necrosis, that arises as a consequence of acute pancreatitis or pancreatic trauma.
- *Acute pseudocyst* is a collection of pancreatic fluid enclosed by a wall of fibrous or granulation tissue, which arises as a consequence of acute pancreatitis, pancreatic trauma, or chronic pancreatitis (see Fig. 87–1D).

PATHOGENESIS AND PATHOPHYSIOLOGY

Acinar Cell Injury

Normal pancreatic anatomy and physiology are discussed in Chapter 86; however, it is important to discuss the

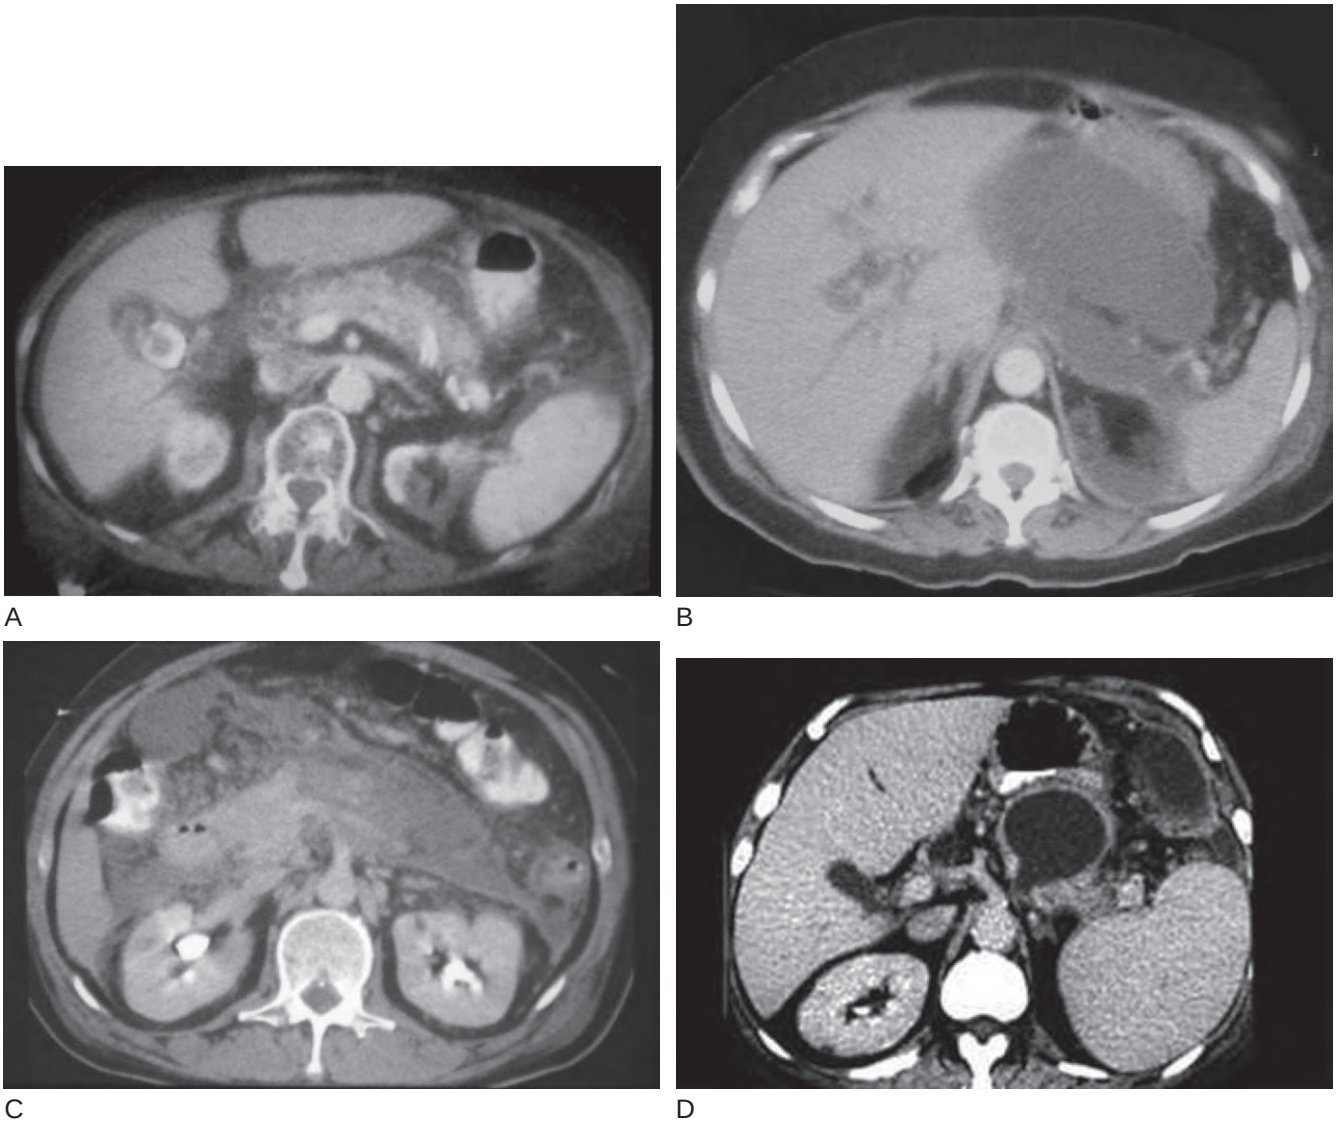

Figure 87–1. **A,** In mild acute pancreatitis, the fully enhanced pancreas shows interstitial edema; mild fat stranding is seen in the peripancreatic tissues. (**A,** From Simms M, Johnson D: Diagnosis of necrotizing pancreatitis using contrast-material–enhanced CT. Probl Gen Surg 13:14, 1996.) **B,** Acute fluid collections are poorly defined collections in the lesser sac and are a distinct clinical and radiologic entity from pancreatic pseudocysts. **C,** Necrotizing pancreatitis is characterized by the absence of enhancement of the parenchyma with intravenous contrast. The head of the pancreas enhances with contrast, whereas the body and tail do not. Note the moderate amount of fat stranding in the peripancreatic soft tissues. **D,** A pancreatic pseudocyst has a well-defined wall of fibrous or granulation tissue and contains clear pancreatic fluid. Note the absence of inflammation in the surrounding tissues.

intracellular events that govern trafficking of proteases and enzymes within acinar cells. During acute pancreatitis, the orderly packaging of digestive enzymes and proteases is disrupted, thereby resulting in colocalization of digestive zymogens and lysosomal hydrolases. The subsequent, premature activation of trypsinogen leads to acinar cell injury.

Under these conditions, intracellular calcium is increased thereby inhibiting autolysis of trypsinogen. Hence, trypsinogen remains activated and propagates acinar cell injury.[7-9] The precipitating event that leads to colocalization and acinar cell injury remains elusive. Observational hypotheses such as the "common channel theory" suggesting that bile reflux into the pancreatic duct induces acinar cell injury have not been supported by rigorous scientific data.

Local Inflammation

Acinar cell injury induces an influx of polymorphonuclear leukocytes into the perivascular pancreatic

parenchyma occurs. Within hours, hyperactivated monocytes are attracted to the site of acinar cell injury and propagate the inflammatory process through production of inflammatory mediators. As this vicious cycle feeds on itself, the ongoing acinar cell injury leads to an amplified inflammatory process, which results in the local and systemic overproduction of interleukins, tumor necrosis factor, nitric oxide, complement, platelet activating factor, free radicals, as well as other macrophage and leukocyte products. Despite their role in the propagation of acute pancreatitis, cytokines (including tumor necrosis factor and interleukin-1) have no direct effect on acinar cells and cannot initiate acute pancreatitis.[10]

Systemic Inflammation and Distant Organ Injury

Although cytokines alone cannot initiate acute pancreatitis, they play a central role in its systemic propagation. Extrapancreatic, macrophage-derived cytokine production in the lungs and liver is associated with histomorphologic organ injury and dysfunction.[11-14] Pancreatic enzymes that gain access to the systemic circulation via the inflamed retroperitoneum induce cytokine production from resident macrophages in distant organs, and a significant body of work suggests that these enzymes are the link between local inflammation and systemic manifestations of acute pancreatitis.[15-17] The mechanisms that initiate and terminate the systemic propagation of acute pancreatitis are poorly understood and warrant further investigation.

ETIOLOGY

Nearly 90% of all episodes of acute pancreatitis are attributable to gallstone disease and alcohol abuse. Geographic variation exists in the United States with urban areas tending to have more alcohol-related acute pancreatitis, whereas gallstone-induced pancreatitis predominates in other areas of the United States as well as in Europe and parts of Asia. Some suggest that alcohol-induced pancreatitis is more common in the United States due to social differences in the perception of alcoholism. Further etiologies of acute pancreatitis and clinical associations are listed in Box 87–1. The most common are briefly discussed, including biliary tract stones, alcohol, postprocedural, trauma, hyperlipidemia, hyperparathyroidism/hypercalcemia, hereditary, pancreas divisum, infection, medications, pregnancy, and idiopathic.

Controversy exists regarding the exact pathophysiology linking an impacted stone in the ampulla to acute pancreatitis; however, increased pressure in the pancreatic duct likely either promotes colocalization of digestive enzymes and lysozymes or causes transductal efflux of pancreatic enzymes directly into pancreatic parenchyma. Although choledocholithiasis can be demonstrated in only 20% of patients with acute pancreatitis, an impacted stone can be demonstrated in only 2% of these patients. Nevertheless, gallstones can be found in the stool of most patients (90%) with gallstone pancreatitis indicating that by the time patients seek medical attention, the offending gallstone may have already passed into the intestinal tract.

The precise pathophysiology is unclear. Several experimental models suggest alcohol increases pancreatic exocrine and protein secretion while increasing ampullary resistance. Alcohol is also associated with ductal hypertension, proteinaceous precipitates, and stones.

The most common cause of postprocedural acute pancreatitis (3% to 4%) is endoscopic retrograde cholangiopancreatography (ERCP). With awareness and experience, its occurrence can be minimized through gentle contrast injection into the pancreatic duct.

Box 87–1 Etiology of Acute Pancreatitis and Clinical Associations

- Pregnancy
- Scorpion *(Tityus trinitatis)* venom
- Idiopathic

ERCP, endoscopic retrograde cholangiopancreatography.

Postoperative acute pancreatitis occurs from retraction or manipulation during procedures on adjacent organs, as well as from extraabdominal procedures (i.e., cardiothoracic and orthopedic operations). Most likely, hypoperfusion occurs in the pancreatic bed during the latter procedures and leads to acinar cell injury.

Although hyperamylasemia is not rare after major blunt abdominal trauma, it is rarely (<5%) associated with the full clinical presentation of acute pancreatitis.[18]

Hereditary hyperlipidemias (including hyperlipoproteinemia types I and V) rarely cause pancreatitis. The cause is unclear, especially since hypertriglyceridemia may be absent between episodes of pancreatitis. It is hypothesized that excess free fatty acids generated by the action of pancreatic lipases within the pancreatic microcirculation initiate acinar cell injury.

Although uncommon, the association of pancreatitis and hypercalcemia often secondary to hyperparathyroidism is documented. Calcium, a known secretagogue for exocrine pancreatic enzymes, may trigger trypsinogen activation and delay its autodigestion within acinar cells.

Hereditary or familial pancreatitis exhibits an autosomal dominant inheritance pattern with incomplete penetrance and is linked to a single point mutation in the trypsinogen gene (7q35) that prevents trypsinogen autolytic inactivation.[19] The sentinel acute pancreatitis event recurs and progresses into chronic pancreatitis, which leads to gland destruction.[7]

Pancreas divisum is a normal variant in 5% to 7% of the population and results from the failure of ventral and dorsal pancreatic ductal fusion during embryonic development. Most patients with pancreas divisum do not develop pancreatitis. For those who do, elimination of gallstone disease is the first step in the management algorithm. Once other etiologies have been excluded, a dorsal pancreatic duct sphincterotomy may relieve symptoms.

In the past, a handful of infections including mumps and *Ascaris lumbricoides* were associated with acute pancreatitis; however, the acquired immunodeficiency syndrome epidemic with its subsequent opportunistic pathogen superinfections and their treatment with toxic medications have expanded the etiologic differential diagnosis of acute pancreatitis. For example, cytomegalovirus as well as antiretroviral and antitubercular medications has been linked to acute pancreatitis.

A growing list of medications is associated with acute pancreatitis (see Box 87–1). Suffice it to say that an exhaustive review of medications should be undertaken once biliary tract disease, alcohol, and other common causes of pancreatitis have been excluded.

Although acute pancreatitis has been linked to pregnancy (0.1%), most include patients with gallstones, alcohol use, or other risk factors.

In some series idiopathic pancreatitis has been reported to be as high as 40%; however, this is truly uncommon, as shown by several recent clinical trials. Specifically, biliary sludge or microlithiasis has been implicated in up to 75% of previously classified idiopathic acute pancreatitis and 83% of unexplained biliary pain.[20,21]

CLINICAL PRESENTATION

The spectrum of clinical presentations of acute pancreatitis is broad. Fortunately, 90% to 95% of patients simply experience a mild, self-limiting bout of acute pancreatitis. Though much less common, 5% to 10% of patients develop a severe, life-threatening episode associated with a prolonged hospitalization, intensive care unit (ICU) stay, and increased morbidity. Patients with severe, acute pancreatitis account for more than 80% of deaths and should be treated aggressively.

The cardinal symptom of acute pancreatitis is the insidious onset of constant epigastric pain, which often radiates to the back; however, other symptoms including anorexia, nausea, emesis, abdominal mass, or fever are often present. Patients with severe, necrotizing acute pancreatitis may develop jaundice, hypotension, shock, and signs of retroperitoneal hemorrhage, specifically an ecchymotic discoloration of the flank (Grey Turner's sign), the umbilicus (Cullen's sign), or the inguinal ligament (Fox's sign).

DIAGNOSIS

Laboratory Tests

Serum amylase and lipase remain the most widely used laboratory tests. The sensitivity of amylase is relatively low since there are multiple causes of hyperamylasemia unrelated to acute pancreatitis (Box 87–2).[22] However, concurrently increased lipase and amylase in the setting of abdominal pain increases the sensitivity and specificity of diagnosing acute pancreatitis to 90% and 95%, respectively.[22,23] Although diagnostic, serum amylase and lipase levels have not been found to correlate with pancreatitis severity. Fractionation of plasma amylase isoenzymes and the calculation of fractional amylase excretion may be helpful in patients with nonpancreatic sources of hyperamylasemia or with renal failure. Nevertheless, the advent of computed tomographic (CT) scan has rendered these latter tests nearly obsolete.

Radiologic Studies

Although the classic sentinel loop in the left upper quadrant and a diffuse ileus are commonly seen on abdominal roentgenograms, neither is pathognomonic. Nonetheless, plain films remain an essential part to exclude other diagnoses in the work-up, including perforated viscus or renal calculi.

Abdominal ultrasound (US) is rapid, inexpensive, and noninvasive. Although operator dependent, it provides information on the gallbladder as well as the biliary ductal system. Although it can detect pancreatic edema, overlying distended bowel limits visualization and renders it suboptimal for staging acute pancreatitis.

Contrast-enhanced dynamic CT with intravenous and oral contrast has an integral role in the diagnosis and management of acute pancreatitis. Not only does CT minimize the impact of operator experience, but it also provides a wealth of anatomic data so often missed or omitted on US. Findings on CT include pancreatic

edema, peripancreatic fluid collections, mesenteric fat stranding, inflammation, biliary tract stones, and bile duct size. Absence of enhancement (>3 cm or >30% of gland) is the hallmark of pancreatic necrosis (see Fig. 87–1C). Additionally, extravisceral gas (Fig. 87–2), pneumoperitoneum, free fluid in the pelvis or gutters, and hemorrhage into the lesser sac are critical findings. Most important, CT scanning provides a tool for staging of pancreatic and peripancreatic inflammation.

Balthazar identified criteria for CT findings in acute pancreatitis: A, normal; B, pancreatic edema; C, peripancreatic fat abnormalities; D, single fluid collection; and E, multiple fluid collections or gas. Later, Balthazar incorporated pancreatic necrosis into a CT severity index (0 to 10). Patients with CT index greater than 7 had a 17% mortality, whereas patients with a CT index less than 3 had no mortality.[24]

An alternative to CT is magnetic resonance imaging using gadolinium and magnetic resonance cholangiopancreatography (MRCP). Their use has been relatively limited and not well-studied. MRCP is an option where ERCP is not technically feasible as a diagnostic modality; however, MRCP precludes the interventional aspects of ERCP.

ERCP is rarely indicated in mild, uncomplicated acute pancreatitis. It is, however, important for diagnostic and therapeutic intervention for severe, acute pancreatitis and its complications. Specifically, ERCP provides an essential tool in our armamentarium to remove impacted stones, decompress the biliary tree, and delineate pancreatic ductal anatomy.

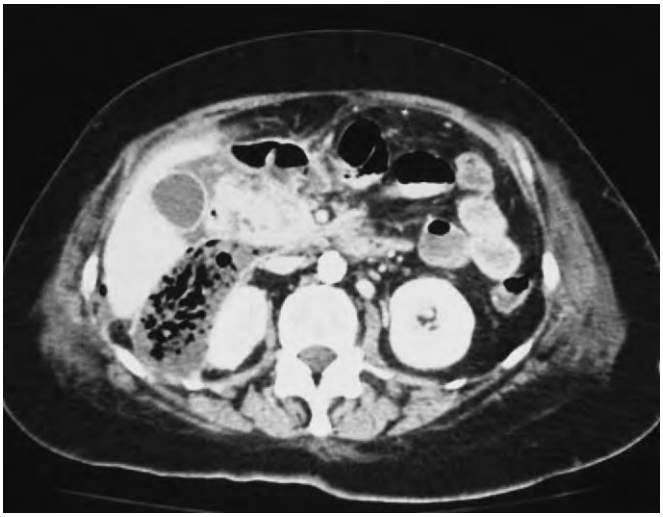

Figure 87–2. Acute pancreatitis complicated by extravisceral air in a fluid collection that was predominantly located in the right pericolic gutter suggestive of perforated viscus or infected necrotizing pancreatitis.

PROGNOSTIC INDICATORS

Because of the variability and seeming unpredictability of acute pancreatitis, clinical scoring systems have been developed to predict the severity of acute pancreatitis and, as important, for patient stratification and enrollment in clinical trials.

Ranson's criteria is the most commonly used scoring system and is based on 11 clinical and laboratory parameters measured within the first 48 hours of admission to the hospital (Table 87–1).[25] Patients with one or two criteria have a predicted mortality of less than 1% compared to patients with three criteria (10%) or four criteria (15%); with more than seven criteria, the predicted mortality approaches 50%. Although specific to acute pancreatitis, complete assessment with this one-time score may not be available until 48 hours after admission.

Modified Glasgow criteria are based on eight clinical and laboratory parameters measured within 48 hours of admission (Table 87–2).[26] Its limitations are similar to Ranson's criteria.

Acute Physiology and Chronic Health Evaluation (APACHE)-II scoring system (Box 87–3)[27] incorporates 12 physiologic and laboratory parameters as well as age and comorbid conditions to estimate severity of any disease process. Specifically, a score greater than 9 signifies severe, acute pancreatitis. The APACHE-II scoring system overcomes the shortcomings of Ranson's criteria such that it can be determined on a daily basis; however, it

Table 87–1 Ranson's Criteria

Ranson's Criteria	Nonbiliary Acute Pancreatitis	Biliary Acute Pancreatitis
Admission		
Age (yr)	>55	>70
WBC count (×1000/mm^3)	>16	>18
Glucose (mg/dl)	>200	>220
AST (IU/L)	>250	>250
LDH (IU/L)	>350	>400
Within 48 Hours of Admission		
Hematocrit decrease (points)	>10	>10
BUN increase (mg/dl)	>5	>2
Base deficit (mEq/L)	>4	>5
Fluid replacement (L)	>6	>4
PaO_2 (mm Hg)	<60	<60
Calcium (mg/dl)	<8	<8

AST, aspartate aminotransaminase; BUN, blood urea nitrogen; LDH, lactate dehydrogenase; WBC, white blood cell.

Table 87–2 Modified Glasgow Criteria: Within 48 Hours of Admission

Criteria	Value
Age (yr)	>55
WBC count (×1000/mm^3)	>15
Glucose (mg/dl)	>180
BUN (mg/dl)	>45
LDH (IU/l)	>600
Albumin (g/dl)	<3.3
PaO_2 (mm Hg)	<60
Calcium (mg/dl)	<8

BUN, blood urea nitrogen; LDH, lactate dehydrogenase; WBC, white blood cell.

remains somewhat cumbersome to calculate and is not specific for acute pancreatitis.

Multiorgan Dysfunction Score (MODS) is similar to APACHE-II; this organ-injury based scoring system has been used to predict disease severity. When applied to acute pancreatitis, a score higher than 2 predicts early mortality.[28]

MANAGEMENT OF MILD ACUTE PANCREATITIS

The mainstay of managing mild, acute pancreatitis is supportive (Fig. 87–3). Since most patients with acute pancreatitis (90% to 95%) fall into this self-limiting category, emphasis is more on determining cause and preventing recurrence. US and CT scan are important in diagnosis and radiologic staging of pancreatitis (see Fig. 87–1A); however, there is essentially no role for diagnostic ERCP. In elderly patients with an index of suspicions for malignancy, a contrast-enhanced dynamic CT should be obtained to evaluate the pancreas in conjunction with surrounding biliary tract and retroperitoneal structures.

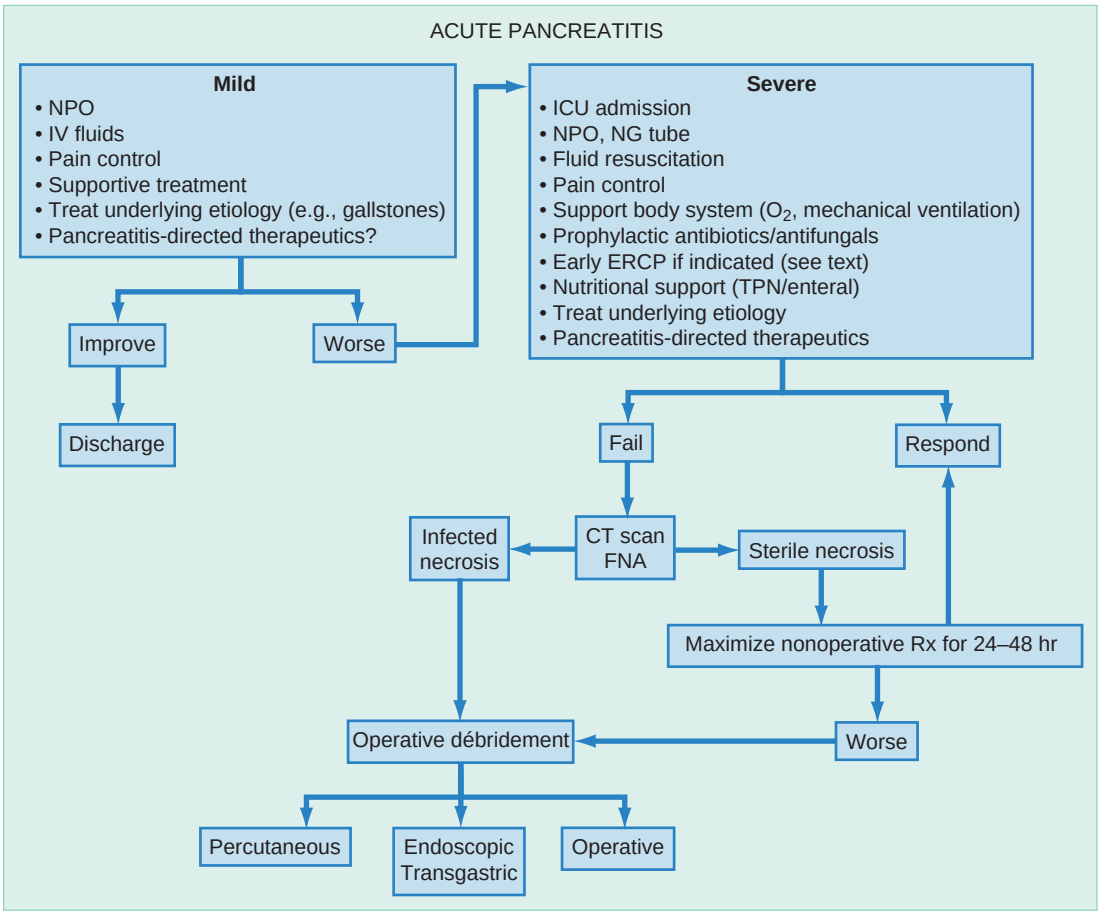

Figure 87–3. Algorithm for treatment of acute (mild to severe) pancreatitis. ERCP, endoscopic retrograde cholangiopancreatography; FNA, fine-needle aspiration; ICU, intensive care unit; IV, intravenous; NG, nasogastric; NPO, nothing by mouth; TPN, total parenteral nutrition.

Supportive Care, Fluid Resuscitation, and Electrolyte Balance

Intravenous fluids and electrolytes should be given until the patient is able to sustain adequate fluid and nutritional intake per os. This usually includes resolution of abdominal pain with normal or normalizing amylase and lipase. The routine use of nasogastric tube decompression has not been shown to alter the course of acute pancreatitis.[29] Patient support and family education are important, especially in the setting of alcoholic pancreatitis and the need for abstinence.

Analgesia

Adequate pain control is important and may require narcotic medications. The theoretical disadvantage of morphine-induced sphincter of Oddi spasm has not been demonstrated to be clinically relevant.

Nutrition

If the patient is unable to meet adequate protein and caloric needs per os within 5 to 10 days of pancreatitis onset, supplemental feedings via a nasoenteric feeding tube is recommended. The need for parenteral nutrition is rare.

Antibiotics

There is no proven role for prophylactic antibiotics during mild, or moderate, acute pancreatitis; however, therapeutic use of antibiotics may be necessary in the event of concomitant biliary obstruction.

Operative Management

Early cholecystectomy during the same hospitalization once symptoms have subsided and cholestatic liver enzymes have returned to normal is recommended for gallstone pancreatitis. If cholestatic enzymes have not returned to normal, consideration must be given to choledocholithiasis and the use of preoperative ERCP or intraoperative cholangiography and stone extraction. Alternatively, retained common bile duct stones diagnosed with intraoperative cholangiography can be extracted by postoperative ERCP.

MANAGEMENT OF SEVERE NECROTIZING PANCREATITIS

The mainstay of management is early diagnosis, aggressive resuscitation, and staging by clinical scoring systems and radiologic imaging (see Fig. 87–3). This aggressive approach is justified to allow proper allocation of resources and prognostication. This rapidly progressing, multiorgan dysfunction occurs in approximately 10% of patients with acute pancreatitis; however, it results in 50% to 80% of mortality from subsequent organ failure and sepsis.

To date, research aimed at manipulation of the inflammatory cascade induced during severe, acute pancreatitis has failed to improve clinical outcomes. Current treatment remains largely supportive with a focus on preventing, minimizing, and correcting complications.

Supportive Care, Fluid Resuscitation, and Electrolyte Balance

Aggressive fluid resuscitation with correction of base deficit and electrolyte imbalance is the primary goal in supporting the early inflammatory and sequestration phase. Invasive cardiac monitoring may be necessary as well as endotracheal intubation as indicated for respiratory insufficiency.

Analgesia

Adequate analgesia should be routinely provided with parenteral narcotics and anti-inflammatory agents.

Nutrition

Nutritional support is extremely important as severe acute pancreatitis is one of the most catabolic conditions. Early nutrition is imperative and can be achieved initially with total parenteral nutrition until enteral access is established.[30] Use of lipids in total parenteral nutrition solutions has not been shown to worsen the course of acute pancreatitis.[31] Resumption of enteral intake or oral feeding should coincide with resolution of gastric ileus that is an early manifestation of acute pancreatitis. The theoretical fear of stimulating an already inflamed pancreas with oral or enteral nutrition is not founded in evidence-based medicine.[32] Intolerance to certain enteral formulations does not constitute worsening of pancreatitis.

Therapeutic ERCP and Management of Biliary Tract Disease

Several clinical trials have shown the benefits of early (<48 hours) ERCP in minimizing biliary tract infectious complications during severe, acute pancreatitis.[33,34] An ERCP is indicated when biliary obstruction is suspected to remove impacted stones; concomitant transpapillary stenting of the common bile duct or pancreatic duct has no impact on the course of pancreatitis. The benefits of therapeutic ERCP in experienced hands outweigh its risks in this setting.

Antibiotics

The use of prophylactic antibiotics in severe, acute pancreatitis has become controversial. Earlier clinical trials that showed benefit in reducing morbidity or mortality were poorly designed or underpowered (Table 87–3).[35-38] The widespread use of imipenem based on its high concentration in pancreatic tissue has not been substantiated in large clinical trials.[39] Nevertheless, a meta-analysis of the use of prophylactic antibiotics demonstrated a significant reduction in sepsis and mortality.[40] Recently, a well-designed trial involving 119 patients showed no benefit from prophylactic use of ciprofloxacin and metronidazole over placebo in severe, acute pancreatitis.[35] These findings prompted a large, multicenter, placebo-controlled, double-blind study of meropenem. Unfortunately, this trial was closed prematurely because of an inability to enroll enough antibiotic-naïve patients, thereby underscoring the difficulty in establishing an evidence-based role for prophylactic antibiotics in severe, acute pancreatitis.

Timing of Cholecystectomy for Gallstone Pancreatitis

Nealon et al. have now established that cholecystectomy should be delayed for patients who survive an episode of moderate to severe acute biliary pancreatitis and demonstrate peripancreatic fluid collections or pseudocysts.[41] Cholecystectomy should be delayed until either the pseudocyst resolves or, if it persists beyond 6 weeks, the pseudocyst can be drained concomitantly and safely at the time of cholecystectomy. Delayed cholecystectomy and concomitant pseudocyst management are associated with fewer septic complications, less morbidity, fewer reoperations, and fewer readmission rates and a shorter length of stay than those undergoing early cholecystectomy.[41]

Other Potential Therapeutic Options

Although a meta-analysis suggested that somatostatin reduced mortality after acute pancreatitis,[42] a more recent study did not demonstrate any benefit of octreotide treatment.[43] Many of the clinical trials designed to suppress pancreatic enzyme secretion including nasogastric decompression, glucagon, polypeptide YY, or cholecystokinin receptor antagonists have failed to definitively impact the outcomes of pancreatitis. Similarly, antiproteases and inhibition of pancreatic enzymes by gabexate mesilate were not effective.

In the past decade, experimental data implicating cytokines in the pathophysiology of acute pancreatitis prompted many clinical trials based on cytokine antagonism.[11] Lexipafant, a potent platelet activating factor inhibitor, showed promise in phase-II trials and in a European phase-III trial, which suggested significant benefit

Table 87–3 Prospective, Randomized Prophylactic Antibiotic Trials in Acute Pancreatitis

Authors, Year	No. of Antibiotics/Control	No. of Institutions	Antibiotics	Outcomes	Strengths/Weaknesses
Isenmann et al., 2004[35]	58/56	19	Ciprofloxacin, metronidazole	No difference in pancreatic infections or mortality	Prospective, randomized, adequately powered
Luiten et al., 1995[36]	52/50	16	Cefotaxime, colistin, amphotericin B, norfloxacin	Decreased local infections and mortality	Utilized selective digestive decontamination
Sainio et al., 1995[37]	30/30	1	Cefuroxime	No difference in pancreatic infections, sepsis; decreased mortality	Underpowered, single center
Pederzoli et al., 1993[38]	33/41	6	Imipenem	Decreased local infections and sepsis; no difference in mortality	Unblinded, underpowered, subgroup analysis

in patients with severe pancreatitis treated within 48 hours of pancreatitis onset.[44] Unfortunately, the double-blind, randomized, controlled, multicenter trial of lexipafant in 1518 patients with pancreatitis failed to confirm a benefit in reducing mortality or organ injury score. Although adequately powered, the study did not reach its end points due to lower than expected mortality as predicted by APACHE-II scores.[45]

Operative Management

The rationale for operative treatment of necrotizing pancreatitis is to remove necrotic peripancreatic and pancreatic tissue that may act as a reservoir for infection and sepsis. As our understanding of the role of necrosectomy in the treatment of necrotizing pancreatitis evolves, several questions arise, as follows:

1. Is necrosectomy required in patients with sterile necrosis?
2. What is the optimal timing of necrosectomy in infected necrosis?
3. What is the role of minimally invasive and image-guided interventions in the treatment of pancreatic necrosis?

Central to the first two questions is the difficulty in delineating sterile versus infected necrosis, because of their unreliable clinical symptoms and radiologic findings. Infected necrosis can be confirmed by CT-guided fine-needle aspiration of necrotic tissue followed by Gram stain and cultures. This is an important consideration, since there is literature to support delaying operative necrosectomy and maximizing supportive care in stable patients with sterile necrosis until demarcation of necrotic material occurs but not longer than 27 days.[46,47] As in many other centers, we have delayed the timing of necrosectomy in stable patients, which has dramatically reduced our utilization of fine-needle aspiration.

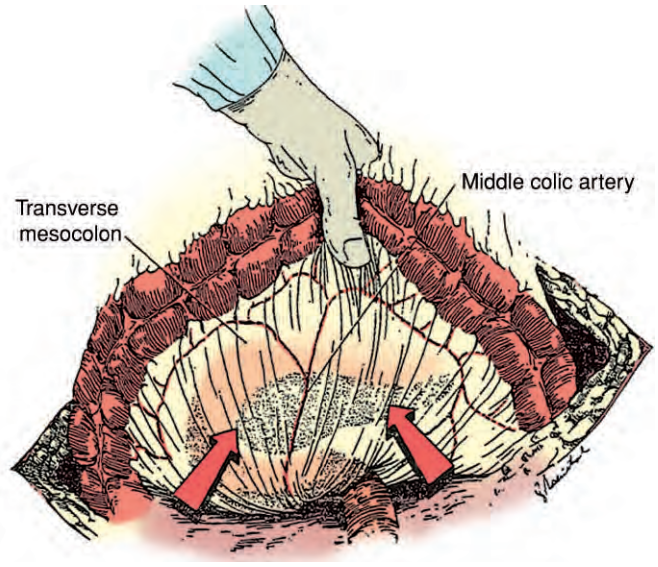
Definitive indications for operative treatment and necrosectomy are the following:

- Failure of nonoperative management with at least 48 hours of maximal ICU support
- Infected necrosis
- Extravisceral air (see Fig. 87–2)
- Hemorrhage uncontrolled by interventional techniques
- Colonic complications

The basic and universal aspect of necrosectomy is débridement of necrotic peripancreatic and pancreatic tissue. Because necrosis is an ongoing process, surgeons have addressed it in a variety of ways, as follows, after the initial necrosectomy:

- Closed packing[47]
- Open drainage[48]
- Closed high-volume lavage of the lesser sac[49]
- Repeated, planned necrosectomy with abdominal wall closure[50]

Peritoneal lavage has no place in the treatment of necrotizing pancreatitis since it addresses neither pancreatic tissue necrosis nor the removal of large particulate matter.



A

B

Figure 87–4. **A,** The lesser sac can be approached through the base of the mesocolon; attention should be paid to avoid injury to the middle colic artery. (**A,** From Del-Castillo F, Warshaw A, Rattner D: Closed packing and drainage following débridement for necrotizing pancreatitis. Probl Gen Surg 13:127, 1996.) **B,** Necrosectomy and closed packing with stuffed Penrose drains.

Necrosectomy and Closed Packing

Briefly, the lesser sac is accessed through the base of the mesocolon (Fig. 87–4A). A thorough, blunt necrosectomy is followed by packing with multiple, stuffed Penrose drains (see Fig. 87–4B).[47] Advocates of this approach cite low mortality and reduced reoperation rates and complications; however, there is a high incidence of intra-abdominal abscess formation (Table 87–4).

Necrosectomy and Open Drainage

An initial blunt necrosectomy is followed by marsupialization of the lesser sac by suturing the omentum to the abdominal wall fascia (Fig. 87–5).[48] Daily unpacking and gentle irrigation are done in the ICU or in the operating room. Advocates of this technique cite the ease by which repeated packing is done; however, the incidence of hemorrhage and fistula formation is high (see Table 87–4).

Figure 87–5. Necrosectomy and open drainage by marsupialization of the lesser sac.

Table 87–4 Comparison of Outcomes Following Operative Management of Necrotizing Pancreatitis

Necrosectomy &	Authors, Year	Reoperation, %	Abscess, %	Pancreatic Fistula, %	GI Fistula, %	Hemorrhage, %	Mortality, %
Closed drainage	Fernandez-del Castillo et al., 1998[47]	11	22	50	19	15	7
Open drainage	Bradley, 1995[48]	N/A	—	45	7	7	14
Closed irrigation	Beger et al., 1999[49]	37	20	19	13	15	13
Staged planned	Murr et al., 1987[49]	N/A	13	19	26	18	22

GI, gastrointestinal; N/A, not applicable.

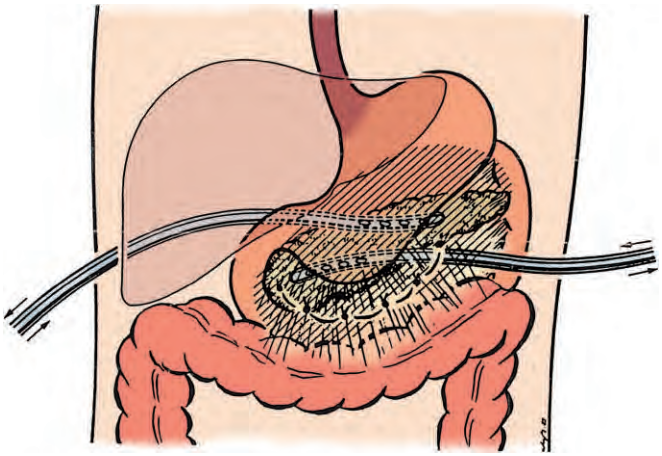


Figure 87–6. Schema of necrosectomy and closed high-volume lavage of the lesser sac. (From Rau B, Beger H: Necrosectomy and closed irrigation for necrotizing pancreatitis. Probl Gen Surg 13:142, 1996.)

Necrosectomy and Closed Lavage

The purported benefit of this method is that it combines operative débridement (of only necrotic tissue to minimize loss of pancreatic parenchyma) with subsequent high-volume lavage of the lesser sac using a peritoneal dialysate (Fig. 87–6).[49] Similar to closed drainage, the incidence of reoperation and abscess formation is high (see Table 87–4).

Planned, Repeated Necrosectomy and Delayed, Primary Abdominal Wall Closure

The initial celiotomy and necrosectomy is followed by a planned, repeated necrosectomy every 48 hours.[50] Our preferred access is through a midline incision because of the ease of closing it. A cholecystectomy and common bile duct exploration, if indicated, are done after abdominal exploration at the initial necrosectomy; otherwise, access to these structures may be limited by edema and adhesions during later explorations. Similarly, a gastrostomy tube for decompression and jejunostomy tube for enteral feedings are also placed during the initial necrosectomy.

The lesser sac is entered through the gastrocolic ligament (Fig. 87–7A), and all areas of necrosis are unroofed and bluntly débrided (see Fig. 87–7B). Because edema and induration may mask anatomic landmarks, a CT scan is essential to direct operative access to all fluid collections, especially in the paracolic gutters and root of the mesentery. Multiple soft drains are placed in both paracolic gutters and the lesser sac. Subsequently, a nonadherent elastic drape or Adaptic gauze is used to line the lesser sac, which is then packed with moist laparotomy pads. Packing keeps the lesser sac open and readily accessible for repeated necrosectomy. Temporary abdominal closure is obtained with a zipper (Fig. 87–8) to prevent retraction of the fascia, maintain abdominal domain, and facilitate primary closure at the final operation. Planned reoperation is scheduled at approximately 48-hour intervals until the necrotic processes have been controlled or resolved. The worst outcomes occurred in patients with APACHE-II score greater than or equal to 13, extensive pancreatic necrosis, and postoperative intra-abdominal hemorrhage.

A

B

Figure 87–7. **A,** Access to the lesser sac through the gastrocolic omentum. The necrotic peripancreatic tissue has a black-gray discoloration. **B,** Débrided peripancreatic necrotic tissue during a necrosectomy. Large pieces of tissue are not amenable to small-bore catheter drainage.

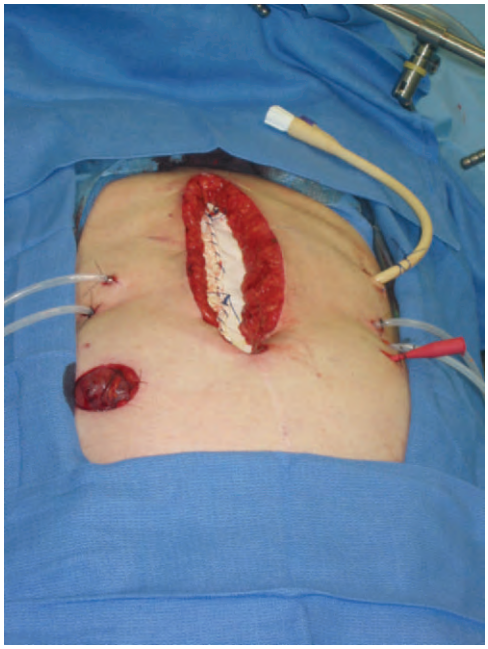

Figure 87–8. The initial necrosectomy with abdominal wall closure using a strip of Gore-Tex mesh included placing a gastrostomy tube (Foley catheter), a jejunostomy feeding tube (red catheter), and four closed-suction drains. A colostomy was also undertaken because of colonic perforation into the lesser sac.

MANAGING SEQUELAE OF ACUTE PANCREATITIS

Acute Peripancreatic Fluid Collections and Necrosis

Endoscopic management of pancreatic fluid collections and necrosis is a new and developing field. Nuances involve patient selection and determining the appropriate waiting period prior to intervention. Additionally, outcomes appear to be linked to endoscopist experience.[51]

Minimally invasive, laparoscopically directed and transgastric necrosectomy or laparoscopic cyst–gastrostomy have been undertaken in select patients.[52,53] In addition, the availability of large-bore catheters and drains has introduced the possibility of percutaneous drainage of localized fluid collections and limited pancreatic necrosis.[54] The experience with laparoscopic and percutaneous necrosectomy is rather limited but holds promise. These novel approaches seem best suited for patients, who have had a stable and uncomplicated course with predominant collections that are easily accessible through the stomach or abdominal wall.

Endocrine and Exocrine Insufficiency

Hereditary pancreatitis, alcoholic pancreatitis, and necrotizing pancreatitis have the highest risk of significant, long-term, pancreatic exocrine and endocrine dysfunction. Such insufficiency occurs in up to 50% of patients following necrosectomy for necrotizing pancreatitis.[6] Exocrine function can actually improve, whereas endocrine function does not typically recover in these patients after discharge.[6]

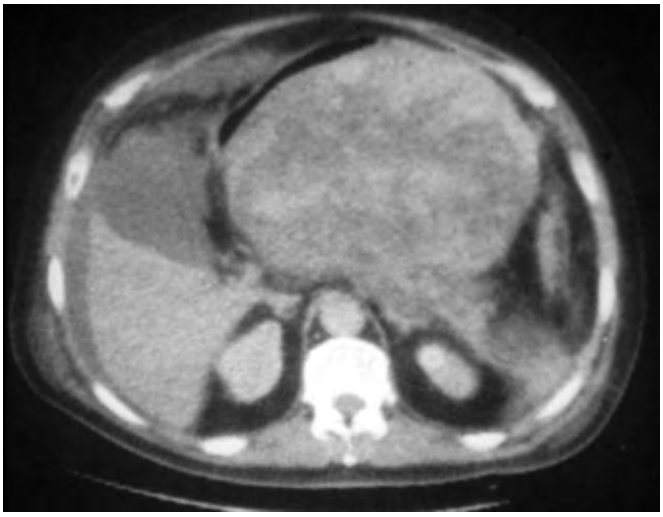

Figure 87–9. Hemorrhage into a pseudocyst can be detected on a CT scan that shows a large collection of fluid that has high density (fresh blood) within the fluid collection. (From Simms M, Johnson D: Diagnosis of necrotizing pancreatitis using contrast material–enhanced CT. Probl Gen Surg 13:17, 1996.)

Pseudocyst

Our recommended nonoperative management parallels others.[55,56] Utilizing a selective approach, two thirds of patients avoided operative pseudocyst drainage, and life-threatening complications requiring emergency operation were uncommon (7%).

Pancreatic ductal anatomy as defined by ERCP provides clear correlation with the failure and success of percutaneous pseudocysts drainage. Percutaneous drainage is best applied to patients with stricture but no pseudocyst-duct communication.[57]

With improvements in CT scanning as well as angiography and interventional radiology, most acute hemorrhage (Fig. 87–9) can be diagnosed, safely controlled, and easily managed with angiographic embolization and/or coiling. Uncommonly, operative control and packing may be required and is associated with poor prognosis.

Fistula

Pancreatic fistula as a consequence of necrosectomy or necrotizing severe, acute pancreatitis is not uncommon. Most fistulas may seal spontaneously with optimization of nutritional status and resolution of sepsis. Persistent fistulas may be associated with main pancreatic ductal disruption best characterized by ERCP. Fistulas in the

pancreatic head or a small ductal disruption may respond to transpapillary stenting. Historically, fistulas from the tail of the pancreas may require distal pancreatectomy.

FUTURE DIRECTIONS

Promising cell signaling–based research for inflammation and pancreatitis has brought forth many potential therapeutics. However, the complex inflammatory response with its inherent redundancy and genetic polymorphisms in humans underscores the complexity of translational research aimed at finding the "magic bullet" in the treatment or prevention of acute pancreatitis and other superinflammatory conditions.

Chronic Pancreatitis

Jakob R. Izbicki · Tim G. Strate · Emre F. Yekebas · Oliver Mann

Despite major advances in the unraveling of the pathogenesis and pathophysiology of chronic pancreatitis, and although literally thousands of reports dealing with this disease have been published, chronic pancreatitis remains an enigmatic process of uncertain pathogenesis, unpredictable clinical course, and unclear treatment. Chronic pancreatitis affects about 8 new patients per 100,000 population per year in the United States, with a prevalence of 26.4 cases per 100,000 population.[1] Autopsy series, however, suggest a higher prevalence of 0.04% to 5%. Chronic pancreatitis is an inflammatory disease characterized by the progressive conversion of pancreatic parenchyma to fibrous tissue. The most frequent causes are excessive alcohol consumption and anatomic variants such as pancreas divisum, cholelithiasis, and individual genetic predisposition. In a substantial number of cases, no currently identifiable predisposing factor can be named. The morphologic and histologic changes that characterize the disease are also extremely variable. Although the term *pancreatitis* implies inflammation, acute inflammatory changes are usually episodic and often absent. It is believed that the process of fibrosis with consecutive loss of pancreatic parenchyma leads to exocrine insufficiency and maldigestion and, in advanced stages of the disease, to diabetes mellitus. In addition to exocrine and endocrine malfunction, mechanical complications occur such as the formation of pancreatic pseudocysts and duodenal and common bile duct obstruction. The peak of presentation occurs in patients between 35 to 55 years of age. Abdominal pain is the leading symptom that characteristically brings the patient to medical attention. Its presentation varies through a wide spectrum, from mild and intermittent, to constant and disabling, leading to hospitalization, inability to work, early retirement, and addiction to analgesics in devastating conditions of chronic pancreatitis. The heterogeneity of this patient population, the subjective nature of pain, and a poor understanding of its pathophysiology all are obstacles to studies directed at effectiveness of pain management. Even abstinence from excessive alcohol consumption, which seems to be the causative agent in most cases, cannot interrupt the process of continuing organ destruction.

NATURAL COURSE AND PATHOGENESIS OF PAIN IN CHRONIC PANCREATITIS

The main rationale for conservative approaches in the past derives from the assumption that most patients with long-standing chronic pancreatitis will become pain-free due to a progressive "burning out" of the organ.[2] However, studies showing that pain alleviation did not occur in more than 50% of the patients[3] as well as the unpredictability of the course of the disease,[3,4] the considerable socioeconomic implications of frequent hospitalization in these mostly young patients,[3] and last, the implementation of more customized surgical techniques has led, at least in part, to a reconsideration of this view.

Pain, by far the most common and intractable indication for medical treatment in chronic pancreatitis, is still only fragmentarily understood and a multifactorial nature is assumed, including inflammation, duct obstruction, high pancreatic tissue pressure, fibrotic encasement of sensory nerves, and a neuropathy characterized by both increased numbers and sizes of intrapancreatic sensory nerves and by inflammatory injury to the nerve sheaths allowing exposure of the neural elements to toxic substances.

DUCTAL AND PARENCHYMATOUS HYPERTENSION

The assumption that pain in chronic pancreatitis is caused by ductal hypertension is based on several observations. Ductal dilation is a common finding that is suggestive for an increased pressure in the pancreatic ductal system, which may be observed[5] in these patients. Patients with the "small duct pancreatitis" also have ductal and parenchymatous hypertension.[6] Hence, elevated intrapancreatic pressure[7] or, in other terms,

a retroperitoneal compartment syndrome yielding reduced pancreatic blood flow and reduction of the intrapancreatic pH level, especially after stimulation of the exocrine pancreatic secretion,[8] has been assumed to cause pain or to interact with its intensity. As a logical consequence of these findings, the concept of surgical and, later, endoscopic, decompression of the main pancreatic duct system arose that leads at least to temporary pain relief.[9-12]

COMPLICATIONS OF CHRONIC PANCREATITIS

In the course of chronic pancreatitis, several complications with less or more life-threatening potential may occur. Extrahepatic cholestasis as well as duodenal obstruction may be a result of an inflammatory tumor, a fibrotic scarring, or both, occurring in the head of the pancreas. Acute inflammatory episodes can lead to chronic pancreatic pseudocysts or internal pancreatic fistula to the abdominal or thoracic cavities. Finally, thrombosis of the splenic vein can occur as a result of the inflammatory reaction of chronic pancreatitis, which results in splenomegaly and localized (so-called left-sided) portal hypertension. The pathophysiology, clinical presentation, and management of these complications of chronic pancreatitis are reviewed in this chapter.

Common Bile Duct Stenosis

Biliary strictures have been recognized as characteristic complications of chronic pancreatitis. In hospitalized patients with pancreatitis, the incidence of biliary stricture accounts for about 5% to 9% and drastically increases to up to 35% in surgical series.[13-16] The main factor for the development of common bile duct stenosis is the close anatomic relationship of the distal common duct to the head of the pancreas, thereby increasing the risk of secondary common bile duct stricture in these patients by cephalic irregularities of any reason. Even though pseudocysts are common in chronic pancreatitis, compression of the common bile duct by pseudocysts is rare. The spectrum of clinical presentation of these patients ranges from being asymptomatic with only biochemical findings such as elevated alkaline phosphatase or bilirubin level, or both, to being septic with cholangitis. Interventional (i.e., surgical) therapy is clearly indicated in patients with common bile duct strictures secondary to chronic pancreatitis. Endoscopic stenting plays a role in patients who are unfit for surgery, but it is not recommended as definitive therapy, particularly with regard to the necessity of repeated endoscopic interventions due to infection, stent displacement, or stent occlusion.[17,18] Of greatest importance is to rule out that biliary obstruction in these patients is a result of a concomitant malignancy in the periampullary region.

Duodenal Obstruction

In patients requiring an operation for chronic pancreatitis, the incidence of duodenal obstruction, which can be either transient or permanent, accounts for 12%.[19] Duodenal obstruction can also occur secondarily to pancreatic pseudocysts.[20] Patients typically present with a history of nausea, vomiting, upper abdominal pain, and weight loss. Endoscopy shows a concave-shaped extraluminal impression without mucosal involvement beginning at the descending portion of the duodenum. Warshaw found that 25% of the patients with common bile duct stenosis caused by chronic pancreatitis also required surgical treatment of duodenal obstruction.[20] In duodenal obstruction, operation is indicated for patients with failure to resolve the obstruction with 1 to 2 weeks of conservative therapy, suggesting the presence of an irreversible duodenal obstruction necessitating further (surgical) treatment. The surgical procedure of choice should definitively address all the individual existing complications of chronic pancreatitis at once. Therefore, combined drainage procedures or resection are used to manage these findings. Gastric outlet obstruction can result from various mechanisms. The most frequent cause in addition to an inflammatory mass due to chronic pancreatitis is a duodenal involvement by pancreatic cancer. If surgery is indicated, the therapeutic aim should be to eliminate the cause of the duodenal stricture, such as an enlarged pancreatic head or an encasement of the duodenum by inflammatory adhesions.

Internal Pancreatic Fistulas

Pancreatic ascites and pancreaticopleural fistulas are known as *internal pancreatic fistulas*. They result from a disruption of the pancreatic duct or leakage from a pseudocyst. Internal pancreatic fistulas are rare but well-recognized conditions associated with a significant morbidity and mortality.[21,22] Misdiagnoses such as in cases of pancreaticopleural or pancreaticobronchial fistula are not uncommon. Three main types of thoracic manifestations include mediastinal pseudocysts, pancreaticopleural fistulas, and pancreaticobronchial fistulas.[23,24] Once an internal pancreatic fistula is suspected, laboratory testing of pleural effusions with special respect to their amylase concentration should be performed. Diagnostic evaluation should in particular address a possibly underlying ductal pathology. Conservative treatment may be indicated in patients with mild to moderate ductal anatomic alterations.[25,26]

Conservative treatment has an efficacy of 30% to 60%, a recurrence rate of 15%, and a mortality rate of 12%.[26,27] Interventional endoscopic therapy would be the next step in patients with persisting fistulas and pleural effusion. Endoscopic treatment is based on the concept that main pancreatic duct disruption arises as a consequence of an increase in intraductal pressure or within a pseudocyst and aims at the reduction of the ductal pressure. In most patients, a pancreatic sphincterotomy via the major papilla is performed to facilitate transpapillary endoscopic placement of a pancreatic duct stent.[28-30] In selected cases, this may be combined with the use of tissue glue for the closure of pancreatic fistulas.[31] Surgical treatment has to focus on the elimination of ductal hypertension that inhibits spontaneous closure of fistulas.

Pancreatic Ascites

Pancreatic ascites is defined as massive accumulation of pancreatic fluid in the peritoneal cavity. The level of amylase in the ascitic fluid is typically above 1000 IU/L and the ascitic fluid to serum amylase ratio is approximately 6.0.[32,33] It has been described in approximately 4% of patients with chronic pancreatitis and in 6% to 14% of those with pancreatic pseudocysts. Sometimes an attack of acute pancreatitis or a traumatic injury to the pancreas can be held responsible; however, two thirds of patients do not give a history of a recent episode of pancreatitis.[34] The establishment of diagnosis is often difficult because pain or symptoms of pancreatic disease may be absent. Especially in patients with alcohol abuse, the diagnosis may be confused with ascites due to cirrhosis and portal hypertension. Diagnostic paracentesis should be performed in every patient with ascites. If pancreatic ascites is suspected, routine tests of ascitic fluid such as cell count, culture, Gram stain, amylase, albumin, and total protein should be obtained. Once the diagnosis has been established, the evaluation of the pancreatic duct morphology is mandatory. There is agreement that endoscopic retrograde cholangiopancreatography should be performed to localize the site of leakage and to perform endoscopic therapy (transpapillary stenting of the pancreatic duct or sealing of the leak) if possible as the procedure of first choice.[29] Although there are no data on the role of magnetic resonance cholangiopancreatography for the diagnosis of this condition, this test can accurately demonstrate the normal pancreatic duct and detect any abnormalities arising from it.[35] Treatment with somatostatin or octreotide together with diuretics and repeated paracentesis may be beneficial for some patients.[36,37] The stent can facilitate healing of ductal disruptions by partially occluding the leaking duct or bypassing the pancreatic sphincter, thereby decreasing the intrapancreatic duct pressure. Some patients fail medical therapy, ultimately requiring surgery.[27] Indications for surgery include persistent or recurrent accumulation of ascites and/or sudden deterioration of clinical status. The type of surgical intervention depends on the ductal anatomy, the site of the leakage from the pancreatic duct or pseudocyst, and the operative findings.[38]

Vascular Irregularities

Portal Hypertension

Extrahepatic portal hypertension (EPH) is defined as extrahepatic hypertension of the portal venous system in the absence of liver cirrhosis. It was first described by Balfour and Steward in 1868. Representing a less common complication of chronic pancreatitis, it may be confined to either the superior mesenteric or splenic venous branch or may involve the whole splenomesentericoportal axis.[39] EPH is characterized by either a complete occlusion of branches of the venous splanchnic system (occlusive form) or a subtotal obstruction of one or more of these branches (nonocclusive form).[40,41] Clinical experience with this condition has remained limited, and no universal agreement exists on whether EPH represents a surgical risk that must be accounted for in the design of a surgical strategy for patients with chronic pancreatitis, and whether EPH per se warrants surgical intervention. Extrahepatic hypertension of the portal venous system is the most common vascular complication in chronic pancreatitis.[41,42] Every part of the splenomesentericoportal venous axis may be involved,[39] resulting in either compromise (nonocclusive variant) or obstruction (occlusive variant) of the lumen and hence of portal venous flow.[41] The pathogenesis of EPH in chronic pancreatitis may include several factors. The inflammatory process is capable of causing initial damage to vascular walls and generating venous spasm, venous stasis, and thrombosis.[43] The intimate relationship with the pancreas and the contiguous course for its entire length leaves the splenic vein most vulnerable to the inflammatory assault. Little and Moossa[43] noted that a single flare of pancreatitis was sufficient to produce splenic vein thrombosis. The most probable cause seems to be the progressive fibrosis characteristic of chronic pancreatitis, leading to progressive constriction of the splenomesentericoportal axis that passes through the pancreatic substance. Support for this assumption is evidenced by the fact that EPH in the authors' series was associated frequently with complications of adjacent organs such as duodenal obstruction or common bile duct stenosis, as pointed out by Warshaw et al.[41] Other factors contributing to EPH in chronic pancreatitis encompass extrinsic compression by pancreatic pseudocysts[44,45] or by the considerable pancreatic head enlargement observed in up to 40% of cases and caused by an inflammatory swelling of the gland, a condition referred to as *inflammatory pseudotumor*.[44,46] The portal and superior mesenteric veins are less frequently affected.[43-45] In 35 patients with chronic pancreatitis, the initial location of splenoportal venous obstruction was the splenic vein in 22 patients (63%), the portal vein in 10 (29%), and the superior mesenteric vein in 3 (9%).[44] In our series, EPH involved the splenic vein in 26 (90%) of 29, the superior mesenteric vein in 21 (72%) of 29, and the central portal vein in 7 (24%) of 29, either alone or in conjunction with other portal branches.[39] It is of note in this regard that EPH was confined in only 14 (39%) of 36 of patients to one branch of the portal venous system (either to the splenic or superior mesenteric vein). Features suggestive of EPH include common bile duct stenosis and evidence of segmental duodenal stenosis at the time of diagnosis.

Collateral routes that spontaneously form in cases of EPH involve

1. The short gastric veins (resulting in isolated fundic varices) bypassing the thrombosed splenic vein and returning the blood either through the coronary vein or via the gastroepiploic and superior mesenteric veins to the portal vein
2. Esophageal veins shifting blood less frequently to the azygos venous system in case of obstruction of the coronary vein, resulting from an obstruction of either the portal vein or the splenic vein, in case the coronary vein drains into the splenic vein (producing combined fundic and esophageal varices)
3. The left gastroepiploic vein conveying blood to the left colic and inferior mesenteric veins (yielding colonic varices at the splenic flexure)

In a literature review of EPH covering 199 patients with previous variceal bleeding, Madsen et al. found isolated gastric varices in 144 patients (75%), combined gastric and esophageal varices in 46 (23%), and colonic varices in 1 (0.5%).[47] Our data suggest no difference in the complication and death rates between surgical procedures emphasizing the resectional aspect (e.g., duodenum-preserving pancreatic head resection described by Beger [classic Whipple]) and surgical decompression by longitudinal pancreaticojejunostomy combined with a limited excision of the pancreatic head (duodenum-preserving resection of the pancreatic head according to Frey).[39] However, regardless of the surgical procedure performed, the complication rate in patients with EPH was distinctly higher than in those without.

An interesting issue is whether EPH per se represents an indication for surgery or not. Although some authors list an entrapment of the splenomesentericoportal-venous axis by an enlarged pancreatic head per se as an indication for pancreatic head resection, advocating an aggressive prophylactic treatment for possible prevention of hemorrhage from esophageal or gastric varices,[46] others have taken a more expectant stance as long as there was no evidence of variceal hemorrhage.[40] Therefore, EPH per se seems not to be an indication for surgical intervention in chronic pancreatitis unless the preoperative work-up cannot rule out a malignancy. Apart from pain, associated complications of adjacent organs (e.g., duodenal or common bile duct stenosis) still remain the main indications for surgery. In the rare circumstances where varices start to bleed, therapeutic options include interventional measures such as sclerotherapy, variceal ligation, and interventional or surgical portosystemic shunting procedures.[41,44] Splenectomy is effective only in cases of isolated splenic vein occlusion.[48] In our experience, EPH does not determine the ultimate outcome after pancreatic surgery once complications in the immediate postoperative period have been overcome. The low frequency of variceal hemorrhage observed in this study suggests that EPH in itself does not entail a major risk in long-standing chronic pancreatitis. In conclusion, the mere presence of EPH does not justify surgery in chronic pancreatitis. When surgical intervention for pancreatitis-related complications is dictated by increasing severity of symptoms, it must be borne in mind that concomitant EPH entails a considerable surgical risk, prolonging operating time, increasing intraoperative blood loss, and imposing significant complications on the individual patient. When surgery is indicated in a symptomatic patient, no definitive recommendation for a procedure can be given. Surgical strategy rather depends on pancreatic morphology than on the intent to abolish EPH.

Thrombosis of the Portal Vein with Cavernous Transformation

Dealing with patients with chronic pancreatitis and coexistent portal vein thrombosis with cavernous transformation complicates the decision-making process enormously (Fig. 88–1). Pancreatitis is the most common extrahepatic, inflammatory disease that causes portal vein thrombosis. Preoperative assessment of patients should routinely include a high-resolution computed tomographic scan and magnetic resonance device providing information with regard to arterial supply and venous drainage.

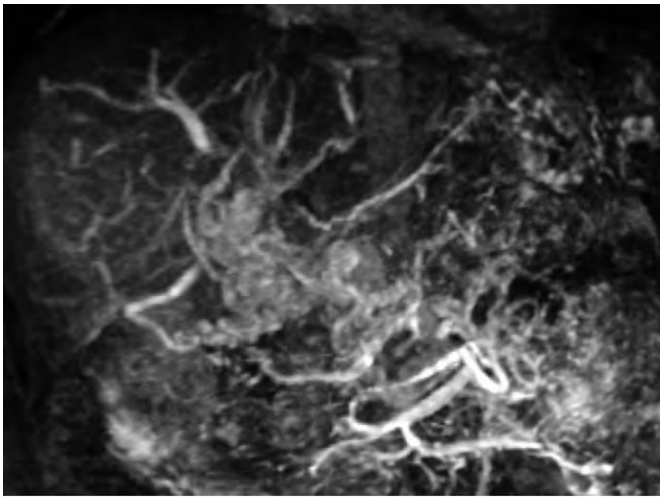

Figure 88–1. Magnetic resonance angiography of portal vein thrombosis with cavernous transformation.

As for other abdominal operations, such as surgery for gastric or duodenal ulcer disease, portal vein thrombosis with cavernous transformation was identified as a major operative risk factor, accounting for prolonged operative time and substantial intraoperative blood loss. What is the ideal operative strategy for a patient with chronic pancreatitis and an inflammatory pancreatic head tumor who has developed portal vein thrombosis with cavernous transformation? Basically, the goals of the operation in patients with or without cavernous transformation do not differ. Hence, the essential landmarks of the surgical strategy resemble those in patients without irregularities of the portal flow. However, any operation in these patients carries particular risks. This notably applies for technical steps that are associated with a dissection of portal collaterals, thereby increasing the amount of postoperative ascites. A transection of the pancreatic parenchyma above the portal vein as required for the Beger procedure, Whipple resection, and duodenum-preserving pancreatic head resection should be avoided by all means because this carries unpredictable risks.

In conclusion, EPH with coexistent cavernous transformation entails a substantial risk in pancreatic surgery for chronic pancreatitis. The mere presence of portal vein thrombosis with cavernous transformation does not justify surgery in chronic pancreatitis. When surgery is considered in a symptomatic patient, surgical strategy is determined more by pancreatic morphology than by the intent to restore portal blood flow. The approach to chronic pancreatitis with associated portal vein thrombosis with cavernous transformation is multidisciplinary,

tailoring the various therapeutic options to meet the individual patient's needs.

INDICATIONS FOR SURGICAL INTERVENTION

The indications for surgical intervention are intractable pain, complications related to adjacent organs, endoscopically not permanently controlled pancreatic pseudocysts in conjunction with ductal pathology, and neither conservatively nor interventionally tractable internal pancreatic fistula.[49-51] Occasionally the inability to exclude pancreatic cancer despite broad diagnostic work-up also requires surgery.[52] The ideal surgical approach should address all these problems.

Rationale for Drainage Procedures

Because 40% to 60% of patients with painful chronic pancreatitis exhibit ductal ectasia, decompression of the pancreatic ductal system has become one of the main therapeutic principles based on the assumption that ductal ectasia indicates intraductal hypertension.[6,10] Obstruction of Wirsung's or Santorini's duct results from single or multiple dominant strictures of the ductal system, from obstruction of the ductal lumen by calcium carbonate–containing stones, or by combination of both. The operative removal of pancreatic stones was already described at the turn of the 19th century.[53,54] Moynihan[54] claimed the underlying rationale for this operative intervention is "alleviation of pain, nausea and emesis, as well as the prevention of pancreatic atrophy." The concept of opening the pancreatic main duct with bypass of the obstruction was first described by Coffey[55] and Link.[56] The first clinical applications of this principle were independently performed by DuVal[57] and Zollinger et al.[58] Decompression of the main pancreatic duct was achieved by resection of the pancreatic tail and retrograde drainage of the pancreatic duct via a terminoterminal or terminolateral pancreaticojejunostomy. However, this procedure proved to be effective only if there was a single dominant obstruction between pancreatic tail and the ampulla of Vater. Especially in patients with alcohol abuse, which is the leading cause of chronic pancreatitis in most patients in the Western hemisphere, a single dominant stricture is found rarely. But even with patent drainage of the duct system, recurrent bouts of severe pain are frequently observed. In 1958, Puestow and Gillesby[59] presented another drainage procedure: decompression of the main pancreatic duct was performed by a longitudinal laterolateral pancreaticojejunostomy after resection of the pancreatic tail and splenectomy. Thus, even in the presence of multiple strictures ("chain of lakes"), the main pancreatic duct could be effectively drained. A modification of the Puestow-Gillesby procedure was introduced by Partington and Rochelle,[60] who performed longitudinal pancreaticojejuonstomy while at the same time avoiding splenectomy and pancreatic tail resection. The rationale for the widespread application of drainage procedures in chronic pancreatitis was the considerable morbidity and mortality rates of resectional procedures (i.e., partial pancreaticoduodenectomy) in the beginning of pancreatic surgery.

Rationale for Resectional Procedures or "Extended" Drainage Procedures

On the other hand, 15% to 40% of patients do not experience permanent pain relief after drainage operations.[9,61-63] Moreover, an inflammatory mass in the pancreatic head is considered a contraindication for a "simple" drainage operation, as associated complications of adjacent organs such as distal common bile duct stenosis or segmental duodenal stenosis require additional bypass procedures.[50,64] Finally, a reliable exclusion of malignant disease is not warranted.[12] Therefore, so-called extended-drainage operations were established as an alternative to classic resectional procedures (e.g., the Whipple or Longmire-Traverso procedure) and as opposed to so-called simple drainage operations (e.g., pancreaticojejunostomy of the Puestow-Gillesby or the Partington-Rochelle type). An inflammatory tumor of the pancreatic head arising in 30% to 50% of patients with chronic pancreatitis generates complications of adjacent organs (e.g., distal common bile duct stenosis, duodenal stenosis, and segmental portal hypertension and/or obstruction of the proximal pancreatic duct system by stones or strictures).[65] Moreover, irrespective of the width of Wirsung's duct, approximately 90% to 95% of patients suffering from chronic pancreatitis present with a problem located in the head of the pancreas (i.e., cephalic ductal alterations with or without the development of an inflammatory mass). Thus, the head of the pancreas has been referred to as the "pacemaker" of the disease.[46,66,67] First steps addressing a more customized approach to these patients were done by Beger and coworkers who inaugurated the duodenum-preserving resection of the head of the pancreas (Fig. 88–2).[68,69] This procedure includes subtotal resection of the pancreatic head following transection of the pancreas above the portal vein. Even in cases of distal common bile duct stenosis or segmental duodenal obstruction, extensive resection with decompression of the bile duct and the duodenum allows for adequate management of these organ complications, while gastroduodenal passage and common bile duct continuity may be preserved.[67,70] Identification of the intrapancreatic course of the distal bile duct is facilitated by insertion of a metal probe into the choledochal duct through a proximal choledochotomy.[71] The body of the pancreas is drained by an end-to-end or end-to-side pancreaticojejunostomy using a Roux-en-Y loop. The same jejunal loop drains the resection cavity by a side-to-side anastomosis to the rim of the resection cavity of the pancreatic head. Whipple, Longmire-Traverso, and Beger types are characterized as resectional procedures to a varying extent and require a transection of the pancreas above the portal vein. Especially in chronic pancreatitis with an inflammatory tumor of the pancreatic head, this operative step may represent the most challenging part of the

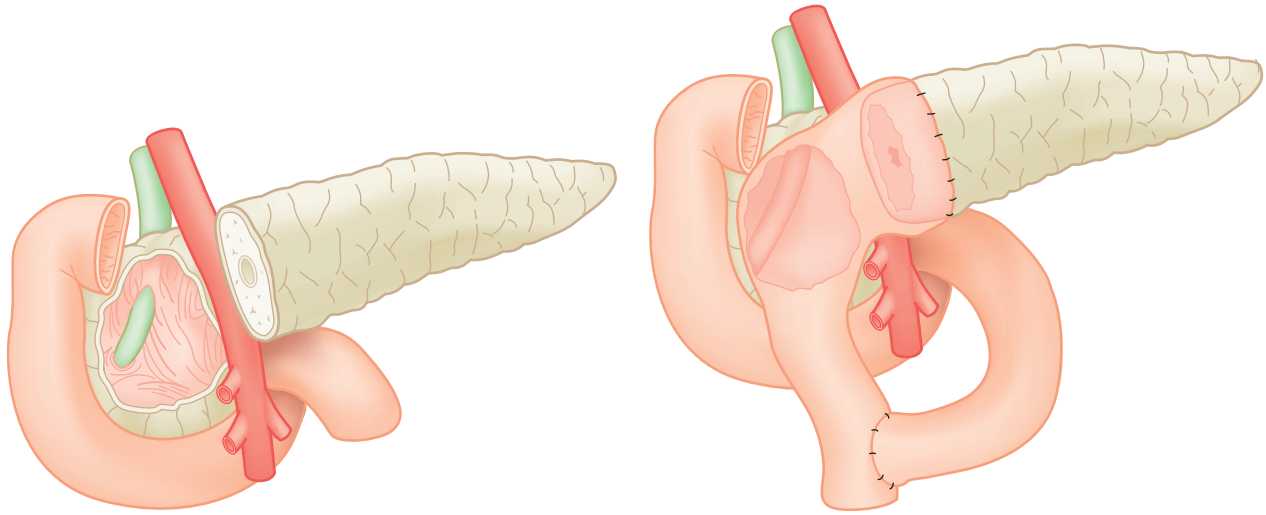

Figure 88–2. **A** and **B,** The duodenum-preserving resection of the pancreatic head, introduced by Beger, addresses the head of the pancreas referred to as the pacemaker of the disease. (**A,** From Beger HG, Buechler M: Duodenum-preserving resection of the head of the pancreas in chronic pancreatitis with inflammatory mass in the head. World J Surg 14:83-87, 1990; **B,** From Beger HG, Krautzberger W, Bittner R, et al: Duodenum-preserving resection of the head of the pancreas in patients with severe chronic pancreatitis. Surgery 97:467-473, 1985.)

operation due to displacement and/or compression of the mesenterico-portal vein axis or massive inflammatory adhesions to these vessels. Therefore, extended-drainage operations were devised that address not only the problem of intraductal and intraparenchymatous hypertension but also the morphologic alterations located in the pancreatic head while at the same time avoiding the sometimes risky maneuver of pancreatic transection. The combination of longitudinal pancreaticojejunostomy of the Partington-Rochelle–type with a transduodenal pancreaticoplasty (e.g., a surgical sphincterotomy of the orifice of the pancreatic duct) is an example of an extended-drainage procedure. This operation warranted adequate drainage of the main pancreatic duct while at the same time addressing the problem of prepapillary obstruction of the proximal pancreatic duct caused by stones or strictures.[72] Probably due to the rapid technologic advancements in interventional endoscopy with the possibility of endoscopic sphincterotomy,[73] this procedure did not gain widespread acceptance. A modified procedure communicated by Frey[68,74,75] combines a longitudinal pancreaticojejunostomy according to Partington and Rochelle[60] with a local excision of the pancreatic head drainage and duodenum-preserving excision (Fig. 88–3). This extended-drainage procedure refrains from pancreatic transection above the portal vein. For reconstruction a longitudinal pancreaticojejunostomy is employed draining the resection cavity of the head, body, and tail of the pancreas. This procedure preserves the physiologic gastroduodenal passage and the continuity of the common bile duct and therefore possesses the same physiologic approach as the duodenum-preserving resection described by Beger.[68,69] This procedure, as well as Beger's, should have considerable advantages over the various types of pancreaticoduodenectomy (e.g., Whipple or Longmire-Traverso). It can at the same time preserve exocrine and endocrine pancreatic function and is able to control complications of adjacent organs such as common bile duct stenosis, duodenal stenosis, and internal pancreatic fistulas. The extent of pancreatic head excision can be modified up to a subtotal excision including the uncinate process leading to the concept of the "Hamburg" modification of the Frey procedure (Fig. 88–4). The major advantage of drainage procedures (Frey's procedure, Hamburg modification) lies in the varying extent of resection that can be customized to the individual morphology of the pancreas.

Operative Modifications of Duodenum-Preserving Resectional Procedures

Modifying the Beger procedure, Warren and coworkers suggested to combine a duodenum-preserving pancreatic head resection with denervation of the body and tail of the pancreas by ligating and dividing the splenic vein at its junction with the superior mesenteric vein.[76] The splenic artery is divided as it approaches the pancreas from the celiac axis. Viability of the spleen is ensured through its extensive arterial and venous collateral circulation, principally the gastroepiploic and short gastric vessels. The entire flap (pancreas, splenic artery and vein, and associated nerve fibers) is freed from all tissue until the pancreas is attached only to the vessels at the hilus of the spleen. This maneuver supposedly severs all somatic and autonomic nerve fibers. Finally, a Roux-en-Y loop of jejunum is prepared and the pancreatic duct anastomosed with a small mucosal opening. Kimura et al. suggested a different modification of a duodenum-preserving pancreatic head resection with detailed

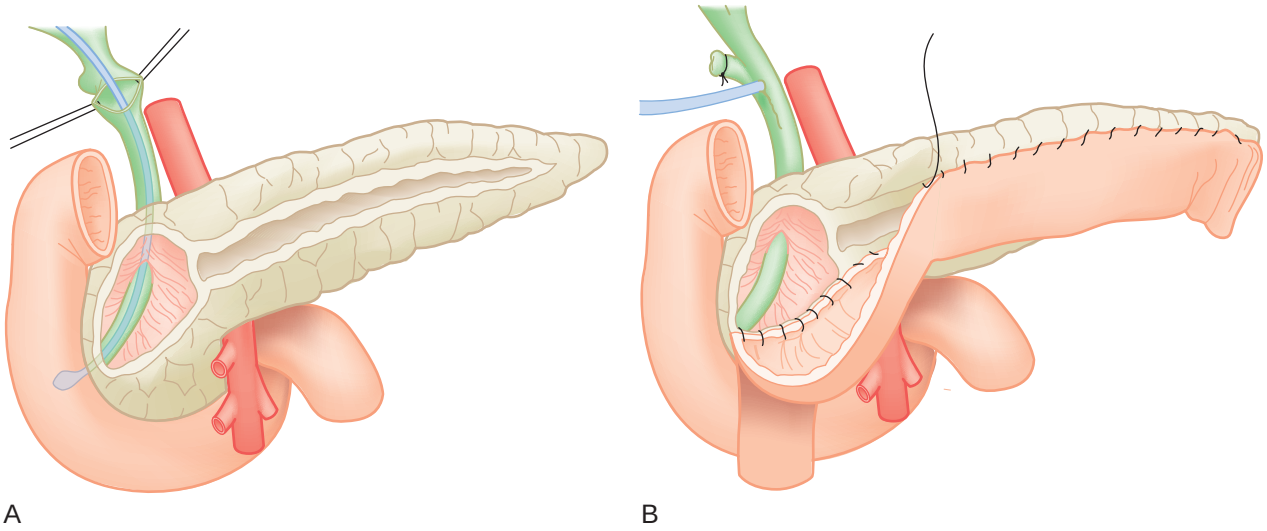

Figure 88–3. **A** and **B,** The Frey procedure. Limited local resection of the head of the pancreas combined with longitudinal pancreaticojejunostomy decompressing of the main duct in the neck, body, and tail of the pancreas. (**A,** From Frey CF, Suzuki M, Isaji S, Zhu Y: Pancreatic resection for chronic pancreatitis. Surg Clin North Am 69:499-528, 1989; **B,** Frey CF, Amikura K: Local resection of the head of the pancreas combined with longitudinal pancreaticojejunostomy in the management of patients with chronic pancreatitis. Ann Surg 220:492-507, 1994.)

description of how to preserve the duodenal blood supply.[77,78] After a complete Kocher maneuver is performed, the pancreas is cut above the portal vein and removed from the third potion of the duodenum. Then the posterior surface of the pancreatic head is removed from the connective tissue membrane, which should be left intact to ensure blood flow to the duodenum. The main pancreatic duct is cut at its junction with the terminal portion of the bile duct. The pancreas is cut on the left aspect of the anterosuperior pancreaticoduodenal artery. Hence, the pancreatic tissue between the duodenum and the common bile duct is left intact to preserve sufficient blood flow to the papilla. After carefully suturing the cut surface of the pancreas with nylon monofilament strings, the remaining body of the pancreas is anastomosed in the posterior wall of the stomach. Nakao described a pancreatic head resection with segmental duodenectomy including minor and major papilla in 1998.[79] After cholecystectomy, the pancreas is divided above the portal vein. The extrapancreatic nerve plexus between the uncinate process and the superior mesenteric artery is preserved, so the inferior pancreaticoduodenal artery is preserved. The posterior inferior pancreaticoduodenal artery is ligated and divided. The anterior inferior pancreaticoduodenal artery is divided near the major papilla. The common bile duct is divided at the upper border of the pancreas. Two to three centimeters of ischemic area of the duodenum is observed including the major and minor papilla. The oral side of the duodenum is divided at 5 to 7 cm from the pyloric ring. The distal part of the duodenum is divided at the margin of the anteroinferior pancreaticoduodenal artery ligation. The gastroduodenal artery is completely spared. The length of the resected duodenum ranges from 3 to 5 cm. The reconstruction of the alimentary tract is performed with pancreaticogastrostomy, duodenoduodenostomy, and choledochoduodenostomy. Most recently, another modification (Bern procedure) has been added to the surgical armamentarium for treatment of chronic pancreatitis.[80] It combines some aspects of the Beger and Frey procedures since it refrains from transection above the portal vein but excises the pancreatic head to a much larger extent than the Frey procedure, therefore potentially preventing a recurrence and definitely decompressing the common bile duct. Early results are promising and randomized trials are under way, but late follow-up results are not available yet. It is our firm belief that the optimal surgical treatment consists of an individually tailored approach (Hamburg procedure). The head of the pancreas should always be cored out to a variable extent including a decompression of the intrapancreatic bile duct. This ensures the removal of altered tissue and includes "inflammatory altered" as well as "hypertensive" tissue. In addition, the procedure can be further customized regarding the pancreatic duct system. If ductal irregularities are present in the pancreatic head and tail, the operation can be extended as a drainage operation much in the way of a Partington-Rochelle procedure into the pancreatic tail.

Is a Drainage Operation Indicated only in Patients with Dilated Ducts?

The normal diameter of the pancreatic main duct amounts to 3 to 5 mm in relation to age.[6,10] In the surgical literature there is considerable controversy regarding the definition of a dilated or narrow pancreatic duct.[6,81] One might develop the impression that definition of a dilated or narrow duct is dependent rather on the view

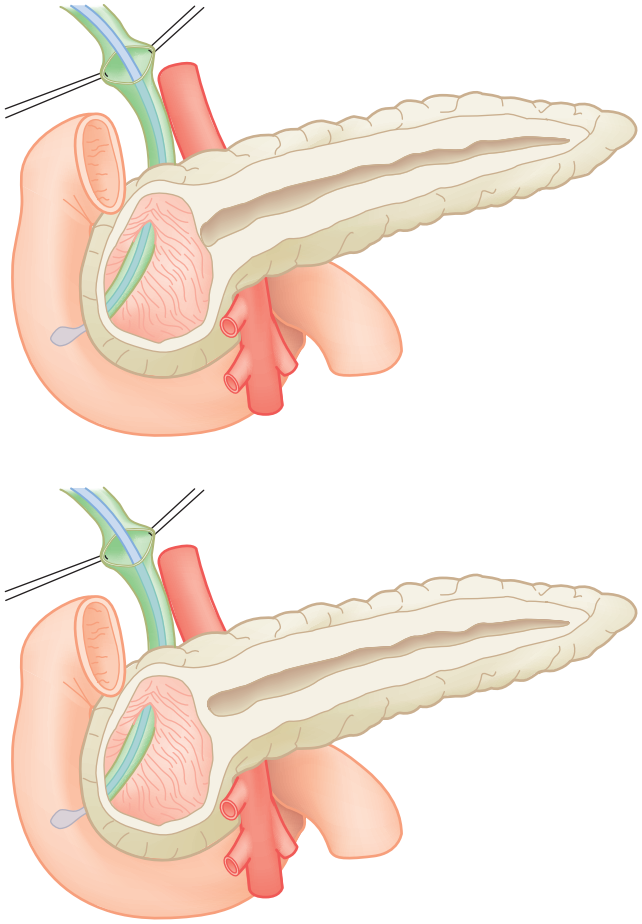

Figure 88–4. The extent of pancreatic head excision can be modified up to a subtotal excision including the uncinate process leading to the concept of the "Hamburg" modification of the Frey procedure. These procedures (original Frey, Hamburg modification) preserve the physiologic gastroduodenal passage and the continuity of the common bile duct and therefore possess the same physiologic approach as the duodenum-preserving resection described by Beger.

of the surgeon towards the technical feasibility to perform a pancreaticojejunostomy than on actual duct size. A survey among members of the American Pancreas Club revealed that most considered a duct size of a minimum of 8 mm sufficient to justify a pancreaticojejunostomy. Others regarded a duct size of 5 mm as the limit to perform a drainage operation, performing a pancreaticoduodenostomy rather than a pancreaticojejunostomy.[6] Most recently, another extended-drainage procedure has been described addressing the rare entity of sclerosing ductal pancreatitis referred to as *small duct disease* with maximal Wirsung duct diameter of less than 3 mm.[82] This operation features a longitudinal V-shaped excision of the ventral aspect of the pancreas combined with a longitudinal pancreaticojejunostomy sewn to the edge of the organ (Fig. 88–5). With this new procedure the role of distal pancreatectomy, which has until now been indicated only in sclerosing chronic pancreatitis limited to the pancreatic body and tail,[83] will be further diminished.

Salvage Procedures

Even though pancreatic surgery for chronic pancreatitis yields excellent results, recurrences may occur. Most frequently, recurrence develops in the remnant of the pancreatic head indicating either insufficient surgical resection of the head of the pancreas or aggressive disease. In these instances, salvage procedures may be indicated ranging from "re-do" pancreas head resections to partial pancreaticoduodenectomy (Whipple procedure, pylorus-preserving pancreaticoduodenectomy). In selected patients (i.e., re-recurrence), even total splenopancreaticoduodenectomy has to be considered. This applies, for instance, to patients in which partial pancreaticoduodenectomy, additional interventional nerve blocks, and surgical denervation fail to achieve definitive pain relief. A biliary stricture in the pancreatic head remnant after duodenum-preserving resection of the pancreatic head without morphologic proof of disease recurrence is most likely is due to ischemia of the intrapancreatic bile duct, especially if the duct was opened during the primary operation. In this case a biliodigestive anastomosis is the procedure of choice. In case of disease recurrence of the body and tail either after duodenum-preserving resection of the pancreatic head or after Whipple or Longmire-Traverso procedure, a V-shaped drainage procedure is the first-line treatment of choice.

CONCLUSION

In our opinion, the ideal procedure for chronic pancreatitis is the duodenum-preserving pancreatic head resection that can be combined with longitudinal duct drainage if ductal pathology is present in the pancreatic body or tail to varying degrees that allows a tailored concept. Looking at the present data, there is no need to transect the pancreatic axis above the portal vein. If portal vein thrombosis is present, the duodenum-preserving pancreatic head resection according to Frey is the treatment of choice. The specimen should always be sent for frozen section, and in case of malignancy, oncologic resections should be performed. In case of small duct disease (pancreatic duct diameter <3 mm), a V-shaped excision most likely will address the patients more effectively than do other procedures. If chronic pancreatitis is focused or limited to the corpus or tail of the pancreas, a spleen-preserving distal pancreatectomy is therapy of primary choice.

Pancreatic surgery is technically demanding and bears many pitfalls and potential complications. It should be left to experts in high-volume hospitals to minimize mortality and morbidity.

New Developments in Chronic Pancreatitis: Before Head Resection, Try Endoscopic Treatment First

L. William Traverso · Richard A. Kozarek

The principles of treatment for chronic pancreatitis are based on the following clinical and anatomic patterns:

1. The head of the gland is usually the pacemaker of chronic pancreatitis; any treatment must be designed around this area.
2. Almost every patient seeks treatment for abdominal pain (a few have chronic fistulas).
3. Surgery is considered only after all conservative treatments methods have failed.

In our institution, surgery is used only after "endotherapy" has failed. Endotherapy is an evolving concept that should be utilized only in pancreaticobiliary centers with extensive endoscopic retrograde cholangiopancreatography (ERCP) experience and where proficient management of complicated pancreatitis is already practiced.

Whether one uses surgical or endoscopic treatment, the patient will not have relief of pain unless the following criteria are met:

1. Chronic pancreatitis is documented using the 1963 Marseille definition[1] of "residual pancreatic damage, either anatomic or functional, that persists even if the primary cause or factors are eliminated." The irreversible change in the pancreas is usually fibrosis.
2. The cause of the chronic pancreatitis (e.g., gallstones, alcohol use, or autoimmune pancreatitis) must have been remedied or eliminated.
3. Imaging studies must show an anatomic defect.
4. The Cambridge classification of image severity[2] of "marked" has been documented (e.g., at least a main pancreatic duct stricture with or without stones) (Table 89–1). A schematic of the items that can be associated with a "marked" Cambridge classification is demonstrated in Figure 89–1.
5. The treatment is designed to address this anatomy, which is almost always in the pancreatic head. It is unusual for the epicenter of the disease to be isolated in the tail. Consider then a neoplastic cause or that the patient is currently abusing alcohol.
6. Once endotherapy has failed, the treatment is head resection if the patient is a surgical candidate; in our institution this is pylorus-preserving pancreaticoduodenectomy (PPPD), but there are several "head resection" techniques that are options depending on surgeon preference.

Using the algorithm just presented, the patient considered for head resection is highly selected. However, after long-term follow-up, these highly selected patients will achieve significant reduction in their disabling pain, and three fourths of them will have complete pain relief.[3] We have preferentially used PPPD for head resection in an attempt to accrue a 20-year follow-up after this procedure. If the head of the pancreas is the pacemaker of chronic pancreatitis, then removal of the entire head should produce the best pain relief. This percentage of pain relief with complete head resection should be the benchmark that other, less extensive, head resection procedures should achieve.[4]

The evolution of endoscopic therapy to treat pancreatic disorders has moderated the need for resection in

Table 89–1 Cambridge Classification of "Image Severity" for Chronic Pancreatitis

Cambridge Class Number	Description	Main Pancreatic Duct	Abnormal Side Branches
1	Normal	Normal	None
2	Equivocal	Normal	<3
3	Mild	Normal	>3
4	Moderate	Abnormal	>3
5	Marked	Abnormal*	>3

*Main pancreatic duct (MPD) terminates prematurely (abrupt, tapering, irregular); there are multiple MPD strictures; the MPD is dilated >10 mm; ductal filling defects (stones) are present; intrapancreatic or extrapancreatic "cavities" are observed; or there is contiguous organ involvement (e.g., stenoses of common bile duct or duodenum, arteriovenous fistula).
Data from Axon ATR, Classen M, Cotton PB, et al: Pancreatography in chronic pancreatitis: International definitions. Gut 25:1107-1112, 1984.

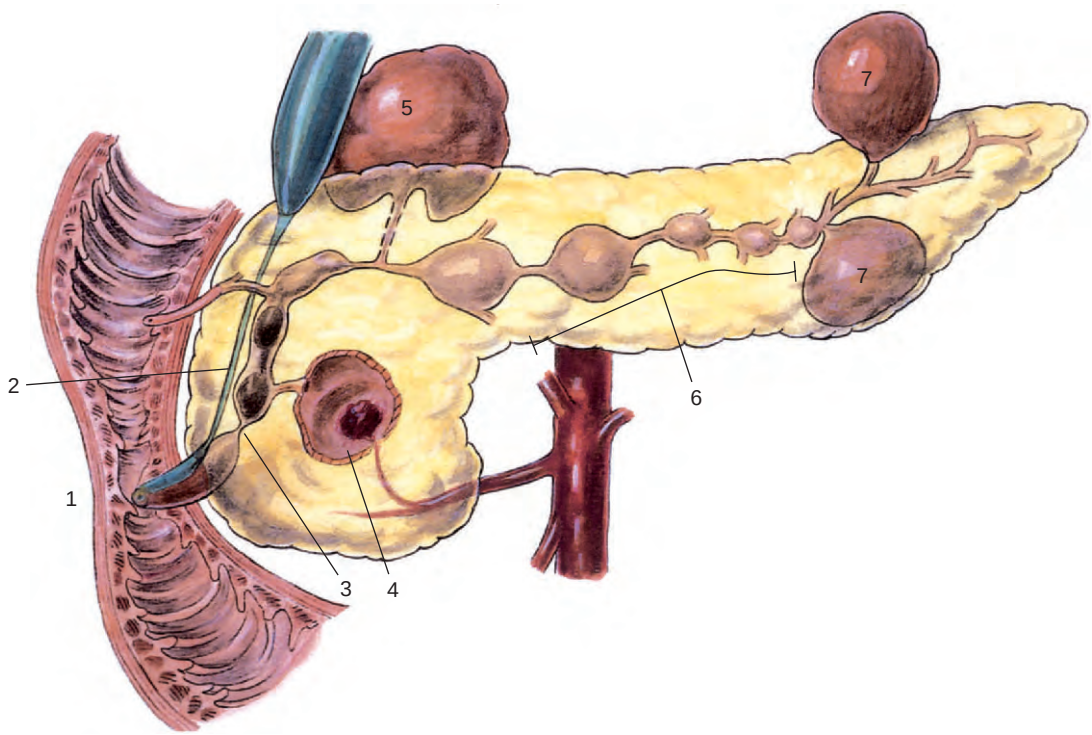

Figure 89–1. Included in this schematic are the possible complications of chronic pancreatitis that the endoscopist or surgeon may encounter when planning therapy. These items should be sought from all imaging studies. Viewing the figure from left to right, the following complications of chronic pancreatitis are depicted: (1) duodenal stenosis; (2) common bile duct stricture; (3) main pancreatic duct stricture (with ductal stones); (4) intrapancreatic pseudocyst with contained pseudoaneurysm (arterial venous connection); (5) ductal disruption at the genu with extrapancreatic pseudocyst formation; (6) chain of lakes ductal dilation; (7) distal pancreatic duct disruptions with focal extrapancreatic pseudocyst collections. (From Traverso LW: The surgical management of chronic pancreatitis: The Whipple procedure. Adv Surg 32:23-39, 1999.)

some centers. Although unable to duplicate the results of pancreatic head resection in patients with multiple strictures and stones associated with pseudotumors of the pancreatic head, endotherapy can nevertheless improve pain as well as decrease relapsing attacks of pancreatitis by approaching *obstructing calculi* and isolated *inflammatory stenoses*. This treatment is not done by endoscopists acting independently but requires access to various forms of lithotripsy, interventional radiologic support, and surgical salvage when endotherapy fails. Head resection is the final option and is the default after multiple sessions in patients where stone extraction is unsuccessful or if

the patient remains stent dependent despite repeated treatment of obstructing stenoses. But how good is endotherapy? The purpose of this chapter is to describe the efficacy for pain relief with endotherapy and, when required, salvage by head resection using PPPD.

ENDOTHERAPY TECHNIQUES

The endoscopic approach to strictures and stones presupposes access to the pancreas through the major or minor papilla. Sphincterotomy can be done using either a conventional or needle knife sphincterotome, usually with a pure cutting current to minimize the chance of cautery transmission. When approaching the pancreatic duct through the major papilla, most endoscopists undertake an initial biliary sphincterotomy to expose the pancreaticobiliary septum and help define the length of the subsequent pancreatic duct (PD) sphincter incision.[5] Slick guidewires (e.g., Tracer or Metro, or Jagwire) are used to provide access and orientation and as the "rail" for all subsequent treatment.

Prior to consideration of endotherapy one must ensure that a pancreatic stricture is benign. The patient will have already had a computed tomographic scan of the "pancreas protocol" variety, an endoscopic ultrasound, and brush cytology of any stricture potentially malignant. These anatomic criteria will have been correlated with the clinical presentation as well as blood tumor markers such as CA 19-9. Clinical follow-up is also a mandatory part of endotherapy as any neoplastic process can masquerade as chronic pancreatitis.

Benign strictures may be dilated by 4- to 6-, 5- to 7-, or 8- to 10-French dilating catheters but are more commonly treated by 4- to 8-mm hydrostatic dilating balloons. Occasionally, extremely tight strictures, particularly those associated with an upstream stone, may need to be breached by a screwlike device called a *Soehendra stent extractor*. Following dilation to a size approximating the downstream pancreatic duct, most endoscopists attempt to place a 7- to 10-French prosthesis across the stricture. This stent is usually retrieved in 2 to 4 months and, if persistent, the stricture is re-treated with additional dilation and replacement of the prosthesis. If initial stent insertion is not helpful to relieve pain, then most endoscopists seek surgical consultation. If the stent insertion is helpful, then the process can be repeated several times over a year's time frame. If the patient becomes stent dependent for symptom relief, most endoscopists consider surgical referral. In contrast to placement of a single stent for a stricture, our practice has evolved into placement of multiple smaller prostheses (5 to 7 French) across the stenosis. Not only does this allow drainage between the stents at time of inevitable stent occlusion, but also, as has been demonstrated in the endoscopic treatment of biliary strictures,[6] multiple stents appear to improve subsequent stricture patency rates.

The removal of obstructing pancreatic calculi is considerably more difficult than the endoscopic removal of bile duct stones.[7] Not only are pancreatic stones frequently associated with downstream strictures but they may also lodge at acute angulations of the duct and result in upstream ductal disruption in the form of a pseudocyst or pancreatic ascites. Approximately half of main pancreatic ductal stones can be removed after PD sphincterotomy, with or without dilation of a concomitant stricture, using conventional biliary stone baskets or an extraction balloon over a guidewires.[8] In the remaining cases, fragmentation is required.

Extremely large, impacted, and irregularly shaped calculi require fragmentation prior to removal. Although the latter can take the form of electrohydraulic, mechanical, or laser lithotripsy, most centers, including our own, prefer extracorporeal shock wave lithotripsy (ESWL).[9-13] Stones can be targeted prior to ERCP, if sufficiently calcified, or may require a baseline ERCP with insertion of a stent or nasopancreatic drain for localization. Once the stone or stones have been localized and fragmented, the fragments must be removed transampullary during an additional endoscopic procedure. Following fragment extraction, prosthesis placement is usually undertaken to minimize obstructive pancreatitis from edema at the site of previously impacted fragments or the sphincterotomy site. In addition, small side-branch calculi frequently migrate into the main pancreatic duct after decompression, and the prosthesis keeps the ductal system decompressed.

RESULTS AFTER ENDOTHERAPY FOR STRICTURE WITHOUT STONES

Multiple recent series have reported a 60% to 80% reduction in attacks of relapsing pancreatitis as well as a comparable relief in chronic pain complaints following endoscopic treatment of pancreatic strictures, although three or four treatment sessions may be required. These results are consistent with the authors' experience.

Several caveats need to be mentioned. Stents themselves can cause "ductitis" and parenchymal injury as a consequence of side-branch occlusion or direct stent pressure by the upstream end or side prongs.[14,15] Additionally, stent placement invariably leads to bacterial colonization within the ductal system. Stent occlusion can occasionally result in upstream duct blowout or even sepsis.

The results of endotherapy for pancreatic duct stricture have to be considered in two categories: persistence of stricture and symptom relief. Anatomically, stricture resolution approximates only 20% to 30% in published series, even when therapy has been undertaken for up to 1 year.[8,16,17] Clinically, most series suggest that only 10% to 20% of patients fail to get relief with initial stent placement, particularly those without upstream ductal dilation or those with multiple stones. In the remaining patients, most achieve a relatively asymptomatic level after stent removal, whereas a minority become stent dependent (15% to 20%) for pain relief. The reason for stent dependence is uncertain but may be related, in part, to location (strictures in the head are more pernicious) or the original cause (those strictures that are a consequence of severe pancreatitis with ductal disruption are often problematic).

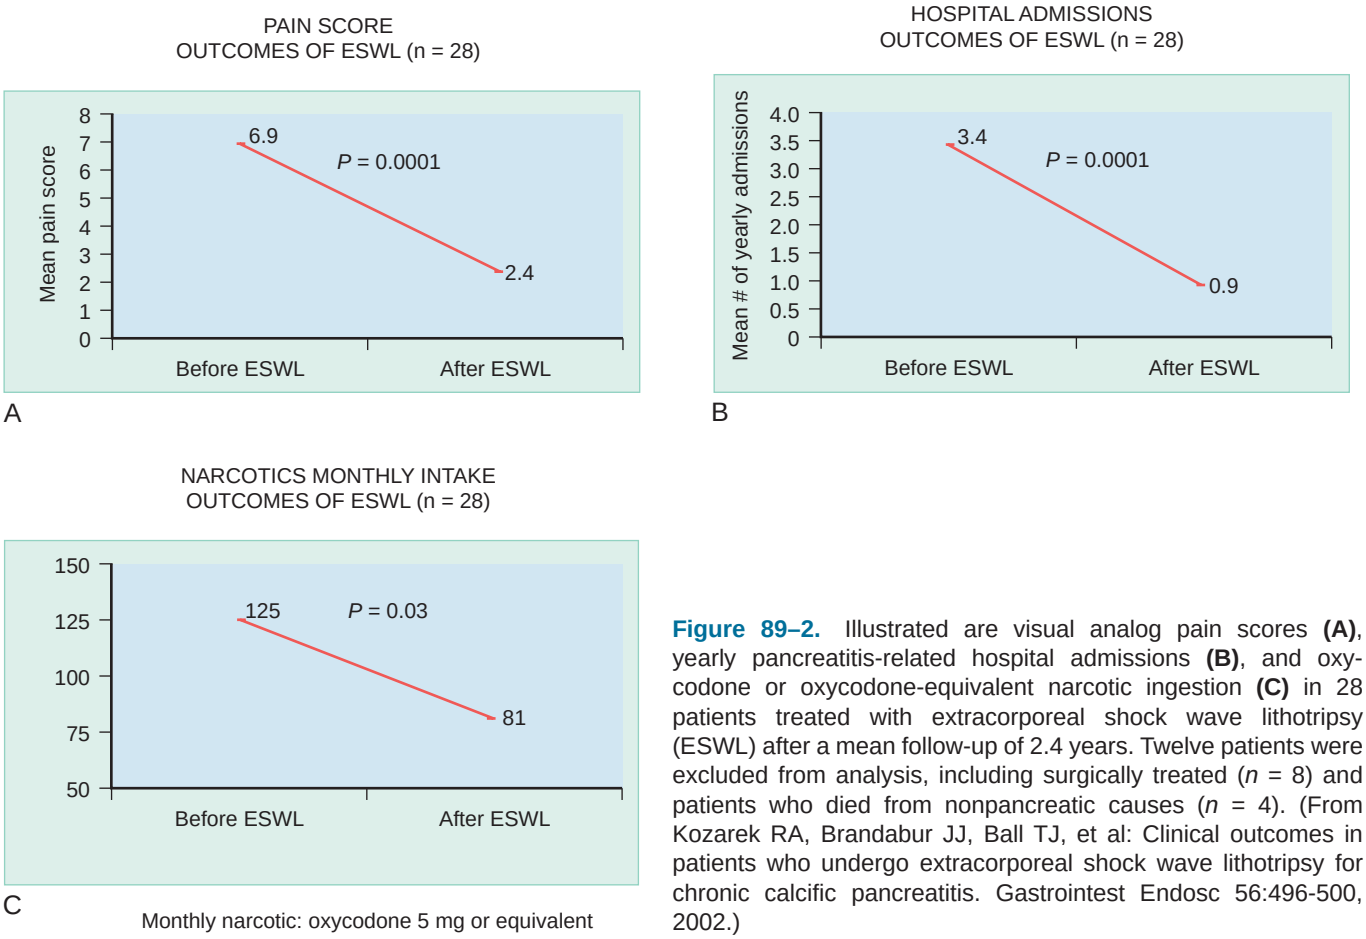

Figure 89–2. Illustrated are visual analog pain scores **(A)**, yearly pancreatitis-related hospital admissions **(B)**, and oxycodone or oxycodone-equivalent narcotic ingestion **(C)** in 28 patients treated with extracorporeal shock wave lithotripsy (ESWL) after a mean follow-up of 2.4 years. Twelve patients were excluded from analysis, including surgically treated (n = 8) and patients who died from nonpancreatic causes (n = 4). (From Kozarek RA, Brandabur JJ, Ball TJ, et al: Clinical outcomes in patients who undergo extracorporeal shock wave lithotripsy for chronic calcific pancreatitis. Gastrointest Endosc 56:496-500, 2002.)

RESULTS AFTER ENDOTHERAPY FOR STONES

About half of the patients will have strictures with stones. In contrast to some of the uncertainty associated with endoscopic treatment of pancreatic duct strictures, data are reasonably good that endotherapy for calculi is associated with short- and long-term symptom relief.[9-11,18,19] This is obviously contingent on successful clearance of stones from the main pancreatic duct, the treatment of concomitant biliary and/or pancreatic ductal stenosis, and patient selection (patients with a pseudotumor have problems not necessarily related to stones and should be excluded from endotherapy).

During the period of 1995-2000 we began our series of pancreatic duct stone extraction.[20] Thirty-five of 40 patients required a single ESWL session, while a total of 86 ERCPs were required to completely clear the main pancreatic duct. There was a 20% rate of minor procedural complications. After a mean follow-up of 2.4 ± 0.6 years, 80% of the patients avoided surgery. Four of these patients died of a cause unrelated to chronic pancreatitis. There was a statistically significant decrease in analog pain scores, oxycodone-equivalent narcotic use, and yearly pancreatitis-related admissions (Fig. 89–2).

Since that time, an additional 90 cases have been added with comparable results. The utilization of endoscopy to approach pancreatic strictures and stones since 1995 has not been associated with an increase in operative drainage or resective procedures for pancreatic duct stones; despite a relative increase in referrals for evaluation of chronic pancreatitis problems. The lack of an increase in surgical procedures may be due to endotherapy. However, as some have suggested, endotherapy might simply delay an inevitable resective or more effective decompressive procedure.

SURGICAL RESECTION TECHNIQUES

As indicated earlier we use PPPD preferentially for head resection in an attempt to document long-term pain relief after complete head resection. This information is important to support head resection in general. Except for a variety of reconstruction methods the pylorus-preserving technique is generally performed in the same manner throughout the world. The procedure removes all of the head of the pancreas and the duodenum (except the duodenal bulb) as is shown in Figure 89–3. Reconstruction in our institution is depicted in Figure 89–4. Note that the duodenojejunostomy is in an antecolic position, a position we believe minimizes delayed gastric emptying.[21,22] Delayed gastric emptying after the PPPD with this antecolic position should be less than 10%[21] and is most often associated with a pancreatic anastomotic leak.

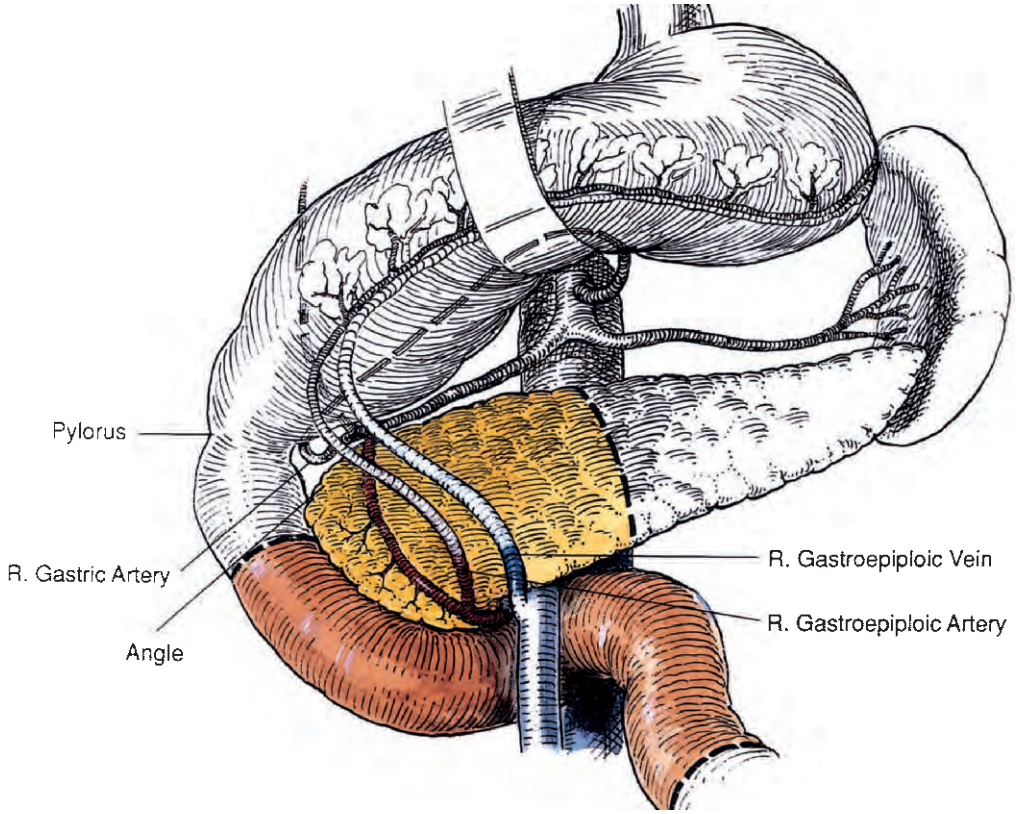

Figure 89–3. The areas in color (also outlined by *dashed lines*) indicate the area of the pancreas, duodenum (parts 2, 3, and 4), and jejunum that are resected with the pylorus-preserving pancreaticoduodenectomy. The complete head of the gland is removed. The right gastroepiploic vessels are divided near their origin as depicted by the color changes. The right gastric artery is also divided away from the stomach near its origin. This allows the neurovascular supply to the antrum and pylorus to be preserved and may minimize the incidence of delayed gastric emptying. (From a black and white photograph, in Traverso LW: The pylorus-preserving Whipple procedure for severe complications of chronic pancreatitis. In Beger HG, Buchler MW, Malfertheimer P [eds]: Standards of Pancreatic Surgery. Heidelberg, Germany, Springer-Verlag, 1993, p 397.)

RESULTS AFTER HEAD RESECTION WITH PYLORUS-PRESERVING PANCREATICODUODENCTOMY

In 1997, we reported the short- and long-term outcomes from 57 patients who had undergone pancreaticoduodenectomy for chronic pancreatitis.[3] Each of these patients had failed to respond to conservative therapy as outlined erlier. The indications for head resection in this group were as follows:

- All patients had intractable abdominal pain and we believed that they had "chronic pancreatitis" according to the Marseilles 1963 classification.
- All patients had the Cambridge image severity of "marked." To be more specific, 96% had main pancreatic duct obstruction and the 4% that did not were patients with intrapancreatic pseudocysts in the head.
- In addition to main pancreatic duct obstruction or pancreatic head pseudocyst, all patients had multiple other elements of the Cambridge classification to support head resection as listed in the footnote of Table 89–1.

The patient characteristics were as follows: 63% were male, 75% were alcohol related, 56% had pancreatic pseudocyst ("cavities") in the head, 23% had previous pancreatic operations such as pseudocyst or main ductal drainage procedures, and 33% were diabetic. The role of endotherapy was prominent in these patients. Common bile duct obstruction was observed in 65% and 47% had undergone prior common bile duct stenting. As listed previously, 96% had pancreatic duct obstruction, 39% had a documented main pancreatic duct blowout, and 35% had undergone pancreatic duct stenting that failed to achieve pain relief. In addition, 19% had required percutaneous drainage of peripancreatic fluid collections.

Ninety-seven percent of these patients underwent PPPD. Since 3% already had an anterectomy from previous ulcer surgery they were reconstructed as a standard Kausch-Whipple procedure. There was no hospital or 30-day mortality.

Follow-up was obtained in 98% of patients after a mean of 42 months. We observed a 5-year actuarial survival rate of 93%. The onset of new diabetes was interesting. In the subset of patients not diabetic preoperatively ($n = 37$), the actual 5-year diabetic occurrence

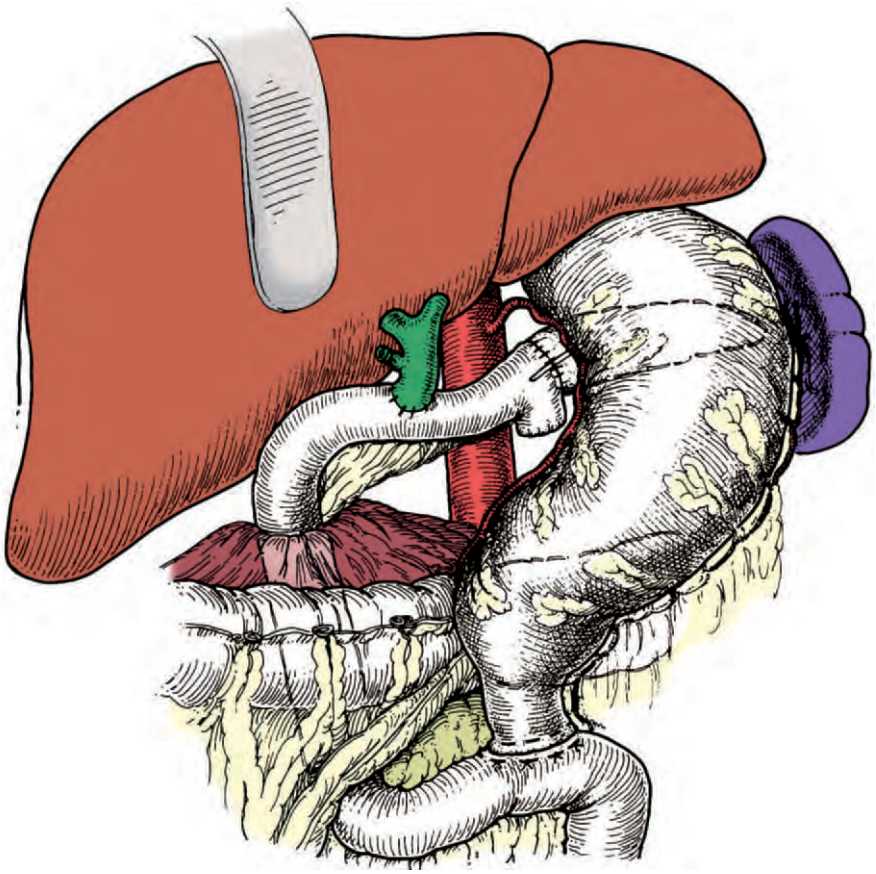

Figure 89–4. Reconstruction of the pancreatic duct and bile duct in a retrocolic fashion. The pancreaticojejunostomy can be made in a side-to-side fashion if a "chain-of-lakes" ductal pattern exists in the pancreatic remnant. The end-duodeno-to-side-jejunostomy is in an antecolic position to isolate the duodenal anastomosis from the pancreatic anastomosis and minimize delayed gastric emptying if the latter should leak. (From Traverso LW: The surgical management of chronic pancreatitis: The Whipple procedure. Adv Surg 32:23-39, 1999.)

rate was 32%. This diabetes was not a consequence of the resection because no patient became diabetic sooner than 12 months after the resection, indicating that the criteria for surgery had been accurate enough to ensure that nonfunctional pancreatic tissue had been excised. These data supported the concept that diabetes was a result of continued fibrosis in the pancreatic remnant. We did not see a predisposition for diabetes due to the pylorus-preserving procedure as has been suggested by others.[23]

Patients that were more than 1 year after their Whipple operation ($n = 43$) were then questioned after a mean follow-up period of 55 months. These patients were asked "do you still have pain and, if so, is it still disabling?" We found a surprising response. In the 96% of patients that originally had disabling pain as an indication for surgery, every patient indicated that he or she had a "good" response to surgery and that the pain was no longer disabling. In addition, 76% of the patients indicated that their pain relief was "excellent" (free of all pain). However, true to the human nature associated with those patients who develop alcohol-associated chronic pancreatitis, 14% of patients were still taking some postoperative narcotic medication (even if they did not have pancreatitis pain) and 24% had resumed drinking alcohol. In regard to activity, 93% of the patients had returned to work, school, or full activity. All patients were able to maintain their preoperative weight, and there were no patients who complained of dumping or significant diarrhea. However, 77% of the patients were taking exocrine enzymes, and 14% indicated that they had diarrhea if they did not take exocrine enzymes.

Another surprising finding was the incidence of marginal ulceration of 14% (6 of 43). Four of these six patients had undergone total pancreatectomy (an operation previously recommended in patients who were diabetic preoperatively). There was a significant correlation of peptic ulceration with the amount of resection; that is, 44% of those patients with total pancreatectomy had peptic ulceration, whereas only 6% with pancreaticoduodenectomy subsequently developed peptic ulceration. Since that time we have avoided total pancreatectomy in almost all patients regardless of their diabetic status. The often-discussed need for total pancreatectomy for small-duct pancreatitis has not been necessary in our practice. Most patients we have seen for "small ductal pancreatitis" were found to be currently drinking alcohol and did not have resective surgery (see list of resection criteria at the beginning of this chapter).

A recent review using "evidence-based medicine" examined a variety of reports that listed pain relief and sequela after all forms of head resection for chronic pancreatitis.[24] Major relief of pain was observed in 70% to 100% of patients from either the standard PD, pylorus-preserving Whipple, duodenum preserving head resection (Beger procedure), or the ventral head resection with upstream ductal drainage (Frey procedure).

These studies were difficult to compare, although many of them were randomized, controlled trials. The problem was the lack of standard selection criteria for head resection. The criteria listed in the current chapter based on imaging studies would be a great opportunity to standardize. Many head resections in Europe are done just for an inflammatory "pseudotumor" of the head without mention of ductal anatomy. The severity of chronic pancreatitis preoperatively is difficult to evaluate without imaging studies that include ductal anatomy. Without ductal anatomy it is also difficult to make an inference on endocrine and exocrine function, unless these are measured preoperatively. The evidence-based medicine review did generalize to state that none of the head resection operations appeared to delay the progression of diabetes better than another. The few prospective trials comparing the complete head resection to partial head resections suffer from low numbers (between 20 and 30 patients in each group). We believe our results (after PPPD) of good to excellent pain relief after long-term follow-up support head resection of any kind, as long as the operation can be done safely and with few long-term sequelae.

In regard to patient safety the morbidity and mortality for all of these operations are also similar. The Beger procedure appears to be practiced mainly in German-speaking countries and the Frey operation appears to be gaining popularity in North America because of less surgical difficulty. Note that any limited head resection such as the Beger or the Frey operation will result in cutting more pancreatic parenchyma than the Whipple procedure where just the neck of the gland is transected. Rapid blood loss occurs from any cut surface of the pancreas. Blood loss would be expected to be higher during parenchymal resection of these limited head resections. The estimated blood loss for the Beger procedure has not been reported. We found the average estimated blood loss for a Whipple procedure in the last 16 reports to be 964 ml while our high-volume center's average blood loss was 204 ml.[22] Since surgeons will not have the opportunity to perform many head resections, then any increased level of difficulty is an important factor in surgeon preference. The infrequency of these chronic pancreatitis cases requiring head resection and the surgical difficulty of the Whipple or the Beger procedures has led many North American surgeons to stay with the more familiar Whipple operation, not try the Beger procedure, or begin using the Frey procedure. This case volume infrequency is further compounded by the promising results of endotherapy for chronic pancreatitis. Perhaps even fewer patients will require head resection.

SUMMARY

Endotherapy for chronic pancreatitis is being used more frequently at our institution. When it fails then the patient is salvaged with PPPD with good pain relief in almost all cases. The technique of endotherapy requires endoscopic access to the pancreatic ductal system where pancreatic strictures can be dilated and stented or pancreatic stones can be removed (with or without ESWL). The technique works best for patients where pancreatic duct stones are exacerbating the pain of chronic pancreatitis. Still, most patients with strictures and no stones will have pain relief sufficient to avoid surgery. Endotherapy has become so effective that the need for surgical drainage and resections has remained constant even though the number of patients referred for problems associated with chronic pancreatitis has increased.

Resection after endotherapy is required for some patients. Generally they comprise two groups. The first group has recalcitrant stone disease behind a main pancreatic duct stricture. The second group has a main pancreatic duct stricture but no stones. Either endotherapy has no effect on their pain or they become stent dependent for pain relief. These two groups form the new and more selected subset that requires head resection. When endotherapy has failed and if the patient meets the criteria for severe chronic pancreatitis centered in the head of the gland, we have observed good to excellent relief of pain after PPPD. Long-term follow-up, which has never been available with cancer patients after the Whipple procedure, has revealed few gastrointestinal side effects from PPPD and without predisposition for diabetes. We avoid total pancreatectomy because of a higher marginal ulceration rate, even if the patient is diabetic.

From this personal experience our understanding of this disease has improved. We can select patients who will benefit from endotherapy most of the time and, if endotherapy fails, these patients can be salvaged for pain relief by head resection using a pylorus-preserving Whipple resection. After long-term follow-up of almost 5 years, the benchmark for disabling pain relief should approach 100% in properly selected patients using anatomic selection criteria. It is hoped that this benchmark could be equaled by a variety of promising operations using a more limited head resection, such as the Frey and Beger operations. First the patients should be selected with a standard list of reliable clinical and anatomic imaging criteria such as those used in this chapter. If the premise is correct that the head of the pancreas is the "pacemaker" of chronic pancreatitis, then limited head resections should approach or equal the pain relief that we have observed after the pylorus-preserving Whipple procedure.

Pseudocysts and Other Complications of Pancreatitis

Ernest L. Rosato · Christopher J. Sonnenday · Keith D. Lillemoe · Charles J. Yeo

PANCREATIC PSEUDOCYSTS

A *pancreatic pseudocyst* is a localized collection of pancreatic secretions surrounded by a wall of fibrous or granulation tissue that arises as a result of acute or chronic pancreatitis, pancreatic trauma, or obstruction of the pancreatic duct by a neoplasm (Figs. 90–1 and 90–2). Pseudocysts account for about 75% of cystic lesions of the pancreas. They are distinguished from other peripancreatic fluid collections (cystic neoplasms and congenital, parasitic, and extrapancreatic cysts) by their lack of an epithelial lining, a high concentration of pancreatic enzymes within the pseudocyst, and formation at least 4 weeks after an episode of pancreatitis or pancreatic trauma (Box 90–1). Pseudocysts are formed by the inflammatory response that occurs after extravasated pancreatic secretions are walled off by the surrounding structures. The capsule of the pseudocyst can be thin fibrous tissue, which can progressively thicken as the pseudocyst matures. Frequently, the liquid contents of the pseudocyst are gradually resorbed by the body, and the pseudocyst resolves, findings indicating that the communication between the pseudocyst and the pancreatic duct has closed. Persistence of a pseudocyst implies ongoing communication with the pancreatic ductal system, regardless of whether the ductal system can be demonstrated radiographically or pathologically.

Terminology

Because pseudocysts may resemble other collections of fluid that can arise as a complication of acute pancreatitis, clear terminology is required to differentiate these different clinical entities. The International Symposium on Acute Pancreatitis, held in 1992, established consensus definitions for pseudocyst, acute fluid collection, and pancreatic abscess.[1]

Acute fluid collections form early in the course of acute pancreatitis and lack a discrete wall of fibrous or granulation tissue (Fig. 90–3). They are common in patients with severe pancreatitis and occur in 30% to 50% of cases.[2] The majority of these lesions regress spontaneously without specifically directed therapy or drainage. Most acute fluid collections do not represent a communication with the pancreatic duct. Instead, they are a serous or exudative reaction to pancreatic inflammation and trauma. Because they lack true communication with the pancreatic duct, acute fluid collections are also referred to as *pseudopseudocysts*. A fluid collection that persists for more than 4 weeks, that is usually surrounded by a well-defined wall, and that may communicate with the pancreatic ductal system is termed a *pancreatic pseudocyst*.

A *pancreatic abscess* is a circumscribed collection of purulent infected fluid that contains little or no necrotic material and arises as a complication of acute pancreatitis or trauma. A pancreatic abscess typically occurs late in the course of severe acute pancreatitis, often 4 or more weeks after the onset of symptoms. Patients have signs and symptoms of infection. The presence of a purulent exudate, a positive culture for bacteria or fungi, and little or no necrotic pancreatic material differentiate a pancreatic abscess from *infected pancreatic necrosis*, a catastrophic complication that often occurs earlier in the course of severe pancreatitis. This distinction is crucial because the mortality associated with infected pancreatic necrosis is double that of pancreatic abscess and the specific therapy for each condition is markedly different. A pancreatic abscess may be treated by percutaneous drainage in many cases, whereas infected pancreatic necrosis typically requires operative débridement.

Figure 90–1. Computed tomography scan of a patient with a pancreatic pseudocyst in the head of the pancreas. The patient had symptoms of abdominal pain and nausea. The gallbladder appears distended, although the results of liver function tests were normal.

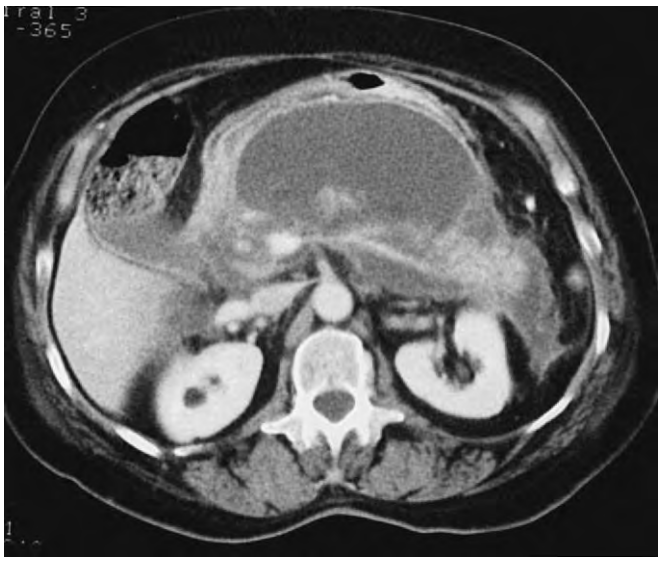

Figure 90–2. Computed tomography scan of a patient with a large retrogastric pancreatic pseudocyst. The patient had symptoms of abdominal pain, back pain, nausea, and early satiety.

Etiology

Pseudocysts have historically been thought to occur in 5% to 10% of patients with acute pancreatitis. As imaging techniques have improved, particularly computed tomography (CT), our knowledge of their prevalence and natural history has improved. Pseudocysts are believed to occur in 10% to 20% of patients with acute pancreatitis and in 20% to 40% of patients with chronic pancreatitis.[3] Pseudocysts occur more commonly in males than in females, a finding that perhaps reflects the frequent occurrence of these lesions in patients with alcoholic pancreatitis. Forty-five percent to 50% of pseudocysts occur in or around the head of the pancreas, whereas the remainder are evenly distributed along the neck, body, and tail of the gland. Pseudocysts are most often solitary round or ovoid collections, but 15% of patients may have multiple pseudocysts. As mentioned, alcohol appears to be the cause of 65% of pancreatitis-related pseudocysts, and gallstones are the origin of another 15% of cases.[4,5] Trauma causes 5% to 10% of pseudocysts, and other less common causes of pancreatitis account for the remainder of cases.

Clinical Features

Abdominal pain, the most common symptom in patients with a pseudocyst, occurs in up to 90% of patients. Pseudocysts that follow an episode of acute pancreatitis are often characterized by persistence or recurrence of upper abdominal pain weeks after the initial attack. A pseudocyst may also be the source of increased or refractory pain in a patient known to have chronic pan-

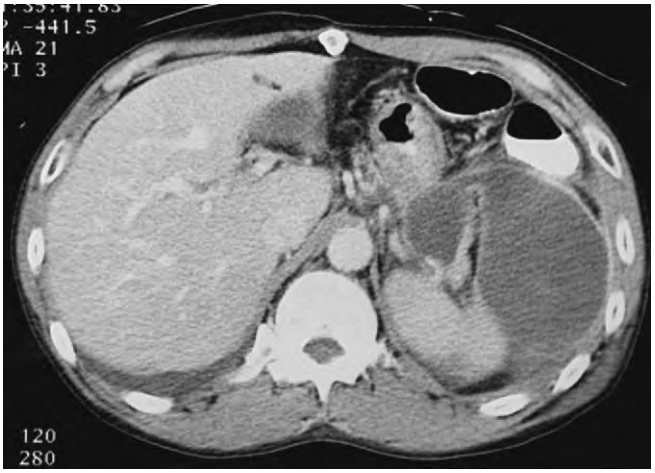

Figure 90–3. Computed tomography scan of a patient with an acute fluid collection 10 days after an episode of acute alcoholic pancreatitis. The collection is located anterior to the spleen and appears to have a thin wall. The acute fluid collection was not causing symptoms and gradually resolved with observation.

creatitis. Other common symptoms include early satiety, nausea and vomiting (50% to 70%), weight loss (20% to 50%), jaundice (10%), and low-grade fever (10%).[6,7] Physical examination reveals upper abdominal tenderness in the majority of patients, and 25% to 45% will have a palpable abdominal mass. The symptoms of early satiety, nausea, and vomiting may be secondary to gastroduodenal obstruction caused by a mass effect of the pseudocyst. Rarely, patients with pseudocysts may not seek medical attention until a secondary complication occurs. Such complications include sepsis secondary to infection, hypovolemic shock secondary to pseudocyst-associated hemorrhage, jaundice secondary to common bile duct obstruction, and severe acute abdominal pain as a result of intraperitoneal rupture of a pseudocyst.

Patients with a pseudocyst secondary to trauma may have similar symptoms at a time remote from the trauma. Pancreatic trauma is uncommon, but it may occur after blunt or penetrating injury. The ductal disruption contributing to pseudocyst formation may occur as a direct result of penetrating trauma or, more commonly, as a result of blunt trauma to the upper part of the abdomen that transects or disrupts the pancreas as it crosses anterior to the vertebral column. These injuries may be missed during initial radiologic evaluation or laparotomy, and the diagnosis of a pseudocyst is often made weeks after the initial injury.

Diagnosis

No definitive laboratory findings are available to establish a diagnosis of pancreatic pseudocyst. Elevated serum amylase and lipase concentrations may occur in half these patients. In fact, persistently elevated amylase after resolution of acute pancreatitis should prompt investigation for a pseudocyst. A few patients with a pseudocyst have mild leukocytosis, whereas others have elevated liver function test results, which may indicate some compression of the biliary tree. An abdominal CT scan is the preferred study for diagnosis of a pancreatic pseudocyst. Ultrasound examination also demonstrates many pseudocysts, and it is a less invasive test that may be used to monitor a known pseudocyst for interval size changes.[8] The use of magnetic resonance imaging (MRI) has been advocated to predict whether solid debris within a pseudocyst will prevent adequate percutaneous drainage.[9] Conventional MRI also has the potential advantage of being coupled with magnetic resonance cholangiopancreatography (MRCP) to help define pancreatic ductal anatomy relative to a pseudocyst.[10] Magnetic resonance pancreatography has shown high specificity and diagnostic accuracy in the evaluation of duct strictures and filling defects.[11] More experience is needed in the use of MRI and MRCP for the evaluation of pseudocysts.

Differentiating pseudocysts from other cystic lesions of the pancreas can be challenging. Several groups have advocated the use of percutaneous aspiration to aid in the differentiation of these structures. Lewandrowski and colleagues evaluated the intracystic fluid from 26 cystic lesions for amylase content, cytology, relative viscosity, and the serologic markers carcinoembryonic antigen (CEA) and cancer antigen 125 (CA-125).[12] The nine pseudocysts were found to have high amylase levels, negative cytologic findings, low viscosity, and low levels of CEA and CA-125. Mucinous cystic neoplasms had variable amylase concentrations, usually positive cytologic findings, high viscosity, and variably high levels of the serologic markers (Table 90–1). Serous cystic neoplasms produced fluid with intermediate results; they were low

Table 90–1 Cyst Fluid Parameters Useful in Diagnosis

Diagnosis	Amylase	Cytology	Viscosity	CEA/CA-125	CA 19-9
Pseudocyst	High	Negative	Low	Low/low	Variable
Serous cystic neoplasm	Variable	Negative	Low	Low/variable	Variable
Mucinous cystic neoplasm	Variable	Usually positive	Usually high	High/variable	High

CA 19-9, cancer antigen 19-9; CA-125, cancer antigen 125; CEA, carcinoembryonic antigen.
Modified from Lewandrowski KB, Southern JF, Pins MR, et al: Cyst fluid analysis in the differential diagnosis of pancreatic cysts: A comparison of pseudocysts, serous cystadenomas, mucinous cystic neoplasms, and mucinous cystadenocarcinoma. Ann Surg 217:41, 1993, with permission.

in viscosity and CEA but had elevated CA-125 levels. The few cystadenocarcinomas in the group had high viscosity, high CEA and CA-125 levels, and positive cytologic findings. The Cooperative Pancreatic Cyst Study prospectively evaluated cyst fluid tumor markers and final pathology in 112 patients. Cyst CEA (>192 ng/ml) demonstrated 79% accuracy in differentiating mucinous from inflammatory cysts.[13] A European pooled analysis of cyst fluid results showed that a CEA level less than 5 ng/ml suggested a pseudocyst or serous cystadenoma with 95% specificity.[14] Furthermore, low CA 19-9 cyst fluid levels were strongly predictive of a nonmucinous cyst. Although these results indicate that some conclusions may be made about the type of cystic lesion based on cyst fluid sampling, percutaneous aspiration is not usually necessary for differentiation between pseudocysts and cystic neoplasms.

Many authors advocate the use of endoscopic retrograde cholangiopancreatography (ERCP) for the diagnosis and treatment planning of patients with pancreatic pseudocysts.[15-18] The obvious advantage of ERCP is the ability to define pancreatic ductal anatomy, of particular benefit in evaluating a pseudocyst in a patient with chronic pancreatitis. Nearly all patients with pseudocysts have some abnormality in their pancreatic ductal system, and 2% to 50% may have abnormal cholangiograms as well. A prospective study by Nealon et al. of ERCP in patients with pseudocysts found that ERCP findings changed operative management in 24 of 41 patients undergoing surgery for a pseudocyst.[19] Nineteen of the patients in the study underwent longitudinal pancreaticojejunostomy for drainage of the pancreatic duct. Unfortunately, this study had no matched controls, and therefore no conclusions regarding an outcome advantage for patients who underwent preoperative ERCP can be made.

ERCP has also been advocated as a method to determine which patients with pseudocysts are candidates for percutaneous drainage. Ahearne et al., in a 1992 study, assumed that pseudocysts associated with disruption of or communication with the main pancreatic duct required surgical drainage whereas those without these ERCP findings could be drained percutaneously.[20] This assumption may not be true. In retrospective fashion, the authors showed that patients treated according to an algorithm based on their stated assumption had fewer adverse outcomes (12%) than did patients treated in a manner that did not follow the algorithm (43% adverse outcomes). This study indicates that use of an ERCP-based algorithm can lower the incidence of adverse outcomes in patients with pancreatic pseudocysts (Fig. 90–4).

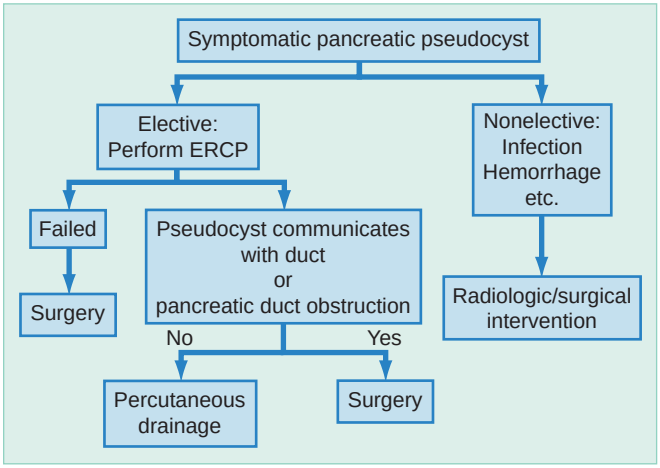

Figure 90–4. Treatment algorithm retrospectively applied to patients with pancreatic pseudocysts. ERCP, endoscopic retrograde cholangiopancreatography. (From Ahearne PM, Baillie JM, Cotton PB, et al: An endoscopic retrograde cholangiopancreatography [ERCP]-based algorithm for the management of pancreatic pseudocysts. Am J Surg 163:111, 1992.)

Natural History

Appropriate management of a patient with a pancreatic pseudocyst requires knowledge of the natural history of these lesions. Before the widespread use of ultrasonography and CT, determination of the natural history of pancreatic pseudocysts relied on other, less accurate diagnostic modalities, such as upper gastrointestinal series, physical examination, and operative and autopsy findings. Data based on these methods indicated that pseudocysts rarely regress spontaneously and that complications occur in up to half of all patients. Therefore, nonoperative, conservative therapy was not advocated in patients with known pancreatic pseudocysts.

A series of studies based on improved imaging techniques increased our understanding of the natural history of pancreatic pseudocysts and led to the era of nonoperative management of the majority of these lesions. In 1979, Bradley and colleagues reported on the natural history of pseudocysts as followed by ultrasonography.[21] Pseudocysts present for less than 6 weeks were found to resolve spontaneously in 40% of cases, although they had a 20% risk for complications. However, pseudocysts documented to be present for longer than 12 weeks did not resolve and were associated with a complication rate of 67%.

In 1990, Yeo et al. reported data from the Johns Hopkins Hospital in Baltimore that evaluated the natural history of pseudocysts by CT scan.[22] Seventy-five patients with pseudocysts were monitored with interval CT scans of the abdomen. All patients with asymptomatic pseudocysts, regardless of size, were initially managed nonoperatively. Operative intervention was performed only for persistent abdominal pain, pseudocyst enlargement, or pseudocyst complications. Nearly half (48%) of these 75 patients were successfully managed nonoperatively. At a 1-year mean follow-up, 60% of patients had complete resolution of the pseudocyst, whereas the remaining 40% had pseudocysts that remained stable or decreased in size. The only significant difference between the two

groups by CT criteria was pseudocyst diameter, with pseudocysts in the nonoperative group averaging 5.8 ± 0.8 cm and pseudocysts in the operative group averaging 7.4 ± 0.6 cm ($P < .05$). Pseudocyst size correlated with the eventual need for surgery: 67% of patients with pseudocysts larger than 6 cm required operative intervention, whereas 40% of patients with pseudocysts 6 cm or smaller required surgical treatment (Table 90–2). Of the patients with pseudocysts larger than 10 cm, 27% were successfully managed nonoperatively.

These data suggested that many patients with pancreatic pseudocysts can be managed nonoperatively with careful clinical and radiologic follow-up, a practice that was confirmed by a study reported from the Mayo Clinic in Rochester, Minnesota.[23] Vitas and Sarr described 68 patients treated nonoperatively, 6 (9%) of whom had a severe complication and only 24 (35%) required operative management. The likelihood of eventual operative intervention did increase with pseudocyst size, although no strict size cutoff could be demonstrated. The success of nonoperative management was independent of the cause of the pseudocyst. The experience of these large centers and others has led to the practice of initial nonoperative management in the majority of patients with pancreatic pseudocysts. According to these data, more than 50% of patients can be expected to require no further intervention. To qualify for conservative, nonoperative management, patients should have no symptoms referable to the pseudocyst, no pseudocyst-related complications, and a stable or decreasing pseudocyst size. Patients who do not meet any of these criteria at follow-up evaluation should undergo appropriate intervention (surgical, endoscopic, or percutaneous).

Management

Patients who do not meet the criteria for conservative, nonoperative management require intervention for the pseudocyst. Associated conditions, such as ductal disruption, biliary obstruction, and chronic pancreatitis, may require concomitant intervention. The recommended management strategies for patients with pancreatic pseudocysts have changed and continue to evolve as more long-term follow-up becomes available for specific procedures. Current management options for a patient with a pseudocyst include percutaneous drainage, endoscopic drainage, operative internal or external drainage, and resection (Box 90–2)

Percutaneous approaches to pseudocyst drainage have been reported since the early 1980s. Although many early studies claimed excellent results, extended follow-up information has revealed that recurrence and failure rates for percutaneous techniques are higher than initially documented. An important distinction should be made between percutaneous aspiration and percutaneous drainage. *Percutaneous aspiration* is aimed at aspirating all pseudocyst fluid at one procedure, without leaving an indwelling drainage catheter. On reviewing the literature to date, less than 50% of patients undergoing this technique will have complete resolution of their pseudocyst.[24] The remaining patients will require repeat aspiration or a second technique (endoscopic or operative drainage). One study attempted to determine which factors could predict successful pseudocyst management with percutaneous aspiration. Patients with pseudocysts in the tail of the pancreas, with pseudocysts less than 100 ml in total volume, and with low intracystic amylase levels appeared to be the best candidates for percutaneous aspiration according to this study of 67 patients.[25] Whereas percutaneous aspiration has largely been supplanted by percutaneous drainage, it is still practiced in some centers, especially as an initial strategy to treat a pseudocyst with minimal intervention.

Percutaneous catheter drainage involves placement of an indwelling catheter into a pseudocyst by the Seldinger technique under ultrasound or CT guidance. The pseudocyst is normally entered through a flank or transgastric approach, and the tract may be dilated to accept a catheter ranging in size from 7 to 14 French. These catheters are typically irrigated or flushed with a

small amount of sterile saline two to three times a day to ensure patency, and they are left to drain into an attached bag by gravity. Contraindications to percutaneous drainage include the presence of significant pancreatic necrosis or solid debris in the pseudocyst, lack of a safe access route, pseudocyst hemorrhage, and complete obstruction of the main pancreatic duct (a controversial contraindication). One review of percutaneous drainage series reported a total recurrence rate of 7%, with 16% of patients counted as treatment failures because of the eventual need for drainage by other techniques.[26] Although most of the studies included in this review consisted of small, selected groups of patients, a large retrospective review from a single center compared patients managed percutaneously, operatively, and expectantly.[24] This review found that only 42% of patients who underwent percutaneous drainage did not require other intervention whereas 88% of patients undergoing operative intervention had a successful outcome. Ninety-three percent of the patients in the expectant group required no intervention. Patients in the expectant group had on average smaller pseudocysts (4 cm versus 7 to 9 cm in the percutaneous and operative groups), but no other significant differences. Although these data conflict with previous series reporting the success of percutaneous drainage, they do emphasize the need for an adequate period of expectant management and careful patient selection before any intervention. The authors rightly called for a prospective study comparing percutaneous and operative intervention in comparable patients. The only prospective study to date has been reported by Lang and colleagues. In this study of severe acute pancreatitis, patients were alternately assigned to either percutaneous or operative drainage.[27] Both procedures had similar rates of success, with 88% of pseudocysts ablated by operative management and 77% through percutaneous drainage. Until this study can be repeated in a more diverse group of patients, percutaneous drainage should continue to be considered an effective method of pseudocyst drainage in selected patients. Furthermore, it is a safe procedure. Most series have reported complication rates of less than 20%, with infection of the drain tract, persistent or recurrent pseudocyst, and pancreaticocutaneous fistula being the most common complications.[24,26] A recent population-based study reviewed outcomes in 14,914 patients treated by surgical or percutaneous drainage. Although selection bias was present in the study, patients treated by percutaneous drainage exhibited increased complications and a longer length of hospital stay. In the modern era of health care cost containment, these issues will certainly play a role in future treatment algorithms.[28]

Endoscopic approaches to the treatment of pseudocysts have also evolved substantially.[29] As with percutaneous methods, long-term follow-up is now becoming available. Current techniques involve the use of flexible upper endoscopy to localize and drain pseudocysts by creating a fistulous tract between the pseudocyst and the stomach or duodenum. This communication is created with electrocautery, and an endoprosthesis is left in place to stent the fistula open. Endoscopic drainage usually requires that the pseudocyst be located in the head or body of the pancreas and that it be well apposed to and bulging into the intestinal lumen. *Endoscopic ultrasound* (EUS) can be used to visualize the pseudocyst and to choose a site for drainage. Risks associated with this procedure include hemorrhage from the gastric or duodenal wall and free perforation. Endoscopic and percutaneous techniques have been combined to localize and drain pseudocysts that are adjacent to the gastric wall but do not bulge into the lumen.[30]

Traditional *transmural endoscopic drainage* has a success rate that compares favorably with that of percutaneous and operative drainage. One literature review by Beckingham and associates summarized a series of pseudocysts drained endoscopically from 1987 to 1997.[31] The review found that approximately 50% of pseudocysts were amenable to transmural drainage based on location and relation to the stomach or duodenum. Successful initial drainage was achieved in 86% of patients, whereas 11% had a recurrence requiring further intervention. About half the recurrences, or 5% of the total group, eventually required operative intervention. Endoscopic cystoduodenostomy was found to be slightly more effective than cystogastrostomy, with fewer recurrences, a finding that most likely relates to the longer patency rates of cystoduodenostomy and the smaller size of these pseudocysts. Complications after both routes of endoscopic drainage were extremely uncommon, with significant bleeding, infection, or perforation occurring in less than 2% of cases. Factors associated with successful endoscopic transmural drainage include location in the head and body of the pancreas, pseudocyst wall thickness less than 1 cm, and pseudocysts secondary to chronic pancreatitis or trauma.[32] Pseudocysts associated with severe necrotizing pancreatitis do not respond well to endoscopic drainage because solid debris obstructs the endoprosthesis.

Experience with the use of *transampullary pancreatic stents* also continues to increase, a development that has applications in the treatment of chronic pancreatitis, pancreatic ductal disruption, pancreatic fistulas, and pseudocysts. Drainage of a pseudocyst via the transampullary (transpapillary) route has been attempted in selected patients with pseudocysts shown to have an obvious communication with the main pancreatic duct by ERCP. Several groups published initial series and described similar techniques and results.[33-35] When possible, stents are placed through the ampulla, along the pancreatic duct, and into the lumen of the pseudocyst. When it is not possible to direct the stent into the pseudocyst, the tip of the stent can be placed as close as possible to the communication between the pancreatic duct and the pseudocyst; one must take care to cross any intervening strictures of the pancreatic duct. Complications associated with this procedure are rare and have included mild postprocedure pancreatitis, bleeding, and abscess formation secondary to stent obstruction. Mean follow-up in the three reported series varied from 15 to 37 months. Some patients underwent traditional transmural endoscopic drainage in addition to transampullary drainage. Initial pseudocyst drainage was successful in 81% to 94%, with 76% to 78% of patients

free of recurrence and requiring no further intervention through the period of follow-up. Clearly, transampullary drainage and pancreatic stenting may play a role in pseudocyst drainage in select patients. Prolonged follow-up of these patients for recurrence and duplication of these excellent results in other centers may lead to more widespread use of this technique.

Although favorable results may be obtained with both percutaneous and endoscopic management of pancreatic pseudocysts, not all patients have pseudocysts that are amenable to these techniques. Furthermore, patients in whom these less invasive techniques fail may require *operative intervention* for definitive treatment of their pseudocyst. Operative intervention also provides the opportunity for biopsy of the pseudocyst wall, a procedure that is necessary to exclude the possibility of a cystic neoplasm. Surgical options include internal drainage, excision of the pseudocyst, and external drainage.

The preferred operative approach for most uncomplicated pseudocysts requiring surgical intervention is *internal drainage*. The three standard options include cystojejunostomy to a Roux-en-Y jejunal limb, cystogastrostomy, and cystoduodenostomy. *Cystojejunostomy* is the most versatile technique of operative drainage and is particularly appropriate when a pseudocyst is located at the base of the transverse mesocolon and is not adherent to the posterior gastric wall (Fig. 90–5). *Cystogastrostomy* is a faster and less technically demanding procedure that is used when the pseudocyst is adherent to the posterior

wall of the stomach (Fig. 90–6). The least frequently used technique is *cystoduodenostomy*, which is appropriate only for pseudocysts in the pancreatic head or uncinate process that lie within 1 cm of the duodenal lumen. Cystoduodenostomy is best performed in a fashion similar to that for cystogastrostomy (i.e., by opening the lateral wall of the duodenum and creating a communication between the pseudocyst and the duodenum through a medial duodenotomy). The risk for duodenal leak and subsequent fistula makes cystoduodenostomy the least attractive method of internal drainage and thus reserved for rare use. Cystojejunostomy and cystogastrostomy have comparable morbidity, mortality, and recurrence rates.[26,36] Operative mortality in some series ranges from 0% to 5%. Cystojejunostomy has a slightly lower recurrence rate (7% versus 10%), but it is associated with significantly more blood loss and operative time. Many authors have advocated cystogastrostomy because of these technical advantages. However, Johnson et al. reported life-threatening postoperative complications, as well as two deaths, in patients with large pseudocysts (greater than 15 cm) that were treated by cystogastrostomy.[37] These complications were attributed to incomplete emptying of the pseudocyst, a finding emphasizing that complete dependent drainage is critical in any internal drainage procedure and that any solid material lining a pseudocyst should be thoroughly débrided at the time of internal drainage.

In addition to the conventional open techniques of internal drainage of pancreatic pseudocysts, several centers have performed *laparoscopic drainage procedures.* Large retrogastric pseudocysts can be drained internally by endogastric approaches, as well as by laparoscopic transgastric and laparoscopic extragastric approaches. Each allows for biopsy of the cyst wall and the opportunity for cyst débridement. Laparoscopic cystojejunostomy can be performed in select patients for better dependent drainage. A recent review of laparoscopic internal drainage revealed an operative success rate of 89% with complications occurring in approximately 7% of patients[38,39] (Fig. 90–7).

A small proportion of pseudocysts are best treated by *pancreatic resection.* Most commonly, this operation involves distal pancreatectomy for pseudocysts located in the body or tail of the gland. Peripancreatic and peripseudocyst inflammation can make distal pancreatectomy a technically challenging procedure in this setting. After distal pancreatectomy, a Roux-en-Y

pancreaticojejunostomy to the remnant pancreas may be required to decompress an obstructed or abnormal proximal pancreatic duct. In a few patients with symptomatic pseudocysts in the head of the pancreas associated with an inflammatory mass, excisional therapy may require *pancreaticoduodenectomy*. In this case, pylorus-preserving pancreaticoduodenectomy is the procedure of choice. Less commonly performed procedures, such as duodenum-preserving resection of the head of the pancreas, may be applicable in some patients.

External drainage of a pancreatic pseudocyst through an operative approach is indicated when gross infection is found at the time of surgery or when an immature, thin-walled pseudocyst is encountered that will not allow for safe internal drainage. When the pseudocyst is initially aspirated, purulent material is retrieved. At this time, the pseudocyst is isolated from the remaining abdominal viscera with moist packs, and the pseudocyst cavity is opened with the electrocautery device. The contents of the pseudocyst cavity are then completely evacuated, and the cavity is closely inspected to ensure adequate hemostasis. At least one closed-suction drainage catheter is then placed into the cavity and brought out through the abdominal wall. Appropriate antibiotic therapy should be instituted, and follow-up CT scans are obtained to ensure that the pseudocyst is entirely drained. External drainage may lead to the development of pancreaticocutaneous fistulas, most of which heal spontaneously as long as the proximal pancreatic duct is not obstructed. Total parenteral nutrition

and octreotide therapy (50 to 250 µg subcutaneously three times per day) may assist in closure of a persistent pancreaticocutaneous fistula.[40] Nealon and Walser reported their experience with lateral pancreaticojejunostomy for pseudocysts associated with dilated pancreatic ducts (>7 mm) in patients with chronic pancreatitis. Forty-seven patients were treated by lateral pancreaticojejunostomy alone as pseudocyst management. Long-term pain relief was achieved in 90% of patients, with pseudocyst recurrence being observed in less than 1%.[41] This unique approach requires preoperative pancreatic duct evaluation by ERCP and appears to offer excellent results in select patients.

Complications

A review of the literature reveals that complications develop in up to 40% of patients with untreated pseudocysts, although most series report complication rates of 10% to 20%.[21-23,26,42] The most frequently reported complications include infection, hemorrhage, obstruction or compression of adjacent structures, and rupture.

Infection

An important distinction should be made between pseudocysts that are colonized or contaminated and those that are truly infected. Some pseudocysts contain small amounts of bacteria that are evident on Gram stain or culture, but the fluid from these pseudocysts is not purulent, and patients do not have clinical evidence of infection. However, in a few patients with pseudocysts (less than 5%), true *infection* can develop, as marked by fever, leukocytosis, and increased pain.[22,23] Aspiration of purulent fluid from the pseudocyst confirms the presence of an infection. The most recent Atlanta International Symposium defined these patients as having a *pancreatic abscess* and recommended that use of the term *infected pseudocyst* be avoided.[1] The bacteriology of a pancreatic abscess is highly variable, but up to 60% of these lesions contain gram-negative aerobic and anaerobic organisms.[43]

A pancreatic abscess is one clinical situation in which percutaneous drainage is clearly the treatment of choice. Success rates of up to 85% have been reported in multiple series.[44-46] Retrospective studies have shown similar

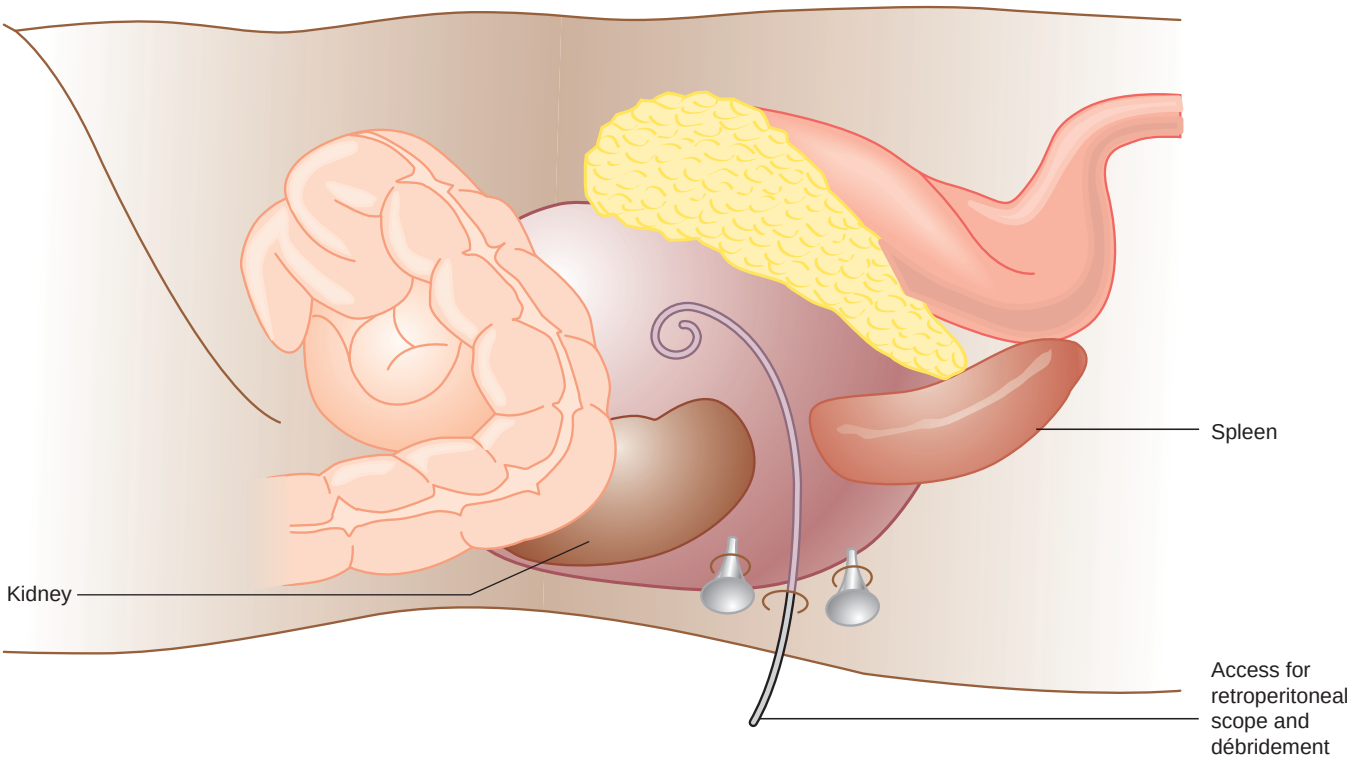

Figure 90–8. Retroperitoneal access to pancreatic necrosis. (From Fernandez-Cruz L, Cesar-Borges G, Lopez-Boado MA, et al: Minimally invasive surgery of the pancreas in progress. Langenbecks Arch Surg 390:342-354, 2005.)

success rates when comparing percutaneous and operative drainage procedures. Furthermore, the mortality rate is lower with percutaneous drainage, and a major open operative procedure is avoided. However, operative external drainage may become necessary in some patients. Percutaneous catheters often do not allow for rapid drainage of thick, purulent material or may not completely address multiloculated collections. Techniques used by interventional radiologists to upsize drainage catheters and to break up loculations are not always successful. In these cases, open operative drainage allows for complete evacuation of all infected material, and external drains may be placed under direct vision. Most recently, percutaneous endoscopic techniques have enabled débridement of necrotic tissue under direct endoscopic vision. Using previous percutaneous drainage tracts, ureteroscopes are advanced into the retroperitoneum and devitalized tissues removed under direct vision while the cavity is continually irrigated. Experience is limited to a few select centers,[47] with promising early results and minimal stress to the patient (Fig. 90–8). Because it is not often possible to predict which pseudocysts or abscesses will be successfully drained percutaneously, patients undergoing percutaneous drainage need to be closely monitored for evidence of resolution, both by clinical parameters and by follow-up imaging techniques. In patients who do not show clinical improvement or who have further progression of their symptoms and in patients who have collections that do not respond to reasonable attempts at percutaneous drainage, operative drainage should be performed.

Hemorrhage

Arterial hemorrhage may occur in up to 10% of patients with pancreatic pseudocysts.[22,23,48] The most common source of pseudocyst-associated bleeding is the splenic artery (up to 50%), with the gastroduodenal and pancreaticoduodenal arteries also accounting for a significant number of hemorrhagic events.[49] Bleeding may also occur from the portal, superior mesenteric, or splenic veins, although such bleeding occurs less commonly. The pathogenesis of arterial hemorrhage seems to follow a predictable sequence, with erosion of the vessel wall leading to pseudoaneurysm formation and eventual rupture. Massive hemorrhage is often preceded by a sentinel hemorrhage. Therefore, any degree of bleeding associated with a pseudocyst should be aggressively investigated. CT scan with intravenous contrast is an appropriate confirmatory test in a stable patient, but angiography may be necessary for diagnosis and provides a mode of treatment.

Initial management of a hemodynamically stable patient is attempted embolization of the pseudoaneurysm or source vessel, a technique performed by most skilled interventional radiologists. Most of these hemorrhages may be effectively controlled by current embolic techniques.[50-53] However, patients in whom embolic therapy fails, who rebleed, or who are hemodynamically unstable require emergency surgical exploration. Control of arterial bleeding may require associated pancreatic resection because oversewing vessels in the setting of the chronic inflammation and

enzymatic erosion associated with pseudocysts is often unsuccessful. When the responsible blood vessel can be effectively ligated, the associated pseudocyst should be externally drained with large-bore catheters. If resection is required, distal pancreatectomy, splenectomy, and splenic artery ligation are the most common procedures. Rarely, emergency pancreaticoduodenectomy may be necessary.

Obstruction

Pancreatic pseudocysts may become symptomatic as a result of the mass effect that they exert on other structures. Although *duodenal obstruction* is the most common manifestation of mechanical obstruction secondary to pseudocyst formation, obstruction of the stomach, esophagus, jejunum, and colon may be identified.[54-58] Obstruction of the mesenteric vasculature and the portal venous system (particularly the splenic vein) may lead to extrahepatic portal hypertension and subsequent splenomegaly and gastric varices.[59] Pseudocysts have also been described as obstructing other retroperitoneal structures, such as the inferior vena cava and the ureters.[60,61] In addition, reports have described pseudocysts with mediastinal and pleural extension impeding cardiac performance secondary to obstruction of preload or increased afterload.[62,63] Congestive heart failure secondary to cardiac compression by a mediastinal pseudocyst has also been reported.[64] Mechanical obstruction of any structure is a relative indication for intervention. At present, no prospective data are available on which to base recommendations for percutaneous, endoscopic, or surgical techniques.

Biliary obstruction secondary to pseudocyst formation is also well described, and it leads to such complications as jaundice, cholangitis, and biliary cirrhosis. Although biliary obstruction may be caused by direct compression of the bile duct by a pseudocyst, most patients have an associated stricture of the intrapancreatic portion of the bile duct that does not improve with pseudocyst drainage alone.[65] Evaluation of any patient with biliary obstruction and a pancreatic pseudocyst requires cholangiography before planning pseudocyst drainage. Treatment of a biliary stricture caused by concomitant chronic pancreatitis may require biliary-enteric bypass, either choledochoduodenostomy or choledochojejunostomy.

Rupture

Spontaneous rupture, the least common complication of pseudocyst formation, occurs in less than 3% of patients, but it may give rise to dramatic clinical manifestations. Spontaneous rupture of a pseudocyst into the peritoneal cavity may lead to severe acute abdominal pain as a result of chemical peritonitis. Such patients are often treated as a surgical emergency, especially those without a known pseudocyst. In patients with a known history of pseudocyst, acute abdominal pain should raise the possibility of free intraperitoneal rupture or rupture into an associated hollow viscus, most commonly a segment of the gastrointestinal tract. Rupture may be secondary to progressive expansion, but it may also indicate the presence of an infected or hemorrhagic pseudocyst. Patients with rupture and sepsis are likely to have either transenteric disruption or an infected pseudocyst that leads to contamination of the peritoneum with enteric bacteria.

Silent rupture of a pseudocyst may also occur. Some pseudocysts are presumed to resolve by rupture or fistulization into an associated portion of the stomach or small bowel, similar to operative or endoscopic enteric drainage. No further therapy is needed in these circumstances. Pseudocysts that rupture silently anteriorly into the peritoneal cavity or posteriorly into the pleural cavity may lead to the development of pancreatic ascites or pancreatic pleural effusion, respectively.[66] Management of these patients is discussed later.

CHRONIC PANCREATITIS

Chronic pancreatitis is a disease with protean clinical manifestations of varying severity, a factor that has made it a difficult disorder to define. The structural changes that have come to be associated with chronic pancreatitis were perhaps first described in 1788, when Cawley noted pancreatic calculi and fibrosis of the gland in a man who had died of malnutrition and diabetes mellitus.[67] However, not until 1963, when the first Symposium of Aetiology and Pathology of Pancreatitis was held in Marseilles, France, was a classification system developed to define chronic pancreatitis and distinguish it from acute pancreatitis.[68] Three of these symposia have now been convened, the last in 1984, and they have produced a definition of chronic pancreatitis based on clinical symptoms (recurrent or persistent abdominal pain), functional pancreatic insufficiency (endocrine and exocrine), and morphologic changes (chronic inflammation, fibrosis, and destruction of exocrine elements).[69,70] Although subsequent groups have attempted to further classify chronic pancreatitis into subgroups based on chronic calcification, chronic obstruction, and chronic inflammation (Rome, 1988), these subgroups are based primarily on histopathologic features that can be difficult to identify in all patients.[71]

Clinical Features

Pain is the initial symptom in up to 95% of patients with chronic pancreatitis and is characteristically described as a dull, boring pain in the epigastrium that may radiate to the left or the right or to the upper lumbar region of the back. The pain is often exacerbated by lying supine, by eating, and by drinking alcohol. Significant weight loss may occur as a result of not only the malabsorption associated with pancreatic exocrine insufficiency but also avoidance of eating secondary to the associated painful attacks. Patients with chronic pancreatitis may describe their pain as episodic or constant. In those with episodic pain, the pain-free intervals may shorten and the painful attacks may become longer as the disease progresses. Up to a third of patients may have spontaneous relief of their pain, an occurrence that usually indicates nearly complete loss of pancreatic exocrine function. However, one

cannot predict which patients will "burn out" and enjoy reprieve from this troublesome symptom. Narcotic addiction is a common problem in patients with chronic pancreatitis and often complicates the management of these patients. Because chronic pancreatitis is often a disease of persons with addictive personalities, such patients may fall easy prey to narcotic dependence.

The pain of chronic pancreatitis appears to be caused by several mechanisms, all of which may have different implications for treatment strategies. *Chronic inflammation* stimulating visceral afferent fibers associated with the sympathetic nervous system is a generally recognized mechanism of pain. Pharmacologic and surgical methods to disrupt transmission along these sympathetic (specifically splanchnic) fibers target this mechanism of pain. *Elevated pressure* in the pancreatic duct and the parenchyma of the gland secondary to precipitation of intraductal proteins and chronic obstruction has also been identified as a potentially correctable source of pancreatic pain. Medical therapy to decrease exocrine secretion and endoscopic and surgical drainage procedures attempt to address this elevated pressure. Evidence of *perineural inflammation* in patients with chronic pancreatitis, an observation first made in 1943 and later revisited, may also play some role in the production of pain.[72,73] Histologic examination of the glands of patients with chronic pancreatitis reveals increased size and density of pancreatic nerves, as well as destruction of the surrounding perineural epithelium by inflammatory cells. This process exposes pancreatic nerves to biologically active molecules, which may generate pain messages (Box 90–3).

From Banks P: Epidemiology, natural history, and predictors of disease outcome in acute and chronic pancreatitis. Gastrointest Endosc 56(Suppl):S226-S230, 2002.

Chronic pancreatitis is further characterized by symptoms of *functional impairment* of the pancreas. *Diarrhea* and *steatorrhea* reflect significant exocrine insufficiency, but they do not usually occur until 90% of the secretory capacity of the pancreas is lost. *Diabetes mellitus* develops in about 50% of patients with chronic pancreatitis, and approximately half of these patients require insulin therapy. A few patients have only evidence of pancreatic endocrine or exocrine insufficiency, without pain. This situation is much more common in elderly patients. Rarely, a patient will have one of the complications of chronic pancreatitis, such as biliary or gastroduodenal obstruction, without any painful symptoms. However, such a finding is rare, and chronic pancreatitis should be diagnosed only after a careful evaluation for underlying malignant disease has been performed.

Complications

The most common reason for referral of a patient with chronic pancreatitis to a surgeon is refractory pain, specifically, pain that is not partially attributable to one of the common complications of chronic pancreatitis, such as a pseudocyst, biliary obstruction, or gastroduodenal obstruction. Patients in this group may have a pancreatic ductal abnormality that can respond favorably to operative treatment through either ductal drainage or resection. Other patients may benefit from more recently advocated techniques such as surgical denervation or duodenum-preserving pancreatic head resection. Surgical treatment of chronic pancreatitis is discussed in Chapter 88.

Although treatment of chronic pancreatitis is multidisciplinary, surgeons often play a primary role in managing the complications of this disease. Some of the common complications of chronic pancreatitis and their management are discussed in the following sections.

Common Bile Duct Obstruction

Although pancreatic inflammation and edema may cause transient partial obstruction of the common bile duct in patients with acute pancreatitis, chronic pancreatitis may lead to a fixed stricture of the intrapancreatic portion of the common bile duct (Fig. 90–9). Early recognition of this problem is essential to prevent the development of cholestasis, cholangitis, and secondary biliary cirrhosis. Furthermore, prompt investigation of biliary obstruction in patients with chronic pancreatitis may allow differentiation from periampullary malignant disease.

Common bile duct strictures caused by the characteristic inflammation and fibrosis of chronic pancreatitis in the head of the pancreas typically have a long, smooth appearance. These strictures most often involve 2 to 4 cm of the intrapancreatic common bile duct, with associated dilatation of the cephalad biliary tree. Biliary obstruction may also be associated with pancreatic pseudocysts located in the head of the gland (Fig. 90–10). Rarely, pseudocysts cause extrinsic compression of the bile duct that resolves with decompression of the pseudocyst. More commonly, patients with pseudocysts have an associated fixed fibrotic stricture of the common bile duct

Figure 90–9. Cholangiogram of a patient with a long distal common bile stricture caused by chronic pancreatitis.

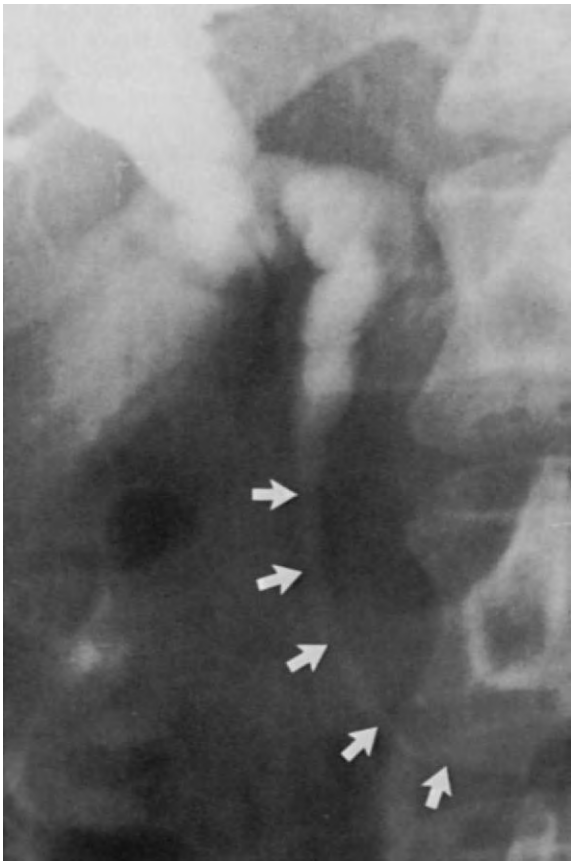

Figure 90–10. Cholangiogram of a patient with a pancreatic pseudocyst showing extrinsic compression of the common bile duct. *Arrows* indicate a narrowed distal common bile duct.

that requires a separate biliary drainage procedure. Warshaw and Rattner reviewed 21 patients with obstructive jaundice associated with a pancreatic pseudocyst.[65] Ten of these patients required biliary decompression because jaundice persisted after drainage of the pseudocyst. In a prospective study, Nealon and colleagues used ERCP to evaluate 44 consecutive patients with pancreatic pseudocysts before operative management.[19] In each of 12 patients with chronic pancreatitis and common bile duct dilatation, a fixed stricture of the intrapancreatic bile duct was identified that required a biliary drainage procedure in addition to management of the pseudocyst.

Historically, common bile duct strictures have been thought to occur in 3% to 29% of patients with chronic alcoholic pancreatitis.[74-77] However, as cholangiography has become more frequently used in patients with chronic pancreatitis, the incidence of common bile duct stricture appears to be even higher than previously thought. ERCP was used by Beger et al. to evaluate 258 patients with chronic pancreatitis; 129 (50%) of these patients were found to have a common bile duct stricture, whereas only 14% were clinically jaundiced at the time of the study.[78] In a similar study, 79 patients with moderately severe chronic pancreatitis underwent ERCP; 36 (46%) of these patients had evidence of stenosis of the intrapancreatic common bile duct.[79]

Common bile duct stricture in chronic pancreatitis may be manifested clinically in a variety of ways. As mentioned earlier, many asymptomatic bile duct stenoses may be identified by cholangiography performed for other indications. Bile duct stricture may also be suggested by laboratory abnormalities in the absence of clinical jaundice. Persistent elevation of serum alkaline phosphatase appears to be the most common abnormal laboratory finding and occurs in up to 80% of patients.[80] Associated elevations in γ-glutamyl transpeptidase can also be observed. At times, the serum bilirubin concentration may be minimally or moderately elevated and is often characterized by a rising and falling pattern. The disproportionate elevation of alkaline phosphatase relative to serum bilirubin is compatible with benign obstruction of the common bile duct in patients with chronic pancreatitis.[81] Malignant obstruction of the bile duct is more commonly manifested as marked, persistent elevation of serum bilirubin. Any elevation of serum bilirubin and alkaline phosphatase in a patient with chronic pancreatitis should suggest the presence of a common bile duct stricture.[82] Even though Beger and colleagues found laboratory abnormalities in only half the patients with ERCP-confirmed common bile duct stricture, nearly all these patients had a history of a previous episode of jaundice.[78] Although patients with chronic pancreatitis may have multiple reasons for the development of jaundice (cirrhosis, hepatitis), a history of intermittent jaundice is typical in patients with a benign common bile duct stricture. A bile duct stricture may also be associated with

abdominal pain, which may be difficult to distinguish from the typical pain of chronic pancreatitis. The initial assessment of a patient with chronic pancreatitis and refractory pain should include evaluation of the biliary tree, particularly if any of the laboratory abnormalities mentioned earlier are present. Failure to consider a common bile duct stricture may lead to failure to relieve a patient's pain despite other interventions for chronic pancreatitis. However, operative intervention limited to the biliary tract in a patient with chronic pancreatitis rarely relieves the pain completely. For example, Stabile and associates obtained adequate pain relief in only 7 of 38 patients who underwent biliary tract decompression alone.[83]

Cholangitis, a potentially life-threatening complication, occurs in approximately 10% of patients with common bile duct strictures secondary to chronic pancreatitis.[80,84] Bile cultures reveal bacterial growth, most likely gram-negative bacilli, in more than half the patients with bile duct strictures.[84,85] Nevertheless, the incidence of cholangitis remains low. The occurrence of cholangitis should lead to a search for a bile duct stricture because cholangitis is uncommon in patients with chronic pancreatitis without a biliary stricture.

Absolute indications for intervention in patients with common bile duct strictures and chronic pancreatitis include refractory pain, persistent jaundice, and cholangitis. Other conditions that may cause jaundice in a patient with chronic pancreatitis, such as cirrhosis, hepatitis, and choledocholithiasis, should be ruled out before the clinician commits to a treatment plan. However, the most important and often difficult differentiation is to determine whether the common bile duct obstruction is being caused by chronic pancreatitis or by a periampullary malignant tumor. Several important clinical features may suggest one condition or the other in the absence of a tissue diagnosis, which may be impossible to obtain without exploration and resection. Wapnick and colleagues found that patients with chronic pancreatitis as the cause of biliary obstruction were significantly younger (average age of 47 versus 62 years) and had a lower serum bilirubin level (5.6 ± 1.5 mg/dl versus 18.5 ± 2.1 mg/dl) than did patients with obstruction secondary to periampullary carcinoma.[86] Patients with obstruction resulting from chronic pancreatitis also tended to have fluctuations in their serum bilirubin level, whereas patients with carcinoma had a persistent rise in the bilirubin level until biliary decompression was accomplished. The combination of historical observations, laboratory findings, and radiologic studies, as discussed later, can differentiate some cases of benign stricture from carcinoma.

The initial imaging study in any patient with suspected biliary tract obstruction is either abdominal ultrasound or CT scan. Although both ultrasound and CT are suitable initial tests, spiral CT scan is the preferred test unless gallstone disease is strongly suspected. CT scan allows better visualization of the pancreas and thus makes it the most useful initial test in a patient with obstructive jaundice. A well-defined mass in the head of the pancreas usually indicates malignant disease. However, some patients with periampullary malignant disease do not have a defined mass. Furthermore, many patients with chronic pancreatitis have diffuse enlargement or inflammation of the head of the pancreas. Pseudocysts may also be well visualized with CT. More support has arisen for the use of MRI in the evaluation of these patients. Dynamic MRI with gadolinium enhancement has been advocated as a good method to differentiate between chronic pancreatitis and pancreatic carcinoma. However, data have not shown any clear distinguishing characteristics between enhancement of the two pathologic entities.[87] At present, MRI appears to have no advantage over CT.

Cholangiography is the definitive study for visualizing the anatomy of the biliary system. Both ERCP and percutaneous transhepatic cholangiography can be useful, although ERCP is preferred. ERCP offers the advantage of visualization of the pancreatic ductal system, which is necessary for planning operative therapy in patients with chronic pancreatitis, and direct visualization of the ampulla of Vater, which allows for biopsy if a mass is visible. Additionally, ERCP is less invasive. Both methods allow decompression of an obstructed biliary tree. Although bile duct strictures in patients with chronic pancreatitis often have a long, smooth, gradually tapered appearance, pancreatic carcinoma frequently causes an abrupt cutoff or tumor meniscus at the genu of the common bile duct. Tumors of the distal common bile duct are most often accompanied by a stricture just above the ampulla, which is not as long as the stricture associated with chronic pancreatitis. Ampullary and duodenal malignant tumors most often cause obstruction at the ampulla, the most distal portion of the bile duct. These latter tumors can be visualized with endoscopy during ERCP, and biopsy is therefore possible. MRCP has gained popularity as a noninvasive method of cholangiography.[10] Although it allows for neither decompression of an obstructed biliary system nor tissue biopsy, MRCP appears to correlate well with ERCP in defining ductal anatomy.[88-92] MRCP was studied specifically in patients with pancreatitis by Sica and colleagues.[93] They found MRCP to have 86% accuracy in characterizing pancreatic ductal anatomy relative to ERCP, with 94% sensitivity in detection of biliary anatomy, results that correspond to earlier studies. Ductal segments not detected by MRCP were defined on ERCP as normal or only slightly dilated or narrowed. Furthermore, MRCP visualized 15 of the 19 obstructed pancreatic ductal segments not seen on ERCP, and all these segments were abnormal. MRCP may play a future role in the diagnosis and planning of operative intervention for biliary obstruction in chronic pancreatitis.

Patients with chronic pancreatitis and an asymptomatic bile duct stricture, often detected during investigation of an elevated serum alkaline phosphatase level, also present a controversy in terms of indications for operative intervention. *Biliary bypass* was first suggested as the appropriate management of these patients by Warshaw and colleagues, who identified changes of secondary biliary cirrhosis in liver biopsy specimens obtained from three of four patients with long-standing asymptomatic biliary obstruction secondary to chronic pancreatitis.[94]

Afroudakis and Kaplowitz supported this finding in a series of liver biopsy specimens obtained from 24 patients who were asymptomatic and anicteric.[74] Nearly 30% of these patients had evidence of secondary biliary cirrhosis, a finding that the authors used to justify their suggestion that operative biliary decompression should be considered in any patient with a documented persistent bile duct stricture. More recently, other groups have advocated reserving operative intervention for patients with acute cholangitis, biliary cirrhosis, or persistent jaundice because their series failed to demonstrate such a high rate of biliary cirrhosis in asymptomatic patients.[76,80] Stahl and colleagues compared 20 patients with bile duct strictures who were observed without surgery with 18 similar patients who underwent operative biliary drainage.[80] The nonoperative group had no increased morbidity over an average period of 3.8 years. In a similar cohort of 648 patients monitored in South Africa by Huizinga and Baker, no cases of biliary cirrhosis were detected in patients undergoing liver biopsy for long-standing bile duct obstruction.[95]

Although the use of endoscopic and percutaneous transhepatic *stenting* procedures for the management of malignant biliary obstruction is well established and accepted, these nonoperative techniques have not been proved effective in the long-term management of benign biliary stricture. In reported series, the relapse rate after endoscopic biliary drainage is high, and surgical biliary-enteric drainage is often necessary.[95-98] Endoscopic or percutaneous techniques may be performed to relieve obstruction in patients with acute cholangitis or be used as a temporizing procedure to allow a patient time to maximize nutritional status before surgical intervention. Some series have reported traditional endoscopic stents to be patent for approximately 3 months, whereas percutaneous transhepatic biliary drains last an average of 2 months before they require exchange for obstruction.[98] Metallic biliary stents have been advocated as a possible long-term alternative in patients with chronic pancreatitis who refuse operative therapy or have significant contraindications to operative intervention.[99] Current metallic stents have an expected patency of only 8 months; thus, further improvement in these "long-term" stents will be required before they can be a durable alternative to surgical therapy.

Patients who undergo surgical procedures for biliary obstruction secondary to chronic pancreatitis are treated by either choledochoduodenostomy or Roux-en-Y choledochojejunostomy. *Choledochoduodenostomy* is preferred in many centers because it maintains the normal flow of bile, can be technically easier to perform, and leaves the jejunum free for subsequent procedures to drain the pancreatic duct. *Choledochojejunostomy*, though thought to be more technically demanding, can also be performed safely and may be necessary when choledochoduodenostomy cannot be safely performed or when the diameter of the common bile duct above the stricture is not 2 cm. In a series of 64 patients undergoing choledochojejunostomy for benign bile duct strictures Nealon and Urrutia reported no operative mortality and excellent clinical and biochemical results at more than 4 years of follow-up.[100] Transduodenal sphincteroplasty and cholecystojejunostomy are not adequate or durable drainage procedures for bile duct strictures secondary to chronic pancreatitis, and they should not be performed.

In many cases, *biliary-enteric bypass* must be accompanied by *pancreatic ductal drainage* to address refractory pain secondary to common bile duct strictures. A *side-to-side longitudinal pancreaticojejunostomy* is the most common associated procedure. If choledochojejunostomy is the biliary bypass procedure performed, a separate limb of jejunum is often used for the pancreatic-enteric anastomosis to prevent continuous bathing of the pancreaticojejunostomy with bile. Any patient undergoing operative decompression of a dilated pancreatic duct who has an associated common bile duct stricture should undergo decompression of both systems. However, performing biliary bypass as a prophylactic procedure (in patients without ductal dilatation who are undergoing pancreaticojejunostomy for chronic pain) is not necessary.[101]

Duodenal and Gastric Outlet Obstruction

Inflammatory diseases of the pancreas are often associated with transient gastroduodenal obstruction. Patients with acute pancreatitis, necrotizing pancreatitis, and pancreatic pseudocysts commonly have symptoms of nausea, emesis, and intolerance of oral intake. In these settings, evidence of duodenal stenosis may be documented by an upper gastrointestinal series or upper endoscopy. Fortunately, these symptoms are often self-limited, and the obstruction resolves as the inflammatory process improves or the space-occupying lesion (pseudocyst, pancreatic abscess) is decompressed. Bradley and Clements reported that up to 25% of patients hospitalized for acute pancreatitis have such a functional duodenal obstruction.[102]

Duodenal or *gastric outlet obstruction* rarely develops in patients with chronic pancreatitis (Fig. 90–11). Such obstruction is far less common than common bile duct or pancreatic duct obstruction. Gastroduodenal obstruction is reported to occur in only 1% of all patients with chronic pancreatitis.[54,102] However, gastroduodenal obstruction is more common in patients with severe chronic pancreatitis. Three series showed that in the subgroup of patients who require operative intervention for chronic pancreatitis, gastroduodenal obstruction may occur in 10% to 25% of such patients. Prinz and colleagues reported that in hospitalized patients undergoing operative decompression of the pancreatic duct, 8 of 55 (15%) required operative therapy for gastric outlet obstruction.[103] In the group of patients with common bile duct stricture, 25% also had coexistent gastroduodenal obstruction. Warshaw reported a 25% incidence of gastroduodenal obstruction associated with common bile duct stricture secondary to severe chronic pancreatitis.[104] Sugerman and coworkers reported on a similar group of patients with severe chronic pancreatitis that had failed to resolve with nonoperative management.[105] In this group of 28 patients, 14% required a gastrojejunostomy at the time of their procedure for chronic pancreatitis.

Like gastroduodenal obstruction in more acute inflammatory diseases of the pancreas, gastroduodenal

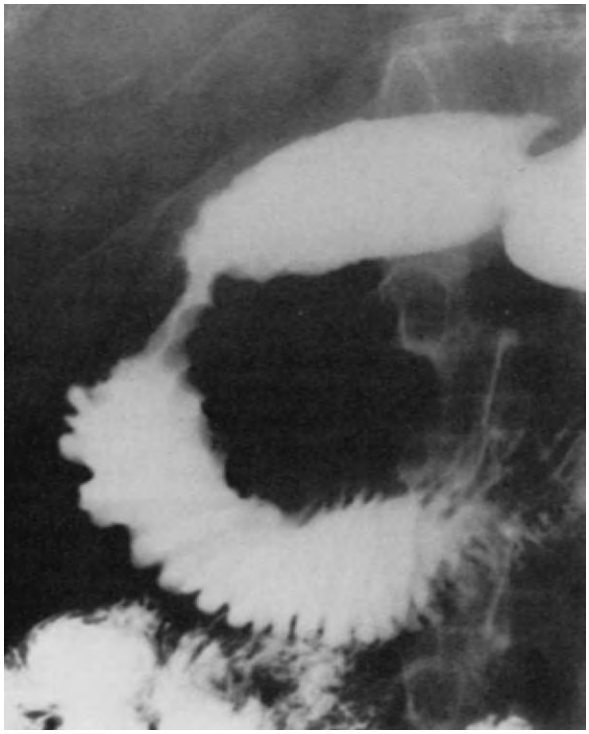

Figure 90–11. Upper gastrointestinal series in a patient with chronic pancreatitis showing a stricture at the junction of the first and second portions of the duodenum.

obstruction in chronic pancreatitis can be episodic and self-limited. These periods of obstruction often occur during exacerbations of the patient's chronic pancreatitis because inflammation and edema in the wall of the duodenum prevent normal peristalsis. Many of these patients already have chronic fibrotic changes in the duodenum that limit normal motility, and acute inflammation effectively limits the passage of enteric contents through the duodenum. These episodes generally resolve spontaneously. Persistent gastroduodenal obstruction that lasts longer than 4 weeks is an indication for further intervention.

Patients with chronic pancreatitis and gastroduodenal obstruction should be evaluated by both upper endoscopy and upper gastrointestinal series. Upper gastrointestinal series with barium may demonstrate complete gastric outlet obstruction or, more commonly, a long, fixed narrowing of the duodenum, which is a classic finding in patients with duodenal stricture secondary to chronic pancreatitis. Endoscopy is necessary to rule out other conditions that may mimic the findings of chronic pancreatitis. Peptic ulcer disease and periampullary malignant disease need to be considered, and they may be diagnosed and confirmed by biopsy performed endoscopically. CT scan should also be performed to evaluate for a pancreatic mass or pseudocyst. ERCP may be important to evaluate the pancreatic and biliary ductal anatomy. Alternatively, such evaluation may also be accomplished by MRCP because the anatomy of many of these patients does not permit intubation of the second portion of the duodenum, which is needed to accomplish ERCP.

An initial period of nonoperative management may be attempted in patients with gastroduodenal obstruction. Bowel rest, nasogastric decompression, and parenteral nutrition may allow for improvement in pancreatic inflammation and resolution of the obstruction. Persistent or recurrent obstruction after a trial of nonoperative management is an indication for surgical therapy, specifically, gastrojejunostomy. This procedure may be performed in conjunction with a biliary or pancreatic drainage procedure in patients with advanced chronic pancreatitis. In patients with chronic pancreatitis primarily involving the head of the pancreas, pancreaticoduodenectomy may be the preferred procedure to relieve pain and obstruction.

Pancreatic Ductal Disruption

Pancreatic ductal disruption is an event leading to complications of chronic pancreatitis. Ductal disruption is most often described as creating an internal pancreatic fistula (as in pancreatic ascites, pancreatic pleural effusion, and pancreaticoenteric fistula) or an external pancreatic fistula that communicates with the skin. Pseudocysts of the pancreas are also the result of disruptions of the pancreatic duct, as discussed earlier.

Pancreatic Ascites and Pleural Effusions The first report of *pancreatic ascites* occurred in 1953,[106] and it was followed by individual case reports of other patients over the subsequent 15 years. In 1967, Cameron and colleagues published the first review of 13 patients with pancreatic ascites.[107] The review established diagnostic criteria for pancreatic ascites and was followed by larger series of patients because the diagnosis was made more frequently. To date, more than 300 reports of pancreatic ascites have been published in the world literature. Parekh and Segal reported on 23 patients with pancreatic ascites or pleural effusions in 1992 and described factors that helped determine which patients would be likely to respond to conservative therapy.[108] Sankaran and Walt described 26 patients with pancreatic ascites and noted that pancreatic ascites occurred in 15% of patients with pseudocysts at their institution.[109] Lipsett and Cameron reported the Johns Hopkins Hospital experience with internal pancreatic fistulas over a 27-year period.[110] Fifty patients were included in the series, including 34 with pancreatic ascites and 7 with pancreatic ascites and pleural effusion.

Pancreatic pleural effusions have been described more recently. In the initial review of internal fistulas from the Johns Hopkins Hospital in 1967, five patients with pleural effusions were reported.[107] A subsequent update described 16 patients with pancreatic pleural effusions.[110] Most authors argue that pancreatic pleural effusions are often unrecognized because the effusions may be attributed to associated cardiac, pulmonary, or hepatic disease without fluid sampling for diagnostic studies. In fact, patients with pancreatic effusions often do not have symptoms of pancreatitis but instead have pulmonary symptoms and respiratory compromise.

The diagnostic criteria for pancreatic ascites and effusion were initially proposed by Cameron et al. in 1967.[107]

Correct diagnosis requires sampling of the fluid and assessment of amylase and albumin levels. Amylase levels are elevated relative to serum values in all patients, and fluid albumin levels are elevated to levels of 3 g/100 ml or more. Serum amylase levels may also be elevated in up to 90% of patients with pancreatic effusions or ascites, a finding that may reflect absorption of amylase from the pleural and peritoneal surfaces rather than active pancreatic inflammation.[111] Patients with markedly depressed serum albumin levels secondary to malnutrition may have fluid albumin levels less than 3 g/100 ml. The fluid of pancreatic effusion or ascites is most often clear or straw colored, but it may appear thick, chylous, or even bloody. The differential diagnosis of these internal pancreatic fistulas often includes ascites secondary to cirrhosis and malignant ascites or effusion. Patients with cirrhotic ascites generally have fluid albumin levels less than 1.5 g/100 ml and most often have low amylase levels. Distinguishing pancreatic effusion or ascites from malignant fluid may be difficult cytologically because pancreatic enzymes appear to be capable of producing metaplastic changes in serosal cells and therefore of creating false-positive results.

The pathogenesis of both pancreatic pleural effusion and ascites involves a disruption of the pancreatic duct and creation of an internal fistula into the retroperitoneum,[111] which then tracks posteriorly into the pleural space (Fig. 90–12) or anteriorly into the peritoneal cavity (Figs. 90–13 and 90–14). At times, the fistula may be contained by adjacent structures and lead to the formation

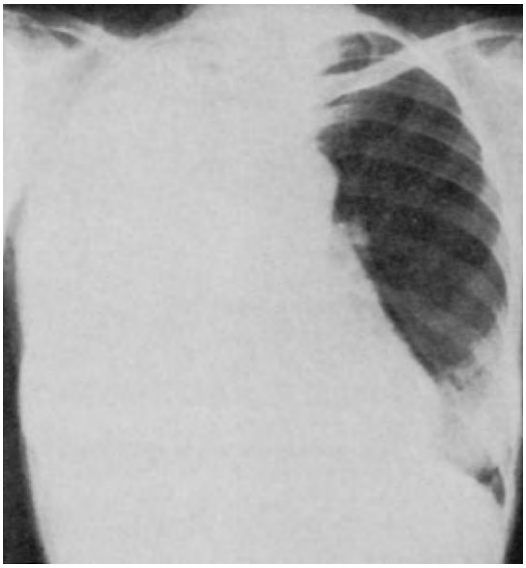

Figure 90–12. Chest radiograph of a patient with chronic massive right-sided pancreatic pleural effusion. (From Cameron JJ, Kieffer RS, Anderson WJ, et al: Internal pancreatic fistulas: Pancreatic ascites and pleural effusions. Ann Surg 184:587, 1976.)

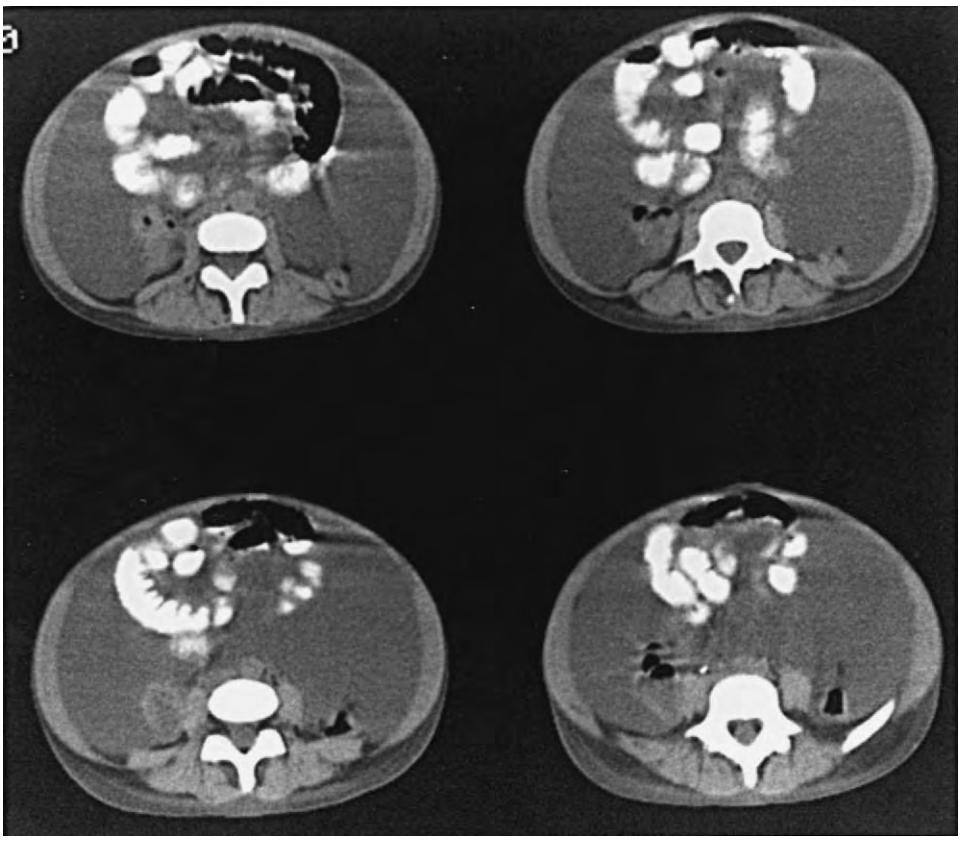

Figure 90–13. Four computed tomography scans showing extensive pancreatic ascites in a young female patient with alcoholism. The small bowel loops float centrally, and ascitic fluid fills the abdomen.

Figure 90–14. Endoscopic retrograde cholangiopancreatogram from the patient with pancreatic ascites whose computed tomography scan is shown in Figure 90–13. Contrast extravasates from the proximal portion of the pancreatic duct into the peritoneal cavity. The visualized portion of the extrahepatic biliary tree is normal.

of a pancreatic pseudocyst. Pancreatic ductal disruptions are most commonly a result of alcoholic pancreatitis, but they may be secondary to blunt or operative trauma, gallstone pancreatitis, or other causes of pancreatitis. Pancreatic ductal injury in children is most commonly the result of trauma.

Most patients with pancreatic ascites or effusions have an indolent illness that may not suggest pancreatic disease. In the Johns Hopkins series, less than 50% of patients had a history of pancreatitis.[110] Only 12% had an acute attack of pancreatitis, whereas 42% gave no history suggestive of pancreatic disease. Patients with pancreatic ascites most often have painless abdominal swelling, frequently associated with weight loss. Other causes of ascites, such as cirrhosis, Budd-Chiari syndrome, tuberculous peritonitis, and carcinomatosis, should be excluded. Patients with pancreatic pleural effusions often complain of shortness of breath that has progressed over time, as well as other respiratory symptoms. Approximately 15% of patients have both pancreatic ascites and pleural effusion.

The diagnosis of pancreatic ascites or pleural effusion is based on the diagnostic criteria discussed earlier. Initial nonoperative management is advocated in all patients. The patient should be strictly denied oral intake to limit pancreatic stimulation and exocrine secretions. Parenteral nutrition should be instituted. The somatostatin analogue octreotide has been used for the treatment of pancreaticocutaneous fistulas, and a few small studies suggest that octreotide may be effective for pancreatic ascites.[112-114] Segal and associates demonstrated that octreotide was able to lead to resolution of pancreatic ductal disruption in a small group of patients in whom conservative therapy had failed.[112] However, no prospective randomized studies have yet been performed to evaluate the use of octreotide in these conditions.

One of the principles of conservative therapy is to encourage the approximation of serosal surfaces and to limit accumulation of ascitic or pleural fluid. Paracentesis or thoracentesis should be performed intermittently to empty the pleural or peritoneal cavity. If repeated high-volume thoracentesis is necessary, tube thoracostomy may be appropriate. A trial of nonoperative therapy should be limited to 3 weeks. In a report from the Johns Hopkins Hospital, limiting the initial nonoperative phase of therapy for pancreatic ascites to 3 weeks resulted in only a single death (in a patient who refused surgery).[110] Pancreatic pleural effusions may also be treated nonoperatively for 3 weeks. Parekh and Segal attempted to identify which pancreatic fistulas will close without surgical intervention.[108] Patients in whom treatment had failed had significantly lower serum sodium and albumin levels, and the ratio of total fluid protein to serum protein was significantly higher in the treatment failures than in patients who responded to conservative therapy. ERCP was also found to be an important predictor of response to nonoperative therapy. Patients with pancreatic ductal changes indicative of severe chronic pancreatitis had a 10% or less chance of resolving their internal fistulas without surgical intervention.

Patients in whom conservative therapy fails should have their pancreatic anatomy more clearly defined. CT should be performed to assess the extent of pancreatic inflammation and to locate any pseudocysts associated with the ductal disruption. ERCP is necessary to evaluate the pancreatic ductal anatomy and to identify the location of the leak. ERCP may identify patients who may be treated by pancreatic duct stenting. Pancreatic duct stents bridging the ductal disruption have shown promise as a method to heal internal pancreatic fistulas. In the small number of reported cases, many stenting procedures have been successful, without complications.[115-118] As experience accumulates with these techniques, operative therapy may be avoided for all but the most complicated ductal disruptions. Anecdotal reports also exist of percutaneous pancreatic duct stents placed under ultrasound and fluoroscopic guidance. These techniques are unlikely to supplant the less demanding endoscopic approaches.

The choice of operative therapy is guided by pancreatic ductal anatomy. Distal pancreatic duct leaks may be addressed by *distal pancreatectomy*, a procedure that can be performed with low expected morbidity and mortality and eliminates the need for a pancreatic anastomosis. In some cases when proximal pancreatic ductal disease is present, the pancreatic remnant should be drained with a *Roux-en-Y loop*. If a direct duct leak is identified, the ductal disruption can be drained internally as a *Roux-en-Y pancreaticojejunostomy* (Fig. 90–15). When ductal disruptions are associated with a pseudocyst, the pseudocyst

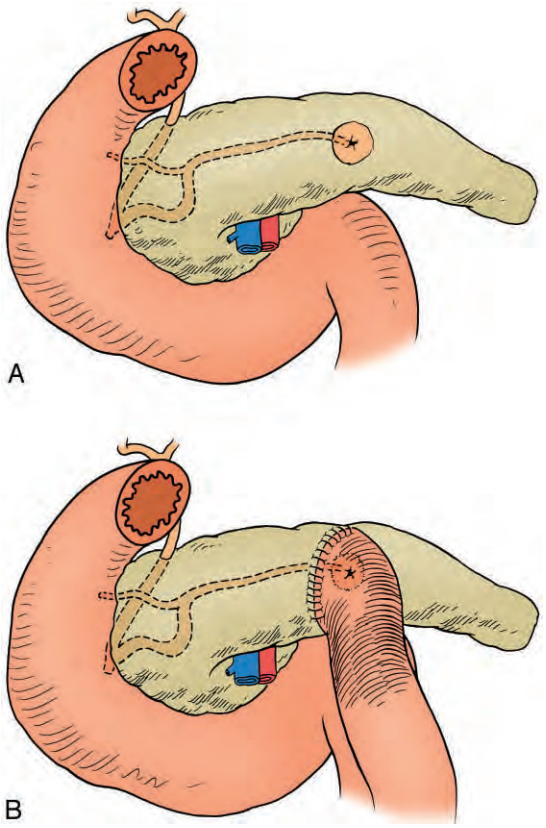

Figure 90–15. **A** and **B,** Schematic of pancreatic duct disruption and pancreatic ascites treated by anastomosing a Roux-en-Y jejunal loop to the duct leak. (From Cameron JJ, Brawley RK, Bender HW, et al: The treatment of pancreatic ascites. Ann Surg 170:668, 1969.)

may be drained either by a Roux-en-Y loop or into the stomach as a *cystogastrostomy*. These internal drainage techniques are always preferable to placement of external drains. Da Cunha and colleagues showed that external drainage procedures are commonly complicated by infection and may require reoperation in up to 50% of cases.[119] Internal drainage, in contrast, has a greater than 90% chance of success. Although early series reported high mortality rates in patients undergoing operative therapy, many of these deaths could be attributed to poor nutritional status and less refined techniques in pancreatic surgery. More recent series report a mortality rate of less than 2%.[110,119,120]

External Pancreatic Fistula

Pancreaticocutaneous fistulas may be the result of trauma, surgical resection, necrotizing and chronic pancreatitis, or percutaneous drainage of a pseudocyst associated with pancreatic duct obstruction or disruption. Most fistulas will close spontaneously with adequate nutrition, resolution of the underlying pancreatic inflammatory process, and adequate local wound care. Refractory pancreaticocutaneous fistulas warrant further evaluation with ERCP or sinograms (or both) to delineate ductal abnormalities that may preclude spontaneous closure. Broadie and colleagues reported on 38 patients evaluated by ERCP for pancreaticocutaneous fistulas. Fistulas originating from the side of the main pancreatic duct closed spontaneously within 11 weeks in 86% of patients. Side fistulas with continued pancreatic inflammation were less likely to close, with a 53% closure rate by 23 weeks. No end fistulas closed.[121]

Surgical treatment of persistent fistulas includes Roux-en-Y fistula tract–jejunostomy, pancreaticojejunostomy, or pancreatic resection. Fistula tract–jejunostomy is viewed as the safest option because it allows internal drainage in an operative field that is distant from the inflamed pancreatic bed. Best results are achieved in a stable patient with a mature fistula tract. A recent review of surgical treatment for pancreatic fistulas found that surgical closure was achieved in 90% of patients; however, operative mortality was noted in roughly 6.3% of the population.[122]

Endoscopic pancreatic duct stenting has been reported as a treatment option for refractory fistulas. Pancreatic stents successfully closed 55% of fistulas in a recent series of 97 patients with duct disruption.[123] This technique may prove to be an effective minimally invasive approach for fistula closure as technology and experience improve.

Splenic Vein Thrombosis

The splenic vein lies posterior to and closely approximated to the body of the pancreas, and it runs from the pancreatic tail to the neck of the gland. Immediately dorsal to the neck, the splenic vein joins with the superior mesenteric vein to form the portal vein. This location makes the splenic vein particularly susceptible to involvement by inflammatory diseases of the pancreas. Invasive neoplastic or inflammatory disease may lead to intrinsic damage to the venous intima or extrinsic compression secondary to edema, fibrosis, mass lesions, or lymphadenopathy. In either case, stasis of splenic vein blood flow occurs and may eventually lead to *splenic vein thrombosis*.

The importance of splenic vein thrombosis in patients with chronic pancreatitis is not completely known. Commonly used imaging techniques (particularly CT scan) have led to an increased diagnosis of splenic vein thrombosis in patients with chronic pancreatitis. Splenic vein thrombosis is clinically silent in the majority of patients. The incidence appears to be approximately 7% to 15% in patients with chronic pancreatitis, with 2% to 5% of patients having extension of the splenic vein thrombosis into the portal vein.[124,125] Splenic vein thrombosis is thought to be a relatively late complication of chronic pancreatitis.

Splenic vein thrombosis causes complications secondary to the development of extrahepatic, "left-sided" portal hypertension. Obstruction of splenic venous outflow leads to the enlargement of collateral vessels along the short gastric and gastroepiploic veins, which results in the formation of *gastric varices* along the greater curvature and fundus of the stomach, as well as *esophageal varices* secondary to increased flow to the coronary vein.

These varices do not form in all patients, and some series have reported such varices in less than 50% of patients with documented splenic vein thrombosis.[124-127] *Splenomegaly* is a related common finding in patients with splenic vein thrombosis. The most common complication of splenic vein thrombosis is *upper gastrointestinal hemorrhage* secondary to gastric or esophageal varices, which occurs in less than 10% of patients with known thrombosis.[124] Patients may also have abdominal pain or, rarely, ascites. Another important manifestation of splenic vein thrombosis is excessive *intraoperative blood loss* as a result of the enlarged venous collateral vessels. Splenic vein thrombosis should be carefully noted in patients with chronic pancreatitis who are to undergo operative therapy.

As the diagnosis of *asymptomatic splenic vein thrombosis* has increased, more information has been obtained about the natural history of this process and the indications for intervention. In a prospective study by Bernades et al., 266 patients with chronic pancreatitis were monitored for a mean period of 8.2 years.[124] These patients were screened with ultrasound for splenic vein thrombosis, which was confirmed by CT or angiography. The incidence of splenic or portal vein thrombosis was 13.2%, with varices occurring in 17% of these patients. One patient required surgery for variceal bleeding. Twenty-three patients with splenic vein thrombosis underwent no therapy, and no episodes of bleeding occurred in more than 2½ years of observation.

Treatment of patients with bleeding gastroesophageal varices secondary to splenic vein thrombosis is *splenectomy*. This operation eliminates splenic artery inflow and venous outflow, with an attendant immediate reduction in variceal blood flow. Moosa and Gadd reported a cure rate of greater than 90% in patients undergoing splenectomy at a mean follow-up of 11 months.[128] "*Nonsurgical splenectomy*" via splenic artery embolization is a nonoperative intervention that may be appropriate for selected patients with extensive comorbidity. These patients are at risk for splenic abscess. Clearly, asymptomatic splenic vein thrombosis deserves no specific intervention. Splenectomy is the treatment of choice in most patients with symptomatic gastroesophageal varices.

Pancreatic Cancer

Perhaps the most challenging aspect of the management of presumed chronic pancreatitis is distinguishing it from *pancreatic carcinoma* (Table 90–3). Patients initially seen with biliary obstruction, duodenal obstruction, or an inflammatory mass in the head of the pancreas may all have benign complications of chronic pancreatitis, but the possibility of pancreatic or other periampullary malignant disease must always be considered. Furthermore, evidence suggests that patients with chronic pancreatitis are at increased risk for the development of pancreatic cancer. Lowenfels and colleagues reported on a cohort of 2015 patients with chronic pancreatitis.[129] The risk for pancreatic cancer increased in linear fashion from the time of diagnosis of chronic pancreatitis, with the incidence increasing from 1.8% at 10 years to 4% at 20 years. Other groups have confirmed these findings in

Table 90–3 Clinical Features Distinguishing Biliary Obstruction Caused by Pancreatic Carcinoma from Chronic Pancreatitis

Feature	Pancreatic Carcinoma	Chronic Pancreatitis
History and physical examination	Persistent jaundice	Intermittent jaundice
	Weight loss	Alcohol abuse
	Older patient	Younger patient
	Palpable gallbladder (Courvoisier's sign)	Frequent attacks of pancreatitis
	Evidence of metastasis	Steatorrhea
Laboratory data	Markedly elevated bilirubin and alkaline phosphatase	Minimally elevated bilirubin
	Prolonged prothrombin time	Elevated alkaline phosphatase
	Decreased serum albumin	
Plain abdominal radiographs	Normal	Pancreatic calcifications
ERCP	Ductal cutoff (common bile duct and pancreatic duct: the "double-duct" sign)	Long, tapered stricture of the intrapancreatic common bile duct
		"Chain of lakes" appearance
		Pancreatic calculi
		Secondary and tertiary pancreatic ducts visualized
CT scan	Mass in the head of the pancreas	Diffuse pancreatic enlargement
	Dilated biliary tree	Dilated common bile duct
	Metastases	Pseudocysts
Angiography	Vessel encasement possible	Normal (usually)

CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography.

similar studies and have concluded that chronic pancreatitis increases the risk for pancreatic cancer by up to three times the risk in the general population.[130,131]

Much effort has been expended to clarify which imaging modalities and diagnostic procedures best distinguish pancreatic cancer from chronic pancreatitis. Conventional CT and ERCP have traditionally been used to distinguish these two diagnoses, with a combined diagnostic accuracy of about 65% to 80%.[132] Because of the high rate of both false-positive and false-negative results, other techniques have been advocated to aid in the diagnosis. EUS is available in many centers. Advocates of this technique claim high sensitivity for the detection of pancreatic masses; Barthet and colleagues claimed 100% sensitivity in detecting pancreatic masses in patients with chronic pancreatitis.[133] Certainly, such a 100% sensitivity rate does not translate into a 100% accuracy rate. EUS is thought to be particularly helpful in the detection of masses smaller than 2 cm, many of which are missed on CT scan.[134] EUS is also reported to allow accurate characterization of the relationship of pancreatic masses to the superior mesenteric vessels and portal vein and thus to predict resectability. However, one study reported that newer high-resolution spiral CT is at least as accurate in determining resectability based on vascular involvement and that CT may be more accurate in determining involvement of the superior mesenteric artery.[135] EUS is an invasive procedure, but it may allow for the establishment of a tissue diagnosis by fine-needle aspiration cytology. However, a negative cytologic study should not delay resection in a patient with an appropriate clinical history and a mass suggestive of pancreatic cancer. Moreover, patients with chronic pancreatitis have been found to have an extremely high rate of false-positive EUS studies that detect a focal mass, so the positive predictive value of EUS for pancreatic cancer is as low as 60%.

MRCP has also been advocated for distinguishing pancreatic cancer from chronic pancreatitis. As with many of its applications, studies of the use of MRCP in diagnosing pancreatic cancer are small, and it is too early to determine the accuracy of this technique. Studies in the radiologic literature have unfortunately found similar MRI enhancement of pancreatic cancer and chronic pancreatitis, a finding that makes a definitive diagnosis difficult.[87] Other groups support the use of positron emission tomography (PET) with fluorodeoxyglucose for the diagnosis of pancreatic cancer. Rose et al. reported that PET scanning was more sensitive and specific than CT in the detection of small pancreatic tumors and that PET scan results led to a change in management in 43% of the patients in their series.[136] Unfortunately, the patients with false-positive results in this series all had chronic pancreatitis, so these findings call into question whether PET offers useful data in the diagnosis of pancreatic cancer in patients with chronic pancreatitis. Imdahl and colleagues argued that the level of glucose uptake in pancreatic masses as measured by PET allowed for differentiation of pancreatic cancer and chronic pancreatitis in a small group of patients.[137] Whether these results would make a difference in the eventual treatment is not clear because patients with concerning clinical findings all underwent resection in this series.

Clearly, no current diagnostic test is sufficiently accurate to differentiate chronic pancreatitis from pancreatic cancer. In the future, molecular genetic techniques focusing on ductal precursor lesions and the characteristic molecular fingerprint of pancreatic cancer may allow better differentiation between benign and malignant pancreatic disease. At present, patients in whom the diagnosis is unclear but the clinical symptoms of pain, jaundice, and weight loss with a noncalculous distal biliary obstruction make the diagnosis of malignant disease possible should undergo surgical exploration with planned pancreaticoduodenectomy. Because the mortality rate of pancreaticoduodenectomy has fallen significantly, particularly in experienced centers, proceeding with surgical resection is one approach.[138,139] Patients found to have chronic pancreatitis without malignant disease have also been shown to benefit from this procedure, particularly regarding quality-of-life issues.[140] Duodenum-preserving resection of the pancreatic head is another possible approach to patients with severe chronic pancreatitis.[141]
