3. Late neonatal VKDB occurs on or after day 8. Manifestations include intracranial, gastrointestinal, or skin bleeding. This disorder is often associated with fat malabsorption (eg, in chronic diarrhea) or alterations in intestinal flora (eg, with prolonged antibiotic therapy). Like classic VKDB, late VKDB occurs almost exclusively in breast-fed infants.

The diagnosis of vitamin K deficiency is suspected based on the history, physical examination, and laboratory results. The PT is prolonged out of proportion to the aPTT (also prolonged). The thrombin time becomes prolonged late in the course. The platelet count is normal. This laboratory profile is similar to the coagulopathy of acute liver disease, but with normal fibrinogen level and absence of hepatic transaminase elevation. The diagnosis of vitamin K deficiency is confirmed by a demonstration of noncarboxylated proteins in the absence of vitamin K in the plasma and by clinical and laboratory responses to vitamin K. Intravenous or subcutaneous treatment with vitamin K should be given immediately and not withheld while awaiting test results. In the setting of severe bleeding, additional acute treatment with FFP or recombinant factor VIIa may be indicated.

4. Uremia

Uremia is frequently associated with acquired platelet dysfunction. Bleeding occurs in approximately 50% of patients with chronic renal failure. The bleeding risk conferred by platelet dysfunction associated with metabolic imbalance may be compounded by decreased vWF activity and procoagulant deficiencies (eg, factor II, XII, XI, IX) due to increased urinary losses of these proteins in some settings of renal insufficiency. In accordance with platelet dysfunction, uremic bleeding is typically characterized by purpura, epistaxis, menorrhagia, or gastrointestinal hemorrhage. Acute bleeding may be managed with infusion of desmopressin acetate, factor VIII concentrates containing vWF, or cryoprecipitate with or without coadministration of FFP. Red cell transfusion may be

required. Prophylactic administration of erythropoietin before the development of severe anemia appears to decrease the bleeding risk. Recombinant VIIa may be useful in refractory bleeding.

VASCULAR ABNORMALITIES ASSOCIATED WITH BLEEDING

1. Henoch-Schönlein Purpura (Anaphylactoid Purpura)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Purpuric cutaneous rash.
- ▶ Migratory polyarthritides or polyarthralgias.
- ▶ Intermittent abdominal pain.
- ▶ Nephritis.

▶ General Considerations

Henoch-Schönlein purpura (HSP), the most common type of small vessel vasculitis in children, primarily affects boys 2–7 years of age. Occurrence is highest in the spring and fall, and upper respiratory infection precedes the diagnosis in two thirds of children.

Leukocytoclastic vasculitis in HSP principally involves the small vessels of the skin, gastrointestinal tract, and kidneys, with deposition of IgA immune complexes. The most common and earliest symptom is palpable purpura, which results from extravasation of erythrocytes into the tissue surrounding the involved venules. Antigens from group A β -hemolytic streptococci and other bacteria, viruses, drugs, foods, and insect bites have been proposed as inciting agents.

▶ Clinical Findings

A. Symptoms and Signs

Skin involvement may be urticarial initially, progresses to a maculopapules, and coalesces to a symmetrical, palpable purpuric rash distributed on the legs, buttocks, and elbows. New lesions may continue to appear for 2–4 weeks, and may extend to involve the entire body. Two thirds of patients develop migratory polyarthralgias or polyarthritides, primarily of the ankles and knees. Intermittent, sharp abdominal pain occurs in approximately 50% of patients, and hemorrhage and edema of the small intestine can often be demonstrated. Intussuscep-

tion may develop. From 25–50% of those affected develop renal involvement in the second or third week of illness with either a nephritic or, less commonly, nephrotic picture. Hypertension may accompany the renal involvement. In males, testicular torsion may also occur, and neurologic symptoms are possible due to small vessel vasculitis.

B. Laboratory Findings

The platelet count is normal or elevated, and other screening tests of hemostasis and platelet function are typically normal. Urinalysis frequently reveals hematuria, and sometimes proteinuria. Stool may be positive for occult blood. The antistreptolysin O (ASO) titer is often elevated and the throat culture positive for group A β -hemolytic streptococci. Serum IgA may be elevated.

► Differential Diagnosis

The rash of septicemia (especially meningococemia) may be similar to skin involvement in HSP, although the distribution tends to be more generalized. The possibility of trauma should be considered in any child presenting with purpura. Other vasculitides should also be considered. The lesions of thrombotic thrombocytopenic purpura are not palpable.

► Treatment

Generally, treatment is supportive. NSAIDs may be useful for the arthritis. Corticosteroid therapy may provide symptomatic relief for severe gastrointestinal or joint manifestations but does not alter skin or renal manifestations. If culture for group A β -hemolytic streptococci is positive or if the ASO titer is elevated, a therapeutic course of penicillin is warranted.

► Prognosis

The prognosis for recovery is generally good, although symptoms frequently (25–50%) recur over a period of several months. In patients who develop renal manifestations, microscopic hematuria may persist for years. Progressive renal failure occurs in less than 5% of patients with HSP, with an overall fatality rate of 3%.

Ronkainen J: Early prednisone therapy in Henoch-Schönlein purpura: A randomized, double-blind, placebo-controlled trial. *J Pediatr* 2006;149:241 [PMID: 16887443].

2. Collagen Disorders

Mild to life-threatening bleeding occurs with some types of Ehlers-Danlos syndrome, the most common inherited collagen disorder. Ehlers-Danlos syndrome is characterized by joint hypermobility, skin extensibility, and easy bruising. Coagulation abnormalities may sometimes be present, including platelet dysfunction and deficiencies of coagulation factors VIII, IX, XI, and XIII. However, bleeding and easy bruising, in most instances, relates to fragility of capillaries and compro-

mised vascular integrity. Individuals with Ehlers-Danlos syndrome types 4 and 6 are at risk for aortic dissection and spontaneous rupture of aortic aneurysms. Surgery should be avoided for patients with Ehlers-Danlos syndrome, as should medications that induce platelet dysfunction.

De Paepe A: Bleeding and bruising in patients with Ehlers-Danlos syndrome and other collagen vascular disorders. *Br J Haematol* 2004;127:491 [PMID: 15566352].

THROMBOTIC DISORDERS

► General Considerations

Although uncommon in children, thrombotic disorders are being recognized with increasing frequency, particularly with heightened physician awareness and improved survival in pediatric intensive care settings. Several clinical conditions have a potential association with thrombotic events in childhood (see Clinical Risk Factors, below).

► Clinical Findings

Initial evaluation of the child who has thrombosis includes an assessment for potential triggering factors, as well as a family history of thrombosis and early cardiovascular or cerebrovascular disease.

A. Clinical Risk Factors

Clinical risk factors are present in more than 90% of children with acute venous thromboembolic events (VTEs). These conditions include the presence of an indwelling vascular catheter, cardiac disease, malignancy, infection, trauma, surgery, immobilization, collagen-vascular or chronic inflammatory disease, renal disease, and sickle cell anemia.

1. Inherited thrombophilia (hypercoagulability) states

A. PROTEIN C DEFICIENCY—Protein C is a vitamin K-dependent protein that is normally activated by thrombin bound to thrombomodulin and inactivates activated factors V and VIII. In addition, activated protein C promotes fibrinolysis. Two phenotypes of hereditary protein C deficiency exist. Heterozygous individuals with autosomal dominant protein C deficiency often present with VTEs as young adults, but the disorder may manifest during childhood or in later adulthood. In the absence of VTEs, prophylaxis is limited to periods of increased prothrombotic risk. Homozygous or compound heterozygous protein C deficiency is rare but phenotypically severe. Affected children generally present within the first 12 hours of life with purpura fulminans and/or VTEs. Retinal thrombosis may result in blindness. Prompt protein C replacement by infusion of FFP every 6–12 hours, or of protein C concentrate (if available), along with therapeutic heparin administration is recommended. Subsequent management requires chronic anticoagulation

with warfarin or protein C concentrate. Recurrent VTEs are common, especially during periods of subtherapeutic anticoagulation or in the presence of conditions associated with increased prothrombotic risk.

B. PROTEIN S DEFICIENCY—Protein S is a cofactor for protein C. Neonates with homozygous protein S deficiency have a course similar to those with homozygous or compound heterozygous protein C deficiency. Lifelong warfarin therapy is indicated in severe deficiency, or in heterozygous individuals who have experienced recurrent VTEs. Efforts must be made to distinguish from these conditions from acquired deficiency.

C. ANTITHROMBIN III (ATIII) DEFICIENCY—ATIII is the most important physiologic inhibitor of thrombin and inhibits activated factors IX, X, XI, and XII. ATIII deficiency is transmitted in an autosomal dominant pattern and is associated with VTEs, typically with onset in adolescence or young adulthood. Therapy for acute VTEs involves replacement with antithrombin concentrate (if available) and therapeutic anticoagulation. The efficiency of heparin may be significantly diminished in the setting of severe ATIII deficiency and anticoagulation with warfarin required. Patients with recurrent VTEs are maintained on lifelong warfarin.

D. FACTOR V LEIDEN MUTATION—An amino acid substitution in the gene coding for factor V results in factor V Leiden, a factor V polymorphism that is resistant to inactivation by activated protein C. The most common cause of activated protein C resistance in Caucasians, factor V Leiden is present in approximately 5% of the Caucasian population, 20% of Caucasian adults with deep vein thrombosis, and 40–60% of those with a family history of VTEs. VTEs occur in both heterozygous and homozygous individuals. In the former case, thrombosis is typically triggered by a clinical risk factor (or else develops in association with additional thrombophilia traits), whereas in the latter case, it is often spontaneous. Population studies suggest that the risk of VTEs is increased 7-fold in the setting of heterozygous factor V Leiden, 35-fold among heterozygous individuals taking the oral contraceptives, and 80-fold in those homozygous for factor V Leiden.

E. PROTHROMBIN MUTATION—The 20210 glutamine to alanine mutation in the prothrombin gene is a relatively common polymorphism in Caucasians that enhances its activation to thrombin. In heterozygous form, prothrombin 20210 has been associated with a threefold increased risk for VTE.

F. OTHER INHERITED DISORDERS—Qualitative abnormalities of fibrinogen (dysfibrinogenemias) are usually inherited in an autosomal dominant manner. Most individuals with dysfibrinogenemia are asymptomatic. Some patients experience bleeding, while others develop venous or arterial thrombosis. The diagnosis is suggested by a prolonged thrombin time with a normal fibrinogen concentration. Hyperhomocysteinemia can be an inherited or an acquired

condition and is associated with an increased risk for both arterial and venous thromboses. In children, it may also serve as a risk factor for ischemic arterial stroke. However, hyperhomocysteinemia is quite uncommon in the setting of dietary folate supplementation (as in the United States), and is observed almost uniquely in cases of metabolic disease (eg, homocystinuria). Furthermore, methylene tetrahydrofolate reductase receptor mutations do not appear to constitute a risk factor for thrombosis in U.S. children when homocysteinine is not elevated.

Lipoprotein(a) is a lipoprotein with homology to plasminogen. In-vitro studies suggest that lipoprotein(a) may both promote atherothrombosis and inhibit fibrinolysis. Case-control studies suggest that elevated plasma concentrations of lipoprotein(a) are associated with an increased odds of VTEs and ischemic arterial stroke in children.

Increased factor VIII may be demonstrated in patients with acute VTEs. This increase has been implicated as a risk factor for VTEs in adults and may be familial.

2. Acquired disorders

A. ANTIPHOSPHOLIPID ANTIBODIES—The development of antiphospholipid antibodies is the most common form of acquired thrombophilia in children. Antiphospholipid antibodies, which include the lupus anticoagulant, anticardiolipin antibodies, and β_2 -glycoprotein-1 antibodies, have become increasingly implicated in VTEs. The lupus anticoagulant is demonstrated in vitro by its inhibition of phospholipid-dependent coagulation assays (eg, aPTT and dilute Russell viper venom time), whereas immunologic techniques (eg, enzyme-linked immunosorbent assays) are often used to detect anticardiolipin and β_2 -glycoprotein-1 antibodies. Although common in persons with autoimmune diseases such as systemic lupus erythematosus, antiphospholipid antibodies may also develop following certain drug exposures, infection, acute inflammation, and lymphoproliferative diseases. Sometimes VTEs and antiphospholipid antibodies may predate other signs of lupus for long periods of time. Viral illness is a common precipitant in children, and in many cases, the inciting infection may be asymptomatic.

If an antiphospholipid antibody persists for 6–12 weeks following the acute thrombotic event, the diagnosis of this syndrome is confirmed and anticoagulation should be continued at least until the antiphospholipid antibody becomes undetectable. In addition, consideration should be given to long-term anticoagulation.

B. DEFICIENCIES OF INTRINSIC ANTICOAGULANTS—Acquired deficiencies of proteins C and S and ATIII may occur in the clinical context of excessive consumption, including sepsis, DIC, major-vessel or extensive VTE, and post-bone marrow transplant sinusoidal obstruction syndrome (formerly termed hepatic veno-occlusive disease). Pilot studies in children have suggested a possible therapeutic role for antithrombin or protein C concentrates in sepsis associated DIC and severe post-transplant sinusoidal obstruction syndrome.

C. ACUTE PHASE REACTANTS—As part of the acute phase response, elevations in plasma fibrinogen concentration, plasma factor VIII, and platelet count may occur, all of which may contribute to an acquired prothrombotic state.

Reactive thrombocytosis is rarely associated with VTEs in children when the platelet count is less than 1 million/ μ L.

B. Symptoms and Signs

Presenting features of thrombosis vary with the anatomic site, extent of vascular involvement, degree of vaso-occlusion, and presence of end-organ dysfunction. The classic presentation of deep venous thrombosis of an upper or lower extremity is painful acute or subacute extremity swelling, while that for pulmonary embolism commonly involves dyspnea and pleuritic chest pain, and in cerebral sinovenous thrombosis often includes severe or persistent headache, with or without neurologic deficit. Arterial thrombosis of the lower extremity (eg, neonatal umbilical artery catheter-associated), as well as vasospasm without identified thrombosis, often manifests with diminished distal pulses and dusky discoloration of the limb.

C. Laboratory Findings

A comprehensive laboratory investigation for thrombophilia (ie, hypercoagulability) is recommended by the International Society on Thrombosis and Haemostasis in order to disclose possible underlying congenital or acquired abnormalities that may affect acute or long-term management. Testing for intrinsic anticoagulant deficiencies (proteins C and S and ATIII), procoagulant factor excesses or activators (eg, factor VIII and antiphospholipid antibodies), genetic mutations mediating enhanced procoagulant activity or reduced sensitivity to inactivation (factor V Leiden and prothrombin 20210 polymorphisms), biochemical mediators of endothelial damage (homocysteine and antiphospholipid antibodies), and markers or regulators of fibrinolysis (eg, D-dimer, plasminogen activator inhibitor-1, and lipoprotein[a]) should be completed. Interpretation of procoagulant factor and intrinsic anticoagulant levels should take into account the age dependence of normal values for these proteins. Among these VTE risk factors, antiphospholipid antibodies and elevated levels of homocysteine and lipoprotein(a) have also been well-demonstrated as risk factors for arterial thrombotic and ischemic events.

D. Imaging

Appropriate radiologic imaging is essential to objectively document the thrombus and to delineate the type (venous versus arterial), possible vaso-occlusion, and extent of thrombosis.

► Treatment

Current guidelines for the treatment of first-episode VTE in children have been largely based on adult experience and include therapeutic anticoagulation for at least 3 months. During the period of anticoagulation, bleeding precautions

should be followed, as previously described (see treatment of Idiopathic Thrombocytopenic Purpura, earlier).

Initial therapy employs continuous intravenous unfractionated heparin or subcutaneous injections of low molecular weight heparin (LMWH) for at least 7 days, monitored by anti-Xa activity level to maintain anticoagulant levels of 0.3–0.7 or 0.5–1.0 IU/mL, respectively. Subsequent extended anticoagulant therapy is given with LMWH or daily oral warfarin, the latter agent monitored by the PT to maintain an international normalized ratio (INR) of 2.0–3.0 (2.5–3.5 in the presence of an antiphospholipid antibody). During warfarin treatment, the INR should be within the therapeutic range for two consecutive days before discontinuation of heparin. Warfarin pharmacokinetics are affected by acute illness, numerous medications, and changes in diet, and require frequent monitoring. LMWH offers the advantage of infrequent need for monitoring but is far more expensive than warfarin. In cases of limb- or life-threatening VTEs, including major proximal pulmonary embolus, and in cases of progressive VTE despite therapeutic anticoagulation, thrombolytic therapy (eg, tissue-type plasminogen activator) is often warranted. A recent cohort study has indicated that initial thrombolytic therapy may also reduce the risk of the post-thrombotic syndrome (PTS) in children with veno-occlusive deep venous thrombosis of the proximal lower extremities in whom adverse prognostic biomarkers (ie, elevated factor VIII and D-dimer levels) are present at diagnosis; however, the safety and efficacy of this approach must be evaluated in a subsequent clinical trial.

► Prognosis

Registries and cohort studies have suggested that recurrent VTE occurs in approximately 10% of children within 2 years. Persistent thrombosis is evident following completion of a standard therapeutic course of anticoagulation in up to 30% of children, with unclear clinical importance. At least 30% of children with deep venous thrombosis involving the extremities develop PTS, a condition of venous insufficiency of varying severity characterized by chronic skin changes, edema, and dilated collateral superficial venous formation, and often accompanied by functional limitation (pain with activities or at rest). The presence of homozygous anticoagulant deficiencies, multiple thrombophilia traits, or persistent antiphospholipid antibodies following VTE diagnosis has been associated with increased risk of recurrent VTE, leading to recommendation for extended anticoagulation in these instances. Recent evidence suggests that elevated plasma levels of factor VIII and D-dimer may be predictive of long-term post-thrombotic outcomes in children, including recurrent VTE, persistent thrombosis, and the development of PTS.

Table 28–9. Causes of chronic splenomegaly in children.

Cause	Associated Clinical Findings	Diagnostic Investigation
Congestive splenomegaly	History of umbilical vein catheter or neonatal omphalitis; signs of portal hypertension (varices, hemorrhoids, dilated abdominal wall veins); pancytopenia; history of hepatitis or jaundice	Complete blood count, platelet count, liver function tests, ultrasonography
Chronic infections	History of exposure to tuberculosis, histoplasmosis, coccidiomycosis, other fungal disease; chronic sepsis (foreign body in bloodstream; subacute infective endocarditis)	Appropriate cultures and skin tests, ie, blood cultures; PPD, fungal serology and antigen tests, chest film; HIV serology
Infectious mononucleosis	Fever, fatigue, pharyngitis, rash, adenopathy, hepatomegaly	EBV antibody titers
Leukemia, lymphoma, Hodgkin disease	Evidence of systemic involvement with fever, bleeding tendencies, hepatomegaly, and lymphadenopathy; pancytopenia	Blood smear, bone marrow examination, chest film, gallium scan, LDH, uric acid
Hemolytic anemia	Anemia, jaundice; family history of anemia, jaundice, and gallbladder disease in young adults	Reticulocyte count, Coombs test, blood smear, osmotic fragility test, hemoglobin electrophoresis
Reticuloendothelioses (histiocytosis X)	Chronic otitis media, seborrheic or petechial skin rashes, anemia, infections, lymphadenopathy, hepatomegaly, bone lesions	Skeletal radiographs for bone lesions; biopsy of bone, liver, bone marrow, or lymph node
Storage diseases	Family history of similar disorders, neurologic involvement, evidence of macular degeneration, hepatomegaly	Biopsy of liver or bone marrow in search for storage cells
Splenic cyst	Evidence of other infections (postinfectious cyst) or congenital anomalies; peculiar shape of spleen	Radionuclide scan, ultrasonography
Splenic hemangioma	Other hemangiomas, consumptive coagulopathy	Radionuclide scan, arteriography, platelet count, coagulation screen

EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; LDH, lactic dehydrogenase; PPD, purified protein derivative.

SPLenic ABNORMALITIES

SPLenomegaly & HyperSplenism

The differential diagnosis of splenomegaly includes the general categories of congestive splenomegaly, chronic infections, leukemia and lymphomas, hemolytic anemias, reticuloendothelioses, and storage diseases (Table 28–9).

Splenomegaly due to any cause may be associated with hypersplenism and the excessive destruction of circulating red cells, white cells, and platelets. The degree of cytopenia is variable and, when mild, requires no specific therapy. In other cases, the thrombocytopenia may cause life-threatening bleeding, particularly when the splenomegaly is secondary to portal hypertension and associated with esophageal varices or the consequence of a storage disease. In such cases, treatment with surgical splenectomy or with splenic embolization may be warranted. Although more commonly associated with acute enlargement, rupture of an enlarged spleen can be seen in more chronic conditions such as Gaucher disease.

Stone DL: Life threatening splenic hemorrhage in two patients with Gaucher's disease. *Am J Hematol* 2000;64:140 [PMID: 10814997].

ASPLENIA & SPLENECTOMY

Children who lack normal splenic function are at risk for sepsis, meningitis, and pneumonia due to encapsulated bacteria such as pneumococci and *H influenzae*. Such infections are often fulminant and fatal because of inadequate antibody production and impaired phagocytosis of circulating bacteria.

Congenital asplenia is usually suspected when an infant is born with abnormalities of abdominal viscera and complex cyanotic congenital heart disease. Howell-Jolly bodies are usually present on the peripheral blood smear, and the absence of splenic tissue is confirmed by technetium radionuclide scanning. The prognosis depends on the underlying cardiac lesions, and many children die during the first few months. Prophylactic antibiotics, usually penicillin, and pneumococcal conjugate and polysaccharide vaccines are recommended.

The risk of overwhelming sepsis following surgical splenectomy is related to the child's age and to the underlying disorder. Because the risk is highest when the procedure is performed earlier in life, splenectomy is usually postponed until after age 5 years. The risk of postsplenectomy sepsis is also greater in children with malignancies, thalassemias, and reticuloendothelioses than in children whose splenectomy is performed for ITP, hereditary spherocytosis, or trauma. Prior to splenectomy, children should be immunized against *Streptococcus pneumoniae*, *H influenzae*, and *Neisseria meningitidis*. Additional management should include penicillin

prophylaxis and prompt evaluation for fever 38.8°C or above or signs of severe infection.

Children with sickle cell anemia develop functional asplenia during the first year of life, and overwhelming sepsis is the leading cause of early deaths in this disease. Prophylactic penicillin reduces the incidence of sepsis by 84%.

Pickering L: American Academy of Pediatrics: Immunization in special circumstances. Red Book 2000;25:66.

TRANSFUSION MEDICINE

DONOR SCREENING & BLOOD PROCESSING: RISK MANAGEMENT

Minimizing the risks of transfusion begins by asking the donor questions that will protect the recipient from transmission of infectious agents as well as other risks of transfu-

sions. In addition, information defining high-risk groups whose behavior increases the possible transmission of HIV, hepatitis, and other diseases is provided, with the request that persons in these groups not donate blood.

Before blood components can be released for transfusion, donor blood is screened for hepatitis B surface antigen; antibodies to hepatitis B, hepatitis C, HIV-1 and HIV-2, and human T-cell lymphotropic virus (HTLV) I and II; and a serologic test for syphilis (Table 28–10). Screening donor blood for viral genome (nucleic acid amplification [NAT] testing) was mandated for HIV, HCV, and West Nile virus. NAT testing for other viruses may be added in the future, and screening for Chagas disease was accepted in 2007. Positive tests are repeated.

Upon their confirmation, the unit in question is destroyed and the donor is notified and deferred from future donations. Many of the screening tests used are very sensitive and have a high rate of false-positive results. As a result, confirmatory tests have been developed to check the initial screen-

Table 28–10. Transmission risks of infectious agents for which screening of blood products is routinely performed.

Disease Entity	Transmission	Screening and Processing Procedures	Approximate Risk of Transmission
Syphilis	Low risk: fresh blood drawn during spirochetemia can transmit infection. Organism not able to survive beyond 72 h during storage at 4°C.	Donor history. RPR or VDRL.	< 1:100,000
Hepatitis A	Units drawn during prodrome could transmit virus. Because of brief viremia during acute phase, absence of asymptomatic carrier phase, and failure to detect transmission in multiple transfused individuals, infection by this agent is unlikely.	Donor history.	1:1,000,000
Hepatitis B	Prolonged viremia during various phases of the disease and asymptomatic carrier state make HBV infection a significant risk of transfusion. Incidence has markedly decreased with screening strategies.	Donor history, education, and self-exclusion. Hepatitis B surface antigen (HBsAg). Surrogate tests for non-A, non-B hepatitis and screen for hepatitis C and retroviruses have helped screen out population at risk for transmitting HBV.	1:500,000–1:200,000
Hepatitis C	Over two thirds of cases of non-A, non-B post-transfusion hepatitis may be due to this agent. Virus has characteristics similar to those of HBV which are responsible for risk from transfusion.	Donor history. Surrogate tests: hepatitis B core antibody (anti-HBc), anti-HCV. Nucleic acid testing for viral genome required.	1:2,000,000
Non-A, non-B, non-C hepatitis	Agents other than HAV, HBV, HCV, Epstein-Barr virus, and cytomegalovirus, which can cause post-transfusion hepatitis.	Donor history. Surrogate tests: anti-HBc.	Undefined.
Human immunodeficiency virus (HIV-1, HIV-2) infection	Retroviruses spread by sexual contact, parenteral (including transfusion) and vertical routes.	Donor history, education, and self-exclusion. Anti-HIV by EIA screening test. Western blot confirmatory, p24 antigen testing. Nucleic acid testing for viral genome required.	1:2,000,000
Human T-cell lymphotropic virus I and II (HTLV-I and II) infection	Retroviruses spread by sexual contact, parenteral (including transfusion) and vertical modes.	Donor history. Anti-HTLV-I and II by enzyme immunoassay screening test. Western blot confirmatory.	1:600,000

AIDS, acquired immunodeficiency syndrome; EIA, enzyme-linked immunosorbent assay; HAV, HBV, HCV, hepatitis A virus, hepatitis B virus, hepatitis C virus; HTLV, human T-cell lymphotropic virus; RPR, rapid plasma reagin; VDRL, syphilis test.

ing results and separate the false-positives from the true-positives. Recently, bacterial culture of platelet concentrates was added to the testing paradigm.

With these approaches, the risk of an infectious complication from blood components has been minimized (see Table 28–10), with the greatest risk being post-transfusion hepatitis (see sections on hepatitis C virus and non-A, non-B, non-C hepatitis in Chapter 21). Autologous donation is recognized by some centers as a safe alternative to homologous blood. Issues of donor size make the techniques of autologous donation difficult to apply to the pediatric population.

Primary CMV infections are significant complications of blood transfusion in transplant recipients, neonates, and immunodeficient individuals. Transmission of CMV can be avoided by using seronegative donors, apheresis platelet concentrates collected by techniques ensuring low numbers of residual white cells, or red cell or platelet products leukocyte-depleted by filtering (< 5 million white blood cells per packed red cell unit or apheresis platelet concentrate equivalent).

STORAGE & PRESERVATION OF BLOOD & BLOOD COMPONENTS

Whole blood is routinely fractionated into packed red cells, platelets, and FFP or cryoprecipitate for most efficient use of all blood components. The storage conditions and biologic characteristics of the fractions are summarized in Table 28–11. The conditions provide the optimal environment to maintain appropriate recovery, survival, and function and are different for each blood component. For example, red cells undergo dramatic metabolic changes during their 35–42-day storage, with a decrease in 2,3-diphosphoglycerate (DPG) by day 14 of storage, a decrease in adenosine triphosphate, and a gradual loss of intracellular potassium. Fortunately, these changes are reversed readily within hours to days after the red cells are transfused. However, in certain clinical conditions, these effects may define the type of components used. For example, blood less than 7–10 days old would be preferred for exchange transfusion in neonates or replacement of red cells in persons with severe cardiopulmonary disease to ensure adequate oxygen-carrying capacity. Storage time is not an issue when administering transfusions to those with chronic anemia.

If extracellular potassium in older packed red cells may present a problem, one may use blood less than 10 days old, making packed cells out of an older unit of whole blood, or washing blood stored as packed cells. Regardless of the blood's age, over 70% of the red cells will circulate after transfusion and approximate normal survival in the circulation.

Platelets are stored at 22°C for a maximum of 5 days; criteria for 7-day storage are being developed. At the extremes of storage, there should be at least a 60% recovery, a survival time that approximates turnover of fresh autologous platelets, and normalization of the bleeding time or PFA-100 in proportion to the peak platelet count. Frozen components, red cells, FFP, and cryoprecipitate are outdated

at 10 years, 1 year, and 1 year, respectively. Frozen red cells retain the same biochemical and functional characteristics as the day they were frozen. FFP contains 80% or more of all of the clotting factors of fresh plasma. Factors VIII and XIII and fibrinogen are concentrated in cryoprecipitate.

PRETRANSFUSION TESTING

Both the donated blood and the recipient are tested for ABO and Rh(D) antigens and for auto- or alloantibodies in the plasma. The cross-match is required on any component that contains red cells. In the major cross-match, washed donor red cells are incubated with the serum from the patient, and agglutination is detected and graded. The antiglobulin phase of the test is then performed; Coombs reagent, which will detect the presence of IgG or complement on the surface of the red cells, is added to the mixture, and agglutination is evaluated. In the presence of a negative antibody screen in the recipient, a negative immediate spin cross-match test confirms the compatibility of the blood and antiglobulin phase is not required. Further testing is required if the antibody screen or the cross-match is positive, and blood should not be given until the nature of the reactivity is delineated. An incompatible cross-match is evaluated first with a DAT or Coombs test to detect IgG or complement on the surfaces of the recipient's red cells. The indirect antiglobulin test is also used to determine the presence of antibodies that will coat or activate complement, and additional studies are completed to define the antibody.

TRANSFUSION PRACTICE

General Rules

Several rules should be observed in administering any blood component:

1. In final preparation of the component, no solutions should be added to the bag or tubing set except for normal saline (0.9% sodium chloride for injection, USP), ABO-compatible plasma, or other specifically approved expanders. Hypotonic solutions cause hemolysis of red cells, and, if these are transfused, a severe reaction will occur. Any reconstitution should be completed by the blood bank.
2. Transfusion products should be protected from contact with any calcium-containing solution (eg, lactated Ringer); recalcification and reversal of the citrate effect will cause clotting of the blood component.
3. Blood components should not be warmed to a temperature greater than 37°C. If a component is incubated in a water bath, it should be enclosed in a watertight bag to prevent bacterial contamination of entry ports.
4. Whenever a blood bag is entered, the sterile integrity of the system is violated, and that unit should be discarded within 4 hours if left at room temperature or within 24 hours if the temperature is 4–6°C.

Table 28-11. Characteristics of blood and blood components.

Component	Storage Conditions	Composition and Transfusion Characteristics	Indications	Risks and Precautions	Administration
Whole blood	4°C for 35 days. RBC characteristics: <ul style="list-style-type: none"> • <i>Survival</i>: recovery decreases during storage, but is always > 70%. Cells that circulate approximate normal survival. • <i>Function</i>: 2,3-DPG levels fall to undetectable after second week of storage. This defect is repaired within 24 h of transfusion. • <i>Electrolytes</i>: with storage, potassium increases in plasma. This rises to high levels after 2 wk of storage. 	Contains RBCs and many plasma compounds of whole blood. Leukocytes and platelets lose activity or viability after a few days under these conditions. Procoagulant clotting factors (particularly VIII and V) deteriorate rapidly during storage. Each unit has about 500 mL volume and Hct 36-40%.	Oxygen carrying capacity (anemia). Volume replacement for blood loss (> 15-20%) or severe shock.	Must be ABO-identical and cross-match-compatible. Infections. Febrile or hemolytic transfusion reactions. Alloimmunization to red cell, white cell, or platelet antigens.	During acute blood loss, as rapidly as tolerated. In other settings, 2-4 h. 10 mL/kg will raise Hct by 5% and support volume.
Packed red cells	Same as for whole blood. Special rejuvenating solutions allow storage for 42 d.	Contains RBCs; most plasma removed in preparation. Status of leukocytes, clotting factors, and platelets same as for whole blood. Hct about 70%, volume 200-250 mL. May request tighter pack to give Hct 80-90%.	Oxygen carrying capacity. Acute trauma or bleeding or situations requiring intensive cardiopulmonary support (Hct < 25-30%). Chronic anemia (Hct < 20%).	Same as for whole blood.	May be given as patient will tolerate, based on cardiovascular status over 2-4 h. Dose of 3 mL packed RBC/kg will raise Hct by 3%. If cardiovascular status is stable, give 10 mL/kg over 2-4 h. If unstable, use smaller volume or do packed RBC exchange.
Washed or filtered red cells	When cells are washed, there is a 24-h outdate. Up to that time, they have the same characteristics as for packed red cells.	Same as for packed red cells.	Same as packed red cells. Depending on technique used and extent of reduction of white blood cells, washed red cells may achieve the following: <ul style="list-style-type: none"> • Avoid febrile reactions • Decrease transmission of CMV. • Decrease incidence of alloimmunization to white cell antigens. 	Same as whole blood. Removal of white cells diminishes the risk of febrile reactions. Filtration with high-efficiency white cell filters may decrease rate of alloimmunization to white cell antigens and transmission of CMV.	Same as for packed red cells.
Frozen red cells	Packed red cells frozen in 40% glycerol solution at less than -65°C. After storage for 10 y, cells retain the same biochemical characteristics, function, and capacity for survival as on the day they were frozen; when thawed, 24-h outdate.	Same as for packed red cells.	Same as packed red cells. Useful for avoiding febrile reactions, decreasing transmission of CMV, autologous blood donation, and developing an inventory of rare red cell blood groups.	Same as for whole blood. Risk of CMV transmission is at same level as using seronegative components.	Same as for packed red cells.

Fresh frozen plasma	Plasma from whole blood stored at less than -18°C for up to 1 y.	Contains > 80% of all procoagulant and anticoagulant plasma proteins.	Replacement of plasma procoagulant and anticoagulant plasma proteins. May provide "other" factors, eg, treatment of TTP.	Need not be cross-matched; should be type-compatible. Volume overload, infectious diseases, allergic reactions. Solvent detergent-treated plasma or donor-retested plasma units have decreased risk for viral transmission.	As rapidly as tolerated by patient, but not > 4 h. Dose: 10–15 mL/kg will increase level of all clotting factors by 10–20%.
Cryoprecipitate	Produced by freezing fresh plasma to less than -65°C , then allowed to thaw 18 h at 4°C . After centrifugation, cryoprecipitable proteins are separated. May be stored at less than -18°C for up to 1 y.	Contains factor VIII, fibrinogen, and fibronectin at concentrations greater than those of plasma. Also contains factor XIII, VIII > 80 IU/pack, fibrinogen 100–350 mg/pack.	Treatment of acquired or congenital deficiencies of fibrinogen. Useful in making biologic glues that contain fibrinogen. Commercial clotting factor concentrates are the treatment of choice for factor VIII deficiency and von Willebrand disease because sterilization procedures further reduce the risk of viral transmission.	Same as for fresh frozen plasma. ABO agglutinogens may also be concentrated and can give positive direct agglutination test if not type-specific.	Cryoprecipitate can be given as a rapid infusion. Dose: $1/2$ pack/kg body weight will increase factor VIII level by 80–100% and fibrinogen by 200–250 mg/dL.
Platelet concentrates from whole blood donation	Separated from platelet-rich plasma and stored with gentle agitation at 22°C for 3–5 d. Containers currently in use are plastic and allow for gas exchange, diffusion of CO_2 helps keep pH > 6, a major factor in keeping platelets viable and functional.	Each unit contains about 5×10^{10} platelets. <i>Survival:</i> Although there may be some loss with storage, 60–70% recovery should be achieved, with stored platelets able to correct platelet function test in proportion to the peak counts reached.	Treatment of thrombocytopenia or platelet function defects.	No cross-match necessary. Should be ABO type-specific. Other risks as for whole blood.	Can be taken during rapid transfusion or as defined by cardiovascular status, not more than 4 h. Dose: 10 mL/kg should increase platelet count by at least 50,000/ μL .
Platelet concentrates by apheresis techniques	Same as random donor units.	Platelet content is equivalent to 6–10 units of random donor concentrates. Depending on technique used, these may be relatively free of leukocytes, which is important for avoiding alloimmunization.	As above, particularly useful in treating patients who have insufficient production and also may have a problem with alloimmunization.	Same as above.	As above.
Granulocytes	Although they may be stored stationary at $20\text{--}24^{\circ}\text{C}$, transfuse as soon as possible after collection.	Contains at least 1×10^{10} granulocytes, but also platelets and red cells. When donors given 10 mcg/kg G-CSF subcutaneously and 8 mg Decadron orally 12–15 h before collection, yield increases to $> 5 \times 10^{10}$ granulocytes.	Severely neutropenic individuals (< 500/ μL) with poor marrow reserves and suspected bacterial or fungal infections not responding to 48–72 h of parenteral antibiotics. Also in patients with neutrophil dysfunction.	Same as for platelets. Pulmonary leukostasis reactions. Severe febrile reactions.	Given in an infusion over 2–4 h. Dose: 1 unit daily for newborns and infants, 1×10^9 granulocytes per kg.

CMV, cytomegalovirus; DPG, diphosphoglycerate; G-CSF, granulocyte colony-stimulating factor; Hct, hematocrit; RBC, red blood cell.

5. Transfusions of products containing red cells should not exceed 4 hours. Blood components in excess of what can be infused during this time period should be stored in the blood bank until needed.
6. Before transfusion, the blood component should be inspected visually for any unusual characteristics, such as the presence of flocculent material, hemolysis, or clumping of cells, and mixed thoroughly.
7. The unit and the recipient should be identified properly.
8. The administration set includes a standard 170–260 micron filter. Under certain clinical circumstances, an additional microaggregate filter may be used to eliminate small aggregates of fibrin, white cells, and platelets that will not be removed by the standard filter.
9. The patient should be observed during the entire transfusion and especially during the first 15 minutes. Any adverse symptoms or signs should be evaluated immediately and reactions to the transfusion reported promptly to the transfusion service.
10. When cross-match–incompatible red cells or whole blood unit(s) must be given to the patient (as with autoimmune hemolytic anemia), a test dose of 10% of the total volume (not to exceed 50 mL) should be administered over 15–20 minutes; the transfusion is then stopped and the patient observed. If no adverse effects are noted, the remainder of the volume can be infused carefully.
11. Blood for exchange transfusion in the newborn period may be cross-matched with either the infant's or the mother's serum. If the exchange is for hemolysis, 500 mL of whole blood stored for less than 7 days will be adequate. If replacement of clotting factors is a key issue, packed red cells (7 days old) reconstituted with FFP may be considered. Based on post-transfusion platelet counts, platelet transfusion may be considered. Other problems to be anticipated are acid-base derangements, hyponatremia, hyperkalemia, hypocalcemia, hypoglycemia, hypothermia, and hypervolemia or hypovolemia.

Choice of Blood Component

Several principles should be considered when deciding on the need for blood transfusion. Indications for blood or blood components must be well defined, and the patient's medical condition, not just the laboratory results, should be the basis for the decision. Specific deficiencies exhibited by the patient (eg, oxygen-carrying capacity, thrombocytopenia) should be treated with appropriate blood components and the use of whole blood minimized. Information about specific blood components is summarized in Table 28–11.

A. Whole Blood

Whole blood may be used in patients who require replacement of oxygen-carrying capacity and volume. More specifically, it should be considered when more than 15% of blood

volume is lost. Doses vary depending on volume considerations (see Table 28–11). In acute situations, the transfusion may be completed rapidly to support blood volume.

B. Packed Red Cells

Packed red cells (which include leukocyte-poor, filtered, or frozen deglycerolized products) prepared from whole blood by centrifugal techniques are the appropriate choice for almost all patients with deficient oxygen-carrying capacity. Exact indications will be defined by the clinical setting, the severity of the anemia, the acuity of the condition, and any other factors affecting oxygen transport.

C. Platelets

The decision to transfuse platelets depends on the patient's clinical condition, the status of plasma phase coagulation, the platelet count, the cause of the thrombocytopenia, and the functional capacity of the patient's own platelets. In the face of decreased production and platelet counts less than 10,000–20,000/ μL , the risk of severe, spontaneous bleeding is increased markedly, and—in the absence of antibody-mediated thrombocytopenia—transfusion should be considered. Under certain circumstances, especially with platelet dysfunction or treatment that inhibits the procoagulant system, transfusions at higher platelet counts may be necessary.

Transfused platelets are sequestered temporarily in the lungs and spleen before reaching their peak concentrations, 45–60 minutes after transfusion. A significant proportion of the transfused platelets never circulate but remain sequestered in the spleen. This phenomenon results in reduced recovery; only 60–70% of the transfused platelets are accounted for when peripheral platelet count increments are used as a measure of response.

In addition to cessation of bleeding, two variables indicate the effectiveness of platelet transfusions. The first is platelet recovery, as measured by the maximum number of platelets circulating in response to transfusion. The practical measure is the platelet count at 1 hour after transfusion. In the absence of immune or drastic nonimmune factors that markedly decrease platelet recovery, one would expect a 7000/ μL increment for each random donor unit and a 40,000–70,000/ μL increment for each single-donor apheresis unit in a large child or adolescent. For infants and small children, 10 mL/kg of platelets will increase the platelet count by at least 50,000/ μL . The second variable is the survival of transfused platelets. Normally, if the recovery is great enough, transfused platelets will approach a normal half-life in the circulation. In the presence of increased platelet destruction, the life span may be shortened to a few days or a few hours. Frequent platelet transfusions may be required to maintain adequate hemostasis.

A particularly troublesome outcome in patients receiving long-term platelet transfusions is the development of a refractory state characterized by poor (< 30%) recovery or

Table 28-12. Adverse events following transfusions.

Event	Pathophysiology	Signs and Symptoms	Management
Acute hemolytic transfusion reaction	Preformed alloantibodies (most commonly to ABO) and occasionally autoantibodies cause rapid intravascular hemolysis of transfused cells with activation of clotting (DIC), activation of inflammatory mediators, and acute renal failure.	Fever, chills, nausea, chest pain, back pain, pain at transfusion site, hypotension, dyspnea, oliguria, hemoglobinuria.	The risk of this type of reaction overall is low (1:30,000), but the mortality rate is high (up to 40%). Stop the transfusion; maintain renal output with intravenous fluids and diuretics (furosemide or mannitol); treat DIC with heparin; and institute other appropriate supportive measures.
Delayed hemolytic transfusion reaction	Formation of alloantibodies after transfusion and resultant destruction of transfused red cells, usually by extravascular hemolysis.	Jaundice, anemia. A small percentage may develop chronic hemolysis.	Detection, definition, and documentation (for future transfusions). Supportive care. Risk, 1:2500.
Febrile reactions	Usually caused by leukoagglutinins in recipient, cytokines, or other biologically active compounds.	Fever. May also involve chills.	Supportive. Consider leukocyte-poor products for future. Risk per transfusion, 1:400–1:200.
Allergic reactions	Most causes not identified. In IgA-deficient individuals, reaction occurs as a result of antibodies to IgA.	Itching, hives, occasionally chills and fever. In severe reactions, may see signs of anaphylaxis: dyspnea, pulmonary edema.	Mild to moderate reactions: diphenhydramine. More severe reactions: epinephrine subcutaneously and steroids intravenously. Risk for mild to moderate allergic reactions, 1:1000. Severe anaphylactic reactions, 1:150,000.
Transfusion-related acute lung injury	Acute lung injury occurring within 6 h after transfusion. Two sets of factors interact to produce the syndrome. Patient factors: infection, surgery, cytokine therapy. Blood component factors: lipids, antibodies, cytokines. Two groups of factors interact during transfusion to result in lung injury indistinguishable from ARDS.	Tachypnea, dyspnea, hypoxia. Diffuse interstitial markings. Cardiac evaluation normal.	May consider younger products: packed red blood cells \leq 2 weeks, platelets \leq 3 days, washing components to prevent syndrome. Management: supportive care. Risk, 1:2000–1:3000 per transfusion. Current preventative procedures include avoiding donors at risk for alloimmunization: use of male-only FFP or white blood cell antibody-negative apheresis FFP or platelet products.
Dilutional coagulopathy	Massive blood loss and transfusion with replacement with fluids or blood components and deficient clotting factors.	Bleeding.	Replacement of clotting factors or platelets with appropriate blood components.
Bacterial contamination	Contamination of units results in growth of bacteria or production of clinically significant levels of endotoxin.	Chills, high fever, hypotension, other symptoms of sepsis or endotoxemia.	Stop transfusion; make aggressive attempts to identify organism; provide vigorous supportive medical care including antibiotics.
Graft-versus-host disease	Lymphocytes from donor transfused in an immunoincompetent host.	Syndrome can involve a variety of organs, usually skin, liver, gastrointestinal tract, and bone marrow.	Preventive management: irradiation ($>$ 1500 cGy) of cellular blood components transfused to individuals with congenital or acquired immunodeficiency syndromes, intrauterine transfusion, very premature infants, and when donors are relatives of the recipient.
Iron overload	There is no physiologic mechanism to excrete excess iron. Target organs include liver, heart, and endocrine organs. In patients receiving red cell transfusions over long periods of time, there is an increase in iron burden.	Signs and symptoms of dysfunctional organs affected by the iron.	Chronic administration of iron chelator such as deferoxamine.

TFN:ARDS, adult respiratory distress syndrome; DIC, disseminated intravascular coagulation.

no response to platelet transfusion (as measured at 1 hour). Most (70–90%) of these refractory states result from the development of alloantibodies directed against HLA antigens on the platelet. Platelets have class I HLA antigens, and the antibodies are primarily against HLA A or B determinants. A smaller proportion of these alloantibodies ($<$ 10%) may be

directed against platelet-specific alloantigens. The most effective approach to prevent HLA sensitization is to use leukocyte-depleted components ($<$ 5 million leukocytes per unit of packed red cells or per apheresis or 6–10 random donor unit concentrates). For the alloimmunized, refractory patient, the best approach is to provide HLA-matched plate-

lets for transfusion. Reports have suggested that platelet cross-matching procedures using HLA-matched or unmatched donors may be helpful in identifying platelet concentrates most likely to provide an adequate response.

D. Fresh Frozen Plasma

The indication for FFP is replacement of plasma coagulation factors in clinical situations in which a deficiency of one or more clotting factors exists and associated bleeding manifestations are present. In some hereditary factor deficiencies, such as factor VIII deficiency or vWD, commercially prepared concentrates contain these factors in higher concentrations and, because of viral inactivation, impose less infectious risk and are more appropriate than plasma.

E. Cryoprecipitate

This component may be used for acquired or congenital disorders of hypofibrinogenemia or afibrinogenemia. Although cryoprecipitate is a rich source for factor VIII or vWF, commercial concentrates that contain these factors are more appropriate (see preceding section). The dose given depends on the protein to be replaced. Cryoprecipitate can be given in a rapid transfusion over 30–60 minutes.

F. Granulocytes

With better supportive care over the past 10 years, the need for granulocytes in neutropenic patients with severe bacterial infections has decreased. Indications still remain for severe bacterial or fungal infections unresponsive to vigorous medical therapy in either newborns or older children with bone marrow failure, or patients with neutrophil dysfunction. Newer mobilization schemes using G-CSF and steroids in donors result in granulocyte collections with at least 5×10^{10} neutrophils. This may provide a better product for patients requiring granulocyte support.

G. Apheresis Products and Procedures

Apheresis equipment allows one or more blood components to be collected from a donor while the rest are returned.

Apheresis platelet concentrates, which have as many platelets as 6–10 units of platelet concentrates from whole blood donations, are one example; granulocytes are another. Apheresis techniques can also be used to collect hematopoietic stem cells that have been mobilized into the blood by cytokines (G-CSF or GM-CSF) given alone or after chemotherapy. These stem cells are used for allogeneic or autologous bone marrow transplantation. Blood cell separators can be used for the collection of single-source plasma or removal of a blood component that is causing disease. Examples include red cell exchange in sickle cell disease and plasmapheresis in Goodpasture syndrome or in Guillain-Barré syndrome.

Adverse Effects

The noninfectious complications of blood transfusions are outlined in Table 28–12. Most complications present a significant risk to the recipient.

Each year approximately 150 of every 1 million children younger than age 20 years are diagnosed with cancer. For children between the ages of 1 and 20 years, cancer is the fourth leading cause of death, behind unintentional injuries, homicides, and suicides. However, combined-modality therapy, including surgery, chemotherapy, and radiation therapy, has improved survival dramatically, such that the overall 5-year survival rate of pediatric malignancies is now greater than 75%. It is estimated that by the year 2020, 1 in 600 adults will be a survivor of childhood cancer.

Because pediatric malignancies are rare, cooperative clinical trials have become the mainstay of treatment planning and therapeutic advances. The Children's Oncology Group (COG), representing the amalgamation of four prior pediatric cooperative groups (Children's Cancer Group, Pediatric Oncology Group, Intergroup Rhabdomyosarcoma Study Group, and the National Wilms Tumor Study Group), offers current therapeutic protocols and strives to answer important treatment questions. A child or adolescent newly diagnosed with cancer should be enrolled in a cooperative clinical trial whenever possible. Because many protocols are associated with significant toxicities, morbidity, and potential mortality, treatment of children with cancer should be supervised by a pediatric oncologist familiar with the hazards of treatment, preferably at a multidisciplinary pediatric cancer center.

Advances in molecular genetics, cell biology, and tumor immunology have contributed and are crucial to the continued understanding of pediatric malignancies and their treatment. Continued research into the biology of tumors will lead to the identification of targeted therapy for specific tumor types with, it is hoped, fewer systemic effects.

Research in supportive care areas, such as prevention and management of infection, pain, and emesis, has improved the survival and quality of life for children undergoing cancer treatment. Long-term studies of childhood cancer survivors are yielding information that provides a rationale for modifying future treatment regimens to decrease mor-

bidity. A guide for caring for childhood cancer survivors is now available to medical providers as well as families and details suggested examinations and late effects by type of chemotherapy received.

MAJOR PEDIATRIC NEOPLASTIC DISEASES

ACUTE LYMPHOBLASTIC LEUKEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Bone marrow aspirate or biopsy specimen shows more than 25% lymphoblasts.
- ▶ Pallor, petechiae, purpura (50%), bone pain (25%).
- ▶ Hepatosplenomegaly (60%), lymphadenopathy (50%).
- ▶ Single or multiple cytopenias: neutropenia, thrombocytopenia, anemia (99%).
- ▶ Leukopenia (15%) or leukocytosis (50%), often with lymphoblasts identifiable on blood smear.
- ▶ Diagnosis confirmed by bone marrow examination.

▶ General Considerations

Acute lymphoblastic leukemia (ALL) is the most common malignancy of childhood, accounting for about 25% of all cancer diagnoses in patients younger than age 15 years. The worldwide incidence of ALL is about 1:25,000 children per year, including 3000 children per year in the United States. The peak age at onset is 4 years; 85% of patients are diagnosed

between ages 2 and 10 years. Children with Down syndrome have a 14-fold increase in the overall rate of leukemia.

ALL results from uncontrolled proliferation of immature lymphocytes. Its cause is unknown, and genetic factors may play a role. Leukemia is defined by the presence of more than 25% malignant hematopoietic cells (blasts) on bone marrow aspirate. Leukemic blasts from the majority of cases of childhood ALL have an antigen on the cell surface called the common ALL antigen (CALLA). These blasts derive from B-cell precursors early in their development, called B-precursor ALL. Less commonly, lymphoblasts are of T-cell origin or of mature B-cell origin. Over 70% of children receiving aggressive combination chemotherapy and early presymptomatic treatment to the central nervous system (CNS) are now cured of ALL.

► Clinical Findings

A. Symptoms and Signs

Presenting complaints of patients with ALL include those related to decreased bone marrow production of red blood cells (RBCs), white blood cells (WBCs), or platelets and to leukemic infiltration of extramedullary (outside bone marrow) sites. Intermittent fevers are common, as a result of either cytokines induced by the leukemia itself or infections secondary to leukopenia. Many patients present due to bruising or pallor. About 25% of patients experience bone pain, especially in the pelvis, vertebral bodies, and legs. Physical examination at diagnosis ranges from virtually normal to highly abnormal. Signs related to bone marrow infiltration by leukemia include pallor, petechiae, and purpura. Hepatomegaly or splenomegaly occurs in over 60% of patients. Lymphadenopathy is common, either localized or generalized to cervical, axillary, and inguinal regions. The testes may occasionally be unilaterally or bilaterally enlarged secondary to leukemic infiltration. Superior vena cava syndrome is caused by mediastinal adenopathy compressing the superior vena cava. A prominent venous pattern develops over the upper chest from collateral vein enlargement. The neck may feel full from venous engorgement. The face may appear plethoric, and the periorbital area may be edematous.

A mediastinal mass can cause tachypnea, orthopnea, and respiratory distress. Leukemic infiltration of cranial nerves may cause cranial nerve palsies with mild nuchal rigidity. The optic fundi may show exudates of leukemic infiltration and hemorrhage from thrombocytopenia. Anemia can cause a flow murmur, tachycardia, and, rarely, congestive heart failure.

B. Laboratory Findings

A complete blood count (CBC) with differential is the most useful initial test because 95% of patients with ALL have a decrease in at least one cell type (single cytopenia): neutropenia, thrombocytopenia, or anemia. Most patients have decreases in at least two blood cell lines. The WBC count is low or normal ($= 10,000/\mu\text{L}$) in 50% of patients, but the

differential shows neutropenia (absolute neutrophil count $< 1000/\mu\text{L}$) along with a small percentage of blasts amid normal lymphocytes. In 30% of patients the WBC count is between 10,000 and 50,000/ μL ; in 20% of patients it is over 50,000/ μL , occasionally higher than 300,000/ μL . Blasts are usually readily identifiable on peripheral blood smears from patients with elevated WBC counts. Peripheral blood smears also show abnormalities in RBCs, such as teardrops. Most patients with ALL have decreased platelet counts ($< 150,000/\mu\text{L}$) and decreased hemoglobin ($< 11 \text{ g/dL}$) at diagnosis. In approximately 1% of patients diagnosed with ALL, CBCs and peripheral blood smears are entirely normal but patients have bone pain that leads to bone marrow examination. Serum chemistries, particularly uric acid and lactate dehydrogenase (LDH), are often elevated at diagnosis as a result of cell breakdown.

The diagnosis of ALL is made by bone marrow examination, which shows a homogeneous infiltration of leukemic blasts replacing normal marrow elements. The morphology of blasts on bone marrow aspirate can usually distinguish ALL from acute myeloid leukemia (AML). Lymphoblasts are typically small, with cell diameters of approximately two erythrocytes. Lymphoblasts have scant cytoplasm, usually without granules. The nucleus typically contains no nucleoli or one small, indistinct nucleolus. Immunophenotyping of ALL blasts by flow cytometry helps distinguish precursor B-cell ALL from T-cell ALL or AML. Histochemical stains specific for myeloblastic and monoblastic leukemias (myeloperoxidase and nonspecific esterase) distinguish ALL from AML. About 5% of patients present with CNS leukemia, which is defined as a cerebrospinal fluid (CSF) WBC count greater than 5/ μL with blasts present on cytocentrifuged specimen.

C. Imaging

Chest radiograph may show mediastinal widening or an anterior mediastinal mass and tracheal compression secondary to lymphadenopathy or thymic infiltration, especially in T-cell ALL. Abdominal ultrasound may show kidney enlargement from leukemic infiltration or uric acid nephropathy as well as intra-abdominal adenopathy. Plain radiographs of the long bones and spine may show demineralization, periosteal elevation, growth arrest lines, or compression of vertebral bodies.

► Differential Diagnosis

The differential diagnosis, based on the history and physical examination, includes chronic infections by Epstein-Barr virus (EBV) and cytomegalovirus (CMV), causing lymphadenopathy, hepatosplenomegaly, fevers, and anemia. Prominent petechiae and purpura suggest a diagnosis of immune thrombocytopenic purpura. Significant pallor could be caused by transient erythroblastopenia of childhood, autoimmune hemolytic anemias, or aplastic anemia. Fevers and joint pains, with or without hepatosplenomegaly and lymphade-

nopathy, suggest juvenile rheumatoid arthritis (JRA). The diagnosis of leukemia usually becomes straightforward once the CBC reveals multiple cytopenias and leukemic blasts. Serum LDH levels may help distinguish JRA from leukemia, as the LDH is usually normal in JRA. An elevated WBC count with lymphocytosis is typical of pertussis; however, in pertussis the lymphocytes are mature, and neutropenia is rarely associated.

► Treatment

A. Specific Therapy

Intensity of treatment is determined by specific prognostic features present at diagnosis, the patient's response to therapy, and specific biologic features of the leukemia cells. The majority of patients with ALL are enrolled in clinical trials designed by clinical groups and approved by the National Cancer Institute; the largest group is COG. The first month of therapy consists of induction, at the end of which over 95% of patients exhibit remission on bone marrow aspirates by morphology. The drugs most commonly used in induction include oral prednisone or dexamethasone, intravenous vincristine and daunorubicin, intramuscular asparaginase, and intrathecal methotrexate. For T-cell ALL, intravenous cyclophosphamide may be added during induction.

Consolidation is the second phase of treatment, during which intrathecal chemotherapy along with continued systemic therapy and sometimes cranial radiation therapy are given to kill lymphoblasts "hiding" in the meninges. Several months of intensive chemotherapy follows consolidation. This intensification has led to improved survival in pediatric ALL.

Maintenance therapy can include daily oral mercaptopurine, weekly oral methotrexate, and, often, monthly pulses of intravenous vincristine and oral prednisone or dexamethasone. Intrathecal chemotherapy, either with methotrexate alone or combined with cytarabine and hydrocortisone, is usually given every 2–3 months.

These drugs have significant potential side effects. Patients need to be monitored closely to prevent drug toxicities and to ensure early treatment of complications. The duration of treatment ranges between 2.2 years for girls and 3.2 years for boys in COG trials. Treatment for ALL is tailored to prognostic, or risk, groups. A child aged 1–9 years with a WBC count below 50,000/ μL at diagnosis and without poor biologic features [t(9;22) or t(4;11)] is considered to be at "standard risk" and receives less intensive therapy than a "high-risk" patient who has a WBC count at diagnosis over 50,000/ μL or is older than age 10 years. Also important is the patient's response to treatment determined by minimal residual disease (MRD) monitoring. This risk-adapted treatment approach has significantly increased the cure rate among patients with less favorable prognostic features while minimizing treatment-related toxicities in those with favorable features. Bone marrow relapse is usually heralded by an abnormal CBC, either during treatment or following completion of therapy.

The CNS and testes are sanctuary sites of extramedullary leukemia. Currently, about one third of all ALL relapses are isolated to these sanctuary sites. Systemic chemotherapy does not penetrate these tissues as well as it penetrates other organs. Thus, presymptomatic intrathecal chemotherapy is a critical part of ALL treatment, without which many more relapses would occur in the CNS, with or without bone marrow relapse. The majority of isolated CNS relapses are diagnosed in an asymptomatic child at the time of routine intrathecal injection, when CSF cell count and differential shows an elevated WBC with leukemic blasts. Occasionally, symptoms of CNS relapse develop: headache, nausea and vomiting, irritability, nuchal rigidity, photophobia, and cranial nerve palsies. Currently, testicular relapse occurs in less than 5% of boys. The presentation of testicular relapse is usually unilateral painless testicular enlargement, without a distinct mass. Routine follow-up of boys both on and off treatment includes physical examination of the testes.

Bone marrow transplantation, now called hematopoietic stem cell transplantation (HSCT), is rarely used as initial treatment for ALL, because most patients are cured with chemotherapy alone. Patients whose blasts contain certain chromosomal abnormalities, such as t(9;22) or hypodiploidy (< 44 chromosomes), and patients with a very slow response to therapy may have a better cure rate with early HSCT from a human leukocyte antigen (HLA)-DR–matched sibling donor, or perhaps a matched unrelated donor, than with intensive chemotherapy alone. HSCT cures about 50% of patients who relapse, provided that a second remission is achieved with chemotherapy before transplant. Children who relapse more than 1 year after completion of chemotherapy (late relapse) may be cured with intensive chemotherapy without HSCT.

Several new biologic agents, including tyrosine kinase inhibitors and immunotoxins, are currently in various stages of research and development. Some of these therapies may prove relevant for future treatment of poor risk or relapsed ALL.

B. Supportive Care

Tumor lysis syndrome should be anticipated when treatment is started. Alkalinization of urine with intravenous sodium bicarbonate, maintaining brisk urine output, and treating with oral allopurinol are appropriate steps in managing tumor lysis syndrome. Serum levels of potassium, phosphorus, and uric acid should be monitored. If superior vena caval or superior mediastinal syndrome is present, general anesthesia is contraindicated temporarily. If hyperleukocytosis (WBC count > 100,000/ μL) is accompanied by hyperviscosity and mental status changes, leukopheresis may be indicated to rapidly reduce the number of circulating blasts and minimize the potential thrombotic or hemorrhagic CNS complications. Throughout the course of treatment, all transfused blood and platelet products should be irradiated to prevent graft-versus-host disease from the transfused lymphocytes. Whenever possible, blood products should be

leukodepleted to minimize CMV transmission, transfusion reactions, and sensitization to platelets.

Due to the immunocompromised state of the patient with ALL, bacterial, fungal, and viral infections are serious and can be life-threatening or fatal. During the course of treatment, fever (temperature = 38.3°C) and neutropenia (absolute neutrophil count < 500/μL) require prompt assessment, blood cultures from each lumen of a central line, and prompt treatment with empiric broad-spectrum antibiotics. Patients receiving ALL treatment must receive prophylaxis against *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*). Trimethoprim–sulfamethoxazole given twice each day on 2 or 3 consecutive days per week is the drug of choice. Patients nonimmune to varicella are at risk for very serious—even fatal—infection. Such patients should receive varicella-zoster immune globulin (VZIG) within 72 hours after exposure and treatment with intravenous acyclovir for active infection.

► Prognosis

Cure rates depend on specific prognostic features present at diagnosis, biologic features of the leukemic blast, and the response to therapy. Two of the most important features are WBC count and age. Children aged 1–9 years whose diagnostic WBC count is less than 50,000/μL have a higher rate of cure than other patients (~85% event-free survival for these children). The rapidity of response to induction treatment has prognostic significance as well, reflecting leukemic blast sensitivity to chemotherapy. Patients are categorized as rapid early responders (RERs) or slow early responders (SERs) based on the percentage of blasts present in bone marrow aspirates within 7–14 days after induction begins. More intensive treatment regimens are given to SERs than RERs to increase their chance of cure.

Certain chromosomal abnormalities present in the leukemic blasts at diagnosis influence prognosis. Patients with t(9;22) generally have a very poor chance of cure even with intensive chemotherapy. Likewise, infants younger than age 6 months with t(4;11) have a poor chance of cure with conventional chemotherapy. In contrast, patients whose blasts are hyperdiploid (containing > 50 chromosomes instead of the normal 46) with trisomies of chromosomes 4, 10, and 17, and patients whose blasts have a t(12;21) and TEL-AML1 rearrangement have a greater chance of cure, approaching 90% survival, than do children without these characteristics.

Techniques based on leukemic blast immunophenotyping or immunoglobulin rearrangements have been developed to detect residual lymphoblasts in bone marrow (MRD), at the end of induction and during remission. Many groups have shown that even low levels of MRD predict an inferior outcome. In the current COG clinical trials, patients with levels of MRD above 0.1% at the end of remission induction will receive intensified therapy, in an attempt to improve their outcome.

ACUTE MYELOID LEUKEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Bone marrow aspirate or biopsy shows 20% or more leukemic blasts.
- Fatigue, bleeding, or infection.
- Adenopathy, hepatosplenomegaly, skin nodules (M4 and M5 subtypes).
- Cytopenias: neutropenia (69%), anemia (44%), thrombocytopenia (33%).

► General Considerations

Approximately 500 new cases of acute myeloid leukemia (AML) occur per year in children and adolescents in the United States. Although AML accounts for only 25% of all leukemias in this age group, it is responsible for at least one third of deaths from leukemia in children and teenagers. Congenital conditions associated with an increased risk of AML include Diamond-Blackfan anemia; neurofibromatosis; Down syndrome; Wiskott-Aldrich, Kostmann, and Li-Fraumeni syndromes; as well as chromosomal instability syndromes such as Fanconi anemia. Acquired risk factors include exposure to ionizing radiation, cytotoxic chemotherapeutic agents, and benzenes. However, the vast majority of patients have no identifiable risk factors. Historically, the diagnosis of AML was based almost exclusively on morphology and immunohistochemical staining of the leukemic cells. AML has eight subtypes (M0–M7) according to the French-American-British (FAB) classification (Table 29–1). Immunophenotypic, cytogenetic, and molecular analyses are increasingly important in confirming the diagnosis of AML and subclassifying it into biologically distinct subtypes that have therapeutic and prognostic implications. Cytogenetic clonal abnormalities occur in 80% of patients with AML and are often predictive of outcome.

Aggressive induction therapy currently results in a 75–85% complete remission rate. However, long-term survival has improved only modestly to approximately 50%, despite

Table 29-1. FAB subtypes of acute myeloid leukemia.

FAB Classification	Common Name	Distribution in Childhood (Age)		Cytogenetic Associations	Clinical Features
		< 2 y	> 2 y		
M0	Acute myeloid leukemia, minimally differentiated	1%		inv (3q26), t(3;3)	
M1	Acute myeloblastic leukemia without maturation	17%	23%		
M2	Acute myeloblastic leukemia with maturation	26%		t(8;21), t(6;9); rare	Myeloblastomas or chloromas
M3	Acute promyelocytic leukemia	4%		t(15;17); rarely, t(11;17) or (5;17)	Disseminated intravascular coagulation
M4	Acute myelomonoblastic leukemia	30%	24%	11q23, inv 3, t(3;3), t(6;9)	Hyperleukocytosis, CNS involvement, skin and gum infiltration
M4Eo	Acute myelomonoblastic leukemia with abnormal eosinophils			inv16, t(16;16)	
M5	Acute monoblastic leukemia	46%	15%	11q23, t(9;11), t(8;16)	Hyperleukocytosis, CNS involvement, skin and gum infiltration
M6	Erythroleukemia	2%			
M7	Acute megakaryoblastic leukemia	7%	5%	t(1;22)	Down syndrome frequent (< age 2 y)

CNS, central nervous system; FAB, French-American-British classification.

the availability of several effective agents, improvements in supportive care, and increasingly intensive therapies.

► Clinical Findings

The clinical manifestations of AML commonly include anemia (44%), thrombocytopenia (33%), and neutropenia (69%). Symptoms may be few and innocuous or may be life-threatening. The median hemoglobin value at diagnosis is 7 g/dL, and platelets usually number fewer than 50,000/ μ L. Frequently the absolute neutrophil count is under 1000/ μ L, although the total WBC count is over 100,000/ μ L in 25% of patients at diagnosis.

Hyperleukocytosis may be associated with life-threatening complications. Venous stasis and sludging of blasts in small vessels cause hypoxia, hemorrhage, and infarction, most notably in the lung and CNS. This clinical picture is a medical emergency requiring rapid intervention, such as leukopheresis, to decrease the leukocyte count. CNS leukemia is present in 5–15% of patients at diagnosis, a higher rate of initial involvement than in ALL. Certain subtypes, such as M4 and M5, have a higher likelihood of meningeal infiltration than do other subtypes. Additionally, clinically significant coagulopathy may be present at diagnosis in patients with M3, M4, or M5 subtypes. This problem manifests as bleeding or an abnormal disseminated intravascular coagulation screen and should be at least partially corrected prior to initiation of treatment, which may transiently exacerbate the coagulopathy.

► Treatment

A. Specific Therapy

AML is less responsive to treatment than ALL and requires more intensive chemotherapy. Toxicities from therapy are common and likely to be life-threatening; therefore, treatment should be undertaken only at a tertiary pediatric oncology center.

Current AML protocols rely on intensive administration of anthracyclines, cytarabine, and etoposide for induction of remission. After remission is obtained patients who have a matched sibling donor undergo allogeneic HSCT while those without an appropriate related donor are treated with additional cycles of aggressive chemotherapy for a total of 6–9 months. Inv16 and t(8;21) may herald a more responsive subtype of AML. In patients with a rapid response to induction, intensive chemotherapy alone may be curative. Trials with risk grouping are ongoing as more is understood about the varying biologic factors.

The biologic heterogeneity of AML is becoming increasingly important therapeutically. The M3 subtype, associated with t(15;17) demonstrated either cytogenetically or molecularly, is currently treated with all *trans*-retinoic acid in addition to chemotherapy with high-dose cytarabine and daunorubicin. All *trans*-retinoic acid leads to differentiation of promyelocytic leukemia cells and can induce remission, but cure requires conventional chemotherapy as well. The use of arsenic trioxide has also been investigated in the treatment of

this subtype of AML with favorable results. This subtype has an increased event-free survival over other AML subtypes.

Another biologically distinct subtype of AML occurs in children with Down syndrome, M7, or megakaryocytic AML. Using less intensive treatment, remission induction rate and overall survival of these children are dramatically superior to non-Down syndrome children with AML. It is important that children with Down syndrome receive appropriate treatment specifically designed to be less intensive.

Biologic agents and new chemotherapeutic agents are increasingly being studied in the treatment of AML. The development and early success of antibody-targeted cytotoxic agents such as gemtuzumab ozogamicin (Mylotarg, a humanized anti-CD33 monoclonal antibody conjugated with calicheamicin) are encouraging steps in the quest for therapeutic agents that result in higher survival rates. Use of this agent as intensive chemotherapy for AML is now being evaluated in a randomized trial. Clofarabine, a newer nucleoside analogue, also has activity in AML and is currently undergoing trials in relapsed and refractory patients.

B. Supportive Care

Tumor lysis syndrome rarely occurs during induction treatment of AML. Nevertheless, when the diagnostic WBC cell count is greater than 100,000/ μ L or significant adenopathy or organomegaly is present, one should alkalinize urine with intravenous sodium bicarbonate, maintain brisk urine output, and follow potassium, uric acid, and phosphorous lab values closely. Hyperleukocytosis (WBC > 100,000/ μ L) is a medical emergency and, in a symptomatic patient, requires rapid intervention such as leukopheresis to rapidly decrease the number of circulating blasts and thereby decrease hyperviscosity. Delaying transfusion of packed RBCs until the WBC can be decreased to below 100,000/ μ L avoids exacerbating hyperviscosity. It is also important to correct the coagulopathy commonly associated with M3, M4, or M5 subtypes prior to beginning induction chemotherapy. As with the treatment of ALL, all blood products should be irradiated and leukodepleted; *Pneumocystis* prophylaxis must be administered during treatment and for several weeks afterward; and patients not immune to varicella must receive VZIG within 72 hours of exposure and prompt treatment with intravenous acyclovir for active infection.

Onset of fever (temperature $\geq 38.3^{\circ}\text{C}$) or chills associated with neutropenia requires prompt assessment, blood cultures from each lumen of a central venous line, other cultures such as throat or urine as appropriate, and prompt initiation of broad-spectrum intravenous antibiotics. Infections in this population of patients can rapidly become life-threatening. Because of the high incidence of invasive fungal infections, there should be a low threshold for initiating antifungal therapy. Filgrastim (granulocyte colony-stimulating factor) may be used to stimulate granulocyte recovery during the treatment of AML and results in shorter periods of neutropenia and hospitalization. It must be stressed that the supportive

care for this group of patients is as important as the leukemia-directed therapy and that this treatment should be carried out only at a tertiary pediatric cancer center.

► Prognosis

Published results from various centers show a 50–60% survival rate at 5 years following first remission for patients who do not have matched sibling hematopoietic stem cell donors. Patients with matched sibling donors fare slightly better, with 5-year survival rates of 60–70% after allogeneic HSCT.

As treatment becomes more sophisticated, outcome is increasingly related to the subtype of AML. Currently, AML in patients with t(8;21), t(15;17), inv 16, or Down syndrome has the most favorable prognosis, with 65–75% long-term survival using modern treatments, including chemotherapy alone. The least favorable outcome occurs in AML patients with monosomy 7 or 5, 7q, 5q-, or 11q23 cytogenetic abnormalities.

MYELOPROLIFERATIVE DISEASES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Leukocytosis with predominance of immature cells.
- Often indolent course.
- Fever, bone pain, respiratory symptoms.
- Hepatosplenomegaly.

Myeloproliferative diseases in children are relatively rare. They are characterized by ineffective hematopoiesis that results in excessive peripheral blood counts. The three most important types are chronic myelogenous leukemia (CML), which accounts for less than 5% of the childhood leukemias, transient myeloproliferative disorder in children with Down syndrome, and juvenile myelomonocytic leukemia (Table 29–2).

Table 29–2. Comparison of JMML, CML, and TMD.

	CML	TMD	JMML
Age at onset	> 3 y	< 3 mo	< 2 y
Clinical presentation	Nonspecific constitutional complaints, massive splenomegaly, variable hepatomegaly	DS features, often no or few symptoms; or hepatosplenomegaly, respiratory symptoms	Abrupt onset; eczematoid skin rash, marked lymphadenopathy, bleeding tendency, moderate hepatosplenomegaly, fever
Chromosomal alterations	t(9;22)	Constitutional trisomy 21, but usually no other abnormality	Monosomy or del (7q) in 20% of patients
Laboratory features	Marked leukocytosis (> 100,000/ μ L), normal to elevated platelet count, decreased to absent leukocyte alkaline phosphatase, usually normal muramidase	Variable leukocytosis, normal to high platelet count, large platelets, myeloblasts	Moderate leukocytosis (> 10,000/ μ L), thrombocytopenia, monocytosis (> 1000/ μ L), elevated fetal hemoglobin, normal to diminished leukocyte alkaline phosphatase, elevated muramidase

CML, chronic myelogenous leukemia; DS, Down syndrome; JMML, juvenile myelomonocytic leukemia; TMD, transient myeloproliferative disorder.

1. Chronic Myelogenous Leukemia

► General Considerations

CML with translocation of chromosomes 9 and 22 (the Philadelphia chromosome, Ph⁺) is identical to adult Ph⁺CML. Translocation 9;22 results in the fusion of the *BCR* gene on chromosome 22 and the *ABL* gene on chromosome 9. The resulting fusion protein is a constitutively active tyrosine kinase that interacts with a variety of effector proteins and allows for deregulated cellular proliferation, decreased adherence of cells to the bone marrow extracellular matrix, and resistance to apoptosis. The disease usually progresses within 3 years to an accelerated phase and then to a blast crisis. It is generally accepted that Ph⁺ cells have an increased susceptibility to the acquisition of additional molecular changes that lead to the accelerated and blast phases of disease.

► Clinical Findings

Patients with CML may present with nonspecific complaints similar to those of acute leukemia, including bone pain, fever, night sweats, and fatigue. However, patients can also be asymptomatic. Patients with a total WBC count of more than 100,000/ μ L may have symptoms of leukostasis, such as dyspnea, priapism, or neurologic abnormalities. Physical findings may include fever, pallor, ecchymoses, and hepatosplenomegaly. Anemia, thrombocytosis, and leukocytosis are frequent laboratory findings. The peripheral smear is usually diagnostic, with a characteristic predominance of myeloid cells in all stages of maturation and relatively few blasts.

► Treatment & Prognosis

Historically, hydroxyurea or busulfan has been used to reduce or eliminate Ph⁺ cells. However, HSCT is the only consistently curative intervention. Reported survival rates for patients younger than age 20 years transplanted in the chronic phase

from matched related donors are 70–80%. Unrelated stem cell transplants result in survival rates of 50–65%.

The understanding of the molecular mechanisms involved in the pathogenesis of CML has led to the rational design of molecularly targeted therapy. Imatinib mesylate (Gleevec) is a tyrosine kinase inhibitor that has had dramatic success in the treatment of CML, with most adults and children achieving cytogenetic remission. The durability of the remission for children is unclear but is now the accepted upfront therapy. However, some patients are resistant to imatinib, and its role in the long-term management of children with CML awaits further studies.

2. Transient Myeloproliferative Disorder

Transient myeloproliferative disorder is unique to patients with trisomy 21 or mosaicism for trisomy 21. It is characterized by uncontrolled proliferation of blasts, usually of megakaryocytic origin, during early infancy and spontaneous resolution. The pathogenesis of this process is not well understood, although mutations in the *GATA1* gene have recently been implicated as initial events.

Although the true incidence is unknown, it is estimated to occur in up to 10% of patients with Down syndrome. Despite the fact that the process usually resolves by 3 months of age, organ infiltration may cause significant morbidity and mortality.

Patients can present with hydrops fetalis, pericardial or pleural effusions, or hepatic fibrosis. More frequently, they are asymptomatic or only minimally ill. Therefore, treatment is primarily supportive. Patients without symptoms are not treated, and those with organ dysfunction receive low doses of chemotherapy or leukaphoresis (or both) to reduce peripheral blood blast counts. Although patients with transient myeloproliferative disorder have apparent resolution of the process, approximately 30% go on to develop acute megakaryoblastic leukemia (AML M7) within 3 years.

3. Juvenile Myelomonocytic Leukemia

Juvenile myelomonocytic leukemia (JMML), accounts for approximately one third of the myelodysplastic and myeloproliferative disorders in childhood. Patients with neurofibromatosis type 1 (NF-1) are at higher risk of JMML than the general population. It typically occurs in infants and very young children and is occasionally associated with monosomy 7 or a deletion of the long arm of chromosome 7.

Patients with JMML present similarly to those with other hematopoietic malignancies, with lymphadenopathy, hepatosplenomegaly, skin rash, or respiratory symptoms. Patients may have stigmata of NF-1 with neurofibromas or café-au-lait spots. Laboratory findings include anemia, thrombocytopenia, leukocytosis with monocytosis, and elevated fetal hemoglobin.

The results of chemotherapy for children with JMML have been disappointing, with estimated survival rates of less than 30%. Approximately 40–45% of patients are projected to survive long term using HSCT, although optimizing conditioning regimens and donor selection may improve these results.

- ▶ Seizures, personality change, blurred vision, diplopia, weakness, decreased coordination, precocious puberty.

▶ General Considerations

The classic triad of morning headache, vomiting, and papilledema is present in fewer than 30% of children at presentation. School failure and personality changes are common in older children. Irritability, failure to thrive, and delayed development are common in very young children with brain tumors. Recent-onset head tilt can result from a posterior fossa tumor.

Brain tumors are the most common solid tumors of childhood, accounting for 1500–2000 new malignancies in children each year in the United States and for 25–30% of all childhood cancers. In general, children with brain tumors have a better prognosis than do adults. Favorable outcome occurs most commonly with low-grade and fully resectable tumors. Unfortunately, cranial irradiation in young children can have significant neuropsychological, intellectual, and endocrinologic sequelae.

Brain tumors in childhood are biologically and histologically heterogeneous, ranging from low-grade localized lesions to high-grade tumors with neuraxis dissemination. High-dose systemic chemotherapy is used frequently, especially in young children with high-grade tumors, in an effort to delay, decrease, or completely avoid cranial irradiation. Such intensive treatment may be accompanied by autologous HSCT or peripheral stem cell reconstitution.

The causes of pediatric brain tumors are unknown. The risk of developing astrocytomas is increased in children with neurofibromatosis or tuberous sclerosis. Several studies show that some childhood brain tumors occur in families with increased genetic susceptibility to childhood cancers in general, brain tumors, or leukemia and lymphoma. A higher incidence of seizures has been observed in relatives of children with astrocytoma. Certain pediatric brain tumors such as ependymoma have been linked to polyomavirus, but the exact relationship is unknown. The risk of developing a brain tumor is increased in children who received cranial irradiation for treatment of meningeal leukemia.

Because pediatric brain tumors are rare, they are often misdiagnosed or diagnosed late; most pediatricians see no more than two children with brain tumors during their careers.

▶ Clinical Findings

A. Symptoms and Signs

Clinical findings at presentation vary depending on the child's age and the tumor's location. Children younger than age 2 years more commonly have infratentorial tumors. Children with such tumors usually present with nonspecific symptoms such as vomiting, unsteadiness, lethargy, and irritability. Signs may be surprisingly few or may include macrocephaly, ataxia,

BRAIN TUMORS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Classic triad: morning headache, vomiting, and papilledema.
- ▶ Increasing head circumference, cranial nerve palsies, dysarthria, ataxia, hemiplegia, papilledema, hyperreflexia, macrocephaly, cracked pot sign.

hyperreflexia, and cranial nerve palsies. Because the head can expand in young children, papilledema is often absent. Measuring head circumference and observing gait are essential in evaluating a child for possible brain tumor. Eye findings and apparent visual disturbances such as difficulty tracking can occur in association with optic pathway tumors such as optic glioma. Optic glioma occurring in a young child is often associated with neurofibromatosis.

Older children more commonly have supratentorial tumors, which are associated with headache, visual symptoms, seizures, and focal neurologic deficits. Initial presenting features are often nonspecific. School failure and personality changes are common. Vaguely described visual disturbance is often present, but the child must be directly asked. Headaches are common, but they often will not be predominantly in the morning. The headaches may be confused with migraine.

Older children with infratentorial tumors characteristically present with symptoms and signs of hydrocephalus, which include progressively worsening morning headache and vomiting, gait unsteadiness, double vision, and papilledema. Cerebellar astrocytomas enlarge slowly, and symptoms may worsen over several months. Morning vomiting may be the only symptom of posterior fossa ependymomas, which originate in the floor of the fourth ventricle near the vomiting center. Children with brainstem tumors may present with facial and extraocular muscle palsies, ataxia, and hemiparesis; hydrocephalus occurs in approximately 25% of these patients at diagnosis.

B. Imaging and Staging

In addition to the tumor biopsy, neuraxis imaging studies are obtained to determine whether dissemination has occurred. It is unusual for brain tumors in children and adolescents to disseminate outside the CNS.

Magnetic resonance imaging (MRI) has become the preferred diagnostic study for pediatric brain tumors. MRI provides better definition of the tumor and delineates indolent gliomas that may not be seen on computed tomography (CT) scan. In contrast, a CT scan can be done in less than 10 minutes—as opposed to the 30 minutes required for an MRI scan—and is still useful if an urgent diagnostic study is necessary or to detect calcification of a tumor. Both scans are generally done with and without contrast enhancement. Contrast enhances regions where the blood-brain barrier is disrupted. Postoperative scans to document the extent of tumor resection should be obtained within 48 hours after surgery to avoid postsurgical enhancement.

Imaging of the entire neuraxis and CSF cytologic examination should be part of the diagnostic evaluation for patients with tumors such as medulloblastoma, ependymoma, and pineal region tumors. Diagnosis of neuraxis drop metastases (tumor spread along the neuraxis) can be accomplished by gadolinium-enhanced MRI incorporating sagittal and axial views. MRI of the spine should be obtained preoperatively in

all children with midline tumors of the fourth ventricle or cerebellum. A CSF sample should be obtained during the diagnostic surgery. Lumbar CSF is preferred over ventricular CSF for cytologic examination. Levels of biomarkers in the blood and CSF, such as human chorionic gonadotropin and α -fetoprotein, may be helpful at diagnosis and in follow-up. Both human chorionic gonadotropin and α -fetoprotein should be obtained from the blood preoperatively for all pineal and suprasellar tumors.

The neurosurgeon should discuss staging and sample collection with an oncologist before surgery in a child newly presenting with a scan suggestive of brain tumor.

C. Classification

About 50% of the common pediatric brain tumors occur above the tentorium and 50% in the posterior fossa. In the very young child, posterior fossa tumors are more common. Most childhood brain tumors can be divided into two categories according to the cell of origin: (1) glial tumors, such as astrocytomas and ependymomas, or (2) nonglial tumors, such as medulloblastoma and other primitive neuroectodermal tumors. Some tumors contain both glial and neural elements (eg, ganglioglioma). A group of less common CNS tumors does not fit into either category (ie, craniopharyngiomas, germ cell tumors, choroid plexus tumors, and meningiomas). Low-grade and high-grade tumors are found in most categories. Table 29–3 lists the locations and frequencies of the common pediatric brain tumors.

Astrocytoma is the most common brain tumor of childhood. Most are juvenile pilocytic astrocytoma (WHO grade I) found in the posterior fossa with a bland cellular morphol-

Table 29–3. Location and frequency of common pediatric brain tumors.

Location	Frequency of Occurrence (%)
Hemispheric	37
Low-grade astrocytoma	23
High-grade astrocytoma	11
Other	3
Posterior fossa	49
Medulloblastoma	15
Cerebellar astrocytoma	15
Brainstem glioma	15
Ependymoma	4
Midline	14
Craniopharyngioma	8
Chiasmal glioma	4
Pineal region tumor	2

Table 29-4. Prognostic factors in children with medulloblastoma.

Factor	Favorable	Unfavorable
Extent of disease	Nondisseminated	Disseminated
Size of primary tumor after surgery	≤ 3 cm (completely resected)	> 3 cm
Histologic features	Undifferentiated	Foci of glial, ependymal, or neuronal differentiation
Age	≥ 4 y	< 4 y

ogy and few or no mitotic figures. Low-grade astrocytomas are in many cases curable by complete surgical excision alone. Chemotherapy is effective in low-grade astrocytomas.

Medulloblastoma and related primitive neuroectodermal tumors are the most common high-grade brain tumors in children. These tumors usually occur in the first decade of life, with a peak incidence between ages 5 and 10 years and a female-to-male ratio of 2.1:1.3. The tumors typically arise in the midline cerebellar vermis, with variable extension into the fourth ventricle. Neuraxis dissemination at diagnosis affects from 10–46% of patients. Prognostic factors are outlined in Table 29-4.

Brainstem tumors are third in frequency of occurrence in children. They are frequently of astrocytic origin and often are high-grade. Children with tumors that diffusely infiltrate the brainstem and involve primarily the pons have a long-term survival rate of less than 15%. Brainstem tumors that occur above or below the pons and grow in an eccentric or cystic manner have a somewhat better outcome. Exophytic tumors in this location may be amenable to surgery. Generally, brainstem tumors are treated without a tissue diagnosis.

Other brain tumors such as ependymomas, germ cell tumors, choroid plexus tumors, and craniopharyngiomas are less common, and each is associated with unique diagnostic and therapeutic challenges.

► Treatment

A. Supportive Care

Dexamethasone should be started prior to initial surgery (0.5–1.0 mg/kg initially, then 0.25–0.5 mg/kg/d in four divided doses). Anticonvulsants (usually phenytoin, 4–8 mg/kg/d) should be started if the child has had a seizure or if the surgical approach is likely to induce seizures. Because postoperative treatment of young children with high-grade brain tumors incorporates increasingly more intensive systemic chemotherapy, consideration should also be given to the use of prophylaxis for prevention of oral candidiasis and *Pneumocystis* infection. Dexamethasone and phenytoin potentially reduce the effectiveness of chemotherapy and should be discontinued as soon after surgery as possible.

Optimum care for the pediatric patient with a brain tumor requires a multidisciplinary team including subspecialists in pediatric neurosurgery, neurooncology, neurology, endocrinology, neuropsychology, radiation therapy, and rehabilitation medicine, as well as highly specialized nurses, social workers, and staff in physical therapy, occupational therapy, and speech and language science.

B. Specific Therapy

The goal of treatment is to eradicate the tumor with the least short- and long-term morbidity. Long-term neuropsychological morbidity becomes an especially important issue related to deficits caused by the tumor itself and the sequelae of treatment. Meticulous surgical removal of as much tumor as possible is generally the preferred initial approach. Technologic advances in the operating microscope, the ultrasonic tissue aspirator, and the CO₂ laser (which is less commonly used in pediatric brain tumor surgery); the accuracy of computerized stereotactic resection; and the availability of intraoperative monitoring techniques such as evoked potentials and electrocorticography have increased the feasibility and safety of surgical resection of many pediatric brain tumors. Second-look surgery after chemotherapy is increasingly being used when tumors are incompletely resected at initial surgery.

Radiation therapy for pediatric brain tumors is in a state of evolution. For tumors with a high probability of neuraxis dissemination (eg, medulloblastoma), craniospinal irradiation is still standard therapy in children older than age 3 years. In others (eg, ependymoma), craniospinal irradiation has been abandoned because neuraxis dissemination at first relapse is rare. Approaches to the delivery of radiation to minimize the adverse effects on normal brain tissue are being explored and include stereotactic irradiation and the use of three-dimensional treatment planning.

Chemotherapy is effective in treating low-grade and malignant astrocytomas and medulloblastomas. A series of brain tumor protocols for children younger than age 3 years involved administering intensive chemotherapy after tumor resection and delaying or omitting radiation therapy. The results of these trials have generally been disappointing but have taught valuable lessons regarding the varying responses to chemotherapy of different tumor types. Future trials may give shorter courses of more intense chemotherapy followed by conformal radiotherapy. Conformal techniques allow the delivery of radiation to strictly defined fields and may limit side effects.

In older children with malignant glioma, the current approach is surgical resection of the tumor and combined-modality treatment with irradiation and intensive chemotherapy. In patients with glioblastoma, the use of high-dose chemotherapy and autologous bone marrow or peripheral stem cell reconstitution is being studied. Initial results have been mixed, but the toxicity of such therapy remains a concern. Surgery is not indicated for diffuse brainstem

gliomas. Traditional treatment of these tumors has been local irradiation. Hyperfractionation to increase the dose from the conventional 54 Gy to 72–78 Gy showed no apparent benefit in a recent Children's Cancer Group (CCG) study. New approaches are needed for this prognostically poor tumor.

The treatment of low-grade astrocytomas is evolving. Increasing numbers of young children are receiving antitumor chemotherapeutic agents such as carboplatin and vincristine after incomplete resection of these tumors. The role of irradiation after subtotal resection even in older children is being questioned.

► Prognosis

Despite improvements in surgery and radiation therapy, the outlook for cure remains poor for children with high-grade glial tumors. For children with high-grade gliomas, an early CCG study showed a 45% progression-free survival rate for children who received radiation therapy and chemotherapy. A follow-up CCG study in which all patients had chemotherapy and radiation therapy showed a 5-year progression-free survival rate of 36%. There is a possibility of effective salvage therapy with high-dose chemotherapy for children who relapse. In addition, the extent of resection appeared to correlate positively with prognosis, with a 3-year progression-free survival rate of 17% for patients receiving biopsy only, 29–32% for patients receiving partial or subtotal resections, and 54% for those receiving 90% resections. Biologic factors that may affect survival are being increasingly recognized. The prognosis for diffuse pontine gliomas remains very poor, with no benefit from high-dose chemotherapy plus radiation therapy versus radiation alone.

The 5- and even 10-year survival rate for low-grade astrocytomas of childhood is 60–90%. However, prognosis depends on both site and grade. A child with a pilocytic astrocytoma of the cerebellum has a considerably better prognosis than a child with a fibrillary astrocytoma of the cerebral cortex. Recently, a new entity of low-grade tumor of childhood, the pilomyxoid astrocytoma has been recognized. Pilomyxoid astrocytomas seem to have a worse prognosis than juvenile pilocytic astrocytomas. For recurrent or progressive low-grade astrocytoma of childhood, relatively moderate chemotherapy may improve the likelihood of survival.

Conventional craniospinal irradiation for children with low-stage medulloblastoma results in survival rates of 60–90%. Ten-year survival rates are lower (40–60%). Chemotherapy allows a reduction in the craniospinal radiation dose while preserving survival rates for average-risk patients (86% survival at 5 years on the most recent COG average-risk protocol). However, even reduced-dose craniospinal irradiation has an adverse effect on intellect, especially in children younger than age 7 years. Five-year survival rates for high-risk medulloblastoma have been 25–40%, but a recent trial reported at the American Society of Clinical Oncology (ASCO) conference in 2007 suggests a dramatically improved

prognosis for patients receiving intensive chemotherapy and irradiation. Children with supratentorial primitive neuroectodermal tumors also benefit from the addition of chemotherapy to craniospinal irradiation.

Major challenges remain in treating brain tumors in children younger than age 3 years and in treating brainstem gliomas and malignant gliomas. The increasing emphasis is on the quality of life of survivors, not just the survival rate.

LYMPHOMAS & LYMPHOPROLIFERATIVE DISORDERS

The term *lymphoma* refers to a malignant proliferation of lymphoid cells, usually in association with and arising from lymphoid tissues (ie, lymph nodes, thymus, spleen). In contrast, the term *leukemia* refers to a malignancy arising from the bone marrow, which may include lymphoid cells. Because lymphomas can involve the bone marrow, the distinction between the two can be confusing. The diagnosis of lymphoma is a common one among childhood cancers, accounting for 10–15% of all malignancies. The most common form is Hodgkin disease, which represents nearly half of all cases. The remaining subtypes, referred to collectively as non-Hodgkin lymphoma, are divided into four main groups: lymphoblastic, small noncleaved cell, large B-cell, and anaplastic large cell lymphomas.

In contrast to lymphomas, lymphoproliferative disorders (LPDs) are quite rare in the general population. Most are polyclonal, nonmalignant (though often life-threatening) accumulations of lymphocytes that occur when the immune system fails to control virally transformed lymphocytes. However, a malignant monoclonal proliferation can also arise. The post-transplant LPDs arise in patients who are immunosuppressed to prevent solid organ or bone marrow transplant rejection, particularly liver and heart transplant patients. Spontaneous LPDs occur in immunodeficient individuals and, less commonly, in immunocompetent persons.

1. Hodgkin Disease

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Painless cervical (70–80%) or supraclavicular (25%) adenopathy; mediastinal mass (50%).
- ▶ Fatigue, anorexia, weight loss, fever, night sweats, pruritus, cough.

▶ General Considerations

Children with Hodgkin disease have a better response to treatment than do adults, with a 75% overall survival rate at more than 20 years following diagnosis. Although adult therapies are applicable, the management of Hodgkin disease in children younger than age 18 years frequently differs. Because excellent disease control can result from several different therapeutic approaches, selection of staging procedures (radiographic, surgical, or other procedures to determine additional locations of disease) and treatment are often based on the potential long-term toxicity associated with the intervention.

Although Hodgkin disease represents 50% of the lymphomas of childhood, only 15% of all cases occur in children aged 16 years or younger. Children younger than age 5 years account for 3% of childhood cases. There is a 4:1 male predominance in the first decade. Notably, in underdeveloped countries the age distribution is quite different, with a peak incidence in younger children.

Hodgkin disease is subdivided into four histologic groups, and the distribution in children parallels that of adults: lymphocyte-predominant (10–20%); nodular sclerosing (40–60%) (increases with age); mixed cellularity (20–40%); and lymphocyte-depleted (5–10%). Prognosis is independent of subclassification, with appropriate therapy based on stage (see later discussion of staging).

▶ Clinical Findings

A. Symptoms and Signs

Children with Hodgkin disease usually present with painless cervical adenopathy. The lymph nodes often feel firmer than inflammatory nodes and have a rubbery texture. They may be discrete or matted together and are not fixed to surrounding tissue. The growth rate is variable, and involved nodes may wax and wane in size over weeks to months.

As Hodgkin disease nearly always arises in lymph nodes and spreads to contiguous nodal groups, a detailed examination of all nodal sites is mandatory. Lymphadenopathy is common in children, so the decision to perform biopsy is often difficult or delayed for a prolonged period. Indications for consideration of early lymph node biopsy include lack of identifiable infection in the region drained by the enlarged node, a node greater than 2 cm in size, supraclavicular

adenopathy or abnormal chest radiograph, and lymphadenopathy increasing in size after 2 weeks or failing to resolve within 4–8 weeks.

Constitutional symptoms occur in about one third of children at presentation. Symptoms of fever greater than 38.0°C, weight loss of 10% in the previous 6 months, and drenching night sweats are defined by the Ann Arbor staging criteria as B symptoms. The A designation refers to the absence of these symptoms. B symptoms are of prognostic value, and more aggressive therapy is usually required for cure. Generalized pruritus and pain with alcohol ingestion may also occur.

Half of patients have asymptomatic mediastinal disease (adenopathy or anterior mediastinal mass), although symptoms due to compression of vital structures in the thorax may occur. A chest radiograph should be obtained when lymphoma is being considered. The mediastinum must be evaluated thoroughly before any surgical procedure is undertaken to avoid airway obstruction or cardiovascular collapse during anesthesia and possible death. Splenomegaly or hepatomegaly is generally associated with advanced disease.

B. Laboratory Findings

The CBC is usually normal, although anemia, neutrophilia, eosinophilia, and thrombocytosis may be present. The erythrocyte sedimentation rate and other acute-phase reactants are often elevated and can serve as markers of disease activity. Immunologic abnormalities occur, particularly in cell-mediated immunity, and anergy is common in patients with advanced-stage disease at diagnosis. Autoantibody phenomena such as hemolytic anemia and an idiopathic thrombocytopenic purpura-like picture have been reported.

C. Staging

Staging of Hodgkin disease determines treatment and prognosis. The most common staging system is the Ann Arbor classification that describes extent of disease by I–IV and symptoms by an A or a B suffix (eg, stage IIIB). A systematic search for disease includes chest radiography; CT scan of the chest, abdomen, and pelvis; and bilateral bone marrow aspirates and biopsies. Technetium bone scanning may show bony involvement and is usually reserved for patients with bone pain, as bone involvement is rare. Gallium scanning defines gallium-avid tumors and is most useful in evaluating residual mediastinal disease at the completion of treatment. Positron emission tomography is increasingly used in the staging and follow-up of patients with Hodgkin disease, often replacing gallium scanning.

The staging laparotomy in pediatrics is rarely performed because almost all patients are given systemic chemotherapy rather than radiation therapy. This shift in favored therapy is due to the toxicities of high-dose, extended-field radiation in children and the complications of laparotomy, including post-splenectomy sepsis.

D. Pathologic Findings

The diagnosis of Hodgkin disease requires the histologic presence of the Reed-Sternberg cell or its variants in tissue. Reed-Sternberg cells are germinal-center B cells that have undergone malignant transformation. Nearly 20% of these tumors in developed countries are positive for EBV, and there is building evidence to implicate EBV in the development of Hodgkin disease.

▶ Treatment & Prognosis

To achieve long-term disease-free survival while minimizing treatment toxicity, Hodgkin disease is increasingly treated by chemotherapy alone—and less often by radiation therapy.

Several combinations of chemotherapeutic agents are effective, and treatment times are relatively short compared with pediatric oncology protocols for leukemia. A current COG study is addressing whether only 9 weeks of therapy with AV-PC (Adriamycin [doxorubicin], vincristine, prednisone, and cyclophosphamide) is sufficient to induce a complete response in patients with low-risk Hodgkin disease. Two additional drugs, bleomycin and etoposide, are currently added in the treatment of intermediate-risk patients for a total of 4–6 months of therapy for patients with intermediate-risk disease. The removal of involved field irradiation in patients with intermediate-risk Hodgkin disease who respond early to chemotherapy is being investigated. Combined-modality therapy with chemotherapy and irradiation is used in advanced disease.

Current treatment gives children with stage I and stage II Hodgkin disease at least a 90% disease-free likelihood of survival 5 years after diagnosis, which generally equates with cure. Two thirds of all relapses occur within 2 years after diagnosis, and relapse rarely occurs beyond 4 years. In more advanced disease (stages III and IV), 5-year event-free survival rates range from over 60% to 90%. With more patients being long-term survivors of Hodgkin disease, the risk of secondary malignancies, both leukemias and solid tumors, is becoming more apparent and is higher in patients receiving radiation therapy. Therefore, elucidating the optimal treatment strategy that minimizes such risk should be the goal of future studies.

Patients with relapsed Hodgkin disease are often salvageable using chemotherapy and radiation therapy. An increasingly popular alternative is autologous HSCT, which may improve survival rates. Allogeneic HSCT is also used, but carries increased risks of complications and may not offer added survival benefit.

2. Non-Hodgkin Lymphoma

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Cough, dyspnea, orthopnea, swelling of the face, lymphadenopathy, mediastinal mass, pleural effusion.
- ▶ Abdominal pain, abdominal distention, vomiting, constipation, abdominal mass, ascites, hepatosplenomegaly.
- ▶ Adenopathy, fevers, neurologic deficit, skin lesions.

▶ General Considerations

Non-Hodgkin lymphomas (NHLs) are a diverse group of cancers accounting for 5–10% of malignancies in children younger than age 15 years. About 500 new cases arise per year in the United States. The incidence of NHLs increases with age. Children aged 15 years or younger account for only 3% of all cases of NHLs, and the disease is uncommon before age 5 years. There is a male predominance of approximately 3:1. In equatorial Africa, NHLs cause almost 50% of pediatric malignancies.

Most children who develop NHL are immunologically normal. However, children with congenital or acquired immune deficiencies (eg, Wiskott-Aldrich syndrome, severe combined immunodeficiency syndrome, X-linked lymphoproliferative syndrome, HIV infection, immunosuppressive therapy following solid organ or marrow transplantation) have an increased risk of developing NHLs. It has been estimated that their risk is 100–10,000 times that of age-matched control subjects.

Animal models suggest a viral contribution to the pathogenesis of NHL, and there is evidence of viral involvement in human NHL as well. In equatorial Africa, 95% of Burkitt lymphomas contain DNA from the Epstein-Barr virus. But in North America, less than 20% of Burkitt tumors contain the EBV genome. The role of other viruses (eg, human herpesviruses 6 and 8), disturbances in host immunologic defenses, chronic immunostimulation, and specific chromosomal rearrangements as potential triggers in the development of NHL is under investigation.

Unlike adult NHL, virtually all childhood NHLs are rapidly proliferating, high-grade, diffuse malignancies. These tumors exhibit aggressive behavior but are usually very responsive to treatment. Nearly all pediatric NHLs are histologically classified into four main groups: lymphoblastic lymphoma (LL), small noncleaved cell lymphoma (Burkitt lymphoma [BL] and Burkitt-like lymphoma [BLL]), large B-cell lymphoma (LBCL), and anaplastic large cell lymphoma (ALCL). Immunophenotyping and cytogenetic features, in addition to clinical presentation, are increasingly important in the classification, pathogenesis, and treatment of NHLs. Comparisons of pediatric NHLs are summarized in Table 29–5.

Table 29-5. Comparison of pediatric non-Hodgkin lymphomas.

	Lymphoblastic Lymphoma	Small Noncleaved Cell Lymphoma (BL and BLL)	Large B-Cell Lymphoma	Anaplastic Large Cell Lymphoma
Incidence (%)	30-40	35-50	10-15	10-15
Histopathologic features	Indistinguishable from ALL lymphoblasts	Large nucleus with prominent nucleoli surrounded by very basophilic cytoplasm that contains lipid vacuoles	Large cells with cleaved or noncleaved nuclei	Large pleomorphic cells
Immunophenotype	Immature T cell	B cell	B cell	T cell or null cell
Cytogenetic markers	Translocations involving chromosome 14q11 and chromosome 7; interstitial deletions of chromosome 1	t(8;14), t(8;22), t(2;8)	Many	t(2;5)
Clinical presentation	Intrathoracic tumor, mediastinal mass (50-70%), lymphadenopathy above diaphragm (50-80%)	Intra-abdominal tumor (90%), jaw involvement (10-20% sporadic BL, 70% endemic BL), bone marrow involvement	Abdominal tumor most common; unusual sites: lung, face, brain, bone, testes, muscle	Lymphadenopathy, fever, weight loss, night sweats, extranodal sites including viscera and skin
Treatment	Similar to ALL therapy; 24 mos duration	Intensive administration of alkylating agents and methotrexate; CNS prophylaxis; 3-9 mo duration	Similar to therapy for BL/BLL	Similar to therapy for lymphoblastic lymphoma or BL/BLL

ALL, acute lymphoblastic leukemia; BL, Burkitt lymphoma; BLL, Burkitt-like lymphoma.

► Clinical Findings

A. Symptoms and Signs

Childhood NHLs can arise in any site of lymphoid tissue, including lymph nodes, thymus, liver, and spleen. Common extralymphatic sites include bone, bone marrow, CNS, skin, and testes. Signs and symptoms at presentation are determined by the location of lesions and the degree of dissemination. Because NHL usually progresses very rapidly, the duration of symptoms is quite brief, from days to a few weeks. Nevertheless, children present with a limited number of syndromes, most of which correlate with cell type.

Children with LL often present with symptoms of airway compression (cough, dyspnea, orthopnea) or superior vena cava obstruction (facial edema, chemosis, plethora, venous engorgement), which are a result of mediastinal disease. *These symptoms are a true emergency necessitating rapid diagnosis and treatment.* Pleural or pericardial effusions may further compromise the patient's respiratory and cardiovascular status. CNS and bone marrow involvement are not common at diagnosis. When bone marrow contains more than 25% lymphoblasts, patients are diagnosed with ALL.

Most patients with BL and BLL present with abdominal disease. Abdominal pain, distention, a right lower quadrant mass, or intussusception in a child older than age 5 years suggests the diagnosis of BL. Bone marrow involvement is common (~65% of patients). BL is the most rapidly prolifer-

ating tumor known and has a high rate of spontaneous cell death as it outgrows its blood supply. Consequently, children presenting with massive abdominal disease frequently have tumor lysis syndrome (hyperuricemia, hyperphosphatemia, and hyperkalemia). These abnormalities can be aggravated by tumor infiltration of the kidney or urinary obstruction by tumor. Although similar histologically, numerous differences exist between cases of BL occurring in endemic areas of equatorial Africa and the sporadic cases of North America (Table 29-6).

Table 29-6. Comparison of endemic and sporadic Burkitt lymphoma.

	Endemic	Sporadic
Incidence	10 per 100,000	0.9 per 100,000
Cytogenetics	Chromosome 8 breakpoint upstream of <i>c-myc</i> locus	Chromosome 8 breakpoint within <i>c-myc</i> locus
EBV association	≥ 95%	≤ 20%
Disease sites at presentation	Jaw (58%), abdomen (58%), CNS (19%), orbit (11%), marrow (7%)	Jaw (7%), abdomen (91%), CNS (14%), orbit (1%), marrow (20%)

CNS, central nervous system; EBV, Epstein-Barr virus.

Large cell lymphomas are similar clinically to the small noncleaved cell lymphomas, although unusual sites of involvement are quite common, particularly with ALCL. Skin lesions, focal neurologic deficits, and pleural or peritoneal effusions without an obvious associated mass are frequently seen.

B. Diagnostic Evaluation

Diagnosis is made by biopsy of involved tissue with histology, immunophenotyping, and cytogenetic studies. If mediastinal disease is present, general anesthesia must be avoided if the airway or vena cava is compromised by tumor. In these cases samples of pleural or ascitic fluid, bone marrow, or peripheral nodes obtained under local anesthesia may confirm the diagnosis. Major abdominal surgery and intestinal resection should be avoided in patients with an abdominal mass that is likely to be BL, as the tumor will regress rapidly with the initiation of chemotherapy. The rapid growth of these tumors and the associated life-threatening complications demand that further studies be done expeditiously so that specific therapy is not delayed.

After a thorough physical examination, a CBC, liver function tests, and a biochemical profile (electrolytes, calcium, phosphorus, uric acid, renal function) should be obtained. An elevated LDH reflects tumor burden and can serve as a marker of disease activity. Imaging studies should include a chest radiograph and chest CT scan, an abdominal ultrasound or CT scan, and possibly a gallium or positron emission tomography scan. Bone marrow and CSF examinations are also essential.

► Treatment

A. Supportive Care

The management of life-threatening problems at presentation is critical. The most common complications are superior mediastinal syndrome and acute tumor lysis syndrome. Patients with airway compromise require prompt initiation of specific therapy. Because of the risk of general anesthesia in these patients, it is occasionally necessary to initiate corticosteroids or low-dose emergency radiation therapy until the mass is small enough for a biopsy to be undertaken safely. Response to steroids and radiation therapy is usually prompt (12–24 hours).

Tumor lysis syndrome should be anticipated in all patients who have NHL with a large tumor burden. Maintaining a brisk urine output (> 5 mL/kg/h) with intravenous fluids and diuretics is the key to management. Allopurinol will reduce serum uric acid, and alkalization of urine will increase its solubility. Rasburicase is an effective intravenous alternative to allopurinol. Because phosphate precipitates in alkaline urine, alkali administration should be discontinued if hyperphosphatemia occurs. Renal dialysis is occasionally necessary to control metabolic abnormalities. Every attempt should be made to correct or minimize metabolic abnormalities before initiating chemotherapy;

however, this period of stabilization should not exceed 24–48 hours.

B. Specific Therapy

Systemic chemotherapy is the mainstay of therapy for NHLs. Nearly all patients with NHL require intensive intrathecal chemotherapy for CNS prophylaxis. Surgical resection is not indicated unless the entire tumor can be resected safely, which is rare. Partial resection or debulking surgery has no role. Radiation therapy does not improve outcome, so its use is confined to exceptional circumstances.

Therapy for LL is generally based on treatment protocols designed for ALL and involves dose-intensive, multiagent chemotherapy. The duration of therapy is 2 years. Treatment of BL and BLL using alkylating agents and intermediate- to high-dose methotrexate administered intensively but for a relatively short time produce the highest cure rates. LBCL is treated similarly, whereas ALCL has been treated with both BL and LL protocols.

Monoclonal antibodies such as rituximab (anti-CD20) allow for more targeted therapy of lymphomas and have been successful in improving outcomes in adults. Studies employing this type of therapy in children are underway in those with newly diagnosed as well as relapsed or refractory B-cell NHL.

► Prognosis

A major predictor of outcome in NHL is the extent of disease at diagnosis. Ninety percent of patients with localized disease can expect long-term, disease-free survival. Patients with extensive disease on both sides of the diaphragm, CNS involvement, or bone marrow involvement in addition to a primary site have a 70–80% failure-free survival rate. Relapses occur early in NHL; patients with LL rarely have recurrences after 30 months from diagnosis, whereas patients with BL and BLL very rarely have recurrences beyond 1 year. Patients who experience relapse may have a chance for cure by autologous or allogeneic HSCT.

3. Lymphoproliferative Disorders

LPDs can be thought of as a part of a continuum with lymphomas. Whereas LPDs represent inappropriate, often polyclonal proliferations of nonmalignant lymphocytes,

lymphomas represent the development of malignant clones, sometimes arising from recognized LPDs.

A. Post-Transplantation Lymphoproliferative Disorders

Post-transplantation lymphoproliferative disorders (PTLDs) arise in patients who have received substantial immunosuppressive medications for solid organ or bone marrow transplantation. In these patients, reactivation of latent EBV infection in B cells drives a polyclonal proliferation of these cells that is fatal if not halted. Occasionally a true lymphoma develops, often bearing a chromosomal translocation.

LPDs are an increasingly common and significant complication of transplantation. The incidence of PTLT ranges from approximately 2% to 15% of transplant recipients, depending on the organ transplanted and the immunosuppressive regimen.

Treatment of these disorders is a challenge for transplant physicians and oncologists. The initial treatment is reduction in immunosuppression, which allows the patient's own immune cells to destroy the virally transformed lymphocytes. However, this is only effective in approximately half of the patients. For those patients who do not respond to reduced immune suppression, chemotherapy of various regimens may succeed. The use of anti-B-cell antibodies, such as rituximab (anti-CD20), for the treatment of PTLTs has been promising in clinical trials.

B. Spontaneous Lymphoproliferative Disease

Immunodeficiencies in which LPDs occur include Bloom syndrome, Chédiak-Higashi syndrome, ataxia-telangiectasia, Wiskott-Aldrich syndrome, X-linked lymphoproliferative syndrome, congenital T-cell immunodeficiencies, and HIV infection. Treatment depends on the circumstances, but unlike PTLT, few therapeutic options are often available. Castleman disease is an LPD occurring in pediatric patients without any apparent immunodeficiency. The autoimmune lymphoproliferative syndrome (ALPS) is characterized by widespread lymphadenopathy with hepatosplenomegaly, and autoimmune phenomena. ALPS results from mutations in the Fas ligand pathway that is critical in regulation of apoptosis.

NEUROBLASTOMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Bone pain, abdominal pain, anorexia, weight loss, fatigue, fever, irritability.
- ▶ Abdominal mass (65%), adenopathy, proptosis, periorbital ecchymosis, skull masses, subcutaneous nodules, hepatomegaly, spinal cord compression.

▶ General Considerations

Neuroblastoma arises from neural crest tissue of the sympathetic ganglia or adrenal medulla. It is composed of small, fairly uniform cells with little cytoplasm and hyperchromatic nuclei that may form rosette patterns. Pathologic diagnosis is not always easy, and neuroblastoma must be differentiated from the other “small, round, blue cell” malignancies of childhood (Ewing sarcoma, rhabdomyosarcoma, peripheral neuroectodermal tumor, and lymphoma).

Neuroblastoma accounts for 7–10% of pediatric malignancies and is the most common solid neoplasm outside the CNS. Fifty percent of neuroblastomas are diagnosed before age 2 years and 90% before age 5 years.

Neuroblastoma is a biologically diverse disease with varied clinical behavior ranging from spontaneous regression to progression through very aggressive therapy. Unfortunately, despite significant advances in our understanding of this tumor at the cellular and molecular level, the overall survival rate in advanced disease has changed little in 20 years, with 3-year event-free survival being less than 15%.

▶ Clinical Findings

A. Symptoms and Signs

Clinical manifestations vary with the primary site of malignant disease and the neuroendocrine function of the tumor. Many children present with constitutional symptoms such as fever, weight loss, and irritability. Bone pain suggests metastatic disease, which is present in 60% of children older than 1 year of age at diagnosis. Physical examination may reveal a firm, fixed, irregularly shaped mass that extends beyond the midline. The margins are often poorly defined. Although most children have an abdominal primary tumor (40% adrenal gland, 25% paraspinal ganglion), neuroblastoma can arise wherever there is sympathetic tissue. In the posterior mediastinum, the tumor is usually asymptomatic and discovered on a chest radiograph obtained for other reasons. Patients with cervical neuroblastoma present with a neck mass, which is often misdiagnosed as infection. Horner syndrome (unilateral ptosis, myosis, and anhydrosis) or heterochromia iridis (differently colored irises) may accompany cervical neuroblastoma. Paraspinal tumors can

extend through the spinal foramina, causing cord compression. Patients may present with paresis, paralysis, and bowel or bladder dysfunction.

The most common sites of metastases are bone, bone marrow, lymph nodes (regional as well as disseminated), liver, and subcutaneous tissue. Neuroblastoma has a predilection for metastasis to the skull, in particular the sphenoid bone and retrobulbar tissue. This causes periorbital ecchymosis and proptosis. Liver metastasis, particularly in the newborn, can be massive. Subcutaneous nodules are bluish in color and associated with an erythematous flush followed by blanching when compressed, probably secondary to catecholamine release.

Neuroblastoma may also be associated with unusual paraneoplastic manifestations. Perhaps the most striking example is opsoclonus-myoclonus, also called dancing eyes/dancing feet syndrome. This phenomenon is characterized by the acute onset of rapid and chaotic eye movements, myoclonic jerking of the limbs and trunk, ataxia, and behavioral disturbances. This process, which often persists after therapy is complete, is thought to be secondary to cross-reacting antineural antibodies. Intractable, chronic watery diarrhea is associated with tumor secretion of vasoactive intestinal peptides. Both of these paraneoplastic syndromes are associated with favorable outcomes.

B. Laboratory Findings

Anemia is present in 60% of children with neuroblastoma and can be due to chronic disease or marrow infiltration. Occasionally, thrombocytopenia is present, but thrombocytosis is a more common finding, even with metastatic disease in the marrow. Urinary catecholamines (vanillylmandelic acid and homovanillic acid) are elevated in at least 90% of patients at diagnosis and should be measured prior to surgery.

C. Imaging

Plain radiographs of the primary tumor may show stippled calcifications. Metastases to bone appear irregular and lytic. Periosteal reaction and pathologic fractures may also be seen. CT scanning provides more information, including the extent of the primary tumor, its effects on surrounding structures, and the presence of liver and lymph node metastases. Classically, in tumors originating from the adrenal gland, the kidney is displaced inferolaterally, which helps to differentiate neuroblastoma from Wilms tumor. MRI is useful in determining the presence of spinal cord involvement in tumors that appear to invade neural foramina.

Technetium bone scanning is obtained for the evaluation of bone metastases, because the tumor usually takes up technetium Metaiodobenzyl-guanidine (MIBG) scanning is also performed to detect metastatic disease.

D. Staging

Staging of neuroblastoma is performed according to the International Neuroblastoma Staging System (INSS) (Table

Table 29-7. International Neuroblastoma Staging System.

Stage	Description
1	Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically.
2A	Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically.
2B	Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor. Enlarged lymph nodes must be negative microscopically.
3	Unresectable unilateral tumor infiltrating across the midline, with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement. The midline is defined as the vertebral column. Tumors originating on one side and crossing the midline must infiltrate to or beyond the opposite side of the vertebral column.
4	Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, or other organs, except as defined for stage 4S.
4S	Localized primary tumor, as defined for stage 1, 2A, or 2B, with dissemination limited to skin, liver, or bone marrow, and limited to infants younger than age 1 y. Marrow involvement should be < 10% of nucleated cells.

29-7). A biopsy of the tumor is performed to determine the biologic characteristics of the tumor. In addition, bilateral bone marrow aspirates and biopsies must be performed to evaluate marrow involvement.

Tumors are classified as favorable or unfavorable based on histologic characteristics. Amplification of the *MYCN* protooncogene is a reliable marker of aggressive clinical behavior with rapid disease progression. Tumor cell DNA content is also predictive of outcome. Hyperdiploidy is a favorable finding, whereas diploid DNA content is associated with a worse outcome.

► Treatment & Prognosis

Patients are treated based on a risk stratification system adopted by the COG based on INSS stage, age, *MYCN* status, histology, and DNA index. The mainstay of therapy is surgical resection coupled with chemotherapy. The usually massive size of the tumor often makes primary resection impossible. Under these circumstances, only a biopsy is performed. Following chemotherapy, a second surgical procedure may allow for resection of the primary tumor. Radiation therapy is sometimes also necessary. Effective chemotherapeutic agents in the treatment of neuroblastoma include cyclophosphamide, doxorubicin, etoposide, cisplatin, vincristine, and topotecan. About 80% of patients achieve

complete or partial remission, although in advanced disease, remission is seldom durable.

For low-risk disease (stage 1 and 2, with good biologic features), surgical resection alone may be sufficient to affect a cure. Infants younger than 1 year with stage 4S disease may need little if any therapy, although chemotherapy may be initiated because of bulky disease causing mechanical complications. In intermediate-risk neuroblastoma (subsets of patients with stage 3 and 4 disease) the primary treatment approach is surgical combined with chemotherapy. High-risk patients (the majority with stage 3 and 4 disease) require multimodal therapy, including surgery, irradiation, chemotherapy, and autologous HSCT. The administration of *cis-retinoic acid*, a differentiating agent, can prolong disease-free survival in advanced-stage neuroblastoma when administered in the setting of minimal residual disease (MRD) after HSCT.

Cooperative clinical trials are underway in high-risk patients using ch14.18 (a monoclonal antibody specific for the predominant antigen on neuroblastoma cells) and cytokines to eradicate MRD. A phase II study is underway using fenretinide, a synthetic retinoid, and radiolabeled MIBG is also being investigated.

For children with stage 1, 2, or 4S disease, the 5-year survival rate is 70–90%. Infants younger than 460 days old have a greater than 80% likelihood of long-term survival. Children older than age 1 year with stage 3 disease have an intermediate prognosis (approximately 40–70%). Older patients with stage 4 disease have a poor prognosis (5–50% survival 5 years from diagnosis), although patients 12–18 months old with hyperdiploidy and nonamplified *MYCN* have an excellent prognosis.

WILMS TUMOR (NEPHROBLASTOMA)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Asymptomatic abdominal mass or swelling (83%).
- ▶ Fever (23%), hematuria (21%).

- ▶ Hypertension (25%), genitourinary malformations (6%), aniridia, hemihypertrophy.

General Considerations

Approximately 460 new cases of Wilms tumor occur annually in the United States, representing 5–6% of cancers in children younger than age 15 years. After neuroblastoma, this is the second most common abdominal tumor in children. The majority of Wilms tumors are of sporadic occurrence. However, in a few children, Wilms tumor occurs in the setting of associated malformations or syndromes, including aniridia, hemihypertrophy, genitourinary malformations (eg, cryptorchidism, hypospadias, gonadal dysgenesis, pseudohermaphroditism, and horseshoe kidney), Beckwith-Wiedemann syndrome, Denys-Drash syndrome, and WAGR syndrome (Wilms tumor, aniridia, ambiguous genitalia, mental retardation).

The median age at diagnosis is related both to gender and laterality, with bilateral tumors presenting at a younger age than unilateral tumors, and males being diagnosed earlier than females. Wilms tumor occurs most commonly between ages 2 and 5 years; it is unusual after age 6 years. The mean age at diagnosis is 4 years.

Clinical Findings

A. Symptoms and Signs

Most children with Wilms tumor present with increasing size of the abdomen or an asymptomatic abdominal mass incidentally discovered by a parent. The mass is usually smooth and firm, well demarcated, and rarely crosses the midline, though it can extend inferiorly into the pelvis. About 25% of patients are hypertensive at presentation. Gross hematuria is an uncommon presentation, although microscopic hematuria occurs in approximately 25% of patients.

B. Laboratory Findings

The CBC is usually normal, but some patients have anemia secondary to hemorrhage into the tumor. Blood urea nitrogen and serum creatinine are usually normal. Urinalysis may show some blood or leukocytes.

C. Imaging and Staging

Ultrasonography or CT of the abdomen should establish the presence of an intrarenal mass. It is also essential to evaluate the contralateral kidney for presence and function as well as synchronous Wilms tumor. The inferior vena cava needs to be evaluated by ultrasonography for the presence and extent of tumor propagation. The liver should be imaged for the presence of metastatic disease. A plain chest radiograph (four views) or chest CT scans (or both) should be obtained to determine whether pulmonary metastases are present.

Approximately 10% of patients will have metastatic disease at diagnosis. Of these, 80% will have pulmonary disease and 15% liver metastases. Bone and brain metastases are extremely uncommon and usually associated with different, more aggressive renal tumors, such as clear cell sarcoma or rhabdoid tumor; hence, bone scans and brain imaging are not routinely performed. The clinical stage is ultimately decided at surgery and confirmed by the pathologist.

► Treatment & Prognosis

In the United States, treatment of Wilms tumor begins with surgical exploration of the abdomen via an anterior surgical approach to allow for inspection and palpation of the contralateral kidney. The liver and lymph nodes are inspected and suspicious areas biopsied or excised. En bloc resection of tumor is performed. Every attempt is made to avoid tumor spillage at surgery as this may change staging and treatment. Because therapy is tailored to tumor stage, it is imperative that a surgeon familiar with the staging requirements perform the operation.

In addition to the staging, the histologic type has implications for therapy and prognosis. Favorable histology (FH; see later discussion) refers to the classic triphasic Wilms tumor and its variants. Unfavorable histology (UH) refers to the presence of diffuse anaplasia (extreme nuclear atypia) and is present in 5% of Wilms tumors. Only a few small foci of anaplasia in a Wilms tumor give a worse prognosis to patients with stage II, III, or IV tumors. Loss of heterozygosity of chromosomes 1p and 16q are adverse prognostic factors in those with favorable histology. Following excision and pathologic examination, the patient is assigned a stage that defines further therapy.

Improvement in the treatment of Wilms tumor has resulted in an overall cure rate of approximately 90%. The National Wilms Tumor Study Group's fourth study (NWT-4) demonstrated that survival rates were improved by intensifying therapy during the initial treatment phase while shortening overall treatment duration (24 weeks vs 60 weeks of treatment).

Table 29–8 provides an overview of the current treatment recommendations in NWT-5. Patients with stage III or IV Wilms tumor require radiation therapy to the tumor bed and to sites of metastatic disease. Chemotherapy is optimally begun within 5 days after surgery, whereas radiation therapy should be started within 10 days. Stage V (bilateral Wilms tumor) disease dictates a different approach, consisting of possible bilateral renal biopsies followed by chemotherapy and second-look renal-sparing surgery. Radiation therapy may also be necessary.

Using these approaches, 4-year overall survival rates through NWT-4 are as follows: stage I FH, 96%; stage II–IV FH, 82–92%; stage I–III UH (diffuse anaplasia), 56–70%; stage IV UH, 17%. Patients with recurrent Wilms tumor have a salvage rate of approximately 50% with surgery, radiation therapy, and chemotherapy (singly or in combina-

Table 29–8. Treatment of Wilms tumor.

Stage/Histologic Subtype	Treatment
I–II FH and I UH	18 weeks (dactinomycin and vincristine)
III–IV FH and II–IV focal anaplasia	24 weeks (dactinomycin, vincristine, and doxorubicin) with radiation
II–IV UH (diffuse anaplasia)	24 weeks (vincristine, doxorubicin, etoposide, and cyclophosphamide with radiation)

FH, favorable histology; UH, unfavorable histology.

tion). HSCT is also being explored as a way to improve the chances of survival after relapse.

Future Considerations

Although progress in the treatment of Wilms tumor has been extraordinary, important questions remain to be answered. Questions have been raised regarding the role of prenephrectomy chemotherapy in the treatment of Wilms tumor. Presurgical chemotherapy seems to decrease tumor rupture at resection but may unfavorably affect outcome by changing staging. Future studies will be directed at minimizing acute and long-term toxicities for those with low-risk disease and improving outcomes for those with high-risk and recurrent disease.

BONE TUMORS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Bone pain.
- Mass lesion noted on examination.

Primary malignant bone tumors are uncommon in childhood with only 650–700 new cases per year. Osteosarcoma accounts for 60% of cases and occurs mostly in adolescents and young adults. Ewing sarcoma is the second most common malignant tumor of bony origin and occurs in toddlers to young adults. Both tumors have a male predominance.

The cardinal signs of bone tumor are pain at the site of involvement, often following slight trauma, mass formation, and fracture through an area of cortical bone destruction.

1. Osteosarcoma

▶ General Considerations

Although osteosarcoma is the sixth most common malignancy in childhood, it ranks third among adolescents and young adults. This peak occurrence during the adolescent growth spurt suggests a causal relationship between rapid bone growth and malignant transformation. Further evidence for this relationship is found in epidemiologic data showing patients with osteosarcoma to be taller than their peers, osteosarcoma occurring most frequently at sites where the greatest increase in length and size of bone occurs, and osteosarcoma occurring at an earlier age in girls than boys, corresponding to their earlier growth spurt. The metaphyses of long tubular bones are primarily affected. The distal femur accounts for more than 40% of cases, with the proximal tibia, proximal humerus, and mid and proximal femur following in frequency.

▶ Clinical Findings

A. Symptoms and Signs

Pain over the involved area is the usual presenting symptom with or without an associated soft tissue mass. Patients generally have symptoms for several months prior to diagnosis. Systemic symptoms (fever, weight loss) are rare. Laboratory evaluation may reveal elevated serum alkaline phosphatase or LDH levels.

B. Imaging and Staging

Radiographic findings show permeative destruction of the normal bony trabecular pattern with indistinct margins. In addition, periosteal new bone formation and lifting of the bony cortex may create a Codman triangle. A soft tissue mass plus calcifications in a radial or sunburst pattern are frequently noted. MRI is more sensitive in defining the extent of the primary tumor and in many centers has replaced CT scanning. The most common sites of metastases are the lung ($\leq 20\%$ of newly diagnosed cases) and the bone (10%). CT scan of the chest and bone scan are essential for detecting metastatic disease. Bone marrow aspirates and biopsies are not indicated.

Despite the rather characteristic radiographic appearance, a tissue sample is needed to confirm the diagnosis. Placement of the incision for biopsy is of critical importance. A misplaced incision could preclude a limb salvage procedure and necessitate amputation. The surgeon who will carry out the definitive surgical procedure should perform the biopsy. A staging system for osteosarcoma based on local tumor extent and presence or absence of distant metastasis has been proposed, but it has not been validated.

▶ Treatment & Prognosis

Historical studies showed that over 50% of patients receiving surgery alone developed pulmonary metastases within 6 months after surgery. This suggests the presence of micro-metastatic disease at diagnosis. Adjuvant chemotherapy trials showed improved disease-free survival rates of 55–85% in patients followed for 3–10 years.

Osteosarcomas are highly radioresistant lesions; for this reason, radiation therapy has no role in its primary management. Chemotherapy is often administered prior to definitive surgery (neoadjuvant chemotherapy). This permits an early attack on micrometastatic disease and may also shrink the tumor, facilitating a limb salvage procedure. Preoperative chemotherapy also makes detailed histologic evaluation of tumor response to the chemotherapy agents possible. If the histologic response is poor ($> 10\%$ viable tumor tissue), postoperative chemotherapy can be changed accordingly. Chemotherapy may be administered intra-arterially or intravenously, although the benefits of intra-arterial chemotherapy are disputed. Agents having efficacy in the treatment of osteosarcoma include doxorubicin, cisplatin, high-dose methotrexate, and ifosfamide.

Definitive cure requires en bloc surgical resection of the tumor with a margin of uninvolved tissue. Amputation and limb salvage are equally effective in achieving local control of osteosarcoma. Contraindications to limb-sparing surgery include major involvement of the neurovascular bundle by tumor; immature skeletal age, particularly for lower extremity tumors; infection in the region of the tumor; inappropriate biopsy site; and extensive muscle involvement that would result in a poor functional outcome.

Postsurgical chemotherapy is generally continued until the patient has received 1 year of treatment. Relapses are unusual beyond 3 years, but late relapses do occur. Histologic response to neoadjuvant chemotherapy is an excellent predictor of outcome. Patients with localized disease having 90% tumor necrosis have a 70–85% long-term, disease-free survival rate. Other favorable prognostic factors include distal skeletal lesions, longer duration of symptoms, age older than 20 years, female gender, and near-diploid tumor DNA index. Patients with metastatic disease at diagnosis or multifocal bone lesions do not fair well, despite advances in chemotherapy and surgical techniques.

2. Ewing Sarcoma

▶ General Considerations

Ewing sarcoma accounts for only 10% of primary malignant bone tumors; fewer than 200 new cases occur each year in the United States. It is a disease primarily of white males, almost never affects blacks, and occurs mostly in the second decade of life. Ewing sarcoma is considered a “small, round, blue cell” malignancy. The differential diagnosis includes rhabdomyosarcoma, lymphoma, and neuroblastoma. Although most commonly a tumor of bone, it may also occur in soft

tissue (extraosseous Ewing sarcoma or peripheral neuroectodermal tumor [PNET]).

► Clinical Findings

A. Symptoms and Signs

Pain at the site of the primary tumor is the most common presenting sign, with or without swelling and erythema. No specific laboratory findings are characteristic of Ewing sarcoma, but an elevated LDH may be present and is of prognostic significance.

B. Imaging and Staging

The radiographic appearance of Ewing sarcoma overlaps with osteosarcoma, although Ewing sarcoma usually involves the diaphyses of long bones. The central axial skeleton gives rise to 40% of Ewing tumors. Evaluation of a patient diagnosed as having Ewing sarcoma should include CT scan or MRI (or both) of the primary lesion to define the extent of local disease as precisely as possible. This is imperative for planning future surgical procedures or radiation therapy. Metastatic disease is present in 25% of patients at diagnosis. The lung (38%), bone (particularly the spine) (31%), and the bone marrow (11%) are the most common sites for metastasis. CT scan of the chest, bone scanning, and bilateral bone marrow aspirates and biopsies are all essential to the staging workup.

A biopsy is essential in establishing the diagnosis. Histologically, Ewing sarcoma consists of sheets of undifferentiated cells with hyperchromatic nuclei, well-defined cell borders, and scanty cytoplasm. Necrosis is common. Electron microscopy, immunocytochemistry, and cytogenetics may be necessary to confirm the diagnosis. A generous tissue biopsy specimen is often necessary for diagnosis but should not delay starting chemotherapy.

A consistent cytogenetic abnormality, t(11;22), has been identified in Ewing sarcoma and PNET and is present in 85–90% of tumors. These tumors also express the protooncogene *c-myc*, which may be helpful in differentiating Ewing sarcoma from neuroblastoma, in which *c-myc* is not expressed.

► Treatment & Prognosis

Therapy usually commences with the administration of chemotherapy after biopsy and is followed by local control measures. Depending on many factors, including the primary site of the tumor and the response to chemotherapy, local control could be achieved by surgery, radiation therapy, or a combination of these methods. Following local control, chemotherapy continues for approximately 1 year. Effective treatment for Ewing sarcoma uses combinations of dactinomycin, vincristine, doxorubicin, cyclophosphamide, etoposide, and ifosfamide. Patients with small localized primary tumors have a 50–70% long-term, disease-free survival rate. For patients with metastatic disease and large pelvic primary

tumors, survival is poor. Autologous HSCT is being investigated for the treatment of these high-risk patients.

RHABDOMYOSARCOMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Painless, progressively enlarging mass; proptosis; chronic drainage (nasal, aural, sinus, vaginal); cranial nerve palsies.
- Urinary obstruction, constipation, hematuria.

► General Considerations

Rhabdomyosarcoma is the most common soft tissue sarcoma occurring in childhood and accounts for 10% of solid tumors in childhood. The peak incidence is at ages 2–5 years; 70% of children are diagnosed before age 10 years. A second smaller peak is seen in adolescents with extremity tumors. Males are affected more commonly than females.

Rhabdomyosarcoma can occur anywhere in the body. When rhabdomyosarcoma imitates striated muscle and cross-striations are seen by light microscopy, the diagnosis is straightforward. Immunohistochemistry, electron microscopy, or chromosomal analysis is sometimes necessary to make the diagnosis. Rhabdomyosarcoma is further classified into subtypes based on pathologic features: embryonal (60–80%), of which botryoid is a variant; alveolar (about 15–20%); undifferentiated sarcoma (8%); pleomorphic, which is seen in adults (1%); and other (11%). These subtypes occur in characteristic locations and have different metastatic potentials and outcomes.

Although the pathogenesis of rhabdomyosarcoma is unknown, in rare cases a genetic predisposition has been determined. Li-Fraumeni syndrome is an inherited mutation of the *p53* tumor suppressor gene that results in a high risk

Table 29–9. Characteristics of rhabdomyosarcoma.

Primary Site	Frequency (%)	Symptoms and Signs	Predominant Pathologic Subtype
Head and neck	35		Embryonal
Orbit	9	Proptosis	
Parameningeal	16	Cranial nerve palsies; aural or sinus obstruction with or without drainage	
Other	10	Painless, progressively enlarging mass	
Genitourinary	22		Embryonal (botryoid variant in bladder and vagina)
Bladder and prostate	13	Hematuria, urinary obstruction	
Vagina and uterus	2	Pelvic mass, vaginal discharge	
Paratesticular	7	Painless mass	
Extremities	18	Adolescents, swelling of affected body part	Alveolar (50%), undifferentiated
Other	25	Mass	Alveolar, undifferentiated

of bone and soft tissue sarcomas in childhood plus breast cancer and other malignant neoplasms before age 45 years. Two characteristic chromosomal translocations [t(2;13) and t(1;13)] have been described in alveolar rhabdomyosarcoma. The t(1;13) translocation appears to be a favorable prognostic feature in patients with metastatic alveolar rhabdomyosarcoma, whereas t(2;13) is associated with poor outcomes.

► Clinical Findings

A. Symptoms and Signs

The presenting symptoms and signs of rhabdomyosarcoma result from disturbances of normal body function due to tumor growth (Table 29–9). For example, patients with orbital rhabdomyosarcoma present with proptosis, whereas patients with rhabdomyosarcoma of the bladder can present with hematuria, urinary obstruction, or a pelvic mass.

B. Imaging

A plain radiograph and a CT or MRI scan should be obtained to determine the extent of the primary tumor and to assess regional lymph nodes. A lung CT scan is obtained to rule out pulmonary metastasis, the most common site of metastatic disease at diagnosis. A skeletal survey and a bone scan are obtained to determine whether bony metastases are present. Bilateral bone marrow biopsies and aspirates are obtained to rule out bone marrow infiltration. Additional studies may be warranted in certain sites. For example, in parameningeal primary tumors, a lumbar puncture is performed to evaluate CSF for tumor cells.

► Treatment

Optimal management and treatment of rhabdomyosarcoma is complex and requires combined modality therapy. When

feasible, the tumor should be excised, but this is not always possible because of the site of origin and size of tumor. When only partial tumor resection is feasible, the operative procedure is usually limited to biopsy and sampling of lymph nodes. Debulking of unresectable tumor may improve outcomes. Chemotherapy can often convert an inoperable tumor to a resectable one. A second-look procedure to remove residual disease and confirm the clinical response to chemotherapy and radiation therapy is generally performed at about week 20 of therapy.

Radiation therapy is an effective method of local tumor control for both microscopic and gross residual disease. It is generally administered to all patients, the only exception being those with a localized tumor that has been completely resected. All patients with rhabdomyosarcoma receive chemotherapy, even when the tumor is fully resected at diagnosis. The exact regimen and duration of chemotherapy are determined by primary site, group, and tumor node metastasis classification. Vincristine, dactinomycin, and cyclophosphamide have shown the greatest efficacy in the treatment of rhabdomyosarcoma.

► Prognosis

The age of the patient, the extent of tumor at diagnosis, the primary site, the pathologic subtype, and the response to treatment all influence the long-term, disease-free survival rate from the time of diagnosis. Children with localized disease at diagnosis have a 70–75% 3-year disease-free survival rate, whereas children with metastatic disease at presentation have a worse outcome (39% 3-year disease-free survival).

Newer treatment strategies for high-risk patients include different drug combinations and dosing schedules with hematopoietic growth factor support, hyperfractionated radiation therapy, and autologous HSCT.

RETINOBLASTOMA

► General Considerations

Retinoblastoma is a neuroectodermal malignancy arising from embryonic retinal cells that accounts for 3% of malignant disease in children younger than age 15 years. It is the most common intraocular tumor in pediatric patients and causes 5% of cases of childhood blindness. In the United States, 200–300 new cases occur per year. This is a malignancy of early childhood, with 90% of the tumors diagnosed before age 5 years. Bilateral involvement occurs in 20–30% of children and typically is diagnosed at a younger age (median age 14 months) than unilateral disease (median age 23 months).

Retinoblastoma is the prototype of hereditary cancers due to a mutation in the retinoblastoma gene (*RB1*), which is located on the long arm of chromosome 13 (13q14). This gene is a tumor-suppressor gene that normally controls cellular growth. When the gene is inactivated, as in retinoblastoma, cellular growth is uncontrolled. Uncontrolled cell growth leads to tumor formation. Inactivation of both *RB1* alleles within the same cell is required for tumor formation.

Retinoblastoma is known to arise in heritable and nonheritable forms. Based on the different clinical characteristics of the two forms, Knudson proposed a “two-hit” hypothesis for retinoblastoma tumor development. He postulated that two independent events were necessary for a cell to acquire tumor potential. Mutations at the *RB1* locus can be inherited or arise spontaneously. In heritable cases, the first mutation arises during gametogenesis, either spontaneously (90%) or through transmission from a parent (10%). This mutation is present in every retinal cell and in all other somatic and germ cells. Ninety percent of persons who carry this germline mutation will develop retinoblastoma. For tumor formation, the loss of the second *RB1* allele within a cell must occur; loss of only one allele is insufficient for tumor formation. The second mutation occurs in a somatic (retinal) cell. In nonheritable cases (60%), both mutations arise in a somatic cell after gametogenesis has taken place.

► Clinical Findings

A. Symptoms and Signs

Children with retinoblastoma generally come to medical attention while the tumor is still confined to the globe.

Although present at birth, retinoblastoma is not usually detected until it has grown to a considerable size. Leukocoria (white pupillary reflex) is the most common sign (found in 60% of patients). Parents may note an unusual appearance of the eye or asymmetry of the eyes in a photograph. The differential diagnosis of leukocoria includes *Toxocara canis* granuloma, astrocytic hamartoma, retinopathy of prematurity, Coats disease, and persistent hyperplastic primary vitreous. Strabismus (in 20% of patients) is seen when the tumor involves the macula and central vision is lost. Rarely (in 7% of patients), a painful red eye with glaucoma, a hyphema, or proptosis is the initial manifestation. A single focus or multiple foci of tumor may be seen in one or both eyes at diagnosis. Bilateral involvement occurs in 20–30% of children.

B. Diagnostic Evaluation

Suspected retinoblastoma requires a detailed ophthalmologic examination under general anesthesia. An ophthalmologist makes the diagnosis of retinoblastoma by the appearance of the tumor within the eye without pathologic confirmation. A white to creamy pink mass protruding into the vitreous matter suggests the diagnosis; intraocular calcifications and vitreous seeding are virtually pathognomonic of retinoblastoma. A CT scan of the orbits detects intraocular calcification, evaluates the optic nerve for tumor infiltration, and detects extraocular extension of tumor. A single focus or multiple foci of tumor may be seen in one or both eyes at diagnosis. Metastatic disease of the marrow and meninges can be ruled out with bilateral bone marrow aspirates and biopsies plus CSF cytology.

► Treatment

Each eye is treated according to the potential for useful vision, and every attempt is made to preserve vision. The choice of therapy depends on the size, location, and number of intraocular lesions. Absolute indications for enucleation include no vision, neovascular glaucoma, inability to examine the treated eye, and inability to control tumor growth with conservative treatment. External beam irradiation has been the mainstay of therapy. A total dose of 35–45 Gy is administered. However, many centers are investigating the role of systemic chemotherapy for the treatment of retinoblastoma confined to the globe and the elimination of external beam radiotherapy is now accepted. Cryotherapy, photocoagulation, and radioactive plaques can be used for local tumor control. Patients with metastatic disease receive chemotherapy.

Children with retinoblastoma confined to the retina (whether unilateral or bilateral) have an excellent prognosis, with 5-year survival rates greater than 90%. Mortality is correlated directly with extent of optic nerve involvement, orbital extension of tumor, and massive choroid invasion. Patients who have disease in the optic nerve beyond the

lamina cribrosa have a 5-year survival rate of only 40%. Patients with meningeal or metastatic spread rarely survive, although intensive chemotherapy and autologous HSCT have produced long-term survivors.

Patients with the germline mutation (heritable form) have a significant risk of developing second primary tumors. Osteosarcomas account for 40% of such tumors. Second malignant neoplasms occur in both patients who have and those who have not received radiation therapy. The 30-year cumulative incidence for a second neoplasm is 35% in patients who received radiation therapy and 6% in those who did not receive radiation therapy. The risk continues to increase over time. Although radiation contributes to the risk, it is the presence of the retinoblastoma gene itself that is responsible for the development of nonocular tumors in these patients.

HEPATIC TUMORS (SEE ALSO CHAPTER 21)

Two thirds of liver masses found in childhood are malignant. Ninety percent of hepatic malignancies are either hepatoblastoma or hepatocellular carcinoma. Hepatoblastoma accounts for the vast majority of liver tumors in children younger than age 5 years, hepatocellular carcinoma for the majority in children aged 15–19 years. The features of these hepatic malignancies are compared in Table 29–10. Of the benign tumors, 60% are hamartomas or vascular tumors such as hemangiomas. There is mounting evidence for a strong association between prematurity and the risk of hepatoblastoma.

Children with hepatic tumors usually come to medical attention because of an enlarging abdomen. Approximately 10% of hepatoblastomas are first discovered on routine examination. Anorexia, weight loss, vomiting, and abdominal pain are associated more commonly with hepatocellular carcinoma. Serum α -fetoprotein is often elevated and is an excellent marker for response to treatment.

Imaging studies should include abdominal ultrasound, CT scan, or MRI. Malignant tumors have a diffuse hyper-echoic pattern on ultrasonography, whereas benign tumors are usually poorly echoic. Vascular lesions contain areas with varying degrees of echogenicity. Ultrasound is also useful for imaging the hepatic veins, portal veins, and inferior vena cava. CT scanning and, in particular, MRI are important for defining the extent of tumor within the liver. CT scanning of the chest and bone scan should be obtained to evaluate for metastatic spread. Because bone marrow involvement is extremely rare, bone marrow aspirates and biopsies are not indicated.

The prognosis for children with hepatic malignancies depends on the tumor type and the resectability of the

Table 29–10. Comparison of hepatoblastoma and hepatocellular carcinoma in childhood.

	Hepatoblastoma	Hepatocellular Carcinoma
Median age at presentation	1 y (0–3 y)	12 y (5–18 y)
Male-to-female ratio	1.7:1	1.4:1
Associated conditions	Hemihypertrophy, Beckwith-Wiedemann syndrome, prematurity, Gardner syndrome	Hepatitis B virus infection, hereditary tyrosinemia, biliary cirrhosis, α_1 -antitrypsin deficiency
Pathologic features	Fetal or embryonal cells; mesenchymal component (30%)	Large pleomorphic tumor cells and tumor giant cells
Solitary hepatic lesion	80%	20–50%
Unique features at diagnosis	Osteopenia (20–30%), isosexual precocity (3%)	Hemoperitoneum, polycythemia
Laboratory features		
Hyperbilirubinemia	5%	25%
Elevated AFP	> 90%	50%
Abnormal liver function tests	15–30%	> 30–50%

AFP, α -fetoprotein.

tumor. Complete resectability is essential for survival. Chemotherapy can decrease the size of most hepatoblastomas. Following biopsy of the lesion, neoadjuvant chemotherapy is administered prior to attempting complete surgical resection. Chemotherapy can often convert an inoperable tumor to a completely resectable one and can also eradicate metastatic disease. Approximately 50–60% of hepatoblastomas are fully resectable, whereas only one third of hepatocellular carcinomas can be completely removed. Even with complete resection, only one third of patients with hepatocellular carcinoma are long-term survivors. A recent CCG/Pediatric Oncology Group trial has shown cisplatin, fluorouracil, and vincristine to be as effective as but less toxic than cisplatin and doxorubicin in treating hepatoblastoma. Other drug combinations that have demonstrated benefit include carboplatin plus etoposide and doxorubicin plus ifosfamide. Radiation as well as liver transplantation is being investigated for patients whose tumors cannot be completely resected following chemotherapy.

LANGERHANS CELL HISTIOCYTOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Seborrheic skin rashes.
- ▶ Diaper rash.
- ▶ Draining ears.
- ▶ Bone pain.

▶ General Considerations

Langerhans cell histiocytosis (LCH; formerly called histiocytosis X) is a rare and poorly understood spectrum of disorders. It can occur as an isolated lesion or as widespread systemic disease involving virtually any body site. Eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease are all syndromes encompassed by this

disorder. LCH is not a true malignancy, but instead is a clonal, reactive proliferation of normal histiocytic cells, perhaps resulting from an immunoregulatory defect.

The distinctive pathologic feature is proliferation of histiocytic cells beyond what would be seen in a normal inflammatory process. Langerhans histiocytes have typical features: on light microscopy, the nuclei are deeply indented (coffee bean-shaped) and elongated, and the cytoplasm is pale, distinct, and abundant. Additional diagnostic characteristics include Birbeck granules on electron microscopy, expression of CD1 on the cell surface, and positive immunostaining for S-100 protein.

▶ Clinical Findings

Because LCH encompasses a broad spectrum of diseases, its presentation can be variable, from a single asymptomatic lesion to widely disseminated disease.

Patients with localized disease present primarily with lesions limited to bone. Occasionally found incidentally on radiographs obtained for other reasons, these lesions are well-demarcated and frequently found in the skull, clavicles, ribs, and vertebrae. These lesions can be painful. Patients can also present with localized disease of the skin, often as a diaper rash that does not resolve.

Bony lesions, fever, weight loss, otitis media, exophthalmos, and diabetes insipidus occur in a small number of children with the disease. Children with this multifocal disease, formerly called Hand-Schüller-Christian disease, commonly present with generalized symptoms and organ dysfunction.

Children with disseminated LCH (formerly called Letterer-Siwe disease) typically present before age 2 years with a seborrheic skin rash, fever, weight loss, lymphadenopathy, hepatosplenomegaly, and hematologic abnormalities.

Diagnosis is made with biopsy of the involved organ. The workup should include a CBC, liver and kidney function tests, a skeletal survey or technetium bone scan, and a urinalysis with specific gravity to rule out diabetes insipidus.

▶ Treatment & Prognosis

The outcome in LCH is extremely variable, but the process usually resolves spontaneously. Isolated lesions may need no therapy at all. Intralesional corticosteroids, curettage, and low-dose radiation therapy are useful local treatment measures for symptomatic focal lesions. Patients with localized disease have an excellent prognosis.

Multifocal disease is often treated with systemic chemotherapy. Prednisone with vinblastine or etoposide can be given repeatedly or continuously until lesions heal; the drugs can then be reduced and finally stopped. HSCT can also be used with success in refractory cases.

Multifocal disease is less predictable, but most cases resolve without sequelae. Age, degree of organ involvement, and response to therapy are the most important prognostic

factors. Infants with disseminated disease tend to do poorly, with mortality rates approaching 50%. New treatment approaches for patients who do not respond to conventional chemotherapy have been evaluated in small studies. 2-Chlorodeoxyadenosine (2-CDA) has been used with some success. Therapeutic strategies targeting the dysregulated immune response using interferon- α or etanercept (anti-tumor necrosis factor- α) have also been reported.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

Amy K. Keating, MD, Roger H. Giller, MD,
& Ralph R. Quinones, MD

INDICATIONS & RATIONALE

Hematopoietic stem cell transplantation (HSCT), often referred to as bone marrow transplantation, involves the intravenous infusion of stem cells to reestablish normal hematopoiesis following marrow ablative or subablative chemotherapy, or radiation therapy (or both). HSCT is considered standard therapy for a variety of malignancies, hematopoietic disorders (aplastic anemia, hemoglobinopathies), storage diseases, and severe immunodeficiencies. It is considered first-line therapy in illnesses such as JMML and severe combined immunodeficiency, as no other curative therapy exists, but most often it is recommended only in high-risk situations or when conventional treatment fails. For example, HSCT is used in sickle cell disease for patients with significant complications and in leukemia patients who have very high-risk cytogenetic features.

The rationale for HSCT in patients with nonmalignant disorders is that the transplanted stem cells replace the absent or defective hematopoietic or lymphoid elements. In patients with storage disorders, such as Hurler disease, HSCT provides enzyme-making donor macrophages that populate host tissues.

In children with oncologic disorders, HSCT is multidimensional. Because marrow function is rescued with hematopoietic stem cells, higher doses of chemotherapy or radiation (or both) can be administered, which may overcome cancer cell resistance and achieve optimal tumor cell kill. Additionally, in patients who receive an allogeneic HSCT (stem cells from another person), the donor lymphoid cells may recognize the cancer as foreign and provide an immunologic attack on the malignancy, a concept known as the graft-versus-tumor (GVT) effect.

PREPARATION FOR HSCT

The selection of the stem cell source for transplantation is an important first step. There are a variety of stem cell sources to consider, and their utility is dependent on the disease process. HSCT sources can be divided into two main categories: autologous (ie, infusion of the patient's own hematopoietic stem cells) and allogeneic (ie, infusion of another individual's hematopoietic stem cells). Stem cells can be obtained from bone marrow, peripheral blood, or umbilical cord blood.

Autologous transplantation, often referred to as "stem cell rescue" is restricted to the treatment of selected pediatric malignancies, such as neuroblastoma, lymphoma, certain brain tumors, and Ewing sarcoma. Autologous transplantation offers the ability to deliver large doses of chemotherapy followed by hematopoietic rescue using an infusion of the patient's own stem cells. Relapse of the original disease continues to be the greatest obstacle to successful autologous transplantation, likely due to limitations in achieving systemic cancer control prior to transplant, collecting sufficient progenitor cells that are not contaminated by tumor cells, and lack of GVT effect.

The selection of a suitable donor for allogeneic transplantation is critical and remains a major challenge. The principle genes known to encode for allogeneic recognition reside within the major histocompatibility complex (MHC) located on chromosome 6. The MHC class I antigens, HLA-A, HLA-B, and HLA-C, and the class II antigens, HLA-DR and HLA-DQ, can mediate graft rejection or graft-versus-host disease (GVHD). Each child expresses one set of paternal and one set of maternal HLA antigens. Thus, the probability of one child inheriting any specific combination and matching another sibling for an allogeneic transplant is 1 in 4. Large worldwide registries for bone marrow and umbilical cord blood donors have been developed; however, finding a closely matched unrelated donor can still be difficult, especially in underrepresented minority populations.

TRANSPLANT FUNDAMENTALS

Transplantation has four major treatment phases: preparative therapy, lymphohematopoietic rescue, supportive care, and long-term follow-up. The preparative phase is designed to be both myeloablative and antineoplastic. In the allogeneic transplant recipient, the preparative treatment also provides the

necessary immunosuppression for successful donor engraftment. Preparative regimens use one or more chemotherapy drugs, often in combination with total body irradiation.

Lymphohematopoietic rescue is accomplished by the intravenous infusion of bone marrow, peripheral blood progenitor cells, or umbilical cord blood. Graft failure after allogeneic transplantation is rare in patients receiving stem cells from genotypically identical related donors but may be as high as 5–15% if the donor and patient are mismatched or unrelated. In allogeneic transplantation, marrow processing prior to infusion may include removal of contaminating RBCs for ABO incompatibility or T-cell depletion to reduce the risk of GVHD. In autologous transplantation, tumor purging or stem cell enrichment procedures can be performed for selected indications.

Supportive care in the initial months after transplantation includes transfusions, infection prophylaxis and treatment, and nutritional support. Immunosuppression for GVHD prophylaxis is necessary in allogeneic transplants. All blood products should be leukocyte-depleted to reduce the risk of CMV transmission. In addition, blood products must be irradiated to prevent GVHD from contaminating lymphocytes that remain even in leukocyte reduced blood products.

Successful engraftment usually occurs 10–28 days following transplantation. Peripheral blood stem cell transplant patients usually recover neutrophil counts earlier than patients receiving bone marrow or cord blood transplants. Platelet recovery generally occurs 6 or more weeks after HSCT. Hematopoietic growth factors such as granulocyte colony-stimulating factor may be used to hasten myeloid recovery.

INFECTIOUS COMPLICATIONS

Infections from bacteria, viruses, fungi, and protozoa account for significant morbidity and mortality in HSCT patients. Certain infections are typically seen at different time intervals after transplantation. During the early phase (0–1 month after transplant), when profound neutropenia and mucosal disruption occur, bacteria from the patient's aerodigestive tract are common culprits in bacteremia. Empiric antibiotic coverage and intravenous immune globulin decrease the risk of bacterial sepsis immediately following transplant. The presence of central venous catheters makes antibiotic coverage against gram-positive bacteria an important consideration in infection management. Reactivation of herpes simplex virus may occur in as many as 70% of seropositive patients; thus, acyclovir prophylaxis is commonly employed. Fungal infections, particularly with *Candida* and *Aspergillus*, have made antifungal prophylaxis routine.

In the intermediate post-HSCT phase (1–6 months after transplant), the patient often has reduced T-lymphocyte numbers and function and thus is susceptible to viral pathogens, including CMV from endogenous reactivation, as well as common viruses found in the general population. The heightened potential of community acquired viral patho-

gens, such as respiratory syncytial virus, adenovirus, influenza, parainfluenza, and human metapneumovirus, to result in life-threatening illness in HSCT recipients is critical to recognize. Reducing acquisition of these infections through careful handwashing and contact restriction is important until immune competence returns. If infection develops, prompt diagnosis and use of available antiviral therapies, such as inhaled ribavirin, can be lifesaving. Prophylactic administration of acyclovir or ganciclovir helps limit CMV and other herpesvirus (herpes simplex virus, varicella-zoster virus) infections. Protozoal infections such as *Pneumocystis jiroveci* pneumonia, also a risk in this intermediate phase, can be prevented by prophylaxis with trimethoprim-sulfamethoxazole, dapsone, or pentamidine.

The late phase (6–12 months after transplant), is characterized by infections from encapsulated bacteria such as *Pneumococcus* due to dysfunction of the reticuloendothelial system. Reactivation of varicella-zoster virus as shingles is also common. Patients on prolonged immunosuppressive treatment for chronic GVHD have increased and protracted risk of all types of infections.

GRAFT-VERSUS-HOST DISEASE

Despite the use of immunosuppressive agents, anti-T-cell antibodies, and T-cell depletion of the donor graft, approximately 20–70% of allogeneic HSCT patients experience some degree of acute GVHD. Factors influencing GVHD risk include the degree of HLA match, stem cell source, patient age, and donor sex. Acute GVHD occurs within the first 100 days after transplantation. The first manifestation typically is a maculopapular skin rash. Skin biopsies may be done to confirm the diagnosis. Intestinal involvement results in secretory diarrhea, and hepatic involvement leads to cholestatic jaundice. Chronic GVHD occurs after day 100 and may involve multiple organ systems. Sclerotic skin, malabsorption, weight loss, keratoconjunctivitis sicca, oral mucositis, chronic lung disease, and cholestatic jaundice are common manifestations. Treatment of GVHD consists of further use of immunosuppressive agents.

LONG-TERM COMPLICATIONS

Long-term follow-up of HSCT patients is essential. Patients are at risk for numerous complications, including pulmonary disease, cataracts, endocrine dysfunction affecting growth and fertility, cardiac dysfunction, avascular necrosis of bone, developmental delay, and secondary malignancies.

Although HSCT has many challenges, it represents an important advance in curative treatment for a variety of serious pediatric illnesses.

LATE EFFECTS OF PEDIATRIC CANCER THERAPY

Late effects of treatment by surgery, radiation, and chemotherapy have been identified in survivors of pediatric cancer. Current estimates are that 1 in every 900 adults younger than age 45 years is a pediatric cancer survivor. One recent study found that 60% of survivors of pediatric cancer diagnosed between 1970 and 1986 have at least one chronic condition. Virtually any organ system can demonstrate sequelae related to previous cancer therapy. This has necessitated the creation of specialized oncology clinics whose function it is to identify and provide treatment to these patients.

The Childhood Cancer Survivor Study, a pediatric multi-institutional collaborative project, was designed to investigate the various aspects of late effects of pediatric cancer therapy in a cohort of over 14,000 survivors of childhood cancer.

GROWTH COMPLICATIONS

Children who have received cranial irradiation are at highest risk of developing growth complications. Growth complications of cancer therapy in the pediatric survivor are generally secondary to direct damage to the pituitary gland, resulting in growth hormone deficiency. However, new evidence in children treated for ALL suggests that chemotherapy alone may result in an attenuation of linear growth without evidence of catch-up growth once therapy is discontinued. Up to 90% of patients who receive more than 30 Gy of radiation to the CNS will show evidence of growth hormone deficiency within 2 years. Approximately 50% of children receiving 24 Gy will have growth hormone problems. The effects of cranial irradiation appear to be age-related, with children younger than age 5 years at the time of therapy being particularly vulnerable. These patients usually benefit from growth hormone therapy. Currently, there is no evidence that such therapy causes a recurrence of cancer.

Spinal irradiation inhibits vertebral body growth. In 30% of treated children, standing heights may be less than the fifth percentile. Asymmetrical exposure of the spine to radiation may result in scoliosis.

Growth should be monitored closely, particularly in young survivors of childhood cancer. Follow-up studies should include height, weight, growth velocity, scoliosis examination, and, when indicated, growth hormone testing.

ENDOCRINE COMPLICATIONS

Thyroid dysfunction, manifesting as hypothyroidism, is common in children who received total body irradiation,

cranial irradiation, or local radiation therapy to the neck. Particularly at risk are children with brain tumors who received more than 3000 cGy and those who received more than 4000 cGy to the neck region. The average time to develop thyroid dysfunction is 12 months after exposure, but the range is wide. Therefore, individuals at risk should be monitored yearly for at least 7 years from the completion of therapy. Although signs and symptoms of hypothyroidism may be present, most patients will have a normal thyroxine level with an elevated thyroid-stimulating hormone level. These individuals should be given thyroid hormone replacement because persistent stimulation of the thyroid from an elevated thyroid-stimulating hormone level may predispose to thyroid nodules and carcinomas. In a recent report from the Childhood Cancer Survivor Study, thyroid cancer occurred at 18 times the expected rate for the general population in pediatric cancer survivors who received radiation to the neck region. Hyperthyroidism, although rare, also occurs in patients who have received neck irradiation.

Precocious puberty, delayed puberty, and infertility are all potential consequences of cancer therapy. Precocious puberty, more common in girls, is usually a result of cranial irradiation causing premature activation of the hypothalamic-pituitary axis. This results in premature closure of the epiphysis and decreased adult height. Luteinizing hormone analogue and growth hormone are used to halt early puberty and facilitate continued growth.

Gonadal dysfunction in males is usually the result of radiation to the testes. Patients who receive testicular irradiation as part of their therapy for ALL, abdominal irradiation for Hodgkin disease, or total body irradiation for HSCT are at highest risk. Radiation damages both the germinal epithelium (producing azoospermia) and Leydig cells (causing low testosterone levels and delayed puberty). Alkylating agents such as ifosfamide and cyclophosphamide can also interfere with male gonadal function, resulting in oligospermia or azoospermia, low testosterone levels, and abnormal follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels. Determination of testicular size, semen analysis, and measurement of testosterone, FSH, and LH levels will help identify abnormalities in patients at risk. When therapy is expected to result in gonadal dysfunction, pretherapy sperm banking should be offered to adolescent males.

Exposure of the ovaries to abdominal radiation may result in delayed puberty with a resultant increase in FSH and LH and a decrease in estrogen. Girls receiving total body irradiation as preparation for HSCT and those receiving craniospinal irradiation are at particularly high risk for delayed puberty as well as premature menopause. In patients at high risk for development of gonadal complications, a detailed menstrual history should be obtained, and LH, FSH, and estrogen levels should be monitored if indicated.

No studies to date have confirmed an increased risk of spontaneous abortions, stillbirths, premature births, congenital malformations, or genetic diseases in the offspring of

childhood cancer survivors. Women who have received abdominal irradiation may develop uterine vascular insufficiency or fibrosis of the abdominal and pelvic musculature or uterus, and their pregnancies should be considered high-risk.

CARDIOPULMONARY COMPLICATIONS

Pulmonary dysfunction generally manifests as pulmonary fibrosis. Therapy-related factors known to cause pulmonary toxicities include certain chemotherapeutic agents, such as bleomycin, the nitrosoureas, and busulfan, as well as lung or total body irradiation. Pulmonary toxicity due to chemotherapy is related to the total cumulative dose received. Pulmonary function tests in patients with therapy-induced toxicity show restrictive lung disease, with decreased carbon monoxide diffusion and small lung volumes. Individuals exposed to these risk factors should be counseled to refrain from smoking and to give proper notification of the treatment history if they should require general anesthesia.

Cardiac complications usually result from exposure to anthracyclines (daunorubicin, doxorubicin, and mitoxantrone), which destroy myocytes and lead to inadequate myocardial growth as the child ages, and eventually result in congestive heart failure. The incidence of anthracycline cardiomyopathy increases in a dose-dependent fashion. At least 5% of patients who have received a cumulative dose of more than 550 mg/m² of anthracyclines experience cardiac dysfunction. In a recent study, complications from these agents appeared 6–19 years following administration of the drugs. Pregnant women who have received anthracyclines should be followed closely for signs and symptoms of congestive heart failure, as peripartum cardiomyopathy has been reported.

Radiation therapy to the mediastinal region, which is a common component of therapy for Hodgkin disease, has been linked to an increased risk of coronary artery disease; chronic restrictive pericarditis may also occur in these patients.

Current recommendations include an exercise echocardiogram and electrocardiogram every 1–5 years, depending on the age at therapy, total cumulative dose received, and presence or absence of mediastinal irradiation. Selective monitoring with various modalities is indicated for those who were treated with anthracyclines when they were younger than age 4 years or received more than 500 mg/m² of these drugs. Measurement of serum levels of cardiac troponin-T or atrial natriuretic peptide may be useful in assessing early cardiotoxicity of anthracyclines.

RENAL COMPLICATIONS

Long-term renal side effects stem from therapy with cisplatin, alkylating agents (ifosfamide and cyclophosphamide), or pelvic irradiation. Patients who have received cisplatin may develop abnormal creatinine clearance, which may or may not be accompanied by abnormal serum creati-

nine levels, as well as persistent tubular dysfunction with hypomagnesemia. Alkylating agents can cause hemorrhagic cystitis, which may continue after chemotherapy has been terminated and has been associated with the development of bladder carcinoma. Ifosfamide can also cause Fanconi syndrome, which may result in clinical rickets if adequate phosphate replacement is not provided. Pelvic irradiation may result in abnormal bladder function with dribbling, frequency, and enuresis.

Patients seen in long-term follow-up who have received nephrotoxic agents should be monitored with urinalysis, appropriate electrolyte profiles, and blood pressure. Urine collection for creatinine clearance or renal ultrasound may be indicated in individuals with suspected renal toxicity.

NEUROPSYCHOLOGICAL COMPLICATIONS

Pediatric cancer survivors who have received cranial irradiation for ALL or brain tumors appear to be at greatest risk for neuropsychological sequelae. The severity of cranial irradiation effects varies among individual patients and depends on the dose and dose schedule, the size and location of the radiation field, the amount of time elapsed after treatment, the child's age at therapy, and the child's gender. Girls may be more susceptible than boys to CNS toxicity because of more rapid brain growth and development during childhood.

The main effects of CNS irradiation appear to be related to attention capacities, ability with nonverbal tasks and mathematics, and short-term memory. Recent studies support the association between treatment with high-dose systemic methotrexate, triple intrathecal chemotherapy, and, more recently, dexamethasone and more significant cognitive impairment.

Additionally, pediatric cancer patients have been reported as having more behavior problems and as being less socially competent than a sibling control group. Adolescent survivors of cancer demonstrate an increased sense of physical fragility and vulnerability manifested as hypochondriasis or phobic behaviors.

Finally, childhood cancer survivors are more likely to report symptoms of depression and somatic distress in adulthood. Pediatric cancer survivors may require ongoing counseling or other psychological interventions once they have completed therapy.

SECOND MALIGNANCIES

Approximately 3–12% of children receiving cancer treatment will develop a new cancer within 20 years of their first diagnosis. This is a tenfold increased incidence when compared with age-matched control subjects. Particular risk factors include exposure to alkylating agents, epipodophylotoxins (VP-16), and radiation therapy, primary diagnosis of retinoblastoma or Hodgkin disease, or the presence of an inherited genetic susceptibility syndrome (Li-Fraumeni syn-

drome or NF). In a recent report, the cumulative estimated incidence of second malignant neoplasms for the cohort of the Childhood Cancer Survivor Study was 3.2% at 20 years from diagnosis.

Second hematopoietic malignancies (acute myelogenous leukemia) occur as a result of therapy with epipodophylotoxins or alkylating agents. It is unclear whether the schedule of drug administration and the total dose are related to the development of this secondary leukemia.

Children receiving radiation therapy are at risk for developing second malignancies, such as sarcomas, carcinomas, or brain tumors, in the field of radiation. A recent report examining the incidence of second neoplasms in a cohort of pediatric Hodgkin disease patients showed the cumulative risk of a second neoplasm to be as high as 8% at 15 years from diagnosis. The most common solid tumor was breast cancer (the majority located within the radiation field) followed by thyroid cancer. Girls aged 10–16 years when they received radiation therapy were at highest risk and had an actuarial incidence that approached 35% by age 40 years.

Pain Management & Palliative Care

Brian S. Greffe, MD
Jeffrey L. Galinkin, MD
Nancy A. King, MSN, RN, CPNP

30

Children experience pain to at least the same level as adults. Multiple studies have shown that neonates and infants perceive pain and remember these painful experiences. Frequently, opioid and nonopioid analgesics are underprescribed and underdosed in children owing to excessive concerns about respiratory depression or incomplete understanding of the need for pain medications in children, or both. Few data are available to guide the dosing of many pain medications, and the majority of pain medications available on the market today are unlabeled for use in pediatric patients.

Taddio A, Katz J: The effects of early pain experience in neonates on pain responses in infancy and childhood. *Paediatr Drugs* 2005;7:245 [PMID: 16118561].

PAIN MANAGEMENT

PAIN ASSESSMENT

Pain Scales

Standardizing pain measurements requires the use of appropriate pain scales. At most institutions, pain scales are stratified by age (Table 30–1) and are used throughout the institution from operating room to medical floor to clinic, creating a common language around a patient’s pain. Pain assessment using such scales has become the “fifth vital sign” in hospital settings and is documented at least as frequently as heart rate and blood pressure at many pediatric centers around the world. Many pain scales are available (see Figures 30–1 and 30–2, and Table 30–2, for examples). The type of scale used is less important than its use on a consistent basis.

Special Populations

Noncommunicative patients such as neonates and the cognitively impaired are often difficult to assess for pain. In these patient populations, use of an appropriate assessment tool

(see Table 30–1) on a frequent basis is essential to assure adequate pain control. An increasing pain score trend is often a sign of discomfort.

ACUTE PAIN

▶ General Considerations

Acute pain is caused by an identifiable source. In most cases it is self-limiting, and treatment is a reflection of severity and type of injury. In children the majority of acute pain is caused by trauma or, if in a hospital setting, an iatrogenic source such as surgery.

▶ Treatment

Treatment of acute pain depends on the disposition of the individual patient. For outpatient care the mainstay of treatment is nonsteroidal anti-inflammatory drugs (NSAIDs; Table 30–3). Acetaminophen is the most commonly used NSAID. Acetaminophen is administered via oral or rectal routes but is more predictable in its effects as an oral dose. Round-the-clock administration has been proved to be more effective than as-needed (PRN) dosing for minor pain or as an adjunct for major pain. The toxicity of acetaminophen is low in clinically used doses; however, liver damage or failure can occur with doses exceeding 200 mg/kg/d. Other oral analgesics available in suspension are ibuprofen and naproxen (see Table 30–3 for dosing).

When pain is more severe oral opioids can be added for short-term use (Table 30–4). Many of these drugs are formulated with an NSAID, for example, oxycodone plus acetaminophen (Percocet) and hydrocodone plus acetaminophen (Lortab). When using combination drugs, the dose of drug is based on the opioid component. Other concomitantly administered similar NSAIDs should be discontinued. The most commonly used oral opioids are oxycodone, hydrocodone, and codeine. Codeine is the least recommended because of its metabolism, which involves conversion of the

Table 30-1. Commonly used pain scales and their age-appropriate use.

Scale	Type	Description	Age Group
Numeric	Self-report	0–10 scale; 0 = no pain, 10 = worst pain you could ever imagine	Children who understand the concept of numbers, rank, and order; generally > 8 y
Bieri and Wong-Baker scales	Self-report	6 faces that range from no pain to the worst pain you can imagine (see Figures 30-1 and 30-2)	Younger children who have difficulty with numeric scale; cognitive age 3–7 y
FLACC ^a	Behavioral observer	5 categories: face, legs, activity, cry, and consolability; range of total score is 0–10; score ≥ 7 is severe pain (see Table 30-2)	Nonverbal children > 1 y
CRIBS, ^b NIPS, PIPP	Behavioral observer	Rates a set of standard criteria and gives a score	Nonverbal infant < 1 y

^aFLACC is an acronym derived from the categories assessed by the scale: face, legs, activity, cry, consolability.

^bCRIBS is an acronym for Crying Requires O₂, saturation, Increased vital signs, Expression and Sleeplessness. NIPS, Neonatal Infant Pain Scale; PIPP, Premature Infant Pain Profile.

parent drug to morphine via the cytochrome P-450 2D6 isoenzyme. Between 1% and 10% of people (Asians, 1–2%; African Americans, 1–3%; Caucasians, 5–10%) have a genetic polymorphism that makes them poor metabolizers of codeine. These patients obtain no effect from this drug. A very small percentage of patients (primarily from East Africa) are ultrarapid metabolizers. These patients convert 10–15 times the amount of parent drug to the active compound, which can result in clinical toxicity. Morphine, oxycodone, and hydrocodone are all available as suspensions, are active as administered, and are metabolized by multiple routes.

For severe pain not amenable to oral analgesics, an intravenous opioid can be titrated to effect; options for pain relief are dependent on the severity and location of pain, and the patient's age. Often the NSAID ketorolac (0.5–1.0 mg/kg) is used as an adjunct for severe pain. Side effects of ketorolac are the same as for adults: renal insufficiency, gastric irritability and prolonged bleeding times due to decreased platelet adhesiveness. Patients with bleeding concerns should not receive ketorolac.

Patient-controlled analgesia (PCA) pumps can be used in children as young as age 6 years with proper instruction and coaching (Table 30-5). Morphine and hydromorphone are the most commonly used drugs for PCA management in the

United States. Whenever PCA is used it is imperative to assess patients frequently (at least hourly) to assure adequate pain relief.

Andersson T et al: Drug-metabolizing enzymes: Evidence for clinical utility of pharmacogenomic tests. *Clin Pharmacol Ther* 2005;78:559 [PMID: 16338273].

CHRONIC PAIN

▶ General Considerations

Chronic pain is pain that persists past the usual course of an acute illness or beyond the time that is expected for an acute injury. In children this is an increasingly recognized problem; it is estimated that chronic pain may affect up to 10–15% of children in the United States. Among the conditions commonly producing chronic pain in children are headache, abdominal pain, myofascial pain, fibromyalgia, juvenile rheumatoid arthritis, complex regional pain syndrome, phantom limb pain, and pain associated with cancer. Multiple contributing factors, including psychosocial issues and family dynamics, often contribute to chronic pain in children. Associating pain with a single physical cause can lead the physician to order repeated invasive laboratory and diagnostic tests,

and to overprescribe medications. A multidimensional assessment to chronic pain is optimal and often required.

► Treatment

A multidisciplinary team approach is standard of care for treating chronic pain in children. All children evaluated for chronic pain should be seen on their initial visit by all primary members of the team to establish a management strategy. Team members should include a physician specializing in pain management, a pediatric psychologist or psychiatrist (or both), occupational and physical therapists, advanced pain nurses (APNs), and a social worker. The majority of pediatric chronic pain management programs in the United States base their approach on combined intensive

rehabilitation and intensive psychotherapy, relying minimally on invasive procedures and pharmacotherapy.

A. Tolerance, Dependence, and Addiction

Adults and children are similar in their physiologic and psychological responses to opioids. A consensus paper by the American Academy of Pain Medicine, American Pain Society, and American Society of Addiction Medicine defined important differences between normal and pathologic responses to opioids. The definitions of tolerance, dependence, and addiction are listed below.

1. Tolerance—A state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug's effects over time. Tolerance develops at different rates for different opioid effects (ie, tolerance develops to sleepiness and respiratory depression before it develops to constipation and analgesia).

2. Dependence—A state of adaptation manifested by a drug class-specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, or decreasing blood level of the drug; by administration of an antagonist; or by a combination of these actions.

Table 30-2. FLACC pain assessment tool.^a

Categories	Score 0	Score 1	Score 2
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested	Frequent to constant frown, clenched jaw, quivering chin
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking, or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid, or jerking
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint	Crying steadily, screams or sobs, frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or being talked to, distractible	Difficult to console or comfort

^aFLACC is an acronym derived from the categories assessed by the scale: face, legs, activity, cry, consolability.

Table 30-3. Suggested doses of nonopioid analgesics in children.

	Route	Dosage Guidelines	Half-life	Duration
Acetaminophen	PO	10–15 mg/kg per dose q 4–6 h Maximum dose 4000 mg/d	Neonates: 2–5 h Adolescents: 2–3 h	4 h
	PR	40 mg/kg loading dose, followed by 10–20 mg/kg per dose q 6 h	—	—
Ibuprofen	PO	4–10 mg/kg per dose q 6–8 h Maximum dose 40 mg/kg/d, not to exceed 2400 mg/d	Children 1–7 y: 1–2 h Adolescents: 2–4 h	6–8 h
Ketorolac	IV	0.5 mg/kg per dose q 6 h Maximum of 30 mg per dose; maximum course of 8 doses	Children: ~ 6 h Adolescents: ~ 5 h	4–6 h

IV, intravenous; PO, by mouth; PR, by rectum.

3. Addiction—A primary, chronic, neurobiologic disease, the development and manifestations of which are influenced by genetic, psychosocial, and environmental factors. Addiction is characterized by behaviors that include one or more of the following (the 3 Cs):

- Loss of Control over use of drug
- Craving and compulsive use of drug
- Use despite adverse Consequences

Addiction is rare when opioids are used appropriately for acute pain in inpatient and outpatient settings. It should be emphasized that tolerance and dependence are not synonymous with addiction.

Heit HA: Addiction, physical dependence, and tolerance: Precise definitions to help clinicians evaluate and treat chronic pain patients. *J Pain Palliat Care Pharmacother* 2003;17:15 [PMID: 14640337].

B. Withdrawal

1. Recognition—Withdrawal symptoms can be expected to occur for all patients after 1 week of opioid treatment. Signs of withdrawal in older children include agitation, irritability, dysphoria, tachycardia, tachypnea, nasal congestion, temperature instability, and feeding intolerance. In neonates with withdrawal (neonatal abstinence syndrome), common symptoms include neurologic excitability, gastrointestinal dysfunction, autonomic signs (increased sweating, nasal stuffiness, fever, mottling, poor weight gain), and skin excoriation caused by excessive rubbing.

2. Treatment protocol—To minimize withdrawal symptoms in patients being weaned from opioid medications, clinicians should devise a schedule for dose reduction in conjunction with the patient and family. The duration of opioid therapy must be taken into consideration. Standard protocols involve switching to an opioid that can be administered once a day (eg, methadone) and decreasing the dose by 10–25% every 1–2 days. The patient should be monitored for

signs of withdrawal over this period. If symptoms develop, consider lorazepam, 0.05–0.1 mg/kg every 6–8 hours or a clonidine patch, 0.1 mg/d (changed every fifth day).

Berens RJ et al: A prospective evaluation of opioid weaning in opioid-dependent pediatric critical care patients. *Anesth Analg* 2006;102:1045 [PMID: 16551896].

PEDIATRIC PALLIATIVE & END-OF-LIFE CARE

It has been estimated that almost 55,000 children die each year in the United States. At least half of these children die during the newborn period or within the first year of life. Many of these children, particularly those older than 1 year of age, suffer from illnesses that are clearly life-limiting. Thousands more are diagnosed with life-limiting illnesses resulting in chronic conditions that may last for many years, even decades. Children who are diagnosed with life-threatening illnesses that may be curable (eg, cancer) continue to live with the potential of a recurrence of their malignancy for many years. In all of these populations palliative and end-of-life care can play an important role during patients' illnesses.

Although commonly used interchangeably, *palliative care* and *end-of-life care* are not synonymous terms. Palliative care aims to prevent, relieve, reduce, or soothe the symptoms produced by potential life-limiting illnesses or their treatments and to maintain the patient's quality of life along the entire continuum of treatment. Provision of palliative care does not imply imminent death nor does it prohibit aggressive curative treatment modalities. Rather, it acknowledges the uncertainty and potential for suffering inherent in a potentially life-limiting condition such as cancer. Understanding how a family defines quality of life and suffering for their child is imperative and provides a framework for decision making between care providers and the family throughout treatment.

While a child is responding well to treatment, the primary focus is on achieving cure of the disease. Palliative care

Table 30-4. Suggested doses of oral and intravenous opioids in infants and children.

Drug	Route	Dosage Guidelines	Onset	Duration
Intravenous Opioids				
Fentanyl	IV intermittent	0.5-1 mcg/kg per dose (best for intermittent short-duration analgesia; titrate to effect)	1-3 min	30-60 min
Hydromorphone	IV	Children: 0.015 mg/kg per dose q 3-6 h Adolescent: 1-4 mg q 3-6 h	15 min	4-5 h
Methadone	IV	0.1 mg/kg per dose q 4 h for 2-3 doses, then q 6-12 h	10-20 min	6-8 h (22-48 h after repeated doses)
Morphine	IV intermittent	0.05- 0.1 mg/kg per dose q 2-4 h	Neonates: 7-8 h 1-3 mo: 6 h 6 mo-2.5 y: 3 h 3-19 y: 1-2 h	2-4 h
Oral Opioids				
Codeine	PO	0.5-1 mg/kg per dose q 4-6 h, maximum of 60 mg per dose	30-60 min	4-6 h
Hydrocodone (in Vicodin, Lortab elixir)	PO	Children: 0.15-0.2 mg/kg per dose q 4-6 h Adolescents: 1-2 tabs q 4-6 h (limited due to acetaminophen content; see acetaminophen recommendations in text)	10-20 min	3-6 h
Hydromorphone	PO	Children: 0.03-0.1 mg/kg per dose q 4-6 h Adolescents: 1-4 mg q 3-4 h	15-30 min	4-5 h
Methadone	PO	0.1 mg/kg per dose q 4-6 h for 2-3 doses, then q 6-12 h	30-60 min	6-8 h (22-48 h after repeated doses)
Morphine	PO-IR PO-ER	0.2-0.5 mg/kg per dose q 4-6 h 0.3-0.6 mg/kg per dose q 12 h	15-60 min 1-2 h	3-5 h 8-12 h
Oxycodone	PO	0.05-0.2 mg/kg q 4-6 h	10-15 min	3 h

ER, extended release; IR, immediate release; IV, intravenous; PO, by mouth (orally).

Based on information in Polaner DM: Acute pain management in infants and children. In Perkins RM et al (editors): *Pediatric Hospital Medicine*, 2nd ed. Lippincott Williams & Wilkins, 2008:743.

goals at this time focus on promoting quality of life in preparation for survivorship in the face of a potentially life-limiting illness. Some of these goals include helping a family come to terms with the diagnosis, addressing issues of treatment-related pain and distress, facilitating reintegration into the social realms of school and community, and promoting as much normalcy in the child's life as possible. When it becomes clear that the chances for cure are poor or present an unreasonable cost to the child's quality of life, the goals of palliative care shift. The focus is still on promoting quality of life but now in preparation for a comfortable and dignified end of life with increasingly less attention given to the treatment or cure of the disease itself.

Palliative care not only comprises support in the pain and symptom management of the disease but also addresses equally the psychosocial, emotional, and spiritual needs of patients with a potential life-limiting illness and their family.

CHILDREN WHO MAY BENEFIT FROM PALLIATIVE CARE

Four groups of conditions have been identified for which palliative care is appropriate:

1. Conditions for which curative treatment is possible but may fail, such as advanced or progressive cancer and complex and severe congenital or acquired heart disease.
2. Conditions requiring intensive long-term treatment aimed at maintaining the quality of life such as HIV/AIDS, cystic fibrosis, and muscular dystrophy.
3. Progressive conditions in which treatment is exclusively palliative after diagnosis, such as progressive metabolic disorders and certain chromosomal abnormalities.
4. Conditions involving severe, nonprogressive disability, causing extreme vulnerability to health complications, such as severe cerebral palsy and anoxic brain injury.

Table 30-5. Patient-controlled analgesia dosing recommendations.

	Morphine	Fentanyl	Hydromorphone
Solution	1 mg/mL	10 mcg/mL	0.1 mg/mL or 1 mg/mL
Initial dose	15-20 mcg/kg (maximum 1.5 mg)	0.25 mcg/kg	3-4 mcg/kg (maximum 0.3 mg)
Lockout time	8-10 min	8-10 min	8-10 min
Basal infusion	0-20 mcg/kg/h	0-1 mcg/kg/h	0-4 mcg/kg/h
Maximum starting dose	100 mcg/kg/h	1-2 mcg/kg/h	20 mcg/kg/h

PAIN MANAGEMENT IN PALLIATIVE CARE

Optimal pain management is critical when providing pediatric palliative care. (See the section on Pain Management, earlier, for definitions and guidelines for treatment.) Children who are opioid-naïve will usually respond very well to conventional dosing of narcotics. Children who have been receiving a long-term narcotic such as codeine for pain management may need a dosage at the higher end of the spectrum when switching to an opioid such as morphine. Adjunctive medications such as NSAIDs can be extremely helpful as well and may help reduce the frequency of narcotic dose escalations. However, children at the end of life may need ongoing upward dose adjustments, which at times may exceed normal dose recommendations. When given with the intent to achieve comfort in the dying child, these escalations are ethically and morally appropriate.

QUALITY-OF-LIFE ADJUNCTS & SYMPTOM MANAGEMENT

Certain nonpain symptoms and signs may develop more quickly in children at the end of life as compared with the adult population. A thorough and complete history and physical examination should be obtained. It is critical to determine how much distress the symptom causes the child and how much it interferes with the child's and family's routine. Areas of management should include pharmacologic intervention, nursing care, and psychosocial support. Symptoms that commonly occur during disease progression and at the end of life in children with a life-limiting condition are listed in Table 30-6, along with suggestions for management.

PSYCHOSOCIAL ASPECTS OF PALLIATIVE CARE

Pediatric palliative care is unique in that caregivers must be familiar with children's normal emotional and spiritual development. Working with a child at his or her level of development through the use of both oral and expressive communication allows the child to be more open with respect to hopes, dreams, and fears. A child's understanding of death depends on his or her stage of cognitive development. Children generally understand death as a changed state by age 3 years, universality by 5-6 years, and personal mortality by 8-9 years.

As end of life approaches, psychosocial support is invaluable to the child and family. Children may need someone to talk to outside of the family unit who can respond to their questions and concerns open and honestly. Parents may need guidance and support in initiating discussions with or responding to questions from their child about death and dying. Children and adolescents may have specific tasks they wish to complete before they die. Some want to have input into funeral and memorial service plans and disposition of their body. Parents often need support in making funeral arrangements, handling financial concerns, talking with siblings and other family members, and coping with their own grief.

It is important to recognize that grief is not an illness but a normal, multidimensional, unique, and dynamic process presenting as pervasive distress due to a perceived loss. Once parents have accepted the reality of the loss of the child, they must then complete the other tasks of grief, such as experiencing the pain of their loss and adjusting to an environment without their child, in order to move on with their lives. Parents who lose a child are at high risk for complicated grief reactions such as absent grief, delayed grief, and prolonged or unresolved grief. Siblings are also at risk for complicated grief and require special attention.

SPIRITUAL & CULTURAL SUPPORT

Health care decisions are often intertwined with a family's culture and belief system. Understanding the influences of a family's beliefs and culture allows the practitioner to provide sensitive, appropriate care, particularly at the end of life. Interaction with members of the family's faith and cultural communities can often be instrumental in helping both the care team and the community support of the family. Allowance for specific prayers, rituals, or other activities may help facilitate procedures and discussions.

Families who speak a foreign language are at risk for inadequate support. They may have fewer opportunities to express their concerns and fears, ask questions, and validate their understanding due to language and cultural constraints. Every effort should be made to find and utilize a qualified interpreter, particularly for any discussion that involves delivering difficult news or making critical decisions. Many times, the role of interpreter is imposed on a bilingual family member or friend who may not understand

Table 30-6. Symptom management in pediatric palliative care.

Symptom	Causes	Management
Nausea and vomiting	Chemotherapy, narcotics, metabolic imbalances	Consider diphenhydramine; hydroxyzine; 5-HT ₃ inhibitors; prokinetic agents for GI motility
Anorexia	Cancer, pain, abnormal taste, GI alterations, metabolic changes, drugs, psychological factors	Treat underlying condition; encourage exercise; arrange dietary consultation; consider appetite stimulants (dronabinol, megestrol, steroids)
Constipation and diarrhea	Narcotics, chemotherapy, malabsorption, drug-related	Laxatives (must be initiated whenever starting narcotics); loperamide for diarrhea
Dyspnea	Airway obstruction; decrease in functional lung tissue due to effusion, infection, metastases; impaired chest wall movement; anemia	Treat specific cause (eg, surgery to alleviate obstruction, red blood cell transfusion, chemotherapy or radiation therapy for metastatic disease); nonpharmacologic management (reassurance, position of comfort, improvement of air circulation using electric fan, oxygen, and relaxation therapy); pharmacologic management with opioids given IV or SQ as continuous infusion; nebulized morphine in older patients; concomitant use of anxiolytics (lorazepam, midazolam) if agitation
Terminal respiratory congestion	Airway or oral secretions at end of life, resulting in rattling, noisy, gurgling breath sounds	Repositioning; anticholinergics such as hycosine IV, SQ, or PO, or transdermal scopolamine
Pressure sores	Direct tissue damage; tissue fragility; immobility; diminished response to pain or irritation	Prevention (avoidance of trauma, pressure relief, good hygiene); treatment with local hygiene, debridement, use of appropriate wound dressings, antibiotics, analgesics
Bone pain	Bony metastases; leukemic infiltration of bone marrow	Palliative radiation; bone-seeking isotopes; bisphosphonates; chemotherapy; analgesics
Agitation	Present in conjunction with pain, dyspnea, terminal phase of illness	Benzodiazepines (midazolam); barbiturates to achieve complete sedation in terminal restlessness
Pruritus	Urticaria, postherpetic neuralgia, cholestasis, uremia, opioids	Antihistamines (cholestasis, uremia, opioids); 5-HT ₃ receptor antagonists (cholestasis, opioids)
Fatigue	Marrow infiltration by malignant cells (leukemia)	Transfusions (red blood cells, platelets) to relieve symptoms; hemostatics (eg, aminocaproic acid)

GI, gastrointestinal; 5-HT₃, 5-hydroxytryptamine 3; IV, intravenous; PO, by mouth (orally); SQ, subcutaneous.

medical terminology well enough to translate clearly or who may deliberately translate the information inaccurately in an attempt to protect the family.

ADVANCE CARE PLANNING

Advance care planning allows patients and families to make known their wishes about what to do in care of serious or life-threatening problems. Advance care planning has been described as a four-step process. First, individuals considered decision makers are identified and included in the process. Second, an assessment of the patient's and family's understanding of the illness and prognosis is made and the impending death is described in terms the child and family can understand. Third, on the basis of their understanding of the illness and prognosis, the goals of care are determined regarding current and future intervention—curative, uncertain, or primarily focused on providing comfort. Finally, shared decisions about the current and future use or abandonment of life-sustaining techniques and aggressive medi-

cal interventions are made. If a disagreement exists between parents or between parents and patient regarding these techniques or interventions, it may be prudent to involve the hospital's ethics committee to aid in resolving these issues.

Some states permit parents to sign an advanced directive that asserts their decision not to have resuscitative attempts made in the event of a cardiac or respiratory arrest outside of the hospital. When an advanced directive is in place, emergency responders are not required to provide cardiopulmonary resuscitation if called to the scene. Some school districts will respect an advanced directive on school property, many will not. If a child with an advanced directive in place wishes to attend school, a discussion between the medical team and school officials should be arranged to determine the best plan should the child have a cardiac or respiratory arrest at school.

Parents, and occasionally the child, may bring up the possibility of donating organs or body tissues after death. Although the tissues that may be donated by a child may be limited in some instances by the type of disease (eg, cancer), some parents find immense comfort in knowing their child was able to

benefit another. If the parents have not discussed donation with the physician by the time of death and donation is possible, the physician should offer the opportunity to the family.

Autopsy is another subject many physicians find difficult to approach with a family, but it is an important option to discuss. In cases of anticipated death from natural causes, autopsies are generally not mandatory; however, information obtained from an autopsy may be useful for parental peace of mind or medical research. If death at home is to be followed by an autopsy, special arrangements for transporting and receiving the body will need to be made with the mortuary or the coroner.

Immunodeficiency

Lora J. Stewart, MD
Richard B. Johnston, Jr., MD
Andrew H. Liu, MD

31

The immune deficiencies of childhood comprise numerous rare disorders that have been well characterized by a combination of clinical patterns, immunologic laboratory evidence, and often molecular identification of the mutant gene. Children with primary immunodeficiency (PID) commonly present with recurrent or severe infections, but most children with frequent minor infections (eg, otitis media or sinusitis) do not have an underlying immune disorder. Immunodeficiency should be considered when infections are severe, persistent, resistant to standard treatment, or caused by opportunistic organisms. Clinical patterns and recurring infections with certain types of microbes are indicative of specific immune deficiencies. Because delay in the diagnosis of PIDs is common, heightened diagnostic suspicion is warranted.

Host immunity can be divided into four main groups for the purpose of categorizing PIDs: antibody immunity (B lymphocytes), combined immunity (T and B lymphocytes), phagocytic immunity (neutrophil or mononuclear cells), and complement (bactericidal proteins also involved in opsonization). Understanding the role each category plays in host defense allows critical evaluation for possible immunodeficiency as the cause of recurrent infections.

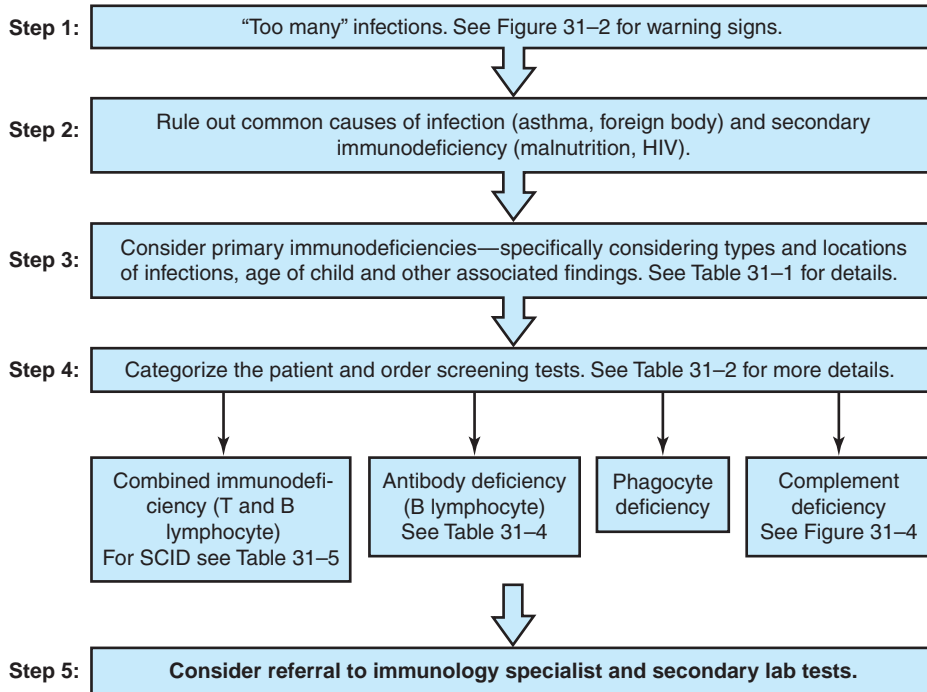

IMMUNODEFICIENCY EVALUATION: PRIMARY CONSIDERATIONS

Before evaluating for a defined primary immunodeficiency, consider conditions that increase susceptibility to infection, such as allergic rhinitis (causing sinusitis), cystic fibrosis (causing failure to thrive, pneumonia, and sinus disease), asthma (causing chronic cough and pneumonia), foreign bodies, and conditions that interfere with skin integrity. Also exclude common causes of secondary immunodeficiency such as HIV infection, malnutrition, drugs, and protein loss via gastroenteropathy or kidney disease. If a single site is involved, exclude anatomic defects and foreign bodies. Figure 31–1 outlines the approach to considering PIDs.

Key clinical patterns can indicate the likelihood of a PID, the category of immune impairment (Table 31–1), and sometimes the specific PID. The frequency and severity of infections can be helpful when considering a PID. The Modell Foundation warning signs for PID are found in Figure 31–2. Children who meet two or more of these signs should be screened for PID. Age at the onset of infections can be a helpful clue, as defects in different arms of the immune system will present at typical ages. For instance, defects of phagocytes and cellular immunity typically present during the first months of life, whereas maternal antibody protects infants with antibody deficiency for 3–6 months. The type of infections should guide initial investigation, as antibody, complement, and phagocyte defects predispose mainly to bacterial infections; but diarrhea, superficial candidiasis, opportunistic infections, and severe herpesvirus infections are more characteristic of T-lymphocyte immunodeficiency. Combined immunodeficiency syndromes will present with a combination of infections typical for B-lymphocyte and T-lymphocyte deficiencies. Table 31–1 classifies PID into four main host immunity categories based on differences in these revealing clinical parameters of age of onset, specific pathogens, affected organs, and other special features. Finally, male gender increases the likelihood of an X-linked PID, while consanguinity increases the likelihood of an autosomal recessive form of PID.

The level of laboratory investigation should be based on the clinical presentation and the suspected category of host immunity impairment. A complete blood count and quantitative immunoglobulin measurement will identify the majority of those with PID, as antibody deficiencies account for at least 50% of PIDs (Figure 31–3). Table 31–2 summarizes the approach to laboratory evaluation of PID.

▲ **Figure 31-1.** General approach to primary immunodeficiencies.

Antibodies & Immunoglobulins

Initial laboratory screening for antibody deficiency measures serum immunoglobulins (IgG, IgM and IgA, but not IgD). The normal ranges of IgG, IgM, and IgA vary by age as the production by B lymphocytes matures (see Table 31-3 for normal ranges). Some patients may have normal immunoglobulin levels but do not make protective specific antibodies; other patients have abnormal immunoglobulin levels but make protective specific antibodies. When interpreting immunoglobulin concentrations, remember that infants have lower normal values compared with adults. Evaluation of specific antibodies includes isohemagglutinins, which are naturally occurring antibodies (except in patients with blood group AB) and are detectable by age 6 months. Additional testing options include tetanus, diphtheria, *Haemophilus*, rubella, and mumps antibody levels following immunization. Assessing antibody response to pneumococcal polysaccharide can be helpful in the face of repeated pneumococcal infections, but as a screening tool it is often difficult to interpret, as the normal immune response to unconjugated polysaccharide vaccines may be weak or difficult to measure. The gold standard is preimmunization and postimmunization titers, with at least a threefold increase in titers 3 weeks postimmunization. Obtaining T- and B-lymphocyte counts is recommended if an initial screen revealed very low immunoglobulin concentrations for all classes, as certain hypogammaglobuline-

mic syndromes have low levels of or absent B lymphocytes (such as X-linked Bruton agammaglobulinemia). Protein electrophoresis can help identify the monoclonal increases seen in the oligoclonal gammopathy of Epstein-Barr virus (EBV) infections in X-linked lymphoproliferative syndrome, and in heavy-chain diseases. Serum albumin should be measured in patients with hypogammaglobulinemia to exclude secondary deficiencies due to protein loss through bowel or kidneys. IgG or IgA subclass measurements may be abnormal in patients with varied immunodeficiency syndromes, but they are rarely helpful in an initial evaluation.

Ballow M: Primary immunodeficiency disorders: Antibody deficiency. *J Allergy Clin Immunol* 2002;109:581 [PMID: 11941303].

T Lymphocytes

Initial laboratory screening for T lymphocytes includes a complete blood cell count with differential to evaluate for a decreased absolute lymphocyte count ($< 1000/\mu\text{L}$). Delayed hypersensitivity skin tests (such as *Candida*, tetanus, or mumps) give good evidence for antigen-specific T-lymphocyte immunity, but a negative or anergic result is not helpful, as it may be due to young age, chronic illness, or poor test technique. Even T-lymphocyte deficiencies will often not manifest energy until the impairment is severe (eg, AIDS). When T-lymphocyte abnormalities are

Table 31-1. Categorical clinical features of primary immunodeficiencies.

Characteristic	Combined Deficiency (T- and B-Lymphocyte Defect)	Antibody Deficiency (B-Lymphocyte Defect)	Phagocyte Defect	Complement Defect
Age at onset of infections	Early onset, usually before 6 mo	Onset after maternal antibodies decline, usually after 3-6 mo; some later childhood or adult	Early onset	Any age
Specific pathogens	Bacteria: <i>Streptococcus pneumoniae</i> , <i>Campylobacter fetus</i> , <i>Staphylococcus aureus</i> , <i>Haemophilus influenzae</i> , <i>Pseudomonas aeruginosa</i> , <i>Mycoplasma hominis</i> , <i>Ureaplasma urealyticum</i> , <i>Listeria monocytogenes</i> , <i>Salmonella typhi</i> , enteric flora, atypical mycobacteria, and BCG Viruses: CMV, EBV, varicella, RSV, enterovirus, rotavirus Fungi/protozoa: <i>Candida albicans</i> , <i>Aspergillus fumigatus</i> Opportunistic: <i>Pneumocystis carinii</i> , <i>cryptosporidium</i> , <i>Toxoplasma gondii</i>	Bacteria: <i>S pneumoniae</i> , <i>C fetus</i> , <i>H influenzae</i> , <i>P aeruginosa</i> , <i>U urealyticum</i> , <i>S aureus</i> , <i>M hominis</i> Viruses: enteroviruses Fungi/protozoa: <i>Giardia lamblia</i> Opportunistic: none	Bacteria: <i>S aureus</i> , enteric flora, <i>P aeruginosa</i> , <i>S typhi</i> , <i>Serratia</i> spp, <i>Nocardia asteroides</i> , <i>Klebsiella</i> spp, atypical mycobacteria, and BCG Viruses: none Fungi/protozoa: <i>C albicans</i> , <i>A fumigatus</i> Opportunistic: none	Bacteria: especially <i>Neisseria</i> spp, <i>S pneumoniae</i> , <i>S aureus</i> , <i>P aeruginosa</i> , <i>H influenzae</i> , <i>U urealyticum</i> Viruses: none Fungi/protozoa: none Opportunistic: none
Affected organs	General: failure to thrive Infectious: severe infection (meningitis, septicemia, sinopulmonary), recurrent candidiasis, protracted diarrhea	Infections: recurrent sinopulmonary, pneumonia, meningitis GI: chronic malabsorption and IBD-like symptoms Other: arthritis	Skin: dermatitis, impetigo, cellulitis Lymph nodes: suppurative adenitis Oral cavity: periodontitis, ulcers Lungs: pneumonia, pneumatoceles Other: abscesses, osteomyelitis	Infections: meningitis, arthritis, septicemia, recurrent sinopulmonary
Special features	GVHD: maternal T cells or blood product transfusion Postvaccination: disseminated BCG or polio Absent lymphoid tissue Absent thymic shadow on chest radiograph	Autoimmunity Lymphoreticular malignancy Postvaccination paralytic polio Chronic enteroviral encephalitis	Poor wound healing; "cold" abscesses	Autoimmune disorders: SLE, vasculitis, dermatomyositis, scleroderma, glomerulonephritis, angioedema

BCG, bacille Calmette-Guérin; CMV, cytomegalovirus; EBV, Epstein-Barr virus; GVHD, graft-versus-host disease; IBD, inflammatory bowel disease; RSV, respiratory syncytial virus; SLE, systemic lupus erythematosus.

suspected, it is important to check for specific antibody production and absolute numbers of T and B lymphocytes and their subsets (including CD3, CD4, CD8, CD19/CD20, and CD16/CD56). Because proper B-lymphocyte function and antibody production is dependent on T-lymphocyte function, most T-lymphocyte deficiencies manifest as combined impairments. Tests of T-lymphocyte proliferation and cytokine production can be supportive for characterizing immunodeficiency detected by initial

tests, but they are not useful screening tests for children with chronic illness, recurrent infections, or young age; additionally, borderline function is often interpreted based on clinical correlation.

Phagocytic Immunity

Initial laboratory screening should include an evaluation for neutropenia with a complete blood count and differen-

10 Warning Signs of Primary Immunodeficiency

Primary Immunodeficiency (PI) causes children and young adults to have infections that come back frequently or are unusually hard to cure. In America alone, up to 1/2 million people suffer from one of the 100 known primary immunodeficiency diseases. If you or someone you know are affected by two or more of the following warning signs, speak to a physician about the possible presence of an underlying primary immunodeficiency.

- | | | | |
|---|---|----|---|
| 1 | Eight or more new ear infections in one year. | 6 | Recurrent, deep skin or organ abscesses. |
| 2 | Two or more serious sinus infections within 1 year. | 7 | Persistent thrush in mouth or elsewhere on skin, after age 1. |
| 3 | Two or more months on antibiotics with little effect. | 8 | Need for intravenous antibiotics to clear infections. |
| 4 | Two or more pneumonias within 1 year. | 9 | Two or more deep-seated infections. |
| 5 | Failure of an infant to gain weight or grow normally. | 10 | A family history of primary immunodeficiency. |

▲ **Figure 31-2.** Warning signs of primary immunodeficiency. (Adapted, with permission, from the Jeffrey Modell Foundation.)

tial. A blood smear can be done to exclude Howell-Jolly bodies of asplenia and to look for normal lysosomal granules in neutrophils. The respiratory burst and generation of bactericidal factors can be tested by nitroblue tetrazolium reduction, but this test has generally been replaced by assessment of reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity using flow cytometry

(dihydrorhodamine flow cytometry assay). Leukocyte adhesion molecules are also screened by flow cytometry methods, although the difference in symptoms of suspected phagocyte defects should dictate which tests are used. Quantification of bacterial ingestion and microbicidal activity may be available.

Complement Pathways (Figure 31-4)

Deficiency of classic complement pathway components can be excluded by a normal hemolytic complement titer (CH50), for which the patient's serum must be separated and frozen to -70°C within 30 minutes of collection to prevent autodegradation of complement components. Alternative complement pathway deficiencies are similarly identified by AH50. Measuring individual complement component levels is not necessary if both CH50 and AH50 are normal. If the CH50 and AH50 are both low, the deficiency must be in their shared terminal pathway (C3, C5, C6, C7, C8, or C9). If CH50 is low, but AH50 is normal, the deficiency must be C1, C4, or C2; if AH50 is low and CH50 is normal, the deficiency must be factor D or B or properdin.

Wen L et al: Clinical and laboratory evaluation of complement deficiency. *J Allergy Clin Immunol* 2004;113:585 [PMID: 15100659].

Table 31-2. Laboratory evaluation for primary immunodeficiency.

Suspected Defect	Screening Evaluation	Secondary Evaluation	Advanced Evaluation
B-lymphocyte defect	Quantitative immunoglobulins (IgG, IgM, and IgA)	B-lymphocyte enumeration panel (CD19/20) Antibody response to prior or repeat immunizations (tetanus, diphtheria, Hib) Isohemagglutinins	Screen for specific genetic mutations Screen for memory B cells (IgM-IgD-CD27+)
Combined T- and B-lymphocyte defect	Absolute lymphocyte count HIV testing	T- and B-lymphocyte enumeration panel (T = CD3, CD4 and CD8; B = CD19/20) Lymphocyte proliferation assay to mitogens and antigens Delayed-type hypersensitivity	DNA analysis for specific genetic mutations ADA or PNP levels of RBC Cytotoxicity studies

- ▶ Inability to make specific antibody to vaccinations or infections.

General Considerations

Antibody deficiencies include both congenital and acquired forms that result in low (hypogammaglobulinemia) or very low (agammaglobulinemia) levels of immunoglobulins (IgM, IgG, and IgA). Deficiencies result in recurrent bacterial infections, specifically with encapsulated bacteria, including pneumonia, otitis, sinusitis, meningitis, cellulitis, and sepsis. As a group, antibody deficiencies represent nearly half of all pri-

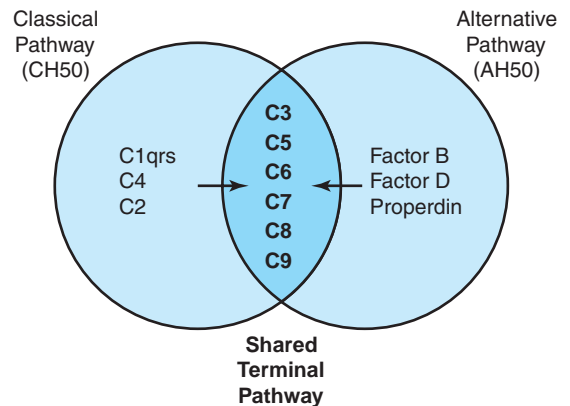

Figure 31-4. Complement proteins and laboratory test pathways.

many immunodeficiencies. Table 31–4 outlines primary antibody deficiency syndromes, laboratory findings, and genetic inheritance in these disorders. Patients who are unable to make specific antibody to vaccinations or infections are candidates for replacement gamma globulin therapy (ie, intravenous immunoglobulin [IVIG]). In contrast, those with secondary or transient hypogammaglobulinemia (ie, low total serum IgG level) who are able to make specific antibodies generally do not need or benefit from replacement IVIG.

1. X-Linked Agammaglobulinemia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Child presents with infections early, usually after age 4 months.
- ▶ Typical bacterial infections include *Haemophilus influenzae* and *Streptococcus pneumoniae*.
- ▶ Risk for severe enteroviral infections with vaccine strains of poliovirus.
- ▶ Failure to thrive and absent lymphoid tissue on examination.
- ▶ Very low levels of immunoglobulins and B lymphocytes.

▶ General Considerations

Children with X-linked agammaglobulinemia (XLA) typically present with infections after 4 months of age, when maternally derived IgG levels have declined. XLA is caused by a mutation on the X chromosome that results in low to absent circulating B lymphocytes and affects male patients. Early detection and diagnosis allow lifesaving replacement therapy with IVIG to be started prior to a potentially life-threatening infection.

▶ Clinical Findings

A. Symptoms and Signs

Infections are usually due to *H influenzae* and *S pneumoniae*, but deep tissue infections and arthritis due to *Ureaplasma* species also are seen. Antibody-deficient patients are also at risk for severe enterovirus infections with vaccine strains of poliovirus resulting in paralysis, and echoviruses causing chronic encephalitis. At presentation, male infants have scant or absent lymphoid tissue including tonsils, adenoids, and lymph nodes. A small proportion also has a history of poor growth.

B. Laboratory Findings

Most patients have low levels of or absent immunoglobulins (IgM, IgG, and IgA) and, despite a normal leukocyte count, have low numbers of or absent B lymphocytes. XLA accounts

for 85% of congenital hypogammaglobulinemia and occurs in about 1:200,000 male births. It results from mutations in the gene encoding the B lymphocyte tyrosine kinase (BTK), which is important for B-lymphocyte maturation. A BTK mutation by molecular analysis confirms the diagnosis of XLA.

▶ Differential Diagnosis

The differential diagnosis includes other causes of antibody deficiency as well as combined immunodeficiencies. Children with XLA are male and typically present at a young age with serious or recurrent bacterial infections, often with encapsulated species. Additionally, compared with other causes of antibody deficiency, XLA patients have the lowest or even absent numbers of B lymphocytes, but normal numbers of T lymphocytes. The normal T-lymphocyte number and function in XLA differ from findings in combined immunodeficiency. Additional causes of recurrent infections and low immunoglobulin levels include protein loss through renal or gastrointestinal disease, but patients with these disorders present with normal numbers of B lymphocytes and, typically, an isolated IgG deficiency.

▶ Treatment

Current therapy is with lifelong replacement IgG. In addition to preventing infections, IVIG replacement usually results in resolution of inflammatory arthritis and improves growth. Because the severity of infections varies and antibiotics are widely used, diagnosis is often delayed for years, but XLA must be considered in males with recurrent infections regardless of severity.

2. Autosomal Recessive Congenital Agammaglobulinemia

▶ General Considerations

Autosomal recessive congenital agammaglobulinemia is rare, accounting for less than 15% of all congenital hypogammaglobulinemia. It occurs in both male and female children and is caused by an abnormality in the immunoglobulin chain expressed on the surface of B lymphocytes. In the most common form, defects of the μ heavy-chain gene result in abnormal or absent IgM.

▶ Clinical Findings

A. Symptoms and Signs

Children present with recurrent infections, but the infections tend to have a very early onset, typically before age 6 months. Infections are bacterial and include pneumonia, otitis, sinusitis, meningitis, cellulitis, and sepsis.

B. Laboratory Findings

Patients usually have low numbers of circulating B lymphocytes and low levels of or absent immunoglobulins. Specific

Table 31-4. Antibody deficiency disorders.

Disease	Serum Ig	Circulating B Cells	Genetic Mutation	Mode of Inheritance
XLA	All isotypes very low or absent	< 2%	Mutations in BTK	X linked
Autosomal recessive congenital hypogammaglobulinemia				
Igα defect	All isotypes low or absent	< 2%	Defect in Igα molecule	AR
Surrogate light chain	All isotypes low or absent	< 2%	Mutations in λ5/14.1	AR
BLNK defect	All isotypes low or absent	< 2%	Mutations BLNK	?
μ Heavy chain	All isotypes low or absent	< 2%	Mutations in μ heavy chain	AR
Common variable immunodeficiency	Variable, some or all isotypes decreased	Normal or decreased	Unknown, likely not a single gene, AD form is TACI	Variable
Autosomal recessive forms of hyper-IgM syndrome	Normal or increased IgM, other isotypes decreased	IgM-bearing B cells only	Mutations in <i>AID</i> or <i>UNG</i> genes	AR
Transient hypogammaglobulinemia of infancy	IgG and IgA decreased, but IgM usually normal	Normal	Defect unknown	?
IgA deficiency	Very low or absent IgA	Normal	Defect unknown	Variable
IgG subclass deficiency	IgG subclasses decreased	Normal	Defect unknown	?

AD, autosomal dominant; AR, autosomal recessive; TACI, transmembrane activator and calcium-modulator and cyclophilin ligand interactor; XLA, X-linked agammaglobulinemia.

Adapted, with permission, from Ballou M: Primary immunodeficiency disorders: Antibody deficiency. *J Allergy Clin Immunol* 2002;109:581.

antibody function is poor. When diagnosis is suspected, detection of a mutation in the μ heavy chain can confirm the most common type. Additional mutations include mutations of the Igα molecule, the BLNK adaptor protein, and the λ5 surrogate light chain.

► **Differential Diagnosis**

The differential diagnosis is similar that of XLA, and includes XLA for male patients.

► **Treatment**

Treatment and prognosis are similar to those outlined for XLA.

3. Common Variable Immunodeficiency

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Recurrent infections, often with *Giardia lamblia* and *Campylobacter jejuni*.
- Decreased levels of IgG and IgA; poor specific antibody responses.
- Often associated with autoimmune diseases.

► **General Considerations**

Common variable immunodeficiency (CVID) is a diagnosis of exclusion after other causes of hypogammaglobulinemia have been eliminated. Onset may be at any age, and the incidence approaches 1:30,000. Many cases are sporadic, but a small percentage of patients have autosomal dominant or recessive inheritance and some cases are associated with HL-DR/DQ alleles.

► **Clinical Findings**

A. Symptoms and Signs

Patients have recurrent infections, most often of the sinopulmonary tract, but chronic gastrointestinal infections may manifest with recurrent diarrhea. Patients with CVID are at risk for developing bronchiectasis, autoimmune diseases (idiopathic thrombocytopenic purpura, autoimmune hemolytic anemia, rheumatoid arthritis, and inflammatory bowel disease), and malignancies (especially gastric carcinoma and lymphoma).

B. Laboratory Findings

Laboratory findings are variable but typically reveal low levels of IgG and IgA, normal numbers of B lymphocytes, low numbers of memory B lymphocytes (evaluated by flow cytometry), and abnormal specific antibody levels and responses. Some patients have evidence of T-lymphocyte

abnormalities as well. Chronic gastrointestinal tract infections are often due to *G lamblia* or *C jejuni*.

Although CVID is typically a diagnosis of exclusion, recent research has yielded multiple specific mutations that have previously been labeled simply as CVID. One example is a mutation in a member of the tumor necrosis factor receptor family, identified as transmembrane activator and calcium-modulator and cyclophilin ligand interactor (TACI), which mediates isotype switching in B lymphocytes. TACI mutations were recently found in 10–15% of patients with CVID, as well as in some relatives of CVID patients with IgA deficiency. The mutations appear to be autosomal dominant with variable penetrance of clinical immunodeficiency and disease.

► Differential Diagnosis

When a patient presents with recurrent infections, low immunoglobulin levels, and potentially autoimmune symptoms, many different diagnoses must be considered, including other causes of low immunoglobulin levels (loss and abnormal production) and autoimmune diseases. CVID patients have normal numbers of B lymphocytes despite their poor specific antibody responses, which differentiates them from patients with XLA and autosomal recessive agammaglobulinemia. Patients with CVID also lack the specific mutations responsible for those disorders.

► Treatment

Treatment includes lifelong replacement therapy with IgG and routine assessment for bronchiectasis, autoimmune disorders, and malignancies. Prognosis depends on time to diagnosis and implementation of IgG replacement therapy, and can be good. Other complications include B-cell hyperplasia in the gut that may be severe enough to resemble Crohn disease, and gastric atrophy with achlorhydria, sometimes followed by pernicious anemia. Lymphoreticular proliferation can occur after EBV infection and is not always malignant.

Castigli E, Geha RS: Molecular basis of common variable immunodeficiency. *J Allergy Clin Immunol* 2006;117:740 [PMID: 16630927].

Kokron CM et al: Clinical and laboratory aspects of common variable immunodeficiency. *Ann Braz Acad Sci* 2004;76:707 [PMID: 15558152].

4. Autosomal Recessive Hyper-IgM Immunodeficiency

Autosomal recessive forms of hyper-IgM immunodeficiency differ from the X-linked form (see section on Other Combined Immunodeficiency Disorders, later), as affected patients have normal expression and function of CD40 ligand.

Patients have mutations in activation-induced cytidine deaminase (AID) or uracil glycosylase (UNG). AID is required for B lymphocytes to switch from producing IgM to production of IgG, IgA, or IgE. UNG is also important for isotype class switching. The clinical presentation of AID- and UNG-deficient patients is less severe than that of X-linked hyper-IgM syndrome and also lacks opportunistic infections. Affected patients often have associated lymphoid hyperplasia compared with the paucity of lymphoid tissue seen in X-linked hyper-IgM syndrome. Treatment with IVIG replacement decreases infections and often normalizes IgM levels.

Etzioni A, Ochs HD: The hyper-IgM syndrome—an evolving story. *Pediatr Res* 2004;56:519 [PMID: 15319456].

5. Acquired Hypogammaglobulinemia

Acquired forms of hypogammaglobulinemia are common and may develop at any age. Causes of secondary hypogammaglobulinemia (nephrotic syndrome and protein-losing enteropathy) should be excluded by measuring serum albumin. Generally, acquired forms are not treated with IVIG because, although immunoglobulin levels are low, antibody function is adequately protective. Morphologic disorders or associated syndromes may point to a specific diagnosis.

Conley ME: Early defects in B cell development. *Curr Opin Allergy Clin Immunol* 2002;2:517 [PMID: 14752335].

6. Transient Hypogammaglobulinemia

Serum IgG levels normally decrease during an infant's first 4–5 months of life as maternal IgG acquired in utero is metabolized. Transient hypogammaglobulinemia represents a delay in the onset of immunoglobulin synthesis that results in a prolonged nadir. Symptomatic patients present with recurrent infections, including upper respiratory tract infections, otitis, and sinusitis. Diagnosis is suspected in infants with low levels of IgG and IgA (usually two standard deviations below normal for age), but normal levels of IgM and normal numbers of circulating B lymphocytes. Importantly, infants have normal specific antibody responses and T-lymphocyte function. Apart from appropriate antibiotics, no treatment is required. Infants with severe infection and hypogammaglobulinemia could be given IVIG replacement, but benefits and risk must be considered and this is rarely necessary. Recovery occurs between 18 and 30 months of age and the prognosis for affected infants is excellent provided infections are treated promptly and appropriately.

7. Selective Immunoglobulin Deficiencies

Selective IgA deficiency is the most common immune abnormality, found in approximately 1:700 persons. It is defined by a serum IgA level less than 7 mg/dL. Serum IgM, IgG, specific antibodies, and B- and T-lymphocyte numbers and function are normal. Most people with low serum IgA are

without symptoms, but when symptoms are present, they include upper respiratory tract infections or diarrhea (or both). Associations also exist with inflammatory bowel disease, allergic disease, asthma, and autoimmune disorders (thyroiditis, arthritis, vitiligo, thrombocytopenia, and diabetes). IgA is primarily effective in its secreted form on mucosal surfaces.

IgA replacement is currently not feasible. For the majority of symptomatic IgA-deficient patients, antibiotics and appropriate autoimmune therapies are sufficient, but some patients have been treated with IVIG replacement. Caution must be exercised, as IgA-deficient patients are at risk for developing anti-IgA antibodies with blood product exposure, and the administration of blood products can result in anaphylaxis. Therefore when blood products are needed, washed packed red blood cells and volume expanders without blood products are recommended.

The possibility that deficiency of an IgG subclass (ie, abnormally low serum IgG2, IgG3, or IgG4) might predispose to recurrent upper respiratory tract infections in patients with normal total serum immunoglobulin levels is not well established. Normally, IgG1 comprises over 60% of total IgG and IgG2 over 10%. IgG3 accounts for about 5%, and IgG4 may be undetectable in up to 20% of healthy persons. Additionally, serum levels are age-related. It has been difficult to establish a link between IgG subclass deficiencies and any consistent pattern of infections. IgG replacement should be reserved for patients with defects in specific antibody production, which is rarely seen in patients with selective IgA or IgG subclass deficiencies.

Treatment of Hypogammaglobulinemia

The mainstay of therapy for hypogammaglobulinemia is replacement IgG, but management of infections is also important. Additional treatment modalities have included the use of cytokine therapy such as interleukin (IL)-2, hormone replacement, and vitamin supplementation. Curative therapy with bone marrow transplantation (BMT) has been successful in patients with XLA. Gene therapy is not yet available outside a research setting. Replacement IgG is usually given by intravenous infusions at a dose of 400–600 mg/kg every 3–4 weeks to maintain trough serum IgG levels above 500–800 mg/dL (a higher trough level is targeted for patients with established pulmonary disease). Subcutaneous replacement is available but requires more frequent injections and may limit maximum dosing. The aim of treatment is to *prevent* future infections and minimize any progression of chronic lung disease (bronchitis or bronchiectasis). Despite the passive immunity provided by replacement IgG, infection remains a persistent risk and prognosis additionally depends on timely and appropriate antibiotics. Typical infecting organisms include encapsulated bacteria, but *Ureaplasma* and *Mycoplasma* species must also be considered. Infusions are generally well tolerated, with most reactions being mild, including headache, back and limb pain, anxiety,

and tightness of the chest. Rare systemic reactions can occur, including tachycardia, shivering, fever, and in severe cases, anaphylactoid shock. For patients with congenital hypogammaglobulinemia, replacement therapy is currently lifelong.

Durandy A et al: Immunoglobulin replacement therapy in primary antibody deficiency diseases—maximizing success. *Int Arch Allergy Immunol* 2005;136:217 [PMID: 15713984].

SEVERE COMBINED IMMUNODEFICIENCY DISEASES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Onset in first year of life.
- ▶ Recurrent infections caused by bacteria, viruses, fungi, and opportunistic pathogens.
- ▶ Chronic diarrhea and failure to thrive.
- ▶ Absent lymphoid tissue.

▶ General Considerations

Combined T- and B-lymphocyte diseases include severe combined immunodeficiency diseases (SCID) that encompass congenital diseases caused by different genetic mutations that result in severe deficiency of T and B lymphocytes. Despite differences in underlying mutations, affected patients present similarly, with recurrent infections caused by bacteria, viruses, fungi, and opportunistic pathogens. Additionally, patients often suffer from chronic diarrhea and failure to thrive. Without treatment, all patients with SCID typically die within the first years of life. SCID must be considered in the differential diagnosis in any infant with diarrhea and hypogammaglobulinemia.

▶ Clinical Findings

A. Symptoms and Signs

Common presentations include persistent cough, tachypnea or hypoxia secondary to underlying *Pneumocystis carinii* infection, or persistent oral or diaper candidiasis. Physical examination is notable for a lack of lymphoid tissue including tonsils and lymph nodes. A chest radiograph usually demonstrates an absent thymic shadow.

B. Laboratory Findings

Laboratory evaluation often reveals lymphopenia and some degree of hypogammaglobulinemia. Occasionally, an infant with SCID will present with normal numbers of lymphocytes resulting from transfusion-related engraftment or maternal T-lymphocyte engraftment via peripartum transfusion. Natural killer (NK) cells and B-lymphocyte numbers may be decreased,

normal, or elevated. Additionally, in-vitro lymphocyte assays show poor response to mitogens, and specific antibodies are absent. Antenatal diagnosis is possible. Once the diagnosis of SCID is suspected, genetic testing should be pursued to confirm the diagnosis and the mutation present for both prognostic and genetic counseling purposes. Nine genes with mutations that result in SCID have been described to date. Clinical presentation and treatment is generally similar. The variants of SCID can be organized by the presence or absence of specific lymphocytes, including T, B, and NK cells (Table 31–5).

► Differential Diagnosis

The differential diagnosis of SCID includes other causes of recurrent and severe infections and abnormal immune responses, most notably HIV disease. Other causes of hypogammaglobulinemia or agammaglobulinemia may be considered but will be ruled out due to abnormal T-lymphocyte function. The infection spectrum and severity of presentation in children with SCID is more severe and of earlier onset than that seen with CVID. Symptoms of congenital abnormalities with combined immunodeficiency features are discussed later in this chapter (see section on Genetic Syndromes Associated with Immunodeficiency).

► Treatment

When SCID is suspected, *Pneumocystis* prophylaxis with trimethoprim-sulfamethoxazole and replacement IgG therapy should be initiated. *Patients with suspected SCID should only be transfused with irradiated blood products and should not receive any live vaccines.* Confirmation of the diagnosis should

include screening for SCID subtypes listed in Table 31–5. BMT offers the best possibility of cure, with use of a human leukocyte antigen (HLA)-matched sibling offering the highest chance of success. In affected patients without HLA-identical donors, T-lymphocyte-depleted HLA haploidentical grafts or umbilical cord stem cells are used. For most patients, myeloablation is not necessary as the patient is without T lymphocytes. Additionally, most patients do not require graft-versus-host disease (GVHD) prophylaxis unless the donor is unrelated. T-lymphocyte reconstitution takes approximately 4 months, but only about 50% of patients regain full B-lymphocyte function, with the majority requiring long-term IVIG replacement. For months post-transplantation, patients are susceptible to many serious infections and prophylaxis is usually continued. Additionally, any signs or symptoms of infection must be promptly investigated and aggressively treated. The highest rate of success is in the youngest patients prior to developing infections (> 95% survival), but overall rates of survival range from 50–100% depending on the underlying mutation. Regarding gene therapy, X-linked SCID has been treated with autologous bone marrow in which normal function was transduced to lymphocytes by retroviral gene transfer. Unfortunately, two patients developed leukemia due to insertion of the retroviral vector near an oncogene. At this time, safer vectors are being sought.

–, absent; +, present; AR, autosomal recessive; IL, interleukin; NK, natural killer; XLR, X-linked recessive.

Adapted, with permission, from Kalman et al: Mutations in genes for T-cell development: *IL7R*, *CD45*, *IL2RG*, *JAK3*, *RAG1*, *RAG2*, *ARTEMIS*, and *ADA* and severe combined immunodeficiency: HuGE review. *Genet Med* 2004;6:16.

1. X-Linked Severe Combined Immunodeficiency

X-linked SCID, the most common form (40%) of SCID, results from mutations in *IL2RG* (IL-2 receptor gene) that encodes the common γ chain. The γ -chain protein is shared by multiple cell surface receptors for cytokines that are essential for T-lymphocyte maturation, including IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. Within the first 3 months of life, male infants present with diarrhea, cough, and rash. Laboratory evaluation reveals low T-lymphocyte numbers, normal numbers of B lymphocytes (which do not produce functional antibody), and absent NK cells.

2. Adenosine Deaminase Deficiency

Adenosine deaminase deficiency (ADA) is an autosomal recessive form of SCID caused by absence of adenosine deaminase, which is important for removal of toxic metabolites formed in T lymphocytes, including adenosine, 2' deoxyadenosine, and 2'O-methyladenosine. Increased levels of these metabolites result in T-lymphocyte death. Subsequently, affected patients develop complete absence of T-lymphocyte function. ADA SCID is distinguished from other variants of SCID by the following findings: the most profound lymphopenia ($< 500/\text{mm}^3$); skeletal abnormalities, including chondro-osseous dysplasia (flared costochondral junctions and bone-in-bone anomalies in vertebrae); and deficiency of all types of lymphocytes. Diagnosis is suspected in patients with profound lymphopenia and recurrent infections. The diagnosis is confirmed with a red blood cell assay for ADA activity. The genetic mutation is on chromosome 20q13.2–13.11. In addition to BMT, restoration of immune competence can occur in some patients with weekly infusions of polyethylene glycol–stabilized ADA enzyme conjugate. Gene therapy of stem cells with an ADA-incorporating retroviral vector has been successful, but the vector had oncogenic adverse effects. The development of safer vectors is yet to come.

3. Janus Kinase 3 Deficiency

Another form of autosomal recessive SCID is due to mutations in the gene encoding janus kinase 3, which is important for intracellular signaling through the common γ chain. The clinical presentation and lymphocyte phenotype most closely resembles X-linked SCID, with low T and NK lymphocytes, and elevated, nonfunctional B lymphocytes.

4. Interleukin-7-Receptor-Alpha-Chain Deficiency

IL-7-receptor-alpha-chain (IL-7R α) deficiency SCID is transmitted by autosomal recessive inheritance. The IL-7 receptor is important for T-lymphocyte maturation and mutations result in low T-lymphocyte numbers, but normal numbers of dysfunctional B lymphocytes and NK cells.

5. Recombinase-Activating Gene Deficiencies

Another form of autosomal recessive SCID is due to mutations in recombinase activating genes (*RAG1* and *RAG2*), which encode proteins critical for assembling antigen receptor genes for both T and B lymphocytes. Several mutations in these genes have been described. The clinical presentation is similar to that of other forms of SCID, but the lymphocyte phenotype differs, as patients with SCID due to *RAG1* or *RAG2* mutations lack both T and B lymphocytes, but maintain normal or elevated numbers of NK cells.

Omenn syndrome is an autosomal recessive syndrome characterized by SCID, eczematoid rash, hepatosplenomegaly, lymphadenopathy, and alopecia. The disease is caused by mutations in *RAG1*, *RAG2*, or *Artemis* (see below). Laboratory evaluation reveals absent B lymphocytes, normal to elevated T-lymphocyte numbers with restricted function, and normal functional NK cells. Additionally, affected patients often have eosinophilia and elevated levels of IgE. The syndrome is typically fatal, although BMT has been used.

Ege M et al: Omenn syndrome due to ARTEMIS mutations. *Blood* 2005;105:4179 [PMID: 15731174].

6. CD3-Delta-Chain Deficiency

CD3-delta-chain (CD3 δ) deficiency is a rare form of autosomal recessive SCID. Homozygous defects in the CD3 δ chain halt T-lymphocyte maturation. Clinical presentation and lymphocyte phenotype are similar to IL-7R α deficiency, but CD3 δ -chain deficiency differs from other forms of SCID in that these patients have a normal appearing thymic silhouette on chest radiograph.

Dadi H et al: Effect of CD3 δ deficiency on maturation of alpha/beta and gamma/delta T-cell lineages in severe combined immunodeficiency. *N Engl J Med* 2003;349:1821 [PMID: 14602880].

7. CD45 Deficiency

Another rare form of autosomal recessive SCID is due to mutations in the gene for CD45. CD45 is a tyrosine phosphatase important for regulating signal transduction. Affected patients have a similar presentation to other forms of SCID and a lymphocyte phenotype with low to absent T and NK cells, but elevated B lymphocytes.

8. Artemis Deficiency

Artemis is a DNA repair factor important for repairing cuts in the double-stranded DNA essential for the assembly of antigen receptors for T and B lymphocytes. Inheritance is autosomal recessive, and clinical presentation and lymphocyte phenotype are similar to those seen in *RAG1* and *RAG2* deficiencies.

9. ZAP-70 Deficiency

Deficiency of zeta-chain-associated protein (ZAP)-70 results in a rare form of autosomal recessive combined immunodeficiency. ZAP-70 is a tyrosine kinase critical for T-lymphocyte signaling and activation. Clinical presentation is similar to that of other forms of SCID, but most affected patients have palpable lymph nodes and visible thymic silhouette. Lymphocyte evaluation reveals absence of CD8⁺ T lymphocytes, normal but nonfunctional CD4⁺ T lymphocytes, normal numbers of poorly functioning B lymphocytes, and normal numbers and function of NK cells.

Elder M: SCID due to ZAP-70 deficiency. *Pediatr Hematol Oncol* 1997;19:546 [PMID: 9407944].

OTHER COMBINED IMMUNODEFICIENCY DISORDERS

Combined immunodeficiencies include defects that directly impair both T and B lymphocytes, as well as T-lymphocyte-specific defects, because proper B-lymphocyte function and antibody production are dependent on T-lymphocyte function. Therefore, most T-lymphocyte deficiencies manifest as combined impairments.

1. Wiskott-Aldrich Syndrome

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Immunodeficiency with recurrent infections.
- ▶ Microplatelet thrombocytopenia.
- ▶ Eczema.
- ▶ Occurs only in males.

▶ General Considerations

Wiskott-Aldrich syndrome (WAS) is an X-linked recessive disease characterized by immunodeficiency, microplatelet thrombocytopenia, and eczema. The syndrome results from mutations of the gene encoding WASP at X11p. WASP is a protein involved in the rearrangement of actin and is important in interactions between T lymphocytes and antigen-presenting cells.

▶ Clinical Findings

A. Symptoms and Signs

Common presenting symptoms include bloody diarrhea, cerebral hemorrhage, and severe infections with polysaccharide-encapsulated bacteria, but clinical presentation can vary from classic severe WAS to mild thrombocytopenia without immunodeficiency, or X-linked thrombocytopenia (XLT), depending on the mutation. Early deaths are due to bleeding and infections,

but malignancies and autoimmune syndromes can develop over time. Survival beyond adolescence is rare in patients not receiving treatment, although XLT is sometimes diagnosed in adults.

B. Laboratory Findings

Laboratory findings that suggest the diagnosis are a low platelet count, low or absent isohemagglutinins, and reduced antibody responses to polysaccharide antigens (*S pneumoniae* and *H influenzae*). IgM may be low; IgA and IgE are often high.

▶ Differential Diagnosis

In addition to WAS and XLT, the differential diagnosis in a patient with a low platelet count must include other causes of platelet consumption, destruction, and abnormal production, such as idiopathic thrombocytopenic purpura, leukemia or myelodysplasia, drug adverse effect, and infection. WAS can be differentiated from these other conditions by small-sized platelets on smear evaluation, the presence of eczema (and atopy), and documented immune dysfunction. Additionally, there is a continuum between WAS and XLT that lacks immunodeficiency. Subsequently, a scoring system has been developed to help clinicians distinguish WAS from XLT.

▶ Treatment

Treatment includes infection prophylaxis with antibiotics (including trimethoprim-sulfamethoxazole for *P carinii* pneumonia) and IgG replacement therapy for patients with deficient antibody responses. Splenectomy to reduce thrombocytopenia has been helpful in some patients with XLT but must be followed by antibiotic prophylaxis because of the increased risk of septicemia and sudden death. Platelet transfusions should be avoided unless severe bleeding has occurred. Finally, BMT using the best-matched donor offers the possibility of a definitive cure, but is associated with morbidity and mortality.

Dupuis Girod S et al: Autoimmunity in Wiskott-Aldrich syndrome: Risk factors, clinical features, and outcome in a single-center cohort of 55 patients. *Pediatrics* 2003;111:e622 [PMID: 12728121].

Ochs HD, Notarangelo LD: X-linked immunodeficiencies. *Curr Allergy Asthma Rep* 2004;4:339 [PMID: 15283872].

2. 22q11.2 Deletion Syndrome (DiGeorge Syndrome)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Congenital heart defects.
- ▶ Hypocalcemia.
- ▶ Distinctive craniofacial features.
- ▶ Thymic hypoplasia.

► General Considerations

DiGeorge syndrome or 22q11.2 deletion syndrome is an autosomal dominant syndrome resulting in defective development of the third and fourth pharyngeal pouches. There is considerable variability in phenotype based on the location and extent of microdeletion. Overlapping syndromes include velocardiofacial syndrome and Shprintzen syndrome. The incidence is about 1:4000 births, and the abnormal chromosome is usually inherited from the mother. The associated immunodeficiency is secondary to the aplastic or hypoplastic thymus, where T-lymphocyte maturation occurs. Surprisingly, most patients have no or only mild immune defects. The term *partial DiGeorge syndrome* is commonly applied to these patients with impaired rather than absent thymus function.

► Clinical Findings

A. Symptoms and Signs

Clinical characteristics include congenital heart defects, hypocalcemia due to hypoparathyroidism, distinctive craniofacial features, renal anomalies, and thymic hypoplasia. Presentation usually results from cardiac failure, or from hypocalcemia 24–48 hours postpartum. The diagnosis is sometimes made during the course of cardiac surgery when no thymus is found in the mediastinum. Additional important clinical issues include delayed speech and behavioral problems.

B. Laboratory Findings

Laboratory evaluation typically reveals normal to decreased numbers of T lymphocytes with preserved T-lymphocyte function and normal B-lymphocyte function. In the rare patient with absent or dysfunctional T lymphocytes, B-lymphocyte function and antibody production may be abnormal as well. Over time, T-lymphocyte numbers normalize in the majority of patients who have low numbers of T lymphocytes at presentation. Diagnosis is confirmed via fluorescence in situ hybridization chromosomal analysis for the microdeletion on chromosome 22.

► Treatment

Treatment of the 22q11.2 deletion syndrome may require surgery for cardiac defects, and vitamin D, calcium, or parathyroid hormone replacement to correct hypocalcemia. Transfusion products should be irradiated. Both thymic grafts and BMT have been used successfully in patients with absent T-lymphocyte immunity.

Sediva A et al: Early development of immunity in DiGeorge syndrome. *Med Sci Monit* 2005;11:CR182 [PMID: 15795698].

3. Ataxia-Telangiectasia

Ataxia-telangiectasia (A-T) is an autosomal recessive disorder characterized by progressive cerebellar ataxia (due to

degeneration of Purkinje cells), telangiectasia, and variable immunodeficiency. Ataxia develops by age 5 years, followed by the appearance of telangiectasias of the conjunctivae and exposed areas (ie, nose, ears, and shoulders). The mutated A-T protein kinase is encoded on chromosome 11 and is required for cell cycle regulation and DNA repair. The Nijmegen breakage syndrome is probably a variant of A-T with more severe clinical features, including microcephaly and birdlike facies. Abnormal findings in A-T include elevated serum α -fetoprotein levels (useful diagnostically); thymic hypoplasia and lymphopenia; immunoglobulin deficiencies, including low levels of IgA, IgE, or IgG; and defective ability to repair radiation-induced DNA fragmentation. Clinically, the most important symptom is progressive loss of motor coordination, followed by weakness. Respiratory tract infections and many types of malignancy (including carcinomas and lymphomas) are the major causes of death. There is no definitive treatment, although IVIG and aggressive antibiotics have been used with limited success. Heterozygotes may have a small increased risk for breast cancer.

Nowak-Wegrzyn A et al: Immunodeficiency and infections in ataxia-telangiectasia. *J Pediatr* 2004;144:505 [PMID: 15069401].

Perlman S et al: Ataxia-telangiectasia: Diagnosis and treatment. *Semin Pediatr Neurol* 2003;10:173 [PMID: 14653405].

4. X-Linked Hyper-IgM Syndrome

X-linked hyper-IgM or CD40 ligand deficiency is the most common form of hyper-IgM and involves a defect in CD40 ligand (CD154) on T lymphocytes. Unlike the autosomal recessive forms of hyper-IgM, the mutation results in both antibody and cell-mediated deficiencies, as the interaction between CD40L (on T cells) and CD40 (on antigen-presenting cells) is important for both antibody production and T-cell activation. Affected males have low levels of IgG and IgA, but normal or elevated levels of IgM and normal numbers of B lymphocytes. Typically, male infants present with recurrent bacterial and opportunistic infections such as *P carinii* pneumonia or *Cryptosporidium* diarrhea. Additionally, affected males have a high frequency of sclerosing cholangitis, increased liver and biliary tract carcinomas, neutropenia, and autoimmune syndromes, including thrombocytopenia, arthritis, and inflammatory bowel disease. Conservative treatment includes IVIG and antibiotic prophylaxis, but because prognosis is still quite poor, BMT has been used with preliminary success.

Etzioni A, Ochs HD: The hyper-IgM syndrome—an evolving story. *Pediatr Res* 2004;56:519 [PMID: 15319456].

Jacobsohn DA et al: Nonmyeloablative hematopoietic stem cell transplant for X-linked hyper-immunoglobulin M syndrome with cholangiopathy. *Pediatrics* 2004;113:e122 [PMID: 14754981].

5. Immunodeficiency Due to Mutations of Nuclear Factor- κ B–Essential Modulator

Immunodeficiency due to mutations in the gene for nuclear factor- κ B–essential modulator (NEMO) is an X-linked syndrome in which male patients manifest ectodermal dysplasia (abnormal teeth, fine sparse hair, and abnormal or absent sweat glands) and defects of T- and B-lymphocytes. Many mutations are fatal in utero for male infants. Female carriers may have incontinentia pigmenti. The mutation results in abnormal immunoreceptor signaling. Surviving males present with early serious infections, including opportunistic infections such as *Pneumocystis* and atypical mycobacteria. Laboratory evaluation reveals hypogammaglobulinemia and poor specific antibody production, but normal numbers of T and B lymphocytes. Functional evaluation of lymphocytes demonstrates variable response. Because patients with confirmed NEMO mutations are quite rare, the best treatment course is unknown, but aggressive antibiotic therapy in combination with IVIG as well as BMT has been used. Prognosis is dependent on the severity of immunodeficiency, with most deaths due to infection.

Orange JS et al: The presentation and natural history of immunodeficiency caused by nuclear factor kappaB essential modulator mutation. *J Allergy Clin Immunol* 2004;113:725 [PMID: 15100680].

6. Combined Immunodeficiency with Defective Expression of Major Histocompatibility Complex Types I & II

Major histocompatibility complex class I (MHC I) deficiency or bare lymphocyte syndrome type I is an autosomal recessive combined immunodeficiency. Affected patients have abnormal TAP proteins important for intracellular transport and expression of MHC I on cell surfaces. Patients with bare lymphocyte syndrome type I present with recurrent sinopulmonary and skin infections. The diagnosis is confirmed by demonstrating an absence of MHC I expression.

Major histocompatibility complex class II (MHC II) deficiency or bare lymphocyte syndrome type II is a rare autosomal recessive combined immunodeficiency in which cells lack MHC II expression. Clinical presentation includes recurrent viral, bacterial, and fungal infections. Patients with bare lymphocyte syndrome type II have normal numbers of T and B lymphocytes, but low CD4⁺ lymphocyte numbers, abnormal lymphocyte function, and hypogammaglobulinemia. They also have a high incidence of sclerosing cholangitis. When this diagnosis is suspected, demonstration of absent MHC class II molecules confirms the disorder. Severe cases are fatal without BMT, but milder phenotypes may be managed with IVIG replacement and aggressive use of antibiotics.

Nekrep N et al: When the lymphocyte loses its clothes. *Immunity* 2003;18:453 [PMID: 12705848].

7. Diseases Due to Defective Interferon Gamma & Interleukin-12 Pathways

The interferon- γ and IL-12 pathways are critical for macrophage, T-lymphocyte, and NK cell immunity toward mycobacterial infections. Multiple defects have been described in both the receptors for these cytokines and the receptors for signal transducer and activator of transcription molecules, with affected patients variably susceptible to atypical mycobacteria or infection after bacille Calmette-Guérin vaccination. Age of onset is variable, and symptoms can manifest in early adulthood. Treatment with supplemental interferon- γ is effective for some patients in combination with appropriate antibiotics. Most patients should also receive long-term mycobacterial prophylaxis.

Fieschi C, Casanova JL: The role of interleukin-12 in human infectious diseases: Only a faint signature. *Eur J Immunol* 2003;33:1461 [PMID: 2778462].

8. Purine Nucleoside Phosphorylase Deficiency

Purine nucleoside phosphorylase (PNP) deficiency is an immunodeficiency due to defects in the gene encoding PNP, which is important in the purine salvage pathway. Deficiency of PNP causes toxic metabolites that result in T-lymphocyte death, but in many patients B lymphocytes are spared. This autosomal recessive disease not only results in recurrent and serious infections, but affected patients have concomitant neurologic (developmental delay, ataxia, and spasticity) and autoimmune disorders. Infections present at variable ages. Laboratory evaluation reveals low numbers of or absent T lymphocytes and a variable B-lymphocyte deficiency. Without BMT, this disease is fatal due to infection or malignancy.

Dror Y et al: Purine nucleoside phosphorylase deficiency associated with a dysplastic marrow morphology. *Pediatr Res* 2004;55:472 [PMID: 14711904].

Myers LA et al: Purine nucleoside phosphorylase deficiency presenting with lymphopenia and developmental delay: Successful correction with umbilical cord blood transplantation. *J Pediatr* 2004;145:710 [PMID: 15520787].

PHAGOCYtic DEFECTS

Phagocytic defects include abnormalities of both numbers (neutropenia) and function of polymorphonuclear leukocytes (neutrophils, eosinophils, and basophils). Functional defects consist of impairments in adhesion, chemotaxis, or bacterial killing.

1. Neutropenia

Evaluation for the presence of neutropenia should be included when considering recurrent infections. The diagnosis and treatment of neutropenia is discussed in Chapter 28. Additionally, some primary immunodeficiency syndromes are associated with neutropenia (eg, XLA).

Dror Y, Sung L: Update on childhood neutropenia: Molecular and clinical advances. *Hematol Oncol Clin North Am* 2004;18:1439 [PMID: 15511624].

2. Chronic Granulomatous Disease

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Recurrent infections with catalase-positive bacteria and fungi.
- ▶ X-linked and autosomal recessive forms.
- ▶ Caused by abnormal superoxide generation within phagocytes.

▶ General Considerations

Chronic granulomatous disease is a rare immunodeficiency caused by defective superoxide generation; specifically, defects are seen in NADPH oxidase. Most cases (65%) are inherited as X-linked recessive diseases, but autosomal recessive forms also exist.

▶ Clinical Findings

A. Symptoms and Signs

Clinical presentation is characterized by recurrent and serious infections of skin, lungs, and liver with catalase-positive bacteria, fungi, and subsequent granuloma formation. Patients also typically have lymphadenopathy, hepatosplenomegaly, and signs of chronic and recurrent skin infections.

B. Laboratory Findings

Patients typically present with serious infection, positive cultures, and normal numbers of white blood cells. The five most common infecting organisms are *Staphylococcus aureus*, *Burkholderia cepacia*, *Serratia marcescens*, *Nocardia* species, and *Aspergillus* species. Patients also present with granuloma development from past infections, including granulomas of the skin, liver, and genitourinary tract. Patients may have an elevated erythrocyte sedimentation rate, even between obvious infections. Diagnosis is confirmed by demonstrating lack of superoxide production via dihydrorhodamine flow cytometry. This test, unlike the nitroblue tetrazolium test, allows differentiation between X-linked and autosomal recessive forms and also demonstrates carrier status of X-linked disease.

▶ Differential Diagnosis

The differential diagnosis includes other phagocytic cell abnormalities or deficiencies described in this section. Additionally, other immunodeficient states leading to recurrent bacterial or fungal infections, such as hypogammaglobinemia, CVID, SCID,

and other combined immunodeficiencies, should be considered. Notably, in contrast to these disorders, chronic granulomatous disease is defined by the absence of the superoxide burst.

▶ Treatment

Treatment includes prophylactic and symptomatic use of antibiotics and antifungals in combination with interferon- γ . Additionally, BMT has been successful.

Jurkowska M et al: Genetic and biochemical background of chronic granulomatous disease. *Arch Immunol Ther Exp (Warsz)* 2004;52:113 [PMID: 15179325].

3. Leukocyte Adhesion Deficiencies Types I & II

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Recurrent serious infections.
- ▶ “Cold” abscesses without pus formation.
- ▶ Poor wound healing.
- ▶ Gingival or periodontal disease (or both).

▶ General Considerations

The ability of white blood cells to travel to peripheral sites of infections is critical for effectiveness of phagocytic immunity. In leukocyte adhesion deficiency (LAD), defects in molecules required for leukocyte adherence and migration prevent these cells from arriving at the sites of infections. LAD I is an autosomal recessive disease caused by mutations in the common chain of the β_2 integrin family (CD18) located on chromosome 21q22.3. These mutations result in impaired neutrophil migration in addition to poor adherence, phagocytosis, and antibody-dependent immunity.

▶ Clinical Findings

A. Symptoms and Signs

Clinically, patients present with variable phenotypes, including recurrent serious infections, lack of pus formation, poor wound healing, and gingival and periodontal disease. The hallmark feature is little inflammation and absent neutrophils on histopathologic evaluation of infected sites (ie, “cold” abscesses) especially when concurrent with peripheral blood neutrophilia. The most severe phenotype manifests with infections in the neonatal period, including delayed separation of the umbilical cord with associated omphalitis.

B. Laboratory Findings

Laboratory evaluation often demonstrates a striking leukocytosis. Diagnosis of suspected cases is confirmed by flow cytometry analysis for CD18.

▶ Treatment

Treatment includes aggressive antibiotic therapy. LAD II is a rare autosomal recessive disease caused by an inborn error in fucose metabolism that results in abnormal expression of sialyl-Lewis X (CD15s), which functions as a selectin ligand. The resulting phenotype is similar to LAD I, characterized by recurrent infections, lack of pus formation, poor wound healing, and periodontal disease, but additionally, LAD II patients have developmental delays, short stature, dysmorphic facies, and the Bombay (hh) blood group. Diagnosis is confirmed by flow cytometry analysis for CD15s, and treatment is usually limited to antibiotics, although fucose supplementation has been reported with some success.

4. Glucose-6-Phosphate Dehydrogenase Deficiency

Severe forms of X-linked glucose-6-phosphate dehydrogenase deficiency result in recurrent infections and increased risk of severe malarial infection due to abnormal neutrophil respiratory burst. Glucose-6-phosphate dehydrogenase-associated immunodeficiency is much less common than the associated hemolytic anemia.

5. Myeloperoxidase Deficiency

Leukocyte myeloperoxidase is important for intracellular destruction of *Candida albicans*. Although deficiency is quite common, few patients present with recurrent or chronic candidal infections. Diagnosis can be confirmed with assays measuring myeloperoxidase levels in leukocytes. Symptomatic and prophylactic antifungal therapy is often necessary in patients with recurrent infections. The myeloperoxidase gene has been localized to chromosome 17.

COMPLEMENT DEFECTS

As a component of the innate immune system, complement works through opsonization, lysis of target cells, and recruitment of phagocytic cells, and by facilitating antibody-mediated immunity. The complement system includes three pathways of enzymatic reactions: classical, alternative, and lectin (see Figure 31–4). All three pathways share C3 cleavage and result in promotion of inflammation, elimination of pathogens, and enhancement of the immune system response. Activation of the complement system occurs through bacterial proteins and surface-bound IgG and IgM antibodies.

1. Complement Factor Deficiencies

Rare deficiencies of individual complement factors (C1–C9) are inherited by autosomal recessive transmission. Deficiencies of factors C1, C2, and C4 do not predispose to increased infections, but are associated with autoimmune disorders such as systemic lupus erythematosus. Primary C3 deficiency

presents with severe pyogenic infections, as C3 is critical for opsonization in both the classical and alternative pathways. There are also acquired forms of C3 deficiency that predispose patients to similar infectious risks. Terminal complement factor deficiency (C5, C6, C7, C8, and C9) or properdin (an alternative pathway factor) deficiency results in recurrent infections with *Neisseria* species. Survivors of meningococcal meningitis and patients with recurrent neisserial infections should be screened for such a deficiency.

Deficiency of mannose-binding lectin has been linked to increased risk of infections, but recent studies have been unable to confirm deficiency as a risk factor.

Dahl M et al: A population-based study of morbidity and mortality in mannose-binding lectin deficiency. *J Exp Med* 2004;199:1391 [PMID: 15148337].

Wen L et al: Clinical and laboratory evaluation of complement deficiency. *J Allergy Clin Immunol* 2004;113:585 [PMID: 15100659].

2. Hereditary Angioedema Due to C1 Esterase Inhibitor Deficiency

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Recurrent episodes of angioedema.
- ▶ No associated urticaria or pruritus.
- ▶ Onset at any age.

▶ General Considerations

Hereditary angioedema is a rare autosomal dominant disorder caused by C1 esterase inhibitor (C1-INH) deficiency in which susceptibility to infection is not increased. There is also an acquired form associated with angiotensin-converting enzyme inhibitor medication use or some B-lymphocyte malignancies.

▶ Clinical Findings

A. Symptoms and Signs

Affected patients can experience edema of skin and bowel and potentially life-threatening edema of the airway. Typical sites of swelling include the face, extremities, and genitals. Trauma, accidental or intentional (eg, due to surgery, childbirth, or dental work), may induce edema. Typical problems include episodic intestinal obstruction and dental procedure-induced upper airway obstruction. The edema is usually nonpainful (unless it involves the bowel) and lasts 48–72 hours. There is no associated urticaria (ie, redness) or pruritus. Age of onset is quite variable, and there is often a positive family history.

B. Laboratory Findings

Initial screening tests for complement that show decreased CH50 or low levels of C4 suggest the diagnosis. Confirmation comes from demonstration of low or absent levels of C1-INH or poor or absent C1-INH function. Additionally, C2 and C4 levels are low, and C1q is normal.

► Differential Diagnosis

Other causes of acquired angioedema, including that associated with certain medications (most notably angiotensin-converting enzyme modifying drugs), autoimmune diseases, and lymphoproliferative diseases, should be considered. Hereditary angioedema is distinguished from the acquired form of the disorder by normal levels of C1q.

► Treatment

Intravenous C1-INH concentrate is the treatment of choice for the emergency management of acute edema (eg, laryngeal or diffuse facial edema, severe abdominal attacks). Volume replacement is often needed due to fluid loss from edema. Fresh-frozen plasma may be used if C1-INH concentrate is not available. Long-term prophylaxis is a consideration when attacks occur monthly or have been life-threatening. The synthetic androgen danazol prevents attacks by increasing C1-INH levels. Antifibrinolytic agents (eg, tranexamic acid) may have a preferable adverse effects profile to androgens. For short-term prophylaxis prior to dental or surgical procedures, C1-INH concentrate is preferred; tranexamic acid, danazol, or fresh-frozen plasma can also be used.

Farkas H et al: Management of hereditary angioedema in pediatric patients. *Pediatrics* 2007;120:e713 [PMID: 17724112].

3. Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria is a rare X-linked disorder with variable disease expression in which affected patients have intravascular hemolysis, bone marrow failure, and thrombosis, but no associated immune defect. Paroxysmal nocturnal hemoglobinuria is caused by a mutation in phosphatidylinositol-glycan complementation class A, which is critical for certain erythrocyte surface proteins. Without these surface proteins, erythrocytes are highly susceptible to complement-mediated lysis. Thrombotic events, particularly intra-abdominal, are the major cause of death. Additional morbidity and mortality is due to bone marrow failure and associated bone marrow malignancies.

Meletis J, Terpos E: Recent insights into the pathophysiology of paroxysmal nocturnal hemoglobinuria. *Med Sci Monit* 2003;9:RA161 [PMID: 12883466].

OTHER WELL-DEFINED IMMUNODEFICIENCY SYNDROMES

1. Hyper-IgE Syndrome

Hyper-IgE syndrome (HIES), also known as Job syndrome, is a rare primary immunodeficiency characterized by elevated levels of IgE (> 2000 IU/mL), neonatal eczematoid rash, recurrent infections with *S aureus*, recurrent pneumonia with pneumatocele formation, and typical facies. Inheritance appears to be sporadic, although autosomal dominant and recessive cases have been reported. Additional clinical findings include retained primary teeth, scoliosis, hyperextensibility, high palate, and osteoporosis. In addition to staphylococcal infections, affected patients also have increased incidence of infections due to *Streptococcus* spp, *Pseudomonas* spp, *C albicans*, and even opportunistic infections with *Pneumocystis carinii*. Laboratory evaluation reveals normal to profoundly elevated levels of IgE and occasionally an associated eosinophilia. However, elevated IgE levels themselves are not a risk factor for HIES, as atopic dermatitis and parasite infection are much more common causes of elevated IgE. Diagnosis is often difficult due to variable presentation, which may become progressively severe with increasing age. Subsequently, diagnosis is often only made over time and evolving syndrome characteristics. The underlying cause of HIES is unknown. The mainstay of treatment is prophylactic and symptomatic antibiotic use in combination with good skin care. IVIG has been used with some success to decrease infections and possibly modify IgE levels.

Grimbacher B et al: Hyper-IgE syndromes. *Immunol Rev* 2005;203:244 [PMID: 15661034].

2. Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-Linked Syndrome

Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome is a rare disease that usually manifests with severe diarrhea and insulin-dependent diabetes mellitus within the first months of life. Affected males also have severe eczema, food allergy, autoimmune cytopenias, lymphadenopathy, splenomegaly, and recurrent infections. Most die before 2 years of age due to malnutrition or sepsis. IPEX syndrome results from mutations in the *FOXP3* gene that encodes a protein essential for developing regulatory T lymphocytes. Leukocyte counts and immunoglobulin levels are generally normal. Immunosuppression and nutritional supplementation produce temporary improvements, but the prognosis is poor and most cases result in early death. BMT has been attempted with variable success.

Chatila TA et al: JM2, encoding a fork head-related protein, is mutated in X-linked autoimmunity-allergic dysregulation syndrome. *J Clin Invest* 2000;106:R75 [PMID: 11120765].

Nieves DS et al: Dermatologic and immunologic findings in the immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome. *Arch Dermatol* 2004;140:466 [PMID: 15096376].

3. X-Linked Lymphoproliferative Syndrome

X-linked lymphoproliferative syndrome is an immunodeficiency that develops following EBV infection. Affected males develop fulminant infectious mononucleosis with hemophagocytic syndrome, multiple organ system failure, and bone marrow aplasia. The mutated gene encodes a signaling protein used by T lymphocytes and NK cells called SLAMF7. Affected boys are immunologically normal prior to EBV infection, and during acute infection they produce antibody to EBV. In most instances, infection with EBV is fatal. Patients who survive the initial episode or who are never infected with EBV in childhood develop lymphomas, vasculitis, hypogammaglobulinemias (with elevated IgM) or common variable immunodeficiency in later life. Antenatal diagnosis is possible.

Latour S, Velette A: Molecular and immunological basis of X-linked lymphoproliferative disease. *Immunol Rev* 2003;192:221 [PMID: 12670406].

4. Chronic Mucocutaneous Candidiasis

There are two forms of chronic mucocutaneous candidiasis (CMC). The first type is an autosomal dominant disorder that is characterized by isolated candidal infections of the skin, nails, and mucous membranes, and is not due to other causes. Systemic disease is not characteristic, but case reports of intracranial mycotic aneurysms exist. Primary CMC most commonly occurs as an isolated syndrome, but can be associated with endocrine or autoimmune disorders. The underlying defect is unknown, but the prognosis is quite good with antifungal therapy.

An autosomal recessive form of CMC with associated autoimmunity, also known as autoimmune polyendocrinopathy, candidiasis, ectodermal dysplasia (APECED) syndrome, is characterized by recurrent candidal infections, abnormal T-lymphocyte response to *Candida*, autoimmune endocrinopathies, and ectodermal dystrophies. APECED is caused by mutations in the gene for an important transcription regulator protein called autoimmune regulator that is critical for normal thymocyte development. Treatment includes antifungal therapy in combination with therapy for associated endocrinopathies.

Soderbergh A et al: Prevalence and clinical associations of 10 defined autoantibodies in autoimmune polyendocrine syndrome type 1. *J Clin Endocrinol Metab* 2004;89:557 [PMID: 14764761].

5. Autoimmune Lymphoproliferative Syndrome

Autoimmune lymphoproliferative syndrome (ALPS) results from mutations of genes important for regulating programmed lymphocyte death (apoptosis). Most commonly, the defect is in Fas (CD95) or Fas ligand, but other defects in the Fas pathway have also been described (eg, caspase 10). Clinical presentation includes lymphadenopathy, splenomegaly, and autoimmune disorders (autoimmune hemolytic anemia, neutropenia, thrombocytopenia, and sometimes arthritis). Occasionally, patients have frequent infections. The diagnosis is suspected when T-lymphocyte subsets by flow cytometry demonstrate elevated numbers of CD3⁺CD4⁻CD8⁻ (double negative) T lymphocytes. Several different types of ALPS are distinguished by the response of lymphocytes to Fas-induced apoptosis. Patients are often heterozygous, and inheritance is mostly autosomal dominant. Treatment with prednisone often controls the lymphadenopathy. Infections should be treated appropriately. In some cases, BMT has been curative. Affected patients are also at risk for lymphoma. Mutations affecting another apoptosis-related protein, caspase 8, cause an ALPS variant syndrome in which the susceptibility to infection by herpes simplex virus also increases.

GENETIC SYNDROMES ASSOCIATED WITH IMMUNODEFICIENCY

Several described genetic syndromes have associated immunodeficiency that is often identified after the syndrome has been diagnosed. Usually, the immune defect is not the major presenting clinical problem.

Ming JE et al: Genetic syndromes associated with immunodeficiency. *Immunol Allergy Clin North Am* 2002;22:261.

Ming JE, Stiehm ER: Syndromic immunodeficiencies with humoral defects. *Immunol Allergy Clin North Am* 2001;21:91.

1. Bloom Syndrome

Characteristics of Bloom syndrome include growth retardation, sun sensitivity, and telangiectasias of the face. The syndrome results from mutations in a DNA helicase that lead to excess sister chromatid exchanges. Affected patients have an increased risk of malignancy and life-threatening infections. Serum IgA and IgM are variably low, and T-lymphocyte function is abnormal.

2. Transcobalamin 2 Deficiency

Transcobalamin 2 deficiency is due to defective cellular transport of cobalamin and results in megaloblastic anemia, diarrhea, and poor growth. Affected patients have hypogammaglobulinemia and poor specific antibody production.

3. Immunodeficiency, Centromeric Instability, Facial Anomalies Syndrome

Immunodeficiency, centromeric instability, facial anomalies (ICF) syndrome is a rare condition caused by abnormal DNA methyltransferase. Unlike other chromosome instability syndromes, ICF syndrome does not have an associated hypersensitivity to sunlight. Affected patients have severe respiratory, gastrointestinal, and skin infections due to low or absent immunoglobulins and abnormal T-lymphocyte numbers and function.

4. Trisomy 21

Patients with trisomy 21 or Down syndrome have increased susceptibility to respiratory infection. Immunodeficiency is variable, and abnormal numbers and function of T and B lymphocytes have been reported. Additionally, patients have an increased incidence of autoimmune diseases.

5. Turner Syndrome

Turner syndrome (partial or complete absence of one X chromosome) is associated with increased risk of otitis media, respiratory infections, and malignancies. Immune defects are variable but may include abnormal T-lymphocyte numbers and function and hypogammaglobulinemia.

6. Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome is a rare autosomal recessive disease caused by mutations in a lysosomal trafficking gene. The neutrophils of affected individuals have giant lysosomes, impaired chemotaxis, neutropenia, and abnormal NK-cell cytotoxicity. Patients present with recurrent infections (particularly periodontitis), partial oculocutaneous albinism, and neuropathy. Most patients progress to generalized lymphohistiocytic infiltration syndrome, which is a common cause of death. Treatment strategies address infections and neuropathy and the use of immunosuppression attempts to slow lymphoproliferative progression.

7. Griscelli Syndrome

Characterized by partial albinism, neutropenia, thrombocytopenia, and lymphohistiocytosis, Griscelli syndrome is a rare autosomal recessive syndrome resulting from mutations in the myosin VA gene. Affected patients have recurrent and serious infections caused by fungi, viruses, and bacteria. Immunologic evaluation demonstrates variable immunoglobulin levels and antibody function with impaired T-

lymphocyte function. BMT can correct the immunodeficiency. Griscelli syndrome is distinguished from Chédiak-Higashi syndrome by the lack of granules in white blood cells.

8. Netherton Syndrome

Patients with the autosomal recessive Netherton syndrome present with trichorrhexis (brittle hair), ichthyosiform rash, and allergic diseases. A subset of patients develops recurrent infections. Immune function is variable but may include hypo- or hypergammaglobulinemia, abnormal T-lymphocyte function, or abnormal phagocyte function. The disease results from mutations in a serine protease inhibitor encoded on the *SPINK5* gene.

9. Cartilage-Hair Hypoplasia

Cartilage-hair hypoplasia is an autosomal recessive form of chondrodysplasia manifesting with short-limbed short stature, hypoplastic hair, defective immunity, and poor erythropoiesis. The immune defect is characterized by mild to moderate lymphopenia and abnormal lymphocyte function, but normal antibody function. Affected patients have increased susceptibility to infections and increased risk of lymphoma. The disorder results from mutation in the *RMRP* gene that encodes the RNA component of an RNase MRP complex. BMT can restore cell-mediated immunity but does not correct the cartilage or hair abnormalities.

Ridanpaa M et al: The major mutation in the *RMRP* gene causing CHH among the Amish is the same as that found in most Finnish cases. *Am J Med Genet C Semin Med Genet* 2003;121:81 [PMID: 12888988].

GRAFT-VERSUS-HOST DISEASE

Graft-versus-host disease (GVHD) occurs when immunologically competent donor T lymphocytes are grafted into a host who is unable to reject them. The immunocompetent donor T lymphocytes recognize the host as foreign, leading to significant morbidity and potentially death. In addition to BMT-associated disease, GVHD can also occur in immunodeficient patients who receive nonirradiated blood products (ie, containing liver donor T lymphocytes) or engraftment of maternally derived T lymphocytes during birth. A progressive skin rash followed by diarrhea, hepatitis, nephritis, pulmonary infiltrates, fever, and marrow damage characterize GVHD. Laboratory evaluation reveals eosinophilia and leukocytosis, and diagnosis is confirmed by biopsy. Prevention is the most successful approach to GVHD. With BMT, GVHD prophylactic immunosuppressant regimens include methotrexate, cyclosporine, and mycophenolate mofetil. Treatment of GVHD includes similar regimens in addition to antithymocyte serum, corticosteroids, and monoclonal antibodies directed against T lymphocytes.

GENERAL CONCEPTS

The classic concept that hormones are secreted substances affecting distant target cells has been updated to account for other mechanisms of hormonal action. Some hormones stimulate or inhibit metabolic processes in neighboring, not distant cells (eg, pancreatic islets or cartilage). This mechanism is termed *paracrine* activity. Other hormones affect the cells that produce them, a mechanism termed *autocrine*. Recognition that insulin, glucagon, ghrelin, somatostatin, cholecystokinin, and other hormones are synthesized by the brain and gut supports the concept of paracrine and autocrine processes in these tissues.

Another concept of modern endocrine physiology is that specific hormone receptors in target tissues are required for hormonal action. For example, in the complete androgen insensitivity syndrome, androgen receptors are defective and affected males have varying degrees of undervirilization of the external genitalia and wolffian duct system despite having both testes (the end organ) and adequate testosterone (the hormone). Similarly, in nephrogenic diabetes insipidus or pseudohypoparathyroidism, affected children have defective antidiuretic hormone or parathyroid hormone receptor function, respectively, and have diabetes insipidus or hypoparathyroidism, despite adequate hormone secretion. Alternatively, abnormal *activation* of a hormone receptor leads to the effects of the hormone in the absence of excessive hormone secretion. Examples of this phenomenon are the McCune-Albright syndrome (precocious puberty and hyperthyroidism), testotoxicosis (familial male precocious puberty), and hypercalciuric hypocalcemia.

HORMONE TYPES

Hormones are of three main chemical types: peptides and proteins, steroids, and amines. The peptide hormones include those released by the anterior and posterior pituitary, pancreatic islet cells, parathyroids, lungs (angiotensin

II), heart and brain (atrial and brain natriuretic hormones), and hypothalamus (releasing hormones), as well as many local growth factors (insulin-like growth factor-1). Steroid hormones are secreted primarily by the adrenal cortex, gonads, and kidney (active vitamin D [$1,25(\text{OH})_2\text{D}_3$]). The amine hormones are secreted by the adrenal medulla (epinephrine) and the thyroid gland (triiodothyronine [T_3] and thyroxine [T_4]).

As a rule, the peptide hormones and epinephrine act rapidly and bind to specific receptors on the surface of their target cell. The metabolic effects of these hormones are usually stimulation or inhibition of the activity of cellular enzymes or transport proteins (*post-translational effects*). The steroid hormones, thyroid hormone, and active vitamin D, in contrast, act more slowly and bind to specific cytoplasmic receptors in the target cell and subsequently to specific regions (genes) on nuclear DNA, where they direct a read-out of specific protein(s). Their metabolic effects are generally stimulation or inhibition of the synthesis of enzymes or transport proteins (*transcriptional effects*), which increases or decreases the amount rather than the activity of these proteins in the target cell.

Metabolic processes that must be regulated rapidly such as blood glucose or calcium are usually under the control of the peptide hormones and epinephrine, whereas processes regulated more slowly such as pubertal development and metabolic rate are under the control of steroid hormones and thyroid hormone. Control of electrolyte homeostasis is intermediate and is regulated by a combination of peptide and steroid hormones (Table 32–1).

FEEDBACK CONTROL OF HORMONE SECRETION

An understanding of feedback control of hormonal secretion is fundamental to the understanding of endocrine disorders of childhood and their treatment. Hormone secretion is generally regulated by feedback in response to changes in the internal environment (see Table 32–1). When the metabolic imbalance

is corrected, the stimulus for the hormone's secretion ceases or is inhibited. Overcorrection of the imbalance stimulates secretion of a counterbalancing hormone or hormones.

Hypothalamic-pituitary control of hormone secretion is also regulated by feedback, so that end-organ failure (endocrine gland insufficiency) causing decreased circulating endocrine gland hormones results in increased secretion of their respective hypothalamic releasing and pituitary hormones (Table 32-1 and Figure 32-1). If restoration of normal circulating concentrations of hormones occurs, feedback inhibition at the pituitary and hypothalamus results in cessation of the previously stimulated secretion of releasing and pituitary hormones and restoration of their circulating concentrations to normal. Similarly, if there is autonomous endocrine gland hyperfunction (eg, McCune-Albright syndrome, Graves disease, or adrenal tumor), the specific hypothalamic releasing and pituitary hormones are suppressed (see Figure 32-1).

DISTURBANCES OF GROWTH

Disturbance of growth and development is the most common problem evaluated by a pediatric endocrinologist. While most cases represent normal developmental variants, it is critical to identify abnormal growth patterns, as deviations from the norm can be the first or only manifestation of many endocrine disorders. Determination of height velocity is the most critical factor in evaluating a child's growth. A persistent increase or decrease in height percentiles between age 2 years and the onset of puberty always warrants evaluation. It is more difficult to distinguish normal from abnormal growth in the first 2 years of life, as infants may have catch-up or catch-down growth during this period.

Appropriate standards must be used to evaluate growth. The National Center for Health Statistics provides standard growth charts for North American children (see Chapter 1). Specific growth charts are also available for some ethnic

▲ **Figure 32-1.** General scheme of the hypothalamus-pituitary-endocrine gland axis. Releasing hormones synthesized in the hypothalamus are secreted into the hypophysial portal circulation. Trophic hormones are secreted by the pituitary gland in response, and they in turn act on specific endocrine glands to stimulate the secretion of their respective hormones. The endocrine gland hormones exert their respective effects on various target tissues (end organs) and exert a negative feedback (feedback inhibition) on their own secretion by acting at the level of the pituitary and hypothalamus. This system is characteristic of those hormones listed in Table 32-1 (third level).

groups. Normal values can vary by country of origin. In addition, growth charts are available for children with specific growth disturbances, such as Turner syndrome and Down syndrome.

TARGET HEIGHT & SKELETAL MATURATION

A child's growth and height potential is determined largely by genetic factors. The target (midparental) height of a child is calculated from the mean parental height plus or minus 6.5 cm for boys and girls, respectively. This calculation helps identify a child's genetic growth potential. Most children achieve an adult height within 8 cm of this number. Another parameter to determine growth potential is skeletal maturation or bone age. Beyond the neonatal period, bone age is evaluated by comparing a radiograph of the child's left hand and wrist with the standards of Greulich and Pyle. Delayed or advanced bone age is not diagnos-

tic of any specific disease, but the extent of skeletal maturation is used to determine remaining growth potential as a percentage of total height and allows prediction of ultimate height.

SHORT STATURE

Short stature has many causes. It is important to distinguish normal variants of growth (familial short stature and constitutional growth delay) and pathologic conditions (Table 32-2). Pathologic short stature is more likely in children whose growth velocity is abnormal (crossing major height percentiles on the growth curve) or who are significantly short for their family. Children with chronic illness or nutritional deficiencies may have poor linear growth, but this is typically associated with inadequate weight gain. In contrast, endocrine causes of short stature are usually associated with normal or excessive weight gain.

1. Familial Short Stature & Constitutional Growth Delay

Children with familial short stature typically have normal birth weight and length. In the first 2 years of life their linear growth velocity decelerates as they near their genetically determined percentile. Once this target percentile is reached, the child has normal linear growth parallel to the growth curve. Skeletal maturation and timing of puberty are consistent with chronologic age. The height percentile the child follows is maintained, and final height is short but appropriate for the family (Figure 32-2). For example, an infant boy of a mother who is 5'0" and father who is 5'5" (calculated midparental height 5'5") may have a birth length at the 50th percentile. However, this child's length percentile will drift downward during the first 2 years of life and will settle in at the fifth percentile where it will stay.

Children with constitutional growth delay do not necessarily have short parents but have a growth pattern similar to those with familial short stature. The difference is that children with constitutional growth delay have a delay in skeletal maturation and a delay in the onset of puberty. In these children, growth continues beyond the time the average child stops growing, and final height is appropriate for target height (Figure 32-3). There is often a history of other family members being "late bloomers."

2. Growth Hormone Deficiency

Human growth hormone (GH) is produced by the anterior pituitary gland under the stimulation of growth hormone-releasing hormone (GHRH) and the inhibition of somatostatin. GH is secreted in a pulsatile pattern in response to sleep, exercise, and hypoglycemia and has direct growth-promoting and metabolic effects (Figure 32-4). GH also promotes growth indirectly by stimulating production of insulin-like growth factors, primarily IGF-1.

Table 32-2. Causes of short stature.

Psychosocial short stature (deprivation dwarfism)</p>

Growth hormone deficiency (GHD) is characterized by decreased growth velocity and delayed skeletal maturation in

the absence of other explanations. Laboratory tests indicate subnormal GH secretion or action. GHD may be isolated or coexist with other pituitary hormone deficiencies. GHD may be congenital (septo-optic dysplasia or ectopic posterior pituitary), genetic (GH or GHRH gene mutation), or acquired (craniopharyngioma, germinoma, histiocytosis, or cranial irradiation). Idiopathic GHD is more common than any other cause, with an incidence of about 1:4000 children. GH resistance syndrome (Laron dwarfism) is caused by a mutation in the GH receptor. Presentation is similar to GHD, but short stature is severe and there is a distinctive facial appearance. Additional forms of GH resistance are caused by mutations in other molecular components of the GH signaling pathway.

Infants with GHD have normal birth weight with only slightly reduced length, suggesting that GH is a minor contributor to intrauterine growth. GH-deficient infants classically present as newborns with hypoglycemia or other pituitary deficiencies such as central hypothyroidism or adrenal insufficiency. Micropenis is a feature of newborn males with gonadotropin and GH deficiency. Because GH promotes lipolysis, many GH-deficient children have truncal adiposity. Growth retardation begins in infancy or may be delayed until later childhood. Regardless of onset, the primary manifestation of idiopathic or acquired GHD is subnormal growth velocity (Figure 32-5).

Laboratory tests to assess GH status may be difficult to interpret. Children with normal and short stature have a broad range of GH secretion patterns, and significant overlap exists between normal and GH-deficient children. Provocative studies are performed using such agents as insulin-induced hypoglycemia, arginine, levodopa, clonidine, or glucagon. Serum concentrations of IGF-1 and IGF-binding protein 3 may give reasonable estimations of GH secretion in the adequately nourished child (see Figure 32-4). When results of GH tests are equivocal, a trial of GH treatment can help determine whether an abnormally short child will benefit from GH. Current treatment for GHD is subcutaneous recombinant GH given 6 or 7 days per week with total weekly dose of 0.15–0.3 mg/kg.

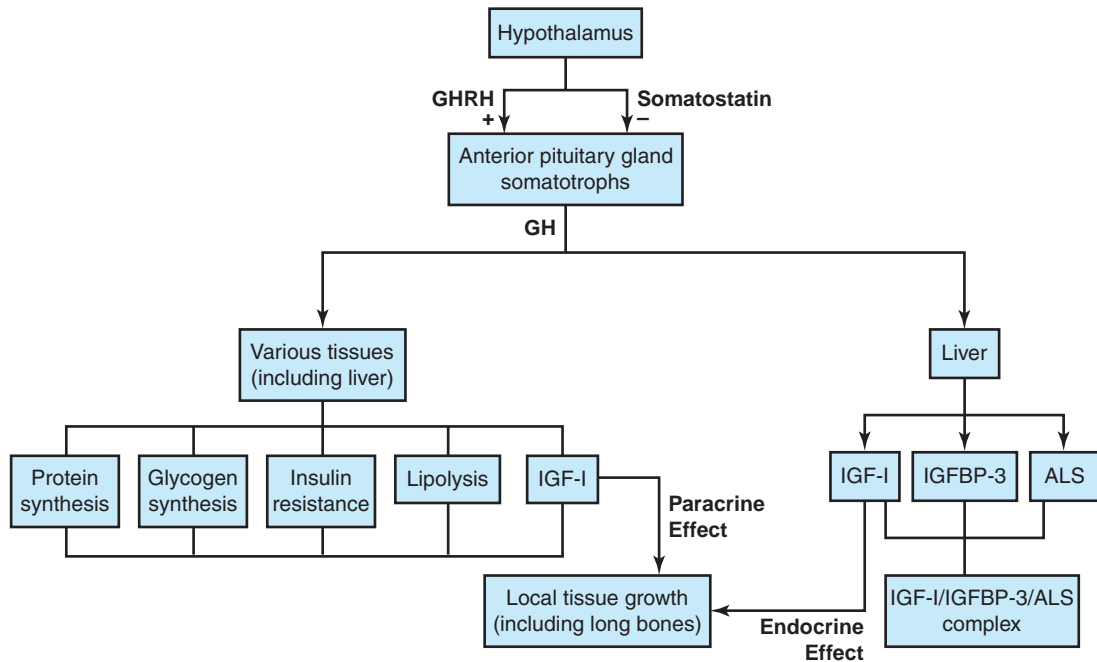

GH therapy is approved by the U.S. Food and Drug Administration (FDA) for children with GHD and growth restriction associated with chronic renal failure, for girls with Turner syndrome, children with Prader-Willi syndrome, and children born small for gestational age (SGA) who fail to demonstrate catch-up growth by age 4. GH therapy has also been approved for children with idiopathic short stature whose current height is more than 2.25 standard deviations below the norm for age. Final height improvement may be 5–7 cm in this population. This last indication is controversial and the role of GH for idiopathic short stature is still unclear. Side effects of recombinant GH are uncommon but include benign intracranial hypertension and slipped capital femoral epiphysis. With early diagnosis and treatment, children with GHD reach normal or near-normal adult height. Recombinant IGF-1 is available for use in children with GH resistance or IGF-1 deficiency.

▲ **Figure 32-2.** Typical pattern of growth in a child with familial short stature. After attaining an appropriate percentile during the first 2 years of life, the child will have normal linear growth parallel to the growth curve. Skeletal maturation and the timing of puberty are consistent with chronologic age. The height percentile the child has been following is maintained, and final height is short but appropriate for the family.

▲ **Figure 32-3.** Typical pattern of growth in a child with constitutional growth delay. Growth slows during the first 2 years of life, similarly to children with familial short stature. Subsequently the child will have normal linear growth parallel to the growth curve. However, skeletal maturation and the onset of puberty are delayed. Growth continues beyond the time the average child has stopped growing, and final height is appropriate for target height.

▲ Figure 32-4. The GHRH/GH/IGF-1 system. The effects of growth hormone (GH) on growth are partly due to its direct anabolic effects in muscle, liver, and bone. In addition, GH stimulates many tissues to produce insulin-like growth factor 1 (IGF-1) locally, which stimulates the growth of the tissue itself (paracrine effect of IGF-1). The action of GH on the liver results in the secretion of IGF-1 (circulating IGF-1), which stimulates growth in other tissues (endocrine effect of IGF-1). The action of growth hormone on the liver also enhances the secretion of IGF-binding protein 3 (IGFBP-3) and acid-labile subunit (ALS), which form a high-molecular-weight complex with IGF-1. The function of this complex is to transport IGF-1 to its target tissues, but the complex also serves as a reservoir and possible inhibitor of IGF-1 action. In various chronic illnesses, the direct metabolic effects of GH are inhibited; the secretion of IGF-1 in response to GH is blunted, and in some cases IGFBP-3 synthesis is enhanced, resulting in marked inhibition in the growth of the child. GHRH, growth hormone–releasing hormone.

3. Small for Gestational Age/ Intrauterine Growth Restriction

Small-for-gestational-age (SGA) infants have birth weights below the 10th percentile for the population’s birth weight/gestational age relationship. SGA infants include constitutionally small infants growing at their potential and infants with intrauterine growth restriction (IUGR). IUGR refers to a heterogeneous group of patients who fail to grow at a normal rate in utero.

SGA/IUGR is a result of poor maternal environment, intrinsic fetal abnormalities, congenital infections, or other fetal malnutrition. Intrinsic fetal abnormalities causing SGA/IUGR (often termed primordial short stature) include Russell-Silver, Seckel, Noonan, Bloom, and Cockayne syndromes, and progeria. Many children with mild SGA/IUGR (except those with intrinsic fetal abnormalities) exhibit catch-up growth during the first 3 years. However, 15–20% remain short throughout life, particularly those whose in-utero growth restriction occurred over several months rather than just the last 2–3 months gestation. Catch-up growth

may also be inadequate in preterm SGA/IUGR infants with inadequate postnatal nutrition. Children who do not show catch-up growth may have normal growth velocity, but they will follow a lower height percentile than expected for the family. In contrast to children with constitutional growth delay, those with SGA/IUGR have skeletal maturation that corresponds to chronologic age or is only mildly delayed.

GH therapy for SGA/IUGR children with growth delay is FDA approved and appears to be effective in increasing growth velocity and final adult height.

4. Disproportionate Short Stature

Skeletal dysplasias cause disproportionate short stature. There are more than 200 types of sporadic and genetic skeletal dysplasias. Measurements of arm span and upper-to-lower body segment ratio are helpful in determining whether a child has normal body proportions. If disproportionate short stature is found, a skeletal survey may be useful because specific radiographic features characterize certain disorders. Because skeletal dysplasias are rare, the effect of GH on most types is unknown.

▲ **Figure 32-5.** Typical pattern of growth in a child with acquired growth hormone deficiency. Children with acquired growth hormone deficiency have an abnormal growth velocity and fail to maintain height percentile during childhood. Other phenotypic features (central adiposity and immaturity of facies) may be present. Children with congenital growth hormone deficiency will cross percentiles during the first 2 years of life, similarly to the pattern seen in familial short stature and constitutional delay, but will fail to attain a steady height percentile subsequently.

5. Short Stature Associated with Syndromes

Short stature is associated with many syndromes, including Turner, Down, and Prader-Willi. Girls with Turner syndrome often have recognizable features such as micrognathia, webbed neck, low posterior hairline, edema of hands and feet, multiple pigmented nevi, and an increased carrying angle. In some girls, however, short stature is the only obvious manifestation. Consequently, any girl with unexplained short stature should have a chromosomal evaluation. Although girls with Turner syndrome are not usually GH-deficient, GH therapy can improve final height by an average of 6.0 cm. Duration of GH therapy is a significant predictor of long-term height gain; consequently, it is important that Turner syndrome be diagnosed early and GH started as soon as possible.

GH is also approved for growth failure in Prader-Willi syndrome. Many of these individuals are GH-deficient. GH improves growth, body composition, and physical activity in these patients. A few deaths have been reported in Prader-Willi children receiving GH. All of the deaths were in very obese children, children with respiratory impairments, sleep apnea, or unidentified respiratory infections. The role of GH, if any, in these deaths is unknown. As a precaution, it is recommended that all Prader-Willi patients be evaluated for upper airway obstruction and sleep apnea prior to starting GH therapy.

Children with Down syndrome should be evaluated for GHD only if their linear growth is abnormal compared with the Down syndrome growth chart.

6. Psychosocial Short Stature (Psychosocial Dwarfism)

Psychosocial short stature refers to growth retardation in association with emotional deprivation. Undernutrition probably contributes to growth retardation in some children. Other symptoms include bizarre eating and drinking habits, bowel and bladder incontinence, social withdrawal, and delayed speech. GH secretion in children with psychosocial short stature is diminished, but GH therapy is usually not beneficial. Foster home placement or a change in the psychological environment at home usually results in improved growth and normalization of GH secretion, personality, and eating behaviors.

Clinical Evaluation

Laboratory investigation should be guided by the history and physical examination. Data included in history and physical include size at birth, pattern of growth since birth, familial growth patterns, pubertal stage, dysmorphic features, body segment proportion, and psychological health. In a child with poor weight gain as the primary disturbance, history of chronic illness and nutritional assessment are indicated. The following laboratory tests may be useful:

1. Radiograph of left hand and wrist for bone age
2. Complete blood count (to detect chronic anemia or infection)

3. Erythrocyte sedimentation rate (often elevated in collagen-vascular disease, cancer, chronic infection, and inflammatory bowel disease)
4. Urinalysis, blood urea nitrogen, and serum creatinine (occult renal disease)
5. Serum electrolytes, calcium, and phosphorus (renal tubular disease and metabolic bone disease)
6. Stool examination for fat, serum endomysial antibody (malabsorption or celiac disease)
7. Karyotype (in girls)
8. Thyroid function tests: free thyroxine (FT4) and thyroid-stimulating hormone (TSH)
9. IGF-1 and IGF-binding protein 3

TALL STATURE

Although we usually think of growth disturbances as producing short stature, potentially serious pathologic conditions may be associated with tall stature and excessive growth (Table 32-3). Excessive GH secretion is rare and is generally associated with a functioning pituitary adenoma. GH excess leads to gigantism if the epiphyses are open and to acromegaly if the epiphyses are closed. Affected children present with an accelerated growth velocity. The diagnosis is confirmed by elevated GH and IGF-1 levels and failure of GH suppression during a standard oral glucose tolerance test.

Constitutional tall stature may be a concern to adolescent girls. However, the upper limit of acceptable height in both sexes is increasing, and concerns about excessive growth for girls are becoming less frequent. When such concerns arise, the family history, growth curve, pubertal stage, and assessment of skeletal maturation allow assessment of predicted

final adult height. Reassurance, counseling, and education may alleviate the family's concerns. Rarely, when the predicted height is excessive and unacceptable, estrogen therapy may accelerate bone maturation and shorten the growth period.

DISORDERS OF THE POSTERIOR PITUITARY GLAND

The posterior pituitary (neurohypophysis) is an extension of the ventral hypothalamus. Its two principal hormones—oxytocin and arginine vasopressin—are synthesized in the supraoptic and paraventricular nuclei of the ventral hypothalamus. After synthesis, these peptide hormones are packaged in granules with specific neurophysins and transported via the axons to their storage site in the posterior pituitary. Vasopressin is essential for water balance; it acts primarily on the kidney to promote reabsorption of water from urine. Oxytocin is most active during parturition and breast feeding and is not discussed further here.

ARGININE VASOPRESSIN (ANTIDIURETIC HORMONE) PHYSIOLOGY

Vasopressin release is controlled primarily by serum osmolality and intravascular volume. Release is stimulated by minor increases in plasma osmolality (detected by osmoreceptors in the anterolateral hypothalamus) and large decreases in intravascular volume (detected by baroreceptors in the cardiac atria). Disorders of vasopressin release and action include (1) central (neurogenic) diabetes insipidus, (2) nephrogenic diabetes insipidus (see Chapter 22), and (3) the syndrome of inappropriate secretion of antidiuretic hormone (see Chapter 43).

CENTRAL DIABETES INSIPIDUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Polydipsia, polyuria ($> 2 \text{ L/m}^2/\text{d}$), nocturia, dehydration, and hypernatremia.
- ▶ Inability to concentrate urine after fluid restriction (urine specific gravity < 1.010 ; urine osmolality $< 300 \text{ mOsm/kg}$).
- ▶ Plasma osmolality $> 300 \text{ mOsm/kg}$ with urine osmolality $< 600 \text{ mOsm/kg}$.
- ▶ Low plasma vasopressin with antidiuretic response to exogenous vasopressin.

General Considerations

Central diabetes insipidus (DI) is an inability to synthesize and release vasopressin. Without vasopressin the kidneys cannot concentrate urine, causing excessive urinary water loss. Genetic causes of central DI are rare and include mutations in the vasopressin gene (mostly in the neurophysin portion of the vasopressin precursor) and the *WFS1* gene that causes DI, diabetes mellitus, optic atrophy, and deafness (Wolfram or DIDMOAD syndrome). Midline brain abnormalities, such as septo-optic dysplasia and holoprosencephaly are also associated with central DI. Traumatic brain injury or neurosurgery in or near the hypothalamus or pituitary can cause transient or permanent DI. Traumatic DI often has three phases. Initially, transient DI is caused by edema in the hypothalamus or pituitary area. In 2–5 days, unregulated release of vasopressin from dying neurons causes the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Finally, permanent DI occurs if a sufficient number of vasopressin neurons are destroyed.

Tumors and infiltrative diseases of the hypothalamus and pituitary may cause DI. In children with craniopharyngioma, DI usually develops after neurosurgical intervention. In contrast, germinomas often present with DI. Germinomas may be undetectable for several years; consequently, children with unexplained DI should have regularly repeated magnetic resonance imaging (MRI). Infiltrative diseases such as histiocytosis and lymphocytic hypophysitis can cause DI. In these conditions, as in germinomas, MRI scans characteristically show thickening of the pituitary stalk. Infections involving the base of the brain also cause transient DI.

Clinical Findings

Onset of DI is often abrupt, characterized by polyuria, nocturia, enuresis, and intense thirst. Children with DI typically crave cold water. Hypernatremia, hyperosmolality, and dehydration occur if insufficient fluid intake due to lack of access or impaired thirst mechanism does not keep up with urinary losses. In infants, symptoms may also include failure to thrive, vomiting, constipation, and unexplained fevers. Some infants may present with severe dehydration, circulatory collapse, and seizures. Vasopressin deficiency may be masked in patients with panhypopituitarism due to the impaired excretion of free water associated with adrenal insufficiency. Treating these patients with glucocorticoids may unmask their DI.

DI is confirmed when serum hyperosmolality is associated with urine hypo-osmolality. If the history indicates that the child can go through the night comfortably without drinking, outpatient testing is appropriate. Oral fluid intake is prohibited after midnight. Osmolality, sodium, and specific gravity of the first morning void are obtained. If urine specific gravity is greater than 1.015, DI is excluded. If urine is not concentrated, a blood sample is obtained within a few

minutes of the urine collection for osmolality, sodium, creatinine, and calcium concentration.

If screening results are unclear or if symptoms preclude safely withholding fluids at home, a water deprivation test performed in the hospital is indicated. In this test, fluid is withheld and the child is monitored. Serum osmolality greater than 290 mOsm/kg associated with inappropriately dilute urine; osmolality less than 600 mOsm/kg is diagnostic for DI. Low serum vasopressin concentration and an antidiuretic response to vasopressin administration at the end of the test distinguishes central from nephrogenic DI. Children with central DI should have a head MRI scan with contrast to look for tumors or infiltrative processes. The posterior pituitary “bright spot” on MRI is often absent in DI.

Decreased ability to concentrate urine also occurs in hypercalcemic disorders and renal tubular abnormalities (eg, Fanconi syndrome). Primary polydipsia must be distinguished from DI. Children with primary polydipsia tend to have lower serum sodium levels and usually can concentrate their urine with overnight fluid deprivation. Some may have secondary nephrogenic DI due to dilution of the renal medullary interstitium and decreased renal concentrating ability, but this resolves with restriction of fluid intake.

► Treatment

Central DI is treated with oral or intranasal desmopressin acetate (DDAVP). The aim of therapy is to provide antidiuresis that allows uninterrupted sleep and approximately 1 hour of diuresis before the next dose. Children hospitalized with acute-onset DI can be managed with intravenous vasopressin. Due to the amount of antidiuresis, intravenous fluids will need to be restricted to two-thirds the maintenance rate and electrolytes closely monitored to avoid water intoxication. Infants with DI should not be treated with DDAVP. Treatment with DDAVP in association with the volume of formula or breast milk needed to ensure adequate caloric intake could cause water intoxication. For this reason, infants are treated with extra free water, rather than DDAVP, to maintain normal hydration. A formula with a low renal solute load and chlorothiazides may be helpful in infants with central DI.

THYROID GLAND

FETAL DEVELOPMENT OF THE THYROID

The fetal thyroid synthesizes thyroid hormone as early as the 10th week of gestation. Thyroid hormone appears in fetal serum by the 11th week of gestation and increases throughout gestation. The fetal pituitary-thyroid axis functions largely independently of the maternal pituitary-thyroid axis because maternal thyroid-stimulating hormone (TSH) cannot cross the placenta. However, maternal thyroid hormone can cross the placenta in limited amounts.

A TSH surge occurs at birth, peaking at about 70 mU/L within 30–60 minutes. The surge causes thyroid hormone levels to increase rapidly in the first days of life. TSH level decreases to childhood levels within a few weeks. This physiologic neonatal TSH surge can cause a false-positive newborn screen for hypothyroidism (ie, high TSH) if the blood sample is collected on the first day of life.

PHYSIOLOGY

Hypothalamic thyrotropin-releasing hormone (TRH) stimulates the anterior pituitary gland to release TSH. In turn, TSH stimulates the thyroid gland to take up iodine, and to synthesize and release the active hormones, thyroxine (T_4) and triiodothyronine (T_3). This process is regulated by negative feedback involving the hypothalamus, pituitary, and thyroid (see Figure 32–1).

T_4 is the predominant thyroid hormone secreted by the thyroid gland. Most circulating T_3 and T_4 is bound to thyroxine-binding globulin (TBG), albumin, and prealbumin. Less than 1% of T_3 and T_4 exists as free T_3 (FT_3) and free T_4 (FT_4). T_4 is deiodinated in the tissues to either T_3 (active) or reverse T_3 (inactive). In peripheral tissues, T_3 binds to high-affinity nuclear thyroid hormone receptors in the cytoplasm and translocates to the nucleus, exerting its biologic effects by modifying gene expression.

The T_4 level is low in hypothyroidism. It may also be low in premature infants, malnutrition, severe illness, and following therapy with T_3 . It is not clear whether premature infants with low T_4 benefit from treatment. T_4 is also low in situations that affect TBG. TBG levels are decreased in familial TBG deficiency, nephrosis, and in patients receiving androgens. In sepsis, TBG cleavage is increased. Treatment with certain medications (heparin, furosemide, salicylates, and phenytoin) results in abnormal binding to TBG. However, since these effects involve primarily TBG levels, and not thyroid function per se, TSH and FT_4 levels remain in the normal range.

T_3 and T_4 levels are high in hyperthyroidism and may be elevated in conditions associated with increased TBG levels (congenital TBG excess, pregnancy, estrogen therapy) and increased thyroid hormone binding to transport proteins.

HYPOTHYROIDISM (CONGENITAL & ACQUIRED HYPOTHYROIDISM)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Growth retardation, decreased physical activity, weight gain, constipation, dry skin, cold intolerance, and delayed puberty.
- ▶ Neonates with congenital hypothyroidism often look normal but may have thick tongue, large fontanelles, poor muscle tone, hoarseness, umbilical hernia, jaundice, and intellectual retardation.
- ▶ T_4 , FT_4 , and T_3 resin uptake are low; TSH levels are elevated in primary hypothyroidism.

▶ General Considerations

Thyroid hormone deficiency may be congenital or acquired (Table 32–4). It can be due to defects in the thyroid gland (primary hypothyroidism) or in the hypothalamus or pituitary (central hypothyroidism).

Congenital hypothyroidism occurs in about 1:3000–1:4000 infants. Untreated, it causes severe neurocognitive impairment. Most cases are sporadic resulting from hypoplasia or aplasia of the thyroid gland or failure of the gland to migrate to its normal anatomic location (ie, lingual or sublingual thyroid gland). Another cause of congenital hypothyroidism is dysmorphogenesis due to enzymatic defects in thyroid hormone synthesis. Since antithyroid drugs, including propylthiouracil (PTU) and methimazole, freely cross the placenta, goitrous hypothyroid newborns may be born to hyperthyroid mothers treated with these drugs during pregnancy.

Low T_4 levels may also be caused by decreased TSH secretion associated with prolonged glucocorticoid use, dopamine, or somatostatin. Cabbage, soybeans, aminosalicic acid, thiourea derivatives, resorcinol, phenylbutazone, cobalt, and excessive iodine intake can cause goiter and hypothyroidism during pregnancy. Many of these agents cross the placenta and should be used with caution during pregnancy. Iodine deficiency also causes hypothyroidism. In severe maternal iodine deficiency, both the fetus and the mother are T_4 -deficient, with irreversible brain damage in the fetus.

Juvenile hypothyroidism, particularly if goiter is present, is usually a result of chronic lymphocytic (Hashimoto) thyroiditis.

Several hundred patients with resistance to thyroid hormone have been described. These syndromes are generally familial and are classified on the basis of the site of resistance (eg, generalized, pituitary, or peripheral tissue).

▶ Clinical Findings

A. Symptoms and Signs

Even when the thyroid gland is completely absent, most newborns with congenital hypothyroidism appear normal at

Table 32–4. Causes of hypothyroidism.

A. Congenital

1. Aplasia, hypoplasia, or maldescent of thyroid
 - a. Embryonic defect of thyroid development
2. Inborn errors of thyroid hormone synthesis, secretion, or recycling (due to autosomal recessive mutations)
 - a. Iodide transport defect
 - b. Organification defect
 - (1) Mutation in iodine peroxidase
 - (2) Mutation in pendrin: Pendred syndrome, associated with congenital sensorineural deafness
 - c. Coupling defect
 - d. Iodotyrosine deiodinase defect
 - e. Abnormal iodinated polypeptide (thyroglobulin)
 - f. Inability to convert T_4 to T_3
3. Maternal antibody-mediated (inhibit TSH binding to receptor)
4. TSH receptor defect
5. Thyroid hormone receptor defect
6. In utero exposures
 - a. Radioiodine
 - b. Goitrogens (propylthiouracil, methimazole)
 - c. Iodine excess
7. Iodide deficiency (endemic cretinism)

B. Acquired (juvenile hypothyroidism)

1. Autoimmune (lymphocytic) thyroiditis
2. Thyroidectomy or radioiodine therapy for
 - a. Thyrotoxicosis
 - b. Thyroid cancer
3. Irradiation to the thyroid
4. Thyrotropin deficiency
 - a. Isolated
 - b. Associated with other anterior pituitary hormone deficiencies
5. TRH deficiency due to hypothalamic injury or disease
6. Medications
 - a. Iodides
 - (1) Excess (eg, amiodarone)
 - (2) Deficiency
 - b. Lithium
 - c. Cobalt
7. Large hemangiomas
8. Idiopathic

T_3 , triiodothyronine; T_4 , thyroxine; TRH, thyrotropin-releasing hormone.

birth and gain weight normally for the first few months of life without treatment. Since congenital hypothyroidism must be treated as early as possible to prevent intellectual impairment, the diagnosis should be based on the newborn screening test and not on signs or symptoms. Jaundice associated with an unconjugated hyperbilirubinemia may be present in newborns with congenital hypothyroidism. Some infants may have obvious findings of thick tongue, hypotonia, large fontanelles, constipation, umbilical hernia, hoarse cry, and dry skin.

Juvenile hypothyroidism often presents with short stature and abnormal weight gain. Other findings include delayed epiphyseal development, delayed closure of fontanelles, and retarded dental eruption. The skin may be dry, thick, scaly, coarse, pale, cool, or mottled, or have a yellowish tinge. The

hair may be dry, coarse, or brittle. Lateral thinning of the eyebrows may occur. Musculoskeletal findings include hypotonia and a slow relaxation component of deep tendon reflexes (best appreciated in the ankles). Muscular hypertrophy (Kocher-Debré-Semélaigne syndrome) is not commonly seen in congenital hypothyroidism. Other findings include physical and mental sluggishness, nonpitting myxedema, constipation, large tongue, hypothermia, bradycardia, hoarse voice or cry, umbilical hernia, and transient deafness. Puberty may be delayed. Metromenorrhagia may occur in older girls. Sometimes, hypothyroidism induces pseudopuberty. Galactorrhea can also occur, due to stimulation of prolactin secretion.

In hypothyroidism resulting from enzymatic defects, ingestion of goitrogens, or chronic lymphocytic thyroiditis, the thyroid gland may be enlarged. Thyroid enlargement in children is usually symmetrical, and the gland is moderately firm and not nodular. In chronic lymphocytic thyroiditis, however, the thyroid frequently has a cobblestone surface.

B. Laboratory Findings

Total T_4 and FT_4 levels are decreased. T_3 resin uptake (T_3RU) is low. In primary hypothyroidism, the serum TSH level is elevated. In central hypothyroidism, the TSH level may be low or inappropriately normal. Circulating autoantibodies to thyroid peroxidase and thyroglobulin may be present. Serum prolactin may be elevated, resulting in galactorrhea. Serum GH may be decreased, with subnormal GH response to stimulation in children with severe primary hypothyroidism, as well as low IGF-1 or IGF-binding protein 3 levels, or both.

C. Imaging

Thyroid imaging, while helpful in establishing the cause of congenital hypothyroidism, is not usually obtained, as it does not affect the treatment plan. Bone age is delayed. Centers of ossification, especially of the hip, may show multiple small centers or a single stippled, porous, or fragmented center (epiphyseal dysgenesis). Cardiomegaly is common. Long-standing primary hypothyroidism may be associated with thyrotrophic hyperplasia characterized by an enlarged sella or pituitary gland.

D. Screening Programs for Neonatal Hypothyroidism

All newborns should be screened for congenital hypothyroidism shortly after birth as most do not have suggestive physical findings. Depending on the state, the newborn screen either measures the total T_4 or TSH level. Abnormal newborn screening results should be confirmed immediately with a T_4 and TSH level. Treatment should be started as soon as possible. Initiation of treatment in the first month of life and good compliance during infancy usually results in a normal neurocognitive outcome.

► Differential Diagnosis

Primary hypothyroidism due to intrinsic defects of the thyroid gland must be differentiated from central hypothyroidism due to pituitary or hypothalamic hormone deficiencies of TSH or TRH. TSH and T_4 levels in combination are the most useful tests. When central hypothyroidism is diagnosed, evaluation for other pituitary hormone deficiencies and head MRI imaging are required.

► Treatment

Levothyroxine (75–100 mcg/m²/d) is the drug of choice for acquired hypothyroidism. In neonates with congenital hypothyroidism, the initial dose is 10–15 mcg/kg/d. Serum total T_4 or FT_4 concentrations are used to monitor the adequacy of initial therapy because the normally high neonatal TSH may not normalize for several days to weeks. Subsequently, T_4 and TSH are used in combination, as elevations of serum TSH are sensitive early indicators of the need for increased medication or better compliance.

THYROIDITIS

1. Chronic Lymphocytic Thyroiditis (Chronic Autoimmune Thyroiditis, Hashimoto Thyroiditis)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Firm, freely movable, nontender, diffusely enlarged thyroid gland.
- Thyroid function is usually normal but may be elevated or decreased depending on the stage of the disease.

▶ General Considerations

Chronic lymphocytic thyroiditis is the most common cause of goiter and acquired hypothyroidism in childhood. It is more common in girls, and the incidence peaks during puberty. The disease is caused by an autoimmune attack on the thyroid. Susceptibility to thyroid autoimmunity (and other endocrine autoimmune disorders) is associated with certain histocompatibility alleles.

▶ Clinical Findings

A. Symptoms and Signs

The thyroid is characteristically enlarged, firm, freely movable, nontender, and symmetrical. It may also be nodular. Onset is usually insidious. Occasionally patients note a sensation of tracheal compression or fullness, hoarseness, and dysphagia. No local signs of inflammation or systemic infection are present. Most patients are euthyroid. Some patients are symptomatically hypothyroid, and few patients are symptomatically hyperthyroid.

B. Laboratory Findings

Laboratory findings vary. Serum concentrations of TSH, T_4 , FT_4 , and T_3RU are usually normal. Some patients are hypothyroid with an elevated TSH and low thyroid hormone levels. Few patients are hyperthyroid with a suppressed TSH and elevated thyroid hormone levels. Thyroid antibodies (antithyroglobulin, antithyroid peroxidase) are frequently elevated. Thyroid uptake scan adds little to the diagnosis. Surgical or needle biopsy is diagnostic but seldom indicated.

▶ Treatment

The treatment of chronic lymphocytic thyroiditis with normal thyroid function is controversial. Full replacement doses of thyroid hormone may decrease the size of the thyroid, but may also result in hyperthyroidism. Hypothyroidism commonly develops over time. Consequently, patients require lifelong surveillance. Children with documented hypothyroidism should receive thyroid hormone replacement.

2. Acute (Suppurative) Thyroiditis

Acute thyroiditis is rare. The most common causes are group A streptococci, pneumococci, *Staphylococcus aureus*, and anaerobes. Oropharyngeal organisms are thought to reach the thyroid via a patent foramen cecum and thyroglossal duct remnant. Thyroid abscesses may form. The patient is always toxic with fever and chills. The thyroid gland is enlarged and exquisitely tender with associated erythema, hoarseness, and dysphagia. Thyroid function tests are typically normal. Patients have a leukocytosis, “left shift,” and elevated erythrocyte sedimentation rate. Specific antibiotic therapy should be administered.

3. Subacute (Nonsuppurative) Thyroiditis

Subacute thyroiditis (de Quervain thyroiditis) is rare. It is thought to be caused by viral infection with mumps, influenza, echovirus, coxsackievirus, Epstein-Barr virus, or adenovirus. Presenting features are similar to acute thyroiditis: fever, malaise, sore throat, dysphagia, and thyroid pain that may radiate to the ear. The thyroid is firm and enlarged. Sedimentation rate is elevated. In contrast to acute thyroiditis, the onset is generally insidious and serum thyroid hormone concentrations may be elevated.

HYPERTHYROIDISM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Nervousness, emotional lability, hyperactivity, fatigue, tremor, palpitations, excessive appetite, weight loss, increased perspiration, and heat intolerance.
- ▶ Goiter, exophthalmos, tachycardia, widened pulse pressure, systolic hypertension, weakness, and smooth, moist, warm skin.
- ▶ TSH is suppressed. Thyroid hormone levels (T_4 , FT_4 , T_3 , T_3RU) are elevated.

▶ General Considerations

In children, most cases of hyperthyroidism are due to Graves disease, caused by antibodies directed at the TSH receptor that stimulate thyroid hormone production. Hyperthyroidism may also be due to acute, subacute, or chronic thyroiditis; autonomous functioning thyroid nodules; tumors producing TSH; McCune-Albright syndrome; exogenous thyroid hormone excess; and acute iodine exposure.

▶ Clinical Findings

A. Symptoms and Signs

Hyperthyroidism is more common in females than males. In children, it most frequently occurs during adolescence. The course of hyperthyroidism tends to be cyclic, with spontaneous remissions and exacerbations. Symptoms include worsening school performance, poor concentration, fatigue, hyperactivity, emotional lability, nervousness, personality disturbance, insomnia, weight loss (despite increased appetite), palpitations, heat intolerance, increased perspiration, diarrhea, polyuria, and irregular menses. Signs include tachycardia, systolic hypertension, increased pulse pressure, tremor, proximal muscle weakness, and moist, warm, skin. Accelerated growth and development may occur. Thyroid storm is a rare condition characterized by fever, cardiac failure, emesis, delirium, coma, and death. Most cases of Graves disease are associated with a diffuse firm goiter. A thyroid bruit and thrill may be

present. Many cases are associated with exophthalmos, but severe ophthalmopathy is rare.

B. Laboratory Findings

TSH is suppressed. T_4 , FT_4 , T_3 , FT_3 , and T_3RU are elevated except in rare cases in which only the serum T_3 is elevated (T_3 thyrotoxicosis). The presence of thyroid-stimulating immunoglobulin (TSI) confirms the diagnosis of Graves disease. TSH receptor binding antibodies (TRaB) are usually elevated.

C. Imaging

In Graves disease, radioactive iodine uptake by the thyroid is increased, whereas in subacute and chronic thyroiditis it is decreased. An autonomous hyperfunctioning nodule takes up iodine and appears as a “hot nodule” while the surrounding tissue has decreased iodine uptake. In children with hyperthyroidism, bone age may be advanced. In infants, accelerated skeletal maturation may be associated with premature fusion of the cranial sutures. Long-standing hyperthyroidism causes osteoporosis.

► Differential Diagnosis

Hypermetabolic states (severe anemia, chronic infections, pheochromocytoma, and muscle-wasting disease) may resemble hyperthyroidism clinically but differ in thyroid function tests.

► Treatment

A. General Measures

In untreated hyperthyroidism, strenuous physical activity should be avoided. Bed rest may be required in severe cases.

B. Medical Treatment

1. β -Adrenergic blocking agents—These agents are adjuncts to therapy. They can rapidly ameliorate symptoms such as nervousness, tremor, and palpitations, and are indicated in severe disease with tachycardia and hypertension. β_1 -Specific agents such as atenolol are preferred because they are more cardioselective.

2. Antithyroid agents (propylthiouracil [PTU] and methimazole)—Antithyroid agents are frequently used in the initial treatment of childhood hyperthyroidism. These drugs interfere with thyroid hormone synthesis. PTU also inhibits the peripheral conversion of T_4 to T_3 . It usually takes a few weeks to produce a clinical response and adequate control is usually achieved within a few months. If medical therapy is unsuccessful, more definitive therapy, such as radioablation of the thyroid or thyroidectomy, should be considered.

A. INITIAL DOSAGE—Methimazole is initiated at a dose of 10–60 mg/d (0.5–1 mg/kg/d) given once a day. PTU is started

at a dose of 150–600 mg/d (5–10 mg/kg/d) in three divided doses. Initial dosing is continued until FT_4 or T_4 have normalized and signs and symptoms have subsided.

B. MAINTENANCE—The optimal dose of maintenance medication remains unclear. Recent studies suggest that 10–15 mg/d of methimazole or 100–150 mg/d of PTU provide adequate long-term control in most patients with a minimum of side effects. If the TSH level becomes elevated, many providers decrease the dose of the antithyroid agent. Some providers continue the same dose of antithyroid agent and add exogenous thyroid hormone replacement.

C. TOXICITY—If rash, vasculitis, arthralgia or arthritis, granulocytopenia, or hepatitis occur, the drug must be discontinued.

3. Iodide—Large doses of iodide usually produce a rapid but short-lived blockade of thyroid hormone synthesis and release. This approach is recommended only for acute management of severely thyrotoxic patients.

C. Radiation Therapy

Radioactive iodine ablation of the thyroid is usually reserved for children whose Graves disease is unresponsive to medications, who develop adverse effects from medications, who fail to remit after several years of medical therapy, or who are poorly adherent with therapy. Some pediatric endocrinologists advocate radioablation as first-line therapy for children with Graves disease. Antithyroid agents should be discontinued 4–7 days prior to radioablation to allow resumption of radioiodine uptake by the thyroid. ^{131}I administered orally concentrates in the thyroid and results in gradual ablation of the gland. In the first 2 weeks following radioablation, hyperthyroidism may worsen as thyroid tissue is destroyed and thyroid hormone is released. Therapy with a β -adrenergic antagonist may be necessary for a few months until FT_4 and T_4 normalize. In most cases, hypothyroidism develops and thyroid hormone replacement is needed. Long-term follow-up studies have not shown any increased incidence of thyroid cancer, leukemia, infertility, or birth defects in patients who receive ablative doses of ^{131}I .

D. Surgical Treatment

Subtotal and total thyroidectomy are infrequently used in children with Graves disease. Surgery is indicated for extremely large goiters, goiters with a suspicious nodule, very young or pregnant patients, or patients refusing radioiodine ablation. Before surgery, a β -adrenergic blocking agent should be given to treat symptoms and antithyroid agents should be given for several weeks to minimize the surgical risks associated with hyperthyroidism. Iodide (eg, Lugol's solution, 1 drop every 8 hours, or saturated solution of potassium iodide, 1–2 drops daily) should be given for 1–2 weeks prior to surgery to reduce thyroid vascularity and inhibit release of thyroid hormone. Surgical complications include hypoparathyroidism, recurrent laryngeal nerve damage, and rarely,

death. An experienced thyroid surgeon is crucial to good surgical outcome. After thyroidectomy, patients become hypothyroid and need thyroid hormone replacement.

► Course & Prognosis

Partial remissions and exacerbations may continue for several years. Treatment with an antithyroid agent results in prolonged remissions in one third to two thirds of children.

Neonatal Graves Disease

Transient congenital hyperthyroidism (neonatal Graves disease) occurs in about 1% of infants born to mothers with Graves disease. It occurs when maternal TSH receptor antibodies cross the placenta and stimulate excess thyroid hormone production in the fetus and newborn. Neonatal Graves disease can be associated with irritability, IUGR, poor weight gain, flushing, jaundice, hepatosplenomegaly, and thrombocytopenia. Severe cases may result in cardiac failure and death. Hyperthyroidism may develop several days after birth, especially if the mother was treated with PTU (which crosses the placenta). Symptoms develop as PTU levels decline in the newborn after birth. Thyroid studies should be obtained at birth and repeated within the first week. Immediate management should focus on the cardiac manifestations. Temporary treatment may be necessary with iodide, antithyroid agents, β -adrenergic antagonists, or corticosteroids. Hyperthyroidism gradually resolves over 1–3 months as maternal antibodies decline. As TSH receptor antibodies may still be present in the serum of previously hyperthyroid mothers after thyroidectomy or radioablation, neonatal Graves disease should be considered in all infants of mothers with a history of hyperthyroidism.

THYROID CANCER

Thyroid cancer is rare in childhood. Children usually present with a thyroid nodule or an asymptomatic asymmetrical neck mass. Dysphagia and hoarseness are unusual but may

occur. Thyroid function tests are usually normal. A “cold” nodule is often seen on a technetium or radioiodine uptake scan of the thyroid. Fine-needle aspiration biopsy of the nodule assists in the diagnosis.

The most common thyroid cancer is papillary thyroid carcinoma, a well-differentiated carcinoma arising from the thyroid follicular cell. Children frequently present with local metastases to the cervical lymph nodes and occasionally with pulmonary metastasis. Despite its aggressive presentation, children with papillary thyroid carcinoma have a relatively good prognosis, with a 20-year survival rate greater than 90%. Treatment consists of total thyroidectomy and removal of all involved lymph nodes, usually followed by radioiodine ablation to destroy residual thyroid remnant and metastatic tissue left behind after surgery. Thyroid hormone replacement is then started to suppress TSH to prevent stimulation of residual thyroid tissue. Since papillary thyroid carcinoma in children is associated with a high recurrence rate, regular follow-up with serum thyroglobulin levels (a tumor marker), neck ultrasound, and radioiodine whole body scan are required.

Follicular thyroid carcinoma, medullary thyroid carcinoma, anaplastic carcinoma, and lymphoma are less common thyroid malignancies. Medullary thyroid carcinoma, due to autosomal dominant mutations in the RET proto-oncogene, arises from the thyroid C cells, which secrete calcitonin. It can occur sporadically or can be inherited in multiple endocrine neoplasia (MEN) type 2 and familial medullary thyroid carcinoma. It is associated with elevated serum calcitonin levels. In affected families, all members should be screened for the mutation, and those identified with the mutation should be treated with prophylactic thyroidectomy in early childhood.

DISORDERS OF CALCIUM & PHOSPHORUS METABOLISM

Serum calcium concentration is tightly regulated by the coordinated actions of the parathyroid glands, kidney, liver, and small intestine. Low serum calcium concentrations, detected by calcium-sensing receptors on the surface of parathyroid cells, stimulate parathyroid hormone (PTH) release. PTH in turn promotes release of calcium and phosphorus from bone, reabsorption of calcium from urinary

filtrate, and excretion of phosphorus in the urine. Another essential cofactor in calcium homeostasis is 1,25-dihydroxy vitamin D (calcitriol). The first step in production of this active form of vitamin D occurs in the liver where dietary vitamin D is hydroxylated to 25-hydroxy vitamin D. The final step in formation of calcitriol is 1-hydroxylation, which takes place in the kidney under control of PTH. The primary effect of calcitriol is to promote the absorption of calcium from the intestines. In concert with PTH, it also facilitates calcium and phosphorus mobilization from bones. Deficiencies or excesses of PTH or calcitriol, abnormalities in their receptors, or abnormalities of vitamin D metabolism lead to clinically significant aberrations in calcium homeostasis. Although calcitonin, released from the thyroid gland C cells, also reduces serum calcium concentration, changes in its serum concentration rarely cause clinically relevant disease.

HYPOCALCEMIC DISORDERS

A normal serum calcium concentration is approximately 8.9–10.2 mg/dL, depending on the laboratory. The normal concentration of ionized calcium is approximately 1.1–1.3 mmol/L. Levels in newborns are slightly lower, and in premature infants may be as low as 7 mg/dL. Fifty to 60% of calcium in the serum is protein-bound and metabolically fairly inactive. Thus, measurement of ionized serum calcium, the metabolically active form, is helpful if serum proteins are low or in conditions such as acidosis that cause abnormal calcium binding to protein.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Tetany with facial and extremity numbness, tingling, cramps, spontaneous muscle contractures, carpopedal spasm, positive Trousseau and Chvostek signs, loss of consciousness, and convulsions.
- ▶ Diarrhea, prolongation of electrical systole (QT interval), and laryngospasm.
- ▶ In hypoparathyroidism or pseudohypoparathyroidism: defective nails and teeth, cataracts, and ectopic calcification in the subcutaneous tissues and basal ganglia.

▶ General Considerations

Hypocalcemia is a consistent feature of conditions such as hypoparathyroidism, pseudohypoparathyroidism, transient tetany of the newborn, and severe vitamin D deficiency rickets and may be present in rare disorders of vitamin D action (receptor defects). Hypocalcemia may also occur in intestinal malabsorption of calcium, chronic renal disease, tumor lysis syndrome, or rhabdomyolysis, or as the result of an activating mutation in the calcium-sensing receptor of the

parathyroid glands and kidneys (hypercalciuric hypocalcemia). (See Table 32–5.)

Deficient PTH *secretion* may due to deficient parathyroid tissue (DiGeorge syndrome), autoimmunity, or sometimes, magnesium deficiency. Decreased PTH *action* may be due to magnesium deficiency, vitamin D deficiency, or defects in the PTH receptor (pseudohypoparathyroidism). Occasionally, PTH deficiency is idiopathic. Table 32–6 summarizes the characteristics of disorders of PTH secretion and action. Autoimmune parathyroid destruction with subsequent hypoparathyroidism may be isolated, or associated with other autoimmune disorders in the APECED syndrome (autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy, or APS-1). Hypoparathyroidism may also result from unavoidable surgical removal in patients with thyroid cancer. Other features of the DiGeorge syndrome (a deletion of 22.q11) include congenital absence of the thymus (with thymus-dependent immunologic deficiency) and cardiovascular anomalies, especially coarctation of the aorta.

Autosomal dominant hypocalcemia (also called familial hypercalciuric hypocalcemia) is associated with a gain-of-function mutation in the calcium receptor, which causes a low serum PTH despite hypocalcemia, and excessive urinary loss of calcium. A family history of hypocalcemia may be the clue that differentiates this condition from other causes of hypocalcemia.

Transient neonatal hypoparathyroidism (transient tetany of the newborn) is caused both by a relative deficiency of PTH secretion and PTH action (see Table 32–6). The early form of this condition (first 2 weeks of life) occurs in newborns with birth asphyxia. In mothers with hyperparathyroidism, maternal hypercalcemia may suppress fetal PTH secretion and cause early transient neonatal hypoparathyroidism. Likewise, women with gestational diabetes may have relative hyperparathyroidism in the third trimester and their infants may experience transient hypoparathyroidism. Associated hypomagnesemia often aggravates the symptoms associated with hypocalcemia. The late form of neonatal hypoparathyroidism (after 2 weeks of age) occurs in infants receiving high-phosphate formulas (whole cow's milk is a well-known example). Phosphate binds calcium and produces functional hypocalcemia.

Tumor lysis syndrome and rhabdomyolysis cause cellular destruction that liberates large amounts of intracellular phosphate that complex with serum calcium, producing functional hypocalcemia. Malabsorption states such as celiac disease impair the absorption of calcium, vitamin D and magnesium, all of which cause hypocalcemia (see Table 32–6). Hypomagnesemia, due to losses from the gastrointestinal tract or kidney, may cause or augment the severity of hypocalcemia by impairing the release of PTH.

Rickets is a term describing the characteristic clinical and bony radiologic features associated with vitamin D deficiency (see Chapter 10). Vitamin D deficiency caused by lack of sunlight exposure or dietary deficiency is the most com-

Table 32-5. Hypocalcemia associated with rickets and other disorders.

Condition	Pathogenesis	Disease States/ Inheritance	Clinical Features	Initial Biochemical Findings			
				Serum Calcium	Serum Phosphorus	Serum Alkaline Phosphatase	Other
Malabsorption	Impairment in intestinal absorption in any or all of the following: calcium, vitamin D, and magnesium	Cystic fibrosis, celiac disease, Shwachman syndrome	Failure to thrive, poor weight gain, steatorrhea, superimposed vitamin D deficiency rickets	Low or normal	Low or normal	Variable: usually high in vitamin D deficiency, but may be low with concomitant zinc deficiency	Potentially low magnesium levels, potentially low 25-OH vitamin D
Chronic renal insufficiency	Decreased renal phosphate excretion, decreased 1-OHase activity	Obstruction, glomerulonephritis, dysplastic kidneys	Uremia, growth failure, acidosis	Low or normal	Elevated	Elevated or normal	Elevated PTH levels in long-standing cases, low 1,25-OH vitamin D
Rhabdomyolysis	Muscle damage with liberation of large amounts of intracellular phosphate	Crush injuries of muscles, Pompe disease, carnitine deficiency	Hypocalcemic tetany, cardiac arrhythmia, risk of renal failure	Low	Elevated	Normal	Myoglobinuria
Tumor lysis syndrome	Release of intracellular phosphate and potassium	Initiation of chemotherapy for ALL, Burkitt lymphoma, or other malignancies	Hypocalcemic tetany, cardiac arrhythmia, risk of renal failure	Low	Elevated	Normal	Hyperkalemia, elevated uric acid
Vitamin D-deficiency rickets	Deficient dietary vitamin D intake, vitamin D malabsorption; other risk factors include dark skin and lack of sunlight exposure	May cluster in families due to shared risk factors	Characteristic skeletal changes appear early, poor growth, symptomatic hypocalcemia is a late finding	Normal until late in course	Low or normal	Elevated	Elevated PTH levels, low 25-OH vitamin D
Vitamin D-dependent rickets	Mutation in 1-hydroxylase enzyme required for synthesis of fully active 1,25-OH vitamin D	Autosomal recessive inheritance	Skeletal changes of rickets, symptomatic hypocalcemia	Low	Low or normal	Elevated	Elevated PTH, low 1,25-OH vitamin D
Vitamin D-resistant rickets	Mutation in 1,25-OH vitamin D receptor	Autosomal recessive inheritance	Severe skeletal changes of rickets, total alopecia, symptomatic hypocalcemia	Low	Low or normal	Elevated	Elevated PTH, elevated 1,25-OH vitamin D
Hypophosphatemic rickets	Excessive loss of phosphate in the urine (? due to abnormal humoral factor)	X-linked dominant	Skeletal changes primarily in the lower extremities—genu varum or valgus, short stature	Normal or low	Very low	Usually high	Normal PTH levels initially, abnormally high urinary phosphate excretion

ALL, acute lymphoblastic leukemia; PTH, parathyroid hormone.

Table 32-6 Hypocalcemia associated with disorders of parathyroid hormone secretion or action.

Condition	Pathogenesis	Inheritance Pattern	Clinical Features	Initial Biochemical Findings ^a			
				Serum Calcium	Serum Phosphorus	Serum Alkaline Phosphatase	Serum PTH
Isolated hypoparathyroidism	Trauma, surgical destruction, isolated autoimmune destruction, rare familial forms	None; reports in familial forms of inheritance as X-linked recessive, autosomal recessive, or autosomal dominant	Symptoms of hypocalcemia	Low	High	Normal/Low	Low
DiGeorge syndrome	Deletion in chromosome 22	Majority represent new mutations	Symptoms of hypocalcemia, cardiac anomalies, immune disorder	Low	High	Normal/Low	Low
APS type 1	Autoimmune destruction	Autosomal recessive	Mucocutaneous candidiasis, Addison disease; potential for autoimmune destruction in other endocrine glands	Low	High	Normal/Low	Low
PHP type IA	Mutation in stimulatory G protein; resistance to PTH action	Autosomal dominant	AHO phenotype, variable hypocalcemia, may have resistance to other hormones using G protein signaling	Low or normal	Elevated or normal	Variable	Elevated
PPHP	Mutation in stimulatory G protein	Autosomal dominant—frequently found within same families with PHP type IA	AHO phenotype, biochemical parameters are normal	Normal	Normal	Normal	Normal
Transient tetany of the newborn—late onset	Deficiency in PTH secretion or action	Sporadic—associated with difficult deliveries, infants of diabetic mothers, or maternal hyperparathyroidism	Onset of symptoms of hypocalcemia within 2 wk of birth	Low	Normal or low	Normal or low	Normal or low
Transient tetany of the newborn—early onset	Deficiency in PTH secretion or action	Sporadic—associated with infant formulas that have a high phosphate content	Onset of symptoms of hypocalcemia after 2 wk of age	Low	Normal or low	Normal or low	Normal or low
Familial hypercalciuric hypocalcemia	Gain of functional mutation of calcium-sensing receptor	Autosomal dominant	Symptoms of hypocalcemia, family history	Low	High	Normal/Low	Low

^aUrinary calcium excretion (calcium/creatinine ratio) is low in all but familial hypercalciuric hypocalcemia.

AHO, Albright hereditary osteodystrophy; APS, autoimmune polyglandular syndrome; PHP, pseudohypoparathyroidism; PPHP, pseudopseudohypoparathyroidism; PTH, parathyroid hormone.

mon cause of rickets. Occult vitamin D deficiency is probably more common than is presently recognized. This concern forms the basis for the recommendation by the American Association of Pediatrics that breast-fed infants receive vitamin D supplementation of 200 IU/d. Rickets can also be caused by defects in the metabolism of vitamin D (see Table 32–5), including liver disease (impaired 25-hydroxylation), kidney disease (impaired 1-hydroxylation of 25-(OH) vitamin D), genetic deficiency of 1α -hydroxylase (vitamin D–dependent rickets), or end-organ resistance to vitamin D (vitamin D–resistant rickets).

Familial hypophosphatemic rickets has skeletal findings similar to those of vitamin D–related rickets. The defect in this condition is abnormal renal phosphate loss. Dietary deficiency of calcium may also cause rickets but more often causes osteopenia.

► Clinical Findings

A. Symptoms and Signs

Prolonged hypocalcemia from any cause is associated with tetany, photophobia, blepharospasm, and diarrhea. The symptoms of tetany are numbness, muscle cramps, twitching of the extremities, carpopedal spasm, and laryngospasm. Tapping the face in front of the ear causes facial spasms (Chvostek sign). Some patients with hypocalcemia exhibit bizarre behavior, irritability, loss of consciousness, and convulsions. Retarded physical and mental development may be present. Headache, vomiting, increased intracranial pressure, and papilledema may occur. In early infancy, respiratory distress may be a presenting finding.

B. Laboratory Findings

In rickets, calcium levels may be low or normal (see Tables 32–5 and 32–6). Phosphate levels in hypocalcemia disorders may be low, normal, or high depending on the cause of the hypocalcemia. Magnesium levels may also be low. PTH levels are reduced in many hypocalcemic conditions, but may be elevated in pseudohypoparathyroidism or severe vitamin D deficiency. Measurement of urinary excretion of calcium as the calcium-to-creatinine ratio can assist in diagnosis and monitoring of therapy in children on calcitriol therapy.

C. Imaging

Soft tissue and basal ganglia calcification may occur in idiopathic hypoparathyroidism and pseudohypoparathyroidism. Various skeletal changes are associated with rickets, including cupped and irregular long bone metaphyses. Torsional deformities can result in genu varum (bowleg). Accentuation of the costochondral junction gives the rachitic rosary appearance seen on the chest wall.

► Differential Diagnosis

Tables 32–5 and 32–6 outline the features of disorders associated with hypocalcemia. In individuals with hypoalbuminemia, the total serum calcium may be low and yet the functional serum ionized calcium is normal. Ionized calcium is the test of choice for hypocalcemia in patients with low serum albumin.

► Treatment

A. Acute or Severe Tetany

Hypocalcemia is corrected acutely by administration of intravenous calcium gluconate or calcium chloride; 10 mg/kg is the usual dose in acute treatment. Intravenous calcium infusions should not exceed 50 mg/min because of possible cardiac arrhythmia. Cardiac monitoring should be performed during calcium infusion.

B. Maintenance Management of Hypoparathyroidism or Chronic Hypocalcemia

The objective of treatment is to maintain the serum calcium and phosphate at near normal levels without excess urinary calcium excretion.

1. Diet—Diet should be high in calcium with added calcium supplements starting at a dose of 50–75 mg of elemental calcium per kilogram of body weight per day divided in three to four doses. The dose may be changed based on response of serum level and urinary calcium excretion. Therapy should be monitored to prevent hypercalcemia. Supplemental calcium can often be discontinued in patients with rickets after vitamin D therapy has stabilized.

2. Vitamin D supplementation—Various vitamin D preparations are available. Ergocalciferol (vitamin D₂) and calcitriol (1,25-dihydroxyvitamin D₃) are used in most cases. Ergocalciferol is preferred for treatment of vitamin D deficiency. However, impaired metabolism of vitamin D to its active end product, 1,25-(OH)₂ vitamin D, or impaired PTH function requires supplementation with calcitriol. Selection and dosage of vitamin D supplements varies with the underlying condition and the response to therapy. Monitoring of therapy is essential to avoid toxicity.

3. Monitoring—Dosages of calcium and vitamin D must be tailored for each patient. Monitoring serum calcium, urine calcium, and serum alkaline phosphatase levels at 1–3-month intervals is necessary to ensure adequate therapy and to prevent hypercalcemia and nephrocalcinosis.

The major goals of monitoring are to ensure (1) maintenance of serum calcium and phosphorus concentrations within normal ranges, (2) normalization of alkaline phosphatase activity for age, (3) regression of skeletal changes, and (4) maintenance of an age-appropriate urine calcium-to-creatinine ratio. The ratio should be less than 0.8 in newborns, 0.3–0.6 in children, and less than 0.25 in adolescents (creatinine and calcium measured in mg/dL).

Monitoring goals are somewhat different in hypophosphatemic rickets. Serum calcium and alkaline phosphatase

should be maintained within normal limits. Phosphorus levels should be corrected only to the low normal range. Monitoring of serum PTH is necessary to ensure that secondary hyperparathyroidism does not develop from excessive phosphate treatment or inadequate calcitriol replacement.

PEUDOHYPOPARATHYROIDISM (RESISTANCE TO PARATHYROID HORMONE ACTION)

In pseudohypoparathyroidism (PHP), PTH production is adequate, but target organs (renal tubule, bone, or both) fail to respond because of receptor resistance. Resistance to PTH action is due to a heterozygous inactivating mutation in the stimulatory G protein subunit associated with the PTH receptor, which leads to impaired signaling. Resistance to other G protein–dependent hormones such as TSH, GHRH, and follicle-stimulating hormone (FSH)/luteinizing hormone (LH), may also be present.

There are several types of PHP with variable biochemical and phenotypic features (see Table 32–6). Biochemical abnormalities in PHP (hypocalcemia and hyperphosphatemia) are similar to those seen in hypoparathyroidism, but the PTH levels are elevated. PHP may be accompanied by a characteristic phenotype known as Albright hereditary osteodystrophy (AHO), which includes short stature; round, full facies; irregularly shortened fourth metacarpal; a short, thick-set body; delayed and defective dentition; and mild mental retardation. Corneal and lenticular opacities and ectopic calcification of the basal ganglia and subcutaneous tissues (osteoma cutis) may occur with or without abnormal serum calcium levels. Treatment is the same as for hypoparathyroidism.

Pseudopseudohypoparathyroidism (PPHP) describes individuals with the AHO phenotype, but normal calcium homeostasis. PHP and PPHP can occur in the same cohort. Genomic imprinting is probably responsible for the different phenotypic expression of disease. Heterozygous loss of the maternal allele causes PHP and heterozygous loss of the paternal allele causes PPHP.

HYPERCALCEMIC STATES

Hypercalcemia is defined as a serum level above 11 mg/dL. Severe hypercalcemia is a level above 13.5 mg/dL.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Abdominal pain, polyuria, polydipsia, hypertension, nephrocalcinosis, failure to thrive, renal stones, intractable peptic ulcer, constipation, uremia, and pancreatitis.
- ▶ Bone pain or pathologic fractures, subperiosteal bone resorption, renal parenchymal calcification or stones, and osteitis fibrosa cystica.
- ▶ Impaired concentration, altered mental status, mood swings, and coma.

General Considerations

More than 80% of hypercalcemic children or adolescents have either hyperparathyroidism or a malignant tumor. Table 32–7 summarizes the differential diagnosis of childhood hypercalcemia.

Hyperparathyroidism is rare in childhood and may be primary or secondary. The most common cause of primary hyperparathyroidism is parathyroid adenoma. Diffuse parathyroid hyperplasia or multiple adenomas may occur in families. Familial hyperparathyroidism may be an isolated disease, or it may be associated with MEN type 1, or rarely type 2A. Hypercalcemia of malignancy is associated with

Table 32–7. Hypercalcemic states.

A. Primary hyperparathyroidism

1. Parathyroid hyperplasia
2. Parathyroid adenoma
3. Familial, including MEN types 1 and 2
4. Ectopic PTH secretion

B. Hypercalcemic states other than primary hyperparathyroidism associated with increased intestinal or renal absorption of calcium

1. Hypervitaminosis D (including idiopathic hypercalcemia of infancy)
2. Familial hypocalciuric hypercalcemia
3. Lithium therapy
4. Sarcoidosis
5. Phosphate depletion
6. Aluminum intoxication

C. Hypercalcemic states other than hyperparathyroidism associated with increased mobilization of bone minerals

1. Hyperthyroidism
2. Immobilization
3. Thiazides
4. Vitamin A intoxication
5. Malignant neoplasms
 - a. Ectopic PTH secretion or PTH-related protein (PTHrP)
 - b. Prostaglandin-secreting tumor and perhaps prostaglandin release from subcutaneous fat necrosis
 - c. Tumors metastatic to bone
 - d. Myeloma

MEN, multiple endocrine neoplasia; PTH, parathyroid hormone.

solid and hematologic malignancies and is due either to local destruction of bone by tumor or to ectopic secretion of PTH-related protein. When ectopic PTH-related protein is present, calcium is elevated, serum PTH is suppressed, and serum PTH-related protein is elevated. Chronic renal disease with impaired phosphate excretion is the most common secondary cause of hyperparathyroidism.

Kollars J et al: Primary hyperparathyroidism in pediatric patients. *Pediatrics* 2005;115:974 [PMID: 15805373].

► Clinical Findings

A. Symptoms and Signs

1. Due to hypercalcemia—Manifestations include hypotonicity and muscle weakness; apathy, mood swings, and bizarre behavior; nausea, vomiting, abdominal pain, constipation, and weight loss; hyperextensibility of joints; and hypertension, cardiac irregularities, bradycardia, and shortening of the QT interval. Coma occurs rarely. Calcium deposits occur in the cornea or conjunctiva (band keratopathy) and are detected by slitlamp examination. Intractable peptic ulcer and pancreatitis occur in adults but rarely in children.

2. Due to increased calcium and phosphate excretion—Loss of renal concentrating ability causes polyuria, polydipsia, and calcium phosphate deposition in renal parenchyma or as urinary calculi with progressive renal damage.

3. Due to changes in the skeleton—Initial findings include bone pain, osteitis fibrosa cystica, subperiosteal bone absorption in the distal clavicles and phalanges, absence of lamina dura around the teeth, spontaneous fractures, and moth-eaten appearance of the skull on radiographs. Later, there is generalized demineralization with high risk of subperiosteal cortical bone.

B. Imaging

Bone changes may be subtle in children. Technetium sestamibi scintigraphy is preferred over conventional procedures (ultrasound, computed tomography [CT], and MRI) for localizing parathyroid tumors.

► Treatment

A. Symptomatic Management

Initial management is vigorous hydration with normal saline and forced calcium diuresis with a loop diuretic such as furosemide (1 mg/kg given every 6 hours). If response is inadequate, glucocorticoids or calcitonin may be used. Bisphosphonates, standard agents for the management of acute hypercalcemia in adults, are being used more often in refractory pediatric hypercalcemia.

B. Chronic Hypercalcemia

Treatment options vary with the underlying cause. Resection of parathyroid adenoma or subtotal removal of hyperplastic

parathyroid glands is the preferred treatment. Postoperatively, hypocalcemia due to the rapid remineralization of chronically calcium-deprived bones may occur. A diet high in calcium and vitamin D is recommended immediately postoperatively and is continued until serum calcium concentrations are normal and stable. Treatment of secondary hyperparathyroidism from chronic renal disease is primarily directed at controlling serum phosphorus levels with phosphate binders. Pharmacologic doses of calcitriol are used to suppress PTH secretion. Long-term therapy for hypercalcemia of malignancy is the treatment of the underlying disorder.

► Course & Prognosis

The prognosis after resection of a single adenoma is excellent. The prognosis following subtotal parathyroidectomy for diffuse hyperplasia or removal of multiple adenomas is usually good and depends on correction of the underlying defect. In patients with multiple sites of parathyroid adenoma or hyperplasia, MEN is likely, and other family members may be at risk. Genetic counseling and DNA analysis to determine the specific gene defect are indicated.

FAMILIAL HYPOCALCIURIC HYPERCALCEMIA (FAMILIAL BENIGN HYPERCALCEMIA)

Familial hypocalciuric hypercalcemia is distinguished by low to normal urinary calcium excretion as a result of high renal reabsorption of calcium. PTH is normal or slightly elevated. In most cases, the genetic defect is a mutation in the membrane-bound calcium-sensing receptor expressed on parathyroid and renal tubule cells. It is inherited as an autosomal dominant trait with high penetrance. There is a low rate of new mutations. Most patients are asymptomatic, and treatment is unnecessary. A severe form of symptomatic neonatal hyperparathyroidism may occur in infants homozygous for the receptor mutation.

HYPERVITAMINOSIS D

Vitamin D intoxication is almost always the result of ingestion of excessive amounts of vitamin D. Signs, symptoms, and treatment of vitamin D–induced hypercalcemia are the same as those in other hypercalcemic conditions. Treatment depends on the stage of hypercalcemia. Severe hypercalcemia requires hospitalization and aggressive intervention. Due to the storage of vitamin D in the adipose tissue, several months of a low-calcium, low-vitamin D diet may be required.

IDIOPATHIC HYPERCALCEMIA OF INFANCY (WILLIAMS SYNDROME)

Williams syndrome is an uncommon disorder of infancy characterized by elfin-appearing facies and hypercalcemia in infancy. Other features include failure to thrive, mental and motor retardation, cardiovascular abnormalities (primarily

supravalvular aortic stenosis), irritability, purposeless movements, constipation, hypotonia, polyuria, polydipsia, and hypertension. A gregarious and affectionate personality is the rule in children with the syndrome. Hypercalcemia may not appear until several months after birth. Treatment consists of restriction of dietary calcium and vitamin D (Calcilo formula) and, in severe cases, moderate doses of glucocorticoids.

A defect in the metabolism of, or responsiveness to, vitamin D is postulated as the cause of Williams syndrome. Elastin deletions localized to chromosome 7 have been identified in more than 90% of patients. Fluorescent in-situ hybridization analysis (FISH) may be the best initial diagnostic tool. The risk of hypercalcemia generally resolves by age 4 years and dietary restrictions can be relaxed.

IMMOBILIZATION HYPERCALCEMIA

Abrupt immobilization, particularly in a rapidly growing adolescent, may cause hypercalcemia and hypercalciuria. Abnormalities often appear 1–3 weeks after immobilization. Medical or dietary intervention may be required in severe cases.

HYPOPHOSPHATASIA

Hypophosphatasia is a rare autosomal recessive condition characterized by deficiency of alkaline phosphatase activity in serum, bone, and tissues. Enzyme deficiency leads to poor skeletal mineralization with clinical and radiographic features similar to rickets. Six different clinical forms are identified. The perinatal form is characterized by severe skeletal deformity and death within a few days of birth. The infantile form includes failure to thrive, hypotonia, and craniosynostosis. The childhood form manifests with variable skeletal findings, reduced bone mineral density, and premature loss of deciduous teeth. Serum calcium levels may be elevated. The diagnosis of hypophosphatasia is made by demonstrating elevated urinary phosphoethanolamine associated with low serum alkaline phosphatase. Therapy is generally supportive. Children who survive the neonatal period may experience gradual improvement. Calcitonin may be of value for the acute treatment of hypercalcemia.

GONADS (OVARIES & TESTES)

DEVELOPMENT & PHYSIOLOGY

The fetal gonads develop from bipotential anlagen in the genital ridge. The genital ridge contains gonadal tissue, and

müllerian and wolffian structures with the potential to differentiate into components of the internal reproductive structures. Table 32–8 summarizes the male and female structures arising from müllerian and wolffian ducts. The *SRY* gene region of the Y chromosome, promotes testicular differentiation of the bipotential gonads. *WT1* and other transcription factors, such as *SF1*, *DAX1*, *WNT4*, and *SOX9*, are also important in gonadal differentiation. Once testicular differentiation has been determined, the fetal testis produces two substances critical for male differentiation. Antimüllerian hormone promotes the regression of müllerian structures, and testosterone stimulates growth of wolffian-based internal structures. Dihydrotestosterone (DHT), formed by 1α -reductase action on testosterone, is primarily responsible for virilization of the external genitalia. In the absence of both antimüllerian hormone and testosterone, differentiation into female internal and external genitalia occurs.

AMBIGUOUS GENITALIA

Ambiguous genitalia is the result of incomplete or disordered genital or gonadal development that causes a discordance between genetic sex, gonadal sex, and phenotypic sex. When an infant is born with ambiguity, immediate consultation with pediatric endocrinology, urology, and if possible psychiatry is required. Disorders of sexual differentiation stem from alterations in three main processes: gonadal differentiation, steroidogenesis, or androgen action.

1. Disorders of Gonadal Differentiation

These abnormalities include XY sex reversal, XX sex reversal, XY gonadal dysgenesis, true hermaphroditism, vanishing testes, and Leydig cell hypoplasia. Patients with XY sex reversal usually have pure gonadal dysgenesis. They have completely normal female external genitalia and present as girls with delayed puberty and amenorrhea. XX sex reversal, characterized by masculine or ambiguous genital development in an XX individual, can be caused by translocation of the *SRY* gene to the X chromosome. A true hermaphrodite may have both ovarian and testicular tissue and typically has a karyotype of 46,XX. Individuals with XY gonadal dysgenesis usually have a mosaic karyotype in which some cell lines are 45,XO and others are 46,XY. These individuals may present with normal male phenotype or ambiguity. Dysgenetic gonads have an increased risk for neoplastic transformation. Because of decreased testosterone production in utero, 46,XY individuals with vanishing testes or Leydig cell hypoplasia will have some degree of undervirilization.

2. Disorders of Steroidogenesis

These disorders generally present as micropenis, genital ambiguity, or complete absence of male external genitalia in an XY individual (Figure 32–6). Testicular tissue is present and produces antimüllerian hormone. Thus, internal struc-

Table 32-8. Sexual differentiation in the female and male.

Internal Duct Derivatives		
Müllerian Duct Derivatives		Wolffian Duct Derivatives ^a
Fallopian tubes (oviducts) and fimbriae		Epididymis
Uterus		Vas deferens
Cervix		Seminal vesicles
Vagina (posterior two thirds)		Ejaculatory duct
External Genitalia Homologues		
Primitive Structure	Female Genitalia	Male Genitalia ^b
Genital tubercle	Clitoris	Glans penis
Genital swelling	Labia majora	Scrotum
Genital/urethral fold	Labia minora	Penile urethra/corpora

^aNormal wolffian duct development is dependent on the local production of testosterone by Leydig cells of the adjacent testis and on testosterone's diffusion into the surrounding embryonic tissues. Thus, females with congenital adrenal hyperplasia who are virilized as the result of circulating androgens do not have wolffian duct development. Normal male development is also dependent on regression of müllerian duct derivatives through the local action of müllerian inhibiting factor elaborated by the Sertoli cells of the adjacent testis.

^bNormal development of male external genitalia depends on an adequate circulating concentration of testosterone, which is converted to dihydrotestosterone in the target tissues by 5 α -reductase. Elevated concentrations of other (adrenal) androgens, as occurs in females with congenital adrenal hyperplasia, can virilize the genital tubercle, and cause genital swelling and genital/urethral folds, resulting in varying degrees of ambiguity.

tures are wolffian. Disorders in this category include enzymatic defects in testosterone synthesis (12-ketoreductase deficiency) or defects in conversion of testosterone to DHT (5 α -reductase deficiency). If the enzyme defect is incomplete, the external genitalia may masculinize at puberty when testosterone production increases. Since the gonads and adrenal gland share common enzymes of steroid hormone production, some of the enzymatic defects associated with male genital ambiguity may also affect production of cortisol and aldosterone, leading to cortisol deficiency and salt wasting (see later section on the Adrenal Cortex). In an XX individual, the most common disorder in this category is congenital adrenal hyperplasia secondary to 21-hydroxylase deficiency. In the classic salt-losing form of this disorder, infant girls present with genital ambiguity but have normal uterus and ovaries.

3. Disorders of Androgen Action

Defects in testosterone action result from absent or defective androgen receptors (androgen insensitivity). Depending on the degree of abnormality in androgen binding, the genital phenotype can range from relatively mild male ambiguity to complete female external development.

4. Miscellaneous Syndromes

Syndromes such as VATER (vertebral defects, anal atresia, tracheoesophageal fistula with esophageal atresia, and radial

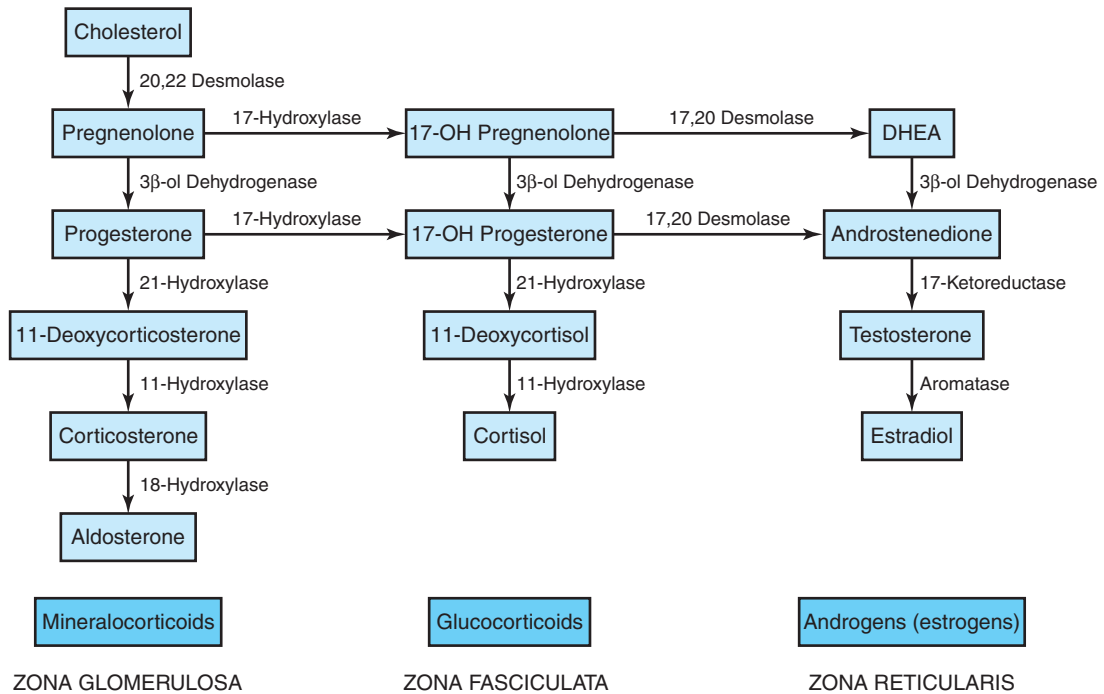

and renal anomalies), WAGR (Wilms tumor, aniridia, genitourinary malformations, and mental retardation), Denys-Drash, and Smith-Lemli-Opitz produce a wide variety of congenital anomalies, including genital ambiguity. Maternal exposure to androgens or androgen antagonists is a rare cause of genital ambiguity in newborns.

ABNORMALITIES IN FEMALE PUBERTAL DEVELOPMENT & OVARIAN FUNCTION

1. Precocious Puberty in Girls

Precocious puberty is defined as pubertal development occurring below the age limit set for normal onset of puberty. Puberty is considered precocious in girls if the onset of secondary sexual characteristics occurs before age 8 years. Precocious puberty is more common in girls than in boys. This disparity is explained by the large number of girls with central idiopathic precocity, a rare condition in boys. Girls between 6 and 8 years of age may also show signs of puberty but it can be a benign, slowly progressing form that requires no intervention. The age of pubertal onset may be advanced by obesity.

▲ Figure 32-6. The corticosteroid hormone synthetic pathway. The pathways illustrated are present in differing amounts in the steroid-producing tissues: adrenal glands, ovaries, and testes. In the adrenal glands, mineralocorticoids from the zona glomerulosa, glucocorticoids from the zona fasciculata, and androgens (and estrogens) from the zona reticularis are produced. The major adrenal androgen is androstenedione, because the activity of 17-ketoreductase is relatively low. The adrenal gland does secrete some testosterone and estrogen, however. The pathways leading to the synthesis of mineralocorticoids and glucocorticoids are not present to any significant degree in the gonads; however, the testes and ovaries each produce both androgens and estrogens. Further metabolism of testosterone to dihydrotestosterone occurs in target tissues of the action of the enzyme 5 α -reductase. DHEA, dehydroepiandrosterone.

Central (gonadotropin-releasing hormone [GnRH]-dependent) precocious puberty involves activation of the hypothalamic GnRH pulse generator, an increase in gonadotropin secretion, and a resultant increase in production of sex steroids (Table 32-9). The sequence of hormonal and physical events in central precocious puberty is identical to that of normal puberty. Central precocious puberty in girls is generally idiopathic but may be secondary to central nervous system (CNS) abnormality that disrupts the prepubertal restraint on the GnRH pulse generator. Such CNS abnormalities include, but are not limited to, hypothalamic hamartomas, CNS tumors, cranial irradiation, hydrocephalus, and trauma. Peripheral precocious puberty (GnRH-independent) occurs independent of gonadotropin secretion. In girls, peripheral precocious puberty is caused by ovarian or adrenal tumors, ovarian cysts, congenital adrenal hyperplasia, McCune-Albright syndrome, or exogenous estrogen. Estrogen-secreting ovarian or adrenal tumors are rare. Girls with these tumors typically present with markedly elevated estrogen levels and rapidly progressive pubertal changes.

Table 32-9. Causes of precocious pubertal development.

<p>A. Central (GnRH-dependent) precocious puberty</p> <ol style="list-style-type: none"> 1. Idiopathic 2. Central nervous system abnormalities <ol style="list-style-type: none"> a. Acquired—abscess, chemotherapy, radiation, surgical trauma b. Congenital—arachnoid cyst, hydrocephalus, hypothalamic hamartoma, septo-optic dysplasia, suprasellar cyst c. Tumors—astrocytoma, craniopharyngioma, glioma <p>B. Peripheral (GnRH-independent) precocious puberty</p> <ol style="list-style-type: none"> 1. Congenital adrenal hyperplasia 2. Adrenal tumors 3. McCune-Albright syndrome 4. Familial male-limited gonadotropin independent precocious puberty 5. Gonadal tumors 6. Exogenous estrogen—oral (contraceptive pills) or topical 7. Ovarian cysts (females) 8. HCG-secreting tumors (eg, hepatoblastomas, choriocarcinomas) (males)

GnRH, gonadotropin-releasing hormone; HCG, human chorionic gonadotropin.

McCune-Albright syndrome is a triad of irregular café-au-lait lesions, polyostotic fibrous dysplasia, and GnRH-independent precocious puberty. It is caused by an activating mutation in the gene encoding the α -subunit of G_s , the G protein that stimulates adenylyl cyclase. Endocrine cells with this mutation have autonomous hyperfunction and secrete excess amounts of their respective hormones.

► Clinical Findings

A. Symptoms and Signs

Female central precocious puberty usually starts with breast development, followed by pubic hair growth and menarche. The order may vary. Girls with ovarian cysts or tumors generally have signs of estrogen excess such as breast development and possibly vaginal bleeding. Adrenal tumors or congenital adrenal hyperplasia produce signs of adrenarche (ie, pubic hair, axillary hair, acne, and sometimes, increased body odor). Children with precocious puberty usually have accelerated growth and may temporarily be tall for age. However, because skeletal maturation advances at a more rapid rate than linear growth, final adult stature may be compromised.

B. Laboratory Findings

One of the first steps in evaluating a child with early pubertal development is obtaining a radiograph of the left hand and wrist to determine skeletal maturity (bone age). If the bone age is advanced, further evaluation is warranted. In central precocious puberty, the basal serum concentrations of FSH and LH may still be in the prepubertal range. Thus, documentation of the maturity of the hypothalamic-pituitary axis depends on demonstrating a pubertal LH response after stimulation with a GnRH agonist. In peripheral precocious puberty, basal serum FSH and LH are low, and the LH response to GnRH stimulation is suppressed by feedback inhibition of the hypothalamic-pituitary axis by the autonomously secreted gonadal steroids (see Figure 32-1). In girls with an ovarian cyst or tumor, estradiol levels will be markedly elevated. In girls with signs of adrenarche and an advanced bone age, androgen levels (testosterone, androstenedione, dehydroepiandrosterone) and possible adrenal intermediate metabolites (such as 17-hydroxyprogesterone) should be measured.

C. Imaging

When a diagnosis of central precocious puberty is made, an MRI of the brain should be done to evaluate for CNS lesions. It is unlikely that an abnormality will be found in girls 6–8 years of age, so the need for an MRI in this age group should be individually assessed. In girls whose laboratory tests suggest peripheral precocious puberty, an ultrasound of the ovaries and adrenal gland is indicated.

► Treatment

Girls with central precocious puberty can be treated with GnRH analogues, such as leuprolide. GnRH analogues downregulate pituitary GnRH receptors and thus decrease gonadotropin secretion. With treatment, physical changes of puberty regress or cease to progress, and linear growth slows to a prepubertal rate. Projected final heights often increase as a result of slowing of skeletal maturation. Usually, GnRH analogues are given as a monthly depot intramuscular injection and side effects are rare. After stopping therapy, pubertal progression resumes, and ovulation and pregnancy have been documented. Therapy is instituted for both psychosocial and final height considerations.

Treatment of peripheral precocious puberty is dependent on the underlying cause. In a girl with an ovarian cyst, intervention is generally not necessary, as the cyst usually regresses spontaneously. Treatment with glucocorticoids is indicated for congenital adrenal hyperplasia. Surgical resection is indicated for the rare adrenal or ovarian tumor.

In McCune-Albright syndrome, therapy with antiestrogens (eg, tamoxifen), agents that block estrogen synthesis (ketoconazole), or aromatase inhibitors (eg, letrozole) may be effective. Regardless of the cause of precocious puberty or the medical therapy selected, attention to the psychological needs of the patient and family is essential.

2. Benign Variants of Precocious Puberty

Premature thelarche (benign early breast development) occurs most commonly at 12–36 months. It is often bilateral but may begin or remain unilateral. In the absence of other signs of pubertal development (accelerated growth rate or skeletal maturation, pubic hair, vaginal mucosal maturation), no laboratory evaluation is necessary. Treatment is parental reassurance regarding the self-limited nature of the condition. Observation of the child every few months is also indicated. Onset of thelarche after age 36 months or in association with other signs of puberty requires evaluation.

Premature adrenarche (benign early adrenal maturation) is manifested by development of pubic hair and body odor, and less commonly, axillary hair and can occur before age 8 years. No increase in growth rate or skeletal maturation occurs, and no abnormal virilization (eg, clitoromegaly) is present. No treatment is required, although girls with premature adrenarche are at risk for developing polycystic ovarian syndrome during puberty.

3. Delayed Puberty

Delayed puberty in girls should be evaluated if there are no pubertal signs by age 13 years or menarche by 16 years. Failure to complete pubertal development to Tanner stage V within 4 years of onset is considered delay. Primary amenorrhea refers to the absence of menarche, and secondary amenorrhea refers to the cessation of established menses for at least 6 months.

The most common cause of delayed puberty is constitutional growth delay (Table 32–10). This growth pattern, characterized by short stature, normal growth velocity, and a delay in skeletal maturation, is described in detail earlier in this chapter. The timing of puberty is related to the bone age, not the chronologic age. Girls may also have delayed puberty from any condition that delays growth and skeletal maturation, such as hypothyroidism and growth hormone deficiency.

Primary hypogonadism in girls refers to a primary abnormality of the ovaries. The most common diagnosis in this category is Turner syndrome, in which the lack of or an abnormal second X chromosome leads to early loss of oocytes and accelerated stromal fibrosis. Other types of primary ovarian insufficiency are less common, including 46,XY gonadal dysgenesis, 46,XX gonadal dysgenesis, galactosemia, and autoimmune ovarian failure. Radiation and chemotherapy can also cause primary ovarian insufficiency.

Central hypogonadism refers to a hypothalamic or pituitary deficiency of GnRH or FSH/LH, respectively. Central hypogonadism can be functional (reversible), or caused by stress, undernutrition, prolactinemia, excessive exercise, or chronic illness. Permanent central hypogonadism is typically associated with conditions that cause multiple pituitary hormone deficiencies, such as congenital hypopituitarism, CNS tumors, or cranial irradiation. Isolated gonadotropin deficiency is rare but may occur in Kallmann syndrome, which

is also characterized by hyposmia or anosmia. In either primary or central hypogonadism, signs of adrenarche are generally present.

Delayed menarche or secondary amenorrhea may result from primary ovarian failure or central hypogonadism, or may be the consequence of hyperandrogenism, anatomic obstruction precluding menstrual outflow, or müllerian agenesis. This latter disorder is called Mayer-Rokitansky-Küster-Hauser syndrome and is characterized by an absent vagina and various uterine abnormalities, with or without renal and skeletal anomalies.

Girls with complete androgen insensitivity syndrome (androgen receptor defect) typically present with primary amenorrhea, breast development, and absence of sexual hair. The affected individual (46,XY) has functioning testes that produce müllerian-inhibiting hormone during fetal life. Thus no müllerian duct (oviduct or uterus) development occurs. External genitalia are female because of the lack of androgen action. At puberty, testosterone produced in the testes is aromatized to estrogen resulting in breast development.

► Clinical Evaluation

The history should ascertain whether and when puberty commenced, level of exercise, nutritional intake, stressors, sense of smell, symptoms of chronic illness, and family history of delayed puberty. Past growth records should be assessed to determine if height and weight velocity have been appropriate. Physical examination includes body proportions, breast and genital development, and stigmata of Turner syndrome. Pelvic examination or pelvic ultrasonography should be considered, especially in girls with primary amenorrhea.

A bone age radiograph should be obtained first. If the bone age is lower than that consistent with pubertal onset (< 12 years in girls), evaluations should focus on finding the cause of the bone age delay. If short stature and normal growth velocity are present, constitutional growth delay is likely. If growth rate is abnormal, laboratory studies may include a complete blood count, erythrocyte sedimentation rate, chemistry panel, and renal and liver function tests to look for unsuspected chronic medical illness. Evaluation for hypothyroidism and growth hormone deficiency may also be indicated. Measurement of FSH and LH may not be helpful in the setting of delayed bone age since prepubertal levels are normally low. Determination of a karyotype should be considered if there is short stature, or any stigmata of Turner syndrome.

If the patient has attained a bone age of more than 12 years consistent with onset of puberty and there are minimal or no signs of puberty on physical examination, FSH and LH levels will distinguish between primary ovarian failure and central hypogonadism. Primary ovarian failure is also called hypergonadotropic hypogonadism, as there is lack of estrogen feedback to the brain with elevated FSH and LH. If gonadotropins are elevated, a karyotype is the next step, as

Table 32–10. Cause of delayed puberty or amenorrhea.

A. Constitutional growth delay

B. Hypogonadism

1. Primary ovarian insufficiency
 - a. Gonadal dysgenesis (Turner syndrome, true gonadal dysgenesis)
 - b. Premature ovarian failure
 - (1) Autoimmune disease
 - (2) Surgery, radiation, chemotherapy
 - c. Galactosemia
2. Central hypogonadism
 - a. Hypothalamic or pituitary tumor, infection, irradiation
 - b. Congenital hypopituitarism
 - c. Kallmann syndrome
 - d. Functional (chronic illness, undernutrition, exercise, hyperprolactinemia)

C. Anatomic

1. Müllerian agenesis (Mayer-Rokitansky-Küster-Hauser syndrome)
2. Complete androgen resistance

Turner syndrome is the most common cause of female hypergonadotropic hypogonadism. Central hypogonadism is characterized by low gonadotropin levels, and evaluation is geared toward determining if the hypogonadism is functional or permanent. Laboratory tests should be directed toward identifying chronic disease and hyperprolactinemia. Cranial MRI may be helpful.

In girls with adequate breast development and amenorrhea, a progesterone challenge may be helpful to determine if sufficient estrogen is being produced. Girls who are producing estrogen have a withdrawal bleed after 5–10 days of oral progesterone, whereas those who are estrogen-deficient have little or no bleeding. The exception is girls with an absent uterus (androgen insensitivity or Mayer-Rokitansky-Küster-Hauser syndrome). They have sufficient estrogen but cannot have withdrawal bleeding. The most common cause of amenorrhea in girls with sufficient estrogen is polycystic ovarian syndrome. Girls who are estrogen-deficient should be evaluated similarly to those who have delayed puberty.

► Treatment

Replacement therapy in hypogonadal girls begins with estrogen alone at the lowest available dosage. Oral preparations such as estradiol or topical patches are used. Cyclic estrogen–progesterone therapy is started 12–18 months later, and eventually the patient may be switched over to a birth control pill for convenience. Progesterone therapy is needed to counteract the effects of estrogen on the uterus, as unopposed estrogen promotes endometrials hyperplasia. Estrogen is also necessary to promote bone mineralization and prevent osteoporosis.

4. Secondary Amenorrhea

See discussion of amenorrhea in Chapter 3.

ABNORMALITIES IN MALE PUBERTAL DEVELOPMENT & TESTICULAR FUNCTION

1. Precocious Puberty in Boys

Puberty is considered precocious in boys if secondary sexual characteristics appear before age 9 years. While the frequency of central precocious puberty is much lower in boys than girls, boys are more likely to have an associated CNS abnormality (see Table 32–9).

Several types of gonadotropin-independent (peripheral) precocious puberty occur in boys (see Table 32–9). Increased adrenal androgen production from an adrenal tumor or

from a virilizing form of congenital adrenal hyperplasia (CAH) will cause pubertal changes in boys. Familial male-limited gonadotropin-independent puberty (testotoxicosis) is a condition in which a mutated LH receptor on the Leydig cell is autonomously activated, resulting in testicular production of testosterone despite prepubertal LH levels. McCune-Albright syndrome can also occur in boys. Leydig cell tumors of the testis cause rapid onset of unilateral testicular enlargement and physical signs of testosterone excess. Human chorionic gonadotropin (HCG)–secreting tumors such as teratomas, CNS germinomas, and hepatoblastomas also cause early puberty in boys as HCG can stimulate the Leydig cells to produce testosterone.

► Clinical Findings

A. Symptoms and Signs

In precocious development, increased growth rate and growth of pubic hair are the most common presenting signs. Testicular size may differentiate central precocity, in which the testes enlarge, from gonadotropin-independent causes in which the testes usually remain small (< 2 cm in the longitudinal axis). Tumors of the testis are associated with either asymmetrical or unilateral testicular enlargement.

B. Laboratory Findings

Elevated testosterone levels verify early pubertal status but do not differentiate the source. As in girls, basal serum LH and FSH concentrations may not be in the pubertal range in boys with central precocious puberty, but the LH response to GnRH stimulation testing is pubertal. Sexual precocity caused by CAH is usually associated with abnormal plasma dehydroepiandrosterone, androstenedione, 17-hydroxyprogesterone (in CAH due to 21-hydroxylase deficiency), 11-deoxycortisol (in CAH due to 11-hydroxylase deficiency), or a combination of these steroids (see later section on the Adrenal Cortex). Serum β -HCG concentrations can signify the presence of an HCG-producing tumor (eg, CNS dysgerminoma or hepatoma) in boys who present with apparent true isosexual precocity (ie, accompanied by testicular enlargement) but suppressed gonadotropins following GnRH testing.

C. Imaging

In all boys with central precocious puberty, cranial MRI should be obtained to evaluate for a CNS abnormality. Ultrasonography may be useful in detecting hepatic, adrenal, and testicular tumors.

► Treatment

Treatment of central precocious puberty in boys is similar to that in girls. Treatment of McCune-Albright syndrome or familial Leydig cell hyperplasia with agents that block steroid synthesis (ketoconazole), with antiandrogens (spironolac-

tone), or a combination of the two has been successful. Estrogen receptor blockers (tamoxifen) or aromatase inhibitors (anastrozole or letrozole) have been used to delay skeletal maturation and early epiphyseal closure.

2. Delayed Puberty

Boys should be evaluated for delayed puberty if they have no secondary sexual characteristics by 14 years of age or if more than 5 years have elapsed since the first signs of puberty without completion of genital growth.

The most common cause of delayed puberty in boys, as in girls, is constitutional growth delay, a normal variant of growth that is described in detail earlier in this chapter. Testicular failure or insufficiency may be a primary, due to absence, malfunction, or destruction of testicular tissue, or central, due to pituitary or hypothalamic insufficiency. Primary testicular failure may be due to anorchia, Klinefelter syndrome (47,XXY) or other sex chromosome abnormalities, enzymatic defects in testosterone synthesis, or inflammation or destruction of the testes following infection (mumps), autoimmune disorders, radiation, trauma, or tumor.

Central hypogonadism may accompany panhypopituitarism, Kallmann syndrome (GnRH deficiency with anosmia), or isolated LH or FSH deficiencies. Destructive lesions in or near the anterior pituitary (especially craniopharyngioma and glioma) or infection may also result in hypothalamic or pituitary dysfunction. Prader-Willi syndrome and Laurence-Moon syndrome (Bardet-Biedl syndrome) are frequently associated with LH and FSH deficiency secondary to GnRH deficiency. Deficiencies in gonadotropins may be partial or complete. Functional or reversible gonadotropin may occur with chronic illness, malnutrition, hyperprolactinemia, hypothyroidism, or excessive exercise.

▶ Clinical Evaluation

The history should focus on whether and when puberty has started, testicular descent, symptoms of chronic illness, nutritional intake, sense of smell, and family history of delayed puberty. Physical examination should include body proportions, height and weight, pubertal stage, and testicular location, size, and consistency. Testes less than 2 cm in length are prepubertal; testes more than 2.5 cm in length suggests early pubertal growth.

A radiograph of the left hand and wrist to assess bone age should be the first step in evaluating a boy with delayed puberty. If bone age is delayed (< 11–12 years) and growth velocity is normal, constitutional growth delay is the most likely diagnosis.

Laboratory evaluation includes LH and FSH levels (especially if bone age is > 12 years). Elevated gonadotropin levels indicate primary hypogonadism or testicular failure. The most common cause of primary hypogonadism in boys is Klinefelter syndrome; however, the usual presentation of this

disorder is not delayed puberty but failure to complete puberty with a discrepancy noted between testicular size (small) and degree of virilization. If gonadotropin values are low, the working diagnosis is central hypogonadism and further evaluation should focus on looking for pituitary hormone deficiencies, chronic disease or undernutrition (or both), hyperprolactinemia, and CNS abnormalities.

▶ Treatment

Boys with simple constitutional delay may be offered a short (4–6 months) course of low-dose depot testosterone (50–75 mg per month) to stimulate their pubertal appearance and “jump-start” their endogenous development. In adolescents with permanent hypogonadism, treatment with depot testosterone, beginning with 50–75 mg intramuscularly each month, may be used until growth is complete. Thereafter, adult dosing (150–200 mg every 2–3 weeks) may be used. An alternative to intramuscular injections is testosterone gel, either in single-dose packets or in a pump set to dispense a preset dose. Gel is applied daily after showering. Specific therapy for GnRH deficiency with pulsatile subcutaneous GnRH may promote fertility in patients with hypothalamic-pituitary insufficiency. However, the inconvenience of treatment and the need for repeated doses for long periods of time have limited its application in pediatrics.

3. Cryptorchidism

Cryptorchidism (undescended testis) is common. It is most often unilateral and right-sided. At birth, approximately 4% of full-term male newborns have an undescended testis, with a higher proportion among premature infants (9–30%). In over 50% of these patients, the cryptorchid testis descends by the third month. By age 1 year, the prevalence of cryptorchidism is about 1%. Further descent may occur through puberty, perhaps stimulated by endogenous gonadotropins.

Infertility and testicular malignancy are major risks of cryptorchidism. The exact incidence of impaired fertility is unknown and incidence figures vary. However, histologic changes clearly occur as early as age 6 months in children with undescended testes. The reported malignancy rate in men with a cryptorchid testis is 48.9 per 100,000, 22 times the rate in the general population. In addition, tumors may develop in the contralateral testis, indicating that abnormal testicular development (dysgenesis) may be bilateral in unilateral cryptorchidism. In most cases, true cryptorchidism is thought to be the result of testicular dysgenesis. Cryptorchid testes frequently have a short spermatic artery and or poor blood supply. Although early scrotal positioning of undescended testes (orchidopexy) obviates further damage related to the intra-abdominal location, the testes generally remain abnormal, spermatogenesis is rare, and the risk of malignant neoplasm is increased.

Cryptorchidism can occur in an isolated fashion or associated with other findings. Abnormalities in the hypothalamic-pituitary axis are common, and the risk of

lamic-pituitary-gonadal axis predispose to cryptorchidism. Androgen biosynthesis or receptor defects also predispose to cryptorchidism and undervirilization.

The diagnosis of bilateral cryptorchidism in an apparently normal male newborn should never be made until the possibility that the child is actually a fully virilized female with potentially fatal salt-losing CAH has been considered.

► Clinical Findings

In infants younger than 3–4 months of age, LH, FSH, and testosterone levels help determine whether testes are present. After this time, an HCG stimulation test is done to confirm the presence or absence of abdominal testes. Ultrasonography, CT scanning, and MRI may detect testes in the inguinal region, but these studies are not completely reliable in finding abdominal testes.

► Differential Diagnosis

In palpating the testis, the cremasteric reflex that causes the testis to retract into the inguinal canal or abdomen (pseudocryptorchidism) may be elicited. To prevent retraction during examination, the fingers first should be placed across the abdominal ring and the upper portion of the inguinal canal to obstruct testicular ascent. Examination while the child is in the squatting position or in a warm bath is helpful. No treatment for retractile testes is necessary, and the prognosis for testicular descent and function is excellent.

► Treatment

A. Surgical Treatment

The current recommendation for treatment of cryptorchidism is that surgical orchidopexy be performed by an experienced surgeon if descent has not occurred by 1 year of age.

B. Hormonal Treatment

HCG at doses ranging from 250–1000 IU twice weekly for 5 weeks has been used for treatment. Such therapy generally causes descent of retractile testes, but is rarely successful in treating cryptorchidism. Androgen treatment (depot testosterone) is indicated as replacement therapy in the male child who lacks functional testes beyond the normal age of puberty.

4. Gynecomastia

Gynecomastia is a common, self-limited condition that may occur in up to 75% of normal pubertal boys. Adolescent gynecomastia typically resolves within 2 years but may not totally resolve if the degree of gynecomastia is extreme. Gynecomastia may sometimes occur as part of Klinefelter syndrome, or it may occur in boys who are taking drugs such as antidepressants or marijuana. Therapy, either medical (antiestrogens or aromatase inhibitors) or surgical, should be considered in prolonged or severe cases (see Chapter 3).

TESTICULAR TUMORS

Most malignant tumors of the testis are seminomas and teratomas. Seminomas are rare in childhood; they may be hormone-producing. The major hormone-producing tumor of the testis is the Leydig cell tumor. It is often associated with sexual precocity. Other testicular tumors (choriocarcinomas and dysgerminomas) have been reported in association with sexual precocity. Treatment of testicular tumors is surgical removal; chemotherapy and radiation therapy are not used in childhood unless there is high-grade malignancy or metastases. The prognosis in patients with Leydig cell tumors is generally good.

ADRENAL CORTEX

The adult adrenal cortex has a regional distribution of terminal steroid production. The outermost zona glomerulosa is the predominant source of aldosterone. The middle zona fasciculata makes cortisol and small amounts of mineralocorticoids. The innermost zona reticularis produces mainly androgens and estrogens. A fetal zone, or provisional cortex, that predominates during fetal development produces glucocorticoids, mineralocorticoids, androgens, and estrogens. The fetal zone is relatively deficient in β -ol dehydrogenase (see Figure 32–6); hence placentally produced progesterone is the major precursor used in fetal adrenal production of cortisol and aldosterone.

The adrenal cortical production of cortisol is under the control of pituitary adrenocorticotrophic hormone (ACTH; see Figure 32–1 and Table 32–1), which is in turn regulated by the hypothalamic peptide, corticotropin-releasing hormone (CRH). The complex interaction of CNS influences on CRH secretion, coupled with negative feedback of serum cortisol, leads to a diurnal pattern of ACTH and cortisol release. ACTH concentration is greatest during the early morning hours with a smaller peak in the late afternoon and a nadir at night. The pattern of serum cortisol concentration follows this pattern with a lag of a few hours. In the absence of cortisol feedback, there is dramatic CRH and ACTH hypersecretion.

Glucocorticoids are critical for gene expression in a many cell types. In excess, glucocorticoids are both catabolic and antianabolic; that is, they promote the release of amino acids from muscle and increase gluconeogenesis while decreasing incorporation of amino acids into muscle protein. They also antagonize insulin activity and facilitate lipolysis. Glucocor-

ticoids help maintain blood pressure by promoting peripheral vascular tone and sodium and water retention.

Mineralocorticoids (primarily aldosterone in humans) promote sodium retention and stimulate potassium excretion in the distal renal tubule. Although ACTH can stimulate aldosterone production, the predominant regulator of aldosterone secretion is the volume- and sodium-sensitive renin-angiotensin-aldosterone system. Elevations of serum potassium also directly influence aldosterone release from the cortex.

Androgen (dehydroepiandrosterone and androstenedione) production by the zona reticularis is insignificant before puberty. At the onset of puberty, androgen production increases and may be an important factor in the dynamics of puberty in both sexes. The adrenal gland is a major source of androgen in the pubertal and adult female.

ADRENOCORTICAL INSUFFICIENCY (ADRENAL CRISIS, ADDISON DISEASE)

The leading causes of adrenal insufficiency are hereditary enzyme defects (congenital adrenal hyperplasia), autoimmune destruction of the glands (Addison disease), central adrenal insufficiency caused by intracranial neoplasm or its treatment, or congenital midline defects associated with optic nerve hypoplasia (septo-optic dysplasia). A rare form of familial adrenal insufficiency occurs in association with cerebral sclerosis and spastic paraplegia (adrenoleukodystrophy). Addison disease may be familial and has been described in association with hypoparathyroidism, candidiasis, hypothyroidism, pernicious anemia, hypogonadism, and diabetes mellitus as one of the polyglandular autoimmune syndromes. Less commonly, the gland is destroyed by tumor, calcification, or hemorrhage (Waterhouse-Friderichsen syndrome). Adrenal disease secondary to opportunistic infections (fungal or tuberculous) is reported in AIDS. In children, central adrenal insufficiency due to anterior pituitary tumor is rare. A temporary salt-losing disorder resulting from partial mineralocorticoid deficiency or renal underresponsiveness (pseudohypoaldosteronism) may occur during infancy or with pyelonephritis.

Acute illness, surgery, trauma, or hyperthermia may precipitate an adrenal crisis in patients with adrenal insufficiency. Patients with primary adrenal insufficiency are at greater risk for life-threatening crisis than patients with central ACTH deficiency because mineralocorticoid secretion and low-level autonomous cortisol secretion remain intact in central ACTH deficiency.

► Clinical Findings

A. Symptoms and Signs

1. Acute form (adrenal crisis)—Manifestations include nausea, vomiting, diarrhea, abdominal pain, dehydration, fever (sometimes followed by hypothermia), weakness, hypotension, circulatory collapse, confusion and coma. In-

creased pigmentation may be associated with primary adrenal insufficiency caused by melanocyte-stimulating activity of the hypersecreted parent molecule, ACTH.

2. Chronic form—Manifestations include fatigue, hypotension, weakness, failure to gain, weight loss, salt craving (primary insufficiency), vomiting, and dehydration. Diffuse tanning with increased pigmentation over pressure points, scars, and mucous membranes may be present in primary adrenal insufficiency. A small heart may be seen on chest radiograph.

B. Laboratory Findings

1. Suggestive of adrenocortical insufficiency—In primary adrenal insufficiency, serum sodium and bicarbonate levels, arterial partial pressure of carbon dioxide, blood pH, and blood volume are decreased. Serum potassium and urea nitrogen levels are increased. Urinary sodium level and the ratio of urinary sodium to potassium are inappropriate for the degree of hyponatremia. In central adrenal insufficiency, serum sodium levels may be mildly decreased as a result of impaired water excretion. Eosinophilia and moderate lymphopenia occur in both forms of insufficiency.

2. Confirmatory tests

A. ACTH (COSYNTROPIN) STIMULATION TEST—In primary adrenal insufficiency (originating in the gland itself), plasma cortisol and aldosterone concentrations do not increase significantly over baseline 60 minutes after an intravenous dose of ACTH (250 mcg). To diagnose central adrenal insufficiency, a low dose of ACTH is given (1 mcg).

B. BASELINE SERUM ACTH CONCENTRATION—Values are elevated in primary adrenal failure and low in central adrenal insufficiency.

C. URINARY FREE CORTISOL AND 17-HYDROXYCORTICOSTEROID EXCRETION—Values are decreased.

D. CRH TEST—This test assesses responsiveness of the entire hypothalamic-pituitary-adrenal axis. After administration of ovine CRH, serum concentrations of ACTH and cortisol are measured over 2 hours. Verification of an intact axis or localization of the site of impairment is possible with careful interpretation of results.

► Differential Diagnosis

Acute adrenal insufficiency must be differentiated from severe acute infections, diabetic coma, various disturbances of the CNS, and acute poisoning. In the neonatal period, adrenal insufficiency may be clinically indistinguishable from respiratory distress, intracranial hemorrhage, or sepsis. Chronic adrenocortical insufficiency must be differentiated from anorexia nervosa, certain muscular disorders (myasthenia gravis), salt-losing nephritis, and chronic debilitating infections, and must be considered in cases of recurrent spontaneous hypoglycemia.

▶ Treatment

A. Acute Insufficiency (Adrenal Crisis)

1. Hydrocortisone sodium succinate—Hydrocortisone sodium succinate is given initially at a dose of 50 mg/m² intravenously over 2–5 minutes or intramuscularly; thereafter, it is given intravenously, 12.5 mg/m², every 4–6 hours until stabilization is achieved and oral therapy can be tolerated.

2. Fluids and electrolytes—In primary adrenal insufficiency, 5–10% glucose in normal saline, 10–20 mL/kg intravenously, is given over the first hour and repeated if necessary to reestablish vascular volume. Normal saline is continued thereafter at 1½–2 times the maintenance fluid requirements. Intravenous boluses of glucose (10% glucose, 2 mL/kg) may be needed every 4–6 hours to treat hypoglycemia. In central adrenal insufficiency, routine fluid management is generally adequate after restoration of vascular volume and institution of cortisol replacement.

3. Fludrocortisone—When oral intake is tolerated, fludrocortisone, 0.05–0.15 mg daily, is started and continued as necessary every 12–24 hours for primary adrenal insufficiency.

4. Inotropic agents—Rarely, inotropic agents such as dopamine and dobutamine are needed. However, adequate cortisol replacement is critical because pressor agents may be ineffective in adrenal insufficiency.

5. Waterhouse-Friderichsen syndrome with fulminant infections—The use of adrenocorticosteroids and norepinephrine in the treatment or prophylaxis of fulminant infections remains controversial. Corticosteroids may augment the generalized Shwartzman reaction in fatal cases of meningococemia. However, corticosteroids should be considered if there is possible adrenal insufficiency, particularly if there is hypotension and circulatory collapse.

B. Maintenance Therapy

Following initial stabilization, the most effective substitution therapy is hydrocortisone, combined with fludrocortisone in primary adrenal insufficiency. Overtreatment should be avoided as it causes obesity, growth retardation, and other cushingoid features. Additional hydrocortisone, fludrocortisone, or sodium chloride, singly or in combination, may be necessary with acute illness, surgery, trauma, or other stress reactions. Supportive adrenocortical therapy should be given whenever surgical operations are performed in patients who have at some time received prolonged therapy with adrenocorticosteroids.

1. Glucocorticoids—A maintenance dosage of 6–10 mg/m²/d of hydrocortisone (or equivalent) is given orally in two or three divided doses. The dosage of all glucocorticoids is increased to 30–50 mg/m²/d during intercurrent illnesses or other times of stress.

2. Mineralocorticoids—In primary adrenal insufficiency, fludrocortisone is given, 0.05–0.15 mg orally daily as a single

dose or in two divided doses. Periodic monitoring of blood pressure is recommended to avoid overdosing.

3. Salt—The child should be given ready access to table salt. Frequent blood pressure determinations in the recumbent position should be made to check for hypertension. In the infant, supplementation of 3–5 mEq Na⁺/kg/d by adding the injectable solution (4 mg/mL) to formula or breast milk is generally required until table foods are introduced.

C. Corticosteroids in Patients with Adrenocortical Insufficiency Who Undergo Surgery

1. Before operation—Hydrocortisone sodium succinate, 30–50 mg/m²/d intravenously 1 hour before surgery.

2. During operation—Hydrocortisone sodium succinate, 25–100 mg intravenously with 5–10% glucose in saline throughout surgery.

3. During recovery—Hydrocortisone sodium succinate, 12.5 mg/m² intravenously every 4–6 hours until oral doses are tolerated. The oral dose of three to five times the maintenance dose is continued until the acute stress is over, at which time the patient can be returned to the maintenance dose.

▶ Course & Prognosis

The course of acute adrenal insufficiency is rapid, and death may occur within a few hours, particularly in infants, unless adequate treatment is given. Spontaneous recovery is unlikely. Patients who have received long-term treatment with adrenocorticosteroids may exhibit adrenal collapse if they undergo surgery or other acute stress. Pharmacologic doses of glucocorticoids during these episodes may be needed throughout life. In all forms of acute adrenal insufficiency, the patient should be observed carefully once the crisis has passed and evaluated with laboratory tests to assess the degree of permanent adrenal insufficiency.

Patients with chronic adrenocortical insufficiency who receive adequate therapy can lead normal lives.

CONGENITAL ADRENAL HYPERPLASIAS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Genital virilization in females, with labial fusion, urogenital sinus, enlargement of the clitoris, or other evidence of androgen action.
- ▶ Salt-losing crises in infant males or isosexual precocity in older males with infantile testes.
- ▶ Increased linear growth and advanced skeletal maturation.

- ▶ Elevation of plasma 17-hydroxyprogesterone concentrations in the most common form; may be associated with hyponatremia, hyperkalemia, and metabolic acidosis, particularly in newborns.

▶ **General Considerations**

Autosomal recessive mutations in the enzymes of adrenal steroidogenesis in the fetus cause abnormal cortisol biosynthesis with increased ACTH secretion. ACTH excess subsequently results in adrenal hyperplasia with increased production of adrenal hormone precursors, including androgens. Increased pigmentation, especially of the scrotum, labia majora, and nipples, is common with excessive ACTH secretion. Congenital adrenal hyperplasia (CAH) is most commonly (> 80% of patients) the result of homozygous 21-hydroxylase (cytochrome P-450 C21) deficiency (see Figure 32–6). In its severe form, excess adrenal androgen production starting in the first trimester of fetal development causes virilization of the female fetus and life-threatening hypovolemic, hyponatremic shock (adrenal crisis) in the newborn. Other enzyme defects that less commonly result in CAH include 11-hydroxylase, 3β-ol dehydrogenase, 20,22-desmolase, 18-hydroxylase-17, and 22-desmolase deficiencies. The clinical syndromes associated with these defects are shown in Figure 32–6 and Table 32–11.

Studies of patients with 21-hydroxylase deficiency indicate that the clinical type (salt-wasting or non-salt-wasting) is usually consistent within a kindred and that a close genetic linkage exists between the 21-hydroxylase gene and the human leukocyte antigen complex on chromosome 6. The latter finding has allowed more precise heterozygote detection and prenatal diagnosis. Population studies indicate that the defective gene is present in 1:250–1:100 people and that the incidence of the disorder is 1:15,000–1:5000. Mass screening for this enzyme defect, using a microfilter paper technique to measure serum 17-hydroxyprogesterone, has been established in some U.S. states.

Nonclassic presentations of 21-hydroxylase deficiency have been reported with increasing frequency. Affected persons have a normal phenotype at birth but develop evidence of virilization during later childhood, adolescence, or early adulthood. In these cases, previously referred to as late-onset or acquired enzyme deficiency, results of hormonal studies are characteristic of 21-hydroxylase deficiency. An asymptomatic form has also been identified in which individuals have none of the phenotypic features of the disorder, but have hormonal study results identical to patients with nonclassic 21-hydroxylase deficiency. The nonclassic form appears to be less severe than the classic form. Because members of the same family may have classic, nonclassic, and asymptomatic forms, the disorders may be due to allelic variations of the same enzyme.

Table 32–11. Clinical and laboratory findings in adrenal enzyme defects resulting in congenital adrenal hyperplasia.

Enzyme Deficiency ^a	Urinary 17-Ketosteroids	Elevated Plasma Metabolite	Plasma Androgens	Aldosterone	Hypertension/Salt Loss	External Genitalia
20,22-Desmolase	↓↓↓	—	↓↓↓	↓↓↓	-/+	Males: ambiguous Females: normal
3β-ol Dehydrogenase	↑↑ (DHEA)	17-OH pregnenolone (DHEA)	↑ (DHEA)	↓↓↓	-/+	Males: ambiguous Females: possibly virilized
17-Hydroxylase	↓↓↓	Progesterone	↓↓	Normal to ↑	+/-	Males: ambiguous Females: normal
21-Hydroxylase ^a	↑↑↑	17-OHP	↑↑	↓↓	-/+	Males: normal Females: virilized
11-Hydroxylase	↑↑	11-Deoxycortisol	↑↑↓↓	(↑ Deoxycorticosterone)	+/-	Males: normal Females: virilized
17,20-Desmolase	↓↓↓	17-Hydroxysteroids (?)	↓↓	Normal	-/-	Males: ambiguous Females: normal

^aChildren with “simple virilizing (non-salt-wasting)” forms of 21-hydroxylase deficiency congenital adrenal hyperplasia (CAH) may have normal aldosterone production and serum electrolytes, but some children have normal aldosterone production and serum electrolytes at the expense of elevated plasma renin activity and are, by definition, compensated salt-wasters. These children usually receive mineralocorticoid as well as glucocorticoid treatment. Children with 21-hydroxylase deficiency CAH should therefore have documented normal plasma renin activity in addition to normal serum electrolytes before they are considered non-salt-wasters.

DHEA, dehydroepiandrosterone; 17-OHP, 17-hydroxyprogesterone.

► Clinical Findings

A. Symptoms and Signs

1. In females—Abnormality of the external genitalia varies from mild enlargement of the clitoris to complete fusion of the labioscrotal folds, forming a scrotum, a penile urethra, a penile shaft, and with clitoral enlargement sufficient to form a normal-sized glans (see Table 32–8). Signs of adrenal insufficiency (salt loss) may occur in the first days of life but more typically appear in the first or second week. Rarely, adrenal insufficiency does not occur for months or years. With milder enzyme defects, salt loss may not occur, and virilization predominates (simple virilizing form). In untreated non–salt-losing 21-hydroxylase or 11-hydroxylase deficiency, growth rate and skeletal maturation are accelerated and patients appear muscular. Pubic hair appears early (often before the second birthday), acne may be excessive, and the voice may deepen. Excessive pigmentation may develop. Final adult height is often compromised.

2. In males—The male infant usually appears normal at birth but may present with salt-losing crisis in the first 2–4 weeks of life. In milder forms, salt-losing crises may not occur. In this circumstance, enlargement of the penis and increased pigmentation may be noted during the first few months. Other symptoms and signs are similar to those of affected females. The testes are not enlarged except in the rare male in whom aberrant adrenal cells (adrenal rests) are present in the testes, producing unilateral or asymmetrical bilateral enlargement. In the rare isolated defect of 17,20-desmolase activity, ambiguous genitalia may be present because of impaired androgen production (see Figure 32–6).

B. Laboratory Findings

1. Blood—Hormonal studies are essential for accurate diagnosis. Findings characteristic of the enzyme deficiencies are shown in Table 32–11.

2. Genetic studies—Rapid chromosomal diagnosis should be obtained in any newborn with ambiguous genitalia.

C. Imaging

Adrenal ultrasonography, CT scanning, and MRI may be useful in defining pelvic anatomy or enlarged adrenals or in localizing an adrenal tumor. Contrast-enhanced radiographs of the vagina and pelvic ultrasonography may be helpful in delineating the internal anatomy in a newborn with ambiguous genitalia.

► Treatment

A. Medical Treatment

Treatment goals in CAH are normalization of growth velocity and skeletal maturation with the smallest dose of glucocorticoid that can suppress adrenal function. Excessive glu-

cocorticoids cause the undesirable side effects of Cushing syndrome. Mineralocorticoid replacement sustains normal electrolyte homeostasis, but excessive mineralocorticoids cause hypertension.

1. Glucocorticoids—Initially, parenteral or oral hydrocortisone (30–50 mg/m²/d) suppresses abnormal adrenal steroidogenesis within 2 weeks. When adrenal suppression has been accomplished, as evidenced by normalization of serum 17-hydroxyprogesterone, patients are placed on maintenance doses of 15–20 mg/m²/d in two or three divided doses. Between 50% and 60% of the daily dose should be given in the late evening to suppress early morning ACTH rise. Dosage is adjusted to maintain normal growth rate and skeletal maturation. Various serum and urine androgens have been used to monitor therapy, including 17-hydroxyprogesterone, androstenedione, and urinary pregnanetriol. No one test is universally accepted. In adolescent girls, normal menses are a sensitive index of the adequacy of therapy. Therapy should be continued throughout life in both males and females because of the possibility of malignant degeneration of the hyperplastic adrenal gland. In pregnant females with CAH, suppression of adrenal androgen secretion is critical to avoid virilization of the fetus, particularly a female fetus.

2. Mineralocorticoids—Fludrocortisone, 0.05–0.15 mg, is given orally once a day or in two divided doses. Periodic monitoring of blood pressure and plasma renin is recommended to adjust dosing.

B. Surgical Treatment

For affected females, consultation with a urologist experienced in female genital reconstruction should be arranged as soon as possible during infancy.

► Course & Prognosis

When therapy is initiated in early infancy, abnormal metabolic effects and progression of masculinization can be avoided. Treatment with glucocorticoids permits normal growth, development, and sexual maturation. If not adequately controlled, CAH results in sexual precocity and masculinization throughout childhood. Affected individuals will be tall as children but short as adults because of a rapid rate of skeletal maturation and premature closure of the epiphyses. If treatment is delayed or inadequate until somatic development is completed (12–14 years as determined by bone age), true central sexual precocity may occur in males and females.

Patient education stressing lifelong therapy is important to ensure compliance in adolescence and later life. Virilization and multiple surgical genital reconstructions are associated with a high risk of psychosexual disturbances in female patients. Ongoing psychological evaluation and support is a critical component of care.

ADRENOCORTICAL HYPERFUNCTION (CUSHING DISEASE, CUSHING SYNDROME)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Truncal adiposity, thin extremities, moon facies, muscle wasting, weakness, plethora, easy bruising, purple striae, decreased growth rate, and delayed skeletal maturation.
- ▶ Hypertension, osteoporosis, and glycosuria.
- ▶ Elevated serum corticosteroids, low serum potassium, eosinopenia, and lymphopenia.

▶ General Considerations

Cushing syndrome may result from excessive secretion of adrenal steroids autonomously (adenoma or carcinoma), excess pituitary ACTH secretion (Cushing disease), ectopic ACTH secretion, or chronic exposure to exogenous glucocorticoid medications. In children younger than 12 years, Cushing syndrome is usually iatrogenic (secondary to exogenous ACTH or glucocorticoids). It may rarely be due to adrenal tumor, adrenal hyperplasia, pituitary adenoma, or extrapituitary ACTH-producing tumor.

▶ Clinical Findings

A. Symptoms and Signs

1. **Excess glucocorticoid**—Manifestations include adiposity, most marked on the face, neck, and trunk (a fat pad in the interscapular area is characteristic); fatigue; plethoric facies; purplish striae; easy bruising; osteoporosis; hypertension; glucose intolerance; back pain; muscle wasting and weakness; and marked retardation of growth and skeletal maturation.
2. **Excess mineralocorticoid**—Patients have hypokalemia, mild hyponatremia with water retention, increased blood volume, edema, and hypertension.
3. **Excess androgen**—Hirsutism, acne, and varying degrees of virilization are present. Menstrual irregularities occur in older girls.

B. Laboratory Findings

1. Blood

A. PLASMA CORTISOL—Values are elevated, with loss of normal diurnal variation. Determination of cortisol level between midnight and 2 AM may be a sensitive indicator of the loss of diurnal variation.

B. SERUM CHLORIDE AND POTASSIUM—Both values are usually low, but serum sodium and bicarbonate concentrations may be elevated with metabolic alkalosis.

C. SERUM ACTH—ACTH concentration is decreased in adrenal tumor and increased with ACTH-producing pituitary or extrapituitary tumors.

D. CBC—Polymorphonuclear leukocytosis with lymphopenia and eosinopenia are common. Polycythemia occurs.

2. Salivary cortisol—This is a less invasive means by which to measure serial cortisol values, and the tests may be performed at home. Salivary cortisol obtained at midnight is a highly specific and sensitive test for hypercortisolism.

3. 24-Hour urinary free cortisol excretion—This value is elevated. It is considered the most useful initial test to document hypercortisolism, although midnight salivary cortisol is considered a reasonable and more practical alternative.

4. Response to dexamethasone suppression testing—The suppression of adrenal function by a small dose (0.5 mg) of dexamethasone is reduced in adrenal hyperfunction; larger doses (4–16 mg/d in four divided doses) of dexamethasone cause suppression of adrenal activity when the disease is due to ACTH hypersecretion, whereas hypercortisolism due to adenomas and adrenal carcinomas is rarely suppressed.

5. CRH test—The CRH stimulation test, in conjunction with petrosal sinus sampling, is effective in distinguishing pituitary and ectopic sources of ACTH excess and for lateralization of pituitary sources prior to surgery.

C. Imaging

Pituitary imaging may demonstrate a pituitary adenoma. Adrenal imaging by CT scan may demonstrate adenoma or bilateral hyperplasia. Radionuclide studies of the adrenals may be useful in complex cases. Osteoporosis, evident first in the spine and pelvis, with compression fractures may occur in advanced cases. Skeletal maturation is usually delayed.

▶ Differential Diagnosis

Children with exogenous obesity accompanied by striae and hypertension are often suspected of having Cushing syndrome. The child's height, growth rate, and skeletal maturation are helpful in differentiating the two. Children with Cushing syndrome have a poor growth rate, relatively short stature, and delayed skeletal maturation, while those with exogenous obesity usually have a normal or slightly increased growth rate, normal to tall stature, and advanced skeletal maturation. The color of the striae (purplish in Cushing syndrome, pink in obesity) and the distribution of the obesity assist in differentiation. The urinary free cortisol excretion (in milligrams per gram of creatinine) may be mildly elevated in obesity, but midnight salivary cortisol is normal.

► Treatment

In all cases of primary adrenal hyperfunction due to tumor, surgical removal, is indicated if possible. Glucocorticoids should be administered parenterally in pharmacologic doses during and after surgery until the patient is stable. Supplemental oral glucocorticoids, potassium, salt, and mineralocorticoids may be necessary until the suppressed contralateral adrenal gland recovers, sometimes over a period of several months. The use of mitotane, a DDT derivative that is toxic to the adrenal cortex, and aminoglutethimide, an inhibitor of steroid synthesis, have been suggested, but their efficacy in children with adrenal tumors has not been determined. Pituitary microadenomas may respond to pituitary surgery or irradiation.

► Prognosis

If the tumor is malignant, the prognosis is poor if it cannot be completely removed. If it is benign, cure is to be expected following proper preparation and surgery.

Yehuda R et al: Relationship between 24-hour urinary-free cortisol excretion and salivary cortisol levels sampled from awakening to bedtime in healthy subjects. *Life Sci* 2003;73:349 [PMID: 12757842].

PRIMARY HYPERALDOSTERONISM

Primary hyperaldosteronism may be caused by an adrenal adenoma or adrenal hyperplasia. It is characterized by paresthesias, tetany, weakness, nocturnal enuresis, periodic paralysis, low serum potassium and elevated serum sodium levels, hypertension, metabolic alkalosis, and production of large

volume, alkaline urine with low specific gravity. The specific gravity does not respond to vasopressin. Glucose tolerance test is frequently abnormal. Plasma and urinary aldosterone are elevated. In contrast to renal disease or Bartter syndrome, plasma renin activity is suppressed, creating a high aldosterone-to-renin ratio. In patients with adrenal tumor, ACTH may further increase the excretion of aldosterone. Marked improvement after the administration of an aldosterone antagonist such as spironolactone may be of diagnostic value.

Treatment is with glucocorticoids (glucocorticoid remediable hyperaldosteronism or familial hyperaldosteronism type 1), spironolactone (familial hyperaldosteronism type 2), or subtotal or total adrenalectomy for hyperplasia, and surgical removal if a tumor is present.

USES OF GLUCOCORTICIDS & ADRENOCORTICOTROPIC HORMONE IN TREATMENT OF NONENDOCRINE DISEASES

Glucocorticoids are used for their anti-inflammatory and immunosuppressive properties in a variety of conditions in childhood. Pharmacologic doses are necessary to achieve these effects, and side effects are common.

Numerous synthetic preparations possessing variable ratios of glucocorticoid to mineralocorticoid activity are available (Table 32–12).

Table 32–12. Potency equivalents for adrenocorticosteroids.

Adrenocorticosteroid	Trade Names	Potency/mg Compared with Cortisol (Glucocorticoid Effect)	Potency/mg Compared with Cortisol (Sodium-Retaining Effect)
Glucocorticoids			
Hydrocortisone (cortisol)	Cortef	1	1
Cortisone	Cortone Acetate	0.8	1
Prednisone	Meticorten, others	4–5	04
Methylprednisolone	Medrol, Meprolone	5–6	Minimal
Triamcinolone	Aristocort, Kenalog Kenacort, Atolone	5–6	Minimal
Dexamethasone	Decadron, others	25–40	Minimal
Betamethasone	Celestone	25	Minimal
Mineralocorticoid			
Fludrocortisone	Florinef	15–20	300–400

Actions

Glucocorticoids exert a direct or permissive effect on virtually every tissue of the body; major known effects include the following:

1. Gluconeogenesis in the liver
2. Stimulation of fat breakdown (lipolysis) and redistribution of body fat
3. Catabolism of protein with an increase in nitrogen and phosphorus excretion
4. Decrease in lymphoid and thymic tissue and a decreased cellular response to inflammation and hypersensitivity
5. Alteration of CNS excitation
6. Retardation of connective tissue mitosis and migration; decreased wound healing
7. Improved capillary tone and increased vascular compartment volume and pressure

Side Effects of Therapy

When prolonged use of pharmacologic doses of glucocorticoids is necessary, clinical manifestations of Cushing syndrome are common. Side effects may occur with the use of synthetic exogenous agents by any route, including inhalation and topical administration, or with the use of ACTH. Use of a larger dose of glucocorticoids given once every 48 hours (alternate-day therapy) lessens the incidence and severity of some of the side effects (Table 32–13).

Tapering of Pharmacologic Doses of Steroids

Prolonged use of pharmacologic doses of glucocorticoids causes suppression of ACTH secretion and consequent adrenal atrophy. The abrupt discontinuation of glucocorticoids may result in adrenal insufficiency. ACTH secretion generally does not restart until the administered steroid has been given in subphysiologic doses ($< 6 \text{ mg/m}^2/\text{d}$ orally) for several weeks.

If pharmacologic glucocorticoid therapy has been given for less than 10–14 days, the drug can be discontinued abruptly (if the condition for which it was prescribed allows) because adrenal suppression will be short-lived. However, it is advisable to educate the patient and family about the signs and symptoms of adrenal insufficiency in case problems arise.

If tapering is necessary in treating the condition for which the glucocorticoid is prescribed, a reduction of 25–50% every 2–7 days is sufficiently rapid to permit observation of clinical symptomatology. An alternate-day schedule (single dose given every 48 hours) will allow for a 50% decrease in the total 2-day dosage while providing the desired pharmacologic effect. If tapering is not required for the underlying disease, the dosage can be rapidly decreased safely to the physiologic range. Although a rapid decrease in dose to the physiologic range will not lead to frank adrenal insufficiency (because adequate exogenous cortisol is being provided), some patients may experience a steroid withdrawal syn-

Table 32–13. Side effects of glucocorticoid use.

A. Endocrine and metabolic effects
1. Hyperglycemia and glycosuria (chemical diabetes)
2. Cushing syndrome
3. Persistent suppression of pituitary-adrenal responsiveness to stress with resultant hypoadrenocorticism
B. Effects on electrolytes and minerals
1. Marked retention of sodium and water, producing edema, increased blood volume, and hypertension (more common in endogenous hyperadrenal states)
2. Potassium loss with symptoms of hypokalemia
3. Hypocalcemia, tetany
C. Effects on protein metabolism and skeletal maturation
1. Negative nitrogen balance, with loss of body protein and bone protein, resulting in osteoporosis, pathologic fractures, and aseptic bone necrosis
2. Suppression of growth, retarded skeletal maturation
3. Muscular weakness and wasting
4. Osteoporosis
D. Effects on the gastrointestinal tract
1. Excessive appetite and intake of food
2. Activation or production of peptic ulcer
3. Gastrointestinal bleeding from ulceration or from unknown cause (particularly in children with hepatic disease)
4. Fatty liver with embolism, pancreatitis, nodular panniculitis
E. Lowering of resistance to infectious agents; silent infection; decreased inflammatory reaction
1. Susceptibility to fungal infections; intestinal parasitic infections
2. Activation of tuberculosis; false-negative tuberculin reaction
3. Stimulation of activity of herpes simplex virus
F. Neuropsychiatric effects
1. Euphoria, excitability, psychotic behavior, and status epilepticus with electroencephalographic changes
2. Increased intracranial pressure with pseudotumor cerebri syndrome
G. Hematologic and vascular effects
1. Bleeding into the skin as a result of increased capillary fragility
2. Thrombosis, thrombophlebitis, cerebral hemorrhage
H. Miscellaneous effects
1. Myocarditis, pleuritis, and arteritis following abrupt cessation of therapy
2. Cardiomegaly
3. Nephrosclerosis, proteinuria
4. Acne (in older children), hirsutism, amenorrhea, irregular menses
5. Posterior subcapsular cataracts; glaucoma

drome, characterized by malaise, insomnia, fatigue, and loss of appetite. These symptoms may necessitate a two- or three-step decrease in dose to the physiologic range.

Once a physiologic equivalent dose (8–10 $\text{mg/m}^2/\text{d}$ hydrocortisone or equivalent) is achieved and the patient's underlying disease is stable, the dose can be decreased to 4–5 $\text{mg/m}^2/\text{d}$ given only in the morning. This will allow the adrenal axis to recover. After this dose has been given for 4–6 weeks, assessment of endogenous adrenal activity is estimated by obtaining fasting plasma cortisol concentrations between 7 and 8 AM prior to the morning steroid dose or by a low-dose ACTH stimulation test (1 mcg cosyntropin fol-

lowed by measurement of cortisol after 45–60 minutes). When an alternate-day schedule is followed, plasma cortisol is measured the morning before treatment. Plasma cortisol concentration in the physiologic range (> 10 mg/dL) indicates return of basal physiologic adrenal rhythm. Exogenous steroids may then be discontinued safely, although it is advisable to continue giving stress doses of glucocorticoids when appropriate until recovery of the response to stress has been documented.

After basal physiologic adrenal function returns, the adrenal reserve or capacity to respond to stress and infection can be estimated by the low-dose ACTH stimulation test, in which 1 mcg of synthetic ACTH (cosyntropin) is administered intravenously. Plasma cortisol is measured prior to (zero time) and at 45–60 minutes after the infusion. A plasma cortisol concentration greater than 18 mg/dL at 60 minutes indicates a satisfactory adrenal reserve.

Even if the results of testing are normal, patients who have received prolonged treatment with glucocorticoids may develop signs and symptoms of adrenal insufficiency during acute stress, infection, or surgery for months to years after treatment has been stopped. Careful monitoring, and the use of stress doses of glucocorticoids, should be considered during severe illnesses and surgery.

ADRENAL MEDULLA PHEOCHROMOCYTOMA

Pheochromocytoma is uncommon and only 10% of the reported cases occur in pediatric patients. The tumor can be located wherever chromaffin tissue (adrenal medulla, sympathetic ganglia, or carotid body) is present, possibly from decreased apoptosis of neural crest cells during development. It may be multiple, recurrent, and sometimes malignant. Familial forms include pheochromocytomas associated with the dominantly inherited neurofibromatosis type 1, MEN type 2, and von Hippel-Lindau syndromes, as well as mutations of the succinate dehydrogenase genes. Neuroblastomas, ganglioneuromas, and other neural tumors, as well as carcinoid tumors may secrete pressor amines and mimic pheochromocytoma.

The symptoms of pheochromocytoma are generally caused by excessive secretion of epinephrine or norepinephrine and most commonly include headache, sweating, tachycardia, and hypertension. Other symptoms are anxiety, hypertension, dizziness, weakness, nausea and vomiting, diarrhea, dilated pupils, blurred vision, abdominal and precordial pain, and vasomotor instability (flushing and postural hypotension). Sustained symptoms may lead to cardiac, renal, optic, or cerebral damage.

Laboratory diagnosis is possible in more than 90% of cases. Serum and urine catecholamines are elevated, but abnormalities may be limited periods of symptomatology or paroxysm. Plasma free metanephrine level (phenoxybenzamine, tricyclic antidepressants, and β -adrenoreceptor blockers can create false-positive results) is the most sensitive test and the gold standard for diagnosis. Levels three times the normal range are diagnostic. Intermediate values may require additional testing, with urinary vanillylmandelic acid and urinary total metanephrines providing the highest specificity. Provocative tests using histamine, tyramine, or glucagon and the phentolamine tests may be abnormal but are dangerous and are rarely necessary. After demonstrating a tumor biochemically, imaging methods including CT or MRI are used to localize the tumor. When available, functional ligands such as (123)I-MIBG, [18 F]DA positron emission tomography scanning and somatostatin receptor scintigraphy (with either [123 I]Tyr3-octreotide or [111 In]DTPA-octreotide) are useful in further diagnostic evaluation.

Laparoscopic tumor removal is the treatment of choice; however, the procedure must be undertaken with great caution and with the patient properly stabilized. Oral phenoxybenzamine or intravenous phentolamine is used preoperatively. Profound hypotension may occur as the tumor is removed but may be controlled with an infusion of norepinephrine, which may have to be continued for 1–2 days.

Unless irreversible secondary vascular changes have occurred, complete relief of symptoms is to be expected after recovery from removal of a benign tumor. However, prognosis is poor in patients with metastases, which occur more commonly with large, extra-adrenal pheochromocytomas.

Diabetes Mellitus

H. Peter Chase, MD
George S. Eisenbarth, MD, PhD

33

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Polyuria, polydipsia, and weight loss.
- ▶ Hyperglycemia and glucosuria with or without ketonuria.

GENERAL CONSIDERATIONS

Type 1 diabetes or immune-mediated diabetes (previously called juvenile diabetes or insulin-dependent diabetes mellitus [IDDM], non-immune-mediated) is the most common type of diabetes in people younger than age 40 years. It is associated with islet cell antibodies (immunologic markers), diminished insulin production, and being ketosis-prone.

Type 2 diabetes (non-insulin-dependent diabetes mellitus [NIDDM], non-immune-mediated) is the most common type in persons older than age 40 years; it is associated with being overweight, insensitivity to insulin, and not being prone to ketosis. Type 2 diabetes is increasing in frequency in children and is found in up to half of black and Hispanic children and in over two thirds of American Indian children who develop diabetes. It occurs most frequently in overweight teenagers.

Maturity-onset diabetes of youth (MODY) is much less common and comprises several forms of diabetes in non-obese children with identified genetic mutations (eg, mutations of glucokinase or hepatic nuclear factor 1 or 2 genes). It presents as a nonketotic form of diabetes without islet cell antibodies and often is associated with a family history of diabetes in several generations.

Neonatal diabetes, which is rare, is associated with several distinct etiologies that require specialty evaluation and specific therapies. For example, some children have transient neonatal diabetes. Others have specific mutations and are best treated with sulfonylurea medications after receiving initial insulin therapy.

▶ Pathogenesis

A. Type 1 Diabetes

Type 1 diabetes results from immunologic damage to the insulin-producing β -cells of the pancreatic islets. This damage occurs gradually—over months or years in most people—and symptoms do not appear until about 90% of the pancreatic islets have been destroyed. The immunologic damage requires a genetic predisposition and is probably influenced by environmental factors.

The importance of genetics is shown by the fact that among identical twins, more than 50% of second twins develop diabetes after the first twin develops the disease. About 6% of siblings or offspring of persons with type 1 diabetes also develop diabetes (compared with prevalence in the general population of 0.2–0.3%). The condition is more common in white children but occurs in all racial groups. There is an association with human leukocyte antigen (HLA)-DR3 and HLA-DR4, and about 95% of white diabetic children have at least one of these HLA types. Forty percent have both HLA-DR3 and HLA-DR4 (one from each parent), compared with only 3% of the general population.

The importance of environmental factors is suggested because not all second identical twins develop diabetes. Important environmental factors may be viral infections or factors in the diet.

The immunologic basis of diabetes is demonstrated by the ability of cyclosporin, a potent immunosuppressive agent, to preserve islet tissue for 1–2 years when given to newly diagnosed patients. However, renal damage from cyclosporin precludes its use. White blood cells are found in the islets of newly diagnosed patients and may release toxic products (free radicals, interleukin-1, and tumor necrosis factor) that injure the islets. Antibodies to islet cells, insulin, glutamic acid decarboxylase, ICA512 (IA-2), and other antigens are present for months to years prior to diagnosis in the serum of over 90% of patients who will develop type 1 diabetes. These antibodies are probably the effect and not the cause of islet β -cell destruction.

B. Type 2 Diabetes

Type 2 diabetes has a strong genetic component, although the inherited defects vary in different families. Obesity (particularly central) and lack of exercise are often major environmental contributing factors. Insulin insensitivity results from all of these circumstances. The prevalence is increased among females, which may be related to its association with the polycystic ovary syndrome. Acanthosis nigricans, a thickening and darkening of the skin over the posterior neck, armpits, or elbows, may aid in the diagnosis of type 2 diabetes.

► Prevention

A. Type 1 Diabetes

Free antibody screening is now available for families having a relative with type 1 diabetes (1-800-425-8361). Intervention trials on antibody-positive first-degree relatives have begun in an effort to try to prevent type 1 diabetes.

B. Type 2 Diabetes

The prevention of type 2 diabetes was evaluated in a large study, the Diabetes Prevention Program. The study found that 30 minutes of exercise per day (5 days/wk) and a low-fat diet reduced the risk of diabetes by 58%. Taking metformin also reduced the risk of type 2 diabetes by 31%.

► Clinical Findings

The classic symptoms of polyuria, polydipsia, and weight loss are now so well recognized that friends or family members often suspect the diagnosis of type 1 diabetes in affected individuals. Other cases may be detected by finding glucosuria on routine office urinalysis. Up to 50% of new cases of diabetes used to be diagnosed in patients presenting in coma, but most are now diagnosed before the individuals develop severe ketonuria, ketonemia, and secondary acidosis. Children often have a preceding minor illness, such as a flulike episode. Blood or urine glucose levels can be checked in a few seconds, which could be life-saving. No disease other than diabetes (mellitus or insipidus) presents with continued frequent urination in spite of a dry tongue. An oral glucose tolerance test is rarely necessary in children. A random blood glucose level above 300 mg/dL (16.6 mmol/L) or a fasting blood glucose level above 200 mg/dL (11 mmol/L) is sufficient to make the diagnosis of diabetes. The 1997 revised guidelines for the diagnosis of diabetes (see references) are a fasting plasma glucose level over 126 mg/dL (7 mmol/L) or a plasma glucose level above 200 mg/dL (11.1 mmol/L) taken randomly (with symptoms of diabetes) or 2 hours after an oral glucose load (1.75 g glucose/kg up to a maximum of 75 g). Confirmation of such abnormalities on more than one occasion is recommended as transient hyperglycemia can occur, particularly with illness. Impaired (not yet diabetic) fasting glucose values are 100–125 mg/dL (5.5–6.9 mmol/L) and impaired 2-hour values are 140–200 mg/dL (7.8–11.1

mmol/L). If the presentation is mild, hospitalization is usually not necessary.

► Treatment

Most children have type 1 diabetes. The five major variables in treatment are (1) insulin type and dosage, (2) diet, (3) exercise, (4) stress management, and (5) blood glucose and ketone monitoring. All must be considered to obtain safe and effective metabolic control. Although teenagers can be taught to perform many of the tasks of diabetes management, they do better when supportive—not overbearing—parents continue to be involved in management of their disease. Children younger than age 10 or 11 years cannot reliably administer insulin without adult supervision because they lack fine motor control and may not understand the importance of accurate dosage.

A. Patient and Family Education

Education about diabetes for all family members is essential for the home management of diabetes. The use of an educational book (see *Understanding Diabetes* in the references) can be very helpful to the family. All caregivers need to learn about diabetes, how to give insulin injections, perform home blood glucose monitoring, and handle acute complications. The stress imposed on the family around the time of initial diagnosis may lead to feelings of shock, denial, sadness, anger, fear, and guilt. Meeting with a counselor to express these feelings at the time of diagnosis helps with long-term adaptation.

A. Insulin

Insulin has three key functions: (1) it allows glucose to pass into the cell; (2) it decreases the physiologic production of glucose, particularly in the liver; and (3) it turns off ketone production.

1. Treatment of new-onset diabetes—The greater the acidemia and ketone production, the greater the amount of insulin needed. If ketonemia is significant, venous blood pH is low (< 7.30), and the patient is dehydrated, intravenous insulin and fluid therapy should be given (see later discussion of ketonuria, ketonemia, and ketoacidosis). If the child is adequately hydrated and has a normal venous blood pH, one or two intramuscular or subcutaneous injections of 0.1–0.2 U/kg of regular insulin—or preferably of insulin lispro (Humalog, [H]) or insulin aspart (NovoLog, [NL])—1 hour apart will help shut down ketone production. If ketone production is insignificant or absent, this regimen is not necessary, and routine subcutaneous injections can be started.

When ketones are not present, the child is usually more responsive to insulin, and a total daily dosage of 0.25–0.5 U/kg/24 h (by subcutaneous injection) can be used. If ketones are or were present, the child usually does not produce as much insulin and will require 0.5–1 U/kg of total insulin per 24 hours.

Children usually receive mixtures of a rapid-acting insulin (to cover food intake or high blood glucose) and a longer-acting insulin (to suppress endogenous hepatic glucose production). This is achieved by combining insulins of different formulations with the desired properties (Table 33–1). The dosages are adjusted with each injection during the first week. In the past, most physicians began treatment of newly diagnosed children with two injections per day of an intermediate-acting insulin (eg, NPH) and a rapid-acting insulin such as Humalog or NovoLog (H or NL). About two thirds of the total dosage is usually given before breakfast and the remainder before dinner. If human regular insulin is used, the injections are given 30–60 minutes before meals; when using H or NL as the rapid-acting insulin, the injections are given 10–15 minutes before eating. In young children who eat irregular amounts of food, it is often helpful to wait until after the meal to give the injection and decide on the appropriate dose of H or NL. Children younger than age 4 years usually need 1 or 2 units of rapid-acting insulin to cover meals; the remainder of the dosage is NPH insulin. Children aged 4–10 years may require up to 4 units of rapid-acting insulin to cover breakfast and dinner, whereas proportionately higher doses (usually 4–10 units) of H or NL or regular insulin are used for older children.

An alternative approach using one of two basal insulins, insulin glargine (Lantus) or insulin Detemir (Levemir), is now available, and many physicians initiate therapy with one of these insulins. The basal insulin is given once or twice daily in the morning, or at dinner, or at bedtime depending on patient and family wishes. The dose is adjusted up or down depending on the morning fasting glucose levels. The most physiologic insulin regimen is then to add H/NL prior to each meal and snack. Children who are unable to consistently receive H or NL at lunch or with snacks can receive

H/NL with NPH at breakfast. The main advantage of Lantus or Levemir over two injections of NPH daily is that severe hypoglycemic episodes (particularly at night) are greatly reduced with their use.

2. Continuing insulin dosage—The total daily insulin dosage may need to be increased gradually to 1 U/kg (especially if ketones are present at onset). When gluconeogenesis and glycolysis are suppressed by insulin, a honeymoon or grace period is a common phenomenon. There is often a temporary decrease in the insulin dose during this period. This occurs 1–4 weeks after diagnosis in over 50% of children and tends to last longer in older children.

In helping families with day-to-day dosing of regular insulin or H or NL, some physicians initially use sliding scales, more recently referred to as “thinking” scales, to emphasize that the family must always be thinking about food recently eaten, or to be eaten, and recent or forthcoming exercise in addition to the blood glucose level. Examples of thinking scales are included in *Understanding Diabetes* (see references).

After the appropriate dosage of intermediate (eg, NPH) or long-acting (Lantus or Levemir) insulin is achieved, daily adjustments usually are not needed. However, small decreases may be made for heavy activity (eg, afternoon sports or overnight events). Many families gradually learn to make small (0.5–1 unit) weekly adjustments in insulin dosage based on home blood glucose testing. Understanding the onset, peak, and duration of insulin activity is essential (see Table 33–1).

As noted earlier, when one of the more physiologic (closer to human insulin output) basal insulins, Lantus or Levemir, is used, it must be given alone in the syringe or pen. When changing a patient from two injections per day of NPH insulin to Lantus or Levemir, the total 24-hour dose of NPH is divided in half to use as the initial dose. The dose of Lantus or Levemir is then increased or decreased 1 or 2 units every few days based on the fasting morning blood glucose levels. Common glucose level goals are 70–180 mg/dL (3.9–10 mmol/L) for preteens and 70–150 mg/dL (3.9–8.3 mmol/L) for teens. A rapid-acting insulin (H or NL) is then given before meals and snacks or a mixture of H or NL and NPH is given in the morning and H or NL at dinner. The dosages of H or NL may initially be based on a “thinking” scale (see previous discussion), and may later be based on carbohydrate-counting as the family becomes more knowledgeable (see discussion of diet, later).

Continuous subcutaneous insulin (insulin pump) therapy is being used more often in children, particularly for emotionally mature teens who are willing to do frequent blood glucose monitoring and to count carbohydrates. Basal insulin doses (usually H/NL) are chosen by the physician, with bolus doses prior to meals selected by the patient (or an appropriate adult) depending on the carbohydrate content of the food to be eaten. Insulin pump therapy is discussed in depth in Chapter 26 of *Understanding Diabetes* (see references).

Table 33–1. Kinetics of insulin action.

Type of Insulin	Begins Working	Main Effect	All Gone
Rapid-acting			
Regular	30 min	2–4 h	6–9 h
Humalog or NovoLog	10–15 min	30–80 min	4 h
Intermediate-acting			
NPH	2–4 h	6–8 h	12–15 h
Long-acting			
Lantus or Levemir	1–2 h	2–23 h	24–26 h
Premixed			
NPH/Regular	30 min	Variable ^a	12–18 h
NPH/75/25 ^b	15 min	1–8 h	12–15 h

^aAvailable in various combinations to fit individual needs.

^bA mixture of 75% NPH and 25% Humalog. NPH, neutral protamine Hagedorn insulin.

The following regimen constitutes intensive diabetes management: (1) three or more insulin injections per day, or insulin pump therapy; (2) four or more blood glucose determinations per day; (3) careful attention to dietary intake; and (4) frequent contact with the health care provider. This approach was shown in the Diabetes Control and Complications Trial (DCCT; see section on diet) to result in improved glucose control and to reduce the risk for retinal, renal, cardiovascular, and neurologic complications of diabetes. All teenagers with suboptimal glucose control who are willing to comply should be considered for intensive diabetes management.

3. Treatment of type 2 diabetes—The treatment of type 2 diabetes in children varies with the severity of the disease. If the glycosylated hemoglobin (HbA_{1c}) fraction is still normal (or near normal) and ketone levels are not moderately or significantly increased, modification of lifestyle (preferably for the entire family) is the first line of therapy. This must include reducing caloric intake and increasing exercise. If the HbA_{1c} fraction is mildly elevated (6.2–9.0%) and ketone levels are not moderately or significantly increased, an oral hypoglycemia agent can be tried. Metformin is usually tried along with modification of lifestyle, starting with a dose of 250–500 mg once daily. If needed, and if gastrointestinal adaptation has occurred, the dose can be gradually increased to 1 g twice daily. If the presentation is more severe, with moderately or significantly increased urine ketone levels, or blood β -hydroxybutyrate is more than 1.0 mmol/L, the initial treatment is similar to that of type 1 diabetes (including intravenous or subcutaneous insulin). Oral hypoglycemic agents may be tried at a later date, particularly if weight loss has been successful.

B. Diet

The mainstays of dietary treatment are discussed in detail in *Understanding Diabetes* (see references). The American Diabetes Association no longer recommends any one diabetic diet. Instead, nutrition therapy for diabetics should be individualized, with consideration given to the patient's customary cultural eating habits and other lifestyle circumstances. Some families and children (particularly those with weight problems) find exchange diets helpful initially while they are learning food categories. Most centers now just use exchanges of carbohydrates, referred to below as carbohydrate-counting or “carb-counting.”

The DCCT found that four nutrition factors contributed to better glucose control (lower HbA_{1c} levels): (1) adherence to a meal plan, (2) avoidance of extra snacks, (3) avoidance of overtreatment of low blood glucose levels (hypoglycemia), and (4) prompt treatment of high blood glucose levels. Two other nutritional factors include adjusting insulin levels for meals and maintaining a consistent schedule of nighttime snacks. The DCCT popularized the carb-counting dietary plan in which the dosage of H/NL or regular insulin is altered with each injection to adjust for the amount of carbohydrate to be eaten and the amount of exercise contemplated. One

carbohydrate count is 15 g of glucose in the United States (10 g in the United Kingdom). A common formula is to use 1 unit of H/NL for each 15 g of carbohydrate eaten, although this ratio must be adjusted (using blood glucose levels 2 hours after meals) for each person.

C. Exercise

Regular aerobic exercise—at least 30 minutes a day—is important for children with diabetes. Exercise fosters a sense of well-being; helps increase insulin sensitivity; and helps maintain proper weight, blood pressure, and blood fat levels. Exercise may also help maintain normal peripheral circulation in later years. It is particularly important for children with type 2 diabetes.

Hypoglycemia during exercise or in the 2–12 hours after exercise (delayed hypoglycemia) can be prevented by careful monitoring of blood glucose before, during, and after exercise; sometimes by reducing the dosage of the insulin active at the time of (or after) the exercise; and by providing extra snacks. Children using insulin pumps should reduce preexercise bolus insulin dosages as well as the basal dosages during (and sometimes after) the exercise. In general, the longer and more vigorous the activity, the greater the reduction in insulin dose. Extra snacks should also be eaten. Fifteen grams of glucose usually covers about 30 minutes of exercise. The use of drinks containing 5–10% dextrose, such as Gatorade, during the period of exercise is often beneficial.

D. Stress Management

Management of stress is important on a short-term basis because stress hormones increase blood glucose levels. Chronic emotional upsets may lead to missed injections or other compliance problems. When this happens, counseling for the family and child becomes an important part of diabetes management.

E. Home Blood Glucose Measurements

All families must be able to monitor blood glucose levels three or four times daily—and more frequently in small infants and patients who have glucose control problems or intercurrent illnesses. Blood glucose levels can be monitored using any of the available meters, which generally have an accuracy of 90% or better. Target levels when no food has been eaten for 2 or more hours vary according to age (Table 33–2).

Blood glucose results should be recorded even if the meter has a memory feature. This allows the family to look for patterns and make changes in insulin dosage. If more than 50% of the values are above the desired range for age or more than 14% below the desired range, the insulin dosage usually needs to be adjusted. Some families are able to make these changes independently (particularly after the first year), whereas others need help from the health care provider. Children with diabetes should be evaluated by a clinician every 3 months. This provides an opportunity to

Table 33-2. Ideal glucose levels after 2 or more hours of fasting.^a

Age (y)	Glucose Level
4 or younger	80-200 mg/dL (4.6-11 mmol/L)
5-11	70-180 mg/dL (3.9-10 mmol/L)
12 or older	70-150 mg/dL (3.9-8.3 mmol/L)

^aAt least half of the values must be below the upper limit to have a good HbA_{1c} value. The values should also be below the upper limits for age when tested 2 h after a meal.

adjust insulin dosages according to changes in growth and blood glucose levels as well as to check for changes noted on physical examination (eg, eyes and thyroid). Continuous glucose monitoring (CGM) is now being used in some children and adolescents. Subcutaneous glucose levels are obtained every 1–5 minutes from a sensor placed under the skin. As with insulin pump therapy, additional education, usually at a specialty diabetes center, is required.

F. Laboratory Evaluations

In addition to home measurements of blood glucose and blood or urine ketone levels, the HbA_{1c} level should be measured every 3 months. This test reflects the frequency of elevated blood glucose levels over the previous 3 months. Normal values vary among laboratories but are usually below 6.2% HbA_{1c}. The desired ranges are based on age. For the HbA_{1c} method, these ranges are as follows: 12–19 years, less than 7.5%; 6–11 years, less than 8.0%; and younger than 5 years, 7.5–8.5%. Higher levels are allowed in younger children to reduce the risk of hypoglycemia because their brains are still developing and they may not relate symptoms of hypoglycemia to a need for treatment. Low HbA_{1c} values are generally associated with a greater risk for hypoglycemia (see the following section). Using either method, longitudinal averages more than 33% above the upper limit of normal are associated with a higher risk for later renal and retinal complications. In the intensive treatment group of the DCCT, the lower HbA_{1c} values resulted in greater than 50% reductions in the retinal, renal, cardiovascular, and neurologic complications of diabetes.

Since atherosclerosis is the major cause of death in older patients with diabetes it is important to measure serum cholesterol, low-density lipoprotein cholesterol, and high-density lipoprotein cholesterol levels once yearly. Cholesterol levels should be below 200 mg/dL and low-density lipoprotein cholesterol levels below 100 mg/dL in postpubertal patients with diabetes.

When puberty is reached and the individual has had diabetes for 3 years or longer, the urinary excretion of albumin should be measured (as microalbumin) in two separate urine samples once yearly (see discussion of chronic compli-

cations, later). This can be done using timed overnight urine collections or first-morning voids (expressed per milligram of creatinine). Normal values differ with the methodology of the laboratory but are generally below 20 mcg/min (or 30 mcg/mg creatinine). People with type 2 diabetes should have this test done soon after diagnosis and then annually.

If the thyroid is enlarged (about 20% of patients with type 1 diabetes), the thyroid-stimulating hormone level should be measured yearly. This is usually the first test to become abnormal in the autoimmune thyroiditis commonly associated with type 1 diabetes.

In recent years antiendomysial and transglutaminase antibodies, reliable predictors of celiac disease, have been shown to be more common in children with diabetes as well as in their siblings. Risk of celiac disease is associated with HLA-DR3 and is more frequent in children with diabetes (celiac disease occurring in about 5%). The celiac antibodies should be checked in diabetic children with poor growth (especially when not related to poor glucose control) or those who present with gastrointestinal symptoms. The 21-hydroxylase autoantibody, a marker of increased risk of Addison disease, is present in approximately 1.3% of patients with type 1 diabetes, although Addison disease develops in only about one third of these antibody-positive individuals.

Type 2 diabetes is not an autoimmune disease, and the islet antibody tests are negative. An elevated insulin or C-peptide level is also helpful, indicating that insulin production is normal or elevated.

A checklist of the physician's contributions to good diabetes care is presented in Table 33-3.

► Acute Complications

A. Hypoglycemia

Hypoglycemia (or insulin reaction) is defined as a blood glucose level below 60 mg/dL (or 3.3 mmol/L). For preschool

Table 33-3. Physician's checklist of good diabetes management.

Variable	Frequency of Measurement	Tests and Values
Blood glucose	3-4 times daily	See Table 33-2
Hemoglobin A _{1c}	Every 3 mo	See text
Urine microalbumin	Annually after 3 y of diabetes (pubertal patients)	< 20 mcg/min
Ophthalmology referral	Annually after 3 y of diabetes (age 10 y or older)	Retinal photographs
Signs of other endocrinopathy	Evaluate at least annually (eg, thyroid enlargement)	(eg: TSH: 0.5-5.0 IU/mL)
Blood lipid panel	Annually	Cholesterol < 200 mg/dL; LDL < 100

TSH, thyroid-stimulating hormone.

children, values below 70 mg/dL (3.9 mmol/L) should be cause for concern. The common symptoms of hypoglycemia are hunger, weakness, shakiness, sweating, drowsiness (at an unusual time), headache, and behavioral changes. Children learn to recognize hypoglycemia at different ages but can often report “feeling funny” as young as age 4–5 years. If low blood glucose is not treated immediately with simple sugar, the hypoglycemia may result in loss of consciousness or convulsions. If hypoglycemia is left untreated for several hours, brain damage or death can occur.

Consistency in daily routine, correct insulin dosage, regular blood glucose monitoring, controlled snacking, compliance of patients and parents, and good education are all important in preventing severe hypoglycemia. In addition, insulin should not be injected prior to getting into a hot tub, bath, or shower. The heat will increase circulation to the skin and cause more rapid insulin uptake. The use of H/NL insulin and of Lantus insulin has also helped to reduce the occurrence of hypoglycemia.

The treatment of mild hypoglycemia involves giving 4 oz of juice, a sugar-containing soda drink, or milk, and waiting 10 minutes. If the blood glucose level is still below 60 mg/dL (3.3 mmol/L), the liquids are repeated. If the glucose level is above 60 mg/dL, solid foods are given. Moderate hypoglycemia, in which the person is conscious but incoherent, is treated by squeezing one-half tube of concentrated glucose (eg, Insta-Glucose or cake frosting) between the gums and lips and stroking the throat to encourage swallowing.

In the DCCT study, 10% of patients with standard management and 25% of those with intensive insulin management—insulin pumps or three or more insulin shots per day—had one or more severe hypoglycemic reactions each year. Families are advised to have glucagon in the home and to treat hypoglycemia by giving subcutaneous or intramuscular injections of 0.3 mL (30 units in an insulin syringe) for children younger than age 5 years and 0.5 mL (50 units) to those older than age 5 years. Some patients (usually those who have had diabetes for more than 10 years) fail to recognize the symptoms of low blood glucose (hypoglycemic unawareness). For these individuals, glucose control must be liberalized to prevent severe hypoglycemic reactions. School personnel, sports coaches, and babysitters must be trained to recognize and treat hypoglycemia.

B. Ketonuria, Ketonemia, and Ketoacidosis

Families must be educated to check blood or urine ketone levels during any illness (including vomiting even once) or any time a fasting blood glucose level is above 240 mg/dL (13.3 mmol/L), or a randomly measured glucose level is above 300 mg/dL (16.6 mmol/L). If moderate or significant ketonuria is detected, or the blood ketone (β -hydroxybutyrate—using the Precision Xtra meter) is above 1.0 mmol/L, the health care provider must be called. Usually 10–20% of the total daily insulin dosage is given subcutaneously as H or NL (or regular) insulin every 2–3 hours until the elevated ketones are gone. This prevents ketonuria and ketonemia

from progressing to ketoacidosis and allows most patients to receive treatment at home by telephone management. Juices and other fluids to help wash out the ketones and to prevent dehydration are encouraged. If deep breathing (Kussmaul respirations) or excessive weakness occurs, the patient should be evaluated promptly by a physician.

Acidosis (venous blood pH < 7.30) is now present in fewer than 25% of newly diagnosed children. Acidosis may also occur in those with known diabetes who do not check blood or urine ketone levels or fail to call the health care provider when ketones levels are elevated. Repeated episodes of ketoacidosis usually result from missed insulin injections and signify that counseling may be indicated, and that a responsible adult must take over the diabetes management. If for any reason this is not possible, a change in the child’s living situation may be necessary.

Treatment of diabetic ketoacidosis (DKA) is based on four physiologic principles: (1) restoration of fluid volume, (2) inhibition of lipolysis and return to glucose utilization, (3) replacement of body salts, and (4) correction of acidosis. Laboratory tests at the start of treatment should include venous blood pH, blood glucose, and an electrolyte panel. Mild DKA is defined as a venous blood pH of 7.2–7.3; moderate DKA, a pH of 7.10–7.19; and severe DKA, a pH below 7.10. Patients with severe DKA should be hospitalized in a pediatric intensive care unit, if available in the area. More severe cases may benefit from determination of osmolality, calcium and phosphorus, and blood urea nitrogen levels. Severe and moderate episodes of DKA generally require hourly determinations of serum glucose, electrolytes, and venous pH levels, whereas these parameters can be measured every 2 hours if the pH level is 7.20–7.30.

1. Restoration of fluid volume—Dehydration is judged by (1) acute loss of body weight (if a recent weight is known), (2) dryness of oral mucous membranes, (3) low blood pressure, and (4) tachycardia. Initial treatment is with physiologic saline (0.9%), 10–20 mL/kg during the first hour. If indicated by continued signs of dehydration, this is repeated during the second hour. The total volume of fluid in the first 4 hours of treatment should not exceed 40 mL/kg because of the danger of cerebral edema (see later discussion). Human albumin, 10 mL/kg of 5% solution, can be given over 30 minutes if the patient is in shock. After initial reexpansion, half-physiologic (0.45%) saline usually is given at 1.5 times maintenance. Maintenance fluids are as discussed in Chapter 43.

2. Inhibition of lipolysis and return to glucose utilization—Insulin turns off fat breakdown and ketone formation. Regular insulin is usually given intravenously at a rate of 0.1 U/kg/h. The insulin solution should be administered by pump and can be made by diluting 30 units of regular insulin in 150 mL of 0.9% saline (1 U/5 mL). If the glucose level falls below 250 mg/dL (13.9 mmol/L), 5% dextrose is added to the intravenous fluids. If the glucose level continues to decrease below 120 mg/dL (6.6 mmol/L), 10% dextrose can be added. If

necessary, the insulin dosage can be reduced to 0.05 U/kg/h, but it should not be discontinued before the venous blood pH reaches 7.30. The half-life of intravenous insulin is 6 minutes, whereas subcutaneous H or NL insulin takes 10–15 minutes, and regular insulin takes 30–60 minutes, to begin activity. Thus it is often better to continue intravenous insulin until subcutaneous insulin can begin acting.

3. Replacement of body salts—In patients with DKA, both sodium and potassium pass into the urine with the ketones and are depleted. In addition to body depletion, serum sodium concentrations may be falsely lowered by hyperglycemia, causing water to be drawn into the intravenous space, and by hyperlipidemia if fat replaces some of the water in the serum used for electrolyte analysis. Sodium is usually replaced adequately by the use of physiologic and half-physiologic saline in the rehydration fluids, as discussed earlier.

Serum potassium levels may be elevated initially because of inability of potassium to stay in the cell in the presence of acidosis (even though total body potassium is low). Potassium should not be given until the serum potassium level is known to be low or normal and the pH is above 7.10. It is then usually given at a concentration of 40 mEq/L, with half of the potassium (20 mEq/L) either as potassium acetate or potassium chloride and the other half as potassium phosphate (20 mEq/L). Hypocalcemia can occur if all of the potassium is given as the phosphate salt; hypophosphatemia occurs if none of the potassium is of the phosphate salt.

4. Correction of acidosis—Acidosis is corrected as the fluid volume and aerobic glycolysis are restored and as insulin is administered to inhibit ketogenesis. As noted earlier, measurement of the venous blood pH (identical to arterial blood pH) reveals the severity of acidosis. Bicarbonate is usually not given, even with severe DKA.

5. Management of cerebral edema—Some degree of cerebral edema has been shown by computed tomography scan to be common in DKA. Associated clinical symptoms are rare, unpredictable, and may be associated with demise. Cerebral edema may be related to overhydration with hypotonic fluids, although the cause is not well understood. It is now recommended that no more than 40 mL/kg of fluids be given in the first 4 hours of treatment. Cerebral edema is more common with a pH lower than 7.1, an arterial partial carbon dioxide pressure lower than 20 mm Hg, or when the serum sodium is noted to be falling rather than rising. Early neurologic signs may include headache, excessive drowsiness, and dilated pupils. Prompt initiation of therapy should include elevation of the head of the bed, hyperventilation, mannitol (1 g/kg over 30 minutes), and fluid restriction. If the cerebral edema is not recognized and treated early, over 50% of patients will die or have permanent brain damage.

▶ Chronic Complications

In the past, about 30–40% of persons with type 1 diabetes eventually developed renal failure or loss of vision. Factors that greatly reduce this likelihood are maintenance of longitudinal HbA_{1c} levels in a good range, maintenance of blood pressure below the 90th percentile for age, and abstinence from smoking or chewing tobacco. Annual retinal examinations and urine microalbumin measurements are important for children aged 10 years or older who have had diabetes for 3 years or longer (see section on laboratory evaluations, earlier). Data now show that the use of angiotensin-converting enzyme inhibitors may reverse or delay kidney damage when it is detected in the microalbuminuria stage (20–300 mcg/min). Similarly, laser treatment to coagulate proliferating capillaries prevents bleeding and leakage of blood into the vitreous fluid or behind the retina. This treatment helps to prevent retinal detachment and to preserve useful vision for many people with proliferative diabetic retinopathy.

Inborn Errors of Metabolism

Janet A. Thomas, MD
Johan L.K. Van Hove, MD, PhD, MBA

Disorders in which single gene defects cause clinically significant blocks in metabolic pathways are called inborn errors of metabolism. For many years after Garrod first described them in 1908, these conditions were considered rare. Because the number of recognized inborn errors has increased, they are now acknowledged to be important causes of disease in children (estimated incidence 1:1500 children). Many of these disorders can now be treated effectively. Even when treatment is not available, correct diagnosis permits parents to make informed decisions about future offspring.

The pathology is almost always due either to accumulation of enzyme substrate behind a metabolic block or to deficiency of the reaction product. In some cases, the accumulated enzyme substrate is diffusible and has adverse effects on distant organs; in other cases, as in lysosomal storage diseases, the substrate primarily accumulates locally.

The clinical manifestations of inborn errors vary widely with both mild and severe forms of virtually every disorder. Many patients do not match the classic phenotype because mutations are not identical in different patients, even though they occur in the same gene.

A first treatment strategy is to enhance the reduced enzyme activity. Gene replacement is a long-term goal, but problems of gene delivery to target organs and control of gene action make this an unrealistic option at present. Enzyme replacement therapy using intravenously administered recombinant enzyme has been developed as an effective strategy in lysosomal storage disorders. Organ transplantation (liver or bone marrow) can provide a source of enzyme for some conditions. Pharmacologic doses of a cofactor such as a vitamin can sometimes be effective in restoring enzyme activity. Alternatively, some strategies are designed to cope with the consequences of enzyme deficiency. Strategies used to avoid substrate accumulation include restriction of precursor in the diet (eg, low-phenylalanine diet for phenylketonuria), avoidance of catabolism, inhibition of an enzyme in the synthesis of the precursor (eg, NTBC in tyrosinemia type I), or removal of accumulated

substrate pharmacologically (eg, glycine therapy for isovaleric acidemia) or by dialysis. An inadequately produced metabolite can also be supplemented (eg, glucose administration for glycogen storage disease type I).

Inborn errors can manifest at any time, can affect any organ system, and can mimic many common pediatric problems. This chapter focuses on when to consider metabolic disorder in the differential diagnosis of common pediatric problems. A few of the more important disorders are then discussed in detail.

DIAGNOSIS

SUSPECTING INBORN ERRORS

Inborn errors must be considered in the differential diagnosis of critically ill newborns, children with seizures, neurodegeneration, mental retardation, developmental delay, recurrent vomiting, Reye-like syndrome, parenchymal liver disease, cardiomyopathy, unexplained metabolic acidosis, hyperammonemia, and hypoglycemia. Inborn errors should be suspected when (1) symptoms accompany changes in diet, (2) the child's development regresses, (3) the child shows specific food preferences or aversions, or (4) the family has a history of parental consanguinity or problems suggestive of inborn error such as retardation or unexplained deaths in first- and second-degree relatives.

Physical findings associated with inborn errors include alopecia or abnormal hair, retinal cherry-red spot or retinitis pigmentosa, cataracts or corneal opacity, hepatomegaly or splenomegaly, coarse features, skeletal changes (including gibbus), neurologic regression, and intermittent or progressive ataxia or dystonia. Other features that may be important in the context of a suspicious history include failure to thrive, microcephaly, rash, jaundice, hypotonia, and hypertonia.

Finding an immediate cause of symptoms does not rule out an underlying inborn error. For example, renal tubular

acidosis and cirrhosis may be due to an underlying inborn error. Acute crises may be brought on by intercurrent infections in some inborn errors. Some inborn errors suggest a diagnosis of nonaccidental trauma (eg, glutaric acidemia type I) or poisoning (eg, methylmalonic acidemia). In addition, children with inborn errors may be at higher risk for child abuse or neglect because of their frustrating irritability.

LABORATORY STUDIES

Table 34–1 lists common clinical and laboratory features of different groups of inborn errors. Table 34–2 lists the most common laboratory tests used to diagnose these diseases and offers suggestions about their use.

Laboratory studies are almost always needed for the diagnosis of inborn errors. Serum electrolytes and pH should be used to estimate anion gap and acid-base status. Serum lactate, pyruvate, and ammonia levels are available in most hospitals but care is needed in obtaining samples appropriately. Amino acid and organic acid studies must be performed at specialized facilities to ensure accurate analysis and interpretation. An increasing number of inborn errors are diagnosed with DNA sequencing, but interpretation of private mutations can be problematic.

The physician should know what conditions a test can detect and when it can detect them. For example, urine organic acids may be normal in patients with medium-chain acyl-CoA dehydrogenase deficiency or biotinidase deficiency; glycine may be elevated only in cerebrospinal fluid (CSF) in patients with glycine encephalopathy. A result that is normal in one physiologic state may be abnormal in another. For instance, the urine of a child who becomes hypoglycemic upon prolonged fasting should be positive for ketones. In such a child, the absence of ketones in the urine suggests a defect in fatty acid oxidation.

Samples used to diagnose metabolic disease may be obtained at autopsy. Samples must be obtained in a timely fashion and may be analyzed directly or stored frozen until a particular analysis is justified by the results of postmortem examination, new clinical information, or developments in the field. Studies of other family members may help establish the diagnosis of a deceased patient. It may be possible to demonstrate that parents are heterozygous carriers of a particular disorder or that a sibling has the condition.

COMMON CLINICAL SITUATIONS

1. Mental Retardation

Some inborn errors can cause mental retardation without other distinguishing characteristics. Measurements of serum amino acids, urine organic acids, and serum uric acid should be obtained in every patient with nonspecific mental retardation. Urine screens for mucopolysaccharides and succinylpurines, and serum testing for carbohydrate-deficient glycoproteins are useful because these disorders do not

always have specific physical findings. Absent speech can point to disorders of creatine. Abnormalities of the brain detected by magnetic resonance imaging can suggest specific groups of disorders (eg, cortical migrational abnormalities in peroxisomal biogenesis disorders).

2. Acute Presentation in the Neonate

Acute metabolic disease in the neonate is most often a result of disorders of protein or carbohydrate metabolism and may be clinically indistinguishable from sepsis. Prominent symptoms include poor feeding, vomiting, altered mental status or muscle tone, jitteriness, seizures, and jaundice. Acidosis or altered mental status out of proportion to systemic symptoms should increase suspicion of a metabolic disorder. Laboratory measurements should include electrolytes, ammonia, lactate, glucose, blood pH, and urine ketones and reducing substances. Glycine in CSF should be measured if glycine encephalopathy is suspected. Serum and urine amino acid, urine organic acid, and serum acylcarnitine analysis should be performed on samples collected before oral intake is discontinued and sent later for analysis if indicated by the results of initial studies. Neonatal cardiomyopathy or ventricular arrhythmias should be investigated with serum acylcarnitine analysis.

3. Vomiting & Encephalopathy in the Infant or Older Child

Electrolytes, ammonia, glucose, urine pH, urine reducing substances, and urine ketones should be measured in all patients with vomiting and encephalopathy before any treatment affects the results. Samples for serum amino acids, serum acylcarnitine profile, and urine organic acid analysis should be obtained early and frozen pending the results of initial studies. In the presentation of a Reye-like syndrome (ie, vomiting, encephalopathy, and hepatomegaly), amino acids, acylcarnitines, carnitine levels, and organic acids should be assessed immediately. Hypoglycemia with inappropriately low urine or serum ketones suggests the diagnosis of fatty acid oxidation defects.

4. Hypoglycemia

Duration of fasting, presence or absence of hepatomegaly, and Kussmaul breathing provide clues to the differential diagnosis of hypoglycemia. Serum insulin, cortisol, and growth hormone should be obtained on presentation. Urine ketones, urine organic acids, plasma lactate, serum acylcarnitine profile, carnitine levels, ammonia, and uric acid should be measured. Ketone body production is usually not efficient in the neonate, and ketonuria in a hypoglycemic or acidotic neonate suggests an inborn error. In the older child, inappropriately low urine ketone levels suggest an inborn error of fatty acid oxidation. Assessment of ketone generation requires simultaneous measurements of quantitative serum 3-hydroxybutyrate, acetoacetate, and free fatty acids

in relation to a sufficient duration of fasting and age. Metabolites obtained during the acute episode can be very helpful and avoid the need for a formal fasting test.

5. Hyperammonemia

Symptoms of hyperammonemia may appear and progress rapidly or insidiously. Decreased appetite, irritability, and behavioral changes appear first with vomiting, ataxia, lethargy, seizures, and coma appearing as ammonia levels increase. Tachypnea is also characteristic and is due to a direct effect on respiratory drive. Physical examination cannot exclude the presence of hyperammonemia, and serum ammonia should be measured whenever hyperammonemia is possible.

Severe hyperammonemia may be due to urea cycle disorders, organic acidemias, or fatty acid oxidation disorders (such as carnitine-acylcarnitine translocase deficiency) or, in the premature infant, transient hyperammonemia of the newborn. The cause can usually be ascertained by measuring quantitative serum amino acids (eg, citrulline), plasma carnitine and acylcarnitine esters, and urine organic acids and orotic acid. Respiratory alkalosis is usually present in urea cycle defects and transient hyperammonemia of the newborn, while acidosis is characteristic of hyperammonemia due to organic acidemias.

6. Acidosis

Inborn errors may cause chronic or acute acidosis at any age, with or without an increased anion gap. Inborn errors

should be considered when acidosis occurs with recurrent vomiting or hyperammonemia and when acidosis is out of proportion to the clinical status. Acidosis due to an inborn error can be difficult to correct. The main causes of anion gap metabolic acidosis are lactic acidosis, ketoacidosis (including abnormal ketone body production such as in β -ketothiolase deficiency), methylmalonic acidemia or other organic acidurias, intoxication (ethanol, methanol, ethylene glycol, and salicylate), and uremia. Causes of non-anion gap metabolic acidosis include loss of base in diarrhea or renal tubular acidosis (isolated renal tubular acidosis or renal Fanconi syndrome). If renal bicarbonate loss is found, then a distinction must be made between isolated renal tubular acidosis and a more generalized renal tubular disorder or renal Fanconi syndrome by testing for renal losses of phosphorus and amino acids. Inborn errors associated with renal tubular acidosis or renal Fanconi syndrome include cystinosis, tyrosinemia type I, carnitine palmitoyltransferase I, and mitochondrial diseases. Serum glucose and ammonia levels and urinary pH and ketones should be examined. Samples for amino acids and organic acids should be obtained at once and may be evaluated immediately or frozen for later analysis, depending on how strongly an inborn error is suspected. It is useful to test blood lactate and pyruvate levels in the chronically acidotic patient even if urine organic acid levels are normal. Lactate and pyruvate levels are difficult to interpret in the acutely ill patient, but in the absence of shock, high levels of lactic acid suggest primary lactic acidosis.

Table 34-2. Obtaining and handling samples to diagnose inborn errors.

Test	Comments
Acid-base status	Accurate estimation of anion gap must be possible. Samples for blood gases should be kept on ice and analyzed immediately.
Blood ammonia	Sample should be kept on ice, and analyzed immediately.
Blood lactic acid and pyruvic acid	Sample should be collected without a tourniquet, kept on ice, and analyzed immediately. Conversion of lactic acid into pyruvic acid must be prevented. Normal literature values are for the fasting, rested state.
Amino acids	Blood and urine should be examined. CSF glycine should be measured if nonketotic hyperglycinemia is to be ruled out. Normal literature values are for the fasting state. Growth of bacteria in urine should be prevented.
Organic acids	Urine preferred for analysis. Serum or CSF organic acids are rarely indicated and often miss diagnoses.
Carnitine and acylcarnitine profile	Blood or plasma may be analyzed for total, free, and esterified carnitine; normal values are for the healthy, nonfasted state. Acylcarnitine profile in blood identifies compounds esterified to carnitine. Rarely urine and bile studies may be needed for certain conditions. Profiling in cultured fibroblasts after fat loading can be helpful in diagnosis of certain conditions.
Urine mucopolysaccharides	Variations in urine concentration may cause errors in screening tests. Diagnosis requires knowing which mucopolysaccharides are increased. Some patients with Morquio disease and many with Sanfilippo disease do not have abnormal mucopolysacchariduria.
Enzyme assays	Specific assays must be requested. Exposure to heat may cause loss of enzyme activity. Enzyme activity in whole blood may become normal after transfusion or vitamin therapy. Leukocyte or fibroblast pellets should be kept frozen prior to assays. Fibroblasts may be grown from skin biopsies taken up to 72 h after death. Tissues such as liver and kidney should be taken as soon as possible after death, frozen immediately, and kept at -70°C until assayed.

CSF, cerebrospinal fluid.

MANAGEMENT OF METABOLIC EMERGENCIES

Patients with severe acidosis, hypoglycemia, and hyperammonemia may be very ill; initially mild symptoms may worsen quickly, and coma and death may ensue within hours. With prompt and vigorous treatment, however, patients can recover completely, even from deep coma. All oral intake should be stopped. Sufficient glucose should be given intravenously to avoid or minimize catabolism in a patient with a known inborn error who is at risk for crisis. Most conditions respond favorably to glucose administration, although a few (eg, primary lactic acidosis due to pyruvate dehydrogenase deficiency) do not. After exclusion of fatty acid oxidation disorders, immediate institution of intravenous fat emulsions (eg, intralipid) can provide crucial caloric input. Severe or increasing hyperammonemia should be treated pharmacologically or with dialysis, and severe acidosis should be treated with bicarbonate. More specific measures can be instituted when a diagnosis is established.

NEWBORN SCREENING

Criteria for screening newborns for a disorder include its frequency, its consequences if untreated, the ability of therapy to mitigate consequences, the cost of testing, and the cost

of treatment. All states in the United States screen newborns for phenylketonuria and hypothyroidism. In most states newborns are screened for galactosemia. Other metabolic disorders for which newborns are frequently screened include maple syrup urine disease, homocystinuria due to cystathionine β -synthase deficiency, and biotinidase deficiency. Expanded newborn screening using tandem mass spectrometry detects several disorders of amino acid, organic acid, and fatty acid metabolism.

Some screening tests measure a metabolite (eg, phenylalanine) that becomes abnormal with time and exposure to diet. In such instances the disease cannot be detected reliably until intake of the substrate is established. Other tests (eg, for biotinidase deficiency) measure enzyme activity and can be performed at any time. Transfusions may cause false-negative results in this instance, and exposure of the sample to heat may cause false-positive results. Technologic advances have extended the power of newborn screening but have brought additional challenges. For example, although tandem mass spectrometry can detect many more disorders in the newborn period, consensus on diagnosis and treatment for some conditions is still under development.

Screening tests are not diagnostic, and diagnostic tests must be undertaken when an abnormal screening result is obtained. Further, because false-negative results occur, a normal newborn screening test does not rule out a condition.

The timing of newborn screening recommended by the American Academy of Pediatrics (between 24 and 72 hours of

life) is appropriate for the detection of phenylketonuria, but hypothyroidism, for instance, can be missed when screening is carried out at the same time. Early discharge of neonates causes significant problems in newborn screening, with both false-negative and false-positive results. Nevertheless, all infants should be screened before discharge from the hospital.

The appropriate response to an abnormal screening test depends on the condition in question and the predictive value of the test. For example, when screening for galactosemia by enzyme assay, complete absence of enzyme activity is highly predictive of classic galactosemia. Failure to treat may rapidly lead to death. In this case, treatment must be initiated immediately while diagnostic studies are pending. In phenylketonuria, however, a diet restricted in phenylalanine is harmful to the infant whose screening test is a false-positive, while diet therapy produces an excellent outcome in the truly affected infant if treatment is established within the first weeks of life. Therefore, treatment for phenylketonuria should only be instituted when the diagnosis is confirmed. Physicians should combine current American Academy of Pediatrics recommendations, state laws and regulations, and consultation with their local metabolic center to arrive at appropriate strategies for each hospital and practice.

DISORDERS OF CARBOHYDRATE METABOLISM

GLYCOGEN STORAGE DISEASES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Types 0, I, III, VI, and IX manifest with hypoglycemia in infants.
- ▶ Types II, V, and VII manifest with rhabdomyolysis or muscle weakness.

Glycogen is a highly branched polymer of glucose that is stored in liver and muscle. Different enzyme defects affect its biosynthesis and degradation. The hepatic forms of the glycogenoses cause growth failure, hepatomegaly, and severe fasting hypoglycemia. They include glucose-6-phosphatase deficiency (type I; von Gierke disease), debrancher enzyme deficiency (type III), hepatic phosphorylase deficiency (type VI), and phosphorylase kinase deficiency (type IX), which normally regulates hepatic phosphorylase activity. There are two forms of glucose-6-phosphatase deficiency: in type Ia, the catalytic glucose-6-phosphatase is deficient, and in type Ib, the glucose-6-phosphate transporter is deficient. The latter form also has neutropenia. Glycogenosis type IV, brancher enzyme deficiency, usually presents with progressive liver cirrhosis.

The myopathic forms of glycogenosis affect skeletal muscle. Skeletal myopathy with weakness or rhabdomyolysis may be seen in muscle phosphorylase deficiency (type V), phosphofructokinase deficiency (type VII), and acid maltase deficiency (type II; Pompe disease). The infantile form of Pompe disease also has hypertrophic cardiomyopathy and macroglossia. The gluconeogenetic disorder fructose-1,6-bisphosphatase deficiency presents with major lactic acidosis and delayed hypoglycemia on fasting.

▶ Diagnosis

Initial tests include glucose, lactate, triglycerides, cholesterol, uric acid, transaminases, and creatine kinase. Functional

testing includes responsiveness of blood glucose to fasting and glucagon; for myopathic forms, an ischemic exercise test is helpful. Diagnostic confirmation requires enzyme assays of leukocytes, liver, or muscle. Disorders diagnosable from analysis of red or white blood cells include deficiency of debrancher enzyme (type III) and phosphorylase kinase (type IX). Pompe disease can usually be diagnosed by assaying acid maltase in a blood spot with confirmation in fibroblasts. Glycogenosis type I can often be diagnosed by molecular analysis.

▶ Treatment

Treatment is designed to prevent hypoglycemia and avoid secondary metabolite accumulations such as elevated lactate in glycogenosis type I. In the most severe hepatic forms, the special diet must be strictly monitored with restriction of free sugars and measured amounts of uncooked cornstarch, which slowly releases glucose in the intestinal lumen. Good results have been reported following continuous nighttime carbohydrate feeding or uncooked cornstarch therapy. Late complications even after years of treatment include focal segmental glomerulosclerosis, hepatic adenoma or carcinoma, and gout. Enzyme replacement therapy in Pompe disease corrects the cardiomyopathy, but the response in skeletal myopathy is variable with optimal results seen in patients treated early and who have some cross-reacting material present.

GALACTOSEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Severely deficient neonates present with vomiting, jaundice and hepatomegaly on initiation of lactose-containing feedings.
- ▶ Renal Fanconi syndrome, cataracts of the ocular lens, hepatic cirrhosis, and sepsis occur in untreated children.
- ▶ Developmental delay, tremor, and ataxia occur in untreated or partially treated children.
- ▶ Delayed speech and ovarian failure occur even with treatment.

Classic galactosemia is caused by almost total deficiency of galactose-1-phosphate uridylyltransferase. Accumulation of galactose-1-phosphate in liver and renal tubules causes hepatic parenchymal disease and renal Fanconi syndrome. Onset of the severe disease is marked in the neonate by vomiting, jaundice (both direct and indirect), hepatomegaly, and rapid onset of liver insufficiency after initiation of milk feeding. Hepatic cirrhosis is progressive. Without treatment, death frequently occurs within a month, often from *Escherichia coli* sepsis. Cataracts, caused by accumulation of galactitol in the lens, usually develop within 2 months in untreated cases, but usually reverse with treatment. With prompt institution of a galactose-free diet, the prognosis for survival without liver disease is excellent. Even when dietary restriction is instituted early, patients with galactosemia are at increased risk for speech and language deficits and ovarian failure. Some patients develop progressive mental retardation, tremor, and ataxia. Milder variants of galactosemia with better prognosis exist in all populations.

The disorder is autosomal recessive with an incidence of approximately 1:40,000 live births. Because disease in infancy may be severe, newborn screening is common. Screening is accomplished by demonstrating enzyme deficiency in red cells with the Beutler test or by demonstrating increased serum galactose.

▶ Diagnosis

In infants receiving foods containing galactose, laboratory findings include galactosuria and hypergalactosemia together with proteinuria and aminoaciduria. Absence of urine-reducing substances does not exclude the diagnosis. Galactose-1-phosphate is elevated in red blood cells. When the diagnosis is suspected, galactose-1-phosphate uridylyltransferase should be assayed in erythrocytes. Blood transfusions give false-negative results and sample deterioration false-positive results.

▶ Treatment

A galactose-free diet should be instituted as soon as the diagnosis is made. Compliance with the diet must be moni-

tored by following galactose-1-phosphate levels in red blood cells. Appropriate diet management requires not only the exclusion of milk but an understanding of the galactose content of foods. Avoidance of galactose should be life-long with appropriate calcium replacement.

HEREDITARY FRUCTOSE INTOLERANCE

Hereditary fructose intolerance is an autosomal recessive disorder in which deficient activity of fructose-1-phosphate aldolase causes hypoglycemia and tissue accumulation of fructose-1-phosphate on fructose ingestion. Other abnormalities include failure to thrive, vomiting, jaundice, hepatomegaly, proteinuria, and generalized aminoaciduria. The untreated condition can progress to death from liver failure.

▶ Diagnosis

The diagnosis is suggested by finding fructosuria or an abnormal transferrin glycoform in the untreated patient. The appearance of hypoglycemia and hypophosphatemia after a closely monitored intravenous fructose loading test (200 mg/kg) is diagnostic. The diagnosis is confirmed by finding reduced enzyme activity of fructose-1-phosphate aldolase in the liver. Some patients may be diagnosed by identification of one of the common mutations on DNA analysis, but their absence does not exclude the diagnosis.

▶ Treatment

Treatment consists of strict dietary avoidance of fructose. Vitamin supplementation is usually needed. Management is complicated by the fact that many drugs and vitamins are dispensed in a sucrose base. Treatment monitoring can be done with transferrin glycoform analysis. If diet compliance is poor, physical growth retardation may occur. Growth will resume when more stringent dietary restrictions are reinstated. If the disorder is recognized early, the prospects for

normal development are good. As affected individuals grow up, they may recognize the association of nausea and vomiting with ingestion of fructose-containing foods and selectively avoid them.

DISORDERS OF ENERGY METABOLISM

The most common disorders of central mitochondrial energy metabolism are pyruvate dehydrogenase deficiency and deficiencies of respiratory chain components. Disorders of the Krebs cycle include deficiencies in fumarase, 2-ketoglutarate dehydrogenase, and succinyl-CoA ligase. In many, but not all patients, lactate is elevated in either blood or CSF. In pyruvate dehydrogenase deficiency, the lactate:pyruvate ratio is normal, whereas in respiratory chain disorders, the ratio is increased. Care must be taken to distinguish an elevated lactate level that is due to these conditions (called primary lactic acidoses) from elevated lactate that is a consequence of hypoxia, ischemia, or sampling problems. Table 34-3 lists some causes of primary lactic acidosis.

Patients with a defect in the pyruvate dehydrogenase complex often have agenesis of the corpus callosum or Leigh syndrome (lesions in the globus pallidus, dentate nucleus, and periaqueductal gray matter). They can have mild facial

Table 34-3. Causes of primary lactic acidosis in childhood.

Defects of the pyruvate dehydrogenase complex

- E₁ (pyruvate decarboxylase) deficiency
- E₂ (dihydrolipoyl transacetylase) deficiency
- E₃ (lipoamide dehydrogenase) deficiency
- Pyruvate decarboxylase phosphate phosphatase deficiency

Abnormalities of gluconeogenesis

- Pyruvate carboxylase deficiency
- Isolated
- Biotinidase deficiency
- Holocarboxylase synthetase deficiency
- Fructose-1,6-diphosphatase deficiency
- Glucose-6-phosphatase deficiency (von Gierke disease)

Defects in the mitochondrial respiratory chain

- Complex I deficiency
- Complex IV deficiency (cytochrome C oxidase deficiency; frequent cause of Leigh disease)
- ATPase deficiency (frequent cause of Leigh disease)
- Complex II deficiency
- Complex III deficiency
- Combined deficiencies
- Coenzyme Q10 deficiency
- Other respiratory chain disorders

Defects in the Krebs cycle

- Succinyl-CoA ligase deficiency

dysmorphism. Recurrent altered mental status, recurrent ataxia, and recurrent acidosis are typical of many disturbances of pyruvate metabolism. The most common genetic defect is in the X-linked E₁ component, with males carrying milder mutations and females carrying severe mutations leading to cystic brain lesions.

The respiratory chain disorders are frequent (1:5000), and involve a heterogeneous group of genetic defects that produce a variety of clinical syndromes (now > 50) of varying severity and presentation. The disorders can affect multiple organs. The following set of symptoms (not intended as a comprehensive listing) can indicate a respiratory chain disorder:

1. General: failure to thrive
2. Brain: progressive neurodegeneration, Leigh syndrome, myoclonic seizures, brain atrophy, and subcortical leukodystrophy
3. Eye: optic neuropathy, retinitis pigmentosa, and progressive external ophthalmoplegia
4. Ears: nerve deafness
5. Muscle: myopathy with decreased endurance or rhabdomyolysis
6. Kidney: renal Fanconi syndrome
7. Endocrine: diabetes mellitus and hypoparathyroidism
8. Intestinal: pancreatic or liver insufficiency or pseudoobstruction
9. Skin: areas of hypopigmentation
10. Heart: cardiomyopathy, conduction defects, and arrhythmias.

Respiratory chain disorders are among the more common causes of static, progressive, or self-limited neurodevelopmental problems in children. Patients may present with nonspecific findings such as hypotonia, failure to thrive, or renal tubular acidosis, or with more specific features such as ophthalmoplegia or cardiomyopathy. Symptoms are often combined in recognizable clinical syndromes with ties to specific genetic causes. Ragged red fibers and mitochondrial abnormalities may be noted on histologic examination of muscle. Thirteen of the more than 100 genes that control activity of the respiratory chain are part of the mitochondrial genome. Therefore inheritance of defects in the respiratory chain may be mendelian or maternal.

▶ Diagnosis

Pyruvate dehydrogenase deficiency is diagnosed by enzyme assay in leukocytes or fibroblasts. Confirmation can be obtained by molecular analysis. Diagnosis of respiratory chain disorders is based on a convergence of clinical, biochemical, morphologic, enzymatic, and molecular data. Classic pathologic features of mitochondrial disorders are the accumulation of mitochondria, which produces ragged red fibers in skeletal muscle biopsy, and abnormal shapes and inclusions on electron microscopy. However, these findings are only present in 5% of children. Enzyme analysis on

skeletal muscle or liver tissue is complicated by an overlap between normal and affected range. Mitochondrial DNA analysis in blood or tissue may identify a diagnostic mutation. A rapidly increasing number of nuclear genes causing respiratory chain defects are being recognized. Children with defects in mtDNA maintenance often present with liver disease and neurodegeneration and are diagnosed by sequencing the causative nuclear genes. Although diagnostic criteria have been published, the cause of lactic acidemia still cannot be defined in many patients. In some instances, the genetics and prognosis may be clear, but in many cases neither prognosis nor genetic risk can be predicted.

▶ Treatment

A ketogenic diet is useful in pyruvate dehydrogenase deficiency. In rare patients with primary coenzyme Q deficiency, coenzyme Q treatment is very effective. Other treatments are of theoretical value, with little data on efficacy. Thiamine and lipoic acid have been tried in patients with pyruvate dehydrogenase complex deficiencies, and coenzyme Q and riboflavin have been helpful in some patients with respiratory chain defects. Dichloroacetic acid has been tried in pyruvate dehydrogenase complex deficiencies and in respiratory chain disorders, with limited clinical response and adverse effects.

DISORDERS OF AMINO ACID METABOLISM

DISORDERS OF THE UREA CYCLE

Ammonia is mostly derived from the catabolism of amino acids and is converted to an amino group in urea by enzymes of the urea cycle. Patients with severe defects (often those enzymes early in the urea cycle) usually present in infancy with severe hyperammonemia, vomiting, and encephalopathy, which is rapidly fatal. In patients with milder genetic defects, the course may be milder with vomiting and encephalopathy after protein ingestion or infection. Although defects in argininosuccinic acid synthetase (citrullinemia) and argininosuccinic acid lyase (argininosuccinic acidemia) may cause severe hyperammonemia in infancy, the usual clinical course is chronic with mental retardation. Ornithine transcarbamylase deficiency is X-linked. The rest of the urea cycle disorders are autosomal recessive. Age at onset of symptoms varies with residual enzyme activity, protein intake, growth, and stresses such as infection. Even within a family, males with ornithine transcarbamylase deficiency may differ by decades in the age of symptom onset. Many female carriers of ornithine transcarbamylase deficiency have protein intolerance. Some develop migraine-like symptoms after protein loads, and others develop potentially fatal episodes of vomiting and encephalopathy after protein ingestion, infections, or during labor and delivery. Trichorhesis nodosa is common in patients with the chronic form of argininosuccinic acidemia.

▶ Diagnosis

Blood ammonia should be measured in any acutely ill newborn in whom a cause is not obvious. In urea cycle defects, early hyperammonemia is associated with respiratory alkalosis. Serum citrulline is low or undetectable in carbamoyl phosphate synthetase and ornithine transcarbamylase deficiency, high in argininosuccinic acidemia, and very high in citrullinemia. Large amounts of argininosuccinic acid are found in the urine of patients with argininosuccinic acidemia. Urine orotic acid is increased in infants with ornithine transcarbamylase deficiency. Citrullinemia and argininosuccinic acidemia can be diagnosed in utero by appropriate enzyme assays, but carbamoyl phosphate synthetase and ornithine transcarbamylase deficiency can be diagnosed in utero only by molecular methods.

▶ Treatment

During treatment of acute hyperammonemic crisis, protein intake should be stopped, and glucose and lipids should be given to reduce endogenous protein breakdown from catabolism. Arginine should be given intravenously, both because it is an essential amino acid for patients with urea cycle defects and because it increases the excretion of waste nitrogen in patients with citrullinemia and argininosuccinic acidemia. Sodium benzoate, either alone or with sodium phenylacetate, can be given intravenously to treat hyperammonemic coma. Additionally, hemodialysis or hemofiltration is indicated for severe or persistent hyperammonemia, as is usually the case in the newborn. Peritoneal dialysis and double-volume exchange transfusion are insufficiently effective in this setting.

Long-term treatment includes oral administration of arginine (or citrulline), adherence to a low-protein diet, and administration of sodium benzoate and sodium phenylbutyrate (a prodrug of sodium phenylacetate), to increase excretion of nitrogen as hippuric acid and phenylacetylglutamine. Symptomatic heterozygous female carriers of ornithine transcarbamylase deficiency should also receive such treatment. Liver transplantation may be curative and is indicated for patients with severe disorders.

The outcome of urea cycle disorders depends on the genetic severity of the condition (residual activity) and the severity and prompt treatment of hyperammonemic episodes. Many patients with urea cycle defects, no matter what the enzyme defect, develop permanent neurologic and intellectual impairments, with cortical atrophy and ventricular dilation seen on computed tomographic scan. Rapid identification and treatment of the initial hyperammonemic episode improves outcome.

PHENYLKETONURIA & THE HYPERPHENYLALANINEMIAS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Mental retardation, hyperactivity, seizures, light complexion, and eczema characterize untreated patients.
- ▶ Newborn screening for elevated serum phenylalanine identifies most infants.
- ▶ Disorders of cofactor metabolism also produce elevated serum phenylalanine level.
- ▶ Early diagnosis and treatment with phenylalanine-restricted diet prevents mental retardation.

Probably the best-known disorder of amino acid metabolism is the classic form of phenylketonuria caused by decreased activity of phenylalanine hydroxylase, the enzyme that converts phenylalanine to tyrosine. In classic phenylketonuria, there is little or no phenylalanine hydroxylase activity. In the less severe hyperphenylalaninemias there may be significant residual activity. Rare variants can be due to deficiency of dihydropteridine reductase or defects in bipterin synthesis.

Phenylketonuria is an autosomal recessive trait, with an incidence in Caucasians of approximately 1:10,000 live births. On a normal neonatal diet, affected patients develop hyperphenylalaninemia. Patients with untreated phenylketonuria exhibit severe mental retardation, hyperactivity, sei-

zures, a light complexion, and eczema. The patient's urine has a "mouse-like" odor.

Success in preventing severe mental retardation in phenylketonuric children by restricting phenylalanine starting in early infancy led to screening programs to detect the disease early. Because the outcome is best when treatment is begun in the first month of life, infants should be screened during the first few days. A second test is necessary when newborn screening is done before 24 hours of age. In such cases the second test should be completed by the third week of life.

▶ Diagnosis & Treatment

The diagnosis of phenylketonuria in a severely mentally retarded older child with typical biochemical and physical characteristics is straightforward, but in the newborn period, especially when there is no family history, the condition must be differentiated from other forms of hyperphenylalaninemia. This is usually done by determining serum phenylalanine and tyrosine levels on a normal diet and by examining pterins in blood and urine.

Prenatal diagnosis of phenylketonuria is possible using molecular methods. Molecular approaches are replacing serum measurements of phenylalanine and tyrosine to determine carrier status. Prenatal diagnosis of defects in pterin metabolism can often be made.

A. Classic Phenylketonuria

Findings include persistently elevated serum levels of phenylalanine (> 20 mg/dL or 1200 μ M on a regular diet), normal or low serum levels of tyrosine, and normal pterins. Poor phenylalanine tolerance persists throughout life. Restriction of dietary phenylalanine intake is indicated, and a favorable outcome is the rule.

Treatment of classic phenylketonuria is to limit dietary phenylalanine intake to amounts that permit normal growth and development. Dietary goals usually aim for a phenylalanine level less than 360 μ M (6 mg/dL). Metabolic formulas deficient in phenylalanine are available but must be supplemented with normal milk and other foods to supply enough phenylalanine to permit normal growth and development. Serum phenylalanine concentrations must be monitored frequently while ensuring that growth, development, and nutrition are adequate. This monitoring is best done in experienced clinics. Although dietary treatment is most effective when initiated during the first months of life, it may also be of benefit in reversing behaviors such as hyperactivity, irritability, and distractibility when started later in life.

Phenylalanine restriction should continue throughout life, both because of subtle changes in intellect and behavior in persons receiving treatment early who later stop the diet, and because of the risk of late development of potentially irreversible neurologic damage after stopping the diet. Counseling should be given during adolescence, and women's diets should be monitored closely prior to conception and throughout pregnancy.

Children with classic phenylketonuria who receive treatment promptly after birth and achieve phenylalanine and tyrosine homeostasis will develop well physically and can be expected to have normal or near-normal intellectual development.

Treatment with R-tetrahydrobiopterin results in improved phenylalanine tolerance in up to 60% of patients with a deficiency in phenylalanine hydroxylase, with best results seen in patients with hyperphenylalaninemia. Provision of high doses of large neutral amino acids results in a moderate reduction in phenylalanine and is used as an adjunctive treatment in some adults with phenylketonuria.

B. Persistent Hyperphenylalaninemia

In infants receiving a normal protein intake, serum phenylalanine levels are usually 240–1200 μM (4–20 mg/dL), and pterins are normal. Phenylalanine restriction is indicated if phenylalanine levels consistently exceed 600 μM (10 mg/dL).

C. Transient Hyperphenylalaninemia

Serum phenylalanine levels are elevated early but progressively decline toward normal. Dietary restriction is only temporary, if required at all.

D. Dihydropteridine Reductase Deficiency

Serum phenylalanine levels vary. The pattern of pterin metabolites is abnormal. Seizures and psychomotor regression occur even with diet therapy, probably because the enzyme defect also causes neuronal deficiency of serotonin and dopamine. These deficiencies require treatment with levodopa, carbidopa, 5-hydroxytryptophan, and folinic acid.

E. Defects in Biopterin Biosynthesis

Serum phenylalanine levels vary. Total pterins are low, and their pattern may suggest the specific defect, which can be at one of several steps in the biosynthetic pathway. Clinical findings include myoclonus, tetraplegia, dystonia, oculogyric crises, and other movement disorders. Treatment is the same as for dihydropteridine reductase deficiency. Tetrahydrobiopterin may be added.

F. Tyrosinemia of the Newborn

Serum phenylalanine levels are lower than those associated with phenylketonuria and are accompanied by marked hyper-tyrosinemia. Tyrosinemia of the newborn usually occurs in premature infants and is due to immaturity of 4-hydroxyphenylpyruvic acid oxidase. The condition resolves spontaneously within 3 months, almost always without sequelae.

G. Maternal Phenylketonuria

Offspring of phenylketonuric mothers may have transient hyperphenylalaninemia at birth. Elevated maternal phenylal-

anine causes mental retardation, microcephaly, growth retardation, and often congenital heart disease or other malformations in the offspring. The risk to the fetus is lessened considerably by maternal phenylalanine restriction with maintenance of phenylalanine levels below 360 μM (6 mg/dL) throughout pregnancy and optimally started before conception.

HEREDITARY TYROSINEMIA

Type 1 hereditary tyrosinemia is caused by deficiency of fumarylacetoacetase. It presents with acute or progressive hepatic parenchymal damage, renal tubular dysfunction with generalized aminoaciduria, hypophosphatemic rickets, or neuropathic crises. Tyrosine and methionine are increased in blood and tyrosine metabolites and δ -aminolevulinic acid in urine. The key diagnostic metabolite is elevated succinylacetone in urine. Liver failure may be rapidly fatal in infancy or

somewhat more chronic, with liver cell carcinoma almost invariable in long-term survivors. The condition is autosomal recessive and is especially common in Scandinavia and in the Chicoutimi–Lac St. Jean region of Quebec. Prenatal diagnosis is possible. Tyrosinemia type II presents with corneal ulcers and keratotic lesions on palms and soles and very high serum tyrosine levels ($> 600 \mu\text{M}$).

▶ Diagnosis

Similar clinical and biochemical findings may occur in other liver diseases such as galactosemia and hereditary fructose intolerance. Increased succinylacetone occurs only in fumarylacetoacetase deficiency, and is diagnostic. Enzyme assay in liver biopsy or mutation analysis can provide further diagnostic confirmation. Diagnostic confirmation of tyrosinemia type II is by molecular methods.

▶ Treatment

A diet low in phenylalanine and tyrosine is indicated and can ameliorate liver disease, but does not prevent carcinoma development. Pharmacologic therapy to inhibit 4-hydroxyphenylpyruvate dehydrogenase using 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) decreases the production of toxic metabolites, maleylacetoacetate and fumarylacetoacetate. It improves the liver disease and renal disease, prevents acute neuropathic attacks, and greatly reduces the risk of hepatocellular carcinoma. Liver transplantation is effective therapy for these children. Tyrosinemia type II symptoms respond to treatment with dietary tyrosine restriction.

MAPLE SYRUP URINE DISEASE (BRANCHED-CHAIN KETOACIDURIA)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Typical presentation is infantile encephalopathy.

Maple syrup urine disease is due to deficiency of the enzyme catalyzing oxidative decarboxylation of the branched-chain

keto acid derivatives of leucine, isoleucine, and valine. Accumulated keto acids of leucine and isoleucine cause the characteristic odor. Only leucine and its corresponding keto acid have been implicated in causing central nervous system dysfunction. Many variants of this disorder have been described, including mild, intermittent, and thiamin-dependent forms. All are autosomal recessive traits.

Patients with classic maple syrup urine disease are normal at birth but after about 1 week develop feeding difficulties, coma, and seizures. Unless diagnosis is made and dietary restriction of branched-chain amino acids is begun, most will die in the first month of life. Nearly normal growth and development may be achieved if treatment is begun before about age 10 days.

▶ Diagnosis

Amino acid analysis shows marked elevations of branched-chain amino acids including alloisoleucine in serum and urine. Alloisoleucine, a transamination product of the keto acid of isoleucine, is almost pathognomonic. Urine organic acids demonstrate the characteristic keto acids. The magnitude and consistency of amino acid and organic acid changes are altered in mild and intermittent forms of the disease. Prenatal diagnosis is possible.

▶ Treatment

Metabolic formulas deficient in branched-chain amino acids are available but must be supplemented with normal milk and other foods to supply enough branched-chain amino acids to permit normal growth and development. Serum levels of branched-chain amino acids must be monitored frequently in the first months of life to deal with changing protein requirements. Acute episodes must be aggressively treated to prevent catabolism and negative nitrogen balance.

HOMOCYSTINURIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Consider in a child of any age with a marfanoid habitus, dislocated lenses, or thrombosis.
- ▶ Identification through newborn screening is essential to ensure early treatment and a normal outcome.

Homocystinuria is most often due to deficiency of cystathionine β -synthase (CBS), but may also be due to deficiency of methylenetetrahydrofolate reductase (MTHFR) or to defects in the biosynthesis of methyl- B_{12} , the coenzyme for N^5 -methyltetrahydrofolate methionine S -methyltransferase (methionine synthase). All known inherited forms of homocystinuria are transmitted as autosomal recessive traits and can be diagnosed in the fetus.

About 50% of patients with untreated CBS deficiency are mentally retarded, and most have arachnodactyly, osteoporosis, and a tendency to develop dislocated lenses and thromboembolic phenomena. Mild variants of CBS deficiency present with thromboembolic events. Milder elevations of homocysteine are increasingly recognized as a factor in the etiology of vascular disease leading to myocardial infarction and stroke. These mild elevations are often caused by mutations leading to heat-sensitive defects in MTHFR. Patients with remethylation defects usually exhibit failure to thrive and a variety of neurologic symptoms, including brain atrophy, microcephaly, and seizures in infancy and early childhood.

▶ Diagnosis

Diagnosis is made by demonstrating homocystinuria in a patient who is not severely deficient in vitamin B_{12} . Serum methionine levels are usually high in patients with CBS deficiency and often low in patients with remethylation defects. When the remethylation defect is due to deficiency of methyl- B_{12} , megaloblastic anemia or hemolytic uremic syndrome may be present, and an associated deficiency of adenosyl- B_{12} may cause methylmalonic aciduria. Studies of cultured fibroblasts may be necessary to make a specific diagnosis.

▶ Treatment

About 50% of patients with CBS deficiency respond to large oral doses of pyridoxine. Early treatment of pyridoxine nonresponders is by dietary methionine restriction. Oral administration of betaine increases methylation of homocysteine to methionine in patients with CBS deficiency or with remethylation defects and improves neurologic function. Early treatment prevents mental retardation, lens dislocation, and thromboembolic manifestations, which justifies the screening of newborn infants. Large doses of vitamin B_{12} (eg, 1–5 mg hydroxycobalamin administered daily intramus-

cularly or subcutaneously) are indicated in some patients with defects in cobalamin metabolism.

NONKETOTIC HYPERGLYCINEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Severely affected newborns have apnea, hypotonia, lethargy, myoclonic seizures, and hiccups.
- ▶ Mental and motor retardation in most patients.
- ▶ Children may present with developmental delay, mild chorea, and seizures.
- ▶ EEG shows burst suppression.
- ▶ Cerebrospinal fluid (CSF) glycine is elevated.

Inherited deficiency of various subunits of the glycine cleavage enzyme causes nonketotic hyperglycinemia. Glycine accumulation in the brain disturbs neurotransmission of the glycinergic receptors and the N -methyl- D -aspartate receptor. In its most severe form, also termed glycine encephalopathy, the condition presents in the newborn as hypotonia, lethargy proceeding to coma, myoclonic seizures, and hiccups, with a burst suppression pattern on electroencephalography. Apnea spells may develop requiring ventilator assistance in the first 2 weeks, followed by spontaneous recovery. The majority of patients develop severe mental retardation and seizures. Some patients have agenesis of the corpus callosum or posterior fossa malformations. Some patients present with seizures, developmental delay, and mild chorea later in infancy or in childhood. All forms of the condition are autosomal recessive.

▶ Diagnosis

Nonketotic hyperglycinemia should be suspected in any neonate or infant with seizures and is confirmed by demonstrating a large increase in glycine in nonbloody CSF, with the ratio of CSF glycine to serum glycine being abnormally high. CSF glycine should be measured in any infant with neonatal apnea and a burst suppression pattern on electroencephalography. Enzyme analysis in a liver sample can confirm the diagnosis and can distinguish between defects in the T-protein or the P- and H-proteins. Molecular analysis is diagnostic in many cases. Prenatal diagnosis is possible only by assaying the enzyme in uncultured chorionic villus samples or by molecular analysis if both mutations are known in advance.

► Treatment

In patients with mild disease, treatment with sodium benzoate (to normalize serum glycine levels) and dextromethorphan or ketamine (to block *N*-methyl-D-aspartate receptors) controls seizures and improves outcome. Treatment of severely affected patients is generally unsuccessful. High-dose benzoate therapy can aid in seizure control but does not prevent severe mental retardation.

ORGANIC ACIDEMIAS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Consider in any child presenting with metabolic acidosis and ketosis in early infancy.

Organic acidemias are disorders of amino and fatty acid metabolism in which nonamino organic acids accumulate in serum and urine. These conditions are usually diagnosed by examining organic acids in urine, a complex procedure that requires considerable interpretive expertise and is usually performed only in specialized laboratories. Table 34–4 lists the clinical features of organic acidemias, together with the urine organic acid patterns typical of each. Additional details about some of the more important organic acidemias are provided in the sections that follow.

PROPIONIC & METHYLMALONIC ACIDEMIA (KETOTIC HYPERGLYICINEMIAS)

Idiopathic hyperglycinemia was first reported in 1961 as a syndrome of mental retardation and episodic ketoacidosis, neutropenia, thrombocytopenia, osteoporosis, and hyperglycinemia induced by protein intake or infection. It was then renamed ketotic hyperglycinemia to distinguish it from nonketotic hyperglycinemia, described in the preceding section. It is now known that the syndrome is almost always due to propionic or methylmalonic acidemia.

The oxidation of threonine, valine, methionine, and isoleucine results in propionyl-CoA, which propionyl-CoA

carboxylase converts into L-methylmalonyl-CoA, which is metabolized through methylmalonyl-CoA mutase to succinyl-CoA. Gut bacteria and the breakdown of odd-chain-length fatty acids also substantially contribute to propionyl-CoA production. Propionic acidemia is due to a defect in the biotin-containing enzyme propionyl-CoA carboxylase, and methylmalonic acidemia is due to a defect in methylmalonyl-CoA mutase. In most cases the latter is due to a defect in the mutase apoenzyme, but in others it is due to a defect in the biosynthesis of its adenosyl-B₁₂ coenzyme. In some of these defects, only the synthesis of adenosyl-B₁₂ is blocked; in others, the synthesis of methyl-B₁₂ is also blocked.

Clinical symptoms in propionic and methylmalonic acidemia vary according to the location and severity of the enzyme block. Children with severe blocks present with acute, life-threatening metabolic acidosis, hyperammonemia, and bone marrow depression early in infancy or with metabolic acidosis, vomiting, and failure to thrive during the first few months of life. Most patients with severe disease have mild or moderate mental retardation. Late complications include pancreatitis, cardiomyopathy, and basal ganglia stroke, and in methylmalonic aciduria, interstitial nephritis.

All known forms of propionic and methylmalonic acidemia are transmitted as autosomal recessive traits and can be diagnosed in utero.

► Diagnosis

Laboratory findings consist of increases in urinary organic acids derived from propionyl-CoA or methylmalonic acid (see Table 34–4). Hyperglycinemia can be present. In some forms of abnormal B₁₂ metabolism homocysteine can be elevated.

► Treatment

Patients with enzyme blocks in B₁₂ metabolism usually respond to massive doses of vitamin B₁₂ given intramuscularly. Vitamin B₁₂ nonresponsive methylmalonic acidemia and propionic acidemia require amino acid restriction, strict prevention of catabolism, and carnitine supplementation to enhance propionylcarnitine excretion. Intermittent metronidazole can help reduce the propionate load from the gut. In the acute setting, hemodialysis or hemofiltration may be needed. Combined liver-renal transplantation is an option for patients with renal insufficiency, and liver transplantation has shown promise for patients with life-threatening cardiomyopathy.

Table 34-4. Clinical and laboratory features of organic acidemias.

Disorder	Enzyme Defect	Clinical and Laboratory Features
Isovaleric acidemia	Isovaleryl-CoA dehydrogenase	Acidosis and odor of sweaty feet in infancy, or growth retardation and episodes of vomiting, lethargy, and acidosis. Isovalerylglycine always present in urine, with 3-hydroxyisovaleric acid during acute episodes.
3-Methylcrotonyl-CoA carboxylase deficiency	3-Methylcrotonyl-CoA carboxylase	Acidosis and feeding problems in infancy, or Reye-like episodes in older child. 3-Methylcrotonylglycine in urine, usually with 3-hydroxyisovaleric acid.
Combined carboxylase deficiency	Holocarboxylase synthetase	Hypotonia and lactic acidosis in infancy. 3-Hydroxyisovaleric acid in urine, often with small amounts of 3-hydroxypropionic and methylcitric acids. Often biotin-responsive.
Biotinidase deficiency	Biotinidase	Alopecia, seborrheic rash, and ataxia in infancy or childhood. Urine organic acids as above. Always biotin-responsive.
3-Hydroxy-3-methylglutaric acidemia	3-Hydroxy-3-methylglutaryl-CoA lyase	Hypoglycemia and acidosis in infancy; Reye-like episodes with nonketotic hypoglycemia or leukodystrophy in older children. 3-Hydroxy-3-methylglutaric, 3-methylglutaconic, and 3-hydroxyisovaleric acids in urine.
3-Ketothiolase deficiency	3-Ketothiolase	Ketotic hyperglycinemia syndrome in infancy, or episodes of vomiting, severe metabolic acidosis (hyperketosis), and encephalopathy. 2-Methyl-3-hydroxybutyric and 2-methylacetoacetic acids and tiglylglycine in urine, especially after isoleucine load.
Propionic acidemia	Propionyl-CoA carboxylase	Hyperammonemia and metabolic acidosis in infancy; ketotic hyperglycinemia syndrome later. 3-Hydroxypropionic and methylcitric acids in urine, with 3-hydroxy- and 3-ketovaleric acids during ketotic episodes.
Methylmalonic acidemia	Methylmalonyl-CoA mutase Defects in B ₁₂ biosynthesis	Clinical features same as in propionic acidemia. Methylmalonic acid in urine, often with 3-hydroxypropionic and methylcitric acids. Clinical features same as above when only adenosyl-B ₁₂ synthesis is decreased; early neurologic features prominent when accompanied by decreased synthesis of methyl-B ₁₂ . In latter instance, hypomethioninemia and homocystinuria accompany methylmalonic aciduria.
Pyroglutamic acidemia	Glutathione synthetase	Acidosis and hemolytic anemia in infancy; chronic acidosis later. Pyroglutamic acid in urine.
Glutaric acidemia type I	Glutaryl-CoA dehydrogenase	Progressive extrapyramidal movement disorder in childhood, with episodes of acidosis, vomiting, and encephalopathy. Glutaric acid and 3-hydroxyglutaric acid in serum and urine.
Glutaric acidemia type II	Electron transfer flavoprotein (ETF) ETF:ubiquinone oxidoreductase (ETF dehydrogenase)	Hypoglycemia, acidosis, hyperammonemia, and odor of sweaty feet in infancy, often with polycystic and dysplastic kidneys. Later onset may be with episodes of hypoketotic hypoglycemia, liver dysfunction, or slowly progressive skeletal myopathy. Glutaric, ethylmalonic, 3-hydroxyisovaleric, isovalerylglycine, and 2-hydroxyglutaric acids in urine, often with sarcosine in serum and urine.
4-Hydroxybutyric acidemia	Succinic semialdehyde dehydrogenase	Seizures and developmental retardation. 4-Hydroxybutyric acid in urine.

ISOVALERIC ACIDEMIA

Isovaleric acidemia, caused by deficiency of isovaleryl-CoA dehydrogenase in the leucine oxidative pathway, was the first organic acidemia to be described in humans. Patients with this disorder usually present with poor feeding, metabolic acidosis, seizures, and an odor of sweaty feet during the first few days of life, with coma and death occurring if the condition is not recognized and treated. Other patients have a more chronic course, with episodes of vomiting and lethargy, hair loss, and pancreatitis precipitated by intercurrent infections or increased protein intake. The condition is autosomal recessive and can be diagnosed in utero.

▶ Diagnosis

Isovalerylglycine is consistently detected in the urine by organic acid chromatography.

▶ Treatment

Providing a low-protein diet or a diet low in leucine is effective. Conjugation with either glycine or carnitine helps in maintaining metabolic stability. Outcome is usually good.

Vockley J, Ensenauer R: Isovaleric acidemia: New aspects of genetic and phenotypic heterogeneity. *Am J Med Genet C Semin Med Genet* 2006;142:95 [PMID: 16602101].

CARBOXYLASE DEFICIENCY

Isolated pyruvate carboxylase deficiency presents with lactic acidosis and hyperammonemia in early infancy. Even if biochemically stabilized, the neurologic outcome is dismal. Isolated 3-methylcrotonyl-CoA carboxylase deficiency is frequently recognized on newborn screening using tandem mass spectrometric analysis of acylcarnitines. It is usually a benign condition that only rarely causes symptoms of acidosis and neurologic depression. All carboxylases require biotin as a cofactor. Holocarboxylase synthetase and biotinidase are two enzymes of biotin metabolism in mammals. Holocarboxylase synthetase covalently binds biotin to the apocarboxylases for pyruvate, 3-methylcrotonyl-CoA, and propionyl-CoA; and biotinidase releases biotin from these proteins and from proteins in the diet. Recessively inherited deficiency of either enzyme causes deficiency of all three carboxylases (ie, multiple carboxylase deficiency). Patients with holocarboxylase synthetase deficiency usually present as neonates with hypotonia, skin problems, and massive acidosis. Those with biotinidase deficiency more often present somewhat later with a syndrome of ataxia, seizures, sebor-

rhea, and alopecia. Newborn screening for the condition is justified because many patients with biotinidase deficiency do not have typical symptoms, but do develop preventable neurologic sequelae.

▶ Diagnosis

This diagnosis should be considered in patients with typical symptoms or in those with primary lactic acidosis. Urine organic acids are usually but not always abnormal (see Table 34–4). Diagnosis is made by enzyme assay. Biotinidase can be assayed in serum, and holocarboxylase synthetase in leukocytes or fibroblasts.

▶ Treatment

Oral administration of biotin in large doses often reverses the organic aciduria within days and the clinical symptoms within days to weeks. Hearing loss can occur in patients with biotinidase deficiency despite treatment.

GLUTARIC ACIDEMIA TYPE I

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Suspect in children with acute basal ganglia necrosis and macrocrania with subdural bleeds.
- ▶ Presymptomatic diagnosis by newborn screening and treatment reduces the incidence of acute encephalopathic crises.

Glutaric acidemia type I is due to deficiency of glutaryl-CoA dehydrogenase. Patients have frontotemporal atrophy with enlarged sylvian fissures and macrocephaly. Sudden or chronic neurodegeneration secondary to neuronal degeneration in the caudate and putamen causes a progressive extrapyramidal movement disorder in childhood with dystonia and athetosis. Children with glutaric acidemia type I may present with retinal hemorrhages and intracranial bleeding and may thus be considered victims of child abuse. Severely debilitated children often die in the first decade, but several reported patients have had only mild neurologic abnormalities. Most patients develop symptoms in the first 6 years of life. The condition is autosomal recessive and prenatal diagnosis is possible.

► Diagnosis

Glutaric acidemia type I should be suspected in patients with acute or progressive dystonia in the first 6 years of life. Magnetic resonance imaging of the brain is highly suggestive. The diagnosis is supported by finding glutaric, 3-hydroxyglutaric acid, and glutarylcarnitine in urine or serum. Demonstration of deficiency of glutaryl-CoA dehydrogenase in fibroblasts, leukocytes, or a mutation in the *GCDH* gene confirms the diagnosis. Prenatal diagnosis is by enzyme assay, quantitative metabolite analysis in amniotic fluid, or mutation analysis.

► Treatment

Aggressive management of catabolism during intercurrent illness and supplementation with large amounts of carnitine may prevent degeneration of the basal ganglia. Dietary lysine and tryptophan are frequently restricted in young patients. Neurologic symptoms, once present, do not resolve. Symptomatic treatment of severe dystonia is important for affected patients.

DISORDERS OF FATTY ACID OXIDATION & CARNITINE

FATTY ACID OXIDATION DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Obtain an acylcarnitine profile for any child with hypoglycemia to evaluate for a fatty acid oxidation defect.
- Early diagnosis and treatment can prevent cardiomyopathy in affected children.

Deficiencies of very-long-chain and medium-chain acyl-CoA dehydrogenase (VLCAD, MCAD) and long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD), three enzymes of fatty acid β -oxidation, usually cause Reye-like episodes of hypoketotic hypoglycemia, mild hyperammonemia, hepatomegaly, and encephalopathy. Sudden death in infancy is a less common presentation. The long-chain defects, which also include carnitine palmitoyltransferase deficiency I and II and carnitine-acylcarnitine translocase deficiency, often also cause skeletal myopathy with hypotonia and cardiomyopathy, and ventricular arrhythmias. Less severe defects present with recurrent episodes of rhabdomyolysis. LCHAD deficiency may produce progressive liver cirrhosis, peripheral neuropathy, and retinitis pigmentosa. Mothers of affected infants can have acute fatty liver of pregnancy or HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets). Mild carnitine palmitoyltransferase I deficiency may cause renal tubular acidosis and hypertriglyceridemia. MCAD deficiency is common, occurring in perhaps 1:9000 live births. Reye-like episodes may be fatal or cause residual neurologic damage. Episodes tend to become less frequent and severe with time. After the diagnosis is made and treatment instituted, morbidity decreases and mortality is avoided in MCAD deficiency.

Short-chain acyl-CoA dehydrogenase (SCAD) deficiency is characterized by the presence of ethylmalonic acid in the urine, and although some patients have symptoms similar to those in MCAD deficiency, many are asymptomatic. Glutaric acidemia type II results from defects in the transfer of electrons from fatty acid oxidation and some amino acid oxidation into the respiratory chain. Some patients with glutaric acidemia type II have a clinical presentation resembling MCAD deficiency. Patients with a severe neonatal presentation also have renal cystic disease and dysmorphic features. The least affected patients can present with late-onset myopathy and be riboflavin responsive. Some develop cardiomyopathy or leukodystrophy. These conditions are autosomal recessive.

► Diagnosis

The hypoglycemic presentation of the Reye episode is associated with a lack of an appropriate ketone response to fasting. Patients with MCAD deficiency may excrete hexanoylglycine, suberylglycine, and phenylpropionylglycine in the urine organic acids. Urine and blood findings in glutaric acidemia type II and SCAD deficiency are often diagnostic. The finding of normal urine organic acids does not exclude these conditions, because excretion of dicarboxylic acids and other products of microsomal and peroxisomal oxidation of fatty acids can be intermittent.

The analysis of acylcarnitine esters is currently the first-line diagnostic test and shows diagnostic metabolites regardless of clinical status. MCAD deficiency is characterized by elevated octanoylcarnitine. A similar typical pattern can be recognized in deficiencies of VLCAD, LCHAD, carnitine

acylcarnitine translocase, and severe carnitine palmitoyltransferase. This is used in neonatal screening. Further confirmation can be obtained from analysis of fatty acid oxidation in fibroblasts. A common mutation in MCAD and in LCHAD deficiency is useful in confirming the diagnosis. Molecular sequencing is available for each defect, and enzyme assays for each enzyme can be done in fibroblasts in specialized laboratories.

► Treatment

Acutely, management involves prevention of hypoglycemia by avoiding prolonged fasting (> 8–12 hours). Chronic therapy includes providing carbohydrate snacks before bedtime and vigorous treatment of fasting associated with intercurrent infections. Because fatty acid oxidation can be compromised by associated carnitine deficiency, patients with MCAD deficiency usually receive oral carnitine. Carnitine use in VLCAD and LCHAD deficiency is less clear. Restriction of dietary long-chain fats is controversial in MCAD deficiency, but is required for VLCAD and LCHAD deficiencies. Medium-chain triglycerides are contraindicated in MCAD deficiency but are an essential energy source for patients with VLCAD and LCHAD deficiencies or carnitine acylcarnitine translocase deficiency. Riboflavin may be beneficial in some patients with glutaric acidemia type II. Outcome in MCAD deficiency is excellent but is more guarded in patients with the other disorders.

CARNITINE

Carnitine is an essential nutrient found in highest concentration in red meat. Its primary function is to transport long-chain fatty acids into mitochondria for oxidation. Primary defects of carnitine transport may manifest as Reye syndrome, cardiomyopathy, or skeletal myopathy with hypotonia. These disorders are rare compared with secondary carnitine deficiency, which may be due to diet (especially intravenous alimentation or ketogenic diet), renal losses, drug therapy (especially valproic acid), and other metabolic disorders (especially disorders of fatty acid oxidation and organic acidemias). The prognosis depends on the cause of the carnitine abnormality. Primary carnitine deficiency is one of the most treatable causes of dilated cardiomyopathy in children.

Free and esterified carnitine can be measured in blood. Muscle carnitine may be low despite normal blood levels, particularly in respiratory chain disorders. If carnitine insufficiency is suspected, the patient should be evaluated to rule out disorders that might cause secondary carnitine deficiency.

Oral or intravenous L-carnitine is used in carnitine deficiency or insufficiency in doses of 25–100 mg/kg/d or higher. Treatment is aimed at maintaining normal carnitine levels. Carnitine supplementation in patients with some disorders of fatty acid oxidation and organic acidosis may also augment excretion of accumulated metabolites. Supplementation may not prevent metabolic crises in such patients.

PURINE METABOLISM DISORDERS

Hypoxanthine-guanine phosphoribosyltransferase is an enzyme that converts the purine bases hypoxanthine and guanine to inosine monophosphate and guanosine monophosphate, respectively. Hypoxanthine-guanine phosphoribosyltransferase deficiency (Lesch-Nyhan syndrome) is an X-linked recessive disorder. The complete deficiency is characterized by central nervous system dysfunction and purine overproduction with hyperuricemia and hyperuricuria. Depending on the residual activity of the mutant enzyme, male hemizygous individuals may be severely disabled by choreoathetosis, spasticity, and compulsive, mutilating lip and finger biting, or they may have only gouty arthritis and urate ureterolithiasis. Enzyme deficiency can be measured in erythrocytes, fibroblasts, and cultured amniotic cells; this disorder can thus be diagnosed in utero. Adenylosuccinate lyase deficiency involves a defect in the synthesis of purines. Patients present with static mental retardation, hypotonia, and seizures.

▶ Diagnosis

Diagnosis of Lesch-Nyhan syndrome is made by demonstrating an elevated uric acid:creatinine ratio in urine, followed by demonstration of enzyme deficiency in red blood cells or fibroblasts. Screening for adenylosuccinate lyase deficiency is by measurement of succinylpurines using the Bratton-Marshall colorimetric test, with confirmation by further metabolite and molecular assays.

▶ Treatment

Hyperhydration and alkalization are essential to prevent kidney stones and urate nephropathy. Allopurinol and probenecid may be given to reduce hyperuricemia and prevent gout but do not affect the neurologic status. Physical restraints are often more effective than neurologic medications for automutilation. No effective treatment exists for adenylosuccinate lyase deficiency.

LYSOSOMAL DISEASES

Lysosomes are cellular organelles in which complex macromolecules are degraded by specific acid hydrolases. Deficiency of a lysosomal enzyme causes its substrate to accumulate in the lysosomes of tissues that degrade it, resulting in a

characteristic clinical picture. These storage disorders are classified as mucopolysaccharidoses, lipidoses, or mucopolipidoses, depending on the nature of the stored material. Two additional disorders, cystinosis and Salla disease, are caused by defects in lysosomal proteins that normally transport material from the lysosome to the cytoplasm. Table 34–5 lists clinical and laboratory features of these conditions. Most are inherited as autosomal recessive traits, and all can be diagnosed in utero.

▶ Diagnosis

The diagnosis of mucopolysaccharidosis is suggested by certain clinical and radiologic findings (dysostosis multiplex). Urine screening tests can detect increased mucopolysaccharides and further identify which specific mucopolysaccharides are present. Diagnosis must be confirmed by enzyme assays of leukocytes or cultured fibroblasts. Analysis of urinary oligosaccharides indicates a specific disorder prior to enzymatic testing. Lipidoses present with visceral symptoms or neurodegeneration. The pattern of the leukodystrophy associated with many lipidoses can indicate a specific condition. Diagnosis is made by appropriate enzyme assays of peripheral leukocytes or cultured skin fibroblasts. Molecular analysis is also available for most conditions.

▶ Treatment

Most conditions cannot be treated effectively, but new avenues have given hope in many conditions. Hematopoietic stem cell transplantation can greatly improve the course of some lysosomal diseases and is first-line treatment in some, such as infantile Hurler syndrome. Several disorders are treated with infusions of recombinant modified enzyme. Treatment of Gaucher disease is very effective and long-term data suggest excellent outcome. Similar treatments have been developed for Fabry disease, several mucopolysaccharidoses, and Pompe disease. Substantial improvements in these conditions have been reported but with limitations. New avenues for treatment under development are offered through substrate inhibition and chaperone therapy. Treatment of cystinosis with cysteamine results in depletion of stored cystine and prevention of complications including renal disease.

Table 34-5. Clinical and laboratory features of lysosomal storage diseases.

Disorder	Enzyme Defect	Clinical and Laboratory Features
I. Mucopolysaccharidoses		
Hurler syndrome	α -Iduronidase	Autosomal recessive. Mental retardation, hepatosplenomegaly, umbilical hernia, coarse facies, corneal clouding, dorsolumbar gibbus, severe heart disease. Heparan sulfate and dermatan sulfate in urine.
Scheie syndrome	α -Iduronidase (incomplete)	Autosomal recessive. Corneal clouding, stiff joints, normal intellect. Clinical types intermediate between Hurler and Scheie common. Heparan sulfate and dermatan sulfate in urine.
Hunter syndrome	Sulfoiduronate sulfatase	X-linked recessive. Coarse facies, hepatosplenomegaly, mental retardation variable. Corneal clouding and gibbus not present. Heparan sulfate and dermatan sulfate in urine.
Sanfilippo syndrome:		Autosomal recessive. Severe mental retardation and hyperactivity, with comparatively mild skeletal changes, visceromegaly, and facial coarseness. Types cannot be differentiated clinically. Heparan sulfate in urine.
Type A	Sulfamidase	
Type B	α - <i>N</i> -Acetylglucosaminidase	
Type C	Acetyl-CoA: α -glucosaminide- <i>N</i> -acetyltransferase	
Type D	α - <i>N</i> -acetylglucosamine-6-sulfatase	
Morquio syndrome	<i>N</i> -Acetylgalactosamine-6-sulfatase	Autosomal recessive. Severe skeletal changes, platyspondylisis, corneal clouding. Keratan sulfate in urine.
Maroteaux-Lamy syndrome	<i>N</i> -Acetylgalactosamine-4-sulfatase	Autosomal recessive. Coarse facies, growth retardation, dorsolumbar gibbus, corneal clouding, hepatosplenomegaly, normal intellect. Dermatan sulfate in urine.
β -Glucuronidase deficiency	β -Glucuronidase	Autosomal recessive. Varies from mental retardation, dorsolumbar gibbus, corneal clouding, and hepatosplenomegaly to mild facial coarseness, retardation, and loose joints. Hearing loss common. Dermatan sulfate or heparan sulfate in urine.
II. Muco lipidoses		
Mannosidosis	α -Mannosidase	Autosomal recessive. Varies from severe mental retardation, coarse facies, short stature, skeletal changes, and hepatosplenomegaly to mild facial coarseness and loose joints. Hearing loss common. Abnormal oligosaccharides in urine.
Fucosidosis	α -Fucosidase	Autosomal recessive. Variable: coarse facies, skeletal changes, hepatosplenomegaly, occasional angiokeratomas. Abnormal oligosaccharides in urine.
I-cell disease (muco lipidosis II)	<i>N</i> -Acetylglucosaminyl-phosphotransferase	Autosomal recessive; severe and mild forms known. Very short stature, mental retardation, early facial coarsening, clear cornea, and stiffness of joints. Increased lysosomal enzymes in serum. Abnormal sialyl oligosaccharides in urine.
Sialidosis	<i>N</i> -Acetylneuraminidase (sialidase)	Autosomal recessive. Mental retardation, coarse facies, skeletal dysplasia, myoclonic seizures, macular cherry-red spot. Abnormal sialyl oligosaccharides in urine.
III. Lipidoses		
Niemann-Pick disease	Sphingomyelinase	Autosomal recessive. Acute and chronic forms known. Acute neuronopathic form common in eastern European Jews. Accumulation of sphingomyelin in lysosomes of RE system and CNS. Hepatosplenomegaly, developmental retardation, macular cherry-red spot. Death by 1-4 y in severe type A; mild type B develops respiratory insufficiency usually in adulthood.
Metachromatic leukodystrophy	Arylsulfatase A	Autosomal recessive. Late infantile form, with onset at 1-4 y, most common. Accumulation of sulfatide in white matter with central leukodystrophy and peripheral neuropathy. Gait disturbances (ataxia), motor incoordination, absent deep tendon reflexes, and dementia. Death usually in first decade.
Krabbe disease (globoid cell leukodystrophy)	Galactocerebroside α -galactosidase	Autosomal recessive. Globoid cells in white matter. Onset at 3-6 mo with seizures, irritability, retardation, and leukodystrophy. Death by 1-2 y. Juvenile and adult forms are rare.

(continued)

Table 34-5. Clinical and laboratory features of lysosomal storage diseases. (Continued)

Disorder	Enzyme Defect	Clinical and Laboratory Features
Fabry disease	α -Galactosidase A	X-linked recessive. Storage of trihexosylceramide in endothelial cells. Pain in extremities, angiokeratoma corporis diffusum and (later) poor vision, hypertension, and renal failure.
Farber disease	Ceramidase	Autosomal recessive. Storage of ceramide in tissues. Subcutaneous nodules, arthropathy with deformed and painful joints, and poor growth and development. Death within first year.
Gaucher disease	Glucocerebrosidase β -glucosidase	Autosomal recessive. Acute neuronopathic form: Accumulation of glucocerebrosidase in lysosomes of RE system and CNS. Retardation, hepatosplenomegaly, macular cherry-red spot, and Gaucher cells in bone marrow. Death by 1-2 y. Chronic form common in eastern European Jews. Accumulation of sphingomyelin in lysosomes of RE system. Hepatosplenomegaly and flask-shaped osteolytic bone lesions. Consistent with normal life expectancy.
G _{M1} gangliosidosis	G _{M1} ganglioside β -galactosidase	Autosomal recessive. Accumulation of G _{M1} ganglioside in lysosomes of RE system and CNS. Infantile form: Abnormalities at birth with dysostosis multiplex, hepatosplenomegaly, macular cherry-red spot, and death by 2 y. Juvenile form: normal development to 1 y of age, then ataxia, weakness, dementia, and death by 4-5 y. Occasional inferior beaking of vertebral bodies of L1 and L2.
G _{M2} gangliosidosis Tay-Sachs disease Sandhoff disease	β -N-Acetylhexosaminidase A β -N-Acetylhexosaminidase A and B	Autosomal recessive. Tay-Sachs disease common in eastern European Jews; Sandhoff disease is panethnic. Clinical phenotypes are identical, with accumulation of G _{M2} ganglioside in lysosomes of CNS. Onset at age 3-6 mo, with hypotonia, hyperacusis, retardation, and macular cherry-red spot. Death by 2-3 y. Juvenile and adult onset forms of Tay-Sachs disease are rare.
Wolman disease	Acid lipase	Autosomal recessive. Accumulation of cholesterol esters and triglycerides in lysosomes of reticuloendothelial system. Onset in infancy with gastrointestinal symptoms and hepatosplenomegaly, and death by 3-6 mo. Adrenals commonly enlarged and calcified.
Niemann-Pick disease type C	NPC1 gene (95%), NPC2 gene (5%)	Autosomal recessive. Blocked transport of lipids and cholesterol from late endosomes to lysosomes. Infantile cholestatic liver disease, or later neurodegeneration with vertical supranuclear gaze palsy, ataxia, seizures, spasticity and loss of speech. Some have splenomegaly.

CNS, central nervous system; RE, reticuloendothelial.

PEROXISOMAL DISEASES

Peroxisomes are intracellular organelles that contain a large number of enzymes, many of which are oxidases linked to catalase. Among the enzyme systems in peroxisomes is one for β -oxidation of unusual very-long-chain fatty acids, phytanic acid, and bile acids, and one for plasmalogen biosynthesis. In addition, peroxisomes contain oxidases for D- and L-amino acids, pipercolic acid, and phytanic acid, and an enzyme (alanine-glyoxylate aminotransferase) that effects transamination of glyoxylate to glycine.

In some peroxisomal diseases, many enzymes are deficient. Zellweger (cerebrohepato-renal) syndrome, the best known among these, is caused by several defects in organelle assembly. Patients present in infancy with seizures, hypotonia, characteristic facies with a large forehead, and cholestatic hepatopathy. At autopsy renal cysts and absent peroxisomes are seen. Patients with a similar but milder biochemical and clinical phenotype have neonatal adrenoleukodystrophy or neonatal Refsum disease. They often have detectable peroxisomes.

In other peroxisomal diseases, only a single enzyme is deficient. Primary hyperoxaluria (alanine-glyoxylate aminotransferase deficiency) causes renal stones and nephropathy. Mutations in the X-linked very-long-chain fatty acid transporter gene, *ABCD1*, cause either a rapid leukodystrophy with loss of function (adrenoleukodystrophy), slow progressive spasticity and neuropathy (adrenomyeloneuropathy), or adrenal insufficiency. Defective phytanic acid oxidation in adult Refsum disease causes ataxia, leukodystrophy, cardiomyopathy, neuropathy, and cataracts. Other isolated enzyme deficiencies can mimic Zellweger syndrome.

Abnormalities of plasmalogen synthesis are clinically associated with rhizomelic chondrodysplasia punctata. Except for adrenoleukodystrophy, all peroxisomal diseases are autosomal recessive and can be diagnosed in utero.

▶ Diagnosis

The best screening test for Zellweger syndrome and other biogenesis disorders is determination of very-long-chain fatty acids in serum or plasma. Urine bile acids are abnormal in other peroxisomal disorders. Phytanic acid and plasmalogens can also be measured. Together, these studies identify most peroxisomal diseases. Tissue biopsy and appropriate enzyme assays are needed for confirmation, especially when the parents plan further pregnancies.

▶ Treatment

Bone marrow transplantation may be an effective treatment at the early stages of adrenoleukodystrophy. Lorenzo's oil, in

combination with a very-low-fat diet and essential fatty acid supplementation, is ineffective in patients with established symptoms, but shows promise in prevention of neurologic symptoms in presymptomatic males with adrenoleukodystrophy. Dietary treatment is used for adult Refsum disease. Liver transplantation protects the kidneys in severe primary hyperoxaluria.

CONGENITAL DISORDERS OF GLYCOSYLATION

Many proteins, including many enzymes, require glycosylation with carbohydrate moieties for normal function. The carbohydrate-deficient glycoprotein syndromes are a family of disorders that result from failure of glycosylation. Children with type Ia disease usually present with prenatal growth disturbance, often with abnormal fat distribution, cerebellar hypoplasia, typical facial dysmorphic features, and mental retardation. The typical course includes chronic liver disease, peripheral neuropathy, endocrinopathies, retinopathy, and in some patients, acute life-threatening events.

Patients with type Ib disease have a variable combination of liver fibrosis, protein-losing enteropathy, and hypoglycemia. More than a dozen other forms are characterized by additional key symptoms, including coloboma, cutis laxa, severe epilepsy, ichthyosis, and Dandy-Walker malformation. Biochemical differences and variations in clinical course (eg, the absence of peripheral neuropathy) characterize the other types. Pathophysiology probably relates to defects of those biochemical pathways that require glycosylated proteins. The syndromes appear so far to be inherited in an autosomal recessive manner, and frequency was initially estimated to be as high as 1:20,000 in northern Europe.

▶ Diagnosis

Diagnosis is supported by finding altered levels of glycosylated enzymes or other proteins such as transferrin, thyroxine-binding globulin, lysosomal enzymes, and clotting factors (IX, XI, antithrombin III, and proteins C and S). However, these levels may be normal in carbohydrate-deficient glycoprotein syndromes or abnormal in other conditions. Diagnosis is confirmed by finding typical patterns of altered isoelectric focusing of selected proteins. Most diagnostic laboratories examine serum transferrin to screen for *N*-linked defects and apoC1 for *O*-linked defects. Follow-up diagnosis is by assaying enzyme activity, analysis of lipid-linked oligosaccharides in fibroblasts, and mutation analysis.

▶ Treatment

Treatment is supportive, with opportunity to monitor and provide early treatment for expected clinical features. Mannose treatment is curative for patients with type Ib deficiency only.

SMITH-LEMLI-OPITZ SYNDROME & DISORDERS OF CHOLESTEROL SYNTHESIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Two- or three-toe syndactyly, facial dysmorphism, cardiac and genitourinary anomalies.
- ▶ Developmental delay, hypotonia, microcephaly, and poor growth in neonates with Smith-Lemli-Opitz (SLO) syndrome.

- ▶ Symptoms range from mild to life threatening.
- ▶ Elevated 7- and 8-dehydrocholesterol in serum and other tissue is diagnostic in SLO syndrome; serum cholesterol is usually low, but may be within normal range.

Several defects of cholesterol synthesis are associated with malformations and neurodevelopmental disability. Smith-Lemli-Opitz (SLO) syndrome is an autosomal recessive disorder caused by a deficiency of the enzyme 7-dehydrocholesterol δ^7 -reductase. It is characterized by microcephaly, poor growth, mental retardation, typical dysmorphic features of face and extremities (particularly two- to three-toe syndactyly), and often malformations of the heart and genitourinary system. Severity ranges from moderate to severe mental retardation to early death. Although deficient synthesis of cholesterol leads directly to deficiency of some hormones and bile acids, the pathophysiology of the malformations is unclear. Frequency is estimated to be between 1:40,000 and 1:20,000. Other cholesterol synthetic defects are seen in Conradi Hünnermann syndrome with chondrodysplasia punctata and atrophic skin. Cholestanolosis (cerebrotendinous xanthomatosis) manifests with progressive ataxia and cataracts.

▶ Diagnosis

In SLO, elevated 7- and 8-dehydrocholesterol in serum or other tissues, including amniotic fluid, is diagnostic. Serum cholesterol levels may be low or in the normal range. Enzymes of cholesterol synthesis may be assayed in cultured fibroblasts or amniocytes, and mutation analysis is possible.

▶ Treatment

Although postnatal treatment does not resolve prenatal injury, supplementation with cholesterol in SLO improves growth and behavior. The role of supplemental bile acids is controversial. Simvastatin reduces 7- and 8-dehydrocholesterol and increases cholesterol levels by induction of its synthetic enzymes, but its effect on clinical symptoms is unclear.

DISORDERS OF NEUROTRANSMITTER METABOLISM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Movement disorder, especially dystonia and oculogyric crises.
- ▶ Severe seizures, abnormal tone, ataxia, and mental retardation occur in severely affected infants.
- ▶ Mildly affected patients have dopa-responsive dystonia with diurnal variability.
- ▶ Deficient serine synthesis causes microcephaly, seizures and failure of myelination in neonates.

Abnormalities of neurotransmitter metabolism are increasingly recognized as causes of significant neurodevelopmental disabilities. Affected patients may present with movement disorders (especially dystonia and oculogyric crises), seizures, abnormal tone, ataxia, or mental retardation. Patients may be mildly affected (eg, dopa-responsive dystonia with diurnal variation) or severely affected (eg, intractable seizures with profound mental retardation). Deficient serine synthesis leads to congenital microcephaly, infantile seizures, and failure of myelination.

Pyridoxine-dependent epilepsy manifests as a severe seizure disorder in the neonatal or early infantile period that responds to high doses of pyridoxine. The disorder is caused by deficient activity of the enzyme α -amino adipic semialdehyde dehydrogenase resulting from mutations in the antiquitin (*ALDH7A1*) gene. Pyridoxal-phosphate-responsive encephalopathy manifests as a severe seizure disorder in infancy that responds to pyridoxal-phosphate. This disorder is caused by mutations in the *PNPO* gene encoding pyridox(am)ine oxidase, which is necessary for activation of pyridoxine.

▶ Diagnosis

Although some disorders can be diagnosed by examining serum amino acids or urine organic acids (eg, 4-hydroxybutyric aciduria), in most cases, diagnosis requires analysis of CSF. Spinal fluid samples for neurotransmitter analysis require special collection and handling, as the neurotransmitter levels are graduated along the axis of the central nervous system and are highly unstable once the sample is collected. A phenylalanine loading test can be diagnostic for mild defects in GTP-cyclohydrolase deficiency, in which neurotransmitter analysis may be insufficiently sensitive. Analysis of CSF amino acids shows elevated threonine in pyridoxal-phosphate-responsive disease and decreased serine and glycine in serine biosynthetic defects.

▶ Treatment

For some conditions, such as pyridoxine-responsive seizures, pyridoxal-phosphate-responsive encephalopathy, or dopa-

responsive dystonia, response to treatment can be dramatic. For others, response to therapy is less satisfactory in part because of poor penetration of the blood-brain barrier. Supplementation with serine and glycine can substantially improve outcome in serine deficiency.

CREATINE SYNTHESIS DISORDERS

Creatine and creatine phosphate are essential for storage and transmission of phosphate-bound energy in muscle and brain. They spontaneously convert to creatinine. Three disorders of creatine synthesis are now known: arginine:glycine amidinotransferase (AGAT) deficiency, guanidinoacetate methyltransferase (GAMT) deficiency, and creatine transporter (CrT1) deficiency. GAMT and AGAT deficiencies are autosomal recessive disorders, whereas CrT1 deficiency is X-linked. All patients demonstrate developmental delay, mental retardation, autistic behavior, seizures, and severe expressive language disturbance. Patients may also show developmental regression and brain atrophy. Patients with GAMT defi-

ciency have more severe seizures and an extrapyramidal movement disorder. The seizure disorder is milder in CrT1-deficient patients. Some female heterozygotes of CrT1 deficiency may also show developmental delay or learning disabilities.

▶ Diagnosis

The common feature of all creatine synthesis defects is a severe depletion of creatine and phosphocreatine in the brain demonstrable by reduction to absence of signal on magnetic resonance spectroscopy. In GAMT deficiency, guanidinoacetate accumulates, whereas in AGAT deficiency, guanidinoacetate is decreased, particularly in urine. Guanidinoacetate seems to be responsible for the severe seizures and movement disorder found in GAMT deficiency. Blood, urine, and CSF creatine levels are decreased in GAMT deficiency but normal in AGAT deficiency. Urine excretion of creatine and creatinine is elevated in CrT1 deficiency. Enzyme and molecular analyses are available for diagnostic confirmation.

▶ Treatment

Treatment with oral creatine supplementation is in part successful in GAMT and AGAT deficiencies. It is not beneficial in CrT1 deficiency. Treatment by combined arginine restriction and ornithine substitution in GAMT deficiency can decrease guanidinoacetate concentrations and improve the clinical course.

Genetics & Dysmorphology

Ellen R. Elias, MD
 Anne Chun-Hui Tsai, MD, MSc
 David K. Manchester, MD

Genetics is an exciting and rapidly evolving field that has significant relevance to the understanding of human embryology, physiology, and disease processes. Tremendous advances in molecular biology and biochemistry are allowing more comprehensive understanding of mechanisms inherent in genetic disorders, as well as improved diagnostic tests and management options. Many of the newer technologies and terms may be unfamiliar to the clinician in practice. Thus, the topics in the first part of the chapter serve as an introduction and review of the basic principles of genetics, including basic knowledge of cytogenetics and molecular biology. The principles of inherited human disorders are reviewed, encompassing different causes of genetic disorders, with a discussion of dysmorphology and teratology. The topics in the second part of the chapter focus on common clinical disorders including descriptions of the diseases, with a discussion of their pathogenesis, diagnosis, and management.

FOUNDATIONS OF GENETIC DIAGNOSIS

CYTOGENETICS

Cytogenetics is the study of genetics at the chromosome level. Chromosomal anomalies occur in 0.4% of all live births and are a common cause of mental retardation and congenital anomalies. The prevalence of chromosomal anomalies is much higher among spontaneous abortions and stillbirths.

Chromosomes

Human chromosomes consist of DNA (the blueprint of genetic material), specific proteins forming the backbone of the chromosome (called histones), and other chromatin structural and interactive proteins. Chromosomes contain most of the genetic information necessary for growth and differentiation. The nuclei of all normal human cells, with the exception of gametes, contain 46 chromosomes, consisting of

23 pairs (Figure 35–1). Of these, 22 pairs are called autosomes. They are numbered according to their size; chromosome 1 is the largest and chromosome 22 the smallest. In addition, there are two sex chromosomes: two X chromosomes in females and one X and one Y chromosome in males. The two members of a chromosome pair are called homologous chromosomes. One homolog of each chromosome pair is maternal in origin (from the egg); the second is paternal (from the sperm). The egg and sperm each contain 23 chromosomes (haploid cells). During formation of the zygote, they fuse into a cell with 46 chromosomes (diploid cell).

Cell Division

Cells undergo cycles of growth and division that are controlled according to their needs and functions.

Mitosis is a kind of cell division, occurring in stages, during which DNA replication takes place and two daughter cells, genetically identical to the original parent cells, are formed. This cell division is typical for all somatic cells (cells other than the sperm or egg, which are called germline cells). There are four phases of mitosis: interphase, prophase, metaphase, and anaphase (Figure 35–2). In interphase, chromosomes are long, thin, and nonvisible. At this time, the genetic material is replicated. In prophase, the chromosomes are more condensed. During metaphase (the phase following DNA replication but preceding cell division), individual chromosomes can be visualized. Each arm consists of two identical parts, called chromatids. Chromatids of the same chromosome are called sister chromatids. In anaphase, the genetic material is separated into two cells.

Meiosis (Figure 35–3), during which eggs and sperm are formed, is cell division limited to gametes. During meiosis, three unique processes take place:

1. Crossing over of genetic material between two homologous chromosomes. This is preceded by the pairing of both members of each chromosome pair, which facilitates the physical exchange of homologous genetic material.

▲ **Figure 35-1.** Normal male and female human karyotype. (Courtesy of Billie Carstens at CGL.)

2. Random assortment of maternally and paternally derived homologous chromosomes into the daughter cells. The distribution of maternal or paternal chromosomes to a particular daughter cell occurs independently in each cell.
3. Two cell divisions, the first of which is a reduction division—that is, separation between the homologous chromosomes. The second meiotic division is like mitosis, separating two sister chromatids into two genetically identical daughter cells.

cartilage, and bone marrow. Chorionic villi or amniocytes are used for prenatal diagnosis. Spontaneously dividing cells without a mitogen are present in bone marrow, and historically, bone marrow biopsy was done when immediate identification of a patient’s chromosome constitution was necessary for appropriate management (eg, to rule out trisomy 13 in a newborn with a complex congenital heart disease). However, this invasive test has been replaced by the availability of the FISH technique (see following discussion).

Chromosome Preparation & Analysis

Chromosome structure is visible only during mitosis, most often achieved in the laboratory by stimulating a blood lymphocyte culture with a mitogen for 3 days. Other tissues used for this purpose include skin, products of conception,

▲ **Figure 35-2.** Stages of mitotic division.

▲ **Figure 35-3.** Meiosis—demonstrating conversion from the diploid somatic cell to the haploid gamete.

Cells processed for routine chromosome analysis are stained on glass slides to yield a light-and-dark band pattern across the arms of the chromosomes (see Figure 35–1). This band pattern is characteristic and reproducible for each chromosome, allowing the chromosomes to be identified. Using different staining techniques, different banding patterns result: G, Q, and R banding. The most commonly used is G banding. The layout of chromosomes on a sheet of paper in a predetermined order is called a karyotype. High-resolution chromosome analysis is the study of more elongated chromosomes in prometaphase. In such an analysis, the bands can be visualized in greater detail, allowing detection of smaller, more subtle chromosomal rearrangements.

Fluorescence in situ hybridization (FISH) is a powerful technique that labels a known chromosome sequence with DNA probes attached to fluorescent dyes, thus enabling visualization of specific regions of chromosomes by fluorescent microscopy. There are many different kinds of probes, including paint probes (a mixture of sequences throughout one chromosome), sequence-specific probes, centromere probes, and telomere probes. A cocktail of differently colored probes, one color for each chromosome, called multi-color FISH, or M-FISH, can detect complex rearrangements between chromosomes. FISH can detect submicroscopic structural rearrangements undetectable by classic cytogenetic techniques and can identify marker chromosomes. (For pictures of FISH studies, go to <http://www.kumc.edu/gec/prof/cytogene.html>.)

FISH also allows interphase cells (lymphocytes, amniocytes) to be screened for numerical abnormalities such as trisomy 13, 18, or 21, and sex chromosome anomalies. However, because of the possible background or contamination of the signal, the abnormality must be confirmed by conventional chromosome analysis.

Array-Based Comparative Genomic Hybridization

Advances in computer chip technology have led to the development of new genetic testing using comparative genomic hybridization with microarray technique. This technique allows detection of very small genetic imbalances anywhere in the genome. Its usefulness has been well documented in cancer research and more recently in assessing small chromosomal rearrangements. In particular, it has been used to detect interstitial and subtelomeric submicroscopic imbalances, to characterize their size at the molecular level, and to define the breakpoints of translocations. Clinically available arrays include (1) focused interest arrays that can pick up all microdeletions detectable by FISH, (2) 1-mb bacterial artificial chromosome arrays that can pick up rearrangements greater than 1 mb, (3) oligonucleotide arrays using special probes that can pick up changes as small as 80 kb, and (4) single nucleotide polymorphism (SNP) arrays, which are used more widely in research settings. Although

this powerful new technology can identify extremely subtle DNA rearrangements and changes, many human polymorphisms, including small deletions and duplications, are not totally understood. Therefore, special caution and parental studies are often required in interpreting these data.

Chromosome Nomenclature

Visible under the microscope is a constriction site on the chromosome called the centromere, which separates the chromosome into two arms: p, for petite, refers to the short arm, and q, the letter following p, refers to the long arm. Each arm is further subdivided into numbered bands visible using different staining techniques. Centromeres are positioned at different sites on different chromosomes and are used to differentiate the chromosome structures seen during mitosis as **metacentric** (p arm and q arm of almost equal size), **submetacentric** (p arm shorter than q arm), and **acrocentric** (almost no p arm). The use of named chromosome arms and bands provides a universal method of chromosome description. Common symbols include *del* (deletion), *dup* (duplication), *inv* (inversion), *ish* (in situ hybridization), *i* (isochromosome), *pat* (paternal origin), *mat* (maternal origin), and *r* (ring chromosome). These terms are further defined under Chromosomal Abnormalities, below.

Chromosomal Abnormalities

There are two types of chromosomal anomalies: numerical and structural.

A. Abnormalities of Chromosomal Number

When a human cell has 23 chromosomes, such as human ova or sperm, it is in the haploid state (n). After conception, in cells other than the reproductive cells, 46 chromosomes are present in the diploid state ($2n$). Any number that is an exact multiple of the haploid number—for example, $46(2n)$, $69(3n)$, or $92(4n)$ —is referred to as euploid. Polyploid cells are those that contain any number other than the usual diploid number of chromosomes. Polyploid conceptions are usually not viable except in a “mosaic state,” with the presence of more than one cell line in the body (see later text for details).

Cells deviating from the multiple of the haploid number are called aneuploid, meaning not euploid, indicating an abnormal number of chromosomes. Trisomy, an example of aneuploidy, is the presence of three of a particular chromosome rather than two. It results from unequal division, called nondisjunction, of chromosomes into daughter cells. Trisomies are the most

common numerical chromosomal anomalies found in humans (eg, trisomy 21 [Down syndrome], trisomy 18, and trisomy 13). Monosomies, the presence of only one member of a chromosome pair, may be complete or partial. Complete monosomies may result from nondisjunction or anaphase lag. All complete autosomal monosomies appear to be lethal early in development and only survive in mosaic forms. Sex chromosome monosomy, however, can be viable.

B. Abnormalities of Chromosomal Structure

Many different types of structural chromosomal anomalies exist. Figure 35–4 displays the formal nomenclature as well as the ideogram demonstrating chromosomal anomalies. In clinical context, the sign (+) or (–) preceding the chromo-

some number indicates increased or decreased number, respectively, of that particular whole chromosome in a cell. For example, 47, XY+21 designates a male with three copies of chromosome 21. The sign (+) or (–) after the chromosome number signifies extra material or missing material, respectively, on one of the arms of the chromosome. For example, 46,XX,8q– denotes a deletion on the long arm of chromosome 8. Detailed nomenclature, such as 8q11, is required to further demonstrate a specific missing region so that genetic counseling can be provided.

1. Deletion (del) (see Figure 35–4A)—This refers to an absence of normal chromosomal material. It may be terminal (at the end of a chromosome) or interstitial (within a chromosome). The missing part is described using the

▲ **Figure 35–4.** Examples of structural chromosomal abnormalities: deletion, duplication, inversion, ring chromosome, translocation, and insertion.

code “del,” followed by the number of the chromosome involved in parentheses, and a description of the missing region of that chromosome, also in parentheses, for example, 46,XX,del(1)(p36.3). This chromosome nomenclature describes the loss of genetic material from band 36.3 of the short arm of chromosome 1, which results in 1p36.3 deletion syndrome. Some more common deletions result in clinically recognizable conditions associated with mental handicaps and characteristic facial features. (See descriptions of common genetic disorders caused by chromosomal deletions later in the chapter.)

2. Duplication (dup) (see Figure 35-4B)—An extra copy of a chromosomal segment can be tandem (genetic material present in the original direction) or inverted (genetic material present in the opposite direction). A well-described duplication of chromosome 22q11 causes cat eye syndrome, resulting in iris coloboma and anal or ear anomalies.

3. Inversion (inv) (see Figure 35-4C)—In this aberration, a rearranged section of a chromosome is inverted. It can be paracentric (not involving the centromere) or pericentric (involving the centromere).

4. Ring chromosome (r) (see Figure 35-4D)—Deletion of the normal telomeres (and possibly other subtelomeric sequences) leads to subsequent fusion of both ends to form a circular chromosome. Ring chromosomal anomalies often cause growth retardation and mental handicap.

5. Translocation (trans) (see Figure 35-4E)—This interchromosomal rearrangement of genetic material may be balanced (the cell has a normal content of genetic material arranged in a structurally abnormal way) or unbalanced (the cell has gained or lost genetic material as a result of chromosomal interchange). Balanced translocations may further be described as reciprocal, the exchange of genetic material between two nonhomologous chromosomes, or robertsonian, the fusion of two acrocentric chromosomes.

6. Insertion (ins) (see Figure 35-4F)—Breakage within a chromosome at two points and incorporation of another piece of chromosomal material is called insertion. This requires three breakpoints and may occur between two chromosomes or within the same chromosome. The clinical presentation or phenotype depends on the origin of the inserted materials.

C. Sex Chromosomal Anomalies

Abnormalities involving sex chromosomes, including aneuploidy and mosaicism, are relatively common in the general population. The most common sex chromosome anomalies include 45,X (Turner syndrome), 47,XXX, 47,XXY (Klinefelter syndrome), 47,YYY, and different mosaic states. (See later text for clinical discussion.)

D. Mosaicism

Mosaicism is the presence of two or more different chromosome constitutions in different cells of the same individual.

For example, a patient may have some cells with 47 chromosomes and others with 46 chromosomes (46,XX/47,XX,+21 indicates mosaicism for trisomy 21; similarly, 45,X/46,XX/47,XXX indicates mosaicism for a monosomy and a trisomy X). Mosaicism should be suspected if clinical symptoms are milder than expected in a nonmosaic patient with the same chromosomal abnormality, or if the patient's skin shows unusual pigmentation. The prognosis is frequently better for a patient with mosaicism than for one with a corresponding chromosomal abnormality without mosaicism. In general, the smaller the proportion of the abnormal cell line, the better the prognosis. In the same patient, however, the proportion of normal and abnormal cells in various tissues, such as skin, brain, internal organs, and peripheral blood, may be significantly different. Therefore, the prognosis for a patient with chromosomal mosaicism can seldom be assessed reliably based on the karyotype in peripheral blood alone.

E. Uniparental Disomy

Under normal circumstances, one member of each homologous pair of chromosomes is of maternal origin from the egg and the other is of paternal origin from the sperm (Figure 35-5A). In uniparental disomy (UPD), both copies of a particular chromosome pair originate from the same parent. If UPD is caused by an error in the first meiotic division, both homologous chromosomes of that parent will be present in the gamete—a phenomenon called heterodisomy (see Figure 35-5B). If the disomy is caused by an error in the second meiotic division, two copies of the same chromosome will be present through the mechanism of rescue, duplication, and complementation (see Figure 35-5C–E)—a phenomenon called isodisomy. Isodisomy may also occur as a postfertilization error (see Figure 35-5F).

A chromosomal analysis would not reveal an abnormality, but DNA analysis would reveal that the child inherited two copies of DNA of a particular chromosome from one parent without the contribution from the other parent. Possible mechanisms for the adverse effects of UPD include homozygosity for deleterious recessive genes and the consequences of imprinting (see later discussion in the Imprinting section). It is suspected that UPD of some chromosomes is lethal.

UPD has been documented for certain human chromosomes, including chromosomes 7, 11, 15, and X, and has been found in patients with Prader-Willi, Angelman, and Beckwith-Wiedemann syndromes. In addition, cystic fibrosis with only one carrier parent (caused by maternal isodisomy) has been reported. UPD may cause severe prenatal and postnatal growth retardation.

F. Contiguous Gene Syndromes

Contiguous gene syndromes result when a deletion causes the loss of genes adjacent to each other on a chromosome. Although many genes may be missing, the deletion may still

▲ Figure 35-5. The assortment of homologous chromosomes during normal gametogenesis and uniparental disomy. **A:** Fertilization of normal gametes. **B:** Heterodisomy by trisomy rescue. **C:** Isodisomy by trisomy rescue. **D:** Isodisomy by monosomy rescue (mitotic duplication). **E:** Gamete complementation. **F:** Postfertilization error.

be too small to be detected by routine karyotype. Therefore, contiguous gene syndromes are sometimes called “microdeletion syndromes.” The genes involved in these syndromes are related only through their linear placement on the same chromosome segments and may not influence each other’s functions directly. Table 35-1 lists examples of some cur-

rently known contiguous gene syndromes and their associated chromosomal abnormalities. These deletions may be familial (passed on by a parent), or occur de novo. The deletions may be diagnosed by high-resolution chromosome analysis in some affected individuals, or may be submicroscopic and detectable only with FISH or DNA analysis.

Table 35–1. Examples of common contiguous gene syndromes.

Syndrome	Abnormal Chromosome Segment
Prader-Willi/Angelman syndrome	del 15q11
Shprintzen/DiGeorge spectrum	del 22q11
Miller-Dieker syndrome	del 17p13
Wilms tumor with aniridia, genitourinary malformations, and mental retardation	del 11p13
Williams syndrome	del 7q11
Smith-Magenis syndrome	del 17p11

G. Chromosome Fragility

It is well known that environmental factors such as exposure to radiation, certain chemicals, and viruses contribute to chromosome breaks and rearrangements. In addition, several well-defined autosomal recessive syndromes caused by DNA repair defects are associated with a greatly increased risk of chromosome aberrations. These are called chromosome instability or breakage syndromes. Examples are:

- **Bloom syndrome**, characterized by small stature and development of telangiectasias on exposure to sunlight. It is caused by a defect in a DNA helicase.
- **Fanconi anemia**, often associated with radial ray defect, pigmentary changes, mild mental retardation, and development of pancytopenia.
- **Ataxia-telangiectasia** (Louis-Bar syndrome), characterized by telangiectasia of the skin and eyes, immunodeficiency, and progressive ataxia; and caused by a DNA repair defect.

The knowledge that specific chromosome aberrations are associated with these syndromes is often the basis for cytogenetic confirmation of their diagnosis. For example, the diagnosis of Fanconi anemia is confirmed by finding increased chromosomal breakage and translocations between nonhomologous quadriradial after diepoxy-butane treatment. Assessment of chromosome breaks and sister chromatid exchanges requires special techniques that lead to enhancement of the breaks, or special staining that allows visualization of the exchanged chromatids.

Levrn O et al: The BRCA 1-interacting helicase BRIP1 is deficient in Fanconi anemia. *Nat Genet* 2005;37:931 [PMID: 16116424].

H. Chromosomal Abnormalities in Cancer

Numerical and structural chromosomal abnormalities are often identified in hematopoietic and solid-tumor neoplasms in individuals with otherwise normal chromosomes. These cytogenetic abnormalities have been categorized as

primary and secondary. In primary abnormalities, their presence is necessary for initiation of the cancer; an example is 13q- in retinoblastoma. Secondary abnormalities appear de novo in somatic cells only after the cancer has developed, for example, Philadelphia chromosome, t(9;22)(q34;q11), in acute and chronic myeloid leukemia. Primary and secondary chromosomal abnormalities are specific for particular neoplasms and can be used for diagnosis or prognosis. For example, the presence of the Philadelphia chromosome is a good prognostic sign in chronic myelogenous leukemia and indicates a poor prognosis in acute lymphoblastic leukemia. The sites of chromosome breaks coincide with the known loci of oncogenes and anti-oncogenes.

MOLECULAR GENETICS

Advances in molecular biology have revolutionized human genetics, as they allow for the localization, isolation, and characterization of genes that encode protein sequences. As the Human Genome Project has moved into the post-cloning era, the function of gene products and their interaction with one another has become the main theme of molecular genetics. Molecular genetics can help explain the complex underlying biology involved in many human diseases.

Molecular diagnosis can be achieved using the following technology. **Southern blot analysis** is the molecular genetic technique used to look for changes in genomic DNA. A similar technique, called **Northern blot analysis**, is used to look for RNA abnormalities. **Western blot analysis** is used to look for protein changes. The **polymerase chain reaction (PCR)** replicates fragments of DNA between predetermined primers so that sufficient DNA is obtained for characterization or sequencing in the space of a few hours. For example, 20 cycles of synthesis will amplify DNA one millionfold. The disadvantage of PCR is that a small contamination with foreign DNA can result in an incorrect diagnosis. **Quantitative fluorescent PCR** combines PCR amplification with fluorescent DNA probes to provide real-time replication and rapid determination of gene copy number and dosage effects.

Molecular Biology in Clinical Genetics & Genetic Diagnosis

Genetic diagnosis can be performed by direct detection of a mutant gene or by indirect methods. Direct detection is possible only when the gene causing the disease and the nature of the mutation are known. The advantage of a diagnostic study using the direct detection of a mutant gene is that it requires the affected individual only and need not involve the testing of other family members. The methods of direct DNA diagnosis include restriction analysis, single strand conformational polymorphism analysis, direct sequencing with assistance of PCR, heteroduplex assay, and protein truncation assay. The molecular mechanisms causing human

diseases include point mutations, deletions, and insertions, and the unstable expansion of trinucleotide repeats, which leads to genetic anticipation. Some disorders that may be diagnosed via direct DNA mutational analysis include Duchenne muscular dystrophy, hemophilia, some forms of craniosynostosis, cystic fibrosis, and fragile X syndrome.

Indirect detection of abnormal genes is used when the gene is known but there is extensive heterogeneity of the molecular defect between families, or when the gene responsible for a disease is unknown but its chromosome location is known.

One form of indirect analysis is the linkage method. Linkage traces the inheritance of the abnormal gene between members in a kindred. This method requires that the affected individual be studied, as well as parents and other relatives, both affected and unaffected. Linkage analysis, is performed by using markers such as a restriction fragment length polymorphisms. Another method uses flanking microsatellite polymorphisms. An increase in density of polymorphisms discovered over the past few years allows the presence or absence of an abnormal copy of a gene in an individual to be predicted with a high degree of confidence, if the relatives have informative polymorphisms. Microsatellite polymorphisms are being used in sibling research studies to identify the multiple genes that contribute to polygenic traits such as diabetes and obesity. They are also used increasingly to identify gene changes in tumors.

Neurofibromatosis is an example of a disorder in which both the direct and indirect assay may be used. An estimated 90–95% of patients with neurofibromatosis type 1 have a mutation or deletion that can be identified using a direct assay of the neurofibromin gene (*NF1*). The other cases must rely on indirect methods such as linkage analysis for prenatal diagnosis.

Molecular Biology in Prevention & Treatment of Human Diseases

Recombinant DNA technology has the potential to prevent genetic disease by facilitating the detection of carriers of defective genes and permitting prenatal diagnosis. Family studies can also clarify the mode of inheritance, thus allowing more accurate determination of recurrence risks and appropriate options. For example, differentiation of gonadal mosaicism from decreased penetrance of a dominant gene has important implications for genetic counseling. In the past, the diagnosis of a genetic disease characterized by late onset of symptoms (eg, Huntington disease) could not be made prior to the appearance of clinical symptoms. In some inborn errors of metabolism, diagnostic tests (eg, measurement of enzyme activities) could be conducted only on inaccessible tissues. Gene identification (mutation analysis) techniques can enormously enhance the ability to diagnose both symptomatic and presymptomatic individuals, heterozygous carriers of gene mutations, and affected fetuses.

However, presymptomatic DNA testing is associated with psychological, ethical, and legal implications and therefore should be used only with informed consent. Formal genetic counseling is indicated to best interpret the results of molecular testing.

A normal gene introduced into an individual affected with a serious inherited disorder during embryonic life (germline therapy) in principle has the potential to be transmitted to future generations, whereas its introduction into somatic cells (somatic therapy) affects only the recipient. Experimental gene therapy by bone marrow transplantation is being tried for adenosine deaminase deficiency. Recombinant enzyme replacement has been successfully applied in treating the non-neurologic form of Gaucher disease, Fabry disease, Pompe disease, mucopolysaccharidosis types I and II, and some types of lysosomal storage disease.

PRINCIPLES OF INHERITED HUMAN DISORDERS

MENDELIAN INHERITANCE

Traditionally, autosomal single gene disorders follow the principles explained by Mendel's observations. To summarize, the inheritance of genetic traits through generations relies on segregation and independent assortment. **Segregation** is the process through which gene pairs are separated during gamete formation. Each gamete receives only one copy of each gene (allele). **Independent assortment** refers to the idea that the segregation of different alleles occurs independently.

Victor McKusick's catalog, *Mendelian Inheritance in Man*, lists more than 10,000 entries in which the mode of inheritance is presumed to be autosomal dominant, autosomal recessive, X-linked dominant, X-linked recessive, and Y-linked. Single genes at specific loci on one or a pair of chromosomes cause these disorders. An understanding of inheritance terminology is helpful in approaching mendelian disorders. Analysis of the pedigree and the pattern of transmission in the family, identification of a specific condition, and knowledge of that condition's mode of inheritance usually allow for explanation of the inheritance pattern.

Terminology

The following terms are important in understanding heredity patterns.

1. Dominant and recessive—As defined by Mendel, concepts for dominant and recessive refer to the **phenotypic expression** of alleles and are not intrinsic characteristics of gene loci. Therefore, it is inappropriate to discuss "a dominant locus."

2. Genotype—Genotype means the genetic status, that is, the alleles an individual carries.

3. Phenotype—Phenotype is the expression of an individual's genotype including appearance, physical features, organ structure, and biochemical and physiologic nature. It may be modified by environment.

4. Pleiotropy—Pleiotropy refers to the phenomenon whereby a single mutant allele can have widespread effects or expression in different tissues or organ systems. In other words, an allele may produce more than one effect on the phenotype. For example, Marfan syndrome has manifestations in different organ systems (skeletal, cardiac, ophthalmologic, etc) due to a single mutation within the *fibrillin* gene.

5. Penetrance—Penetrance refers to the proportion of individuals with a particular genotype that express the same phenotype. Penetrance is a proportion that ranges between 0 and 1.0 (or 0 and 100%). When 100% of mutant individuals express the phenotype, penetrance is **complete**. If some mutant individuals do not express the phenotype, penetrance is said to be **incomplete**, or **reduced**. Dominant conditions with incomplete penetrance, therefore, are characterized by “skipped” generations with unaffected, obligate gene carriers.

6. Expressivity—Expressivity refers to the variability in degree of phenotypic expression (severity) seen in different individuals with the same mutant genotype. Expressivity may be extremely variable or fairly consistent, both within and between families. Intrafamilial variability of expression may be due to factors such as epistasis, environment, genetic anticipation, presence of phenocopies, mosaicism, and chance (stochastic factors). Interfamilial variability of expression may be due to the previously mentioned factors, but may also be due to allelic or locus genetic heterogeneity.

7. Genetic heterogeneity—Several different genetic mutations may produce phenotypes that are identical or similar enough to have been traditionally considered as one diagnosis. “Anemia” or “mental retardation” are examples of this. There are two types of genetic heterogeneity, locus heterogeneity and allelic heterogeneity.

A. LOCUS HETEROGENEITY—Locus heterogeneity describes a phenotype caused by mutations at more than one genetic locus; that is, mutations at different loci cause the same phenotype or a group of phenotypes that appear similar enough to have been previously classified as a single disease, clinical “entity,” or diagnostic spectrum. An example would be Sanfilippo syndrome (mucopolysaccharidosis types IIIA, B, C, and D), in which the same phenotype is produced by four different enzyme deficiencies.

B. ALLELIC HETEROGENEITY—This term is applied to a phenotype causing different mutations at a single gene locus. As an example, cystic fibrosis may be caused by many different genetic changes, such as homozygosity for the common $\Delta F508$ mutation, or $\Delta F508$ and an *R117H* mutation. The latter example represents **compound heterozygosity**.

8. Phenotypic heterogeneity or “clinical heterogeneity”—This term describes the situation in which more than one phenotype is caused by different allelic mutations at a single locus. For example, different mutations in the *FGFR2* gene can cause different craniosynostosis disorders, including Crouzon syndrome, Jackson-Weiss syndrome, Pfeiffer syndrome, and Apert syndrome. These syndromes are clinically distinguishable and are due to the presence of a variety of genetic mutations within single genes.

9. Homozygous—A cell or organism that has identical alleles at a particular locus is said to be homozygous. For example, a cystic fibrosis patient with a $\Delta F508$ mutation on both alleles would be called homozygous for that mutation.

10. Heterozygous—A cell or organism that has nonidentical alleles at a genetic locus is said to be heterozygous. In autosomal dominant conditions, a mutation of only one copy of the gene pair is all that is necessary to result in a disease state. However, an individual who is heterozygous for a recessive disorder will not manifest symptoms (see next section).

Hereditary Patterns

A. Autosomal Dominant Inheritance

Autosomal dominant inheritance has the following characteristics:

1. Affected individuals in the same family may experience variable expressivity.
2. Nonpenetrance is common, and the penetrance rate varies for each dominantly inherited condition.
3. Both males and females can pass on the abnormal gene to children of either sex, although the manifestations may vary according to sex. For example, pattern baldness is a dominant trait but affects only males. In this case, the trait is said to be sex-limited.
4. Dominant inheritance is typically said to be vertical, that is, the condition passes from one generation to the next in a vertical fashion (Figure 35–6).
5. In some cases, the family history seems to be completely negative, and the patient appears to be the first affected individual. This spontaneous appearance may be caused by a new mutation. In more severe disorders, where there is a decrease in reproductive fitness, there is a high rate of new mutations. The mutation rate increases with advancing paternal age (particularly after age 40 years). Several other explanations for a negative family history are possible, however, including:
 - a. Nonpaternity.
 - b. Decreased penetrance or mild manifestations in one of the parents.

▲ **Figure 35-6.** Autosomal dominant inheritance. Variable expressivity in neurofibromatosis type 1.

- c. Germline mosaicism (ie, mosaicism in the germ cell line of either parent), in which case the risk of recurrence increases. Germline mosaicism may mimic autosomal recessive inheritance, because it leads to situations in which two children of completely normal parents are affected with a genetic disorder. The best example of this is osteogenesis imperfecta type II. Laboratory studies have documented germline mosaicism by finding that only one allele of the paired collagen genes is abnormal in the severe form instead of both, as would be expected in a recessive disease. The recurrence risk in this form of osteogenesis imperfecta is 7%.
 - d. The abnormality present in the patient may be a phenocopy, or it may be a similar but genetically different abnormality with a different mode of inheritance.
6. As a general rule, dominant traits are more often related to structural abnormalities of protein, as for example in Marfan syndrome.
 7. If a parent is affected, the risk for each offspring of inheriting the abnormal dominant gene is 50%, or 1:2. This is true whether the gene is penetrant or not in the parent.
 8. The severity of the condition in the offspring is not related to the severity in the affected parent. In some disorders, it may be related to the sex of the parent transmitting the gene. For example, if the gene for myotonic dystrophy is passed through the mother, there is a 10–20% chance that the child (regardless of sex) may have a severe congenital form of the disease. Conversely, if the gene for Huntington disease is passed through the father, the probability is 5–10% that the offspring may have the severe, rigid juvenile form. In these two conditions the inheritance of the gene is associated with expansion of the triplet repeats (see section on Genetic Anticipation, later).

9. If an abnormality represents a new mutation of a dominant trait, the parents of the affected individual run a low risk during subsequent pregnancies, but the risk for the offspring of the affected individual is 50%. Although a mutation is thought to be new because the parents are not affected, the risk for an affected sibling is still slightly increased over the general population, because of the possibility of germline mosaicism.
10. Prevention options available for future pregnancies include prenatal diagnosis, artificial insemination, and egg or sperm donation, depending on which parent has the abnormal gene.

B. Autosomal Recessive Inheritance

Autosomal recessive inheritance also has some distinctive characteristics:

1. There is less variability among affected persons. Parents are carriers and are clinically normal. (There are, however, exceptions to this rule. For example, carriers of sickle cell trait may become symptomatic if they become hypoxic.)
2. Males and females are affected equally.
3. Inheritance is horizontal; siblings may be affected (Figure 35-7).
4. Recessive conditions are usually rare; the rarer the condition, the more likely it is that consanguinity is present. Conversely, if a child whose parents are related presents with an unrecognized abnormality, a recessive condition must be suspected.

▲ **Figure 35-7.** Autosomal recessive inheritance: cystic fibrosis.

- The family history is usually negative, with the exception of siblings. However, in common conditions such as cystic fibrosis, a second- or third-degree relative may be affected.
- Recessive conditions are frequently associated with enzyme defects.
- The recurrence risk for parents of an affected child is 25%, or 1:4 for each pregnancy. The gene carrier frequency in the general population can be used to assess the risk of having an affected child with a new partner, for unaffected siblings, and for the affected individuals themselves.
- In rare instances, a child with a recessive disorder and a normal karyotype may have inherited both copies of the abnormal gene from one parent and none from the other. This uniparental disomy (UPD) was first described in a girl with cystic fibrosis and growth retardation. This phenomenon is of unknown frequency, but it is more likely to be present in a child with more than one autosomal recessive condition, or in a patient with unexpected and seemingly unrelated abnormalities or severe growth retardation. Molecular testing can confirm the presence of UPD. The recurrence risk is obviously lower in such a situation, although the factors predisposing to UPD are unknown. Maternal age may play a role in these situations.
- Options available for future pregnancies include prenatal diagnosis, adoption, artificial insemination, and egg or sperm donation.

C. X-Linked Inheritance

When a gene for a specific disorder is on the X chromosome, the condition is said to be X-linked, or sex-linked. Females may be either homozygous or heterozygous, because they have two X chromosomes. Males, by contrast, have only one X, and a male is said to be hemizygous for any gene on his X chromosome. The severity of any disorder is greater in males than in females (within a specific family). According to the Lyon hypothesis, because one of the two X chromosomes in each cell is inactivated, and this inactivation is random, the clinical picture in females depends on the percentage of mutant versus normal alleles inactivated. The X chromosome is not inactivated until about 14 days of gestation, and parts of the short arm remain active throughout life.

D. X-Linked Recessive Inheritance

The following features are characteristic of X-linked recessive inheritance:

- Males are affected, and heterozygous females are either normal or have mild manifestations.
- Inheritance is diagonal through the maternal side of the family (Figure 35–8A).
- A female carrier has a 50% chance that each daughter will be a carrier and a 50% chance that each son will be affected.

- All of the daughters of an affected male are carriers, and none of his sons are affected. Because a father can give only his Y chromosome to his sons, male-to-male transmission excludes X-linked inheritance except in the rare case of UPD, in which a son receives both the X and the Y from his father.
- The mutation rate is high in some X-linked disorders, particularly when the affected male dies or is so incapacitated by the disorder that reproduction is unlikely. In such instances, the mutation is thought to occur as a new mutation in the affected male, and in the mother, each one third of the time and to be present in earlier generations one third of the time. For this reason, genetic counseling may be difficult in families with an isolated case.
- On rare occasions, a female may be fully affected. Several possible mechanisms may account for a fully affected female: (a) unfavorable lyonization; (b) 45,X karyotype; (c) homozygosity for the abnormal gene; (d) an X-autosome translocation, or other structural abnormality of one X chromosome, in which the X chromosome of normal structure is preferentially inactivated; (e) UPD; and (f) nonrandom inactivation, which may be controlled by an autosomal gene.

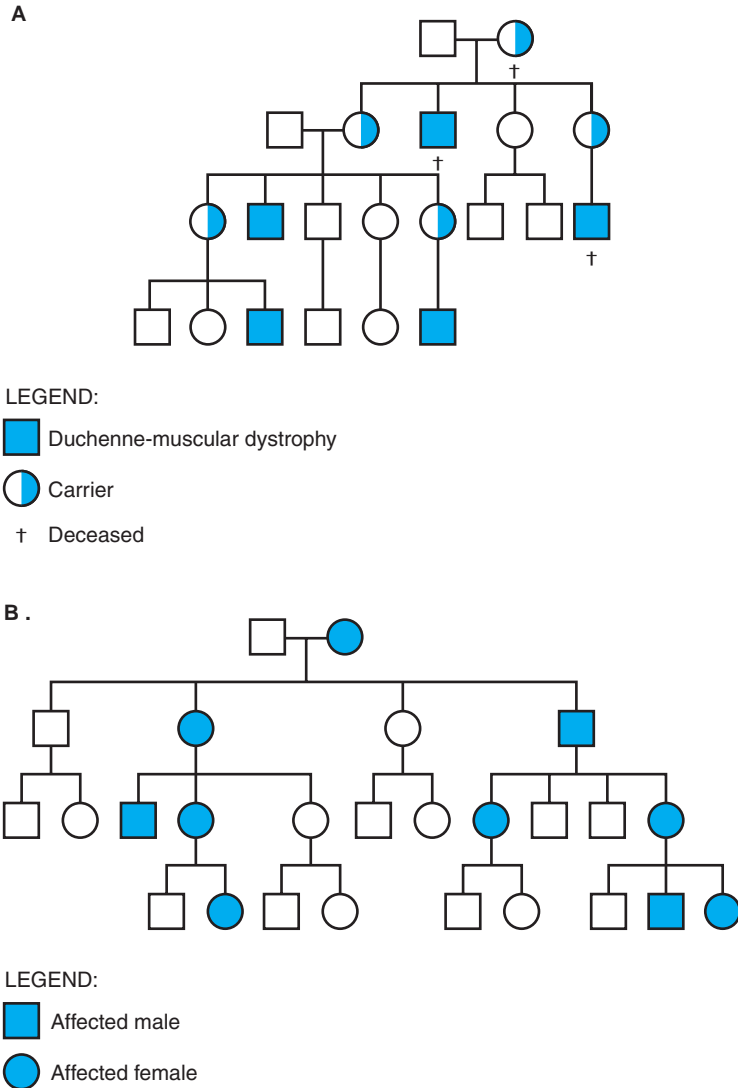

E. X-Linked Dominant Inheritance

The X-linked dominant inheritance pattern is much less common than the X-linked recessive type. Examples include incontinentia pigmenti and hypophosphatemic or vitamin D-resistant rickets.

- The heterozygous female is symptomatic, and the disease is twice as common in females because they have two X chromosomes that can have the mutation.
- Clinical manifestations are more variable in females than in males.
- The risk for the offspring of heterozygous females to be affected is 50% regardless of sex.
- All of the daughters but none of the sons of affected males will have the disorder (see Figure 35–8B).
- Although a homozygous female is possible (particularly in an inbred population), she would be severely involved. All of her children would also be affected but more mildly.
- Some disorders (eg, incontinentia pigmenti) are lethal in males (and in homozygous females). Affected women have twice as many daughters as sons and an increased incidence of miscarriages, because affected males will be spontaneously aborted. A 47,XXY karyotype has allowed affected males to survive.

F. Y-Linked Inheritance

In Y-linked inheritance, also known as “holandric” inheritance, a disorder is caused by genes located on the Y chromo-

▲ **Figure 35-8.** **A:** X-linked recessive inheritance. **B:** X-linked dominant inheritance.

some. These conditions are relatively rare with only about 40 entries listed in McKusick’s catalog. Male-to-male transmission is seen in this category, with all sons of affected males being affected and no daughters or females being affected.

MULTIFACTORIAL INHERITANCE

Many common attributes, such as height, are familial, and are the result of the actions of multiple rather than single genes. Inheritance of these traits is described as **polygenic** or **multifactorial**. The latter term recognizes that environmental factors such as diet also contribute to these traits. Geneticists are now finding that multiple genes are often expressed

in hierarchies, in which the action of a small number of genes, two or three, explains much of the variation observed within affected populations.

Studies of twins have proven useful in determining the relative importance of genetic versus environmental factors in the expression of polygenic traits. If genetic factors are of little or no importance, then the concordance between monozygotic and dizygotic twins should be the same. (Dizygotic twins are no more genetically similar to each other than to other siblings.) If an abnormality is completely genetic, the concordance between identical twins should be 100%. In polygenic conditions, the concordance rate for identical twins is usually higher than that seen in dizygotic twins but

is still not 100%, indicating that both genetic and environmental factors are playing a role.

Many disorders and congenital abnormalities that are clearly familial but do not segregate as mendelian traits (eg, autosomal dominant, recessive, etc) show polygenic inheritance. For the most part, these conditions become manifest when thresholds of additive gene actions or contributing environmental factors are exceeded. Many common disorders ranging from hypertension, stroke, and thrombophlebitis to behavioral traits such as alcoholism demonstrate multifactorial (polygenic) inheritance. Some common birth defects, including isolated congenital heart disease, cleft lip and palate, and neural tube defects, also demonstrate polygenic inheritance. Neural tube defects provide a good model illustrating how identification of both environmental and genetic contributions to multifactorial traits can lead to preventive measures.

Polygenic or multifactorial inheritance has several distinctive characteristics:

1. The risk for relatives of affected persons is increased. The risk is higher for first-degree relatives (those who have 50% of their genes in common) and lower for more distant relations, although the risk for the latter is higher than for the general population (Table 35–2).
2. The recurrence risk varies with the number of affected family members. For example, after one child is born with a neural tube defect, the recurrence risk is 2–3%. If a second affected child is born, the risk for any future child increases to 10–12%. This is in contrast to single gene disorders, in which the risk is the same no matter how many family members are affected.
3. The risk is higher if the defect is more severe. In Hirschsprung disease, another polygenic condition, the longer the aganglionic segment, the higher is the recurrence risk.
4. Sex ratios may not be equal. If a marked discrepancy exists, the recurrence risk is higher if a child of the less commonly affected sex has the disorder. This assumes that more genetic factors are required to raise the more resistant sex above the threshold. For example, pyloric stenosis is more common in males. If the first affected child is a female, the recurrence risk is higher than if the child is a male.
5. The risk for the offspring of an affected person is approximately the same as the risk for siblings, assuming that the spouse of the affected person has a negative family history. For many conditions, however, assortative mating, “like marrying like,” adds to risks in offspring.

NONMENDELIAN INHERITANCE

Epigenetic Regulation

Although development is regulated by genes, it is initiated and sustained by nongenetic processes. Epigenetic events are points

Table 35–2. Empiric risks for some congenital disorders.

Anencephaly and spina bifida: incidence (average) 1:1000	
One affected child:	2–3%
Two affected children:	10–12%
One affected parent:	4–5%
Hydrocephalus: incidence 1:2000 newborns	
Occasional X-linked recessive	
Often associated with neural tube defect	
Some environmental etiologies (eg, toxoplasmosis)	
Recurrence risk, one affected child	
Hydrocephalus:	1%
Some central nervous system abnormality:	3%
Nonsyndromic cleft lip and/or palate: incidence (average) 1:1000	
One affected child:	2–4%
One affected parent:	2–4%
Two affected children:	10%
One affected parent, one affected child:	10–20%
Nonsyndromic cleft palate: incidence 1:2000	
One affected child:	2%
Two affected children:	6–8%
One affected parent:	4–6%
One affected parent, one affected child:	15–20%
Congenital heart disease: incidence 8:1000	
One affected child:	2–3%
One affected parent, one affected child:	10%
Clubfoot: incidence 1:1000 (male: female = 2:1)	
One affected child:	2–3%
Congenital dislocated hip: incidence 1:1000 (female > male) with marked regional variation	
One child affected:	2–14%
Pyloric stenosis: Incidence, males: 1:200; females: 1:1000	
Male index patient	
Brothers	3.2%
Sons	6.8%
Sisters	3.0%
Daughters	1.2%
Female index patient	
Brothers	13.2%
Sons	20.5%
Sisters	2.5%
Daughters	11.1%

of interaction between developmental programs and the physicochemical environments in differentiating cells. Genetic imprinting and DNA methylation are examples of epigenetic

processes that affect development. Certain genes important in regulation of growth and differentiation are themselves regulated by chemical modification that occurs in specific patterns in gametes. For example, genes that are methylated are “turned off” and not transcribed. The pattern of which genes are methylated may be determined or affected by the sex of the parent of origin (see next section). Expression of imprinted genes may sometimes be limited to specific organs (eg, the brain), and imprinting may be relaxed and methyl groups lost as development progresses. Disruption of imprinting is now recognized as contributing to birth defect syndromes (described later in this chapter). Certain techniques developed to assist infertile couples (advanced reproductive technology) may affect epigenetic processes and lead to genetic disorders in the offspring conceived via these methods.

Niemitz EL, Feinberg AP: Epigenetics and assisted reproductive technology: A call for investigation. *Am J Hum Genet* 2004;74:599 [PMID: 14991528].

Imprinting

Although the homologs of chromosome pairs may appear identical on routine karyotype analysis, it is now known that the parental origin of each homolog can affect which genes are actually transcribed and which are inactivated. The term *imprinting* refers to the process by which preferential transcription of certain genes takes place, depending on the parental origin, that is, which homolog (maternal or paternal) the gene is located on. Certain chromosomes, particularly chromosome X, and the autosomes 15, 11, and 7, have imprinted regions where certain genes are only read from one homolog (ie, either the maternal or paternal allele) under normal circumstances, and the gene on the other homolog is normally inactivated. Errors in imprinting may arise because of UPD (in which a copy from one parent is missing), by a chromosomal deletion causing loss of the gene normally transcribed, or by mutations in the imprinting genes that normally code for transcription or inactivation of other genes downstream. A good example of how imprinting may affect human disease is Beckwith-Wiedemann syndrome, the gene for which is located on chromosome 11p15.

Cohen MM et al: *Overgrowth Syndromes*. Oxford University Press, 2002.

Genetic Anticipation

Geneticists coined the term “anticipation” to describe an unusual pattern of inheritance in which symptoms became manifest at earlier ages and with increasing severity as traits are passed to subsequent generations. Mapping of the genes responsible for these disorders led to the discovery that certain repeat sequences of DNA at disease loci were not stable when passed through meiosis. Repeated DNA sequences, in particular triplets (eg, CGG and CAG), tended to increase their copy number. As these runs of triplets

expanded, they eventually affected the expression of genes and produced symptoms. Curiously, all the disorders undergoing triplet repeat expansion detected thus far produce neurologic symptoms. Most are progressive. In general, the size of the triplet expansion is roughly correlated with the timing and severity of symptoms. The reasons for the meiotic instability of these sequences are not yet understood. The mechanisms appear to involve interactions between DNA structure (eg, formation of hairpin loops) and replication enzymes (DNA polymerase complexes) during meiosis.

Triplet repeat instability can modify the inheritance of autosomal dominant, autosomal recessive, and X-linked traits. Autosomal dominant disorders include several spinal cerebellar atrophies, Huntington disease, and myotonic dystrophy. Unstable triplet repeat expansion contributes to at least one autosomal recessive disorder, Friedreich ataxia. The most common X-linked disorder demonstrating triplet repeat instability and expansion is fragile X syndrome.

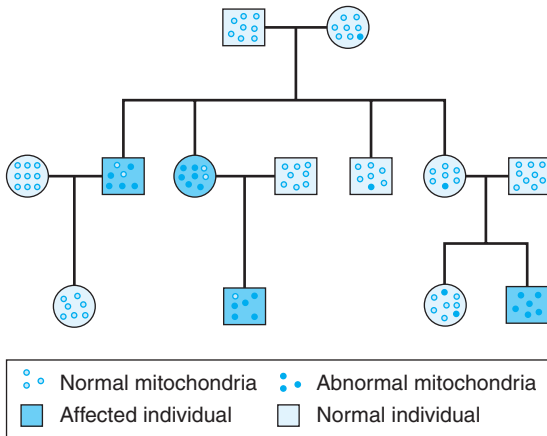

Mitochondrial Inheritance

Mitochondrial DNA is double-stranded, circular, and smaller than nuclear DNA, and is found in the cytoplasm. It codes for enzymes involved in oxidative phosphorylation, which generates adenosine triphosphate. Since the 1990s, enormous advances in technology and improved clinical documentation have led to a better understanding of the interesting disorders caused by mutations in mitochondrial DNA (mtDNA).

Mitochondrial disorders have been associated with deletions or duplications in mtDNA. Large deletions are usually sporadic, but smaller deletions may be secondary events due to defects in dominantly inherited nuclear genes. Mitochondrial dysfunction may also be caused by mutations in nuclear genes encoding mitochondrial proteins and can be inherited as dominant, recessive, or X-linked traits. Because of the difficulty in diagnosing mitochondrial disorders and the variability of the clinical course, it is often difficult to calculate specific recurrence risks.

Mitochondrial disorders have the following characteristics:

1. They show remarkable phenotypic variability.
2. They are maternally inherited, because only the egg has any cytoplasmic material, and during early embryogenesis any sperm-born mitochondrial material will be eliminated.
3. In most mitochondrial disorders, cells are heteroplasmic (Figure 35–9). That is, all cells contain both normal and mutated or abnormal mtDNA. The proportion of normal to abnormal mtDNA in the mother’s egg seems to determine the severity of the offspring’s disease and the age at onset in most cases.
4. Those tissues with the highest adenosine triphosphate requirements—specifically, central nervous system (CNS) and skeletal muscle—seem to be most susceptible to mutations in mtDNA.

▲ **Figure 35-9.** Mitochondrial inheritance. Mutations are transmitted through the maternal line.

- Somatic cells show an increase in mtDNA mutations and a decline in oxidative phosphorylation function with age. This explains the later onset of some of these disorders and may indeed be a clue to the whole aging process.

Hayashida K et al: The sperm mitochondria—Specific translocator has a key role in maternal mitochondrial inheritance. *Cell Biol Int* 2005;29:472 [PMID: 15979907].

FAMILY HISTORY & PEDIGREE

The first step in the collection of information regarding the genetics of a syndromic diagnosis is the construction of a family tree or pedigree. Underused by most medical personnel, the pedigree is a valuable record of genetic and medical information, which is much more useful in visual form than in list form. Tips for pedigree preparation include the following:

- Start with the proband—the patient’s siblings and parents, and obtain a three-generational history if possible.
- Always ask about consanguinity.
- Obtain data from both sides of the family.
- Ask about spontaneous abortions, stillbirths, infertility, children relinquished for adoption, and deceased individuals.

In the course of taking the family history, one may find information that is not relevant in elucidating the cause of the patients’ problem but may indicate a risk for other important health concerns. Such information should be appropriately followed and addressed. Such conditions that may arise are an overwhelming family history of early-onset breast and ovarian cancer, or multiple pregnancy losses necessitating chromosome analyses.

Dysmorphology & Human Embryology

Birth defects are the leading cause of death in the first year of life. They are evident in 2–3% of newborn infants and in up to 7% of adults. Many are now detected by ultrasound prior

to birth. Clinical investigation of the causes and consequences of birth defects is called dysmorphology.

MECHANISMS

Developmental Genetics

Most birth defects are multifactorial: They result from imbalances between genetic processes regulating development and the environments in which they unfold. Specific causes of maldevelopment can be identified in about 35% of cases, but advances in developmental biology and human genetics promise better understanding. So far, single gene mutations and chromosomal abnormalities account for at least 25% of birth defects, with the numbers of specific genes and chromosome loci now being associated with recurring phenotypes, or syndromes, rapidly increasing.

Genes for the fundamental processes regulating cell division, or proliferation, and those that program cell death, or apoptosis, are now being described. Both cellular proliferation and apoptosis are very active in embryogenesis and the balance between these processes is easily disrupted. Imbalances in the regulation of cell cycles are an important determinant of birth defects and may contribute to such commonly occurring problems as neural tube defects, branchial arch anomalies, limb reductions, and congenital heart disease.

Morphogenic processes and the genes that regulate them have been highly conserved through evolution. Thus, experiments in lower organisms such as *Drosophila* (fruit flies) can identify candidate genes for human birth defects. For example, mutations in *pax* genes, which are involved in eye development in *Drosophila* produce “small eye” in mice, and aniridia and other abnormalities of the anterior chamber of the eyes of humans.

Embryology and developmental biology have recently and rapidly moved from descriptive to experimental disciplines that use tools such as in situ hybridization to visualize the expression of genes in embryos, and transgenic animals in which developmentally active genes are “knocked out” to determine the contributions of specific genes to organ development. These investigations have uncovered, for example, important regulatory interactions such as the hedgehog signaling pathway, which affects morphogenesis in organs as diverse as limbs, the heart, and the CNS. Human mutations in one evolutionarily conserved gene, sonic hedgehog (*SHH*), can result in holoprosencephaly, a severe birth defect in which the CNS fails to complete its normal hemispheric division.

Cellular Interactions

The picture emerging from experimental studies of morphogenesis is one of a hierarchy of gene expression during development. Morphogenesis begins with expression of genes encoding transcription factors. These proteins bind to DNA in undifferentiated embryonic cells and recruit them into developmental fields, groups of cells primed to respond to specific signals later in development. This recruitment also establishes spatial relationships and orients cells with respect to their neighbors. As

fields differentiate into identifiable tissues (eg, ectoderm, mesoderm, and endoderm), cellular proliferation, migration, and further differentiation are mediated through genes encoding cell signaling proteins.

Signaling proteins include growth factors and their receptors, cellular adhesion molecules, and extracellular matrix proteins that both provide structure and position signals within developing structures. During morphogenesis groups of primed cells repeatedly proliferate, migrate, and then differentiate in response to locally expressed growth factors or signaling proteins. Within these interactions are keys to understanding not only many human birth defects but also cancer. The genes that organize cell proliferation and differentiation during development are often precisely those that mutate during carcinogenesis.

Environmental Factors

The effects of exogenous agents during development are also mediated through genetically regulated pathways. At the cellular level, xenobiotics (compounds foreign to nature) cause birth defects either because they disrupt cell signaling and thereby misdirect morphogenesis, or because they are cytotoxic and lead to cell death in excess of the usual developmental program.

In general, drug receptors expressed in embryos and fetuses are the same molecules that mediate pharmacologic effects in adults. However, effector systems may be different, reflecting incomplete morphogenesis and differences between fetal and postnatal physiology. These circumstances allow prediction of dose-response relationships during development on the one hand, but call for caution about predicting effects on the other.

Xenobiotics must traverse the placenta to affect embryonic and fetal tissues. The human placenta is a relatively good barrier against microorganisms, but it is ineffective at excluding drugs and many chemicals. The physicochemical properties (eg, molecular size, solubility, and charge) that allow foreign chemicals to be absorbed into the maternal circulation also allow them to cross the placenta. The placenta can metabolize some xenobiotics but it is far more active against steroid hormones and low-level environmental contaminants than drugs.

The timing of xenobiotic exposures is an important determinant of their effects. Morphogenic processes express so-called critical periods, during which the organs they produce are particularly susceptible to maldevelopment. Figure 35–10 shows critical periods of development for the major organs of the fetus. Periods of susceptibility are not all confined to early gestation. Note, in particular, that the developing brain is susceptible to toxicity throughout pregnancy.

As discussed, over-the-counter, prescribed, and abused drugs that are pharmacologically active in mothers will, in general, equilibrate to the same levels across the placenta. Agents known to produce cytotoxicity at these levels in adults are therefore likely to be teratogenic (ie, cause birth defects). Abused substances such as alcohol that are toxic to adults are predictably toxic to embryos and fetuses. Drugs generally safe in adults will be generally safe for fetuses. However, keeping in

mind that embryonic and fetal physiology may differ from that of an adult in response to pharmacologic agents, some risk for abnormal development must always be considered. Risk assessment requires continuous monitoring of populations exposed to drugs during pregnancy.

Effects of toxic environmental contaminants on the embryo and fetus are also dose-dependent. Thus, the level of exposure to a toxin frequently becomes the primary determinant of its risk. Exposures producing symptoms in mothers can be assumed to be potentially toxic to the fetus.

Environmental mutagens present a special problem. Animal experiments indicate that high levels of exposure to mutagenic agents are also teratogenic. Most effects are mediated through increased apoptosis responding to DNA damage. This is especially true for the developing brain. At lower doses attempts to repair DNA damage in embryonic or fetal cells may lead to somatic mutations that can contribute to carcinogenesis or be expressed as mosaic organ dysgenesis.

Not all transplacental pharmacologic effects are toxic. The potential for therapeutic uses of drugs during pregnancy is increasing. For example, folic acid supplementation can lower risks for birth defects such as spina bifida, and maternally administered corticosteroids can induce fetal synthesis and secretion of pulmonary surfactants prior to delivery.

MECHANICAL FACTORS

Much of embryonic development and all of fetal growth occurs normally within the low pressure and space provided by amniotic fluid. Loss or inadequate production of amniotic fluid can have disastrous effects, as can disruption of placental membranes. When this occurs early in gestation, for whatever reason, major, often lethal, distortion of the embryo (early amnion disruption sequence) results. Later, deformation or even amputation of fetal extremities (amnion band sequence) can occur.

Movement is also important for morphogenesis. Fetal movement is necessary for normal development of joints and is the principal determinant of folds and creases present at birth in the face, hands, feet, and other areas of the body. Clubfoot is an etiologically heterogeneous condition in which the foot is malpositioned at birth. It more often results from mechanical constraint secondary to intrauterine crowding, weak fetal muscles, or abnormal neurologic function than from primary skeletal maldevelopment.

Lung and kidney development are particularly sensitive to mechanical forces. Constriction of the chest through maldevelopment of the ribs, lack of surrounding amniotic fluid, or lack of movement (fetal breathing) leads to varying degrees of pulmonary hypoplasia in which lungs are smaller than normal and develop fewer alveoli. Mechanically induced pulmonary hypoplasia is a common cause of respiratory distress at birth and may be lethal.

Cystic renal dysplasia commonly accompanies birth defects that obstruct ureters or outflow from the bladder. As urinary pressure within obstructed collecting systems increases it distorts cell surface interactions in developing tissues and alters

▲ **Figure 35-10.** Critical periods in human gestation.

histogenesis. Developing kidneys exposed to increased internal pressures for long periods eventually become nonfunctional.

CLINICAL DYSMORPHOLOGY

Terminology

Classification of dysmorphic features strives to reflect mechanisms of maldevelopment. However, much of the terminology that describes abnormal development in humans remains historical and documents recognition of patterns prior to understanding of their biology. For example, birth defects are referred to as **malformations** when they result from altered genetic or developmental processes. When physical forces interrupt or distort morphogenesis, their effects are termed **disruptions** and **deformations**, respectively. The term **dysplasia** is used to denote abnormal histogenesis. Malformations occurring together more frequently than would be expected by chance alone may be classified as belonging to **associations**. Those in which the order of maldevelopment is understood may be referred to as **sequences**. For example, Robin sequence (or Pierre Robin anomalad) is used to describe cleft palate that has occurred because poor growth of the jaw (retrognathia) has displaced the tongue and prevented posterior closure of the palate. **Syndromes** are simply recurrent patterns of maldevelopment.

Evaluation of the Dysmorphic Infant

Physicians caring for infants with birth defects frequently must seek accurate diagnoses and provide care under conditions of great stress. The extent of an infant's abnormalities may not be immediately apparent, and parents who feel grief and guilt are often desperate for information. As with any medical problem, however, the history and physical examination provide most of the clues to diagnosis. Special aspects of these procedures are outlined in the following sections.

A. History

Pregnancy histories nearly always contain important clues to the diagnosis. Parental recall after delivery of an abnormal infant is better than recall after a normal birth. An obstetric wheel can help document gestational age and events of the first trimester: the last menstrual period, the onset of symptoms of pregnancy, the date of diagnosis of the pregnancy, the date of the first prenatal visit, and the physician's impressions of fetal growth at that time. Family histories should always be reviewed. Environmental histories should include descriptions of parental habits and work settings in addition to medications and use of drugs, tobacco, and alcohol.

B. Physical Examination

Meticulous physical examination is crucial for accurate diagnosis in dysmorphic infants and children. In addition to the routine procedures described in Chapter 1, special attention should be paid to the neonate's physical measurements (Figure

35–11). Photographs are helpful and should include a ruler for reference.

C. Imaging and Laboratory Studies

Radiologic and ultrasonographic examinations can be extremely helpful in the evaluation of dysmorphic infants. Films of infants with apparent limb or skeletal anomalies should include views of the skull and all of the long bones in addition to frontal and lateral views of the axial skeleton. Chest and abdominal films should be obtained when indicated. The pediatrician should consult a radiologist for further workup. Computed tomography (CT), magnetic resonance imaging (MRI), and ultrasonography are all useful diagnostic tools, but their interpretation in the face of birth defects may require considerable experience.

Cytogenetic analysis provides specific diagnoses in approximately 5% of dysmorphic infants who survive the newborn period. Chromosomal abnormalities are recognized in 10–15% of infants who die. Common disorders such as trisomies 21 and 18 can be determined rapidly through use of FISH, but this technique is limited and should always be accompanied by a complete karyotype. A normal karyotype does not rule out the presence of significant genetic disease. Any case requiring rapid diagnosis should be discussed with an experienced clinical geneticist.

D. Perinatal Autopsy

When a dysmorphic infant dies, postmortem examination can provide important diagnostic information. The pediatrician should discuss the case thoroughly with the pathologist, and photographs should always be taken. Radiologic imaging should be included whenever limb anomalies or disproportionate growth is present. Tissue, most often skin, should be submitted for cytogenetic analysis. The pediatrician and the pathologist should also consider whether samples of blood, urine, or other tissue should be obtained for biochemical analyses. Placental as well as fetal tissue can be used for viral culture.

CHROMOSOMAL DISORDERS: ABNORMAL NUMBER

TRISOMIES

1. Trisomy 21 (Down Syndrome)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Small, brachycephalic head; characteristic facies of upslanting palpebral fissures, epicanthal folds, midface hypoplasia, and small, dysplastic pinnae.
- ▶ Generalized hypotonia.

Measurement	Range (cm)	
	Term (38–40 week)	Preterm (38–40 week)
1 Head circumference	32–37	27–32
2 Anterior fontanelle $\left(\frac{L-W}{2}\right)$	0.7–3.7	...
3 Interpupillary distance	3.3–4.5	3.1–3.9
4 Palpebral fissure	1.5–2.1	1.3–1.6
5 Inner canthal distance	1.5–2.5	1.4–2.1
6 Outer canthal distance	5.3–7.3	3.9–5.1
7 Philtrum	0.6–1.2	0.5–0.9
8 Ear length	3–4.3	2.4–3.5
9 Chest circumference	28–38	23–29
10 Internipple distance*	6.5–10	5–6.5
11 Height	47–55	39–47
12 Ratio $\frac{\text{Upper body segment}}{\text{Lower body segment}}$	1.7	...
13		
14 Hand (palm to middle finger)	5.3–7.8	4.1–5.5
15 Ratio of middle finger to hand	0.38–0.48	0.38–0.5
16 Penis (pubic bone to tip of glans)	2.7–4.3	1.8–3.2

*Internipple distance should not exceed 25% of chest circumference.

▲ **Figure 35-11.** Neonatal measurements.

- ▶ Cognitive disabilities (mild to severe).
- ▶ Associated with congenital heart disease and gastrointestinal anomalies.

Down syndrome occurs in about 1:600 newborns; however, the incidence is greater if the mother is older than age 35 years. Cognitive disabilities are characteristic of Down syndrome, with typical intelligence quotients (IQs) between 20 and 80 (mostly between 45 and 55). Generalized hypotonia is common. Sexual development is delayed, especially in males, who are usually sterile. The affected newborn may have prolonged physiologic jaundice, polycythemia, and a transient leukemoid reaction. Later, there is an increased tendency for thyroid dysfunction, hearing loss, celiac disease, and atlanto-occipital instability. Leukemia is 12–20 times more common in Down syndrome patients than in unaffected children.

▶ Clinical Findings

The principal physical findings include a small, brachycephalic head, characteristic facies (up-slanting palpebral fissures, epicanthal folds, midface hypoplasia, and small, dysplastic pinnae), and minor limb abnormalities. About one third to one half of children with Down syndrome have congenital heart disease, most often endocardial cushion defects or other septal defects. Anomalies of the gastrointestinal tract, including esophageal and duodenal atresias, are seen in about 15% of cases.

Information regarding health care guidelines for patients with Down syndrome can be found at <http://www.downsyn.com/guidelines/healthcare.html>.

2. Trisomy 18 Syndrome

The incidence of trisomy 18 syndrome is about 1:4000 live births, and the ratio of affected males to females is approximately 1:3. Trisomy 18 is characterized by prenatal and postnatal growth retardation that is often severe, and hypertonicity. Complications are related to associated birth defects. Death is often caused by heart failure or pneumonia and usually occurs in infancy or early childhood, although a small percentage of patients reach adulthood. Surviving children show significant developmental delay.

▶ Clinical Findings

Infants with trisomy 18 are often small for gestational age and have dysmorphic features including a characteristic facies and extremities (overlapping fingers and rockerbottom feet), and congenital heart disease (often ventricular septal defect or patent ductus arteriosus). To see clinical pictures of patients with trisomy 18, go to the following web site: http://medgen.genetics.utah.edu/photographs/pages/trisomy_18.htm.

3. Trisomy 13 Syndrome

The incidence of trisomy 13 is about 1:12,000 live births, and 60% of affected individuals are female. Most infants with trisomy 13 have congenital anomalies that are incompatible with

survival. Surviving children demonstrate failure to thrive, developmental retardation, apneic spells, seizures, and deafness. Death usually occurs in early infancy or by the second year of life, commonly as a result of heart failure or infection.

▶ Clinical Findings

The symptoms and signs include prenatal and postnatal growth deficiency (although, unlike trisomy 18, infants may have a normal birth weight), CNS malformations, arrhinencephaly, eye malformations (anophthalmia, colobomas), cleft lip and palate, polydactyly or syndactyly, and congenital heart disease (usually ventricular septal defect). The facies of an infant with trisomy 13 can be viewed at the following web site: http://medgen.genetics.utah.edu/photographs/pages/trisomy_13.htm.

Treatment of Trisomies

A. Medical Therapy

No convincing documentation is available relative to the merit of any of the forms of alternative therapy that have been attempted in Down syndrome, ranging from megadoses of vitamins to amino acid solutions. However, interventions for specific issues such as surgery or medications for heart problems, antibiotics for infections and thyroid function tests, infant stimulation programs, special education, and physical, occupational, and speech therapies are all indicated. The goal of treatment is to help affected children develop to their full potential. Parents' participation in support groups such as the local chapter of the National Down Syndrome Congress should be encouraged. See the following web site: <http://www.ndss.org/>.

There is no treatment, other than general supportive care, for trisomy 13 or 18. Because it is sometimes necessary to decide immediately after birth how extensive therapy should be for a severely malformed infant, trisomies 13 and 18 can be screened for in interphase nuclei of blood lymphocytes by FISH and confirmed by direct chromosome analysis of blood or bone marrow mitoses. A support group for families of children with trisomies 13 and 18 who survive beyond infancy is called SOFT. See the following web site: <http://www.trisomy.org/>.

B. Genetic Counseling

Most parents of trisomic infants have normal karyotypes. The risk of having a child affected with a trisomy varies with maternal age. For trisomy 21, age-specific risks are 1:2000 for mothers younger than 25 years; 1:200 for mothers 35 years of age; and 1:100 for mothers at age 40. The recurrence risk for trisomy in future pregnancies is equal to 1:100 plus the age-specific maternal risk; for example, a 40-year-old mother who has already given birth to a child with Down syndrome would have a risk of 1:100 for her age, plus 1:100 for her prior history, or 1:50.

If the child has a trisomy resulting from a translocation, and the parent has an abnormal karyotype, the risks are increased. When the mother is the carrier of a balanced 14/21 translocation, there is a 10–15% chance that the child will be

affected and a 33% chance that the child will be a balanced translocation carrier. When the father is the carrier, there is a smaller than 0.5% chance of having another affected child. If the child has a 21/21 translocation and one parent has the translocation, the recurrence risk is 100%.

The recurrence risks in other trisomies are analogous to those for Down syndrome. The mother's age at the time of conception and the nature of the chromosomal abnormality are important in genetic counseling, which is indicated for prevention of all chromosomal abnormalities. Prenatal diagnosis is available.

SEX CHROMOSOME ABNORMALITIES

1. Turner Syndrome (Monosomy X, Gonadal Dysgenesis)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Webbed neck, triangular facies, short stature, wide-set nipples, amenorrhea, and absence of secondary sex characteristics.
- ▶ Associated with coarctation of the aorta and genitourinary malformations.
- ▶ IQ is usually normal but learning disabilities are common.
- ▶ Mosaic individuals may manifest only short stature and amenorrhea.

The incidence of Turner syndrome is 1:10,000 females. However, it is estimated that 95% of conceptuses with monosomy X are miscarried and only 5% are liveborn.

▶ Clinical Findings

Newborns with Turner syndrome may have webbed neck, edema of the hands and feet, coarctation of the aorta, and a characteristic triangular facies. Later symptoms include short stature, a shield chest with wide-set nipples, streak ovaries, amenorrhea, absence of secondary sex characteristics, and infertility. Some affected girls, particularly those with mosaicism, have only short stature and amenorrhea, without dysmorphic features.

Complications relate primarily to coarctation of the aorta, when present. Rarely, the dysgenetic gonads may become neoplastic (gonadoblastoma). The incidence of malformations of the urinary tract is increased. Learning disabilities are common, secondary to difficulties in perceptual motor integration. Patients with pseudohypoparathyroidism and Noonan syndrome have a similar phenotype to patients with Turner syndrome, but have normal chromosomes.

▶ Treatment

In Turner syndrome the identification and treatment of perceptual difficulties before they become problematic is very important. Teenage patients need counseling to cope with the stigma

of their condition and to understand the need for hormone therapy. Estrogen replacement therapy will permit development of secondary sex characteristics and normal menstruation and prevent osteoporosis. Growth hormone therapy has been used to increase the height of affected girls. Females with 45,X or 45,X mosaicism have a low fertility rate, and those who become pregnant have a high risk of fetal wastage (spontaneous miscarriage, ~30%; stillbirth, 6–10%). Furthermore, their liveborn offspring have an increased frequency of chromosomal abnormalities involving either sex chromosomes or autosomes, and congenital malformations. Thus, prenatal ultrasonography and chromosome analysis are indicated for the offspring of females with sex chromosome abnormalities.

2. Klinefelter Syndrome (XXY)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Diagnosis is rarely made before puberty.
- ▶ Key findings include microorchidism; lack of libido; minimal facial hair; and tall, eunuchoid build.
- ▶ IQ can vary (normal to borderline or even severely retarded, depending on karyotype).

The incidence of Klinefelter syndrome in the newborn population is roughly 1:1000, but it is about 1% among mentally retarded males and about 3% among males seen at infertility clinics. The maternal age at birth is often advanced. Unlike Turner syndrome, Klinefelter syndrome is rarely the cause of spontaneous abortions. The diagnosis is seldom made before puberty except as a result of prenatal diagnosis, because prepubertal boys have a normal phenotype.

▶ Clinical Findings

The characteristic findings after puberty include microorchidism associated with otherwise normal external genitalia, azoospermia, sterility, gynecomastia, normal to borderline IQ, diminished facial hair, lack of libido and potency, and a tall, eunuchoid build. In chromosome variants with three or four X chromosomes (XXXY and XXXXY), mental retardation may be severe, and radioulnar synostosis may be present as well as anomalies of the external genitalia and cryptorchidism. In the XXXXY cases, these findings are especially prominent, and microcephaly, short stature, and dysmorphic features also occur. In general, the physical and mental abnormalities associated with Klinefelter syndrome increase as the number of sex chromosomes increases.

▶ Treatment

Males with Klinefelter syndrome require testosterone replacement therapy. The presence of the extra X chromosome may allow expression of what might normally be a lethal X-linked disorder to occur.

3. XYY Syndrome

Newborns with XYY syndrome in general are normal. Affected individuals may on occasion exhibit an abnormal behavior pattern from early childhood and may have mild retardation. Fertility may be normal. Many males with an XYY karyotype are normal. There is no treatment. Long-term problems may relate to low IQ and environmental stress.

4. XXX Syndrome

The incidence of females with an XXX karyotype is approximately 1:1000. Females with XXX are phenotypically normal. However, they tend to be taller than usual and to have lower IQs than their normal siblings. Learning and behavioral issues are relatively common. This is in contrast to individuals with XXXX, a much rarer condition causing more severe developmental issues, and a dysmorphic phenotype reminiscent of Down syndrome.

Jones KL: *Smith's Recognizable Patterns of Human Malformation*, 6th ed. Elsevier, 2006.

Chromosomal Abnormalities: Abnormal Structure

Chromosomal abnormalities most often present in newborns as multiple congenital anomalies in association with intrauterine growth retardation. In addition to trisomies as just described, other more subtle chromosomal abnormalities are also common. In some cases, the karyotype is normal, but a subtle chromosomal rearrangement can be detected by FISH. Another new technology, called comparative genomic hybridization array, enables screening for multiple submicroscopic chromosomal abnormalities (ie, microdeletions) simultaneously, and may be a very helpful tool in evaluating the child with a suspected chromosomal abnormality.

Although most cases of severe chromosomal abnormality such as trisomy are lethal, some individuals may survive if the abnormality exists in mosaic form. Two examples of this include trisomy 8 and cat eye syndrome, caused by extra genetic material, which is derived from a portion of chromosome 22.

Visser LE et al: Array-based comparative genomic hybridization for genome-wide detection of submicroscopic chromosomal abnormalities. *Am J Hum Genet* 2003;73:1261 [PMID: 14628292].

CHROMOSOME DELETION DISORDERS

Three common chromosomal deletion disorders that are often detected on routine karyotype analysis, and easily confirmed via FISH assay are 1p36– syndrome, Wolf-Hirschhorn syndrome (4p–), and cri du chat syndrome (5p–).

1. Deletion 1p36 Syndrome

Microcephaly and a large anterior fontanelle are characteristic features of 1p36– syndrome. Cardiac defects are common, and

dilated cardiomyopathy may present in infancy. Mental retardation, hypotonia, hearing loss, and seizures are usually seen.

2. Wolf-Hirschhorn Syndrome

Also known as 4p– (deletion of 4p16), this syndrome is characterized by microcephaly and unusual development of the nose and orbits that produces an appearance suggesting an ancient Greek warrior's helmet. Other anomalies commonly seen include cleft lip and palate, and cardiac and renal defects. Seizure disorders are common, and the majority of patients have severe mental retardation.

3. Cri du Chat Syndrome

Also known as 5p– (deletion of terminal chromosome 5p), this disorder is characterized by unique facial features, growth retardation, and microcephaly. Patients have an unusual catlike cry. Most patients have major organ anomalies and significant developmental delay.

CHROMOSOME MICRODELETION DISORDERS

Four common contiguous gene disorders (microdeletion disorders), which are usually suspected on the basis of an abnormal phenotype and then confirmed by FISH assay, are Williams syndrome, Miller-Dieker syndrome, Smith-Magenis syndrome, and velocardiofacial syndrome.

1. Williams Syndrome

Williams syndrome is a contiguous gene disorder involving the elastin gene and other neighboring genes at 7q11.2. It is characterized by short stature; congenital heart disease (supravalvular aortic stenosis); coarse, elfin-like facies with prominent lips; hypercalcemia or hypercalciuria in infancy; developmental delay; and neonatal irritability evolving into an overly friendly personality. Calcium restriction may be necessary in early childhood to prevent nephrocalcinosis. The hypercalcemia often resolves during the first year of life. The natural history includes progression of cardiac disease and predisposition to hypertension and spinal osteoarthritis in adults. Most patients have mild to moderate intellectual deficits.

2. Miller-Dieker Syndrome

A contiguous gene syndrome involving 17p13, this abnormality is characterized by microcephaly and severe CNS dysgenesis. The most commonly seen CNS malformation is termed *lissencephaly* ("smooth brain" as the brain is lacking its normal convolutions and gyri). An unusually developed face and forehead reflect abnormal migration of neuronal germinal matrix cells. Mutations in the gene *MDS1*, which is located in the critical region, can cause isolated lissencephaly, without the full picture of Miller-Dieker. Severe cognitive and developmental delay and seizure disorders are common.

3. Smith-Magenis Syndrome

This syndrome is associated with microdeletion of 17p11 and is characterized by prominent forehead, deep-set eyes, cupid-shaped upper lip, self-mutilating behavior (pulling nails and hair, putting objects into body orifices), sleep disturbance, and developmental delay. Some patients also have seizure disorders. Some individuals with larger deletions involving *PMP22* can present with peripheral neuropathy.

4. Velocardiofacial Syndrome (Deletion 22q11 Syndrome)

Also known as DiGeorge syndrome, this abnormality was originally described in newborns presenting with cyanotic congenital heart disease, usually involving great vessel abnormalities; thymic hypoplasia leading to immunodeficiency; and hypocalcemia due to absent parathyroid glands. This chromosomal abnormality is associated with a highly variable phenotype. Characteristics include mild microcephaly, palatal clefting or incompetence, speech and language delays, and congenital heart disease (ventricular or atrial septal defect). Midline defects such as umbilical hernia and hypospadias can be associated anomalies. In some cases, individuals have an apparent predisposition to psychosis.

MENDELIAN DISORDERS

AUTOSOMAL DOMINANT DISORDERS

Neurofibromatosis, Marfan syndrome, achondroplasia, osteogenesis imperfecta, and the craniosynostoses are among the most well known autosomal dominant disorders. There are many other common autosomal dominant disorders, including Treacher Collins syndrome, associated with a distinct craniofacial phenotype including malar and mandibular hypoplasia, and Noonan syndrome, which has a phenotype similar to Turner syndrome and is characterized by short stature and a webbed neck. Two other common genetic disorders whose causative genes were recently identified and found to be dominant mutations are CHARGE syndrome and Cornelia de Lange syndrome.

1. Neurofibromatosis Type 1

Neurofibromatosis type 1 (NF-1) is one of the most common autosomal dominant disorders, occurring in 1:3000 births and seen in all races and ethnic groups. In general, the disorder is progressive, with new manifestations appearing over time. Neurofibromatosis type 2 (NF-2), characterized by bilateral acoustic neuromas, with minimal or no skin manifestations, is a different disease caused by a different gene.

The gene for NF-1 is on the long arm of chromosome 17 and seems to code for a protein similar to a tumor suppressor factor. NF results from many different mutations of this gene. Approximately half of all NF cases are caused by new mutations. Careful evaluation of the parents is necessary to provide accurate genetic counseling. Recent evidence suggests that pene-

trance is close to 100% in those who carry the gene if individuals are examined carefully.

Café-au-lait macules may be present at birth, and about 80% of individuals with NF-1 will have more than six by age 1 year. Neurofibromas are benign tumors consisting of Schwann cells, nerve fibers, and fibroblasts; they may be discrete or plexiform. The incidence of Lisch nodules, which can be seen with a slit lamp, also increases with age. Affected individuals commonly have a large head, bony abnormalities on radiographic studies, scoliosis, and a wide spectrum of developmental problems. Although the average IQ is within the normal range, it is lower than in unaffected family members. (For more details of medical evaluation and treatment, see Chapter 23 of this book.) Useful information is provided on the following web site: <http://www.nfinc.org>.

Hyperpigmented macules can occur in other conditions such as Albright, Noonan, and Leopard syndromes, but the lesions are either single or different in character.

2. Marfan Syndrome

- ▶ Skeletal abnormalities (Ghent criteria).
- ▶ Lens dislocation.
- ▶ Dilation of the aortic root.
- ▶ Dural ectasia.
- ▶ Positive family history.

▶ Clinical Findings

Genetic testing is available for mutations causing Marfan syndrome, but the diagnosis remains largely clinical and is based on the Ghent criteria (available at <http://www.genetests.org>). Children most often present with a positive family history, suspicious skeletal findings, or ophthalmologic complications. Motor milestones are frequently delayed due to joint laxity and mild myopathy. Adolescents are prone to spontaneous pneumothorax. Dysrhythmias may be present. Aortic and valvular complications are not common in children but are more likely in sporadic cases. The characteristic facies is long and thin, with down-slanting palpebral fissures. The palate is high arched, and dentition is often crowded. The uvula may be bifid.

Marfan syndrome is genetically heterogeneous. Mutations in the gene for fibrillin1 proteins (*FBN1*) are most common but mutations in (*FBN2*) and in transforming growth factor β receptors (*TGFBR1* and *2*) can also produce phenotypes that fit criteria for a clinical diagnosis of Marfan syndrome.

▶ Differential Diagnosis

Homocystinuria should be excluded through metabolic testing in all individuals with marfanoid skeletal features. An

X-linked recessive disorder, **Lujan syndrome**, combines marfanoid habitus with mental retardation. Other connective tissue disorders, **Ehlers-Danlos syndrome**, and **Stickler syndrome** should also be considered.

Genes mutated in Marfan syndrome can also be mutated in related disorders: **Beal syndrome** (*FBN2*), **Shprintzen-Goldberg Syndrome** (*FBN1*) and the recently described **Loeys-Dietz syndrome** (*TGFBR1* and *2*). The reader is referred to reviews available at <http://www.genetests.org> for descriptions of these disorders.

► Complications

The skeletal problems including scoliosis are progressive. Astigmatism and myopia are very common and surveillance for lens dislocation is necessary.

The most serious associated medical problems involve the heart. Although many patients with Marfan syndrome have mitral valve prolapse, the most serious concern is progressive aortic root dilation, which may lead to aneurysmal rupture and death, and progressive or acute valvular (aortic more frequently than mitral) incompetency.

Families and practitioners seeking additional information about Marfan syndrome can be referred to the National Marfan Foundation (<http://www.marfan.org>).

► Treatment

A. Medical Therapy

Medical treatment for patients with Marfan syndrome includes surveillance for and appropriate management of the ophthalmologic, orthopedic, and cardiac issues. Serial echocardiograms are indicated to diagnose and follow the degree of aortic root enlargement, which can be managed medically or surgically, in more severe cases. Prophylactic β -adrenergic blockade can slow the rate of aortic dilation and reduce the development of aortic complications.

Interest in the effects of deficient extracellular fibrillin-1 has led to the discovery that the mild myopathy in Marfan syndrome reflects excessive signaling by transforming growth factor β (TGF β), an inhibitor of myoblast differentiation. Animal studies suggest that aortic aneurysm can be prevented by TGF β antagonists, including blockers of angiotensin II type 1 receptors. Research studies are currently underway using this approach in human patients.

B. Genetic Counseling

Genetic testing for mutations in *FBN1* and *2* and in *TGFBR1* and *2* should be considered in all individuals with Marfan syndrome as penetrance is variable and apparently unaffected family members can carry and pass on mutations.

3. Achondroplasia

Achondroplasia, the most common form of skeletal dysplasia, is caused by a mutation in *FGFR3*.

► Clinical Findings

The classic phenotype includes relative macrocephaly, mid-face hypoplasia, short-limbed dwarfism, and trident-shaped hands. The phenotype is apparent at birth. Individuals with achondroplasia are cognitively normal.

► Treatment

A. Medical Therapy

Orthopedic intervention is necessary for spinal problems including severe lumbar lordosis and gibbus deformity. Long bone lengthening surgery, such as the Ilizarov procedure, is used in some centers to increase height and upper extremity function, but its use is controversial.

Head circumference during infancy must be closely monitored and plotted on a diagnosis-specific head circumference chart. Bony overgrowth at the level of the foramen magnum may lead to progressive hydrocephalus and brainstem compression, and may warrant neurosurgical intervention.

Many patients find support through organizations such as the Little People of America, at the following web site: <http://www.lpaonline.org>.

B. Genetic Counseling

The vast majority of cases (approximately 90%) represent a new mutation. Two hemizygous parents with achondroplasia have a 25% risk of having a child homozygous for *FGFR3* mutations, which is a lethal disorder.

4. Osteogenesis Imperfecta

Osteogenesis imperfecta (OI), or brittle bone disease, is a relatively common disorder, caused by mutations in type I collagen. Most patients with more severe disease represent new mutations for this disorder.

► Clinical Findings

There are four main types of OI.

- Type I is a mild form, with increased incidence of fracturing and blue sclerae.
- Type II is generally lethal in the newborn period with multiple congenital fractures and severe lung disease.
- Type III is the severe form causing significant bony deformity secondary to multiple fractures (many of which are congenital), blue sclerae, short stature, and mild restrictive lung disease.
- Type IV is a mild form with increased incidence of fracturing (*not* usually congenital); dentinogenesis imperfecta is common.

► Treatment

A. Medical Therapy

A major advancement in the treatment of OI patients has been the use of pamidronate, a bisphosphonate compound, which

has been reported to lead to a reduced incidence of fracture and improvement in bone density. Patients should be followed by an experienced orthopedist, as rodding of long bones and surgery to correct scoliosis are often required. Hearing assessments are indicated, because of the association between OI and deafness. Close dental follow-up is also necessary.

B. Genetic Counseling

All four types of OI are associated with mutations in the gene coding for type I collagen. Collagen analysis is usually performed in skin fibroblasts to confirm the diagnosis. DNA analysis in blood is also possible. The milder forms may be seen as the result of dominant inheritance, while the more severe forms of OI generally result from new mutations.

5. Craniosynostoses Syndromes

The craniosynostoses disorders are common dominant disorders associated with premature fusion of cranial sutures. This class of disorders is now known to be caused by mutations in *FGFR* genes.

Crouzon syndrome is the most common of these disorders and is associated with multiple suture fusions, but with normal limbs. Other craniosynostosis disorders have limb as well as craniofacial anomalies, and include Pfeiffer, Apert, Jackson-Weiss, and Saethre-Chotzen syndromes.

Facial features associated with craniosynostosis include shallow orbits leading to proptosis, midface narrowing that may result in upper airway obstruction, and hydrocephalus that may require shunting. Children with craniosynostosis undergo multiple staged craniofacial and neurosurgical procedures to address these issues.

6. CHARGE Syndrome

CHARGE syndrome affects structures derived from rostral neural crest cells but also includes abnormal development of the eyes and midbrain. The acronym CHARGE serves as a mnemonic for associated abnormalities that include colobomas, congenital heart disease, choanal atresia, growth retardation, genital abnormalities (hypogenitalism), and ear abnormalities, with deafness. Facial asymmetry is a common finding. CHARGE is now known to be caused by mutations in the *CHD7* gene on chromosome 8q. A web site with information on CHARGE syndrome is available at <http://www.chargesyndrome.org/>.

Visser LE et al: Mutations in a new member of the chromo-domain gene family cause CHARGE syndrome. *Nat Genet* 2004;36:955 [PMID: 15300250].

7. Cornelia de Lange Syndrome

Cornelia de Lange syndrome is characterized by severe growth retardation; limb, especially hand, reduction defects (50%); congenital heart disease (25%); and stereotypical facies with hirsutism, medial fusion of eyebrows (synophrys), and thin, down-turned lips. The course and severity are variable, but the prognosis for survival and normal development is poor. Muta-

tions of the *NIBPL* gene are present in the majority of patients; however, a mutation of *SMC1* on the X chromosome is responsible for a subset of patients with the syndrome.

Jones KL: *Recognizable Patterns of Human Malformation*, 6th ed. Elsevier, 2006.

8. Noonan Syndrome

Noonan syndrome is an autosomal dominant disorder characterized by short stature, congenital heart disease, abnormalities of cardiac conduction and rhythm, occasional bleeding diatheses, webbed neck, down-slanting palpebral fissures, hearing loss, and low-set ears. Affected children may be large at birth and have mild subcutaneous edema. The phenotype evolves with age and may be difficult to recognize in older relatives. Mild developmental delays are often present. Mutations in the *PTPN11* gene cause most cases of Noonan syndrome, but others are the result of mutations in other proto-oncogenes. Products of these genes help control cell cycling through RAS-MAPK signal transduction pathways. Cell cycling controls are also affected by mutations in other genes that produce more complicated Noonan-like disorders (ie, Costello and cardiofaciocutaneous syndromes) in which cardiomyopathies are prominent. Because mutations causing NF-1 also affect RAS proto-oncogene signaling, it is not surprising that there is an NF-1 subtype with a so-called Noonan phenotype.

AUTOSOMAL RECESSIVE DISORDERS

1. Cystic Fibrosis

The gene for cystic fibrosis, *CFTR*, is found on the long arm of chromosome 7. Approximately 1 in 22 persons are carriers. Over 600 different mutations have been identified: the most common in the Caucasian population, known as $\Delta F508$, is a three-base deletion coding for phenylalanine.

Cloning of the gene for cystic fibrosis and identification of the mutation in the majority of cases have completely changed genetic counseling and prenatal diagnosis for this disorder, although the sweat chloride assay is still important in confirming the diagnosis. The American College of Medical Genetics recommends the 25-mutation assay using PCR-based techniques, which can cover 85–90% of the mutations.

The identification of the mutation in the cystic fibrosis gene has also raised the issue of mass newborn screening, because of the high frequency of this gene in the Caucasian population. Some states, such as Colorado, have offered newborn screening by trypsinogen assay, which can detect 70% of patients with cystic fibrosis. Although early detection can ensure good nutritional status starting at birth, newborn screening is controversial as there is no cure for cystic fibrosis. (For more details of medical management, see Chapters 18 and 21 in this text.)

2. Smith-Lemli-Opitz Syndrome

Smith-Lemli-Opitz syndrome is caused by a metabolic error in the final step of cholesterol production, resulting in low

cholesterol levels and accumulation of the precursor 7-dehydrocholesterol (7-DHC). (See also Chapter 34.)

► Clinical Findings

Patients with Smith-Lemli-Opitz syndrome present with a characteristic phenotype, including dysmorphic facial features (Figure 35–12), multiple congenital anomalies (including defects of the CNS, heart, cleft palate, cardiac system, kidneys, genitalia, and limbs), hypotonia, growth failure, and mental retardation. The diagnosis can be confirmed via a simple blood test looking for the presence of the precursor, 7-DHC, which is not detectable in an unaffected individual. This blood test can only be done in special laboratories. Prenatal testing is available.

► Treatment

Treatment with cholesterol can ameliorate the growth failure and lead to improvement in behavior and developmental course, although treatment does not cure this complex disorder.

3. Sensorineural Hearing Loss

Although there is marked genetic heterogeneity in causes of sensorineural hearing loss, including dominant, recessive, and X-linked patterns, nonsyndromic, recessively inherited deafness is the predominant form of severe inherited childhood deafness. Several hundred genes are known to cause hereditary hearing loss and deafness. The hearing loss may be conductive, sensorineural, or a combination of both; syndromic or nonsyndromic; and prelingual (before language develops) or postlingual (after language develops). The genetic forms of hearing loss are diagnosed by otologic, audiologic, and physical examination; family history; ancillary testing (such as CT examination of the temporal bone); and molecular genetic testing. Molecular genetic tests are available for many types of syndromic and nonsyndromic deafness, but often only on a research basis. In the clinical setting, molecular genetic testing is available for some recessive conditions including Usher syndrome types 2A (*USH2A* gene) and 3 (one mutation in *USH3A*), and at least six other rare forms of genetically caused deafness.

Testing for deafness-causing mutations in two more common genes, *GJB2* (which encodes the protein connexin 26) and *GJB6* (which encodes the protein connexin 30), plays a prominent role in diagnosis and genetic counseling. Mutations in connexin 26 are present in 49% of cases of prelingual deafness.

Nance WE: The genetics of deafness. *Ment Retard Dev Disabil Res Rev* 2003;9:109 [PMID: 12784229].

4. Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) is an autosomal recessive neuromuscular disorder in which anterior horn cells in the spinal cord degenerate. The mechanism for the loss of cells

▲ **Figure 35–12.** Child with Smith-Lemli-Opitz syndrome, featuring bitemporal narrowing, upturned nares, ptosis, and small chin.

appears to involve apoptosis of neurons in the absence of the product of the *SMN1* (survival motor neuron) gene located on chromosome 5q. Loss of anterior horn cells leads to progressive atrophy of skeletal muscle. The disorder has an incidence of approximately 1 in 12,000, with the majority of the cases presenting in infancy. Carrier frequencies approach 1 in 50 in populations with European ancestry.

► Clinical Findings

Three clinical subtypes are recognized based on age of onset and rate of progression. SMA I is the most devastating. Mild weakness may be present at birth but is clearly evident by 3 months and is accompanied by loss of reflexes and fasciculations in affected muscles. Progression of the disorder leads to eventual respiratory failure, usually by age 1 year. Symptoms of SMA II begin later, with weakness and decreased reflexes generally apparent by age 2 years. Children affected with SMA III begin to become weak as they approach adolescence.

Homozygous deletion of exon 7 of *SMN1* is detectable in approximately 95–98% of cases of all types of SMA and confirms the diagnosis. The *SMN1* region on chromosome 5q is complex

and variability in presentation appears to involve expression of neighboring genes, including a more centromeric *SMN2* pseudo-gene. Approximately 2–5% of patients affected with SMA will be compound heterozygotes in whom there is one copy of *SMN1* with exon 7 deleted and a second copy with a point mutation.

Prenatal diagnosis is available through genetic testing, but careful molecular analysis of the proband and demonstration of carrier status in parents is advised since, in addition to the problem of potential compound heterozygosity, 2% of cases occur as a result of a *de novo* mutation in one *SMN1* allele. In this case one of the parents is not a carrier and recurrence risks are low. Carrier testing is further complicated by a duplication of *SMN1* in 4% of the population that results in there being two *SMN1* genes on one of their chromosomes. Hence reproductive risk assessment, carrier testing and prenatal diagnosis of SMA are best undertaken in the context of careful genetic counseling.

5. Metabolic Disorders

Most inborn errors of metabolism are inherited in an autosomal recessive pattern. (See Chapter 34 in this text for detailed explanations of these disorders.)

X-LINKED DISORDERS

1. Duchenne & Becker Muscular Dystrophies

Duchenne muscular dystrophy (DMD) results from failure of synthesis of the muscle cytoskeletal protein dystrophin, the gene for which is located on the X chromosome, Xp12. Approximately 1 in 4000 male children are affected. Mutations in the same gene that result in partial expression of the dystrophin protein produce a less severe phenotype, Becker muscular dystrophy (BMD). In both DMD and BMD, progressive degeneration of skeletal and cardiac muscle occurs. Boys with DMD exhibit proximal muscle weakness and pseudo-hypertrophy of calf muscles by age 5–6 years. Patients become nonambulatory by age 13. Serum creatine kinase levels are markedly elevated. Boys with DMD frequently die in their 20s of respiratory failure and cardiac dysfunction. The prognosis for BMD is more variable. Although corticosteroids are useful in maintaining strength, they do not slow progression of the disorder.

The gene for dystrophin is very large and a common target for mutation. Large deletions or duplications can be detected in the gene for dystrophin in 65% of cases. Methods for detecting small and even point mutations have now been developed. Mutation testing and careful clinical assessment are replacing muscle biopsies in making the diagnosis of DMD.

One third of DMD cases presenting with a negative family history are likely to be new mutations. Genetic counseling is complicated by the fact that germline mosaicism for mutations in the dystrophin gene occur in approximately 15–20% of families. Therefore, if a mutation has been detected in a proband, prenatal diagnosis is routinely offered to his mother regardless of her apparent carrier status. It is also necessary to look for mutations in all sisters of affected

boys. Since mutations are now detected in the great majority of DMD cases, there is considerably less need for estimating carrier risks based on creatine kinase levels or using genetic linkage for prenatal diagnosis. Nonetheless, counseling and prenatal diagnosis remain difficult in some families. (Additional information about muscular dystrophies is included in Chapter 23.)

2. Hemophilia

Hemophilia A is an X-linked, recessive, bleeding disorder caused by a deficiency in the activity of coagulation factor VIII. Affected individuals develop a variable phenotype of hemorrhage into joints and muscles, easy bruising, and prolonged bleeding from wounds. The disorder is caused by heterogeneous mutations in the factor VIII gene, which maps to Xq28. Carrier detection and prenatal diagnosis can be done by direct detection of selected mutations, especially the inversions, the most common gene change, as well as indirectly by linkage analysis. Replacement of factor VIII is done using a variety of preparations derived from human plasma or recombinant techniques. Although replacement therapy is effective in most cases, 10–15% of treated individuals develop neutralizing antibodies that decrease its effectiveness. (See Chapter 28 in this text for additional discussion.)

3. Metabolic Disorders

Some important inborn errors are inherited as X-linked disorders, such as adrenoleukodystrophy. (See Chapter 32 in this text for more detailed descriptions.)

NONMENDELIAN DISORDERS

DISORDERS OF IMPRINTING

1. Beckwith-Wiedemann Syndrome

The association of macrosomia (enlarged body size), macroglossia (enlarged tongue), and omphalocele constitutes the Beckwith-Wiedemann syndrome (BWS), now known to be related to abnormal expression of genes located at chromosome 11p15. Other associated findings include mild facial dysmorphism (hypertelorism, unusual ear creases), infantile hypoglycemia due to transient hyperinsulinemia, multiple congenital anomalies (cleft palate and genitourinary anomalies common), and increased risk for certain malignancies, especially Wilms tumor (7–10%).

A growth factor gene, *IGF2*, is imprinted such that the maternal allele is ordinarily not expressed during intrauterine development. Chromosomal abnormalities affecting expression of this gene, such as duplication of the paternal 11p15 region, or paternal UPD, are associated with BWS. Paternal UPD may also lead to loss of expression of a tumor suppressor gene (*H19*), normally read from the maternal homolog, contributing to the increased predisposition to cancer seen in

this disorder. Supporting evidence for the role of imprinting in BWS is that paternal imprinting has been documented in about 10% of BWS patients, and that about 70% of Wilms tumors from patients with BWS show loss of imprinting of the genes coding for *IGF2* and *H19*. Children affected with BWS should undergo tumor surveillance protocols, including an abdominal ultrasound every 3 months until they reach age 7 years, as diagnosing malignancy at early stages leads to a significant improvement in outcome.

2. Prader-Willi Syndrome

Prader-Willi syndrome results from lack of expression of several imprinted genes, including *SNRPN*, located on chromosome 15q11. Clinical characteristics include severe hypotonia in infancy that often necessitates placement of a feeding gastrostomy tube. In older children, characteristic facies evolve over time, including almond-shaped eyes, along with frequent strabismus. Short stature, obesity, hypogonadism, and small hands and feet with tapering fingers are now believed to be associated with growth hormone deficiency. Obsessive hyperphagia (usual onset 3–4 years) and type 2 (adult-onset) diabetes mellitus are common features.

Multiple chromosomal rearrangements and mutations have been reported to disrupt expression of the genes that contribute to this syndrome. Of these, deletion of the paternally inherited allele of chromosome 15q11 (detected by FISH) is the most common chromosomal abnormality causing Prader-Willi syndrome, followed by maternal UPD, diagnosed by DNA methylation studies.

3. Angelman Syndrome

Angelman syndrome also involves imprinting and results from a variety of mutations that inactivate a ubiquitin-protein ligase gene, *UBE3A*, located in the same region of chromosome 15 as *SNRPN*, the maternally imprinted gene involved in Prader-Willi syndrome (see preceding section). *UBE3A* is paternally imprinted, and during normal development the maternal allele is expressed only in the brain. The classic phenotype includes severe mental retardation with prognathism, seizures, and marked delay in motor milestones, abnormal puppet-like gait and posturing, poor language development, and paroxysmal laughter and tongue thrusting.

Angelman syndrome is most commonly caused when sequences detectable by FISH on 15q11 are deleted from the maternal homolog. Uniparental paternal disomy 15 is the least common cause. Mutations in *UBE3A* cause the disorder in about one fourth of cases. Imprinting errors, which may be associated with advanced reproductive techniques, may also result in Angelman syndrome.

Niemitz EL, Feinberg AP: Epigenetics and assisted reproductive technology: A call for investigation. *Am J Hum Genet* 2004;74:599 [PMID: 14991528].

4. Uniparental Disomy for Chromosome 7

Certain genes on chromosome 7 are now known to be imprinted. UPD7 has been reported to cause cystic fibrosis in a child who inherited two copies of the $\Delta F508$ deletion from one parent. That child also had Russell-Silver syndrome, a syndrome associated with intrauterine growth failure and dwarfism. Imprinting abnormalities and UPD may prove to be associated with growth abnormalities.

DISORDERS ASSOCIATED WITH ANTICIPATION

1. (Autosomal Dominant) Myotonic Dystrophy

Most myotonic dystrophy, an autosomal dominant condition characterized by muscle weakness and tonic muscle spasms (myotonia) along with hypogonadism, frontal balding, cardiac conduction abnormalities, and cataracts, presents in adults. This disorder occurs when a CTG repeat in the *DMPK* gene on chromosome 19 expands to 50 or more copies. Normal individuals have from 5–35 CTG repeat copies. Individuals carrying 35–49 repeats are generally asymptomatic, but repeat copies greater than 35 are meiotically unstable and tend to further expand when passed to subsequent generations. Individuals with 50–100 copies may be only mildly affected (eg, cataracts). Most individuals with repeat copies greater than 100 will have symptoms or electrical myotonia as adults.

As unstable alleles continue to expand and copy numbers approach 400, symptoms become evident in children. Expansion greater than 1000 copies produces fetal and neonatal disease that can be lethal. Expansion from approximately 200–400 repeat copies produces mild, often clinically undetected symptoms, while very large copy numbers (800–2000) are associated with fetal manifestations (polyhydramnios and arthrogryposis). This occurs most frequently when the unstable repeats are passed through an affected mother. Therefore, an important component in the workup of the floppy or weak infant is a careful neurologic assessment of both parents for evidence of weakness or myotonia. Molecular testing that measures the number of CTG repeats is diagnostic clinically and prenatally. (See Chapter 23 for additional discussion.)

2. (Autosomal Recessive) Friedreich Ataxia

Symptoms of Friedreich ataxia include loss of coordination (cerebellar dysfunction) with both motor and sensory findings beginning in preadolescence and typically progressing through the teenage years. The gene involved, *FRDA*, is located on chromosome 9. Normal individuals carry 7–33 GAA repeats at this locus. Close to 96% of affected patients are homozygous for repeat expansions that exceed 66 copies. However, point mutations in the gene also occur. Meiotic instability for GAA repeats is more variable than for others

and contractions occur more frequently than do expansions. Relationships between genotype and phenotype are also more complex. Molecular diagnostic testing requires careful interpretation with respect to prognosis and reproductive risks. (See Chapter 23 for additional discussion.)

3. (X-Linked) Fragile X Syndrome

Fragile X syndrome, present in approximately 1 in 1000 males, is the most common cause of cognitive disabilities (mental retardation) in males. The responsible gene is *FMR1*, which has unstable CGG repeats at the 5' end. Normal individuals have up to 50 CGG repeats. Individuals with 51–200 CGG repeats have a premutation and may manifest symptoms including developmental, behavioral, and physical traits, premature ovarian failure in a subset of females; and a progressive, neurologic deterioration in older males called FXTAS (fragile X–associated tremor-ataxia syndrome). Affected individuals with fragile X syndrome (full mutation) have more than 200 CGG repeats and also have hypermethylation of both the CGG expansion and an adjacent CpG island. This methylation turns off the *FMR1* gene. DNA analysis, rather than cytogenetic testing, is the method of choice for confirming the diagnosis of fragile X syndrome.

► Clinical Features

Most males with fragile X syndrome present with intellectual disabilities, oblong facies with large ears, and large testicles, especially after puberty. Other physical signs include symptoms suggestive of a connective tissue disorder (eg, hyperextensible joints or mitral valve prolapse). Many affected individuals are hyperactive and exhibit infantile autism or autistic-like behavior.

About half of females with the fragile X full mutation show normal intelligence, but may evidence mild learning disabilities and behavioral problems. Unlike other X-linked disorders where female heterozygotes are asymptomatic, half of females with the full mutation have lower IQs in the range of mental retardation and more severe behavioral problems. Females have more mild phenotypic changes than the males. Clinical expression of fragile X differs in male and female offspring depending on which parent is transmitting the gene. The premutation can change into the full mutation only when passed through a female. Identification of the abnormal DNA amplification by direct DNA analysis can confirm the diagnosis of fragile X in an affected individual and can detect asymptomatic gene carriers of both sexes. Therefore, DNA analysis is a reliable test for prenatal and postnatal diagnosis of fragile X syndrome and facilitates genetic counseling. (Management considerations for patients with fragile X syndrome are described in Chapter 2.)

Hagerman PJ, Hagerman RJ: The fragile-X premutation: A maturing perspective. *Am J Hum Genet* 2004;74:805 [PMID: 15052536].

DISORDERS ASSOCIATED WITH MITOCHONDRIAL INHERITANCE

More than 100 point mutations and rearrangements of mtDNA have been identified, which are associated with a large number of human diseases. Symptoms of mitochondrial disorders are secondary to deficiency in the respiratory chain enzymes of oxidative phosphorylation, which supply energy to all cells. Mitochondrial diseases are usually progressive disorders with neurologic dysfunction including hypotonia, developmental delay, and seizures. Ophthalmologic issues, hearing loss, gastrointestinal tract dysfunction with growth failure, renal, endocrine, cardiac, and autonomic dysfunction are some of the many issues which can affect patients with mitochondrial diseases. The following disorders are three of the more common ones.

1. MELAS

MELAS is an acronym for **m**itochondrial **e**ncephalopathy, **l**actic acidosis, and **s**trokelike episodes. Symptoms occur in the pediatric age group and include recurrent episodes resembling stroke (blindness, paralysis), headache, vomiting, weakness of proximal muscles, and elevated blood lactate. (**Note:** Lactate may be falsely elevated secondary to technical difficulties in obtaining a free-flowing blood specimen or delay in laboratory measurement.) The most common mutation causing MELAS is in the tRNA^{Leu} gene (A3243G).

2. MERRF

MERRF is an acronym for **m**yoelonus **e**pilepsy with **r**agged **r**ed fibers. Children with MERRF present with a variety of neurologic symptoms, including myoclonus, deafness, weakness of muscles, and seizures. Eighty percent of cases are due to a missense mutation in the mitochondrial tRNA^{Lys} gene (A8344G).

3. Leigh Subacute Necrotizing Encephalomyelopathy

Multiple different abnormalities in respiratory chain function lead to Leigh disease, a very severe disorder associated with progressive loss of developmental milestones, along with extrapyramidal symptoms and brainstem dysfunction. Episodes of deterioration are frequently associated with an intercurrent febrile illness. Symptoms include hypotonia, unusual choreoathetoid hand movements, feeding dysfunction with failure to thrive, and seizures. Focal necrotic lesions of the brainstem and thalamus are hallmarks on MRI scan. Mitochondrial mutations affecting the respiratory chain, especially complexes I, II, and IV, and nuclear DNA mutations affecting complex II have been identified as causing Leigh disease.

Kahler SG, Fahey MC: Metabolic disorders and mental retardation. *Am J Med Genet C Semin Med Genet* 2003;117:31 [PMID: 12561056].

DISORDERS OF MULTIFACTORIAL INHERITANCE

CLEFT LIP & CLEFT PALATE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Cleft lip is more common in males, cleft palate in females.
- ▶ Cleft lip and palate may be isolated defects (nonsyndromic) or associated with other anomalies as part of a genetic disorder (syndromic).
- ▶ Pierre Robin anomalad, the association of cleft palate, micrognathia, and glossoptosis may lead to severe airway complications in young infants, necessitating tracheostomy.

▶ General Considerations

From a genetic standpoint, cleft lip with or without cleft palate is distinct from isolated cleft palate. Although both can occur in a single family, particularly in association with certain syndromes, this pattern is unusual. Racial background is a factor in the incidence of facial clefting. Among Asians, Caucasians, and blacks, the incidence is 1.61, 0.9, and 0.31, respectively, per 1000 live births.

▶ Clinical Findings

A cleft lip may be unilateral or bilateral and complete or incomplete. It may occur with a cleft of the entire palate or just the primary (anterior and gingival ridge) or secondary (posterior) palate. An isolated cleft palate can involve only the soft palate or both the soft and hard palates. It can be a V-shaped or a wide horseshoe, U-shaped cleft. When the cleft palate is associated with micrognathia and glossoptosis (a tongue that falls back and causes respiratory or feeding problems), it is called the **Pierre Robin sequence** or **anomalad**. Among individuals with facial clefts—more commonly those with isolated cleft palate—the incidence of other congenital abnormalities is increased, with up to a 60% association with other anomalies or syndromes. The incidence of congenital heart disease, for example, is 1–2% in liveborn infants, but among those with Pierre Robin sequence it can be as high as 15%. Associated abnormalities should be looked for in the period immediately after birth and before surgery.

▶ Differential Diagnosis

A facial cleft may occur in many different circumstances. It may be an isolated abnormality or part of a more generalized syndrome. Prognosis, management, and accurate determi-

nation of recurrence risks all depend on accurate diagnosis. In evaluating a child with a facial cleft, the physician must determine if the cleft is nonsyndromic or syndromic.

A. Nonsyndromic

In the past, nonsyndromic cleft lip or cleft palate was considered a classic example of polygenic or multifactorial inheritance. More recently, however, this mode of inheritance has been questioned, and several studies have suggested one or more major autosomal loci, both recessive and dominant (or co-dominant). Empirically, however, the recurrence risk is still in the range of 2–3% because of nonpenetrance or the presence of other contributing genes.

B. Syndromic

Cleft lip, with or without cleft palate, and isolated cleft palate may occur in a variety of syndromes that may be environmental, chromosomal, single gene, or of unknown origin (Table 35–3). Prognosis and accurate recurrence risks depend on the correct diagnosis.

▶ Complications

Problems associated with facial clefts include early feeding difficulties, which may be severe; airway obstruction necessitating tracheostomy; recurrent serous otitis media associated with fluctuating hearing and language delays; speech problems, including language delay, hypernasality, and articulation errors; and dental and orthodontic complications.

▶ Treatment

A. Medical Therapy

Long-term management ideally should be provided through a multidisciplinary cleft palate clinic.

Table 35–3. Syndromic isolated cleft palate (CP) and cleft lip with or without cleft palate (CL/CP).

Environmental
Maternal seizures, anticonvulsant usage (CL/CP or CP)
Fetal alcohol syndrome (CP)
Amniotic band syndrome (CL/CP)
Chromosomal
Trisomies 13 and 18 (CL/CP)
Wolf-Hirschhorn or 4p- syndrome (CL/CP)
Shprintzen or 22q11.2 deletion syndrome (CP)
Single-gene disorders
Treacher Collins syndrome, AD (CP)
Stickler syndrome, AD (CP)
Smith-Lemli-Opitz, AR (CP)
Unknown cause
Moebius syndrome (CP)

AD, autosomal dominant; AR, autosomal recessive.

B. Genetic Counseling

Accurate counseling depends on accurate diagnosis and the differentiation of syndromic from nonsyndromic clefts. A complete family history must be taken, and the patient and both parents must be examined. The choice of laboratory studies is guided by the presence of other abnormalities and clinical suspicions, and may include chromosome analysis, FISH, eye examination, and radiologic studies. Clefts of both the lip and the palate can be detected on detailed prenatal ultrasound.

NEURAL TUBE DEFECTS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Various defects, ranging from anencephaly to open or skin-covered lesions of the spinal cord, may occur in isolation or as part of a syndrome.
- ▶ Myelomeningocele is usually associated with hydrocephalus, neurogenic bladder and bowel, and congenital paralysis in the lower extremities.
- ▶ Anomalies of the CNS, heart, and kidneys may also be seen.
- ▶ MRI helps determine the extent of the anatomic defect in skin covered lesions.

▶ General Considerations

Neural tube defects comprise a variety of malformations, including anencephaly, encephalocele, spina bifida (myelomeningocele), sacral agenesis, and other spinal dysraphisms. Evidence suggests that the neural tube develops via closure at multiple rather than just two closure sites and that each closure site is mediated by different genes and affected by different teratogens. Hydrocephalus associated with the Arnold-Chiari type II malformation commonly occurs with myelomeningocele. Sacral agenesis, also called the caudal regression syndrome, occurs more frequently in infants of diabetic mothers.

▶ Clinical Findings

At birth, neural tube defects can present as an obvious rachischisis (open lesion), or as a more subtle skin-covered lesion. In the latter case, MRI should be conducted to better define the anatomic defect. The extent of neurologic deficit depends on the level of the lesion and may include clubfeet, dislocated hips, or total flaccid paralysis below the level of the lesion. Hydrocephalus may be apparent at birth or may develop after the back has been surgically repaired. Neurogenic bladder and bowel are commonly seen. Other anomalies of the CNS may be present, as well as anomalies of the heart or kidneys.

▶ Differential Diagnosis

Neural tube defects may occur in isolation (nonsyndromic) or as part of a genetic syndrome. They may result from teratogenic exposure to alcohol or the anticonvulsant valproate. Any infant with dysmorphic features or other major anomalies in addition to a neural tube defect should be evaluated by a geneticist, and a chromosome analysis should be performed.

▶ Treatment

A. Neurosurgical Measures

Infants with an open neural tube defect should be placed in prone position, and the lesion kept moist with sterile dressing. Neurosurgical closure should occur within 24–48 hours after birth to reduce risk of infection. The infant should be monitored closely for signs of hydrocephalus. Shunts are required in about 85% of cases of myelomeningocele and are associated with complications including malfunction and infection. Symptoms of the Arnold-Chiari II malformation include feeding dysfunction, abducens nerve palsy, vocal cord paralysis with stridor, and apnea. Shunt malfunction may cause an acute worsening of Arnold-Chiari symptoms that may be life-threatening.

B. Orthopedic Measures

The child's ability to walk varies according to the level of the lesion. Children with low lumbar and sacral lesions walk with minimal support, while those with high lumbar and thoracic lesions are rarely functional walkers. Orthopedic input is necessary to address foot deformities and scoliosis. Physical therapy services are indicated.

C. Urologic Measures

Neurogenic bladders have variable presentations. Urodynamic studies are recommended early on to define bladder function, and management is guided by the results of these studies. Continence can often be achieved by the use of anticholinergic or sympathomimetic agents, clean intermittent catheterization, and a variety of urologic procedures. Renal function should be monitored regularly, and an ultrasound examination should be periodically repeated. Symptomatic infections should be treated.

Symptoms of neurogenic bowel include incontinence and chronic constipation and are managed with a combination of dietary modifications, laxatives, stool softeners, and rectal stimulation. A surgical procedure called ACE (antegrade continence enema) may be recommended for patients with severe constipation that is unresponsive to conservative management.

D. Genetic Counseling

Most isolated neural tube defects are polygenic, with a recurrence risk of 2–3% in future pregnancies. The recur-

rence risk for siblings of the parents and siblings of the patients is 1–2%. A patient with spina bifida has a 5% chance of having an affected child. Prenatal diagnosis is possible. In fetuses with open neural tube defects, maternal serum α -fetoprotein levels measured at 16–18 weeks' gestation are elevated. α -Fetoprotein and acetylcholine esterase levels in amniotic fluid are also elevated. Ultrasound studies alone will detect approximately 90% of neural tube defects.

Prophylactic folic acid can significantly lower the incidence and recurrence rate of neural tube defects, if the intake of the folic acid starts at least 3 months prior to conception and continues for the first month of pregnancy, at a dose of 4 mg/d for women at increased risk. For women of childbearing age without a family history of neural tube defects, the dose is 0.4 mg of folic acid daily. Folic acid supplementation prior to conception may also lower the incidence of other congenital malformations such as conotruncal heart defects.

► Special Issues & Prognosis

All children requiring multiple surgical procedures (ie, patients with spina bifida or urinary tract anomalies) have a significant risk for developing hypersensitivity type I (IgE-mediated) allergic reactions to latex. For this reason, nonlatex medical products are now routinely used when caring for patients with neural tube defects.

Most individuals with spina bifida are cognitively normal, but learning disabilities are common. Individuals with encephalocele or other CNS malformations generally have a much poorer intellectual prognosis. Individuals with closed spinal cord abnormalities (eg, sacral lipomas) have more mild issues in general, and intelligence is usually normal. Problems in older patients include the development of spinal cord tethering, which usually presents with back pain, progressive scoliosis, and changes in bowel or bladder function. This often requires neurosurgical intervention.

Individuals with neural tube defects have lifelong medical issues, requiring the input of a multidisciplinary medical team. A good support for families is the national Spina Bifida Association, at the following web site: <http://www.sbaa.org>.

COMMON RECOGNIZABLE DISORDERS WITH VARIABLE OR UNKNOWN CAUSE

The text that follows describes several important and common human malformation syndromes. The best illustrations of these syndromes are found in *Smith's Recognizable Patterns of Human Malformation*. An excellent Internet site at the University of Kansas Medical Center can be consulted for further information: <http://www.kumc.edu/gec/support>.

1. Arthrogyposis Multiplex

Arthrogyposis multiplex is due to lack of fetal movement. Causes most often involve constraint, CNS maldevelopment or

injury, and neuromuscular disorders. Polyhydramnios is often present as a result of lack of fetal swallowing. Pulmonary hypoplasia may also be present, reflecting lack of fetal breathing. The workup includes brain imaging, careful consideration of metabolic disease, neurologic consultation, and, in some cases, electrophysiologic studies and muscle biopsy. The parents should be examined, and a family history reviewed carefully for findings such as muscle weakness or cramping, cataracts, and early-onset heart disease, suggesting myotonic dystrophy.

2. Goldenhar Syndrome

Goldenhar syndrome, also known as vertebro-auriculo-facial syndrome, is an association of multiple anomalies involving the head and neck. The classic phenotype includes hemifacial microsomia (one side of the face smaller than the other), and abnormalities of the pinna on the same side with associated deafness. Ear anomalies may be quite severe and include anotia. A characteristic benign fatty tumor in the outer eye, called an epibulbar dermoid, is frequently present, as are preauricular ear tags. Vertebral anomalies, particularly of the cervical vertebrae, are common. The Arnold-Chiari type I malformation (herniation of the cerebellum into the cervical spinal canal) is a common associated anomaly. Cardiac anomalies and hydrocephalus are seen in more severe cases. Most patients with Goldenhar syndrome have normal intelligence. The cause is unknown; however, there is significant overlap with the Townes-Brocks syndrome, now known to be caused by mutations in the *SALL1* gene.

3. Kabuki Syndrome

Kabuki syndrome is a disorder of unknown cause characterized by a distinctive facial appearance (hypertelorism with long palpebral fissures, large pinnae), developmental delay, and hearing loss. Most cases are sporadic, although a few cases with dominant transmission have been reported. Anomalies of the heart and genitourinary system are occasionally seen.

4. Oligohydramnios Sequence (Potter Sequence)

This condition presents in newborns as severe respiratory distress due to pulmonary hypoplasia in association with positional deformities of the extremities, usually bilateral clubfeet, and typical facies consisting of suborbital creases, depressed nasal tip and low-set ears, and retrognathia. The sequence may be due to prolonged lack of amniotic fluid. Most often it is due to leakage, renal agenesis, or severe obstructive uropathy.

5. Opitz G/BBB Syndrome

Disrupted development of midline structures is a feature of several overlapping malformation syndromes, a number of them heritable. Hypertelorism (wide set eyes), midbrain anomalies (agenesis of the corpus callosum), cardiac septal defects, and genitourinary tract anomalies (hypospadias) are the most

common features. Current clinical genetic terminology refers to these conditions as Opitz G/BBB syndrome. Hypotonia and problems with swallowing and gastroesophageal reflux are hallmark symptoms. Mentation is usually subnormal. Both autosomal dominant and X-linked inheritance have been documented. Linkage studies have recently identified a candidate gene dubbed *M101* on the X chromosome. Several patients with Opitz G/BBB syndrome have also been shown by FISH to have deletions of 22q11. Additional resources include the Opitz Family Network and the Opitz G/BBB Family Network and the following web site: <http://www.opitznet.org/joinus.html>.

6. Overgrowth Syndromes

Overgrowth syndromes are becoming increasingly recognized as important childhood conditions. They may present at birth and are characterized by macrocephaly, motor delays (cerebral hypotonia), and, in many cases, asymmetry of extremities. Bone age may be advanced. The most common overgrowth syndrome is **Sotos syndrome**. Patients with Sotos syndrome have a characteristic facies with a prominent forehead and down-slanting palpebral features. The cause of the syndrome is unknown. Patients have a small but increased risk of cancer.

Other overgrowth syndromes include **Beckwith-Wiedemann syndrome** (BWS), described earlier, and two single gene disorders, Simpson-Golabi-Behmel syndrome and Bannayan-Riley-Ruvalcaba syndrome. Patients with **Simpson-Golabi-Behmel syndrome** exhibit a BWS-like phenotype, but with additional anomalies, including polydactyly and more severe facial dysmorphism. Unlike patients with BWS, who have normal intelligence, patients with Simpson-Golabi-Behmel syndrome often have developmental delay. It is inherited as an X-linked disorder. Patients with **Bannayan-Riley-Ruvalcaba syndrome** have macrosomia, macrocephaly, and unusual freckling of the penis. They have mild developmental issues and may present with autism. They may develop hemangiomas or lymphangiomatous growths and have a predisposition to intestinal malignancies. The cause of Bannayan-Riley-Ruvalcaba syndrome was recently found to be a mutation of the *PTEN* gene implicated in Cowden syndrome, the association of intestinal polyposis with malignant potential.

7. Rubinstein-Taybi Syndrome

Rubinstein-Taybi syndrome is a genetic disorder of unknown cause, characterized by developmental delay, growth failure, and a distinctive facial dysmorphism comprising microcephaly, prominent nose, and small chin. Feeding problems are common. About 25% of patients have been found with a microdeletion of chromosome 16 detectable by FISH, but most patients have a normal karyotype.

8. Syndromic Short Stature

Short stature is an important component of numerous syndromes, or it may be an isolated finding. In the absence of nutritional deficiencies, endocrine abnormalities, evidence of

skeletal dysplasia (disproportionate growth with abnormal skeletal films), or a positive family history, intrinsic short stature can be due to UPD. The phenotype of Russell-Silver syndrome—short stature with normal head growth (pseudohydrocephalus), normal development, and minor dysmorphic features (especially fifth finger clinodactyly)—has been associated in some cases with maternal UPD7.

9. VACTERL Association

VACTERL association is described by an acronym denoting the association of:

- ▶ **V**ertebral defects (segmentation anomalies).
- ▶ **I**mperforate anus.
- ▶ **C**ardiac malformation (most often ventricular septal defect).
- ▶ **T**racheo-esophageal fistula.
- ▶ **R**enal anomalies.
- ▶ **L**imb (most often radial ray) anomalies.

The disorder is sporadic, and some of the defects may be life-threatening. The prognosis for normal development is good. The cause is unknown, but a high association with monozygotic twinning suggests a mechanism dating back to events perhaps as early as blastogenesis. Recently, disturbance of the sonic hedgehog pathway was suggested to be part of the mechanism for VACTERL, based on a mouse model.

Careful examination and follow-up are important, because numerous other syndromes have overlapping features, such as the *SALL4* mutation that leads to Okhiro syndrome, Duane-Radial ray syndrome, and IVIC syndrome, which has a recurrence risk of 50%. In addition, Feingold syndrome, which is caused by mutation in the *MYCN* gene, and a newly described STAR syndrome due to a novel gene identified on the X chromosome need to be excluded. Chromosomal studies and genetic consultation are warranted.

Paradisi I, Arias S: IVIC syndrome is caused by a c.2607delA mutation in the *SALL4* locus. *Am J Med Genet* 2007;143A:326 [PMID: 17256792].

EVALUATION OF THE DEVELOPMENTALLY DELAYED CHILD

Cognitive disabilities or developmental delays affect 8% of the population. Disorders associated with symptoms of delayed development are heterogeneous but frequently include heritable components. Evaluation should be multidisciplinary; Table 35-4 lists the main features of developmental delay, emphasizing

ing the major clinical and genetic considerations. (See Chapter 2 for additional information about developmental delay and intellectual disability/mental retardation.)

Obtaining a detailed history, including pertinent prenatal and perinatal events, is critical. Feeding issues and slow growth velocity are seen in many genetic disorders causing developmental delay. Rate of developmental progress and particularly a history of loss of skills are important clues, as the latter might suggest a metabolic disorder with a neurodegenerative component. Family history can provide clues to suggest possible genetic etiologies, particularly if there is a history of consanguinity or a family pattern of other affected individuals.

Physical examination provides helpful clues. Referral to a clinical geneticist is indicated whenever unusual features are encountered. Neurologic, ophthalmologic, and audiologic consultation should be sought when indicated. Brain imaging should be requested in cases involving unexplained deviations from normal head growth. Neuroimaging and skeletal studies may also be indicated when dysmorphic features are present.

Metabolic and genetic testing procedures other than those listed in the Table 35–4 may also be indicated.

Interpretation & Follow-Up

Clinical experience indicates that specific diagnoses can be made in approximately half of patients evaluated according to the protocol presented here. With specific diagnosis comes prognosis, ideas for management, and insight into recurrence risks. Prenatal diagnosis may also become possible.

Follow-up is important both for patients in whom diagnoses have been made and for those patients initially lacking a diagnosis. Genetic information is accumulating rapidly and can be translated into new diagnoses and better understanding with periodic review of clinical cases.

Autism

Autism is a developmental disorder comprising abnormal function in three domains: language development, social development, and behavior. The majority of patients with autism also have cognitive disabilities and might be appropriately evaluated according to the recommendations above. However, given the enormous increase in prevalence of autism in the past decade, it is worth discussing the genetic evaluation of autism separately.

There are multiple known genetic causes of autism. Advances in molecular diagnosis, understanding of metabolic derangements, and technologies such as FISH are allowing more patients with autism to be identified with specific genetic disorders. This allows more accurate genetic counseling for recurrence risk, as well as diagnosis-specific interventions which may improve prognosis.

With this in mind, recommendations for the genetic evaluation of a child with autism include the following:

1. Genetic referral if dysmorphic features or cutaneous abnormalities are present (ie, hypopigmented spots such as those seen in patients with **tuberous sclerosis**).

Table 35–4. Evaluation of the child with developmental delay.

History

- Pregnancy history
- Growth parameters at birth
- Neonatal complications
- Feeding history
- History of somatic growth
- Motor, language, and psychosocial milestones
- Seizures
- Loss of skills
- Abnormal movements
- Results of previous tests and examinations

Family history

- Developmental and educational histories
- Psychiatric disorders
- Pregnancy outcomes
- Medical history
- Consanguinity

Physical examination

- General pediatric examination, including growth parameters
- Focused dysmorphic evaluation including measurement of facial features and limbs
- Complete neurologic examination
- Parental growth parameters (especially head circumferences) and dysmorphic features should also be assessed

Imaging studies

- See text

Laboratory assessment^a

- Chromosomes (high-resolution analysis)
- Fragile X testing (analysis of *FMRT* gene for triplet repeats)
- FISH analyses guided by dysmorphic features
- Comparative genomic hybridization (CGH) microarray
- Other blood analyses: complete blood count, electrolytes, liver function tests, creatinine kinase (CK), lactate, pyruvate
- Serum amino acid analysis
- Urine amino and organic acid analyses
- Urine analysis for mucopolysaccharides (if coarse features and organomegaly)

^aIn many cases, negative results may be important. FISH, fluorescence in situ hybridization.

2. Laboratory testing to include the following:
 - a. Chromosomes with high-resolution banding.
 - b. Molecular testing for **fragile X syndrome**.
 - c. FISH testing for 22q deletions and 15q derangements.
 - d. Methylation testing for UPD15 if phenotype is suggestive of **Angelman syndrome**.
 - e. Measurement of cholesterol and 7-dehydrocholesterol if syndactyly is present between the second and third toes, to rule out mild form of **Smith-Lemli-Opitz syndrome**.
 - f. *MECP2* testing if clinical course is suggestive of **Rett syndrome** (ie, neurodegenerative course, progressive microcephaly, and seizures in a female patient).

Autism spectrum disorders are discussed in more detail in Chapter 2 of this text.

PERINATAL GENETICS

TERATOGENS

1. Drug Abuse & Fetal Alcohol Syndrome

Fetal alcohol syndrome results from excessive exposure to alcohol during gestation and affects 30–40% of offspring of mothers whose daily intake of alcohol exceeds 3 ounces. Features of the syndrome include short stature, poor head growth (may be postnatal in onset), developmental delay, and midface hypoplasia characterized by a poorly developed long philtrum, narrow palpebral fissures, and short nose with anteverted nares. Facial findings may be subtle, but careful measurements and comparisons with standards (see Figure 35–11) are helpful. Structural abnormalities occur in half of affected children. Cardiac anomalies and neural tube defects are commonly seen. Genitourinary tract anomalies are frequent. Neurobehavioral effects also occur and may be stereotypic with poor judgment and inappropriate social interactions such as lack of stranger anxiety in toddlers commonly found. Behavioral problems may occur without other classic features of fetal alcohol syndrome.

Maternal abuse of drugs and other psychoactive substances is also associated with increased risks for adverse perinatal outcomes including miscarriage, preterm delivery, growth retardation, and increased risk for injury to the developing CNS. Methamphetamine and crack cocaine appear to be particularly dangerous. Maternal abuse of inhalants such as glue appears to be associated with findings similar to those of fetal alcohol syndrome. For most abused substances, the link between exposures and specific adverse outcomes is less well demonstrated than with alcohol. Multiple factors are probably involved, and it should be recognized that substance abuse often involves more than one drug.

Careful evaluation for other syndromes and chromosomal disorders should be included in the workup of exposed infants. Behavioral abnormalities in older children may be the result of maternally abused substances but they may also reflect evolving psychiatric disorders. Psychiatric disorders, many recognized as heritable, affect large numbers of men and women with substance abuse problems. Fetal alcohol spectrum disorders are discussed in more detail in Chapter 2.

2. Maternal Anticonvulsant Effects

Anticonvulsant exposure during pregnancy is associated with adverse outcomes in approximately 10% of children born to women treated with these agents. A syndrome characterized by small head circumference, anteverted nares, cleft lip and palate (occasionally), and distal digital hypoplasia was first described in association with maternal use of phenytoin but also occurs with other anticonvulsants including carbamazepine. Risks for spina bifida are increased, especially in pregnancies exposed to valproic acid.

3. Retinoic Acid Embryopathy

Vitamin A and its analogs are potent morphogens that have considerable teratogenic potential. Developmental toxicity occurs in approximately one third of pregnancies exposed in the first trimester to the synthetic retinoid isotretinoin, commonly prescribed to treat acne. Exposure disrupts migration of rostral neural crest cells and produces CNS maldevelopment, especially of the posterior fossa; ear anomalies (often absence of pinnae); congenital heart disease (great vessel anomalies); and tracheoesophageal fistula. These findings constitute a partial phenocopy of DiGeorge syndrome and demonstrate the continuum of contributing genetic and epigenetic factors in morphogenesis. It is now recognized that vitamin A itself, when taken as active retinoic acid in doses exceeding 25,000 IU/d during pregnancy, can produce similar fetal anomalies. For safety, vitamin A intake is therefore limited to 10,000 IU/d of retinoic acid. Maternal ingestion of large amounts of vitamin A taken as retinol during pregnancy, however, does not increase risks, because conversion of this precursor to active retinoic acid is internally regulated.

ASSISTED REPRODUCTION

Assisted reproductive technologies including in vitro fertilization now contribute significantly to human reproduction. Although healthy live births are accepted as the usual outcomes resulting from successful application of these procedures, questions about the risks of adverse effects on development are beginning to be raised. Increased rates of twinning, both monozygotic and dizygotic, are well recognized while the possibility of increased rates of birth defects remains controversial. Abnormal imprinting appears to be associated with in-vitro fertilization. Evidence supports increased prevalence of Beckwith-Wiedemann and Angelman syndromes among offspring of in vitro pregnancies.

PRENATAL DIAGNOSIS

Prenatal screening for birth defects is now routinely offered to pregnant women of all ages. Prenatal diagnosis for specific genetic disorders is indicated in 7–8% of pregnancies. Prenatal diagnosis introduces options for management including termination of abnormal pregnancies, preparation for specialized perinatal care, and, in some cases, fetal therapies.

Prenatal assessment of the fetus includes techniques that screen maternal blood, image the conceptus, and sample fetal and placental tissues (Table 35–5).

Maternal Blood Analysis

Elevated levels of maternal serum α -fetoprotein correlate with open neural tube defects but low levels are associated with Down syndrome and other chromosomal abnormalities. First trimester measurements of PAPA (pregnancy-

hCG, human chorionic gonadotropin; MRI, magnetic resonance imaging.

associated plasma protein A) and the free β -subunit of human chorionic gonadotropin screen for trisomies 21 and 18. In the second trimester maternal α -fetoprotein, human chorionic gonadotropin, unconjugated estradiol, and inhibin combine to estimate risks for trisomies 21 and 18. Low estradiol levels can also predict cases of Smith-Lemli-Opitz syndrome, a devastating autosomal recessive disorder discussed earlier.

Fetal cells, including lymphocytes, trophoblasts, and nucleated red blood cells, circulate at low frequency in maternal blood and may eventually provide access to direct information about the conceptus.

Analysis of Fetal Samples

A. Amniocentesis

Whereas maternal blood levels are screened for fetal abnormalities, genetic amniocentesis is applied to make specific diagnoses. This procedure samples fluid surrounding the fetus; the cells obtained are cultured for cytogenetic, molecular, or metabolic analyses. α -Fetoprotein and other chemical markers can also be measured. This is a safe procedure

with a complication rate (primarily for miscarriage) of less than 1% in experienced hands.

B. Chorionic Villus Sampling (Placental)

Chorionic villus sampling is now available in most perinatal centers and is generally performed at 11–12 weeks’ gestation. Tissue obtained by chorionic villus sampling provides DNA for molecular analysis and contains dividing cells (cytotrophoblasts) that can be rapidly karyotyped. However, direct cytogenetic preparations may be of poor quality. In addition, chromosomal abnormalities detected by this technique may be confined to the placenta (**confined placental mosaicism**). Cultured preparations may be more relevant.

C. Fetal Blood and Tissue

Fetal blood can be sampled directly in late gestation through ultrasound-guided percutaneous umbilical blood sampling. A wide range of diagnostic tests ranging from biochemical to cytogenetic can be applied. Fetal urine sampled from the bladder or dilated proximal structures can provide important information about fetal renal function.

It is occasionally necessary to obtain biopsy specimens of fetal tissues such as liver or muscle for accurate prenatal diagnosis; however, these procedures are available in only a few perinatal centers.

D. Embryo Biopsy

With the advent of single-cell PCR techniques as well as interphase FISH it is now possible to make genetic diagnoses in preimplantation human embryos by removing and analyzing blastocyst cells. How useful and accepted this technique will become remains to be seen.

Fetal Imaging

Fetal ultrasonography and MRI imaging are becoming increasingly common during pregnancy while radiographs are seldom employed. Ultrasonography has joined maternal blood sampling as a screening technique for common chromosomal aneuploidies, neural tube defects, and other structural anomalies. Pregnancies at increased risk for CNS anomalies, skeletal dysplasias, and structural defects of the heart and kidneys should be monitored by careful ultrasound examinations. Although MRI has had limited use to date, it appears that there will be a definite place for it in defining abnormalities of the fetal brain.

Allergic Disorders

Mark Boguniewicz, MD

Ronina A. Covar, MD

David M. Fleischer, MD

Allergic disorders are among the most common problems seen by pediatricians and primary care physicians, affecting over 25% of the population in developed countries. In the most recent National Health and Nutrition Examination Survey conducted in the United States between 1988 and 1994, 54% of the population had positive test responses to one or more allergens. In children, the increased prevalence of asthma, allergic rhinitis, and atopic dermatitis has been accompanied by significant morbidity and school absenteeism, with adverse consequences for school performance and quality of life, as well as economic burden measured in billions of dollars. Understanding the language of allergy and the basic mechanisms involved may help physicians when treating these disorders. In this chapter, atopy refers to a genetically determined predisposition to develop IgE antibodies found in patients with asthma, allergic rhinitis, and atopic dermatitis. This chapter discusses the major allergic disorders seen in pediatric practice.

ASTHMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Episodic symptoms of airflow obstruction including wheezing, cough, and chest tightness.
- ▶ Airflow obstruction at least partially reversible.
- ▶ Exclusion of alternative diagnoses.

▶ General Considerations

Asthma is the most common chronic disease of childhood, affecting over 6 million children in the United States, and almost two of every three children affected have had at least one attack due to asthma in the past year. Despite advances in the understanding of asthma, associated morbidity and

mortality rates are still historically high. Recent data suggest that death rates appear to have stabilized, yet the rate has not declined for black children. Although asthma prevalence in children increases with age, health care utilization is most marked among the very young. The prevalence, morbidity, and mortality rates for asthma are higher among minority and inner city populations. The reasons for this are unclear but may be related to a combination of more severe disease, poor access to health care, lack of asthma education, delay in prescribing appropriate controller therapy, and environmental factors (eg, irritants including smoke and air pollutants, and perennial allergen exposure).

Up to 80% of children with asthma develop symptoms before their fifth birthday. Atopy (personal or familial) is the strongest identifiable predisposing factor. Exposure to tobacco smoke, especially from the mother, is also a risk factor for asthma. About 40% of infants and young children who have wheezing with viral infections in the first few years of life will have continuing asthma through childhood. Sensitization to inhalant allergens increases over time and is found in the majority of children with asthma. The principal allergens associated with asthma are perennial aeroallergens such as dust mite, animal dander, cockroach, and *Alternaria* (a soil mold). Rarely, foods may provoke isolated asthma symptoms. Other triggers include exercise, cold air, cigarette smoke, pollutants, strong chemical odors, and rapid changes in barometric pressure. Aspirin sensitivity is uncommon in children. Psychological factors may precipitate asthma exacerbations and place the patient at high risk from the disease.

Pathologic features of asthma include shedding of airway epithelium, edema, mucus plug formation, mast cell activation, and collagen deposition beneath the basement membrane. The inflammatory cell infiltrate includes eosinophils, lymphocytes, and neutrophils, especially in fatal asthma exacerbations. Airway inflammation contributes to airway hyperresponsiveness, airflow limitation, and disease chronicity. Persistent airway inflammation can lead to airway wall remodeling and irreversible changes.

► Clinical Findings

A. Symptoms and Signs

Wheezing is the most characteristic sign of asthma, although some children may have recurrent cough and shortness of breath. Complaints may include “chest congestion,” prolonged cough, exercise intolerance, dyspnea, and recurrent bronchitis or pneumonia. If symptoms are absent or mild, chest auscultation during forced expiration may reveal prolongation of the expiratory phase and wheezing. As the obstruction becomes more severe, wheezes become more high-pitched and breath sounds diminished. With severe obstruction, wheezes may not be heard because of poor air movement. Flaring of nostrils, intercostal and suprasternal retractions, and use of accessory muscles of respiration are signs of severe obstruction. Flushed, moist skin may be noted, and mucous membranes may be dry. Cyanosis of the lips and nail beds may be seen with underlying hypoxia. Tachycardia and pulsus paradoxus also occur. Agitation and lethargy may be signs of impending respiratory failure.

B. Laboratory Findings

Airway hyperresponsiveness to nonspecific stimuli is a hallmark of asthma. These include inhaled pharmacologic agents such as histamine and methacholine as well as physical stimuli such as exercise and cold air. Airways may exhibit hyperresponsiveness or twitchiness even when pulmonary function tests are normal. Giving increasing amounts of a bronchoconstrictive agent to induce a decrease in lung function (usually a 20% drop in forced expiratory volume in 1 second [FEV₁]) is the most common method of testing

airway responsiveness. Hyperresponsiveness in normal children younger than age 5 years is greater than in older children. The level of airway hyperresponsiveness usually correlates with the severity of asthma.

During acute asthma exacerbations, FEV₁ is diminished and the flow-volume curve shows a “scooping out” of the distal portion of the expiratory portion of the loop (Figure 36–1). The residual volume, functional residual capacity, and total lung capacity are usually increased, while the vital capacity is decreased. Reversal or significant improvement of these abnormalities in response to inhaled bronchodilator therapy alone or with anti-inflammatory therapy is observed. Increased airway resistance also results in a decreased peak expiratory flow rate (PEFR). Diurnal variation in PEFR (ie, the difference between morning and evening measurements) of greater than 15–20% has been used as a defining feature of asthma. Significant changes in PEFR may occur before symptoms become evident. In more severe cases, PEFR monitoring enables earlier recognition of suboptimal asthma control. Exercise, cold air, and methacholine or histamine challenges may help to establish a diagnosis of asthma when the history, examination, and pulmonary function tests are not definitive. Alternatively, a diagnostic trial of inhaled bronchodilators and anti-inflammatory medications may be helpful, especially in infants and young children in whom underdiagnosis and undertreatment are common. Infant pulmonary function can be measured in sedated children with compression techniques. The forced oscillation technique can be used to measure airway resistance in younger children.

Hypoxemia is present early with a normal or low PCO₂ level and respiratory alkalosis. Hypoxemia may be aggravated

▲ **Figure 36–1.** Representative flow-volume loops in persons with normal lung function, asthma, and vocal cord dysfunction.

during treatment with a β_2 -agonist due to ventilation-perfusion mismatch. Oxygen saturation less than 91% is indicative of significant obstruction. Respiratory acidosis and increasing CO_2 tension may ensue with further airflow obstruction and signal impending respiratory failure. Hypercapnia is usually not seen until the FEV_1 falls below 20% of predicted value. Metabolic acidosis has also been noted in combination with respiratory acidosis in children with severe asthma and indicates imminent respiratory failure. PaO_2 less than 60 mm Hg despite oxygen therapy and PaCO_2 over 60 mm Hg and rising more than 5 mm Hg per hour are relative indications for mechanical ventilation in a child in status asthmaticus.

Pulsus paradoxus may be present with moderate or severe asthma exacerbation. In moderate asthma exacerbation in a child, this may be between 10 and 25 mm Hg, and in severe asthma exacerbation between 20 and 40 mm Hg. Absence of pulsus paradoxus in a child with severe asthma exacerbation may signal respiratory muscle fatigue.

Clumps of eosinophils on sputum smear and blood eosinophilia are frequent findings. Their presence tends to reflect disease activity and does not necessarily mean that allergic factors are involved. Leukocytosis is common in acute severe asthma without evidence of bacterial infection and may be more pronounced after epinephrine administration. Hematocrit can be elevated with dehydration during prolonged exacerbations or in severe chronic disease. Potential noninvasive measures of airway inflammation include serum eosinophil cationic protein levels, exhaled nitric oxide, and induced sputum. Each test has its strengths and weaknesses.

C. Imaging

On chest radiographs, bilateral hyperinflation with flattening of the diaphragms, peribronchial thickening, prominence of the pulmonary arteries, and areas of patchy atelectasis may be present. Atelectasis may be misinterpreted as the infiltrates of pneumonia. High-resolution computed tomography has been used to quantify hyperinflation and bronchial wall thickening as a marker of airway remodeling in children with severe asthma and define peripheral airways disease and is useful in ruling out certain diagnoses in patients with difficult to manage asthma.

Allergy testing is discussed in the general measures section under Treatment, Chronic Asthma.

► Differential Diagnosis

Diseases that may be mistaken for asthma are often related to the patient's age (Table 36–1). Congenital abnormalities must be excluded in infants and young children. Asthma can be confused with croup, acute bronchiolitis, pneumonia, and pertussis. Immunodeficiency may be associated with cough and wheezing. Foreign bodies in the airway may cause dyspnea or wheezing of sudden onset, and on auscultation wheezing may be unilateral. Asymmetry of the lungs secondary to air trapping may be seen on a chest radiograph, especially with forced expiration. Cystic fibrosis can be associated with or mistaken for asthma.

Table 36–1. Differential diagnosis of asthma in infants and children.

Viral bronchiolitis
Aspiration
Laryngotracheomalacia
Vascular rings
Airway stenosis or web
Enlarged lymph nodes
Mediastinal mass
Foreign body
Bronchopulmonary dysplasia
Obliterative bronchiolitis
Cystic fibrosis
Vocal cord dysfunction
Cardiovascular disease

Vocal cord dysfunction is an important masquerader of asthma, although the two can coexist. It is characterized by the paradoxical closure of the vocal cords that can result in dyspnea and wheezing. Diagnosis is made by direct visualization of the vocal cords. In normal individuals, the vocal cords abduct during inspiration and may adduct slightly during expiration. Asthmatic patients may have narrowing of the glottis during expiration as a physiologic adaptation to airway obstruction. In contrast, patients with isolated vocal cord dysfunction typically show adduction of the anterior two thirds of their vocal cords during inspiration, with a small diamond-shaped aperture posteriorly. Because this abnormal vocal cord pattern may be intermittently present, a normal examination does not exclude the diagnosis. Exercise or methacholine challenges can often precipitate symptoms of vocal cord dysfunction. The flow-volume loop may provide additional clues to the diagnosis of vocal cord dysfunction. Truncation of the inspiratory portion can be demonstrated in most patients during an acute episode, and some patients continue to show this pattern even when they are asymptomatic (see Figure 36–1). Children with vocal cord dysfunction, especially adolescents, tend to be overly competitive, primarily in athletics and scholastics. A psychiatric consultation may help define underlying psychological issues and provide appropriate therapy.

Treatment of isolated vocal cord dysfunction includes education regarding the condition and appropriate breathing exercises. Hypnosis, biofeedback, and psychotherapy have been effective for some patients. During an acute episode, a helium–oxygen mixture (heliox) can be administered because the low density of the gas mixture facilitates movement of air through the adducted vocal cords.

► Conditions That May Increase Asthma Severity

Chronic hyperplastic sinusitis is frequently found in association with asthma. Upper airway inflammation has been

shown to contribute to the pathogenesis of asthma, and asthma may improve after treatment of sinusitis. However, sinus surgery is usually not indicated for initial treatment of chronic mucosal disease associated with allergy.

A significant correlation has been observed between nocturnal asthma and gastroesophageal reflux. Patients may not complain of burning epigastric pain or have other reflux symptoms—cough may be the only sign. For patients with poorly controlled asthma, particularly with a nocturnal component, investigation for gastroesophageal reflux may be warranted even in the absence of suggestive symptoms.

The risk factors for death from asthma include psychological and sociological factors. They are probably related to the consequences of illness denial as well as to nonadherence with prescribed therapy. Recent studies have shown that less than 50% of inhaled asthma medications are taken as prescribed and that compliance does not improve with increasing severity of illness. Moreover, children requiring hospitalization for asthma, or their caregivers, have often failed to institute appropriate home treatment.

► Complications

With acute asthma, complications are primarily related to hypoxemia and acidosis and can include generalized seizures. Pneumomediastinum or pneumothorax can be a complication in status asthmaticus. With chronic asthma, recent studies point to airway wall remodeling and loss of pulmonary function with persistent airway inflammation. Childhood asthma independent of any corticosteroid therapy has been shown to be associated with delayed maturation and slowing of prepubertal growth velocity. However, attainment of final predicted adult height does not appear to be compromised.

► Treatment

A. Chronic Asthma

1. General measures—Management of asthma should include identification of precipitating factors and comorbid conditions that may worsen asthma, evaluation of the patient's and family's knowledge and skills for self-management, and assessment of asthma severity and control. Patients should avoid exposure to tobacco smoke and allergens to which they are sensitized, exertion outdoors when levels of air pollution are high, β -blockers, and sulfite-containing foods. Patients with persistent asthma should be given the inactivated influenza vaccine yearly unless they have a contraindication.

For patients with persistent asthma, the clinician should use the patient's history to assess sensitivity to seasonal allergens and *Alternaria* mold; use skin testing or in-vitro testing to assess sensitivity to perennial indoor allergens; assess the significance of positive tests in the context of the patient's history; and identify relevant allergen exposures. For dust mite–allergic children, important environmental control measures include encasing the pillow and mattress in

an allergen-impermeable cover and washing the sheets and blankets on the patient's bed weekly in hot water. Other measures include keeping indoor humidity below 50%, minimizing the number of stuffed toys, and washing such toys weekly in hot water. Children allergic to furred animals or feathers should avoid indoor exposure to pets, especially for prolonged periods of time. If removal of the pet is not possible, the animal should be kept out of the bedroom with the door closed. Carpeting and upholstered furniture should be removed. While a high-efficiency particle-arresting filter unit in the bedroom may reduce allergen levels, clinical symptoms may persist if the pet remains indoor. For cockroach-allergic children, control measures need to be instituted when infestation is present in the home. Poison baits, boric acid, and traps are preferred to chemical agents, which can be irritating if inhaled by asthmatic individuals. Indoor molds are especially prominent in humid or damp environments. Measures to control dampness or fungal growth in the home may be of benefit. Patients can reduce exposure to outdoor allergens by staying in an air-conditioned environment. Allergen immunotherapy may be useful for implicated aeroallergens that cannot be avoided. However, it should be administered only in facilities staffed and equipped to treat life-threatening reactions.

The patient and family must understand the role of asthma triggers, the importance of disease activity even without obvious symptoms, how to use objective measures to gauge disease activity, and the importance of airway inflammation—and they must learn to recognize the warning signs of worsening asthma, allowing for early intervention. A stepwise care plan should be developed for all patients with asthma. This educational process extends to school personnel and all those who care for children with asthma.

Because the degree of airflow limitation is poorly perceived by many patients, peak flow meters can aid in the assessment of airflow obstruction and day-to-day disease activity. Peak flow rates may provide early warning of worsening asthma. They are also helpful in monitoring the effects of medication changes. Spacer devices optimize delivery of medication from metered-dose inhalers to the lungs and, with inhaled steroids, minimize side effects. Large-volume spacers are preferred.

Patients should be treated for rhinitis, sinusitis, or gastroesophageal reflux, if present. Treatment of upper respiratory tract symptoms is an integral part of asthma management. Intranasal corticosteroids are recommended to treat chronic rhinosinusitis in patients with persistent asthma because they reduce lower airway hyperresponsiveness and asthma symptoms. Intranasal cromolyn reduces asthma symptoms during the ragweed season but less so than intranasal corticosteroids. Treatment of rhinosinusitis includes medical measures to promote drainage and the use of antibiotics for acute bacterial infections (see Chapter 17). Medical management of gastroesophageal reflux includes avoiding eating or drinking 2 hours before bedtime, elevating the head of the bed with 6- to 8-inch blocks, and using appropriate pharmacologic therapy.

2. Pharmacologic therapy—A revised stepwise approach to pharmacologic therapy, broken down by age categories, is recommended in the National Asthma Education and Prevention Program's *Expert Panel Report 3* (<http://www.nhlbi.nih.gov>) (Tables 36–2 through 36–10). This approach is based on the concepts of asthma severity, asthma control, and responsiveness to therapy. A separate set of recommendations for younger children is provided given the lack of tools which can be used to assess lung function and quality of life otherwise available for older children. Treatment recommendations for older children and adults are better supported by stronger evidence from available clinical trials, whereas those for younger children have been extrapolated from studies in older children and adults.

Asthma severity is the intrinsic intensity of disease, and assessment is generally most accurate in patients not receiving controller therapy. Hence, assessing asthma severity directs the level of initial therapy. The two general categories are intermittent and persistent asthma, the latter further subdivided into mild, moderate, and severe. In contrast, asthma

control refers to the degree to which symptoms, ongoing functional impairments and risk of adverse events are minimized and goals of therapy are met. Assessment of asthma control is important in adjusting therapy and is categorized as well controlled, not well controlled, and very poorly controlled. Responsiveness to therapy is the ease with which asthma control is attained by treatment. It can also encompass monitoring for adverse effects related to medication use.

Classification of asthma severity and control is premised on the domains of current impairment and risk, recognizing that these domains may respond differently to treatment. The level of asthma severity or control is based on the most severe impairment or risk category. Generally, the assessment is symptom based, except for the use of lung function for school-aged children and youths. Impairment includes an assessment of the patient's recent symptom frequency and intensity and functional limitations (ie, nighttime awakenings, need for short-acting β_2 -agonists for quick relief, work or school days missed, ability to engage in normal or desired activities, and quality of life assessments) and airflow compromise using

Table 36–2. Classifying asthma severity and initiating treatment in children aged 0–4 years: assessing severity and initiating treatment for patients who are not currently taking long-term control medications.

Components of Severity		Classification of Asthma Severity (0–4 y)			
		Intermittent	Persistent		
			Mild	Moderate	Severe
Impairment	Symptoms	≤ 2 d/wk	> 2 d/wk but not daily	Daily	Throughout the day
	Nighttime awakenings	0	1–2×/mo	3–4×/mo	> 1×/wk
	SABA use for symptoms (not EIB pretreatment)	≤ 2 d/wk	> 2 d/wk but not daily	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Risk	Exacerbations requiring systemic corticosteroids	0–1/y	≥ 2 exacerbations in 6 mo requiring systemic corticosteroids, or ≥ 4 wheezing episodes/1y lasting > 1 d AND risk factors for persistent asthma		
Recommended step for initiating therapy		Step 1	Step 2	Step 3 and consider short course of oral systemic corticosteroids	
		In 2–6 wk, depending on severity, evaluate level of asthma control that is achieved. If no clear benefit is observed within 4–6 wk, stop treatment and consider adjusting therapy or alternative diagnoses.			

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- Level of severity is determined by both impairment and risk. Assess impairment domain by caregiver's recall of previous 2–4 weeks. Assign severity to the most severe category in which any feature occurs.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. In general, more frequent and severe exacerbation (eg, requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate greater underlying disease severity. For treatment purposes, patients who had ≥ 2 exacerbations requiring oral systemic corticosteroids in the past 6 months, or ≥ 4 wheezing episodes in the past year, and who have risk factors for persistent asthma may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma. EIB, exercise-induced bronchospasm; SABA, short-acting β_2 -agonist use.

Adapted from the National Asthma Education and Prevention Program: Expert Panel Report 3 (EPR 3): Guidelines for the Diagnosis and Management of Asthma—Summary Report 2007. *J Allergy Clin Immunol* 2007;120(Suppl):S94–138. Available at: <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>.

preferably spirometry. On the other hand, risk refers to an evaluation of the patient’s likelihood of developing asthma exacerbations, reduced lung growth in children (or progressive decline in lung function in adults), or risk of untoward effects from medications.

The choice of initial therapy is based on assessment of asthma severity, and for patients who are already on controller therapy, revision of treatment is based on assessment of asthma control and responsiveness to therapy. The goals of therapy are to reduce the components of both impairment (eg, preventing chronic and troublesome symptoms, allowing infrequent need of quick relief medications, maintaining

“normal” lung function, maintaining normal activity levels including physical activity and school attendance, meeting families’ expectations and satisfaction with asthma care) and risk (eg, preventing recurrent exacerbations, reduced lung growth, and medication adverse effects).

1. The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
2. In the absence of persistent symptoms, the new clinical guidelines recommend considering initiation of long-term controller therapy for infants and younger children who

Table 36-3. Classifying asthma severity and initiating treatment in children aged 5–11 years: assessing severity and initiating treatment for patients who are not currently taking long-term control medications.

Components of Severity		Classification of Asthma Severity (5–11 y)				
		Intermittent	Persistent			
			Mild	Moderate	Severe	
Impairment	Symptoms	≤ 2 d/wk	> 2 d/wk but not daily	Daily	Throughout the day	
	Nighttime awakenings	≤ 2×/mo	3–4×/mo	> 1×/wk but not nightly	Often 7×/wk	
	SABA use for symptoms (not EIB pretreatment)	≤ 2 d/wk	> 2 d/wk but not daily	Daily	Several times per day	
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited	
	Lung function	Normal FEV ₁ between exacerbations				
		FEV ₁ > 80% predicted FEV ₁ /FVC > 85%	FEV ₁ > 80% predicted FEV ₁ /FVC > 80%	FEV ₁ = 60–80% predicted FEV ₁ /FVC = 75–80%	FEV ₁ < 60% predicted FEV ₁ /FVC < 75%	
Risk	Exacerbations requiring systemic corticosteroids	0–1/y (see note)	≥ 2/y (see note)			
		Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time. Relative annual risk of exacerbations may be related to FEV ₁ .				
Recommended step for initiating therapy		Step 1	Step 2	Step 3, medium-dose ICS option	Step 3, medium-dose ICS option, or Step 4	
		In 2–6 wk, evaluate level of asthma control that is achieved, and adjust therapy accordingly.				

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
 - Level of severity is determined by both impairment and risk. Assess impairment domain by patient’s or caregiver’s recall of previous 2–4 weeks and spirometry. Assign severity to the most severe category in which any feature occurs.
 - At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. In general, more frequent and intense exacerbations (eg, requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate greater underlying disease severity. For treatment purposes, patients who had ≥ 2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have persistent asthma, even in the absence of persistent levels consistent with persistent asthma.
- EIB, exercise-induced bronchospasm; SABA, short-acting β₂-agonist use; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; ICS, inhaled corticosteroids.

Table 36-4. Classifying asthma severity and initiating treatment in children 12 years and older and adults: assessing severity and initiating treatment for patients who are not currently taking long-term control medications.

Components of Severity		Classification of Asthma Severity (>12 y)			
		Intermittent	Persistent		
			Mild	Moderate	Severe
Impairment	Symptoms	≤ 2 d/wk	> 2 d/wk but not daily	Daily	Throughout the day
	Nighttime awakenings	≤ 2×/mo	3-4×/mo	> 1×/wk but not nightly	Often 7×/wk
	SABA use for symptoms (not EIB pretreatment)	≤ 2 d/wk	> 2 d/wk but not daily and not more than 1× on any day	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	Normal FEV ₁ between exacerbations			
	Normal FEV ₁ /FVC: 8-19 y, 85% 20-39 y, 80% 40-59 y, 75% 60-80 y, 70%	FEV ₁ >80% predicted FEV ₁ /FVC normal	FEV ₁ > 80% predicted FEV ₁ /FVC normal	FEV ₁ = 60-80% predicted FEV ₁ /FVC reduced 5%	FEV ₁ < 60% predicted FEV ₁ /FVC reduced > 5%
Risk	Exacerbations requiring systemic corticosteroids	0-1/y (see note) Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time for patients in any severity category. Relative annual risk of exacerbations may be related to FEV ₁ .	≥ 2/y		
Recommended step for initiating therapy		Step 1	Step 2	Step 3 Consider short course of oral systemic corticosteroids	Step 4 or 5
		In 2-6 wk, evaluate level of asthma control that is achieved and adjust therapy accordingly.			

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
 - Level of severity is determined by assessment of both impairment and risk. Assess impairment domain by patient's or caregiver's recall of previous 2-4 weeks and spirometry. Assign severity to the most severe category in which any feature occurs.
 - At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. In general, more frequent and intense exacerbations (eg, requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate greater underlying disease severity. For treatment purposes, patients who had ≥ 2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.
- EIB, exercise-induced bronchospasm; SABA, short-acting β₂-agonist use; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; ICU, intensive care unit. Adapted from the National Asthma Education and Prevention Program: Expert Panel Report 3 (EPR 3): Guidelines for the Diagnosis and Management of Asthma—Summary Report 2007. *J Allergy Clin Immunol* 2007;120(Suppl):S94-138. Available at: <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>.

have risk factors for asthma (ie, modified asthma predictive index: parental history of asthma, physician-diagnosed atopic dermatitis, or sensitization to aeroallergens or two of the following: wheezing apart from colds, sensitization to foods, or peripheral eosinophilia) and four or more episodes of wheezing over the past year that lasted longer than 1 day and affected sleep or two or more exacerbations in 6 months requiring systemic corticosteroids.

3. Inhaled corticosteroids, either as monotherapy or in combination with adjunctive therapy, are preferred treatment for all levels of persistent asthma.
4. Along with medium-dose inhaled corticosteroids, combination therapy with inhaled corticosteroids plus any of the following adjunctive therapies—long-acting inhaled β₂-agonists (LABAs), leukotriene modifying agents, cromones, and theophylline—is recommended as step 3

Table 36-5. Assessing asthma control and adjusting therapy in children aged 0–4 years.

Components of Control		Classification of Asthma Control (0–4 y)		
		Well Controlled	Not Well Controlled	Very Poorly Controlled
Impairment	Symptoms	≤ 2 d/wk	> 2 d/wk	Throughout the day
	Nighttime awakenings	≤ 1×/mo	> 1×/mo	> 1×/wk
	SABA use for symptoms (not EIB pretreatment)	≤ 2 d/wk	> 2 d/wk	Several times per day
	Interference with normal activity	None	Some limitation	Extremely limited
Risk	Exacerbations requiring oral systemic corticosteroids	0–1/y	2–3/y	> 3 y
	Treatment-related adverse effects	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.		
Recommended action for treatment		Maintain current treatment. Regular follow up every 1–6 mo. Consider step down if well controlled for at least 3 mo.	Step up (1 step) and Reevaluate in 2–6 wk. If no clear benefit in 4–6 wk, consider alternative diagnoses or adjusting therapy. For side effects, consider alternative treatment options.	Consider short course of oral systemic corticosteroids. Step up (1–2 steps), and Reevaluate in 2 wk. If no clear benefit in 4–6 wk, consider alternative diagnoses or adjusting therapy. For side effects, consider alternative treatment options.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- The level of control is based on the most severe impairment or risk category. Assess impairment domain by caregiver's recall of previous 2–4 weeks. Symptom assessment for longer periods should reflect a global assessment such as inquiring whether the patient's asthma is better or worse since the last visit.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (eg, requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate poorer disease control. For treatment purposes, patients who had ≥ 2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.
- Before step-up therapy:
 - a. Review adherence to medications, inhaler technique, and environmental control.
 - b. If alternative treatment option was used in a step, discontinue it and use preferred treatment for that step.

EIB, exercise-induced bronchospasm.

Adapted from the National Asthma Education and Prevention Program: Expert Panel Report 3 (EPR 3): Guidelines for the Diagnosis and Management of Asthma—Summary Report 2007. *J Allergy Clin Immunol* 2007(Suppl);120:S94–138. Available at: <http://www.nhlbi.nih.gov/guidelines/asthma/asthdgln.htm>.

treatment for moderate persistent asthma, or as step-up therapy for uncontrolled persistent asthma for school-aged children and youths. In children aged 0–4 years, medium-dose inhaled corticosteroids as monotherapy remain the step 3 therapy, and combination therapy to be initiated only as a step 4 treatment. A rescue course of systemic corticosteroids may be necessary at any step.

Asthma medications are classified as long-term controller medications and quick-relief medications. The former include anti-inflammatory agents, long-acting bronchodila-

tors, and leukotriene modifiers. Unlike the other asthma controller medications, LABAs cannot be administered as monotherapy.

Inhaled corticosteroids are the most potent inhaled anti-inflammatory agents currently available. Different inhaled corticosteroids are not equivalent on a per puff or microgram basis (Table 36–11). Early intervention with inhaled corticosteroids can improve asthma control and prevent exacerbations during treatment, but they do not prevent the development of persistent asthma nor do they alter its natural history. Inhaled corticosteroids may be

Table 36-6. Assessing asthma control and adjusting therapy in children aged 5–11 years.

Components of Control		Classification of Asthma Control (5–11 y)		
		Well Controlled	Not Well Controlled	Very Poorly Controlled
Impairment	Symptoms	≤ 2 d/wk but not more than once on each day	> 2 d/wk or multiple times on ≤ 2 d/wk	Throughout the day
	Nighttime awakenings	≤ 1×/mo	≥ 2×/mo	≥ 2×/wk
	SABA use for symptoms (not EIB pretreatment)	≤ 2 d/wk	> 2 d/wk	Several times per day
	Interference with normal activity	None	Some limitation	Extremely limited
	Lung function	FEV ₁ or peak flow > 80% predicted or personal best FEV ₁ /FVC > 80%	FEV ₁ or peak flow = 60–80% predicted or personal best FEV ₁ /FVC = 75–80%	FEV ₁ or peak flow < 60% predicted or personal best FEV ₁ /FVC < 75%
Risk	Exacerbations requiring oral systemic corticosteroids	0–1/y Consider severity and interval since last exacerbation.	≥ 2/y	≥ 2/y
	Reduction in lung growth	Evaluation requires long-term follow-up.		
	Treatment-related adverse effects	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.		
Recommended action for treatment		Maintain current treatment step. Regular follow up every 1–6 mo. Consider step down if well controlled for at least 3 mo.	Step up at least 1 step and Reevaluate in 2–6 wk. For side effects, consider alternative treatment options.	Consider short course of oral systemic corticosteroids. Step up (1–2 steps), and Reevaluate in 2 wk. For side effects, consider alternative treatment options.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- The level of control is based on the most severe impairment or risk category. Assess impairment domain by patient's or caregiver's recall of previous 2–4 weeks and by spirometry or peak flow measures. Symptom assessment for longer periods should reflect a global assessment such as inquiring whether the patient's asthma is better or worse since the last visit.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (eg, requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate poorer disease control. - Before step-up therapy:
 - a. Review adherence to medications, inhaler technique, environmental control, and comorbid conditions.
 - b. If alternative treatment option was used in a step, discontinue it and use preferred treatment for that step.

EIB, exercise-induced bronchospasm; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity.

Adapted from the National Asthma Education and Prevention Program: Expert Panel Report 3 (EPR 3): Guidelines for the Diagnosis and Management of Asthma—Summary Report 2007. *J Allergy Clin Immunol* 2007;120(Suppl):S94–138. Available at: <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>.

associated with slowing of growth velocity in children, although a study of asthmatic children treated with budesonide (mean dose, 412 mcg/d) for a mean of 9.2 years showed no adverse effect on final adult height. Possible risks from inhaled corticosteroids need to be weighed against the risks from undertreated asthma. The adverse effects from inhaled corticosteroids are generally dose and duration dependent, so that greater risks for systemic adverse effects are expected with high doses. The various

inhaled corticosteroids are delivered in different devices such as metered dose inhaler (MDI) (beclomethasone, fluticasone, flunisolide and triamcinolone), dry powder inhaler (DPI) (Flovent Diskus, Pulmicort Flexhaler or Turbohaler, and Asmanex Twisthaler) and nebulized aerosol suspensions (Pulmicort respules). Except for triamcinolone, the inhaled corticosteroids delivered in MDI now use the more ozone friendly hydrofluoroalkane (HFA) propellant, which has replaced chlorofluorocarbons (CFC).

Table 36-7. Assessing asthma control and adjusting therapy in youths aged 12 years or older and adults.

Components of Control		Classification of Asthma Control (≥ 12 y)		
		Well Controlled	Not Well Controlled	Very Poorly Controlled
Impairment	Symptoms	≤ 2 d/wk	> 2 d/wk	Throughout the day
	Nighttime awakenings	≤ 2 ×/mo	1-3 ×/wk	≥ 4 ×/wk

	Interference with normal activity	None	Some limitation	Extremely limited
	Lung function	FEV ₁ or peak flow $> 80\%$ predicted or personal best	FEV ₁ or peak flow = 60-80% predicted or personal best	FEV ₁ or peak flow $< 60\%$ predicted or personal best
	Validated questionnaires			
	ATAQ	0	1-2	3-4
ACQ	$\leq 0.75^a$	≥ 1.5	N/A	
ACT	≥ 20	16-19	≤ 15	
Risk	Exacerbations requiring oral systemic corticosteroids	0-1/y Consider severity and interval since last exacerbation.	≥ 2 /y	≥ 2 /y
	Progressive loss of lung function	Evaluation requires long-term follow-up.		
	Treatment-related adverse effects	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.		
Recommended action for treatment		Maintain current treatment step. Regular follow up every 1-6 mo to maintain control. Consider step down if well controlled for at least 3 mo.	Step up (1 step) and and Reevaluate in 2-6 wk. For side effects, consider alternative treatment options.	Consider short course of oral systemic corticosteroids. Step up (1-2 steps), and Reevaluate in 2 wk. For side effects, consider alternative treatment options.

^aACQ values of 0.76-1.40 are indeterminate regarding well-controlled asthma.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
 - The level of control is based on the most severe impairment or risk category. Assess impairment domain by patient's recall of previous 2-4 weeks and by spirometry or peak flow measures. Symptom assessment for longer periods should reflect a global assessment, such as inquiring whether the patient's asthma is better or worse since the last visit.
 - At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (eg, requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate poorer disease control. For treatment purposes, patients who had ≥ 2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.
- Validated questionnaires for the impairment domain (the questionnaires do not assess lung function or the risk domain):

- ATAQ= Asthma Therapy Assessment Questionnaire
- ACQ= Asthma Control Questionnaire
- ACT= Asthma Control Test

Minimal Important Difference: 1.0 for ATAQ; 0.5 for the ACQ; not determined for ACT

• Before step-up therapy:

- Review adherence to medications, inhaler technique, environmental control, and comorbid conditions.
- If alternative treatment option was used in a step, discontinue it and use preferred treatment for that step.

EIB, exercise-induced bronchospasm; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity.

Available at: <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>.

Table 36-8. Stepwise approach for managing asthma in children aged 0–4 years.

Intermittent Asthma	Persistent Asthma: Daily Medication ^a					Step up if needed (first check adherence, inhaler technique, and environmental control)
Consult with asthma specialist if step 3 or higher is required.						
Consider consultation at step 2.						Assess Control Step down if possible (and asthma is well controlled at least 3 mo)
Step 1 <i>Preferred</i> SABA prn	Step 2 <i>Preferred</i> Low-dose ICS <i>Alternative:</i> cromolyn or montelukast	Step 3 <i>Preferred</i> Medium-dose ICS	Step 4 <i>Preferred</i> Medium-dose ICS + either LABA or montelukast	Step 5 <i>Preferred</i> High-dose ICS + either LABA or montelukast	Step 6 <i>Preferred</i> High-dose ICS + either LABA or montelukast Oral systemic corticosteroids	
Patient Education and Environmental Control at Each Step						
Quick-Relief Medication for All Patients						
<ul style="list-style-type: none"> • SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms. • With viral respiratory infection: SABA q 4–6 h up to 24 h (longer with physician consult). Consider short course of systemic corticosteroids if exacerbation is severe or patient has history of previous severe exacerbations. • Caution: frequent use of SABA may indicate the need to step up treatment. 						

^aAlphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- If clear benefit is not observed within 4–6 weeks and patient/family medication technique and adherence are satisfactory, consider adjusting therapy or an alternative diagnosis.
- Studies on children aged 0–4 years are limited. Step 2 preferred therapy is based on Evidence A. All other recommendations are based on expert opinion and extrapolation from studies in older children.

ICS, inhaled corticosteroid; LABA, inhaled long-acting β_2 -agonist; prn, as needed; SABA, inhaled short acting β_2 -agonist.

Adapted from the National Asthma Education and Prevention Program: Expert Panel Report 3 (EPR 3): Guidelines for the Diagnosis and Management of Asthma—Summary Report 2007. *J Allergy Clin Immunol* 2007;120(Suppl):S94–138. Available at: <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>.

Only inhaled corticosteroids have been shown to be effective in long-term clinical studies with infants. Nebulized budesonide is approved for children as young as 12 months. The suspension (available in quantities of 0.25 mg/2 mL, 0.5 mg/2 mL, and 1.0 mg/2 mL) is usually administered either once or twice daily in divided doses. Notably, this drug should not be given by ultrasonic nebulizer. Limited data suggest that inhaled corticosteroids may be effective even in very young children when delivered by metered-dose inhaler with a spacer and mask.

Fewer data are available with nedocromil, although data from the Childhood Asthma Management Program study showed that an inhaled corticosteroid was superior to nedocromil with respect to several efficacy parameters, including rate of hospitalization, symptom-free days, need for albuterol rescue, and longer time to treatment with prednisone, when each was compared to a placebo.

Sustained-release theophylline, an alternative long-term control medication for older children, may have particular risks of adverse effects in infants, who frequently have febrile illnesses that increase theophylline concentrations. Hence, theophylline use requires monitoring of serum concentration to prevent numerous dose-related acute toxicities.

Salmeterol and formoterol (both LABAs) can be used as adjunctive therapy with anti-inflammatory medications for long-term symptom control. They should not be used for treatment of acute symptoms, nor should they be used without any inhaled corticosteroid therapy, even if the patient feels better. Salmeterol is available as an inhalation powder (1 inhalation twice daily for patients aged 4 years and older). It is also available combined with fluticasone (50 mcg salmeterol with 100, 250, or 500 mcg fluticasone in a DPI or 21 mcg salmeterol with 45, 115, or 230 mcg fluticasone in an MDI).

Table 36-9. Stepwise approach for managing asthma in children aged 5–11 years.

Intermittent Asthma	Persistent Asthma: Daily Medication ^a Consult with asthma specialist if step 4 or higher is required. Consider consultation at step 3.					
Step 1 <i>Preferred</i> SABA prn	Step 2 <i>Preferred</i> Low-dose ICS <i>Alternative:</i> cromolyn, LTRA, nedocromil, or theophylline	Step 3 <i>Preferred</i> Either Low dose ICS + either LABA, LTRA, or theophylline <i>Or:</i> Medium-dose ICS	Step 4 <i>Preferred</i> Medium-dose ICS + LABA <i>Alternative</i> Medium-dose ICS + either LTRA or theophylline	Step 5 <i>Preferred</i> High dose ICS + LABA <i>Alternative:</i> High-dose ICS + either LTRA or theophylline	Step 6 <i>Preferred</i> High dose ICS + LABA + oral systemic corticosteroid <i>Alternative:</i> High-dose ICS + either LTRA or theophylline + oral systemic corticosteroid	Step up if needed (first check adherence, inhaler technique, and environmental control, and comorbid conditions) Assess Control Step down if possible (and asthma is well controlled at least 3 mo)
Patient Education, Environmental Control, and Management of Comorbidities at Each Step						
Steps 2–4: consider subcutaneous allergen immunotherapy for patients who have persistent allergic asthma.						
Quick-Relief Medication for All Patients						
<ul style="list-style-type: none"> • SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatments at 20-min intervals as needed. Short course of oral systemic corticosteroids may be needed. • Caution: Increasing use of SABA or use > 2 d/wk for symptom relief (not prevention of EIB) generally indicates inadequate control and the need to step up treatment. 						

^aAlphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Theophylline is a less desirable alternative due to the need to monitor serum concentration levels.
- Step 1 and 2 medications are based on Evidence A. Step 3 ICS and ICS plus adjunctive therapy are based on Evidence B for efficacy of each treatment and extrapolation from comparator trials in older children and adults—comparator trials are not available for this age group; steps 4–6 are based on expert opinion and extrapolation from studies in older children and adults.
- Immunotherapy for steps 2–4 is based on Evidence B for house dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults. Clinicians who administer immunotherapy should be prepared and equipped to identify and treat anaphylaxis that may occur.

ICS, inhaled corticosteroid; LABA, inhaled long-acting β_2 -agonist; LTRA, leukotriene receptor antagonist; prn, as needed; SABA, inhaled short-acting β_2 -agonist
Adapted from the National Asthma Education and Prevention Program: Expert Panel Report 3 (EPR 3): Guidelines for the Diagnosis and Management of Asthma—Summary Report 2007. *J Allergy Clin Immunol* 2007;120(Suppl):S94–138. Available at: <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>.

For children 12 years and older, 1 inhalation DPI or 2 inhalations MDI, can be taken twice daily. (**Note:** The 100/50 fluticasone/salmeterol combination is approved in children aged 4 and older.) It can also be used 30 minutes before exercise (but not in addition to regularly used LABAs). Formoterol has a more rapid onset of action and is available singly as a DPI (Aerolizer, 12 mcg) or combined with an inhaled corticosteroid (formoterol fumarate, 4.5 mcg, with budesonide, 80 or 160 mcg, in an MDI). Formoterol DPI is approved for use in children 5 years and older, 1 inhalation (12 mcg) twice daily, while the combination product is approved for children 12 years and older, 2 inhalations twice

daily. For long-term control, formoterol should be used in combination with an anti-inflammatory agent. It can be used for exercise-induced bronchospasm in patients 5 years and older, 1 inhalation at least 15 minutes before exercise (but not in addition to regularly used LABAs). Of note, the U.S. Food and Drug Administration (FDA) has requested the manufacturers of Advair Diskus and HFA (salmeterol and fluticasone), Serevent Diskus (salmeterol xinafoate), Foradil Aerolizer (formoterol fumarate), Symbicort HFA, and Brovana (arformoterol tartrate inhalation solution, a LABA approved for chronic obstructive pulmonary disease) to update their product information warning sections regarding an increase in severe

Table 36–11. Estimated comparative inhaled corticosteroid doses.

exercise-induced bronchoconstriction. Additional information, including copies of the Patient and Healthcare Professional information sheets, can be found at: <http://www.fda.gov/cder/drug/infopage/LABA/default.htm>.

Montelukast and zafirlukast are leukotriene-receptor antagonists available in oral formulations. Montelukast is given once daily and has been approved for treatment of chronic asthma in children aged 1 year and older. It is also indicated for seasonal allergic rhinitis in patients 2 years and older, and for perennial allergic rhinitis in patients 6 months and older. To date, no drug interactions have been noted. The dosage is 4 mg for children 1–5 years (oral granules are available for children aged 12–23 months), 5 mg for children aged 6–14 years, and 10 mg for those aged 15 years and older. The drug is given without regard to mealtimes, preferably in the evening. Zafirlukast is approved for patients aged 5 years and older. The dose is 10 mg twice daily for those 5–11 years and 20 mg twice daily for those 12 years and older. It should be taken 1 hour before or 2 hours after meals. Zileuton is a 5-lipoxygenase inhibitor indicated for chronic treatment in children 12 years of age and older, 600 mg four times a day. Patients need to have hepatic transaminase levels evaluated at

initiation of therapy, then once a month for the first 3 months, every 2–3 months for the remainder of the first year, and periodically thereafter if receiving long-term zileuton therapy. Rare cases of Churg-Strauss syndrome have been reported in adult patients with severe asthma whose steroid dosage was being tapered during concomitant treatment with leukotriene-receptor antagonists (as well as inhaled corticosteroids), but no causal link has been established. Both zafirlukast and zileuton are microsomal P450 enzyme inhibitors that can inhibit the metabolism of drugs such as warfarin and theophylline. Of note, in a study of children with mild to moderate persistent asthma that looked at whether responses to an inhaled corticosteroid and a leukotriene-receptor antagonist are concordant for individuals or whether asthmatic patients who do not respond to one medication respond to the other, response to fluticasone and montelukast were found to vary considerably. Children with low pulmonary function or high levels of markers associated with allergic inflammation responded better to the inhaled corticosteroid.

Quick-relief medications include short-acting inhaled β_2 -agonists (SABAs) such as albuterol, levalbuterol, pirbuterol, or terbutaline. Albuterol can be given by nebulizer, 0.05 mg/kg

(with a minimal dose of 0.63 mg and a maximum of 5 mg) in 2–3 mL saline (although it is also available in a 0.63 mg/3 mL and 1.25 mg/3 mL dosing) or by MDI. It is better to use SABAs as needed rather than on a regular basis. Increasing use, including more than one canister per month, may signify inadequate asthma control and the need to intensify anti-inflammatory therapy. Levalbuterol, the (*R*)-enantiomer of racemic albuterol, is available in solution for nebulization in patients aged 6–11 years, 0.31 mg every 8 hours, and in patients 12 years and older, 0.63–1.25 mg every 8 hours. It has recently become available in an HFA formulation for children 4 years and older, 2 inhalations (90 mcg) every 4–6 hours as needed. Anticholinergic agents such as ipratropium, 1–3 puffs or 0.25–0.5 mg by nebulizer every 6 hours, may provide additive benefit when used together with an inhaled SABA. Systemic corticosteroids such as prednisone, prednisolone, and methylprednisolone can be given in a dosage of 1–2 mg/kg, usually up to 60 mg/d in single or divided doses for 3–10 days. There is no evidence that tapering the dose following a “burst” prevents relapse.

Anti-IgE (omalizumab) is a recombinant DNA-derived humanized IgG₁ monoclonal antibody that selectively binds to human IgE. It inhibits the binding of IgE to the high-affinity IgE receptor (FcεRI) on the surface of mast cells and basophils. Reduction in surface-bound IgE on FcεRI-bearing cells limits the degree of release of mediators of the allergic response. Treatment with omalizumab also reduces the number of FcεRI receptors on basophils in atopic patients. Omalizumab is indicated for patients 12 years of age and older with moderate to severe persistent asthma who have a positive skin test or in-vitro reactivity to a perennial aeroallergen with serum IgE of 700 IU/mL or less, and whose symptoms are inadequately controlled with inhaled corticosteroids. Omalizumab has been shown to decrease the incidence of asthma exacerbations in these patients. Dosing is based on the patient’s weight and serum IgE level and is given subcutaneously every 2–4 weeks. The FDA has ordered a black box warning to the label because of new reports of serious and life-threatening anaphylactic reactions (bronchospasm, hypotension, syncope, urticaria, and angioedema of the throat or tongue) in patients after treatment with Xolair (omalizumab). Based on reports from approximately 39,500 patients, anaphylaxis following Xolair treatment occurred in at least 0.1% of treated people. Although these reactions occurred within 2 hours of receiving a Xolair subcutaneous injection, they also included reports of serious delayed reactions 2–24 hours or even longer after receiving the injections. Anaphylaxis occurred after any dose of Xolair (including the first dose), even in patients with no allergic reaction to previous doses. Omalizumab-treated patients should be observed in the facility for an extended period after the drug is given, and medical providers who administer the injection should be prepared to manage life-threatening anaphylactic reactions. Patients who receive omalizumab should be fully informed about the signs and symptoms of anaphylaxis, their chance of developing

delayed anaphylaxis following each injection, and how to treat it, including the use of autoinjectable epinephrine.

Continual monitoring is necessary to ensure that control of asthma is achieved and sustained. Once control is established, gradual reduction in therapy is appropriate and may help determine the minimum amount of medication necessary to maintain control. Regular follow-up visits with the clinician are important to assess the degree of control and consider appropriate adjustments in therapy. At each step, patients should be instructed to avoid or control exposure to allergens, irritants, or other factors that contribute to asthma severity.

Referral to an asthma specialist for consultation or co-management is recommended if there are difficulties in achieving or maintaining control. For children younger than age 5 years, referral is recommended for moderate persistent asthma or if the patient requires step 3 or 4 care and should be considered if the patient requires step 2 care (see Table 36–8). For children 5 years and older, consultation with a specialist is recommended if the patient requires step 4 care or higher and should be considered at step 3 (see Tables 36–9 and 36–10). Referral is also recommended if allergen immunotherapy or anti-IgE therapy is being considered.

3. Exercise-induced bronchospasm—Exercise-induced bronchospasm should be anticipated in all asthma patients. It typically occurs during or minutes after vigorous activity, reaches its peak 5–10 minutes after stopping the activity, and usually resolves over the next 20–30 minutes. Participation in physical activity should be encouraged in children with asthma, although the choice of activity may need to be modified based on the severity of illness, presence of other triggers such as cold air, and, rarely, confounding factors such as osteoporosis. Treatment immediately prior to vigorous activity or exercise is usually effective. SABAs, cromolyn, or nedocromil can be used before exercise. The combination of a SABA with either cromolyn or nedocromil is more effective than either drug alone. Salmeterol and formoterol may block exercise-induced bronchospasm for up to 12 hours (as discussed earlier). However, decreased duration of protection against exercise-induced bronchospasm can be expected with regular use. Montelukast may be effective up to 24 hours. Occasionally an extended warm-up period may induce a refractory state, allowing patients to exercise without a need for repeat medications. If symptoms occur during usual play activities, a step-up in long-term therapy is warranted. Poor endurance or exercise-induced bronchospasm can be an indication of poorly controlled persistent asthma.

B. Acute Asthma

1. General measures—The most effective strategy in managing asthma exacerbations involves early recognition of warning signs and early treatment. For patients with moderate or severe persistent asthma or a history of severe exacerbations, this should include a written action plan. The latter usually defines the patient’s peak flow zones and steps to take

if peak flows are between 50% and 80% or below 50% of personal best. The child, parents, and other caregivers must be able to assess asthma severity accurately. Prompt communication with the clinician is indicated with severe symptoms or a drop in peak flow or with decreased response to SABAs. At such times, intensification of therapy may include a short course of oral corticosteroids. The child should be removed from exposure to any irritants or allergens that could be contributing to the exacerbation.

2. Management at home—Early treatment of asthma exacerbations may prevent progression to severe disease. Initial treatment should be with a SABA such as albuterol or levalbuterol; 2–6 puffs from an MDI can be given every 20 minutes up to three times, or a single treatment can be given by nebulizer (0.05 mg/kg [minimum dose, 1.25 mg; maximum, 2.5 mg] of 0.5% solution of albuterol in 2–3 mL saline; or 0.075 mg/kg [minimum dose, 1.25 mg; maximum, 5 mg] of levalbuterol). If the response is good as assessed by sustained symptom relief or improvement in PEF_r to over 80% of the patient's best, the SABA can be continued every 3–4 hours for 24–48 hours. Patients should be advised to seek medical care once excessive doses of bronchodilator therapy are used or for prolonged periods (eg, > 12 puffs/d for more than 24 hours). Doubling the dose of inhaled corticosteroids is not proven sufficient to prevent worsening of exacerbations. If the patient does not completely improve from the initial therapy or PEF_r falls between 50% and 80% predicted or personal best, the SABA should be continued, an oral corticosteroid should be added, and the patient should contact the physician urgently. If the child experiences marked distress or if PEF_r persists at 50% or less, the patient should repeat the SABA immediately and go to the emergency department or call 911 or another emergency number for assistance.

3. Management in the office or emergency department—Functional assessment of the patient includes obtaining objective measures of airflow limitation with PEF_r or FEV₁ and monitoring the patient's response to treatment; however, very severe exacerbations may prevent the execution of lung function measurements using maximal expiratory maneuver. Flow-volume loops should be obtained to differentiate upper and lower airway obstruction, especially in patients with atypical presentation. Other tests may include oxygen saturation and blood gases. Chest radiographs are not recommended routinely but should be considered to rule out pneumothorax, pneumomediastinum, pneumonia, or lobar atelectasis. If the initial FEV₁ or PEF_r is over 40%, initial treatment can be with a SABA by inhaler (albuterol, 4–8 puffs) or nebulizer (0.15 mg/kg of albuterol 0.5% solution; minimum dose, 2.5 mg), up to three doses in the first hour. Oxygen should be given to maintain oxygen saturation at greater than 90%. Oral corticosteroids (1–2 mg/kg/d in divided doses; maximum of 60 mg/d for children ≤ age 12 years and 80 mg/d for those > 12 years) should be instituted if the patient responds poorly to therapy or if the patient has

recently been on oral corticosteroids. Sensitivity to adrenergic drugs may improve after initiation of corticosteroids. If the initial FEV₁ or PEF_r is under 40%, initial treatment should be with a high-dose SABA plus ipratropium bromide (0.25–0.5 mg every 20 minutes) by nebulizer or continuously for the first hour (0.5 mg/kg/h). Oxygen should be given to maintain oxygen saturation at greater than 90%, and systemic corticosteroids should be administered. For patients with severe exacerbation having no response to initial aerosolized therapy, or for those who cannot cooperate with or who resist inhalation therapy, adjunctive therapies such as intravenous magnesium sulfate (25–75 mg/kg up to 2 g in children) and heliox-driven albuterol nebulization should be considered. Epinephrine 1:1000 or terbutaline 1 mg/mL (both 0.01 mg/kg up to 0.3–0.5 mg) may be administered subcutaneously every 20 minutes for three doses; although the use of intravenous β_2 -agonists is still unproven. For impending or ongoing respiratory arrest, patients should be intubated and ventilated with 100% oxygen, given intravenous corticosteroids, and admitted to an intensive care unit (ICU). Potential indications for ICU admission also include any FEV₁ or PEF_r less than 25% of predicted that improves less than 10% after treatment or values that fluctuate widely. (See Asthma [life-threatening] in Chapter 13.) Further treatment is based on clinical response and objective laboratory findings. Hospitalization should be considered strongly for any patient with a history of respiratory failure.

4. Hospital management—For patients who do not respond to outpatient and emergency department treatment, admission to the hospital becomes necessary for more aggressive care and support. The decision to hospitalize should also be based on presence of risk factors for mortality from asthma, duration and severity of symptoms, severity of airflow limitation, course and severity of previous exacerbations, medication use at the time of the exacerbation, access to medical care, and home and psychosocial conditions. Fluids should be given at maintenance requirements unless the patient has poor oral intake secondary to respiratory distress or vomiting, because overhydration may contribute to pulmonary edema associated with high intrapleural pressures generated in severe asthma. Potassium requirements should be kept in mind because both corticosteroids and β_2 -agonists can cause potassium loss. Moisturized oxygen should be titrated by oximetry to maintain oxygen saturation above 90%. Inhaled β_2 -agonist should be continued by nebulization in single doses as needed or by continuous therapy, along with systemic corticosteroids (as discussed earlier). Ipratropium is no longer recommended during hospitalization. In addition, the role of methylxanthines in hospitalized children remains controversial. Antibiotics may be necessary to treat coexisting bacterial infection. Sedatives and anxiolytic agents are contraindicated in severely ill patients owing to their depressant effects on respiration. Chest physiotherapy is usually not recommended for acute exacerbations.

5. Patient discharge—Criteria for discharging patients home from the office or emergency department should include a sustained response of at least 1 hour to bronchodilator therapy with FEV₁ or PEFR greater than 70% of predicted or personal best and oxygen saturation greater than 90% in room air. Prior to discharge, the patient's or caregiver's ability to continue therapy and assess symptoms appropriately needs to be considered. Patients should be given an action plan for management of recurrent symptoms or exacerbations, and instructions about medications should be reviewed. The inhaled SABA and oral corticosteroids should be continued, the latter for 3–10 days. Finally, the patient or caregiver should be instructed about the follow-up visit, typically within 1 week. Hospitalized patients should receive more intensive education prior to discharge. Referral to an asthma specialist should be considered for all children with severe exacerbations or multiple emergency department visits or hospitalizations.

► Prognosis

Since the 1970s, morbidity rates for asthma have increased, and mortality rates may have stabilized. Mortality statistics indicate that a high percentage of deaths have resulted from under-recognition of asthma severity and undertreatment, particularly in labile asthmatic patients and in asthmatic patients whose perception of pulmonary obstruction is poor. Long-term outcome studies suggest that children with mild symptoms generally outgrow their asthma, while patients with more severe symptoms, marked airway hyperresponsiveness, and a greater degree of atopy tend to have persistent disease. In a recently published report of an unselected birth cohort from New Zealand, more than one in four children had wheezing that persisted from childhood to adulthood or that relapsed after remission. Recent evidence suggests that early intervention with anti-inflammatory therapy does not alter the development of persistent asthma, and it is also unclear if such intervention or environmental control measures influence the natural history of childhood asthma. Nonetheless, the pediatrician or primary care provider together with the asthma specialist has the responsibility to optimize control and, it is hoped, reduce the severity of asthma in children. Interventions that can have long-term effects such as halting progression or inducing remission are necessary to decrease the public health burden of this common condition.

ALLERGIC RHINOCONJUNCTIVITIS

After exposure to allergen:

- Sneezing.
- Itching of nose and eyes.
- Clear rhinorrhea or nasal congestion.

► General Considerations

Allergic rhinoconjunctivitis is the most common allergic disease and significantly affects quality of life as well as school performance and attendance. It frequently coexists with asthma and is a risk factor for subsequent development of asthma. Prevalence of this disease increases during childhood, peaking at 15% in the postadolescent years. Although allergic rhinoconjunctivitis is more common in boys during early childhood, there is little difference in incidence between the sexes after adolescence. Race and socioeconomic status are not considered to be important factors.

The pathologic changes in allergic rhinoconjunctivitis are chiefly hyperemia, edema, and increased serous and mucoid secretions caused by mediator release, all of which lead to variable degrees of nasal obstruction, pruritus, and rhinorrhea. This process may involve the eyes and other structures,

including the sinuses and possibly the middle ear. Inhaled allergens are primarily responsible for symptoms, but food allergens can cause symptoms as well. Children with allergic rhinitis seem to be more susceptible to—or at least may experience more symptoms from—upper respiratory infections, which, in turn, may aggravate the allergic rhinitis.

Allergic rhinoconjunctivitis has been classified as perennial, seasonal (hay fever), or episodic; however, there are areas where pollens and soil molds may be present year round while exposure to typical perennial allergens such as indoor furred animals may be intermittent. For this reason, the preferred terms are *intermittent* (ie, symptoms present < 4 days a week or for < 4 weeks) and *persistent* (ie, symptoms present > 4 days a week and for > 4 weeks). In addition, severity should be noted as *mild* (ie, without impairment or disturbance of sleep, daily activities, leisure, sport, school, or work, or the presence of troublesome symptoms) or *moderate-severe* (ie, presence of one or more of the aforementioned). The major pollen groups in the temperate zones include trees (late winter to early spring), grasses (late spring to early summer), and weeds (late summer to early fall), but seasons can vary significantly in different parts of the country. Mold spores also cause seasonal allergic rhinitis, principally in the summer and fall. Seasonal allergy symptoms may be aggravated by coincident exposure to perennial allergens.

▶ Clinical Findings

A. Symptoms and Signs

Patients may complain of itching of the nose, eyes, palate, or pharynx and loss of smell or taste. Nasal itching can cause paroxysmal sneezing and epistaxis. Repeated rubbing of the nose (so-called allergic salute) may lead to a horizontal crease across the lower third of the nose. Nasal obstruction is associated with mouth breathing, nasal speech, allergic salute, and snoring. Nasal turbinates may appear pale blue and swollen, with dimpling, or injected, with minimal edema. Typically, clear and thin nasal secretions are increased, with anterior rhinorrhea, sniffing, postnasal drip, and congested cough. Nasal secretions often cause poor appetite, fatigue, and pharyngeal irritation. Conjunctival injection, tearing, periorbital edema, and infraorbital cyanosis (so-called allergic shiners) are frequently observed. Increased pharyngeal lymphoid tissue (“cobblestoning”) from chronic drainage and enlarged tonsillar and adenoidal tissue may be present.

B. Laboratory Findings

Eosinophilia often can be demonstrated on smears of nasal secretions or blood. This is a frequent but nonspecific finding and may occur in nonallergic conditions. Although serum IgE may be elevated, measurement of total IgE is a poor screening tool owing to the wide overlap between atopic and nonatopic subjects. Skin testing to identify allergen-specific IgE is the most sensitive and specific test for inhaled allergies; alternatively, the Phadia ImmunoCAP

assay, radioallergosorbent test (RAST), or other in-vitro tests can be done for suspected allergens.

▶ Differential Diagnosis

Disorders that need to be differentiated from allergic rhinitis include infectious rhinosinusitis. Foreign bodies and structural abnormalities such as choanal atresia, marked septal deviation, nasal polyps, and adenoidal hypertrophy may cause chronic symptoms. Overuse of topical nasal decongestants may result in rhinitis medicamentosa (rebound congestion). Use of medications such as propranolol, clonidine, and some psychoactive drugs may cause nasal congestion. Illicit drugs such as cocaine can cause rhinorrhea. Spicy or hot foods may cause gustatory rhinitis. Nonallergic rhinitis with eosinophilia syndrome is usually not seen in young children. Vasomotor rhinitis is associated with persistent symptoms but without allergen exposure. Less common causes of symptoms that may be confused with allergic rhinitis include pregnancy, congenital syphilis, hypothyroidism, tumors, and cerebrospinal fluid rhinorrhea.

▶ Complications

Sinusitis may accompany allergic rhinitis. Allergic mucosal swelling of the sinus ostia can obstruct sinus drainage, interfering with normal sinus function and predisposing to chronic mucosal disease. Nasal polyps due to allergy are unusual in children, and cystic fibrosis should be considered if they are present.

▶ Treatment

A. General Measures

The value of identification and avoidance of causative allergens cannot be overstated. Reducing indoor allergens through environmental control measures as discussed in the section on asthma can be very effective. Nasal saline irrigation may be useful.

B. Pharmacologic Therapy

Pharmacologic management of mild intermittent rhinitis includes oral or intranasal H₁ antihistamines and intranasal decongestants (for < 10 days and not to be repeated more than twice a month). Oral decongestants are not usually recommended in children. Options for moderate-severe intermittent rhinitis are oral or intranasal antihistamines, oral H₁ antihistamines and decongestants, intranasal corticosteroids, and cromones. The same medication options are available for persistent rhinitis, but a stepwise approach is proposed both for treatment of mild and moderate-severe persistent rhinitis. For mild persistent rhinitis, reassessment after 2–4 weeks is recommended and treatment should be continued, with a possible reduction in intranasal corticosteroids, even if the symptoms have abated. If, however, the patient has persistent mild symptoms while on H₁ antihista-

mines or cromones, an intranasal corticosteroid is appropriate. For moderate-severe persistent disease, use of intranasal corticosteroids as first-line therapy is recommended. For severe nasal congestion, either a short 1- to 2-week course of an oral corticosteroid or an intranasal decongestant for less than 10 days may be added. If the patient improves, the treatment should last for at least 3 months or until the pollen season is over. If the patient does not improve within 2–4 weeks despite adequate compliance and use of medications, comorbidities such as nasal polyps, sinusitis, and significant allergen exposure, should be considered, as well as the possibility of misdiagnosis. Once these are ruled out, options include increasing the dose of the intranasal corticosteroid, combination therapy with an H₁ antihistamine (particularly if major symptoms are sneezing, itching, or rhinorrhea), ipratropium bromide (if major symptom is rhinorrhea), or an oral H₁ antihistamine and decongestant. Referral to a specialist may be considered if the treatment is not sufficient.

1. Antihistamines—Antihistamines help control itching, sneezing, and rhinorrhea. Sedating antihistamines include diphenhydramine, chlorpheniramine, hydroxyzine, and clemastine. Sedating antihistamines may cause daytime somnolence and negatively affect school performance and other activities, especially driving. Second-generation antihistamines include loratadine, desloratadine, cetirizine, and fexofenadine. Cetirizine is approved for use in children aged 6–23 months (2.5 mg daily), 2–5 years (2.5–5.0 mg/d or 2.5 mg twice a day), and 6 years or older (5–10 mg/d). It is now available without a prescription. Loratadine is approved for use in children aged 2–5 years (5 mg/d) and 6 years or older (10 mg/d), and is available without prescription in tablet, rapidly disintegrating tablet, and liquid formulations. Desloratadine is approved for use in children aged 6–11 months (1 mg/d), 1–5 years (1.25 mg/d), and for 12 years and older (5 mg/d). Fexofenadine is approved for children aged 6–23 months (15 mg twice a day), 2–11 years (30 mg twice a day), and 12 years or older (60 mg twice a day or 180 mg once daily). Levocetirizine (5 mg/d) is approved for children aged 6 years and older. Loratadine, fexofenadine, and cetirizine are available in combination with pseudoephedrine for patients aged 12 years or older. Azelastine is available in a nasal spray and levocabastine and emedastine as ophthalmic preparations.

2. Decongestants— α -Adrenergic agents help to relieve nasal congestion. Topical decongestants such as phenylephrine and oxymetazoline should not be used for more than 4 days for severe episodes because prolonged use may be associated with rhinitis medicamentosa. Oral decongestants, including pseudoephedrine, phenylephrine, and phenylpropanolamine, are often combined with antihistamines or expectorants and cough suppressants in over-the-counter (OTC) cold medications, but there are no convincing data to support the use of OTC decongestants for upper respiratory illnesses in children. They may cause insomnia, agitation, tachycardia, and, rarely, cardiac arrhythmias. Of note, the FDA has recommended the

removal of phenylpropanolamine from all drug products due to a public health advisory concerning the risk of hemorrhagic stroke associated with its use.

3. Corticosteroids—Intranasal corticosteroid sprays are effective in controlling allergic rhinitis if used chronically. They are minimally absorbed in usual doses and are available in pressurized nasal inhalers and aqueous sprays. Mometasone and fluticasone furoate nasal sprays have been approved for use in children as young as age 2 years (1 spray in each nostril once daily) and in children 12 years or older (2 sprays/nostril once daily). Fluticasone propionate nasal spray is approved for children 4 years or older, and budesonide and triamcinolone nasal sprays are approved for those 6 years or older (1–2 sprays/nostril once daily). Flunisolide is approved for ages 6–14 years (1 spray/nostril three times a day or 2 sprays/nostril twice a day). Side effects include nasal irritation, soreness, and bleeding, although epistaxis occurs commonly in patients with allergic rhinitis if corticosteroids are used chronically. Rarely, these drugs can cause septal perforation. Excessive doses may produce systemic effects, especially if used together with orally inhaled steroids for asthma. Onset of action is within hours, although clinical benefit is usually not observed for a week or more. They may be effective alone or together with antihistamines.

4. Other pharmacologic agents—Montelukast is approved for perennial allergic rhinitis in children aged 6 months and older (4 mg/d for ages 6–23 months) and seasonal allergic rhinitis in children 2 years and older in doses as discussed in the preceding section, under pharmacologic therapy for chronic asthma. Intranasal ipratropium can be used as adjunctive therapy for rhinorrhea. Intranasal cromolyn may be used alone or in conjunction with oral antihistamines and decongestants. It is most effective when used prophylactically, 1–2 sprays/nostril, four times a day. This dose may be tapered if symptom control is achieved. Rarely, patients complain of nasal irritation or burning. Most patients find complying with four-times-daily dosing difficult. Cromolyn is also available in an ophthalmic solution. (See also Chapter 15.) Other ophthalmic mast cell stabilizers include lodoxamide 0.1% solution, 1–2 drops four times a day, and nedocromil, 1–2 drops two times a day. Olopatadine 0.1%, epinastine 0.05%, and ketotifen 0.025% ophthalmic solutions have antihistamine and mast cell-stabilizing actions and can be given to children older than age 3 years as 1 drop twice a day (8 hours apart) apart for olopatadine and every 8–12 hours for ketotifen, respectively. Olopatadine 0.2% is the first once-daily ophthalmic medication available for the treatment of ocular pruritus associated with allergic conjunctivitis.

C. Surgical Therapy

Surgical procedures, including turbinectomy, polypectomy, and functional endoscopic sinus surgery, are rarely indicated in allergic rhinitis or chronic hyperplastic sinusitis.

D. Immunotherapy

Allergen immunotherapy should be considered when symptoms are severe and due to unavoidable exposure to inhalant allergens, especially if symptomatic measures have failed. Immunotherapy is the only form of therapy that may alter the course of the disease. It should not be prescribed by sending the patient's serum to a laboratory where extracts based on in-vitro tests are prepared for the patient (ie, the remote practice of allergy). Subcutaneous immunotherapy should be done in a facility where a physician prepared to treat anaphylaxis is present. Patients with concomitant asthma should not receive an injection if their asthma is not under good control (ie, peak flows preinjection are below 80% of personal best), and the patient should wait for 25–30 minutes after an injection before leaving the facility. Outcomes with single allergen immunotherapy show success rates of approximately 80%. The optimal duration of therapy is unknown, but data suggest that immunotherapy for 3–5 years may have lasting benefit.

► Prognosis

Allergic rhinoconjunctivitis associated with sensitization to indoor allergens tends to be protracted unless specific allergens can be identified and eliminated from the environment. In seasonal allergic rhinoconjunctivitis, symptoms are usually most severe from adolescence through mid-adult life. After moving to a region devoid of problem allergens, patients may be symptom-free for several years, but they can develop new sensitivities to local aeroallergens.

ATOPIC DERMATITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pruritus.
- Facial and extensor involvement in infants and young children.
- Flexural lichenification in older children and adolescents.
- Chronic or relapsing dermatitis.
- Personal or family history of atopic disease.

► General Considerations

Atopic dermatitis is a chronically relapsing inflammatory skin disease typically associated with respiratory allergy.

Over half of patients with atopic dermatitis will develop asthma and allergic rhinitis—often as they outgrow their atopic dermatitis. A subset of patients with atopic dermatitis has been shown to have mutations in the gene encoding filaggrin, a protein essential for normal epidermal barrier function. These patients have early-onset, more severe and persistent disease. Mutations in filaggrin have also been associated with increased risk for asthma, but only in patients with atopic dermatitis. Atopic dermatitis may result in significant morbidity, leading to school absenteeism, occupational disability, and emotional stress. The disease presents in early childhood, with onset prior to age 5 years in approximately 90% of patients.

► Clinical Findings

A. Symptoms and Signs

Atopic dermatitis has no pathognomonic skin lesions or laboratory parameters. Diagnosis is based on the clinical features, including severe pruritus, a chronically relapsing course, and typical morphology and distribution of the skin lesions. Acute atopic dermatitis is characterized by intensely pruritic, erythematous papules associated with excoriations, vesiculations, and serous exudate; subacute atopic dermatitis by erythematous, excoriated, scaling papules; and chronic atopic dermatitis by thickened skin with accentuated markings (lichenification) and fibrotic papules. Patients with chronic atopic dermatitis may have all three types of lesions present concurrently. Patients usually have dry, “lackluster” skin. During infancy, atopic dermatitis involves primarily the face, scalp, and extensor surfaces of the extremities. The diaper area is usually spared. When involved, it may be secondarily infected with *Candida*. In older patients with long-standing disease, the flexural folds of the extremities are the predominant location of lesions.

B. Laboratory Findings

Identification of allergens involves taking a careful history and performing selective immediate hypersensitivity skin tests or in-vitro tests when appropriate. Negative skin tests with proper controls have a high predictive value for ruling out a suspected allergen. Positive skin tests have a lower correlation with clinical symptoms in suspected food allergen-induced atopic dermatitis and should be confirmed with double-blind, placebo-controlled food challenges unless there is a coincidental history of anaphylaxis to the suspected food. Alternatively, specific IgE levels to milk, egg, peanut, and fish proteins have been established with the Phadia ImmunoCAP assay correlating with a greater than 95% chance of a clinical reaction.

Elevated serum IgE levels can be demonstrated in 80–85% of patients with atopic dermatitis, and a similar number have positive immediate skin tests or in-vitro tests with food and inhalant allergens. Several well-controlled studies suggest that specific allergens can influence the course of this

disease. However, triggers for clinical disease cannot be predicted simply by performing allergy testing. Double-blind, placebo-controlled food challenges show that food allergens can cause exacerbations in a subset of patients with atopic dermatitis. Although lesions induced by single positive challenges are usually transient, repeated challenges, more typical of real-life exposure, can result in eczematous lesions. Furthermore, elimination of food allergens results in amelioration of skin disease and a decrease in spontaneous basophil histamine release. Exacerbation of atopic dermatitis can occur with exposure to aeroallergens such as house dust mites, and environmental control measures have been shown to result in clinical improvement. Patients can make specific IgE directed at *Staphylococcus aureus* toxins secreted on the skin, and this correlates with clinical severity better than total serum IgE levels. Eosinophilia may occur. Routine skin biopsy does not differentiate atopic dermatitis from other eczematous processes and is not usually indicated.

► Differential Diagnosis

Scabies can present as a pruritic skin disease. However, distribution in the genital and axillary areas and the presence of linear lesions as well as skin scrapings may help to distinguish it from atopic dermatitis. Seborrheic dermatitis may be distinguished by a lack of significant pruritus; its predilection for the scalp (so-called cradle cap); and its coarse, yellowish scales. Allergic contact dermatitis may be suggested by the distribution of lesions with a greater demarcation of dermatitis than in atopic dermatitis. Occasionally, allergic contact dermatitis superimposed on atopic dermatitis may appear as an acute flare of the underlying disease. Nummular eczema is characterized by coin-shaped plaques. Although unusual in children, mycosis fungoides or cutaneous T-cell lymphoma has been described and is diagnosed by skin biopsy. Eczematous rash has been reported in patients with HIV infection. Other disorders that may resemble atopic dermatitis include Wiskott-Aldrich syndrome, severe combined immunodeficiency disease, hyper-IgE syndrome, IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) syndrome, zinc deficiency, phenylketonuria, and Letterer-Siwe disease.

► Complications

Ocular complications associated with atopic dermatitis can lead to significant morbidity. Atopic keratoconjunctivitis is always bilateral, and symptoms include itching, burning, tearing, and copious mucoid discharge. It is frequently associated with eyelid dermatitis and chronic blepharitis, and may result in visual impairment from corneal scarring. Vernal conjunctivitis is a severe bilateral recurrent chronic inflammatory process of the upper eyelid conjunctiva, occurring primarily in younger patients. (See Chapter 15.) It has a marked seasonal incidence, often in the spring. The associated intense pruritus is exacerbated by exposure to

irritants, light, or perspiration. Examination of the eye reveals a papillary hypertrophy or cobblestoning of the upper inner eyelid surface. Keratoconus in atopic dermatitis is believed to result from persistent rubbing of the eyes in patients with atopic dermatitis and allergic rhinitis. Anterior subcapsular cataracts may develop during adolescence or early adult life.

Patients with atopic dermatitis have increased susceptibility to infection or colonization with a variety of organisms. These include viral infections with herpes simplex, molluscum contagiosum, and human papillomavirus. Of note, even a past history of atopic dermatitis is considered a contraindication for receiving the current smallpox (vaccinia) vaccine. Superimposed dermatophytosis may cause atopic dermatitis to flare. *S aureus* can be cultured from the skin of more than 90% of patients with atopic dermatitis, compared with only 5% of normal subjects. Patients with atopic dermatitis often have toxin-secreting *S aureus* cultured from their skin and can make specific IgE antibodies against the toxins found on their skin. *S aureus* toxins can act as superantigens, contributing to persistent inflammation or exacerbations of atopic dermatitis. Patients without obvious superinfection may show a better response to combined antistaphylococcal and topical corticosteroid therapy than to corticosteroids alone. Although recurrent staphylococcal pustulosis can be a significant problem in atopic dermatitis, invasive *S aureus* infections occur rarely and should raise the possibility of an immunodeficiency such as hyper-IgE syndrome. Patients with atopic dermatitis may be predisposed to colonization and infections by microbial organisms due to decreased synthesis of antimicrobial peptides in the skin, which may be mediated by increased levels of TH2-type cytokines.

Patients with atopic dermatitis often have a nonspecific hand dermatitis. This is frequently irritant in nature and aggravated by repeated wetting.

Nutritional disturbances may result from unwarranted and unnecessarily vigorous dietary restrictions imposed by physicians and parents.

Poor academic performance and behavioral disturbances may be a result of uncontrolled intense or frequent itching, sleep loss, and poor self-image. Severe disease may lead to problems with social interactions and self-esteem.

► Treatment

A. General Measures

Patients with atopic dermatitis have a lowered threshold of irritant responsiveness. Avoidance of irritants such as detergents, chemicals, and abrasive materials as well as extremes of temperature and humidity is important in managing this disease. New clothing should be washed to reduce the content of formaldehyde and other chemicals. Because residual laundry detergent in clothing may be irritating, using a liquid rather than a powder detergent and adding an extra rinse cycle is beneficial. Occlusive clothing should be avoided

in favor of cotton or cotton blends. Temperature in the home and work environments should be controlled to minimize sweating. Swimming is usually well tolerated; however, because swimming pools are treated with chlorine or bromine, patients should shower and use a mild cleanser to remove these chemicals, then apply a moisturizer or occlusive agent. Sunlight may be beneficial to some patients with atopic dermatitis, but nonsensitizing sunscreens should be used to avoid sunburn. Prolonged sun exposure can cause evaporative losses, overheating, and sweating, all of which can be irritating.

In children who have undergone controlled food challenges, eggs, milk, peanuts, soy, wheat, and fish account for approximately 90% of the food allergens that exacerbate atopic dermatitis. Avoidance of foods implicated in controlled challenges can lead to clinical improvement. Extensive elimination diets, which can be nutritionally unsound and burdensome, are almost never warranted because even patients with multiple positive skin tests rarely react to more than three foods on blinded challenges.

In patients who demonstrate specific IgE to dust mite allergen, environmental control measures aimed at reducing the dust mite load improve atopic dermatitis. These include use of dust mite–proof covers on pillows and mattresses, washing linens weekly in hot water, decreasing indoor humidity levels, and in some cases removing bedroom carpeting.

Counseling may be of benefit when dealing with the frustrations associated with atopic dermatitis. Relaxation, behavioral modification, or biofeedback training may help patients with habitual scratching. Patients with severe or disfiguring disease may require psychotherapy.

Clinicians should provide the patient and family with both general information and specific written skin care recommendations. The patient or parent should demonstrate an appropriate level of understanding to help ensure a good outcome. Educational pamphlets and a video about atopic dermatitis can be obtained from the National Eczema Association, a national nonprofit, patient-oriented organization, at: (800) 818-7546; <http://www.nationaleczema.org>.

B. Hydration

Patients with atopic dermatitis have evaporative losses due to a defective skin barrier, so soaking the affected area or bathing for 10–15 minutes in warm water, then applying an occlusive agent to retain the absorbed water, is an essential component of therapy. Oatmeal or baking soda added to the bath may feel soothing to certain patients but does not improve water absorption. Atopic dermatitis of the face or neck can be treated by applying a wet facecloth or towel to the involved area. The washcloth may be more readily accepted by a child if it is turned into a mask and also allows the older patient to remain functional. Lesions limited to the hands or feet can be treated by soaking in a basin. Daily baths may be needed and increased to several times daily during flares of atopic dermatitis, while showers may be adequate for

patients with mild disease. It is important to use an occlusive preparation within a few minutes after soaking the skin to prevent evaporation, which is both drying and irritating.

C. Moisturizers and Occlusives

An effective emollient combined with hydration therapy will help skin healing and can reduce the need for topical corticosteroids. Moisturizers are available as lotions, creams, and ointments. Because lotions contain more water than creams, they are more drying because of their evaporative effect. Preservatives and fragrances in lotions and creams may cause skin irritation. Moisturizers often need to be applied several times daily on a long-term basis and should be obtained in the largest size available. Crisco shortening can be substituted as an inexpensive alternative. Petroleum jelly (Vaseline) is an effective occlusive agent when used to seal in water after bathing. Topical nonsteroidal creams approved as medical devices (thus, currently requiring prescriptions) for relief and management of signs and symptoms of dermatoses include Atopiclair and Mimyx.

D. Corticosteroids

Corticosteroids reduce the inflammation and pruritus in atopic dermatitis. Topical corticosteroids can decrease *S aureus* colonization. Systemic corticosteroids, including oral prednisone, should be avoided in the management of this chronic relapsing disease. The dramatic improvement observed with systemic corticosteroids may be associated with an equally dramatic flaring of atopic dermatitis following their discontinuation.

Topical corticosteroids are available in a wide variety of formulations, ranging from extremely high-potency to low-potency preparations (see Table 14–3). Choice of a particular product depends on the severity and distribution of skin lesions. Patients need to be counseled regarding the potency of their corticosteroid preparation and its potential side effects. In general, the least potent agent that is effective should be used. However, choosing a preparation that is too weak may result in persistence or worsening of the atopic dermatitis. Side effects include thinning of the skin, telangiectasias, bruising, hypopigmentation, acne, and striae, although these occur infrequently when low- to medium-potency topical corticosteroids are used appropriately. In contrast, use of potent topical corticosteroids for prolonged periods—especially under occlusion—may result in significant atrophic changes as well as systemic side effects. The face (especially the eyelids) and intertriginous areas are especially sensitive to corticosteroid side effects, and only low-potency preparations should be used routinely on these areas. Because topical corticosteroids are commercially available in a variety of bases, including ointments, creams, lotions, solutions, gels, and sprays, there is no need to compound them. Ointments are most occlusive and in general provide better delivery of the medication while preventing evapora-

tive losses. However, in a humid environment, creams may be better tolerated than ointments because the increased occlusion may cause itching or even folliculitis. Creams and lotions, while easier to spread, can contribute to skin dryness and irritation. Solutions can be used on the scalp and hirsute areas, although they can be irritating, especially to open lesions. With clinical improvement, a less potent corticosteroid should be prescribed and the frequency of use decreased. Topical corticosteroids can be discontinued when inflammation resolves, but hydration and moisturizers need to be continued. Several topical steroids including fluticasone 0.05% cream and desonide 0.05% hydrogel have been approved in infants as young as 3 months of age for up to 28 days.

E. Topical Calcineurin Inhibitors

Tacrolimus and pimecrolimus are immunomodulatory agents that inhibit the transcription of proinflammatory cytokines as well as other allergic mediators and target key cells in allergic inflammation. They are available in topical formulations, and long-term studies up to 12 months have confirmed both efficacy and safety. Local burning at the site of application, which occurs more frequently with tacrolimus ointment, has been the most common side effect, although this is usually a transient problem. Tacrolimus ointment—0.03% for children 2–15 years of age and 0.1% for older patients—is approved for twice daily short-term and intermittent long-term use in moderate-to-severe atopic dermatitis. Pimecrolimus 1% cream is approved for patients 2 years of age or older who have mild-to-moderate atopic dermatitis. As a precaution, patients should wear sunscreen with both drugs. More recently, several studies in children as young as 3 months of age with all disease severities have been performed for up to 12 months with pimecrolimus 1% cream used at the earliest sign of disease activity (eg, erythema and pruritus). With this early intervention approach, the need for topical corticosteroid rescue was significantly decreased.

Although there is no evidence of a causal link between cancer and the use of topical calcineurin inhibitors, the FDA has issued a boxed warning for pimecrolimus cream and tacrolimus ointment because of a lack of long-term safety data (see U.S. package inserts for Elidel [Novartis], and Protopic [Astellas]). The new labeling states that these drugs are recommended as second-line treatments and that their use in children under the age of 2 years is currently not recommended.

F. Tar Preparations

Tar preparations are used primarily in shampoos and rarely as bath additives. Side effects associated with tar products include skin dryness or irritation, especially if applied to inflamed skin, and, less commonly, photosensitivity reactions and folliculitis.

G. Wet Dressings

Wet dressings are used together with hydration and topical corticosteroids primarily for the treatment of severe atopic dermatitis. They can also serve as an effective barrier against the persistent scratching that often undermines therapy. Total body dressings can be applied by using wet pajamas or long underwear with dry pajamas or a sweat suit on top. Hands and feet can be covered by wet tube socks with dry tube socks on top. Alternatively, wet gauze with a layer of dry gauze over it can be used and secured in place with an elastic bandage. Dressings can be removed when they dry out, usually after several hours, and are often best tolerated at bedtime. Incorrect use of wet dressings can result in chilling, maceration of the skin, or secondary infection.

H. Anti-Infective Therapy

Systemic antibiotic therapy may be important when treating atopic dermatitis secondarily infected with *S aureus*. For limited areas of involvement, a topical antibiotic such as mupirocin or retapamulin ointment may be effective. A first- or second-generation cephalosporins or semisynthetic penicillin is usually the first choice for oral therapy, as erythromycin-resistant organisms are fairly common. Maintenance antibiotic therapy is rarely indicated and may result in colonization by methicillin-resistant bacteria. Some pediatric dermatologists have recommended bleach baths (6% sodium hypochlorite, $\frac{1}{4}$ – $\frac{1}{2}$ cup in a full tub of water) for 10–15 minutes two or three times per week for patients with recurrent methicillin-resistant *S aureus*.

Disseminated eczema herpeticum usually requires treatment with systemic acyclovir. Patients with recurrent cutaneous herpetic lesions can be given prophylactic oral acyclovir. Superficial dermatophytosis and *Malassezia sympodialis* infection can be treated with topical or (rarely) systemic antifungal agents.

I. Antipruritic Agents

Pruritus is usually the least well-tolerated symptom of atopic dermatitis. Oral antihistamines and anxiolytics may be effective owing to their tranquilizing and sedating effects and can be taken mostly in the evening to avoid daytime somnolence. Nonsedating antihistamines may be less effective in treating pruritus, although beneficial effects have been reported in blinded studies. Use of topical antihistamines and local anesthetics should be avoided because of potential sensitization.

J. Recalcitrant Disease

Patients who are erythrodermic or who appear toxic may need to be hospitalized. Hospitalization may also be appropriate for those with severe disease who fail outpatient management. Marked clinical improvement often occurs when the patient is removed from environmental allergens or stressors. In the hospital, compliance with therapy can be

monitored, the patient and family can receive intense education, and controlled provocative challenges can be conducted to help identify triggering factors.

Ultraviolet light therapy can be useful for chronic recalcitrant atopic dermatitis in a subset of patients under the supervision of a specialist. Photochemotherapy with oral methoxypsoralen therapy followed by UVA (ultraviolet A) has been used in a limited number of children with severe atopic dermatitis unresponsive to other therapy, and significant improvement has been noted. However, the increased long-term risk of cutaneous malignancies from this therapy prevents its widespread use.

Limited published data are available on use of the systemic immunosuppressive agent cyclosporine in children. In an open study, children given oral cyclosporine, 5 mg/kg daily for 6 weeks, improved significantly and tolerated the treatment well. Unfortunately, discontinuation of treatment resulted in relapse, although the relapse rate was variable. Patients treated with this agent should have their dose titrated to the lowest effective dose after the disease is brought under control with appropriate monitoring, under the care of a specialist familiar with the drug.

K. Experimental and Unproved Therapies

Several uncontrolled trials have suggested that desensitization to specific allergens may improve atopic dermatitis; however, controlled trials with standardized extracts of relevant allergens in atopic dermatitis are needed before this form of therapy can be recommended. Treatment of atopic dermatitis with high-dose intravenous immunoglobulin and omalizumab is currently investigational. Although disturbances in the metabolism of essential fatty acids have been reported in patients with atopic dermatitis, controlled trials with fish oil and evening primrose have shown no clinical benefit.

► Prognosis

Although it has been held that most children outgrow atopic dermatitis by adolescence, recent studies present less optimistic outcomes. In one study, atopic dermatitis had disappeared in only 18% of children followed from infancy until age 13 years, although the symptoms had become less severe in 65%. In a prospective study from Finland, 77–91% of adolescent patients receiving treatment for moderate or severe atopic dermatitis had persistent or frequently relapsing dermatitis as adults, although only 6% had severe disease. More than half of adolescents receiving treatment for mild dermatitis experienced a relapse of disease as adults. Adults whose childhood atopic dermatitis has been in remission for a number of years may present with hand dermatitis, especially if daily activities require repeated hand wetting.

URTICARIA & ANGIOEDEMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Urticaria: erythematous, blanchable, circumscribed, pruritic, edematous papules ranging from 1–2 mm to several centimeters in diameter and involving the superficial dermis. Individual lesions can coalesce.
- Angioedema: edema extending into the deep dermis or subcutaneous tissues.
- Both resolve without sequelae—urticaria usually within hours (individual lesions rarely lasting up to 24 hours), angioedema within 72 hours.

► General Considerations

Urticaria and angioedema are common dermatologic conditions, occurring at some time in up to 25% of the population. About half of patients will have concomitant urticaria and angioedema, whereas 40% will have only urticaria and 10% only angioedema. Urticarial lesions are arbitrarily designated as acute, lasting less than 6 weeks, or chronic, lasting more than 6 weeks. Acute versus chronic urticaria can also be distinguished by differences in histologic features. A history of atopy is common with acute urticaria or angioedema. In contrast, atopy does not appear to be a factor in chronic urticaria.

Mast cell degranulation, dilated venules, and dermal edema are present in most forms of urticaria or angioedema. The dermal inflammatory cells may be sparse or dense depending on the chronicity of the lesions. Mast cells are thought to play a critical role in the pathogenesis of urticaria or angioedema through release of a variety of vasoactive mediators. Mast cell activation and degranulation can be triggered by different stimuli, including cross-linking of Fc receptor-bound IgE by allergens or anti-FcεRI antibodies. Non-IgE-mediated mechanisms have also been identified, including complement anaphylatoxins (C3a, C5a), radiocontrast dyes, and physical stimuli. Chronic urticarial lesions

have greater numbers of perivascular mononuclear cells, consisting primarily of T cells. There is also a marked increase in cutaneous mast cells. The cause of acute disease can be identified in about half of patients and includes allergens such as foods, aeroallergens, latex, drugs, and insect venoms. Infectious agents, including streptococci, mycoplasmas, hepatitis B virus, and Epstein-Barr virus, can cause acute urticaria. Urticaria or angioedema can occur after the administration of blood products or immunoglobulin. This results from immune complex formation with complement activation, vascular alterations, and triggering of mast cells by anaphylatoxins. Opiate analgesics, polymyxin B, tubocurarine, and radiocontrast media can induce acute urticaria by direct mast cell activation. These disorders can also occur following ingestion of aspirin or nonsteroidal anti-inflammatory agents (see later section on Adverse Reactions to Drugs & Biologicals).

Physical urticarias represent a heterogeneous group of disorders in which urticaria or angioedema is triggered by physical stimuli, including pressure, cold, heat, water, or vibrations. Dermographism is the most common form of physical urticaria, affecting up to 4% of the population and occurring at skin sites subjected to mechanical stimuli. Many physical urticarias are considered to be acute because the lesions are usually rapid in onset, with resolution within hours. However, symptoms can recur for months to years.

The cause of chronic urticaria is usually not due to allergies and typically cannot be determined. It can be associated with an underlying systemic disease such as thyroid disease. Some studies have demonstrated IgG autoantibodies directed at the high-affinity receptor for IgE or at IgE, suggesting that chronic urticaria may be an autoimmune disease.

► Clinical Findings

A. Symptoms and Signs

Cold-induced urticaria or angioedema can occur within minutes of exposure to a decreased ambient temperature or as the skin is warmed following direct cold contact. Systemic features include headache, wheezing, and syncope. If the entire body is cooled, as may occur during swimming, hypotension and collapse can occur. Two forms of dominantly inherited cold urticaria have been described. The immediate form is known as familial cold urticaria, in which erythematous macules appear rather than wheals, along with fever, arthralgias, and leukocytosis. The delayed form consists of erythematous, deep swellings that develop 9–18 hours after local cold challenge without immediate lesions.

In solar urticaria, which occurs within minutes after exposure to light of appropriate wavelength, pruritus is followed by morbilliform erythema and urticaria.

Cholinergic urticaria occurs after increases in core body and skin temperatures and typically develops after a warm bath or shower, exercise, or episodes of fever. Occasional episodes are triggered by stress or the ingestion of certain

foods. The eruption appears as small punctate wheals surrounded by extensive areas of erythema. Rarely the urticarial lesions become confluent and angioedema develops. Associated features can include one or more of the following: headache, syncope, bronchospasm, abdominal pain, vomiting, and diarrhea. In severe cases, systemic anaphylaxis may develop. In pressure urticaria or angioedema, red, deep, painful swelling occurs immediately or 4–6 hours after the skin has been exposed to pressure. The immediate form is often associated with dermatographism. The delayed form, which may be associated with fever, chills, and arthralgias, may be accompanied by elevated erythrocyte sedimentation rate and leukocytosis. Lesions are frequently diffuse, tender, and painful rather than pruritic. They typically resolve within 48 hours.

B. Laboratory Findings

Laboratory tests are selected on the basis of the history and physical findings. Testing for specific IgE antibody to food or inhalant allergens may be helpful in implicating a potential cause. Specific tests for physical urticarias, such as an ice cube test or a pressure test, may be indicated. Intradermal injection of methacholine reproduces clinical symptoms locally in about one third of patients with cholinergic urticaria. A throat culture for streptococcal infection may be warranted with acute urticaria. In chronic urticaria, selected screening studies to look for an underlying disease may be indicated, including a complete blood count, erythrocyte sedimentation rate, biochemistry panel, and urinalysis. Anti-thyroid antibodies may be considered. Intradermal testing with the patient's serum has been suggested as a method of detecting histamine-releasing activity, including autoantibodies. Other tests should be done based on suspicion of a specific underlying disease. If the history or appearance of the urticarial lesions suggests vasculitis, a skin biopsy for immunofluorescence is indicated. Patient diaries occasionally may be helpful to determine the cause of recurrent hives. A trial of food or drug elimination may be considered.

► Differential Diagnosis

Urticarial lesions are usually easily recognized—the major dilemma is the etiologic diagnosis. Lesions of urticarial vasculitis typically last for more than 24 hours. “Papular urticaria” is a term used to characterize multiple papules from insect bites, found especially on the extremities, and is not true urticaria. Angioedema can be distinguished from other forms of edema because it is transient, asymmetrical, and nonpitting and does not occur predominantly in dependent areas. Hereditary angioedema is a rare autosomal dominant disorder caused by a quantitative or functional deficiency of C1-esterase inhibitor and characterized by episodic, frequently severe, nonpruritic angioedema of the skin, gastrointestinal tract, or upper respiratory tract. Life-threatening laryngeal angioedema may occur.

► Complications

In severe cases of cholinergic urticaria, systemic anaphylaxis may develop. In cold-induced disease, sudden cooling of the entire body as can occur with swimming can result in hypotension and collapse.

► Treatment

A. General Measures

The most effective treatment is identification and avoidance of the triggering agent. Underlying infection should be treated appropriately. Patients with physical urticarias should avoid the relevant physical stimulus. Epinephrine can be used for treatment of acute episodes, especially when laryngeal edema complicates an attack (see next section on Anaphylaxis). Intubation may be indicated for life-threatening laryngeal edema.

B. Antihistamines

For the majority of patients, H₁ antihistamines given orally or systemically are the mainstay of therapy. Antihistamines are more effective when given on an ongoing basis rather than after lesions appear. For breakthrough symptoms, the dose may need to be increased. In the case of cold urticaria, the best treatment appears to be cyproheptadine. Cholinergic urticaria can be treated with hydroxyzine and dermographism with hydroxyzine or diphenhydramine. The addition of H₂ antihistamines may benefit some patients who fail to respond to H₁-receptor antagonists alone. Second-generation antihistamines (discussed previously under Allergic Rhinoconjunctivitis) are long acting, show good tissue levels, are non- or minimally sedating at usual dosing levels, and lack anticholinergic effects.

C. Corticosteroids

Although corticosteroids are usually not indicated in the treatment of acute or chronic urticaria, severe recalcitrant cases may require alternate-day therapy in an attempt to diminish disease activity and facilitate control with antihistamines. Systemic corticosteroids may also be needed in the treatment of urticaria or angioedema secondary to necrotizing vasculitis, an uncommon occurrence in patients with serum sickness or collagen-vascular disease.

D. Other Pharmacologic Agents

Limited studies suggest that some patients may benefit from treatment with a leukotriene-receptor antagonist. The tricyclic antidepressant doxepin blocks both H₁ and H₂ histamine receptors and may be particularly useful in chronic urticaria, although its use may be limited by the sedating side effect. A limited number of patients—including euthyroid patients—with chronic urticaria and antithyroid antibodies have improved when given thyroid hormone. Treatment of chronic urticaria with hydroxychloroquine,

nifedipine, colchicine, dapsone, sulfasalazine, cyclosporine, or intravenous immune globulin should be considered investigational.

► Prognosis

Spontaneous remission of urticaria and angioedema is frequent, but some patients have a prolonged course. Reassurance is important, because this disorder can cause significant frustration. Periodic follow-up is indicated, particularly for patients with laryngeal edema, to monitor for possible underlying cause.

Boguniewicz M: Chronic urticaria in children. *Allergy Asthma Proc* 2005;26:13 [PMID: 15813283].

ANAPHYLAXIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Serious allergic reaction that is rapid in onset and may cause death after exposure to allergen in a previously sensitized person.
- Generalized pruritus, anxiety, urticaria, angioedema, throat fullness, wheezing, dyspnea, hypotension, and collapse.

► General Considerations

Anaphylaxis is an acute life-threatening clinical syndrome that occurs when large quantities of inflammatory mediators are rapidly released from mast cells and basophils after exposure to an allergen in a previously sensitized patient. Anaphylactoid reactions mimic anaphylaxis but are not mediated by IgE antibodies. They may be mediated by anaphylatoxins such as C3a or C5a or through nonimmune mast cell degranulating agents. Some of the common causes of anaphylaxis or anaphylactoid reactions are listed in Table 36–12. Idiopathic anaphylaxis by definition has no recognized external cause. The clinical history is the most important tool in making the diagnosis of anaphylaxis.

► Clinical Findings

A. Symptoms and Signs

The symptoms and signs of anaphylaxis or anaphylactoid reactions depend on the organs affected. Onset typically occurs within minutes after exposure to the offending agent and can be short-lived, protracted, or biphasic, with recurrence after several hours despite treatment.

Table 36–12. Common causes of systemic allergic and pseudoallergic reactions.

Causes of anaphylaxis	
Drugs	Antibiotics
	Anesthetic agents
Foods	Peanuts, tree nuts, shellfish, and others
Biologicals	Latex
	Insulin
	Allergen extracts
	Antisera
	Blood products
	Enzymes
	Monoclonal antibodies (eg omalizumab)
	Insect venoms
Causes of anaphylactoid reactions	
	Radiocontrast media
	Aspirin and other nonsteroidal anti-inflammatory drugs
	Anesthetic agents

Anaphylaxis is highly likely when any one of the following three criteria are fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (eg, generalized hives, pruritus or flushing, swollen lips-tongue-uvula) *and at least one of the following*:
 - a. Respiratory compromise (eg, dyspnea, wheeze-bronchospasm, stridor, reduced peak expiratory flow, hypoxemia)
 - b. Reduced blood pressure or associated symptoms of end-organ dysfunction (eg, hypotonia [collapse], syncope, incontinence)
2. Two or more of the following that occur rapidly after exposure to a *likely* allergen for that patient (minutes to several hours):
 - a. Involvement of the skin-mucosal tissue (eg, generalized urticaria, itch-flush, swollen lips-tongue-uvula)
 - b. Respiratory compromise (eg, dyspnea, wheeze-bronchospasm, stridor, reduced PEF, hypoxemia)
 - c. Reduced blood pressure or associated symptoms (eg, hypotonia [collapse], syncope, incontinence)
 - d. Persistent gastrointestinal symptoms (eg, crampy abdominal pain, vomiting)
3. Reduced blood pressure after exposure to a *known* allergen for that patient (minutes to several hours)
 - a. Infants and children: low systolic blood pressure (age specific) or greater than 30% decrease in systolic pressure
 - b. Low systolic blood pressure in children, defined as less than 70 mm Hg in those aged from 1 month to 1 year, less than (70 mm Hg + [2 × age]) in those 1–10 years of age, and less than 90 mm Hg in those 11–17 years

B. Laboratory Findings

Tryptase released by mast cells can be measured in the serum and may be helpful when the diagnosis of anaphylaxis is in question. The blood sample should be obtained within 3 hours of onset of the reaction, although tryptase levels are often normal, particularly in individuals with food-induced anaphylaxis. The complete blood count may show an elevated hematocrit due to hemoconcentration. Elevation of serum creatine kinase, aspartate aminotransferase, and lactic dehydrogenase may be seen with myocardial involvement. Electrocardiographic abnormalities may include ST-wave depression, bundle branch block, and various arrhythmias. Arterial blood gases may show hypoxemia, hypercapnia, and acidosis. The chest radiograph may show hyperinflation.

► Differential Diagnosis

Although shock may be the only sign of anaphylaxis, other diagnoses should be considered, especially in the setting of sudden collapse without typical allergic findings. Other causes of shock along with cardiac arrhythmias must be ruled out. (See Chapters 11 and 13.) Respiratory failure associated with asthma may be confused with anaphylaxis. Mastocytosis, hereditary angioedema, scombroid poisoning, vasovagal reactions, vocal cord dysfunction, and anxiety attacks may cause symptoms mistaken for anaphylaxis.

► Complications

Depending on the organs involved and the severity of the reaction, complications may vary from none to aspiration pneumonitis, acute tubular necrosis, bleeding diathesis, or sloughing of the intestinal mucosa. With irreversible shock, heart and brain damage can be terminal. Risk factors for fatal or near-fatal anaphylaxis include age (adolescents and young adults), reactions to peanut or tree nuts, associated asthma, strenuous exercise, and ingestion of medications such as β -blockers.

► Prevention

Strict avoidance of the causative agent is extremely important. An effort to determine its cause should be made, beginning with a thorough history. Typically there is a strong temporal relationship between exposure and onset of symptoms. Testing for specific IgE to allergen with either in-vitro or skin testing may be indicated. With exercise-induced anaphylaxis, patients should be instructed to exercise with another person and to stop exercising at the first sign of symptoms. If prior ingestion of food has been implicated, eating within 4 hours—perhaps up to 12 hours—before exercise should be avoided. Patients with a history of anaphylaxis should carry epinephrine for self-administration (eg, EpiPen or Twinject in 0.15-mg and 0.3-mg doses), and they and all caregivers should be instructed on its use. They should also carry an oral antihistamine such as diphenhydramine,

preferably in liquid or fast-melt preparation to hasten absorption, and wear a medical alert bracelet. Patients with idiopathic anaphylaxis may require prolonged treatment with oral corticosteroids. Specific measures for dealing with food, drug, latex, and insect venom allergies as well as radiocontrast media reactions are discussed in the next sections.

▶ Treatment

A. General Measures

Anaphylaxis is a medical emergency that requires rapid assessment and treatment. Exposure to the triggering agent should be discontinued. Airway patency should be maintained and blood pressure and pulse monitored. The patient should be placed in a supine position with the legs elevated unless precluded by shortness of breath or emesis. Oxygen should be delivered by mask or nasal cannula with pulse oximetry monitoring. If the reaction is secondary to a sting or injection into an extremity, a tourniquet may be applied proximal to the site, briefly releasing it every 10–15 minutes.

B. Epinephrine

Epinephrine is the treatment of choice for anaphylaxis. Epinephrine 1:1000, 0.01 mg/kg to a maximum of 0.5 mg, should be injected intramuscularly, without delay. This dose may be repeated at intervals of 5–15 minutes as necessary for controlling symptoms and maintaining blood pressure. If the precipitating allergen has been injected intradermally or subcutaneously, absorption may be delayed by giving 0.1 mL of epinephrine subcutaneously at the injection site unless the site is a digit. There is no precisely established dosing regimen for intravenous epinephrine in anaphylaxis, but a 5–10-mcg intravenous bolus for hypotension and 0.1–0.5 mg intravenously for cardiovascular collapse have been suggested.

C. Antihistamines

Diphenhydramine, an H₁-blocker, 1–2 mg/kg up to 50 mg, can be given intramuscularly or intravenously. Intravenous antihistamines should be infused over a period of 5–10 minutes to avoid inducing hypotension. Addition of ranitidine, an H₂-blocker, 1 mg/kg up to 50 mg intravenously, may be more effective than an H₁-blocker alone, especially for hypotension, but histamine blockers should be considered second-line treatment for anaphylaxis.

D. Fluids

Treatment of persistent hypotension despite epinephrine requires restoration of intravascular volume by fluid replacement, initially with a crystalloid solution, 20–30 mL/kg in the first hour.

E. Bronchodilators

Nebulized β_2 -agonists such as albuterol 0.5% solution, 2.5 mg (0.5 mL) diluted in 2–3 mL saline, or levalbuterol, 0.63

mg or 1.25 mg, may be useful for reversing bronchospasm. Intravenous methylxanthines are generally not recommended because they provide little benefit over inhaled β_2 -agonists and may contribute to toxicity.

F. Corticosteroids

Although corticosteroids do not provide immediate benefit, when given early they may prevent protracted or biphasic anaphylaxis. Intravenous methylprednisolone, 1–2 mg/kg, or hydrocortisone, 5 mg/kg, can be given every 4–6 hours. Oral prednisone, 1 mg/kg up to 50 mg, might be sufficient for less severe episodes.

G. Vasopressors

Hypotension refractory to epinephrine and fluids should be treated with intravenous vasopressors such as noradrenaline, vasopressin, or dopamine. (See Chapter 13.)

H. Observation

The patient should be monitored after the initial symptoms have subsided, because biphasic or protracted anaphylaxis can occur despite ongoing therapy. Biphasic reactions occur in 1–20% of anaphylactic reactions, but no reliable clinical predictors have been identified. Observation periods should be individualized based on the severity of the initial reaction, but a reasonable time for observation is 4–6 hours in most patients, with prolonged observation or admission for severe or refractory symptoms.

▶ Prognosis

Anaphylaxis can be fatal. In two reports describing children, adolescents, and adults who died from food-induced anaphylaxis (eg, from peanuts, tree nuts, fish, shellfish, and milk) over the past 12 years, treatment with epinephrine was delayed for more than 1 hour after onset as it was not readily accessible in the majority of subjects. The prognosis, however, is good when signs and symptoms are recognized promptly and treated aggressively, and the offending agent is subsequently avoided. Exercise-induced and idiopathic anaphylaxis may be recurrent. Because accidental exposure to the causative agent may occur, patients, parents, and caregivers must be prepared to recognize and treat anaphylaxis (emergency action plan).

ADVERSE REACTIONS TO DRUGS & BIOLOGICALS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Most adverse drug reactions are not allergic although patients or caregivers often report them as a drug allergy.
- ▶ Antibiotics constitute the most frequent cause of allergic drug reactions.
- ▶ Reliable testing for most drugs other than penicillins and a few large protein molecules is not available.

The majority of adverse drug reactions are not immunologically mediated and may be due to idiosyncratic reactions, overdosage, pharmacologic side effects, nonspecific release of pharmacologic effector molecules, or drug interactions.

Patients or caregivers often describe an adverse drug reaction as being allergic in nature, and clinicians may document a drug allergy in the patient's medical record based solely on this history. Adverse drug reactions are any undesirable and unintended response elicited by a drug. Allergic or hypersensitivity drug reactions are adverse reactions involving immune mechanisms. Although hypersensitivity reactions account for only 5–10% of all adverse drug reactions, they are the most serious, with 1:10,000 resulting in death.

1. Antibiotics

Antibiotics constitute the most frequent cause of allergic drug reactions. Amoxicillin, trimethoprim–sulfamethoxazole, and ampicillin are the most common causes of cutaneous drug reactions.

Most antibiotics and their metabolites are low-molecular-weight compounds that do not stimulate immunity until they have become covalently bound to a carrier protein. The penicillins and other β -lactam antibiotics, including cephalosporins, carbacephems, carbapenems, and monobactams, share a common β -lactam ring structure and a marked propensity to couple to carrier proteins. Penicilloyl is the predominant metabolite of penicillin and is called the major determinant. The other penicillin metabolites are present in low concentrations and are referred to as minor determinants. Sulfonamide reactions are mediated presumably by a reactive metabolite (hydroxylamine) produced by cytochrome P-450 oxidative metabolism. Slow acetylators appear to be at increased risk. Other risk factors for drug reactions include previous exposure, previous reaction, age (20–49 years), route (parenteral), and dose of administration (high, intermittent). Atopy does not predispose to development of a reaction, but atopic individuals have more severe reactions.

Immunopathologic reactions to antibiotics include type I (IgE-mediated) reactions resulting from a drug or metabo-

lite interaction with preformed specific IgE bound to the surfaces of tissue mast cells or circulating basophils. Release of mediators such as histamine and leukotrienes contributes to the clinical development of angioedema, urticaria, bronchospasm, or anaphylaxis. Type II (cytotoxic) reactions involve IgG or IgM antibodies that recognize drug bound to cell membranes. In the presence of serum complement, the antibody-coated cell is either cleared or destroyed, causing drug-induced hemolytic anemia or thrombocytopenia. Type III (immune complex) reactions are caused by soluble complexes of drug or metabolite with IgG or IgM antibody. If the immune complex is deposited on blood vessel walls and activates the complement cascade, serum sickness may result. Type IV (T-cell-mediated) reactions require activated T lymphocytes that recognize a drug or its metabolite as seen in allergic contact dermatitis. Sensitization usually occurs via the topical route of administration. Immunopathologic reactions not fitting into the type I–IV classification include Stevens-Johnson syndrome, exfoliative dermatitis, and the maculopapular rash associated with penicillin or ampicillin. The prevalence of morbilliform rashes in patients given ampicillin is between 5.2% and 9.5% of treatment courses. However, patients given ampicillin during Epstein-Barr virus and cytomegalovirus infections or with acute lymphoblastic anemia have a 69–100% incidence of non-IgE-mediated rash. Serum sickness–like reactions resemble type III reactions, although immune complexes are not documented; β -lactams, especially cefaclor, and sulfonamides, have been implicated most often. They may result from an inherited propensity for hepatic biotransformation of drug into toxic or immunogenic metabolites. The incidence of “allergic” cutaneous reactions to trimethoprim–sulfamethoxazole in patients with AIDS has been reported to be as high as 70%. The mechanism is thought to relate to the severe immune dysregulation, although it may be due to glutathione deficiency resulting in toxic metabolites.

▶ Clinical Findings

A. Symptoms and Signs

Allergic reactions can result in pruritus, urticaria, angioedema, or anaphylaxis. Serum sickness is characterized by fever, rash, lymphadenopathy, myalgias, and arthralgias. Cytotoxic drug reactions can result in symptoms and signs associated with the underlying anemia or thrombocytopenia. Delayed-type hypersensitivity may cause contact dermatitis.

B. Laboratory Findings

Skin testing is the most rapid, useful, and sensitive method of demonstrating the presence of IgE antibody to a specific allergen. Skin testing to nonpenicillin antibiotics may be difficult, however, because many immunologic reactions are due to metabolites rather than to the parent drug and because the relevant metabolites for most drugs other than penicillin have not been identified. Because metabolites are

usually low-molecular-weight haptens, they must combine with carrier proteins to be useful for diagnosis. In the case of contact sensitivity reactions to topical antibiotics, a 48-hour patch test can be useful.

Solid-phase in-vitro immunoassays for IgE to penicillins are available for identification of IgE to penicilloyl but are considerably less sensitive and give less information than skin testing. Assays for specific IgG and IgM have been shown to correlate with a drug reaction in immune cytopenias, but in most other instances such assays are not clinically useful. Skin testing for immediate hypersensitivity is helpful only in predicting reactions caused by IgE antibodies. Most nonpruritic maculopapular rashes will not be predicted by skin testing.

Approximately 80% of patients with a history of penicillin allergy will have negative skin tests. Penicillin therapy in patients with a history of an immediate hypersensitivity reaction to penicillin, but with negative skin tests to both penicilloyl and the minor determinant mixture, is accompanied by a 1–3% chance of urticaria or other mild allergic reactions at some time during therapy, with anaphylaxis occurring in less than 0.1% of patients. In contrast, the predictive value of a positive skin test is approximately 60%. Testing with penicilloyl linked to polylysine (PPL) alone has a sensitivity of about 76%; use of both PPL and penicillin G (used as a minor determinant) increases sensitivity to about 95%. Not using the minor determinant mixture in skin testing can result in failure to predict potential anaphylactic reactions. Unfortunately the minor determinant mixture is still not commercially available, although most academic allergy centers make their own. Approximately 4% of subjects tested who have no history of penicillin allergy have positive skin tests, and most fatalities occur in patients with no prior history of reaction. Rarely, patients may have skin test reactivity only to a specific semisynthetic penicillin. Resensitization in skin test–negative children occurs infrequently (< 1%) after a course of oral antibiotic.

The degree of cross-reactivity of determinants formed from cephalosporins with IgE to other β -lactam drugs remains unresolved, especially because haptens that may be unique to cephalosporin metabolism remain unknown. The degree of clinical cross-reactivity is much lower than the in-vitro cross-reactivity. A clinical adverse reaction rate of 3–7% for cephalosporins may be expected in patients with positive histories of penicillin allergy. Antibodies to the second- and third-generation cephalosporins appear to be directed at the unique side chains rather than at the common ring structure. The present literature suggests that a positive skin test to a cephalosporin used at a concentration of 1 mg/mL would place the patient at increased risk for an allergic reaction to that antibiotic. However, a negative skin test would not exclude sensitivity to a potentially relevant metabolite. One review concluded that there is no increased incidence of allergy to second- and third-generation cephalosporins in patients with penicillin allergy and that penicillin skin testing

does not identify patients who develop cephalosporin allergy. However, another study suggested that although only 2% of penicillin-allergic patients would react to a cephalosporin, they would be at risk for anaphylaxis.

Carbacephems (loracarbef) are similar to cephalosporins, although the degree of cross-reactivity is undetermined. Carbapenems (imipenem) represent another class of β -lactam antibiotics with a bicyclic nucleus and a high degree of cross-reactivity with penicillin. In contrast, monobactams (aztreonam) contain a monocyclic rather than bicyclic ring structure, and limited data suggest that aztreonam can be safely administered to most penicillin-allergic subjects.

Skin testing for non- β -lactam antibiotics is less reliable, because the relevant degradation products are for the most part unknown or multivalent reagents are unavailable.

▶ Treatment

A. General Measures

Withdrawal of the implicated drug is usually a central component of management. Acute IgE-mediated reactions such as anaphylaxis, urticaria, and angioedema are treated according to established therapeutic guidelines that include the use of epinephrine, H₁- and H₂-receptor blocking agents, volume replacement, and systemic corticosteroids (see previous sections). Antibiotic-induced immune cytopenias can be managed by withdrawal of the offending agent or reduction in dose. Drug-induced serum sickness can be suppressed by drug withdrawal, antihistamines, and corticosteroids. Contact allergy can be managed by avoidance and treatment with antihistamines and topical corticosteroids. Reactions such as toxic epidermal necrolysis and Stevens-Johnson syndrome require immediate drug withdrawal and supportive care.

B. Alternative Therapy

If possible, subsequent therapy should be with an alternative drug that has therapeutic actions similar to the drug in question but with no immunologic cross-reactivity.

C. Desensitization

Administering gradually increasing doses of an antibiotic either orally or parentally over a period of hours to days may be considered if alternative therapy is not acceptable. This should be done only by a physician familiar with desensitization, typically in an intensive care setting. Of note, desensitization is only effective for the course of therapy for which the patient was desensitized, unless maintained on a chronic prophylactic dose of the medication as patients revert from a desensitized to allergic state after the drug is discontinued. In addition, desensitization does not reduce or prevent non-IgE-mediated reactions. Patients with Stevens-Johnson syndrome should not be desensitized because of the high mortality rate.

▶ Prognosis

The prognosis is good when drug allergens are identified early and avoided. Stevens-Johnson syndrome and toxic epidermal necrolysis may be associated with a high mortality rate.

2. Latex Allergy

▶ General Considerations

Allergic reactions to latex and rubber products have become increasingly common since the institution of universal precautions for exposure to bodily fluids. Children with spina bifida appear to have a unique sensitivity to latex, perhaps because of early and frequent latex exposure as well as altered neuroimmune interactions. Atopy—especially symptomatic latex allergy—appears to be significantly increased in patients with spina bifida experiencing anaphylaxis during general anesthesia. Other conditions requiring chronic or recurrent exposure to latex such as urogenital anomalies and ventriculoperitoneal shunt have also been associated with latex hypersensitivity. The combination of atopy and frequent exposure seems to synergistically increase the risk of latex hypersensitivity.

Latex is the milky fluid obtained by tapping the cultivated rubber tree, *Hevea brasiliensis*. During manufacture of latex products, various antioxidants and accelerators such as thiurams, carbamates, and mercaptobenzothiazoles are added. Latex products are typically produced by dipping a porcelain mold into a tank of latex and then vulcanizing it to enhance mechanical stability. The product is washed or “leached” of excess proteins, then dry-lubricated with a powder such as corn starch.

Latex is a complex biologic mixture composed of rubber particles in a phospholipoprotein envelope and a serum containing sugars, lipids, nucleic acids, minerals, and various proteins. The protein component is thought to contain the allergenic properties. Extra leaching steps may reduce the protein content and hence the allergenicity of the final product. IgE from latex-sensitized individuals reacts with different protein components, supporting the notion that more than one clinically important latex antigen exists. New allergenic epitopes are generated during the manufacturing process. Thus, polypeptides from latex glove extracts vary both quantitatively and qualitatively with different brands and lots of gloves. Identification of the causative antigens is important because it may be possible to alter the manufacturing process to reduce the final allergen content.

Latex is ubiquitous in medical settings, and many sources may be inconspicuous. Synthetic alternatives to some latex products—including gloves, dressings, and tape—are available. Avoidance of contact with latex-containing items, however, may be insufficient to prevent allergic reactions, because lubricating powders may serve as vehicles for aerosolized latex antigens. The use of powder-free latex gloves is an important control measure for airborne latex allergen.

Nonmedical sources of latex are also common and include balloons, toys, rubber bands, erasers, condoms, and shoe soles. Pacifiers and bottle nipples have also been implicated as sources of latex allergen, although these products are molded rather than dipped, and allergic reactions to molded products are less common. Latex-allergic patients and their caregivers must be continuously vigilant for hidden sources of exposure.

▶ Clinical Findings

A. Symptoms and Signs

The clinical manifestations of IgE-mediated reactions to latex can involve the full spectrum of symptoms associated with mast cell degranulation. Localized pruritus and urticaria occur after cutaneous contact; conjunctivitis and rhinitis can result from aerosol exposure or direct facial contact. Systemic reactions, including bronchospasm, laryngospasm and hypotension, may occur with more substantial exposure or in extremely sensitive individuals. Finally, vascular collapse and shock leading to fatal cardiovascular events may occur. Intraoperative anaphylaxis represents a common and serious manifestation of latex allergy.

Allergic contact dermatitis to rubber products typically appears 24–48 hours after contact. The primary allergens include accelerators and antioxidants used in the manufacturing process. The diagnosis is established by patch testing. Shoe soles are an important source of exposure. The skin lesions appear primarily as a patchy eczema on exposed surfaces, although reactions can become generalized.

B. Laboratory Findings

Epicutaneous prick testing is a rapid, inexpensive, and sensitive test that detects the presence of latex-specific IgE on skin mast cells. Obstacles to its use include lack of a standardized antigen. Reports of life-threatening anaphylactic events have been associated with skin testing to latex, and intradermal testing may be especially dangerous. A commercially available extract is pending FDA approval.

Immunoassay testing involves the in-vitro measurement of specific IgE, which binds latex antigens. Antigen sources used for testing have included native plant extracts, raw latex, and finished products. When compared with a history of latex-induced symptoms or positive skin tests, the sensitivity of immunoassays testing for latex antigens ranges from 50–100% with specificity between 63% and 100%. These broad ranges may reflect the patient population studied and the source of latex antigen as well as the assay employed. A positive immunoassay test to latex in the presence of a highly suggestive latex allergy history is useful and may circumvent the potential concerns associated with prick skin testing in certain patients.

Cross-reactivity has been demonstrated between latex and a number of other antigens such as foods. Banana, avocado, and chestnut have been found to be antigenically similar to latex both immunologically and clinically.

► Complications

Complications may be similar to those caused by other allergens. Prolonged exposure to aerosolized latex may lead to persistent asthma. Chronic allergic contact dermatitis, especially on the hands, can lead to functional disability.

► Treatment

Avoidance remains the cornerstone of treatment for latex allergy. Prevention and supportive therapy are the most common methods for managing this problem. Patients identified as being allergic to latex may need to have a personal supply of vinyl or latex-free gloves for use when visiting a physician or dentist. “Hypoallergenic gloves” are poorly classified with respect to their ability to induce IgE-mediated reactions; the FDA currently uses this term to designate products that have a reduced capacity to induce contact dermatitis. Gloves made from synthetic materials include Neolon (Becton-Dickinson), Tactyl 1 (Smart Practice), and Elastyren (Hermal). Autoinjectable epinephrine and medical identification bracelets may be prescribed for latex-allergic patients along with avoidance counseling.

Prophylactic premedication of latex-allergic individuals has been used in some surgical patients at high risk for latex allergy. The rationale for this therapy is derived from the pretreatment protocols developed for iodinated radio-contrast media and anesthetic reactions. Although there has been some success using this regimen, anaphylaxis has occurred despite pretreatment. This approach should not substitute for careful avoidance measures.

► Prognosis

Owing to the ubiquitous nature of natural rubber, the prognosis is guarded for patients with severe latex allergy. Chronic exposure to airborne latex particles may lead to chronic asthma. Chronic dermatitis can lead to functional disability.

3. Vaccines

Mumps-measles-rubella (MMR) vaccine has been shown to be safe in egg-allergic patients (although rare reactions to gelatin or neomycin can occur). The ovalbumin content in influenza vaccine is variable, and skin testing with the specific vaccine lot is warranted in patients with egg allergy. (**Note:** Some patients who tolerate cooked egg, that is, denatured protein, may still react to the vaccine.) In addition, the newly introduced live intranasal influenza vaccine is contraindicated in egg-allergic children.

4. Radiocontrast Media

Non-IgE-mediated anaphylactoid reactions may occur with radiocontrast media with up to a 30% reaction rate on reexposure. Management involves using a low-molarity agent and premedication with prednisone, diphenhydramine, and possibly an H₂-blocker.

5. Insulin

Approximately 50% of patients receiving insulin have positive skin tests, but IgE-mediated reactions occur rarely. Insulin resistance is mediated by IgG. If less than 24 hours has elapsed after an allergic reaction to insulin, do not discontinue insulin but rather reduce the dose by one third, then increase by 2–5 units per injection. Skin testing and desensitization are necessary if the interval between the allergic reaction and subsequent dose is greater than 24 hours.

6. Local Anesthetics

Less than 1% of reactions to local anesthetics are IgE-mediated. Management involves selecting a local anesthetic from another class. Esters of benzoic acid include benzocaine and procaine; amides include lidocaine and mepivacaine. Alternatively, the patient can be skin tested with the suspected agent, followed by a provocative challenge. To rule out paraben sensitivity, skin testing can be done with 1% lidocaine from a multidose vial.

7. Aspirin & Other Nonsteroidal Anti-Inflammatory Drugs

Adverse reactions to aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) include urticaria and angioedema; rhinosinusitis, nasal polyps, and asthma; anaphylactoid reactions; and NSAID-related hypersensitivity pneumonitis. After a systemic reaction, a refractory period of 2–7 days occurs. Most aspirin-sensitive patients tolerate sodium salicylate. All NSAIDs inhibiting cyclooxygenase (COX) cross-react with aspirin. Cross-reactivity between aspirin and tartrazine (yellow dye No. 5) has not been substantiated in controlled trials. No skin test or in-vitro test is available to diagnose aspirin sensitivity. Oral challenge can induce severe bronchospasm. Desensitization and cross-desensitization to NSAIDs can be achieved in most patients and maintained long-term. Leukotriene-receptor antagonists or 5-lipoxygenase inhibitors attenuate the reaction to aspirin challenge and may be beneficial adjunct treatment in aspirin-sensitive asthmatic patients. Preliminary studies suggest that COX-2 inhibitors may be tolerated by patients with ASA-induced asthma.

8. Biological Agents

In recent years, a growing number of biological agents have become available for the treatment of autoimmune, neoplastic, cardiovascular, infectious, and allergic diseases, among others. Their use may be associated with a variety of adverse reactions including hypersensitivity reactions. The FDA issued a boxed warning regarding risk of anaphylaxis and need for patient monitoring with use of omalizumab (see pharmacologic therapy section under Treatment, Chronic Asthma, earlier).

FOOD ALLERGY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Temporal relationship between ingestion of a suspected food and onset of allergic symptoms.
- ▶ For IgE-mediated reactions, positive prick skin test or in-vitro test to a suspected food allergen confirmed by a double-blind, placebo-controlled food challenge (except in cases of anaphylaxis).

▶ General Considerations

Food allergy, defined as an adverse immune response to food proteins, affects 6% of young children and 3–4% of adults. The most common IgE-associated food allergens in children are egg (1.3%), milk (2.5%), peanut (0.8%), soy (0.4%), wheat (0.4%), tree nuts (0.2%), fish (0.2%), and shellfish (0.1%). In older patients, fish (0.4%), shellfish (2%), peanut (0.6%) and tree nuts (0.5%) are most often involved in allergic reactions, and may be lifelong allergies. The highest prevalence of food allergy is found in children with moderate-to-severe atopic dermatitis, with approximately 35% affected, whereas chronic conditions such as urticaria and asthma are much less likely due solely to food allergy. Of note, food allergy can be caused by non-IgE (cell)-mediated mechanisms, in conditions such as food-protein-induced enterocolitis or proctocolitis. It can also be caused by mixed IgE- and cell-mediated mechanisms, as in allergic eosinophilic esophagitis and gastroenteritis.

Some adverse reactions diagnosed by patients or physicians as food allergy involve pharmacologic or metabolic mechanisms and reactions to food toxins. Foods containing significant amounts of vasoactive amines such as chocolate,

cheese, and some wines and beers may precipitate migraine headaches in some patients. Claims that dyes, sugar, and food additives may contribute to hyperactivity in children with attention-deficit/hyperactivity disorder are controversial. In the occasional case in which a child appears to benefit from a restricted diet, there is no evidence for an IgE-mediated etiology. Anaphylactoid reactions can occur after ingestion of foods such as certain fish containing high amounts of histamine.

▶ Clinical Findings

A. Symptoms and Signs

Most reactions to foods occur minutes to 2 hours after ingestion. A history of a temporal relationship between the ingestion of a suspected food and onset of a reaction—as well as the nature and duration of symptoms observed—is important in establishing the diagnosis of food allergy. With chronic atopic dermatitis or persistent urticaria, the association with food may be less obvious (see earlier sections on Atopic Dermatitis and Urticaria). At times, acute symptoms may occur, but the cause may not be obvious because of hidden food allergens. A symptom diary kept for 7–14 days may be helpful in establishing an association between ingestion of foods and symptoms and also provides a baseline observation for the pattern of symptom expression. It is important to record both the form in which the food was ingested and the foods ingested concurrently.

Hives, flushing, facial angioedema, and mouth or throat itching are common. In severe cases, angioedema of the tongue, uvula, pharynx, or upper airway can occur. Contact urticaria can occur without systemic symptoms in some children. Gastrointestinal symptoms include abdominal discomfort or pain, nausea, vomiting, and diarrhea. Children with food allergy may occasionally have isolated rhinoconjunctivitis or wheezing. Rarely, anaphylaxis to food may involve only cardiovascular collapse (see section on Anaphylaxis).

B. Laboratory Findings

Typically, fewer than 50% of histories of food allergy will be confirmed by blinded challenge (although this percentage is much higher in food-induced anaphylaxis). Prick skin testing is useful to rule out a suspected food allergen, because the predictive value is high for a properly performed negative test with an extract of good quality (negative predictive accuracy of greater than 95%). In contrast, the predictive value for a positive test is approximately 50%. RAST and other in-vitro tests have lower specificity and positive predictive values. In contrast, specific IgE levels to milk, egg, peanut, and fish proteins have been established with the Phadia ImmunoCAP assay correlating with a greater than 95% chance of a clinical reaction. Measurement of IgG to foods is not clinically useful as IgG responses are a reflection of normal immune recognition of foreign food proteins.

The double-blind, placebo-controlled food challenge is considered the gold standard for diagnosing food allergy except in severe reactions. If there is high suspicion of possible allergic reactivity to a food with a negative skin test or undetectable ImmunoCAP level (or both), a food challenge may be necessary to confirm the presence or absence of allergy. Even when multiple food allergies are suspected, most patients will test positive to three or fewer foods on blinded challenge. Therefore, extensive elimination diets are almost never indicated. Elimination without controlled challenge is a less desirable but at times more practical approach for suspected food allergy. Elimination diets and food challenges may also be the only tools for evaluation of suspected non-IgE-mediated food reactions.

► Differential Diagnosis

Repeated vomiting in infancy may be due to pyloric stenosis or gastroesophageal reflux. With chronic gastrointestinal symptoms, enzyme deficiency (eg, lactase), cystic fibrosis, celiac disease, chronic intestinal infections, gastrointestinal malformations, and irritable bowel syndrome should be considered.

► Treatment

Treatment consists of eliminating and avoiding foods that have been documented to cause allergic reactions. This involves educating the patient, parent, and caregivers regarding hidden food allergens, the necessity for reading labels, and the signs and symptoms of food allergy and its appropriate management (emergency action plan). New food labeling laws went into effect in January 2006 requiring simple terms to indicate the presence of the major food allergens listed previously (eg, milk instead of casein). Consultation with a dietitian familiar with food allergy may be helpful, especially when common foods such as milk, egg, peanut, soy, or wheat are involved. All patients with a history of IgE-mediated food allergy should carry self-injectable epinephrine (see section on Anaphylaxis) and a fast-acting antihistamine, and consider wearing medical identification jewelry. Monoclonal anti-IgE, Chinese herbal formula, oral and sublingual immunotherapy, and vaccines have shown promise as possible future treatments of food allergy.

► Prognosis

The prognosis is good if the offending food can be identified and avoided. Unfortunately, accidental exposure to food allergens in severely allergic patients can result in death. Most children outgrow their food allergies to milk, egg, wheat, and soy but not to peanut or tree nuts (only 20% and 10% of children may outgrow peanut and tree nut allergy, respectively). The natural history of food allergy can be followed by measuring food-specific IgE levels by ImmunoCAP assay, as discussed earlier, and performing food chal-

lenges when indicated. Approximately 2% of children will have food allergy as adults. Resources for food-allergic patients include the Food Allergy and Anaphylaxis Network, at: (800) 929-4040; <http://www.foodallergy.org>.

Sicherer SH et al: Food Allergy. *J Allergy Clin Immunol* 2006;117:S470 [PMID: 16455349].

INSECT ALLERGY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Local or systemic allergic signs and symptoms after insect sting.

Allergic reactions to insects include symptoms of respiratory allergy as a result of inhalation of particulate matter of insect origin, local cutaneous reactions to insect bites, and anaphylactic reactions to stings. The latter are almost exclusively caused by Hymenoptera and result in approximately 40 deaths each year in the United States. The order Hymenoptera includes honey bees, yellow jackets, yellow hornets, white-faced hornets, wasps, and fire ants. Africanized honey bees, also known as killer bees, are a concern because of their aggressive behavior and excessive swarming, not because their venom is more toxic. Rarely, patients sensitized to reduviid bugs (also known as kissing bugs) may have episodes of nocturnal anaphylaxis. Lepidopterism refers to adverse effects secondary to contact with larval or adult butterflies and moths. Salivary gland antigens are responsible for immediate and delayed skin reactions in mosquito-sensitive patients.

► Clinical Findings

A. Symptoms and Signs

Insect bites or stings can cause local or systemic reactions ranging from mild to fatal responses in susceptible persons. The frequency increases in the summer months and with outdoor exposure. Local cutaneous reactions include urticaria as well as papulovesicular eruptions and lesions that resemble delayed hypersensitivity reactions. Papular urticaria is almost always the result of insect bites, especially of mosquitoes, fleas, and bedbugs. Toxic systemic reactions consisting of gastrointestinal symptoms, headache, vertigo, syncope, convulsions, or fever can occur following multiple stings. These reactions result from histamine-like substances in the venom. In children with hypersensitivity to fire ant venom, sterile pustules occur at sting sites on a nonimmunologic basis due to the inherent toxicity of piperidine alkaloids in the venom. Mild systemic reactions include itching, flushing, and urticaria. Severe systemic reactions may include dyspnea, wheezing, chest tightness,

hoarseness, fullness in the throat, hypotension, loss of consciousness, incontinence, nausea, vomiting, and abdominal pain. Delayed systemic reactions occur from 2 hours to 3 weeks following the sting and include serum sickness, peripheral neuritis, allergic vasculitis, and coagulation defects.

B. Laboratory Findings

Skin testing is indicated for children with systemic reactions. Venoms of honeybee, yellow jacket, yellow hornet, white-faced hornet, and wasp are available for skin testing and treatment. Fire ant venom is not yet commercially available, but an extract made from fire ant bodies appears adequate to establish the presence of IgE antibodies to fire ant venom. Of note, venom skin test results can be negative in patients with systemic allergic reactions, especially in the first few weeks after a sting, and the tests may need to be repeated. The presence of a positive skin test denotes prior sensitization but does not predict whether a reaction will occur with the patient's next sting, nor does it differentiate between local and systemic reactions. It is common for children who have had an allergic reaction to have positive skin tests to more than one venom. This might reflect sensitization from prior stings that did not result in an allergic reaction or cross-reactivity between closely related venoms. In-vitro testing (compared with skin testing) has not substantially improved the ability to predict anaphylaxis. With venom RAST, there is a 15–20% incidence of both false-positive and false-negative results. Tests for mosquito saliva antigens or other insect allergy are not commercially available.

► Complications

Secondary infection can complicate allergic reactions to insect bites or stings. Serum sickness, nephrotic syndrome, vasculitis, neuritis, and encephalopathy may be seen as late sequelae of reactions to stinging insects.

► Treatment

For cutaneous reactions caused by biting insects, symptomatic therapy includes cold compresses, antipruritics (including antihistamines), and occasionally potent topical corticosteroids. Treatment of stings includes careful removal of the stinger, if present, by flicking it away from the wound and not by grasping in order to prevent further envenomation. Topical application of monosodium glutamate, baking soda, or vinegar compresses is of questionable efficacy. Local reactions can be treated with ice, elevation of the affected extremity, oral antihistamines, and NSAIDs as well as potent topical corticosteroids. Large local reactions, in which swelling extends beyond two joints or an extremity, may require a short course of oral corticosteroids. Anaphylactic reactions following Hymenoptera stings should be managed essentially the same as anaphylaxis (see section on Anaphylaxis). Children who have had severe or anaphylactic reactions to Hymenoptera stings—or their parents and caregivers—should be instructed in the use of epinephrine. Patients at risk for anaphylaxis from an insect sting should also wear a medical alert bracelet indicating their allergy. Children at risk from insect stings should avoid wearing bright-colored clothing and perfumes when outdoors and should wear long pants and shoes when walking in the grass. Patients who experience severe systemic reactions and have a positive skin test should receive venom immunotherapy. Immunotherapy is not indicated for children with only urticarial or local reactions.

► Prognosis

Children generally have milder reactions than adults after insect stings, and fatal reactions are extremely rare. Patients aged 3–16 years with reactions limited to the skin, such as urticaria and angioedema, appear to be at low risk for more severe reactions with subsequent stings.

Antimicrobial Therapy

John W. Ogle, MD

37

PRINCIPLES OF ANTIMICROBIAL THERAPY

Antimicrobial therapy of infections is arguably the most important scientific development of 20th-century medicine. It contributes significantly to the quality of life of many people and reduces the morbidity and mortality due to infectious disease. The remarkable success of antimicrobial therapy has been achieved with comparatively little toxicity and expense. The relative ease of administration and the widespread availability of these drugs have led many to adopt a philosophy of broad-spectrum empiric antimicrobial therapy for many common infections.

Unfortunately this era of cheap, safe, and reliable therapy may be coming to a close owing to the increasing frequency of antimicrobial resistance in previously susceptible microorganisms. The problem of antimicrobial resistance is certainly not new—resistance was recognized for sulfonamides and penicillins shortly after their introduction. What is new is the worldwide dissemination of resistant clones of microorganisms, such as *Streptococcus pneumoniae* and *Staphylococcus aureus*, which are inherently virulent and commonly cause serious infections, not only among hospitalized patients but also among outpatients.

Until recently the recognition of new resistant clones was balanced by the promise of newer and more potent antimicrobial agents. Today, because fewer new agents are under development, clinicians are beginning to encounter limitations in their ability to treat some serious bacterial infections. Many factors contribute to the selection of resistant clones. Our success in treating chronic diseases and immune-compromising conditions, which has resulted in additional years of life for patients, has increased opportunities for selection of resistant strains in inpatient units and chronic care facilities. Overuse of antimicrobial agents also contributes to the selection of resistant strains. Examples include medications for mildly ill patients with self-limited conditions such as viral infections, and administration of broad-spectrum antimicrobials for patients whose conditions can be treated with

narrow-spectrum agents. Similarly, failure to document infection with cultures obtained prior to starting therapy limits our willingness to stop or narrow the spectrum of antimicrobials. Insufficient research has been conducted to determine the optimal duration of therapy, with the result that we probably often treat longer than is necessary. Prophylactic strategies, as used for prevention of recurrent otitis media or urinary tract infection, create a selection pressure for antibiotic resistance.

The decision-making process for choosing an appropriate antimicrobial agent is summarized in Table 37–1. Accurate clinical diagnosis is based on the history, physical examination, and initial laboratory tests. The clinical diagnosis then leads to a consideration of the organisms most commonly associated with the clinical condition, the usual pattern of antimicrobial susceptibility of these organisms, and past experience with successful treatment regimens.

Cultures should be obtained in potentially serious infections. Empiric antimicrobial therapy may be initiated, then modified according to the patient's response and the culture results. Often several equally safe and efficacious antimicrobials are available. In this circumstance, the relative cost and ease of administration of the different choices should be considered.

Other important considerations include the patient's age, immune status, and exposure history. Neonates and young infants may present with nonspecific signs of infection, making the differentiation of serious disease from mild illness difficult. In older children, clinical diagnosis is more precise, which may permit therapy to be avoided or allow use of a narrower-spectrum antibiotic. Immune deficiency may increase the number and types of potential infecting organisms that need to be considered, including organisms that are usually avirulent but may cause infections that are serious and difficult to treat. An abnormal immune response may also diminish the severity of the clinical signs and symptoms of infection and thus lead to underestimation of the severity of illness. The exposure history may suggest the greater likelihood of certain types of infecting organisms.

Table 37-1. Steps in decision making for use of antimicrobial agents.

Step	Action	Example
1	Determine diagnosis	Septic arthritis
2	Consider age and preexisting condition	Previously healthy 2-year-old child
3	Consider common organisms	<i>Staphylococcus aureus</i> , <i>Kingella kingae</i>
4	Consider organism susceptibility	Penicillin- or ampicillin-resistant, frequency MRSA ^a in community
5	Obtain proper cultures ^b	Blood, joint fluid
6	Initiate empiric therapy based on above considerations and past experience (eg, personal, literature)	Nafcillin and cefotaxime, substitute vancomycin for nafcillin if obviously ill or MRSA prevalent.
7	Modify therapy based on culture results and patient response	<i>S aureus</i> isolated. Discontinue cefotaxime. Substitute nafcillin for vancomycin if susceptible.
8	Follow clinical response	Interval physical examination
9	Stop therapy	Clinically improved or well, minimum 3-4 weeks

^aMethicillin-resistant *S aureus*.

^bIndicated for serious or unusual infections or those with unpredictable clinical response to empiric therapy.

This history includes exposures from family members, classmates, and day care environments and exposure to unusual organisms by virtue of travel, diet, or contact with animals.

Final important considerations are the pace and seriousness of the illness. A rapidly progressive and severe illness should be treated initially with broad-spectrum antimicrobials until a specific etiologic diagnosis is made. A mildly ill outpatient should receive treatment preferentially with narrow-spectrum antimicrobials.

Antimicrobial susceptibility, antimicrobial families, and dosing recommendations are listed in Tables 37-2 to 37-6.

ANTIMICROBIAL SUSCEPTIBILITY TESTING

Cultures and other diagnostic material must be obtained prior to initiating antimicrobial therapy—especially when the patient has a serious infection, initial attempts at therapy have failed, or multiagent therapy is anticipated. Whenever cultures identify the causative organism, therapy can be narrowed or optimized according to susceptibility results. Antimicrobial susceptibility testing should be done in a laboratory using carefully defined procedures (Clinical and Laboratory Standards Institute).

There are several ways to test antimicrobial susceptibility. Identification of an antibiotic-destroying enzyme (eg, β -

lactamase) implies resistance to β -lactam-containing antimicrobial agents. Tube or microtiter broth dilution techniques can be used to determine the minimum inhibitory concentration (MIC) of antibiotic, which is the amount of antibiotic (in mcg/mL) necessary to inhibit the organism under specific laboratory conditions. Disk susceptibility testing (also performed under carefully controlled conditions) yields similar results. The E-test is a standardized test for some organisms that correlates well with MICs. Clinical laboratories usually define antimicrobial susceptibility (susceptible, intermediate, and resistant) in relation to levels of the test antibiotic achievable in the blood or another body fluid (cerebrospinal fluid [CSF] or urine).

Organisms are usually considered susceptible to an antibiotic if the MIC of the antibiotic for the organism is significantly lower than levels of that agent achieved in the blood using appropriate parenteral dosages. This assumption of susceptibility should be reconsidered whenever the patient has a focus of infection (eg, meningitis, osteomyelitis, or abscess) in which poor antibiotic penetration might occur, because the levels of antibiotic in such areas might be lower than the MIC. Conversely, although certain organisms may be reported to be resistant to an antibiotic because sufficiently high blood concentrations cannot be achieved, urine concentrations may be much higher. If so, a urinary tract infection might respond to an antibiotic that would not be adequate for treatment of septicemia.

Thus, antimicrobial susceptibility testing, although a very important part of therapeutic decision making, reflects assumptions that the clinician must understand, especially for serious infections. Ultimately the true test of the efficacy of therapy is patient response. Patients who do not respond to seemingly appropriate therapy may require reassessment, including reconsidering the diagnosis, reculturing, and repeat susceptibility testing, to determine whether resistant strains have evolved or superinfection with a resistant organism is present. Antimicrobial therapy cannot be expected to cure some infections unless additional supportive treatment (usually surgical) is undertaken.

ALTERATION OF DOSE & MEASUREMENT OF BLOOD LEVELS

Certain antimicrobial agents have not been approved (and often not tested) for use in newborns. For those that have been approved, it is important to recognize that both dose and frequency of administration may need to be altered (see Tables 37-4 and 37-5), especially in young (7 days or younger) or low-birth-weight neonates (≤ 2000 g).

Antimicrobial agents are excreted or metabolized through various physiologic mechanisms (eg, renal, hepatic). It is important to consider these routes of excretion and alter the antimicrobial dosage appropriately in any patient with some degree of organ dysfunction. (See Chapter 43.) As indicated in Table 37-4, an assessment of renal or hepatic

Table 37-2. Susceptibility of some common pathogenic microorganisms to various antimicrobial drugs.

Organism	Potentially Useful Antibiotics ^a
Bacteria	
Anaerobic bacteria ^b	Cefotetan, ^c ceftioxin, ^c clindamycin, ertapenem, ^c imipenem, ^c meropenem, metronidazole, penicillins with or without β -lactamase inhibitor, tigecycline ^c
<i>Bacillus anthracis</i>	Amoxicillin, ciprofloxacin, clindamycin, doxycycline, rifampin, vancomycin
<i>Bartonella henselae</i>	Azithromycin, ciprofloxacin, clarithromycin, doxycycline, erythromycin, rifampin
<i>Bordetella pertussis</i>	Amoxicillin, azithromycin, clarithromycin, erythromycin, trimethoprim-sulfamethoxazole
<i>Borrelia burgdorferi</i>	Amoxicillin, cefuroxime, cephalosporins (III), ^d clarithromycin, doxycycline
<i>Campylobacter</i> spp	Azithromycin, carbapenems, erythromycin, fluoroquinolones, ^{c,e} tetracyclines
<i>Clostridium</i> spp	Clindamycin, metronidazole, penicillins, tetracyclines
<i>Clostridium difficile</i>	Bacitracin (PO), metronidazole, vancomycin (PO)
<i>Corynebacterium diphtheriae</i>	Clindamycin, erythromycin, penicillins
Enterobacteriaceae ^f	Aminoglycosides, ^g ampicillin, aztreonam, cefepime, cephalosporins, ertapenem, fluoroquinolones, ^{c,e} imipenem, meropenem, tigecycline, trimethoprim-sulfamethoxazole
<i>Enterococcus</i>	Ampicillin (with aminoglycoside), carbapenems (not <i>E faecium</i>), linezolid, quinupristin-dalfopristin ^c (<i>E faecium</i> only), tigecycline, vancomycin,
<i>Haemophilus influenzae</i>	Amoxicillin-clavulanate, ampicillin (if β -lactamase-negative), ^h cephalosporins (II and III), ^d chloramphenicol, fluoroquinolones, ^{c,e} rifampin, trimethoprim-sulfamethoxazole
<i>Listeria monocytogenes</i>	Ampicillin with aminoglycoside, trimethoprim-sulfamethoxazole, vancomycin
<i>Moraxella catarrhalis</i>	Amoxicillin-clavulanate, ampicillin (if β -lactamase-negative), ^h cephalosporins (II, III), ^d erythromycin, fluoroquinolones, trimethoprim-sulfamethoxazole
<i>Neisseria gonorrhoeae</i>	Ampicillin (if β -lactamase-negative), ^h cephalosporins (II and III), ^d penicillins, selected fluoroquinolones (only if known susceptible), ^{c,e} spectinomycin
<i>Neisseria meningitidis</i>	Ampicillin, cephalosporins (II and III), ^d fluoroquinolones, ^{c,e} penicillins, rifampin
<i>Nocardia asteroides</i>	Tetracycline, trimethoprim-sulfamethoxazole (+ amikacin for severe infections) Meropenem or cephalosporins (II, III) ^d for brain abscess
<i>Pasteurella multocida</i>	Amoxicillin-clavulanate, ampicillins, penicillins, tetracyclines
<i>Pseudomonas aeruginosa</i>	Aminoglycosides, ^g anti- <i>Pseudomonas</i> penicillins, ^c aztreonam, cefepime, ceftazidime, ciprofloxacin, ^c imipenem, meropenem
<i>Salmonella</i> spp	Ampicillin, azithromycin, cephalosporins (III), ^d fluoroquinolones, ^{c,e} trimethoprim-sulfamethoxazole
<i>Shigella</i> spp	Ampicillin, azithromycin, cephalosporins (III), ^d fluoroquinolones, ^{c,e} tetracyclines, trimethoprim-sulfamethoxazole
<i>Staphylococcus aureus</i>	Antistaphylococcal penicillins, ⁱ cefepime, cephalosporins (I and II), ciprofloxacin, clindamycin, erythromycin, rifampin, trimethoprim-sulfamethoxazole, vancomycin
<i>S aureus</i> (methicillin-resistant)	Clindamycin, daptomycin, ^c linezolid, quinupristin-dalfopristin, ^c tigecycline, ^c trimethoprim-sulfamethoxazole, vancomycin
Staphylococci (coagulase-negative)	Cephalosporins (I and II), ^j clindamycin, rifampin, vancomycin
Streptococci (most species)	Ampicillin, cephalosporins, clindamycin, enhanced fluoroquinolones, ^{c,k} erythromycin, meropenem, penicillins, vancomycin
<i>Streptococcus pneumoniae</i> ^l	Ampicillin, cephalosporins, enhanced fluoroquinolones, ^{c,k} erythromycin, meropenem, penicillin, vancomycin
Intermediate organisms	
<i>Chlamydia</i> spp	Clarithromycin, erythromycin, levofloxacin, ^c ofloxacin, ^c tetracyclines
<i>Mycoplasma</i> spp	Azithromycin, clarithromycin, erythromycin, fluoroquinolones, ^{c,e} tetracyclines
<i>Rickettsia</i> spp	Fluoroquinolones, ^{c,e} tetracyclines

(continued)

Table 37-2. Susceptibility of some common pathogenic microorganisms to various antimicrobial drugs. (Continued)

Organism	Potentially Useful Antibiotics ^a
Fungi	
<i>Candida</i> spp	Amphotericin B, caspofungin, fluconazole, flucytosine, itraconazole, ketoconazole, micafungin, posaconazole, voriconazole
Fungi, systemic ^b	Amphotericin B, caspofungin, fluconazole, itraconazole, ^c ketoconazole, micafungin, posaconazole, voriconazole
Dermatophytes	Butenafine, ciclopirox olamine, clotrimazole, econazole, fluconazole, griseofulvin, itraconazole, ^c ketoconazole, miconazole, naftifine, oxiconazole, terbinafine
<i>Pneumocystis jiroveci</i>	Atovaquone, clindamycin-primaquine, dapsone, pentamidine, trimethoprim-sulfamethoxazole
Viruses	
Herpes simplex	Acyclovir, penciclovir, ^c famciclovir, ^c foscarnet, trifluridine, valacyclovir ^c
Human immunodeficiency virus	Five classes: (1) nucleoside reverse transcriptase inhibitors, (2) non-nucleoside reverse transcriptase inhibitors, (3) protease inhibitors, (4) fusion inhibitors, (5) integrase inhibitors; optimally combinations of ≥ 3 drugs should be used (see Chapter 39)
Influenza virus	Amantadine, ^m oseltamivir, rimantidine, ^m zanamivir
Respiratory syncytial virus	Ribavirin ⁿ
Varicella-zoster virus	Acyclovir, famciclovir, ^c valacyclovir ^c
Cytomegalovirus	Cidofovir, fomivirsen (topical or intravitreal), foscarnet, ganciclovir, valganciclovir
Hepatitis B ^c	Adefovir, interferon alfa, lamivudine
Hepatitis C ^c	Interferon alfa, ribavirin

^aIn alphabetical order. Selection depends on patient's age, diagnosis, site of infection, severity of illness, antimicrobial susceptibility of suspected organism, and drug risk.

^bSpecies-dependent.

^cNot FDA-approved for use in children.

^dRefer to second- (II) or third- (III) generation cephalosporins.

^eIncludes ciprofloxacin, levofloxacin, lomefloxacin, norfloxacin, ofloxacin, moxifloxacin, gatifloxacin, gemifloxacin.

^fIncludes *E coli*, *Klebsiella* spp, *Enterobacter* spp, and others; antimicrobial susceptibilities should always be measured.

^gAmikacin, gentamicin, kanamycin, tobramycin.

^hAlso applies to amoxicillin and related compounds.

ⁱCloxacillin, dicloxacillin, methicillin, nafcillin, oxacillin.

^jOnly if the coagulase-negative *Staphylococcus* is also methicillin- or oxacillin-sensitive.

^kIncludes levofloxacin, lomefloxacin, moxifloxacin, gatifloxacin, gemifloxacin.

^lBecause of increasing frequency of *S pneumoniae* strains resistant to penicillin and cephalosporins, presumptive therapy for severe infections (eg, meningitis) should include vancomycin until susceptibility studies are available.

^mInfluenza A only. Resistance is common, not currently recommended in the United States.

ⁿFDA-approved for therapy of respiratory syncytial virus by aerosol, but clinical studies show variable efficacy.

function may be routinely necessary for patients receiving certain drugs (eg, renal function for aminoglycosides, hepatic function for erythromycin or clindamycin); otherwise, harmful drug levels may accumulate. If significant organ dysfunction is present, drug clearance may be delayed and dosage modification may be necessary (see detailed descriptions in individual drug information packets), and measurement of drug levels may be indicated.

Serum levels of drugs posing a high risk of toxicity (eg, aminoglycosides) are ordinarily measured, and measurement of other drugs (eg, vancomycin) may be useful in selected circumstances (see following discussion). For certain other serious bacterial infections (eg, bacterial endocar-

ditis), measurement of the serum concentration of an antimicrobial may be important to deliver optimal therapy.

Certain drug interactions may require modification of drug dosage or other therapeutic alterations. (See Chapter 43.) For example, rifampin stimulates the metabolism of warfarin, birth control pills, prednisone, and anticonvulsants by stimulating the cytochrome P-450 (CYP-450) metabolic pathway. Dosage adjustments or alternative medications may be necessary to avoid significant adverse events. Another common example is erythromycin, which may inhibit the metabolism of theophylline, resulting in toxic theophylline levels. Although many drug interactions are known and well documented, it may be difficult to predict

Table 37-3. Groups of common antibacterial agents.

Group	Examples	Some Common Susceptible Organisms ^a	Common Resistant Organisms	Common or Unique Adverse Reactions
Penicillin group				
Penicillins	Penicillin G, V	<i>Streptococcus</i> , <i>Neisseria</i>	<i>Staphylococcus</i> , <i>Haemophilus</i> , Enterobacteriaceae	Rash, anaphylaxis, drug fever, bone marrow suppression
Ampicillins	Ampicillin, amoxicillin	(Same as penicillins), plus <i>Haemophilus</i> (β -lactamase negative), <i>Escherichia coli</i> , <i>Enterococcus</i>	<i>Staphylococcus</i> , many Enterobacteriaceae	Diarrhea
Anti-staphylococcal penicillins	Cloxacillin, dicloxacillin, methicillin, nafcillin, oxacillin	<i>Streptococcus</i> , <i>Staphylococcus aureus</i>	Gram-negative, <i>Staphylococcus</i> (coagulase-negative), <i>Enterococcus</i>	Renal (interstitial nephritis)
Anti- <i>Pseudomonas</i> penicillins	Azlocillin, piperacillin, ticarcillin	(Same as ampicillins), plus <i>Pseudomonas</i>	(Same as ampicillins)	Decreased platelet adhesiveness, hypokalemia, hypernatremia
Penicillin with β -lactamase inhibitor combination	Amoxicillin-clavulanate, ampicillin-sulbactam, ticarcillin-clavulanate	Broad-spectrum	Some Enterobacteriaceae, <i>Pseudomonas</i>	Diarrhea
Carbapenems	Imipenem-cilastatin meropenem, ertapenem	Broad-spectrum, gram-negative rods, anaerobes, <i>Pseudomonas</i>	MRSA, ^b many enterococci	Central nervous system (CNS), seizures
Cephalosporin group				
First-generation (I)	Cefazolin, cephalexin, cephalothin, cephapirin, cephadrine	Gram-positive	Gram-negative, <i>Enterococcus</i> , some <i>Staphylococcus</i> (coagulase-negative)	Rash; anaphylaxis, drug fever
Second-generation (II)	Cefaclor, cefamandole, cefprozil, cefonicid, cefuroxime, loracarbef Cefoxitin, cefotetan	Gram-positive, some <i>Haemophilus</i> , some Enterobacteriaceae Same as second-generation plus anaerobes	<i>Enterococcus</i> , <i>Pseudomonas</i> , some <i>Staphylococcus</i> (coagulase-negative)	Serum sickness (cefaclor)
Third-generation (III)	Cefotaxime, ceftizoxime, ceftriaxone, cefpodoxime, ceftibuten, cefdinir Ceftazidime, cefepime ^c	<i>Streptococcus</i> , <i>Haemophilus</i> , Enterobacteriaceae, <i>Neisseria</i> (Same as other third-generation cephalosporins), plus <i>Pseudomonas Staphylococcus</i>	<i>Pseudomonas</i> , <i>Staphylococcus</i>	Biliary sludging (ceftriaxone) rash
Other drugs				
Clindamycin	Clindamycin	Gram-positive, anaerobes, some MRSA	Gram-negative, <i>Enterococcus</i>	Nausea, vomiting, hepatotoxicity
Vancomycin	Vancomycin	Gram-positive	Gram-negative	"Red man" syndrome, shock, ototoxicity, renal
Macrolides and azilides	Erythromycin, clarithromycin, azithromycin	Gram-positive <i>Bordetella</i> , <i>Haemophilus</i> , <i>Mycoplasma</i> , <i>Chlamydia</i> , <i>Legionella</i> , <i>Salmonella</i> , <i>Shigella</i>	Some Gram-negative	Nausea and vomiting
Monobactams	Aztreonam	Gram-negative aerobes, <i>Pseudomonas</i>	Gram-positive cocci	Rash, diarrhea

(continued)

Table 37-3. Groups of common antibacterial agents. (Continued)

Group	Examples	Some Common Susceptible Organisms ^a	Common Resistant Organisms	Common or Unique Adverse Reactions
Oxazolidinones	Linezolid	Gram-positive aerobes	Gram-negative aerobes	Diarrhea, thrombocytopenia
Streptogramins	Quinupristin-dalfopristin	Gram-positive aerobes	Gram-negative aerobes	Arthralgia, myalgia
Fluoroquinolones ^d	Ciprofloxacin, ofloxacin	Gram-negative, <i>Chlamydia</i> , <i>Mycoplasma</i> , <i>Pseudomonas</i> (ciprofloxacin)	<i>Enterococcus</i> , <i>Streptococcus</i> , <i>S pneumoniae</i> , anaerobes, <i>Staphylococcus</i>	Gastrointestinal (GI), rash, CNS
	Gatifloxacin, levofloxacin, moxifloxacin	Gram-negative, streptococci, <i>S pneumoniae</i> , staphylococci	Some <i>Enterococcus</i>	GI, rash, CNS
Tetracyclines	Chlortetracycline, tetracycline, doxycycline, minocycline	Anaerobes, <i>Mycoplasma</i> , <i>Chlamydia</i> , <i>Rickettsia</i> , <i>Ehrlichia</i>	Many Enterobacteriaceae, <i>Staphylococcus</i>	Teeth stained, ^e rash, flora overgrowth, hepatotoxicity, pseudotumor cerebri
Sulfonamides	Many	Gram-negative (urine)	Gram-positive	Rash, renal, bone marrow suppression, Stevens-Johnson syndrome
Trimethoprim-sulfamethoxazole	Trimethoprim-sulfamethoxazole	<i>S aureus</i> , gram-negative, <i>S pneumoniae</i> , <i>Haemophilus influenzae</i>	<i>Streptococcus</i> , <i>Pseudomonas</i> , anaerobes	Rash, renal, bone marrow suppression, Stevens-Johnson syndrome
Rifampin	Rifampin	<i>Neisseria</i> , <i>Haemophilus</i> , <i>Staphylococcus</i> , <i>Streptococcus</i>	Resistance develops rapidly if used as sole agent	Rash, GI, hepatotoxicity, CNS, bone marrow suppression, alters metabolism of other drugs
Aminoglycosides	Amikacin, gentamicin, kanamycin, streptomycin, tobramycin	Gram-negative, including <i>Pseudomonas aeruginosa</i>	Gram-positive, anaerobes, some pseudomonads	Nephrotoxicity, ototoxicity, potentiates neuromuscular blocking agents

^aNot all strains susceptible; always obtain antimicrobial susceptibility tests on significant isolates.

^bMRSA = methicillin-resistant *S aureus*.

^cSafety and efficacy are not established in children younger than age 2 months.

^dNot approved for children.

^eDose-dependent in children younger than age 9 years.

interactions that result from a combination of four, five, or more different medications. A high level of suspicion regarding adverse clinical events should be maintained.

THE USE OF NEW ANTIMICROBIAL AGENTS

New antibiotics are introduced frequently, often with claims about unique features that distinguish these usually more expensive products from existing compounds. Often these drugs share many properties with existing drugs. The role that any new antimicrobial will play can only be determined over time, during which new or previously unrecognized side effects might be described and the clinical efficacy established. Clinical trials may not be confirmed in the larger number of patients subsequently treated in practice. Because this may take many years, a conservative approach to using new antibiotics seems fitting, especially because their costs are often higher, and appropriate antimicrobial choices for most common infections already exist. It is appropriate to ask if a new antimicrobial has been proved to be as effective as (or

more effective than) the current drug of choice, and whether its side effects are comparable (or less common) and its cost reasonable. The withdrawal of moxalactam and caution regarding use of trovafloxacin due to unexpected serious side effects, which were not anticipated despite extensive premarket testing, highlight the caution necessary before using new antimicrobials. The heavy marketing of new cephalosporins and fluoroquinolones, which are very similar to existing drugs, is typical of the difficulty in evaluating antimicrobials.

The development of new antibiotics is important as a response to the emergence of resistant organisms and for treatment of infections that are clinically difficult to treat (eg, viruses, fungi, and some resistant bacteria). Fortunately these infections are either rare or (usually) self-limited in immunocompetent hosts.

PROPHYLACTIC ANTIMICROBIAL AGENTS

Antimicrobials can be used to decrease the incidence of postoperative infections (Table 37-7). A dose of an anti-

Table 37-4. Guidelines for use of common parenteral antibacterial agents^a in children age 1 month or older.

Agent	Route	Dose ^b (mg/kg/d)	Maximum Daily Dose	Interval (hours)	Adjustment ^c	Blood Levels ^d (mcg/mL)	
						Peak	Trough
Amikacin	IM, IV	15-22.5	1.5 g	8	R	15-25	< 10
Ampicillin	IM, IV	100-400	12 g	4-6	R

Tetracycline ^d	25-50 ^e	6	Teeth stained < 9 years
Trimethoprim-sulfamethoxazole	8-12 (TMP)	12	Stevens-Johnson syndrome

^aNot including some newly released drugs, ones not recommended for use in children, or ones not widely used.

^bAlways consult package insert for complete prescribing information. Dosage may differ for alternative routes, newborns (see Table 37-6), or patients with liver or renal failure (see Table 37-4, Adjustment column) and may not be recommended for use in pregnant women or newborns. Maximum dosage may be indicated only in severe infections or by parenteral routes.

^cHigher dose amoxicillin indicated for therapy of otitis media in regions where rates of penicillin-resistant *Streptococcus pneumoniae* are high.

^dUse with caution in children younger than age 9 years because of tooth staining with repeated doses.

^ePreparation-dependent.

crobal given 30 minutes to 2 hours prior to surgery can reduce postoperative wound infection. The goal is to achieve high levels in the serum at the time of incision and by this means—along with good surgical technique—to minimize viable bacterial contamination of the wound. During a

lengthy procedure, a second dose may be given. No evidence exists that multiple subsequent doses of antimicrobials confer additional benefit. The antimicrobial(s) used for prophylaxis are directed toward the flora that most commonly cause postoperative infection at a given anatomic site. Gram-

^aNeonates weighting < 1200 g may require even smaller doses. Antibiotic levels should be closely monitored.

^bPenicillin dosages are in units/kg/d. Other preparations (eg, benzathine penicillin) may be given IM. See specific diseases for dosage.

^cTarget peak and trough vancomycin levels are not well correlated with either toxicity or outcome.

positive cocci such as *S aureus* are usually targeted, and a first-generation cephalosporin (eg, cefazolin) is a cost-effective choice. Third-generation cephalosporins and other broad-spectrum agents are more expensive and offer less benefit because they are less active than cefazolin against *S aureus*. Cefoxitin or cefotetan is useful for procedures such as colorectal surgery, although cefazolin is appropriate for most gynecologic patients. In colorectal surgery, orally administered antimicrobials such as neomycin and erythromycin may be as effective as parenteral antimicrobials.

In hospitals where the predominant *S aureus* strains are methicillin-resistant or in cases where the patient is allergic to penicillin and cephalosporins, vancomycin can be considered. However, prophylactic vancomycin has caused hypotension at the time of induction of general anesthesia. Frequent use of vancomycin as a prophylactic antimicrobial will contribute to the development of vancomycin-resistant strains such as *Enterococcus faecalis*. For these reasons, vancomycin should generally not be used for prophylaxis,

although it might prove useful for individual patients at extremely high risk.

Prophylactic antimicrobials are given in several other circumstances. Endocarditis prophylaxis is indicated during dental and colorectal or genitourinary procedures in patients with high-risk heart lesions, such as prosthetic cardiac valves, surgically corrected systemic pulmonary shunts, and mitral valve prolapse with regurgitation. Patients with indwelling vascular catheters, such as Broviac catheters, should receive prophylaxis during similar procedures, which are likely to induce a transient bacteremia. Prophylaxis against infection with group A streptococci reduces the recurrence rate for acute rheumatic fever. Postexposure prophylaxis is given after exposure to pertussis, *Haemophilus influenzae* type b (Hib) infection (depending on age), meningococcus, gonococcus, tuberculosis (household exposure), plague, aerosolized tularemia or anthrax, and other high-risk infections. Family or close contacts of patients with severe invasive streptococcal disease may benefit from prophylaxis. Silver nitrate, erythromycin, povidone-iodine, and tetra-

Table 37-7. Antimicrobial prophylaxis and preferred prophylactic agents: Selected conditions and pathogens.^a

Pathogen (Indication)	Prophylactic Agent
<i>Bacillus anthracis</i> ^b	Amoxicillin (if proved susceptible), ciprofloxacin, doxycycline
Bacterial endocarditis ^c	Ampicillin, ampicillin and gentamicin, amoxicillin, or other approved regimens
<i>Bordetella pertussis</i> (exposure to respiratory secretions)	Azithromycin, clarithromycin, erythromycin
<i>Chlamydia trachomatis</i> (genital contact)	Erythromycin
<i>Haemophilus influenzae</i> type b ^d (household exposure)	Rifampin
<i>Mycobacterium tuberculosis</i> (household exposure)	Isoniazid
<i>Neisseria meningitidis</i> (household exposure)	Rifampin, sulfadiazine, ^e ciprofloxacin
<i>Neisseria gonorrhoeae</i> (ophthalmia neonatorum)	Erythromycin, silver nitrate ophthalmic
<i>N gonorrhoeae</i> (sexual contact)	Ceftriaxone, cefixime, cefpodoxime
<i>Treponema pallidum</i> (sexual contact)	Penicillin
<i>Streptococcus pneumoniae</i> (sickle cell disease, asplenia)	Penicillin
Postoperative wound infection ^f	Cefazolin, other regimens ^f
Group A streptococci (rheumatic fever) ^g	Benzathine penicillin G, penicillin, sulfadiazine
Group B streptococcal sepsis	Ampicillin to mother prior to delivery
Pneumonic <i>Yersinia pestis</i> ^h (exposure)	Tetracycline ⁱ
<i>Francisella tularensis</i> ^h (aerosolized exposure)	Tetracycline ⁱ
<i>Vibrio cholera</i>	Tetracycline, ^j trimethoprim-sulfamethoxazole
Recurrent urinary tract infection	Nitrofurantoin, trimethoprim-sulfamethoxazole
<i>Pneumocystis jiroveci</i> (formerly <i>Pneumocystis carinii</i>)—(HIV, some immunocompromised patients)	Atovaquone, clindamycin-primaquine, dapsone, trimethoprim-sulfamethoxazole, pentamidine

^aDecisions for prophylaxis must take a number of factors into account, including the evidence for efficacy of therapy, the degree of the exposure to an infecting agent, the risk and consequences of infection, the susceptibility of the infecting agent to antimicrobials, and the patient's ability to tolerate and comply with the antimicrobial agent. See individual chapters of the text for discussion.

^bDecisions for prophylaxis should be made in accordance with the responsible public health department recommendations.

^cSee discussion in Chapter 19 (Cardiovascular Diseases).

^dProphylaxis provided to family if contacts include children younger than age 4 years. Some experts provide prophylaxis in day care settings after one case and some after two cases of *H influenzae* type B infection.

^eOnly for known sulfadiazine-susceptible strains.

^fAlternative regimens may be used, depending on the site of surgery and the degree of contamination.

^gOral prophylaxis may be indicated in some patients. Alternative regimens indicated for penicillin-allergic patients. See discussion in chapter.

^hProphylaxis not well established. Carefully assess risk on a case-by-case basis.

ⁱUsually not indicated for children younger than age 9 years because of tooth staining with repeated doses.

cycline can be used in ophthalmic preparations for prevention of gonococcal ophthalmia neonatorum. Children with asplenia or sickle cell disease receive prophylactic penicillin to protect against overwhelming *S pneumoniae* sepsis, usually started immediately with the onset of fever.

Prophylactic antimicrobials are sometimes used for some children at high risk for recurrent urinary tract infection, but the rate of infection is not decreased in recent studies.

INITIAL EMPIRIC ANTIMICROBIAL CHOICES FOR SELECTED CONDITIONS

General recommendations for specific conditions are as follows. A specific selection depends on the patient's age, diagno-

sis, site of infection, severity of illness, antimicrobial susceptibility of bacterial isolates, and history of drug allergy. Always consult the package insert for detailed prescribing information. Tables 37-2 to 37-6 include further information.

Neonatal Sepsis & Meningitis

The newborn with sepsis may have signs of focal infection, such as pneumonia or respiratory distress syndrome, or may have subtle nonfocal signs. Group B streptococci, *Escherichia coli*, other gram-negative rods, and *Listeria monocytogenes* are commonly encountered. Ampicillin and gentamicin (or another aminoglycoside) are preferred. If meningitis is present, many clinicians substitute a third-generation cephalosporin for the

aminoglycoside. *S pneumoniae* is an uncommon cause of meningitis in neonates. However, if the Gram stain shows gram-positive cocci suggesting *S pneumoniae*, substitution of vancomycin for ampicillin should be considered. In the newborn with cellulitis, *S aureus* including methicillin-resistant *S aureus* (MRSA) and group A streptococci are additional considerations. Nafcillin, oxacillin, or a first-generation cephalosporin is usually added. Vancomycin is added if MRSA is common. Omphalitis is often polymicrobial, and *Enterococcus* species, gram-negative aerobes, and anaerobes may be causative. Clindamycin, ampicillin, and an aminoglycoside or cefotaxime cover the most likely organisms; early surgical intervention is indicated.

Sepsis in an Infant

S pneumoniae and *Neisseria meningitidis* are most commonly encountered in infants. Hib infection may occur in unimmunized children. A third-generation cephalosporin is appropriate. Intermediate-level penicillin and cephalosporin resistance in *S pneumoniae* usually do not cause therapy to fail unless meningitis or another difficult-to-treat infection, such as endocarditis or osteomyelitis is present.

Occult bacteremia may be encountered in young infants with high fever. Prior to immunization with vaccines effective against Hib, persistent bacteremia and complications including meningitis were seen in approximately 50% of children infected with occult Hib bacteremia. With widespread use of Hib vaccine, Hib is a very uncommon cause of occult bacteremia in young children with fever. Similarly, prior to the introduction of the 7-valent conjugate pneumococcal (PCV7) vaccine, *S pneumoniae* bacteremia was demonstrated in 3–5% of infants aged 3–36 months with fever of 39°C or greater, no identified source for fever on examination, and white blood cell count (WBC) of 15,000/mm³. The risk of bacteremia increased to 6–10% in younger children with progressively high fever and high WBCs. The risk of developing meningitis due to persistent *S pneumoniae* is estimated at 3% of those who are known to be bacteremic. The risk of *S pneumoniae* bacteremia and its complications is significantly reduced in children immunized with the PCV7 vaccine. In clinical trials and subsequent nationally surveillance for the incidence of disease, this vaccine reduced the incidence of invasive pneumococcal diseases by approximately 90%. Observation without antimicrobials, but with appropriate plans for follow-up examinations, is appropriate for most febrile young children who are fully immunized.

Nosocomial Sepsis

Many bacterial pathogens can cause infection in hospitalized patients. Recent local experience is usually the best guide to etiologic diagnosis. For example, some intensive care units experience frequent infections due to *Enterobacter cloacae*, whereas in other units *Klebsiella pneumoniae* is the most common nosocomial isolate. Initial therapy should include antibiotics effective for MRSA and resistant *Pseudomonas*

aeruginosa if these are frequent isolates. *E faecalis* is a common cause of nosocomial bacteremia in patients with central catheters, particularly in units where cephalosporins are heavily used. Coagulase-negative staphylococci are commonly isolated from patients with indwelling central catheters. In seriously ill patients, when the local experience suggests that *Enterococcus* species or coagulase-negative staphylococci are common, the initial regimen should include vancomycin. Because *Enterococcus* species and coagulase-negative staphylococci commonly cause fever without significant morbidity or mortality, initial regimens without vancomycin are appropriate, with adjustment of treatment after susceptibility is known. If *P aeruginosa* or other resistant gram-negative rods are common, ceftazidime or cefepime should be included in initial therapy.

Meningitis

Bacterial meningitis in neonates is usually caused by infection with group B streptococci, *E coli*, other gram-negative rods, or *L monocytogenes*. A combination of ampicillin and gentamicin or another aminoglycoside—or ampicillin and a third-generation cephalosporin—is started initially. In an infant or older child, *S pneumoniae* or *N meningitidis* are the most common isolates. As previously noted, Hib is uncommon now because of widespread immunization. Increasingly, *S pneumoniae* with multiple resistances to penicillin, cephalosporins, and other drugs is isolated. In many communities, 30–40% of *S pneumoniae* isolates have intermediate susceptibility to penicillin (MIC between 0.1 and 2 mcg/mL), and 5–10% of isolates may be highly resistant to penicillin (MIC > 2 mcg/mL). Resistance to a third-generation cephalosporin (MIC > 2 mcg/mL) may occur in 3–5% of isolates.

In bacterial meningitis, peak CSF antimicrobial concentrations 10 or more times greater than the MIC of the organism are desirable, but this may be difficult to achieve if organisms are resistant. The therapeutic problem is complicated if dexamethasone, which reduces the entry of some antimicrobials into the CSF, is also given.

Initial therapy of bacterial meningitis in an older child thus should include vancomycin and a third-generation cephalosporin. Alternatively, meropenem has also been successful. A lumbar puncture should be considered 24–48 hours after the start of therapy to assess the sterility of the CSF. Rifampin should be added if the Gram stain or cultures of CSF are positive on repeated lumbar puncture, if the child has failed to improve, or if an organism with a very high MIC to ceftriaxone is isolated. The optimal therapy of highly resistant *S pneumoniae* meningitis is not well established by clinical data.

Meningitis in a child with a ventriculoperitoneal shunt is most commonly caused by coagulase-negative staphylococci, many of which are methicillin-resistant, and *Corynebacterium* species, which are resistant to many antimicrobials. In many of these patients who are not seriously ill, therapy should be postponed while awaiting the appropriate shunt fluid for Gram stain and culture. Seriously ill patients should initially be given vancomycin and a third-generation cepha-

losporin, because *S aureus* and gram-negative rods are also possible and can cause serious infection.

Urinary Tract Infection

E coli is the most common isolate from the urinary tract. Outpatients with symptoms of lower urinary tract disease or with mild illness can be given ampicillin, cephalexin, or trimethoprim-sulfamethoxazole (TMP-SMX). Local experience and resistance rates should guide initial therapy. In selected patients with pyelonephritis, outpatient therapy is effective using parenteral aminoglycosides or ceftriaxone once per day. Oral cefixime has been used in place of ceftriaxone for outpatient therapy. Ciprofloxacin has been approved by the U.S. Food and Drug Administration (FDA) for therapy of urinary tract infection in children older than 1 year, but it should be reserved for complicated cases. For hospitalized patients with genitourinary tract infection and suspected bacteremia, ampicillin and gentamicin or a third-generation cephalosporin is appropriate. Gram stain should be used to guide the initial choice. For patients with known or suspected resistant organisms, such as *P aeruginosa*, or for patients with urosepsis, an aminoglycoside and ceftazidime, cefepime, or ticarcillin may be started. Unit-specific data on typical bacterial species and their patterns of susceptibility should guide the antimicrobial choice for nosocomial urinary tract infections.

Bacterial Pneumonia

Bacterial pneumonia in newborns generally should be treated with the same antimicrobial choices as sepsis. Infants and older children are frequently infected with *S pneumoniae*. Ampicillin and amoxicillin are effective in most patients eligible for outpatient therapy. Children who require hospitalization may benefit from a second- or third-generation cephalosporin. The broader initial coverage is indicated because of the greater severity of disease. A rapidly progressive pneumonia, with pneumatoceles or large pleural effusions, may be due to MRSA or group A streptococci, Hib, or another gram-negative rod. Vancomycin should be used in addition to a third-generation cephalosporin.

Children aged 6 years and older frequently have infection with *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, or *S pneumoniae*. Erythromycin, clarithromycin, or azithromycin is usually indicated for initial empiric therapy.

Skin & Soft Tissue Infections

S aureus and *Streptococcus pyogenes* are the most common causes of skin and soft tissue infections (SSTIs) in children. Community-acquired MRSA infections are common in many communities and complicate clinical decision making. Culture and susceptibility testing of abscesses, cellulitis, and more serious SSTIs is very important for optimal clinical management. Children with cellulitis more commonly have infection with group A streptococci, and empiric outpatient therapy with cephalexin or dicloxacillin is preferred. Children with small (< 5 cm) abscesses usually are effectively treated with incision

and drainage without an antimicrobial. Outpatient therapy of large (> 5 cm) abscesses includes incision and drainage and empiric clindamycin or TMP-SMX depending on local susceptibility patterns. Group A streptococcal infections are not adequately treated with TMP-SMX. However, in many communities, 50% or more of MRSA isolates are also resistant to clindamycin, fluoroquinolones, and erythromycin. Adequate cultures, the thoroughness of drainage procedures, and careful outpatient follow-up are needed to ensure optimal outcomes.

SPECIFIC ANTIMICROBIAL AGENTS

PENICILLINS

Aminopenicillins

Penicillin remains the drug of choice for streptococcal infections, acute rheumatic fever prophylaxis, syphilis, oral anaerobic infections, dental infections, *N meningitidis* infection, leptospirosis, rat-bite fever, actinomycosis, and infections due to *Clostridium* and *Bacillus* species. For oral therapy of minor infections, amoxicillin or ampicillin is usually equivalent. For systemic therapy, aqueous penicillin G is preferable. For treatment of streptococcal pharyngitis, some experts recommend a first-generation cephalosporin. Amoxicillin is preferred for oral therapy of Lyme disease in children. For dog or cat bites, where *Pasteurella multocida* is commonly encountered, amoxicillin-clavulanate provides good coverage of *Pasteurella* as well as *Staphylococcus*. An alternative is separate prescriptions for penicillin and an antistaphylococcal drug such as cephalexin, or clindamycin and TMP-SMX in penicillin-allergic patients. For human bites, amoxicillin-clavulanate provides adequate therapy for *Eikenella corrodens* and other mixed oral aerobes and anaerobes. The β -lactamase inhibitor sulbactam combined with ampicillin is given parenterally for human and animal bites, and some other infections due to organisms from the oral flora, in which mixed aerobic and anaerobic bacteria may be resistant to ampicillin due to β -lactamase production.

Penicillinase-Resistant Penicillins

S aureus is usually resistant to penicillin and amoxicillin owing to penicillinase production. Nafcillin, oxacillin, methicillin, and first- and second-generation cephalosporins are stable to penicillinase and are usually equivalent for intravenous therapy. Methicillin is associated with more frequent interstitial nephritis. Oxacillin and methicillin are renally excreted, whereas nafcillin is excreted through the biliary tract. These properties are occasionally considered in children with renal or liver failure. Cost should usually be the deciding factor for choosing an agent. Often both *S aureus* and *S pyogenes* are suspected initially (eg, in cellulitis or postoperative wound infections). The penicillinase-resistant penicillins (PRPs) and first- and second-generation cephalosporins are efficacious for most streptococcal infections, although penicillin remains the drug of choice.

MRSA is an increasingly common and serious community-acquired infection in children and may cause nosocomial infection. MRSA infections are also resistant to other PRPs and to other cephalosporins. Vancomycin is effective against MRSA and coagulase-negative staphylococci. *S aureus* infections range in severity from minor infections treated on an outpatient basis to life-threatening infections. Severe infections due to MRSA are a serious concern in many communities. It is important to culture and determine antimicrobial susceptibility of suspected *S aureus* infections. In communities with frequent MRSA infections in children, initial therapy of seriously ill children should include vancomycin. MRSA may also be resistant to macrolides and clindamycin by alteration in the bacterial 23S ribosomal RNA. Many strains reported as clindamycin-susceptible and erythromycin-resistant are truly resistant to clindamycin. This inducible resistance to clindamycin may be detected in erythromycin-resistant MRSA that demonstrates a D-zone in disk susceptibility testing to clindamycin. Community-acquired MRSA is more likely to be susceptible to TMP-SMX, clindamycin, and gentamicin than hospital-acquired infections.

For outpatient therapy, cloxacillin, dicloxacillin, and first- or second-generation cephalosporins are usually equally effective for infections due to susceptible *S aureus*. Cost may determine the choice between drugs.

Anti-Pseudomonas Penicillins

Ticarcillin, mezlocillin, and piperacillin are active intravenously against streptococci, ampicillin-susceptible enterococci, *H influenzae*, gram-negative rods (including more resistant gram-negative rods such as *Enterobacter*, *Proteus*, and *Pseudomonas aeruginosa*), and gram-negative anaerobes such as *Bacteroides fragilis*. *P aeruginosa* is inherently resistant to most antimicrobials, and high levels of these drugs are usually required. The combination of ticarcillin and an aminoglycoside is synergistic against *P aeruginosa* and many other enteric gram-negative rods. Ticarcillin in a fixed combination with clavulanic acid that has activity against β -lactamase-producing strains of *Klebsiella*, *S aureus*, and *Bacteroides*. Piperacillin is more active in vitro against many gram-negative enteric infections and may be advantageous in some circumstances, but it is not FDA-approved in children. Piperacillin-tazobactam is another combination antimicrobial and β -lactamase inhibitor that has enhanced activity against many β -lactamase producers.

Antipseudomonal penicillins cause the same toxicities as penicillin and therefore are usually very safe. Carbenicillin, ticarcillin, and piperacillin contain large amounts of sodium, which may cause problems for some patients with cardiac or renal disease.

GLYCOPEPTIDE AGENTS

Vancomycin and teicoplanin are glycopeptide antimicrobial agents active against the cell wall of gram-positive organisms. Only vancomycin is licensed in the United States. Vancomycin

is useful for parenteral therapy of resistant gram-positive cocci such as penicillin- and cephalosporin-resistant *S pneumoniae*, MRSA, methicillin-resistant coagulase-negative staphylococci, and ampicillin-resistant enterococci. Vancomycin is also used orally for therapy of colitis due to *Clostridium difficile*, although it should not be used as the drug of first choice.

The empiric use of vancomycin has increased tremendously over the last several years. As a result, vancomycin-resistant enterococci (VRE) and coagulase-negative staphylococci have become problems, particularly in inpatient units, intensive care units, and oncology wards. *S aureus* with increased MICs to vancomycin has been reported in the United States and Japan. This resistance is of concern because of the inherent virulence of many *S aureus* strains. Vancomycin use should be monitored carefully in hospitals and their intensive care units. It should not be used empirically when an infection is mild or when other antimicrobial agents are likely to be effective. Vancomycin should be stopped promptly if infection is found to be due to organisms susceptible to other antimicrobials. Infection control guidelines for prevention of spread of VRE are published by the Centers for Disease Control and Prevention.

Rapid infusion of vancomycin is associated with the “red man syndrome,” characterized by diffuse red flushing, at times pruritus, and occasionally tachycardia and hypotension. As a result, vancomycin is infused slowly over 1 hour or longer in some cases. Diphenhydramine or hydrocortisone (or both) may also be used as premedication.

Measurement of peak-and-trough serum vancomycin concentrations is not necessary in most clinical situations, because the levels achieved with standard dosing are usually predictable and nontoxic. Measurement of serum concentrations is helpful in patients with abnormal or unpredictable renal function; in those with altered volume of distribution, as occurs in nephrotic syndrome or shock; and in those receiving higher-dose therapy (eg, for meningitis or other difficult-to-treat infections). For patients receiving antimicrobials for weeks to months, weekly monitoring of clinical signs and symptoms and of urinalysis, creatinine, and complete blood count will allow detection of toxicity.

OXAZOLIDINONES

Linezolid is the first drug in this new class of antimicrobials which have a distinct new mechanism of action; they bind to the 50s-ribosomal RNA subunit and prevent initiation of protein synthesis. Because of this unique mechanism, there is no cross-resistance with other classes of antimicrobials. The in-vitro development of resistance has also been uncommon.

Linezolid is active against aerobic gram-positive organisms, including streptococci, staphylococci, enterococci, and pneumococci. Because linezolid is active against gram-positive organisms resistant to other antimicrobials (eg, MRSA, methicillin-resistant, coagulase-negative staphylococci, VRE, and penicillin-resistant *S pneumoniae*), it is useful for these difficult-to-treat infections.

Linezolid is safe and well tolerated in children. Gastrointestinal symptoms are the most commonly encountered side effect. Neutropenia and thrombocytopenia have been reported, and linezolid should therefore be used with monitoring in patients at increased risk for these problems or in patients receiving therapy for 2 weeks or longer. Linezolid is an inhibitor of monoamine oxidase (MAO) and should not be used in patients taking MAO inhibitors, or in patients taking phenylpropanolamine or pseudoephedrine.

Linezolid should be used only for infections due to a proven gram-positive pathogen that is known or strongly suspected to be resistant to other available agents.

QUINUPRISTIN–DALFOPRISTIN

Quinupristin and dalfopristin are two antimicrobials of the streptogramin class, which individually are bacteriostatic, but in combination are synergistic and bacteriocidal. These drugs are combined in a fixed ratio of 70:30, known as Synercid. Streptogramins inhibit protein synthesis by binding to the 50s ribosomal subunit. The streptogramins were discovered many years ago, but interest has increased only recently due to the activity of these agents against some very difficult-to-treat gram-positive infections.

The quinupristin–dalfopristin combination has activity against staphylococci, streptococci, pneumococci, and some enterococci. Quinupristin–dalfopristin is primarily indicated for serious infections due to vancomycin-resistant *Enterococcus faecium* and MRSA. Quinupristin–dalfopristin is not active against *E faecalis* and, therefore, differentiation of these strains from *E faecium* is important prior to initiating therapy.

Quinupristin–dalfopristin is not approved for therapy in children. Nonetheless, therapy has been initiated under a compassionate release program in some pediatric patients seriously ill with difficult-to-treat infections due to resistant organisms.

Arthralgias and myalgias have at times been severe in adult patients. Other significant side effects include elevated bilirubin and inflammation at intravenous sites.

Quinupristin–dalfopristin is a significant inhibitor of CYP-450 3A4 and, therefore, must be used with caution in patients receiving drugs metabolized by this mechanism (eg, clarithromycin, itraconazole, erythromycin, and many others).

The use of quinupristin–dalfopristin should be limited to serious infections due to proven *E faecium* or *S aureus* infections, or infections due to proven gram-positive cocci that are resistant to other agents.

CEPHALOSPORINS

Cephalosporin agents make up a large and often confusing group of antimicrobials. Many of these drugs are similar in antibacterial spectrum and side effects and may have similar names. Clinicians should learn well the properties of one or two drugs in each class. Cephalosporins are often grouped as “generations” to signify their similar antimicrobial activity. First-generation cephalosporins such as cefazolin intrave-

nously and cephalexin orally are useful mainly for susceptible *S aureus* infection and urinary tract infection due to susceptible *E coli*. Second-generation cephalosporins, such as cefuroxime intravenously and cefprozil and cefuroxime orally, have somewhat reduced, but acceptable, activity against gram-positive cocci, and greater activity against some gram-negative rods compared with first generation cephalosporins. They are active against *H influenzae* and *Moraxella catarrhalis*, including strains that produce β -lactamase capable of inactivating ampicillin. Third-generation cephalosporins have substantially less activity against gram-positive cocci, such as *S aureus*, but greatly augmented activity against aerobic gram-negative rods. Cefotaxime and ceftriaxone are examples of intravenous drugs, whereas cefpodoxime and cefitibuten are representative oral drugs. Cefepime is a new antimicrobial often described as fourth-generation because of its broad activity against gram-positive and gram-negative organisms, including *P aeruginosa*. Cefepime is stable to β -lactamase degradation and is a poor inducer of β -lactamase. Cefepime will be most useful for organisms resistant to other drugs. Cefepime is not approved for use in children younger than age 2 months.

No cephalosporin agent has substantial activity against *L monocytogenes*, enterococci, or MRSA. The only cephalosporins useful for treating anaerobic infections are cefoxitin and cefotetan, which are second-generation cephalosporins with excellent activity against *B fragilis*. Ceftazidime is a third-generation cephalosporin with appreciable activity against *P aeruginosa*.

Allergy to β -lactam antimicrobials is reported commonly by parents. Immediate hypersensitivity reactions, including anaphylaxis or hives, most commonly predict true allergy. In contrast, many delayed reactions and nonspecific rashes are likely due to the underlying infection or nonallergic reactions. (See Chapter 36.) Cephalosporins should be used with caution in children with immediate hypersensitivity reactions to penicillins or cephalosporins.

Resistance to cephalosporins is common among aerobic gram-negative rods. The presence of inducible cephalosporinases in some gram-negative rod organisms, such as *P aeruginosa*, *Serratia marcescens*, *Citrobacter*, and *Enterobacter*, has led to clinical failures because of the emergence of resistance during therapy. Extended-spectrum β -lactamases mediate broad resistance to all penicillins, aminopenicillins, cephalosporins, and monobactams. Carbapenems, fluoroquinolones, or combinations including these drugs are used for serious infections due to gram-negative organisms with these enzymes. Active laboratory-based surveillance is necessary to detect resistance in these gram-negative organisms.

AZTREONAM

Aztreonam is the only monobactam antimicrobial agent approved in the United States. Although it is not approved for use in children younger than age 9 months, there is considerable pediatric experience with its use, including in neonates and premature infants. Aztreonam is active against aerobic

gram-negative rods, including *P aeruginosa*. Aztreonam has activity against *H influenzae* and *M catarrhalis*, including those that are β -lactamase producers. Most patients with allergy to penicillin or cephalosporins are not sensitized to aztreonam, except that children with prior reactions to ceftazidime may have reactions to aztreonam because aztreonam and ceftazidime have a common side chain.

CARBAPENEMS

Meropenem, ertapenem, and imipenem are broad-spectrum β -lactam antimicrobials. Imipenem–cilastatin is a combination of an active antibiotic and cilastatin, which inhibits the metabolism of imipenem in the kidney and thereby results in high serum and urine levels of imipenem. These carbapenems are also active against *S pneumoniae*, including many penicillin-resistant and cephalosporin-resistant strains. Carbapenems have been used successfully to treat meningitis and may be considered if vancomycin is not tolerated. An increased frequency of seizures is encountered when central nervous system infections are treated with carbapenems. These agents are broadly active against streptococci, MRSA, some enterococci, and gram-negative rods such as *P aeruginosa*, β -lactamase-producing *H influenzae*, and gram-negative anaerobes. Ertapenem has less activity against *P aeruginosa*, *Acinetobacter* species, and *Enterococcus* species than meropenem and imipenem. Because carbapenems are active against so many species of bacteria, there is a strong temptation to use them as single-drug empiric therapy. Units that have used carbapenems heavily have encountered resistance in many different species of gram-negative rods.

MACROLIDES & AZILIDES

Erythromycin was once the most commonly used macrolide antimicrobial agent but now azithromycin and clarithromycin are often preferred because of decreased side effects. It is active against many bacteria that are resistant to cell wall-active antimicrobials and is the drug of choice for *Bordetella pertussis*, *Legionella pneumophila*, *C pneumoniae*, *M pneumoniae*, and *Chlamydia trachomatis* infections (in children in whom tetracycline is not an option). Erythromycin is used for outpatient therapy of streptococcal and staphylococcal infections in patients with penicillin allergy. More serious infections due to streptococci and staphylococci are usually treated with penicillins, clindamycin, PRPs, or cephalosporins because of a significant incidence of erythromycin resistance in both species. *S pneumoniae* resistant to erythromycin and the related macrolides are now frequent in many communities. This limits the ability of macrolide antimicrobials for therapy of otitis media and sinusitis. Gastrointestinal side effects are common. Interactions with theophylline, carbamazepine, terfenadine, cycloserine, and other drugs may require dosage modifications of erythromycin and clarithromycin. Significant interactions with azithromycin are less common. Erythromycin exposure is associated with

pyloric stenosis in newborns, so azithromycin is preferred in most neonates.

Erythromycin is available in many formulations, including the base, estolate, ethyl succinate, and stearate. Transient hepatic toxicity occurs in adults, but is much less common in children. Erythromycin base and stearate should be taken with meals for best absorption.

Clarithromycin and azithromycin, macrolide and azalide antimicrobials, respectively, are much less likely than erythromycin to cause nausea, vomiting, and diarrhea. These agents are useful in children who cannot tolerate erythromycin. Clarithromycin is more active than erythromycin against *H influenzae*, *M catarrhalis*, and *Neisseria gonorrhoeae* and is the drug of choice, usually in combination, for some nontuberculous mycobacterial infections. Azithromycin has a prolonged tissue half-life that achieves a prolonged antimicrobial effect. Azithromycin is dosed once daily for 5 days, but must be taken 1 hour before or 2 hours after meals because food interferes with absorption. Although azithromycin is active against *H influenzae*, some authors report poor eradication of *H influenzae* from the middle ear. Azithromycin can be used for single-dose therapy of *C trachomatis* infections. It is beneficial in adolescents when compliance with erythromycin or tetracycline is a concern. Azithromycin is useful for therapy of *Shigella* and *Salmonella* infections, including typhoid fever resistant to ampicillin and TMP–SMX. Alternatives include third-generation cephalosporins and fluoroquinolones. Clarithromycin is effective against Lyme disease, but 7 days of azithromycin for that indication was inferior to amoxicillin. Clarithromycin and azithromycin are alternative drugs for toxoplasmosis in sulfonamide-allergic patients and as alternatives to erythromycin in legionellosis. In-vitro and limited clinical experience in providing treatment to contacts of pertussis patients suggests efficacy equal to that of erythromycin. Clarithromycin and azithromycin are considerably more expensive than most erythromycin formulations, which for that reason are usually preferred, but they are advantageous by virtue of their twice-daily and once-daily dosing, respectively. Some failures of the newer macrolides have occurred in *S pneumoniae* sepsis and meningitis, perhaps because of low serum levels despite the high tissue levels achieved. High rates of resistance to macrolides and azalides have been encountered in some communities. The frequent use of azithromycin for respiratory infections and acute otitis media has contributed to selection of resistant strains.

CLINDAMYCIN

Clindamycin is active against *S aureus*, some MRSA, *S pyogenes*, other streptococcal species except enterococci, and both gram-positive and gram-negative anaerobes. Clindamycin or metronidazole is frequently combined with other antimicrobials for empiric therapy of suspected anaerobic or mixed anaerobic and aerobic infections. Empiric use of clindamycin is justified in suspected anaerobic infections because cultures frequently cannot be obtained and, if

obtained, may be slow in confirming anaerobic infection. Examples are pelvic inflammatory disease, necrotizing enterocolitis, other infections in which the integrity of the gastrointestinal or genitourinary tracts is compromised, and sinusitis. Clindamycin does not achieve high levels in CSF, but brain abscesses, toxoplasmosis, and other central nervous system infections, where disruption of the blood-brain barrier occurs, may be successfully treated with clindamycin. Clindamycin should be added to regimens for treatment of serious streptococcal and staphylococcal infections, such as necrotizing fasciitis and toxic shock syndrome. Both in-vitro and clinical data suggest increased bactericidal killing and improved outcomes occur with clindamycin. For most oral anaerobes (eg, in a dental abscess), penicillin is more active than clindamycin. Clindamycin has been associated with the occurrence of *C difficile*-related pseudomembranous colitis. Although diarrhea is a frequent side effect, pseudomembranous colitis is uncommonly due to clindamycin in children.

SULFONAMIDES

Sulfonamides—the oldest class of antimicrobials—remain useful for treatment of urinary tract infections. They are used also for other infections due to *E coli* and for *Nocardia*. Although useful for rheumatic fever prophylaxis in penicillin-allergic patients, sulfonamides fail to eradicate group A streptococci and cannot be used for treatment of acute infections.

TMP-SMX is a fixed combination that is more active than either drug alone. Gram-positive cocci, including some *S pneumoniae*, many staphylococci, *Haemophilus*, and many gram-negative rods, are susceptible. Unfortunately, resistance to TMP-SMX has become more common. *S pneumoniae* resistant to penicillin and cephalosporins is often also resistant to TMP-SMX and erythromycin. In some communities, *Shigella* and *Salmonella enteritidis* strains remain susceptible, as do most *E coli*. TMP-SMX is therefore very useful for treatment of urinary tract infections and bacterial dysentery. TMP-SMX is also the drug of choice for treatment or prophylaxis against *Pneumocystis jiroveci* infection. Dermatologic and myelosuppressive side effects limit the use of TMP-SMX in some children infected with HIV.

Sulfonamide is associated with several cutaneous reactions, including urticaria, photosensitivity, Stevens-Johnson syndrome, purpura, and maculopapular rashes. Hematologic side effects such as leukopenia, thrombocytopenia, and hemolytic anemia are uncommon. Common gastrointestinal side effects are nausea and vomiting. The dermatologic and hematologic side effects are thought to be more common and more severe with TMP-SMX than with sulfonamide alone.

TETRACYCLINES

Tetracyclines, which are effective against a broad range of bacteria, are not commonly used in children because alternative effective drugs are available. Many different tetracycline

formulations are available. Tetracyclines are effective against *B pertussis* and *E coli* and many species of *Rickettsia*, *Chlamydia*, and *Mycoplasma*. Doxycycline or minocycline is the drug of choice for eradication of *C trachomatis* in pelvic inflammatory disease and nongonococcal urethritis.

Staining of permanent teeth was noted in young children given repeated courses of tetracyclines. As a result, tetracyclines are generally not given to children younger than age 9 years unless alternative drugs are unavailable. A single course of tetracycline does not pose a significant risk of tooth staining. Mucous membrane candidiasis, photosensitivity, nausea, and vomiting are other common side effects. Tetracycline should be taken on an empty stomach, either 1 hour before or 2 hours after a meal. Doxycycline is well absorbed even in the presence of food; administration with food may minimize gastrointestinal side effects. Doxycycline is often preferred because it is better tolerated than tetracycline, and twice-daily administration is convenient.

Tetracycline is used for therapy of rickettsial infections such as Rocky Mountain spotted fever, ehrlichiosis, rickettsialpox, murine typhus, and Q fever; as an alternative to erythromycin for *M pneumoniae* and *C pneumoniae* infections; and for treatment of psittacosis, brucellosis, *P multocida* infection, and relapsing fever.

Tigecycline is a new polyketide antimicrobial that is an analogue of tetracycline and a bacteriostatic inhibitor of protein synthesis. Tigecycline is active against gram-negative aerobes, anaerobes, and many gram-positive cocci including MRSA. It is approved for intravenous therapy of adults with complicated SSTIs and complicated intra-abdominal infections.

AMINOGLYCOSIDES

The aminoglycosides bind to ribosomal subunits and inhibit protein synthesis. They are active against aerobic gram-negative rods, including *P aeruginosa*. Streptomycin was the first drug in this class, but today it is used only to treat tuberculosis and the occasional cases of plague and tularemia.

Aminoglycosides are used to treat serious gram-negative infections and are given intravenously or intramuscularly. They are also used to treat pyelonephritis, suspected gram-negative sepsis, and in other settings where *P aeruginosa* infections are common, such as cystic fibrosis and burns. Aminoglycosides have activity against gram-positive organisms and, combined with penicillin or ampicillin, may achieve synergistic killing of *L monocytogenes* and group B streptococci. Penicillin, ampicillin, or vancomycin combined with gentamicin is indicated for therapy of serious enterococcal infections, such as sepsis or endocarditis because of more rapid clinical improvement with combined therapy. Aminoglycosides have activity against *S aureus* but are always used in combination with other antistaphylococcal antibiotics.

Aminoglycosides are not active in an acidic environment and may not be effective against abscesses. Aminoglycosides

diffuse poorly into the CSF and achieve only about 10% of serum concentrations. As a result, a third-generation cephalosporin is preferred for treatment of bacillary meningitis.

Aminoglycosides kill bacteria in a concentration-dependent manner. They also have a prolonged suppressive effect on the regrowth of susceptible organisms (postantibiotic effect). These principles have led some investigators to establish guidelines for once-daily dosing of aminoglycosides, using larger initial doses given every 24 hours. Although aminoglycosides are associated with both renal and eighth nerve toxicity, the entry of the drug into renal and cochlear cells is saturable. It therefore was predicted that once-daily dosing would result in less toxicity than traditional twice-daily or three-times-daily dosing. Studies in adult patients confirm that once-daily dosing is as efficacious as traditional dosing and is associated with less toxicity. Although there is extensive experience with dosing intervals of 18–36 hours in premature infants, small total daily doses are customarily used (2.0–2.5 mg/kg per dose of gentamicin or tobramycin). A convenient and cost-effective approach in children is based on the experience with adult patients and uses larger daily doses (4–7 mg/kg per dose every 24 hours). Nevertheless, traditional twice-daily or three-times-daily dosing regimens of aminoglycosides, with monitoring of serum levels, are still widely used. Careful monitoring is necessary, particularly in children with abnormal or changing renal function, premature infants, and infants with rapidly changing volumes of distribution. Aminoglycosides are usually infused over 30–45 minutes, and the peak serum concentration is measured 30–45 minutes after the end of the infusion. A trough serum concentration is measured prior to the next dose. The efficacious and nontoxic serum concentrations for gentamicin and tobramycin are trough less than 2 mcg/mL and peak 5–10 mcg/mL; for amikacin, trough less than 10 mcg/mL and peak 15–25 mcg/mL (see Table 37–4). Aminoglycoside levels and creatinine levels should be measured in children expected to receive more than 3 days of therapy, and repeated weekly in children on long-term therapy, even when renal function is normal and stable.

FLUOROQUINOLONES

Modification of the quinolone structure of nalidixic acid has led to many new compounds called fluoroquinolones, which are well absorbed after oral administration and possess excellent antibacterial activity against resistant gram-negative pathogens. The seven currently available fluoroquinolones vary in their activity against specific organisms. Fluoroquinolones are active against most of the Enterobacteriaceae, including *E coli*, *Enterobacter*, *Klebsiella*, in some cases *P aeruginosa*, and many other gram-negative bacteria such as *H influenzae*, *M catarrhalis*, *N gonorrhoeae*, and *N meningitidis*. Some fluoroquinolones (ofloxacin and levofloxacin) are active against *C trachomatis* and *Mycoplasma*. The fluoroquinolones are active against some enterococci, *S aureus*, MRSA, and coagulase-

negative staphylococci. The newer quinolones have good activity against penicillin and cephalosporin-resistant *S pneumoniae*, but clinical experience in children is limited.

Ciprofloxacin and its otic and ophthalmic preparations are the only fluoroquinolone antimicrobials currently FDA-approved for use in children older than 1 year, although fluoroquinolones offer very attractive alternatives to approved agents. The objection to quinolones is based on the recognition that nalidixic acid and other quinolones cause arthropathy when tested experimentally in newborn animals of many species. The fear that children would also be more susceptible than adults to cartilage injury has not been realized in clinical experience. Both retrospective long-term follow-up studies of children given nalidixic acid and prospective studies of children receiving treatment under protocols with fluoroquinolones have shown similar rates of toxicity compared with adult patients. Arthropathy occurs uncommonly, although tendon rupture is a reported rare, serious complication. For these reasons, quinolones should be considered for use in children when the benefit clearly outweighs the risk, when no alternative drug is available, and after discussion with the parents.

Ciprofloxacin is useful for oral therapy of resistant gram-negative urinary tract infections, such as those caused by *P aeruginosa*. Ofloxacin, levofloxacin, ciprofloxacin, and gatifloxacin are useful for single-dose therapy of uncomplicated gonorrhea, and ofloxacin and levofloxacin are an alternative therapy for treating *Chlamydia* infections and pelvic inflammatory disease. Ciprofloxacin and ofloxacin are used as therapy of resistant cases of shigellosis. Levofloxacin and ciprofloxacin are usually the drugs of choice for treatment of traveler's diarrhea. Ciprofloxacin is useful for treatment of *P aeruginosa* infection in patients with cystic fibrosis, and as therapy for chronic suppurative otitis media. Several quinolones are used as therapy for pneumonia due to *Legionella*, *Mycoplasma*, or *Chlamydia pneumoniae*, although a macrolide is often preferred, and as prophylactic therapy of meningococcal infection. Ofloxacin and levofloxacin are used for treatment of some cases of *Mycobacterium tuberculosis* and some atypical mycobacterial infections.

METRONIDAZOLE

Metronidazole has excellent activity against most anaerobes, particularly gram-negative anaerobes, such as *Bacteroides* and *Fusobacterium*, and against gram-positive anaerobes such as *Clostridium*, *Prevotella*, and *Porphyromonas*. Gram-positive anaerobic cocci such as *Peptococcus* and *Peptostreptococcus* are often more susceptible to penicillin or to clindamycin. Because metronidazole lacks activity against aerobic organisms, it is usually given with one or more other antibiotics. Metronidazole is well absorbed after oral administration and has excellent penetration into the central nervous system. Metronidazole is the drug of choice for bacterial vaginosis and for *C difficile* enterocolitis. It is active against many parasites, including *Giardia lamblia* and *Entamoeba histolytica*.

DAPTOMYCIN

Daptomycin has broad bactericidal activity against gram-positive cocci. Daptomycin is a lipopeptide that binds to bacterial cell membranes, resulting in membrane depolarization and cell death. Daptomycin is active against methicillin-sensitive and -resistant *S aureus*, *S pyogenes*, and *Streptococcus agalactiae*, as well as *E faecium* (including vancomycin-resistant strains), and *E faecalis* (vancomycin-sensitive strains). Daptomycin is given as a once-daily intravenous infusion of 4 mg/kg and is approved for therapy of complicated SSTIs, but has not been sufficiently studied in children younger than 18 years to make recommendations for dosing and use. Daptomycin therapy of pneumonia was unsuccessful in a large percentage of cases, and should not be used. Daptomycin is excreted renally, so a modification of dosing is needed in patients with impaired renal function. Nausea, constipation, and headache are the most common side effects of therapy. In patients with muscle pain, monitoring creatinine phosphokinase levels should be done.

Infections: Viral & Rickettsial

Myron J. Levin, MD
Adriana Weinberg, MD

38

VIRAL INFECTIONS

Viruses cause most pediatric infections. Mixed viral or viral-bacterial infections of the respiratory and intestinal tracts are rather common, as is prolonged asymptomatic shedding of some viruses in childhood. Thus the detection of a virus is not always proof that it is the cause of a given illness. Viruses are often a predisposing factor for bacterial respiratory infections (eg, otitis, sinusitis, and pneumonia).

Many respiratory and herpes viruses can now be detected within 24–48 hours by combining culture and monoclonal antibody techniques (“rapid culture technique”). Diagnosis of many viral illnesses is also possible through antigen or nucleic acid detection techniques. These techniques are more rapid than isolation of viruses in tissue culture and in most cases are equally sensitive or more so. Polymerase chain reaction (PCR) amplification of viral genes has led to recognition of previously undetected infections. New diagnostic tests have changed some basic concepts about viral diseases and made diagnosis of viral infections both more certain and more complex. Only laboratories with excellent quality-control procedures should be used, and the results of new tests must be interpreted cautiously. The availability of specific antiviral agents increases the value of early diagnosis for some serious viral infections. Table 38–1 lists viral agents associated with common clinical signs, and Table 38–2 lists diagnostic tests. The viral diagnostic laboratory should be contacted for details regarding specimen collection, handling, and shipping. Table 38–3 lists common causes of red rashes in children that should be considered in the differential diagnosis of certain viral illnesses.

RESPIRATORY INFECTIONS

Many viral infections cause upper or lower respiratory tract signs and symptoms. Those that produce a predominance of these signs and symptoms are described in the text that follows. Many so-called respiratory viruses can also produce

distinct nonrespiratory disease (eg, enteritis or cystitis caused by adenoviruses; parotitis caused by parainfluenza viruses). Respiratory viruses can cause disease in any area of the respiratory tree. Thus they can cause coryza, pharyngitis, sinusitis, tracheitis, bronchitis, bronchiolitis, and pneumonia—although certain viruses tend to be closely associated with one anatomic area (eg, parainfluenza with croup, respiratory syncytial virus [RSV] with bronchiolitis) or discrete epidemics (eg, influenza, RSV, parainfluenza). Nevertheless it is impossible on clinical grounds to be certain of the viral cause of an infection in a given child. This information is provided by the virology laboratory and is often important for epidemiologic, therapeutic, and preventive reasons. In immunocompromised patients these annoying, but otherwise benign, viruses can cause severe pneumonia.

VIRUSES CAUSING THE COMMON COLD

The common cold syndrome (also called upper respiratory infection) is characterized by combinations of runny nose, nasal congestion, sore throat, tearing, cough, and sneezing. Low-grade fever may be present. The causal agent is usually not sought or determined. Epidemiologic studies indicate that rhinoviruses, which are the most common cause (30–40%), are present throughout the year but are more prevalent in the colder months in temperate climates. Adenoviruses also cause colds in all seasons, but epidemics are common. Respiratory syncytial, parainfluenza, and influenza viruses cause the cold syndrome during epidemics from late fall through winter. Coronaviruses, including the recently identified strains NL63 and HKU1, account for 5–10% of colds in winter. Equally prevalent are other newly identified respiratory viruses such as the human bocavirus, a parvovirus, and the KI polyomavirus. Enteroviruses cause the “summer cold.” One outcome of these infections is morbidity continuing for 5–7 days. It is likely also that changes in respiratory epithelium, local obstruction, and altered local immunity are sometimes the precursors of more severe illnesses such as otitis

ND: Not done.

ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction; RBC, red blood cell.

media, pneumonia, and sinusitis. During and following a cold the bacterial flora change, and bacteria are found in normally sterile areas of the upper airway. Asthma attacks are frequently provoked by viruses that cause the common cold. There is no evidence that antibiotics will prevent these complications, and the unjustified widespread use of antibiotics for cold symptoms has contributed to the emergence of antibiotic-resistant respiratory flora.

In 5–10% of children, symptoms from these virus infections persist for more than 10 days. This overlap with the symptoms of bacterial sinusitis presents a difficult problem for clinicians, especially because colds can produce an abnormal computed tomography (CT) scan of the sinuses. Viruses that cause a minor illness in immunocompetent children, such as rhinoviruses, can cause severe lower respiratory disease in immunologically or anatomically compromised children.

There is no evidence that symptomatic relief for children can be achieved with oral antihistamines, decongestants, or cough suppressants. Topical decongestants provide temporary improvement in nasal symptoms. Zinc and vitamin C have not been shown to have a significant preventative or therapeutic role.

INFECTIONS DUE TO ADENOVIRUSES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Multiple syndromes, depending on the type of adenovirus.
- ▶ Upper respiratory infections; most notable is severe pharyngitis with tonsillitis and cervical adenopathy.
- ▶ Conjunctivitis.
- ▶ Pneumonia.
- ▶ Enteric adenoviruses cause mild diarrheal illnesses.
- ▶ Definitive diagnosis by antigen detection, PCR, or culture.

There are over 50 types of adenoviruses, which account for 5–10% of all respiratory illnesses in childhood, usually pharyngitis or tracheitis. Adenoviral infections are common early in life. Enteric adenoviruses are an important cause of childhood diarrhea. Epidemic respiratory disease occurs in winter and spring, especially in closed environments such as day care centers and institutions. Because of latent infection in lymphoid tissue, asymptomatic shedding from the respiratory or intestinal tract is common.

Table 38-3. Red rashes in children.

Condition	Incubation Period (days)	Prodrome	Rash	Laboratory Tests	Comments, Other Diagnostic Features
Adenovirus	4-5	URI; cough; fever	Morbilloform (may be petechial)	Normal; may see leukopenia or lymphocytosis	Upper or lower respiratory symptoms are prominent. No Koplik spots. No desquamation.
Drug allergy	—	None, or fever alone, or with myalgia, pruritus	Macular, maculopapular, urticarial, or erythroderma	Leukopenia, eosinophilia	Rash variable. Severe reactions may resemble measles, scarlet fever; Kawasaki disease; marked toxicity possible.
Enterovirus	2-7	Variable fever, chills, myalgia, sore throat	Usually macular, maculopapular on trunk or palms, soles; vesicles or petechiae also seen	Variable	Varied rashes may resemble those of many other infections. Pharyngeal or hand-foot-mouth vesicles may occur.
Ehrlichiosis (monocytic)	5-21	Fever; headache; flulike; myalgia; GI symptoms	Variable; maculopapular, petechial, scarlatiniform, vasculitic	Leukopenia, thrombocytopenia, abnormal liver function. Serology for diagnosis; morulae in monocytes.	Geographic distribution is a clue; seasonal; tick exposure; rash present in only 45%.
Erythema multiforme	—	Usually none or related to underlying cause	Discrete, red maculopapular lesions; symmetrical, distal, palms and soles; target lesions classic	Normal or eosinophilia	Reaction to drugs (especially sulfonamides), or infectious agents (mycoplasma; herpes simplex virus). Urticaria, arthralgia also seen.
Kawasaki disease	Unknown	Fever, cervical adenopathy, irritability	Polymorphous (may be erythroderma) on trunk and extremities; red palms and soles, conjunctiva, lips, tongue, pharynx. Desquamation is common.	Leukocytosis, thrombocytosis, elevated ESR or C-reactive protein; pyuria; decreased albumin; negative cultures and streptococcal serology; resting tachycardia	Swollen hands, feet; prolonged illness; uveitis; aseptic meningitis; no response to antibiotics. Vasculitis and aneurysms of coronary and other arteries occur (cardiac ultrasound).
Leptospirosis	4-19	Fever (biphasic), myalgia, chills	Variable erythroderma	Leukocytosis; hematuria, proteinuria; hyperbilirubinemia	Conjunctivitis; hepatitis, aseptic meningitis may be seen. Rodent, dog contact.
Measles	9-14	Cough, rhinitis, conjunctivitis	Maculopapular; face to trunk; lasts 7-10 d; Koplik spots in mouth	Leukopenia	Toxic. Bright red rash becomes confluent, may desquamate. Fever falls after rash appears. Inadequate measles vaccination.
Parvovirus (erythema infectiosum)	10-17 (rash)	Mild (flulike)	Maculopapular on cheeks ("slapped cheek"), forehead, chin; then down limbs, trunk, buttocks; may fade and reappear for several weeks	IgM-EIA; PCR	Purpuric stocking-glove rash is rare, but distinctive; aplastic crisis in patients with chronic hemolytic anemia. May cause arthritis or arthralgia.
Rocky Mountain spotted fever	3-12	Headache (retro-orbital); toxic; GI symptoms; high fever; flulike	Onset 2-6 d after fever; palpable maculopapular on palms, soles, extremities, with spread centrally; petechial	Leukopenia; thrombocytopenia; abnormal liver function; CSF pleocytosis; Serology positive at 7-10 d of rash; biopsy will give earlier diagnosis	Eastern seaboard and southeastern United States; April-September; tick exposure.

(continued)

Table 38-3. Red rashes in children. (Continued)

Condition	Incubation Period (days)	Prodrome	Rash	Laboratory Tests	Comments, Other Diagnostic Features
Roseola (exanthem subitum) (HHV-6)	10-14	Fever (3-4 d)	Pink, macular rash occurs at end of febrile period; transient	Normal	Fever often high; disappears when rash develops; child appears well. Usually occurs in children 6 mo-3 y of age. Seizures may complicate.
Rubella	14-21	Usually none	Mild maculopapular; rapid spread face to extremities; gone by day 4	Normal or leukopenia	Postauricular, occipital adenopathy common. Polyarthralgia in some older girls. Mild clinical illness. Inadequate rubella vaccination.
Staphylococcal scalded skin	Variable	Irritability, absent to low fever	Painful erythroderma, followed in 1-2 d by cracking around eyes, mouth; bullae form with friction (Nikolsky sign)	Normal if only colonized by staphylococci; leukocytosis and sometimes bacteremia if infected	Normal pharynx. Look for focal staphylococcal infection. Usually occurs in infants.
Staphylococcal scarlet fever	1-7	Variable fever	Diffuse erythroderma; resembles streptococcal scarlet fever except eyes may be hyperemic, no "strawberry" tongue, pharynx spared	Leukocytosis is common because of infected focus	Focal infection usually present.
Stevens-Johnson syndrome	—	Pharyngitis, conjunctivitis, fever, malaise	Bullous erythema multiforme; may slough in large areas; hemorrhagic lips; purulent conjunctivitis	Leukocytosis	Classic precipitants are drugs (especially sulfonamides), <i>Mycoplasma pneumoniae</i> and herpes simplex infections. Pneumonitis and urethritis also seen.
Streptococcal scarlet fever	1-7	Fever, abdominal pain, headache, sore throat	Diffuse erythema, "sandpaper" texture; neck, axillae, inguinal areas; spreads to rest of body; desquamates 7-14 d	Leukocytosis; positive group A <i>Streptococcus</i> culture of throat or wound; positive streptococcal antigen test in pharynx	Strawberry tongue, red pharynx with or without exudate. Eyes, perioral and periorbital area, palms, and soles spared. Pastia lines. Cervical adenopathy. Usually occurs in children 2-10 y of age.
Toxic shock syndrome	Variable	Fever, myalgia, headache, diarrhea, vomiting	Nontender erythroderma; red eyes, palms, soles, pharynx, lips	Leukocytosis; abnormal liver enzymes and coagulation tests; proteinuria	<i>Staphylococcus aureus</i> infection; toxin-mediated multiorgan involvement. Swollen hands, feet. Hypotension or shock.

CSF, cerebrospinal fluid; EIA, enzyme immunoassay; ESR, erythrocyte sedimentation rate; GI, gastrointestinal; HHV-6, human herpesvirus 6; IFA, immunofluorescent assay; PCR, polymerase chain reaction; URI, upper respiratory infection.

Specific Adenoviral Syndromes

A. Pharyngitis

Pharyngitis is the most common adenoviral disease in children. Fever and adenopathy are common. Tonsillitis may be exudative. Rhinitis and an influenza-like systemic illness may be present. Laryngotracheitis or bronchitis may accompany pharyngitis.

B. Pharyngoconjunctival Fever

Conjunctivitis may occur alone and be prolonged, but most often is associated with preauricular adenopathy, fever, pharyngitis, and cervical adenopathy. Foreign body sensation and other symptoms last less than a week. Lower respiratory symptoms are uncommon.

C. Epidemic Keratoconjunctivitis

Symptoms are severe conjunctivitis with punctate keratitis and occasionally visual impairment. A foreign body sensation, photophobia, and swelling of conjunctiva and eyelids are characteristic. Preauricular adenopathy and subconjunctival hemorrhage are common.

D. Pneumonia

Severe pneumonia may occur at all ages. It is especially common in young children (younger than age 3 years). Chest radiographs show bilateral peribronchial and patchy ground-glass interstitial infiltrates in the lower lobes. Symptoms persist for 2–4 weeks. Adenoviral pneumonia can be necrotizing and cause permanent lung damage, especially bronchiectasis. A pertussis-like syndrome with typical cough and lymphocytosis can occur with lower respiratory tract infection. A new variant of adenovirus serotype 14, which appeared in 2006 in the United States, can cause unusually severe, sometimes fatal pneumonia in children and adults.

E. Rash

A diffuse morbilliform (rarely petechial) rash resembling measles, rubella, or roseola may be present. Koplik spots are absent.

F. Diarrhea

Enteric adenoviruses (types 40 and 41) cause 3–5% of cases of short-lived diarrhea in afebrile children.

G. Mesenteric Lymphadenitis

Fever and abdominal pain may mimic appendicitis. Pharyngitis is often associated. Adenovirus-induced adenopathy may be a factor in appendicitis and intussusception.

H. Other Syndromes

Immunosuppressed patients, including neonates, may develop severe or fatal pulmonary or gastrointestinal infections

or multisystem disease. Other rare complications include encephalitis, hepatitis, and myocarditis. Adenoviruses have been implicated in the syndrome of idiopathic cardiomyopathy. Hemorrhagic cystitis can be a serious problem in immunocompromised children.

▶ Laboratory & Diagnostic Studies

Diagnosis is by culture of conjunctival, respiratory, or stool specimens. Several days to weeks are required for growth in conventional cultures. Viral culture using the rapid culture technique with immunodiagnostic reagents detects virus in 48 hours. Adenovirus infection can also be diagnosed using these reagents directly on respiratory secretions. This is quicker but less sensitive than the culture methods. PCR is an important, relatively rapid diagnostic method for adenovirus infections. Special cells are needed to isolate enteric adenoviruses. Enzyme-linked immunosorbent assay (ELISA) tests rapidly detect enteric adenoviruses in diarrheal specimens. Respiratory adenovirus infections can be detected retrospectively by comparing acute and convalescent sera, but this is not helpful during an acute illness.

▶ Treatment

There is no specific treatment for adenovirus infections. Intravenous immune globulin (IVIG) may be tried in immunocompromised patients with severe pneumonia. There are anecdotal reports of successful treatment of immunocompromised patients with ribavirin or cidofovir, but only cidofovir inhibits adenovirus in vitro.

INFLUENZA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Fever, cough, pharyngitis, malaise, congestion.
- ▶ Pneumonia.
- ▶ Encephalitis.
- ▶ Seasonal: late fall through mid-spring.
- ▶ Detection of virus, viral antigens, or nucleic acid in respiratory secretions.

Symptomatic infections are common in children because they lack immunologic experience with influenza viruses. Infection rates in children are greater than in adults and are instrumental in initiating community outbreaks. Epidemics occur in fall and winter. Three main types of influenza viruses (A/H1N1, A/H3N2, B) cause most human epidemics, with antigenic drift ensuring a supply of susceptible hosts of all ages. Recently, avian influenza A/H5N1 caused human outbreaks in Asia.

► Clinical Findings

Spread of influenza occurs by way of airborne respiratory secretions. The incubation period is 2–7 days.

A. Symptoms and Signs

Influenza infection in older children and adults produces a characteristic syndrome of sudden onset of high fever, severe myalgia, headache, and chills. These symptoms overshadow the associated coryza, pharyngitis, and cough. Usually absent are rash, marked conjunctivitis, adenopathy, exudative pharyngitis, and dehydrating enteritis. Fever, diarrhea, vomiting, and abdominal pain are common in young children. Infants may develop a sepsis-like illness and apnea. Chest examination is usually unremarkable. Unusual clinical findings or variants include croup (most severe with type A influenza), exacerbation of asthma, myositis (especially calf muscles), myocarditis, parotitis, encephalopathy (distinct from Reye syndrome), nephritis, and a transient maculopapular rash. Acute illness lasts 2–5 days. Cough and fatigue may last several weeks. Viral shedding may persist for several weeks in young children.

B. Laboratory Findings

The leukocyte count is normal to low, with variable shift. Influenza infections may be more difficult to recognize in children than in adults even during epidemics, and therefore a specific laboratory test is highly recommended. The virus may be found in respiratory secretions by direct fluorescent antibody staining of nasopharyngeal epithelial cells, ELISA, optic immunoassay (OIA), or PCR. It can also be cultured within 3–7 days from pharyngeal swabs or throat washings. Many laboratories use the rapid culture technique by centrifuging specimens onto cultured cell layers and detecting viral antigen after 48 hours. Other body fluids or tissues (except lung) rarely yield the virus in culture and are more appropriately tested by PCR, which, due to its high sensitivity, can increase influenza detection in respiratory specimens. A late diagnosis may be made with paired serology, using hemagglutination inhibition assays.

C. Imaging

The chest radiograph is nonspecific; it may show hyperaeration, peribronchial thickening, diffuse interstitial infiltrates, or bronchopneumonia in severe cases. Hilar nodes are not enlarged. Pleural effusion is rare in uncomplicated influenza.

► Differential Diagnosis

The following may be considered: all other respiratory viruses, *Mycoplasma pneumoniae* or *Chlamydia pneumoniae* (longer incubation period, prolonged illness), streptococcal pharyngitis (pharyngeal exudate or petechiae, adenitis, no cough), bacterial sepsis (petechial or purpuric rash may occur), toxic shock syndrome (rash, hypotension), and rickettsial infections (rash, different season, insect exposure). High fever, the nature of preceding or concurrent illness in family members, and the presence of influenza in the community are distinguishing features from parainfluenza or RSV infections.

► Complications & Sequelae

Lower respiratory tract symptoms are most common in children younger than age 5 years. Hospitalization rates are highest in children younger than 2 years. Influenza can cause croup in these children. Secondary bacterial infections (classically staphylococcal) of the middle ear, sinuses, or lungs are most common. Of the viral infections that precede Reye syndrome, varicella and influenza (usually type B) are most notable. During an influenza outbreak, ill children who develop protracted vomiting or irrational behavior should be evaluated for Reye syndrome. Influenza can also cause viral or postviral encephalitis, with cerebral symptoms much more prominent than those of the accompanying respiratory infection. Although the myositis is usually mild and resolves promptly, severe rhabdomyolysis and renal failure have been reported.

Children with underlying cardiopulmonary, metabolic, neuromuscular, or immunosuppressive disease may develop severe viral pneumonia.

► Prevention

The inactivated influenza vaccine is moderately protective in older children (see Chapter 9). A new, live-attenuated influenza vaccine (FluMist) is significantly more efficacious in children and is currently recommended for immunocompetent children 2 years of age or older. It is currently recommended that all children 6–59 months of age should be immunized and that two doses be administered during the first year of immunization. New recommendations include immunization of all children older than age 6 months to 18 years of age. Medical staff and family members should also be immunized to protect high-risk patients. Due to the increase in type A influenza virus resistance to adamantanes, when indicated, chemoprophylaxis should be done with a neuraminidase inhibitor such as zanamivir (2 inhalations twice daily if older than age 7 years) or oseltamivir (children < 15 kg, 30 mg twice daily; those 15–23 kg, 45 mg twice daily; those 23–40 kg, 60 mg twice daily; and those > 40 kg, 75 mg twice daily). For outbreak prophylaxis, therapy should be maintained for 2 weeks or more and for 1 week after the last case of influenza is diagnosed. Chemoprophylaxis should be

considered during an epidemic for high-risk children who cannot be immunized or who have not yet developed immunity (about 6 weeks after primary vaccination or 2 weeks after a booster dose).

► Treatment & Prognosis

Treatment consists of general support and management of pulmonary complications, especially bacterial superinfections. Antivirals are of some benefit in immunocompetent hosts if begun within 48 hours after symptom onset. Studies in lung transplant patients indicate that oseltamivir might be useful for treatment of influenza in this immunocompromised population.

Recovery is usually complete unless severe cardiopulmonary or neurologic damage has occurred. Fatal cases occur in immunodeficient and anatomically compromised children.

Effective treatment or prophylaxis of influenza in children markedly reduces the incidence of acute otitis media and antibiotic usage during the flu season.

PARAINFLUENZA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever, nasal congestion, sore throat, cough.
- Croup.
- Detection of live virus, antigens, or nucleic acid in respiratory secretions.

Parainfluenza viruses (types 1–4) are the most important cause of croup. Most infants are infected with type 3 within the first 3 years of life, often in the first year. Infection with types 1 and 2 is experienced gradually over the first 5 years of life. Types 1 and 2 occur in the fall; type 3 appears annually, with a peak in the spring or summer. Most primary infections are symptomatic and frequently involve the lower respiratory tract.

► Clinical Findings

A. Symptoms and Signs

Clinical diseases include febrile upper respiratory infection (especially in older children with re-exposure), laryngitis,

tracheobronchitis, croup, and bronchiolitis (second most common cause after RSV). The relative incidence of these manifestations is type-specific. Parainfluenza viruses (especially type 1) cause 65% of cases of croup in young children, 25% of tracheobronchitis, and 50% of laryngitis. Types 1 and 2 are more likely to cause bronchiolitis. Pneumonia occurs in infants and immunodeficient children, and it leads to particularly high mortality among stem cell recipients. Onset is acute. Most children are febrile. Symptoms of upper respiratory tract infection often accompany croup.

B. Laboratory Findings

Diagnosis is often based on clinical findings. These viruses can be identified by conventional or rapid culture techniques (48 hours), by direct immunofluorescence on nasopharyngeal epithelial cells in respiratory secretions (< 3 hours), or by PCR (< 48 hours).

► Differential Diagnosis

Parainfluenza-induced respiratory syndromes are difficult to distinguish from those caused by other respiratory viruses. Croup must be distinguished from epiglottitis caused by *Haemophilus influenzae* (abrupt onset, toxicity, drooling, dyspnea, little cough, left shift of blood smear, and a history of inadequate immunization).

► Treatment

No specific therapy or vaccine is available. Croup management is discussed in Chapter 18. Ribavirin is active in vitro and has been used in immunocompromised children, but its efficacy is unproved.

Fry AM et al: Seasonal trends of human parainfluenza viral infections: United States, 1990–2004. *Clin Infect Dis* 2006;43:1016 [PMID: 16983614].

RESPIRATORY SYNCYTIAL VIRUS DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Diffuse wheezing and tachypnea following upper respiratory symptoms in an infant (bronchiolitis).
- Epidemics in late fall to early spring (January–February peak).
- Hyperinflation on chest radiograph.
- Detection of RSV antigen in nasal secretions.

► General Considerations

RSV is the most important cause of lower respiratory tract illness in young children, accounting for more than 70% of

cases of bronchiolitis and 40% of cases of pneumonia. Outbreaks occur annually, and attack rates are high; 60% of children are infected in the first year of life, and 90% by age 2 years. During peak season (cold weather in temperate climates), the clinical diagnosis of RSV infection in infants with bronchiolitis is as accurate as most laboratory tests. Despite the presence of serum antibody, reinfection is common. Distinct genotypes predominate in a community. Yearly shift in these is a partial explanation for reinfection. However, reinfection generally causes only upper respiratory symptoms in anatomically normal children. No vaccine is available. Immunosuppressed patients may develop progressive severe pneumonia. Children with congenital heart disease with increased pulmonary blood flow, children with chronic lung disease (eg, cystic fibrosis), and premature infants younger than age 6 months are also at higher risk for severe illness.

► Clinical Findings

A. Symptoms and Signs

Initial symptoms are those of upper respiratory infection. Low-grade fever may be present. The classic disease is bronchiolitis, characterized by diffuse wheezing, variable fever, cough, tachypnea, difficulty feeding, and, in severe cases, cyanosis. Hyperinflation, crackles, prolonged expiration, wheezing, and retractions are present. The liver and spleen may be palpable because of lung hyperinflation, but are not enlarged. The disease usually lasts 3–7 days in previously healthy children. Fever is present for 2–4 days; it does not correlate with pulmonary symptoms and may be absent during the height of lung involvement.

Apnea may be the presenting manifestation, especially in premature infants, in the first few months of life; it usually resolves after a few days, often being replaced by obvious signs of bronchiolitis. No explanation for apnea has been found.

RSV infection in subsequent years is more likely to cause tracheobronchitis or upper respiratory tract infection. Exceptions are immunocompromised hosts and children with severe chronic lung or heart disease, who may have especially severe or prolonged primary infections and are subject to additional attacks of severe pneumonitis.

B. Laboratory Findings

Rapid detection of RSV antigen in nasal or pulmonary secretions by fluorescent antibody staining or ELISA requires only several hours and is more than 90% sensitive and specific. Rapid tissue culture methods take 48 hours and have comparable sensitivity.

C. Imaging

Diffuse hyperinflation and peribronchiolar thickening are most common; atelectasis and patchy infiltrates also occur in uncomplicated infection, but pleural effusions are rare. Consolidation (usually subsegmental) occurs in 25% of children with lower respiratory tract disease.

► Differential Diagnosis

Although almost all cases of bronchiolitis are due to RSV during an epidemic, other viruses, particularly human metapneumovirus, cannot be excluded. Mixed infections with other viruses, chlamydiae, or bacteria can occur. Wheezing may be due to asthma, a foreign body, or other airway obstruction. RSV infection may closely resemble chlamydial pneumonitis when fine crackles are present and fever and wheezing are not prominent. The two may also coexist. Cystic fibrosis may resemble RSV infection; a positive family history or failure to thrive associated with hyponatremia or hypoalbuminemia should prompt a sweat chloride test. Pertussis should also be considered in this age group, especially if cough is prominent and if the infant is younger than age 6 months. A markedly elevated leukocyte count should suggest bacterial superinfection (neutrophilia) or pertussis (lymphocytosis).

► Complications

RSV commonly infects the middle ear. Symptomatic otitis media is more likely when secondary bacterial infection is present (usually due to pneumococci or *H influenzae*). This is the most common complication (10–20%). Bacterial pneumonia complicates only 0.5–1% of hospitalized patients. Sudden exacerbations of fever and leukocytosis should suggest bacterial infection. Respiratory failure or apnea may require mechanical ventilation, but occurs in less than 2% of hospitalized previously healthy full-term infants. Cardiac failure may occur as a complication of pulmonary disease or myocarditis. RSV—as well as parainfluenza and influenza viruses—commonly causes exacerbations of asthma. Nosocomial infection is so common during outbreaks that elective hospitalization or surgery, especially for those with underlying illness, should be postponed. Well-designed hospital programs to prevent nosocomial spread are imperative (see next section).

► Prevention & Treatment

Children who are very hypoxic or cannot feed because of respiratory distress must be hospitalized and given humidified oxygen and tube or intravenous feedings. Antibiotics, decongestants, and expectorants are of no value in routine infections. Such children should be kept in respiratory isolation. Cohorting ill infants in respiratory isolation during peak season (with or without rapid diagnostic attempts) and emphasizing good hand-washing may greatly decrease nosocomial transmission.

The utility of bronchodilator therapy has not been consistently demonstrated. Often a trial of bronchodilator therapy is given to determine response and is subsequently discontinued if there is no improvement. Racemic epinephrine occasionally works when albuterol fails. The use of corticosteroids is also controversial. A meta-analysis of numerous studies indicates a significant effect on hospital stay, especially in those most ill at the time of treatment. The

use of a single dose of corticosteroids has no lasting effect on respiratory status and does not prevent hospitalization.

Ribavirin is the only licensed antiviral therapy used for RSV infection. It is given by continuous aerosolization. There is great controversy about its efficacy, and its use is infrequent in infants without significant anatomic or immunologic defects. At best, there is a very modest effect on disease severity in immunocompetent infants with no underlying anatomic abnormality. Even in high-risk infants, clinical response to ribavirin therapy was not demonstrated in several studies. Nevertheless, ribavirin is sometimes used in severely ill children who are immunologically or anatomically compromised, in those with severe cardiac disease, and in those with evidence of severe RSV infection.

Monthly intramuscular administration of humanized RSV monoclonal antibody is now recommended to prevent severe disease in high-risk patients during epidemic periods. Monthly administration should be considered during the RSV season for high-risk children, as described in Chapter 9.

Use of passive immunization for immunocompromised children is logical, but not established. RSV antibody is not effective for treatment of established infection.

► Prognosis

Although mild bronchiolitis does not produce long-term problems, 30–40% of patients hospitalized with this infection will wheeze later in childhood, and RSV infection in infancy may be one important precursor to asthma. Chronic restrictive lung disease and bronchiolitis obliterans are rare sequelae.

HUMAN METAPNEUMOVIRUS INFECTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cough, coryza, sore throat.
- Bronchiolitis.
- Detection of viral antigens or nucleic acid in respiratory secretions.

► General Considerations

After its discovery in 2001, human metapneumovirus (hMPV) was identified as a common agent of respiratory

tract infections that is very similar to RSV in epidemiologic and clinical characteristics. Like RSV, parainfluenza, mumps, and measles, hMPV belongs to the paramyxovirus family. Humans are its only known reservoir. Seroepidemiologic surveys indicate that the virus has worldwide distribution. More than 90% of children contract hMPV infection by age 5 years, typically during late autumn through early spring outbreaks. hMPV accounts for 15–25% of the cases of bronchiolitis and pneumonia in children younger than 2 years of age. Older children and adults can also develop symptomatic infection.

► Clinical Findings

A. Symptoms and Signs

The most common symptoms are fever, cough, rhinorrhea, and sore throat. Bronchiolitis and pneumonia occur in 40–70% of the children who acquire hMPV before the age of 2 years. Asymptomatic infection is uncommon. Other manifestations include otitis, conjunctivitis, diarrhea, and myalgia. Acute wheezing has been associated with hMPV in children of all ages, raising the possibility that this virus, like RSV, might trigger reactive airway disease. Dual infection with hMPV and RSV or other respiratory viruses seems to be a common occurrence and may increase morbidity and mortality.

B. Laboratory Findings

The virus has very selective tissue culture tropism, which accounts for its late discovery in spite of its presence in archived specimens from the mid-1900s. The preferred method of diagnosis is PCR performed on respiratory specimens. Rapid shell vial culture is an acceptable, albeit less sensitive, alternative. Antibody tests are available, but are most appropriately used for epidemiologic studies.

► C. Imaging

Lower respiratory tract infection frequently shows hyperinflation and patchy pneumonitis on chest radiographs.

► Treatment & Prognosis

No antiviral therapies are available to treat hMPV. Children with lower respiratory tract disease may require hospitalization and ventilatory support, but less frequently than with RSV-associated bronchiolitis. Duration of hospitalization in hMPV is typically shorter than in RSV.

INFECTIONS DUE TO ENTEROVIRUSES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Acute febrile illness with headache and sore throat.
- ▶ Summer–fall epidemics.
- ▶ Other common features: rash, nonexudative pharyngitis.
- ▶ Common cause of aseptic meningitis.
- ▶ Complications: myocarditis, neurologic damage, life-threatening illness in newborns.

Enteroviruses are a major cause of illness in young children. The multiple types are physically and biochemically similar and may produce identical syndromes. The multiplicity of types makes vaccine development impractical and has hindered development of antigen detection and serologic tests. However, common RNA sequences and group antigens have led to diagnostic tests for viral nucleic acid and proteins. A PCR assay is available in many medical centers, but tissue culture is still used in some centers as a diagnostic method for echoviruses, polioviruses, and coxsackie B viruses. Although cultures may turn positive in 2–4 days, the relatively rapid answer obtained with PCR facilitates clinical decisions, particularly in cases of meningoencephalitis and severe unexplained illness in neonates.

Transmission is fecal-oral or from upper respiratory secretions. Multiple enteroviruses circulate in the community at any one time; summer–fall outbreaks are common in temperate climates, but infections are seen year-round. After poliovirus, coxsackie B virus is most virulent, followed by echovirus. Neurologic, cardiac, and overwhelming neonatal infections are the most severe forms of illness.

ACUTE FEBRILE ILLNESS

Accompanied by nonspecific upper respiratory or enteric symptoms, sudden onset of fever and irritability in infants or young children is often enteroviral in origin, especially in late summer and fall. More than 90% of enteroviral infections are not distinctive. Occasionally a petechial rash is seen; more often a diffuse maculopapular or morbilliform eruption (often prominent on palms and soles) occurs on the second to fourth day of fever. Rapid recovery is the rule. More than one febrile enteroviral illness can occur in the same patient in one season. The leukocyte count is usually normal. Infants, because of fever and irritability, may undergo an evaluation for bacteremia or meningitis and be hospitalized to rule out sepsis. Approximately half of these infants have aseptic meningitis. In the summer months enterovirus infection is more likely than human herpesvirus 6 to cause an acute medical visit for fever. Duration of illness is 4–5 days.

RESPIRATORY TRACT ILLNESSES

1. Febrile Illness with Pharyngitis

This syndrome is most common in older children, who complain of headache, sore throat, myalgia, and abdominal discomfort. The usual duration is 3–4 days. Vesicles or papules may be seen in the pharynx. There is no exudate. Occasionally, enteroviruses are the cause of croup, bronchitis, or pneumonia. They may also exacerbate asthma.

2. Herpangina

Herpangina is characterized by an acute onset of fever and posterior pharyngeal grayish white vesicles that quickly form ulcers (< 20 in number), often linearly arranged on the posterior palate, uvula, and tonsillar pillars. Bilateral faucial ulcers may also be seen. Dysphagia, vomiting, abdominal pain, and anorexia also occur and, rarely, parotitis or vaginal ulcers. Symptoms disappear in 4–5 days. The epidemic form is due to a variety of coxsackie A viruses; coxsackie B viruses and echoviruses cause sporadic cases.

The differential diagnosis includes primary herpes simplex gingivostomatitis (ulcers are more prominent anteriorly, and gingivitis is present), aphthous stomatitis (fever absent, recurrent episodes, anterior lesions), trauma, hand-foot-and-mouth disease (see later discussion), and Vincent angina (painful gingivitis spreading from the gum line, underlying dental disease). If the enanthema is missed, tonsillitis might be incorrectly diagnosed.

3. Acute Lymphonodular Pharyngitis

Coxsackievirus A10 has been associated with a febrile pharyngitis characterized by nonulcerative yellow-white posterior pharyngeal papules in the same distribution as herpangina. The duration is 1–2 weeks; therapy is supportive.

4. Pleurodynia (Bornholm Disease, Epidemic Myalgia)

Caused by coxsackie B virus (epidemic form) or many nonpolio enteroviruses (sporadic form), pleurodynia is associated with an abrupt onset of unilateral or bilateral spasmodic pain of variable intensity over the lower ribs or upper abdomen. Associated symptoms include headache, fever, vomiting, myalgias, and abdominal and neck pain. Physical findings include fever, chest muscle tenderness, decreased thoracic excursion, and occasionally a friction rub. The chest radiograph is normal. Hematologic tests are nondiagnostic. The illness generally lasts less than 1 week.

This is a disease of muscle, but the differential diagnosis includes bacterial pneumonia, empyema, tuberculosis, and endemic fungal infections (all excluded radiographically and by auscultation), costochondritis (no fever or other symptoms), and a variety of abdominal problems, especially those causing diaphragmatic irritation.

There is no specific therapy. Potent analgesic agents and chest splinting alleviate the pain.

RASHES (INCLUDING HAND-FOOT-AND-MOUTH DISEASE)

The rash may be macular, maculopapular, urticarial, scarlatiniform, petechial, or vesicular. One of the most characteristic is that of hand-foot-and-mouth disease (caused by coxsackieviruses, especially types A5, A10, and A16), in which vesicles or red papules are found on the tongue, oral mucosa, hands, and feet. Often they appear near the nails and on the heels. Associated fever, sore throat, and malaise are mild. The rash may appear when fever abates, simulating roseola.

1. Cardiac Involvement

Myocarditis and pericarditis may be caused by a number of nonpolio enteroviruses, particularly type B coxsackieviruses. Most commonly, upper respiratory symptoms are followed by substernal pain, dyspnea, and exercise intolerance. A friction rub or gallop may be detected. Ultrasound will define ventricular dysfunction, and electrocardiography may show pericarditis or ventricular irritability. Creatine phosphokinase may be elevated. The disease may be mild or fatal; most children recover completely. In infants, other organs may be involved at the same time; in older patients, cardiac disease is usually the sole manifestation (see Chapter 19 for therapy). Enteroviral RNA is present in cardiac tissue in some cases of dilated cardiomyopathy or myocarditis; the significance of this finding is unknown. Epidemics of enterovirus 71, which occur in Asia, as well as sporadic cases in the United States, are associated with severe left ventricular dysfunction and pulmonary edema following typical mucocutaneous manifestations of enterovirus infection. Enterovirus 71 also can cause isolated severe neurologic disease or neurologic disease in combination with myocardial disease.

2. Severe Neonatal Infection

Sporadic and nosocomial nursery cases of severe systemic enteroviral disease occur. Clinical manifestations include combinations of fever, rash, pneumonitis, encephalitis, hepatitis, gastroenteritis, myocarditis, pancreatitis, and myositis. The infants, usually younger than 1 week old, may appear septic, with cyanosis, dyspnea, and seizures. The differential diagnosis includes bacterial and herpes simplex infections, necrotizing enterocolitis, other causes of heart or liver failure, and metabolic diseases. Diagnosis is suggested by the finding of cerebrospinal fluid (CSF) mononuclear pleocytosis and confirmed

by the isolation of virus or detection of enteroviral RNA in urine, stool, CSF, or pharynx. Therapy is supportive. IVIG is often administered, but its value is uncertain. Passively acquired maternal antibody may protect newborns from severe disease. For this reason, labor should not be induced in pregnant women near term who have suspected enteroviral disease.

CENTRAL NERVOUS SYSTEM ILLNESSES

1. Poliomyelitis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Inadequate immunization or underlying immune deficiency.
- ▶ Headache, fever, muscle weakness.
- ▶ Aseptic meningitis.
- ▶ Asymmetrical, flaccid paralysis; muscle tenderness and hyperesthesia; intact sensation; late atrophy.

▶ General Considerations

Poliovirus infection is subclinical in 90–95% of cases; it causes nonspecific febrile illness in about 5% of cases and aseptic meningitis, with or without paralytic disease, in 1–3%. In endemic areas, most older children and adults are immune because of prior inapparent infections. Occasional cases in the United States occur in patients who travel to foreign countries. Most recent cases were in immunodeficient patients who received the oral poliovirus vaccine (OPV) or were exposed to recent vaccinees. Severe poliovirus infection was a rare complication of OPV vaccination as a result of reversion of the vaccine virus. The incidence of vaccine-associated paralytic poliomyelitis (VAPP) in the United States was 1:750,000 and 1:2.4 million doses for the first and second dose of OPV, respectively. Although rare, VAPP became more common than wild-type poliomyelitis in the United States in the 1980s. This led to change in the recommended immunization regimen, substituting inactivated polio vaccine (IPV) for OPV (see Chapter 9).

▶ Clinical Findings

A. Symptoms and Signs

The initial symptoms are fever, myalgia, sore throat, and headache for 2–6 days. In less than 10% of infected children,

several symptom-free days are followed by recurrent fever and signs of aseptic meningitis: headache, stiff neck, spinal rigidity, and nausea. Mild cases resolve completely. In only 1–2% of these children does high fever, severe myalgia, and anxiety portend progression to loss of reflexes and subsequent flaccid paralysis. Sensation remains intact, although hyperesthesia of skin overlying paralyzed muscles is common and pathognomonic.

Paralysis is usually asymmetrical. Proximal limb muscles are more often involved than distal, and lower limb involvement is more common than upper. Bulbar involvement affects swallowing, speech, and cardiorespiratory function and accounts for most deaths. Bladder distention and marked constipation characteristically accompany lower limb paralysis. Paralysis is usually complete by the time the temperature normalizes. Weakness often resolves completely. Atrophy is usually apparent by 4–8 weeks. Most improvement of muscle paralysis occurs within 6 months.

B. Laboratory Findings

In patients with meningeal symptoms, the CSF contains up to several hundred leukocytes (mostly lymphocytes) per microliter; the glucose level is normal, and protein concentration is mildly elevated. Poliovirus is easy to grow in cell culture and can be readily differentiated from other enteroviruses. It is rarely isolated from spinal fluid but is often present in the throat and stool for several weeks following infection. Paired serology is also diagnostic. Laboratory methods are available to differentiate wild from attenuated vaccine isolates.

► Differential Diagnosis

Aseptic meningitis due to poliovirus is indistinguishable from that due to other viruses. Paralytic disease in the United States is usually due to nonpolio enteroviruses. Polio may resemble Guillain-Barré syndrome (variable sensory loss, symmetrical loss of function; minimal pleocytosis, high protein concentration in spinal fluid), polyneuritis (sensory loss), pseudoparalysis due to bone or joint problems (eg, trauma, infection), botulism, or tick paralysis.

► Complications & Sequelae

Complications are the result of the acute and permanent effects of paralysis. Respiratory, pharyngeal, bladder, and bowel malfunction are most critical. Deaths are usually due to complications arising from respiratory dysfunction. Limbs injured near the time of infection, such as by intramuscular injections, excessive prior use, or trauma, tend to be most severely involved and have the worst prognosis for recovery (provocation paralysis). Postpolio muscular atrophy occurs in 30–40% of paralyzed limbs 20–30 years later, characterized by increasing weakness and fasciculations in previously affected, partially recovered limbs.

► Treatment & Prognosis

Therapy is supportive. Bed rest, fever and pain control (heat therapy is helpful), and careful attention to progression of weakness (particularly of respiratory muscles) are important. No intramuscular injections should be given during the acute phase. Intubation or tracheostomy for secretion control and catheter drainage of the bladder may be needed. Assisted ventilation and enteral feeding may also be needed. Pleconaril, which is an antiviral drug active against most enteroviruses, has no effect on polioviruses. Postpolio paralysis is mild in about 30%, permanent in 15%, and results in death in 5–10%. Disease is worse in adults and pregnant women than in children.

2. Nonpolio Viral Meningitis

Nonpolio enteroviruses cause over 80% of cases of aseptic meningitis at all ages. In the summer and fall, multiple cases may be seen associated with circulation of neurotropic strains. Nosocomial outbreaks also occur.

► Clinical Findings

The usual enteroviral incubation period is 4–6 days. Because many enteroviral infections are subclinical or not associated with CNS symptoms, a history of contact with a patient with meningitis is unusual. Neonates may acquire infection from maternal blood, vaginal secretions, or feces at birth; occasionally the mother has had a febrile illness just prior to delivery.

A. Symptoms and Signs

Onset is usually acute with variable fever, marked irritability, and lethargy in infants. Incidence is much greater in children younger than age 1 year. Older children also describe frontal headache, photophobia, and myalgia. Abdominal pain, diarrhea, and vomiting may occur. The incidence of rash varies with the infecting strain. If rash occurs, it is usually seen after several days of illness and is diffuse, macular or maculopapular, occasionally petechial, but not purpuric. Oropharyngeal vesicles and rash on the palms and soles suggest an enterovirus. The anterior fontanelle may be full. Meningismus may be present. The illness may be biphasic, with nonspecific symptoms and signs preceding those related to the CNS. In older children, it is easier to demonstrate meningeal signs. Seizures are unusual, and focal neurologic findings, which are rare, should lead to a search for an alternative cause. Frank encephalitis, which is also uncommon at any age, occurs most often in neonates. Because of the overall frequency of enteroviral disease in children, 10–20% of all cases of encephalitis of proved viral origin are caused by enteroviruses. Enterovirus 71 infections that begin with typical mucocutaneous manifestations of enteroviruses can be complicated by severe brainstem encephalitis and polio-like flaccid paralysis. Enterovirus 70 outbreaks have

resulted in hemorrhagic conjunctivitis together with paralytic poliomyelitis. Very pathogenic enteroviruses are now appearing in the United States. Other nonpolio enteroviruses cause sporadic cases of acute motor weakness similar to that seen with poliovirus infection. Children with congenital immune deficiency, especially agammaglobulinemia, are subject to chronic enteroviral meningoencephalitis that is often fatal or associated with severe sequelae.

B. Laboratory Findings

Blood leukocyte counts are nonspecific and often normal. The spinal fluid leukocyte count is 100–1000/μL. Early in the illness, polymorphonuclear cells predominate; a shift to mononuclear cells occurs within 8–36 hours. In about 95% of cases, spinal fluid parameters include a total leukocyte count less than 3000/μL, protein less than 80 mg/dL, and glucose more than 60% of serum values. Marked deviation from any of these findings should prompt consideration of another diagnosis (see following section). The syndrome of inappropriate secretion of antidiuretic hormone may occur but is rarely clinically significant.

Culture of CSF may yield an enterovirus within a few days (< 70%). However, PCR for enteroviruses is the most useful diagnostic method in many centers (sensitivity > 90%) and can give an answer within 24–48 hours. Virus may be detected in acellular CSF. Detection of an enterovirus from throat or stool suggests, but does not prove, enteroviral meningitis. Vaccine poliovirus present in feces in infants being evaluated for aseptic meningitis (outside of the United States) may confuse the diagnosis but can usually be distinguished by growth characteristics.

C. Imaging

Cerebral imaging is not often indicated; if done, it is usually normal. Subdural effusions, infarcts, edema, or focal abnormalities seen in bacterial meningitis are absent except for the rare case of focal encephalitis.

► Differential Diagnosis

In the prevaccine era, mumps and polio were leading causes of aseptic meningitis, but now this is usually caused by enteroviruses, especially in the summer and fall. Other causative viruses are mosquito-borne viruses (flavivirus, bunyavirus). These are usually considered during an investigation of encephalitis, but many of them are more likely to cause isolated meningitis and should be considered when seasonal clusters of viral meningitis occur. Primary herpes simplex infection can cause aseptic meningitis in adolescents who have a genital herpes infection. In neonates, early herpes simplex meningoencephalitis may mimic enteroviral disease (see next section on Infections Due to Herpesviruses). This is an important alternative diagnosis to exclude because of the need for urgent specific therapy. Lymphocytic choriomeningitis virus causes meningitis in children in contact with rodents (pet or environmental exposure).

Meningitis occurs in some patients at the time of infection with human immunodeficiency virus (HIV).

Other causes of aseptic meningitis that may resemble enteroviral infection include partially treated bacterial meningitis (recent antibiotic treatment, CSF parameters resembling those seen in bacterial disease and bacterial antigen sometimes present); parameningeal foci of bacterial infection such as brain abscess, subdural empyema, mastoiditis (predisposing factors, glucose level in CSF may be lower, focal neurologic signs, and characteristic imaging); tumors or cysts (malignant cells detected by cytologic examination, a history of neurologic symptoms, higher protein concentration or lower glucose level in CSF); trauma (presence, without exception, of red blood cells, which may be erroneously assumed to be due to traumatic lumbar puncture, but are crenated and fail to clear); vasculitis (other systemic or neurologic signs, found in older children); tuberculous or fungal meningitis (see Chapters 40 and 41); cysticercosis; parainfectious encephalopathies (*M pneumoniae*, cat-scratch disease, respiratory viruses [especially influenza]); Lyme disease; leptospirosis; and rickettsial diseases.

► Prevention & Treatment

No specific therapy exists. Infants are usually hospitalized, isolated, and treated with fluids and antipyretics. Moderately to severely ill infants are given appropriate antibiotics for bacterial pathogens until cultures are negative for 48–72 hours. This practice is changing somewhat, and hospital stay shortened, in areas where the PCR assay for enteroviruses is available. If patients—especially older children—are mildly ill, antibiotics may be withheld and the child observed. The illness usually lasts less than 1 week. Codeine compounds or other strong analgesics may be needed. C-reactive protein and lactate levels are usually low in the CSF of children with viral meningitis; both may be elevated with bacterial infection. With clinical deterioration, repeat lumbar puncture, cerebral imaging, neurologic consultation, and more aggressive diagnostic tests should be considered. Herpesvirus encephalitis is an important consideration in such cases, particularly in infants younger than age 1 month, and this may warrant empiric acyclovir therapy until an etiologic diagnosis is made.

Measures to prevent enteroviral infection include good hygiene, scrupulous hand washing, and proper isolation in the hospital.

► Prognosis

In general, enteroviral meningitis has no significant short-term neurologic or developmental sequelae. Developmental delay may follow severe neonatal infections. Unlike mumps, enterovirus infections rarely cause hearing loss.

INFECTIONS DUE TO HERPESVIRUSES

HERPES SIMPLEX INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Grouped vesicles on an erythematous base, typically in or around the mouth or genitals.
- ▶ Tender regional adenopathy, especially with primary infection.
- ▶ Fever and malaise with primary infection.
- ▶ Recurrent episodes in many patients.

▶ General Considerations

There are two types of herpes simplex viruses. Type 1 (HSV-1) causes most cases of oral, skin, and cerebral disease. Type 2 (HSV-2) causes most (80–85%) genital and congenital infections. Latent infection in sensory ganglia routinely follows primary infection. Recurrences may be spontaneous or induced by external events (eg, fever, menstruation, or sunlight) or immunosuppression. Transmission is by direct contact with infected secretions. Herpes simplex viruses are very susceptible to antiviral drugs.

Primary infection with HSV-1 often occurs early in childhood, although many adults (20–50%) have never been infected. Primary infection with HSV-1 is subclinical in 80% of cases and causes gingivostomatitis in the remainder. HSV-2, which is transmitted sexually, is also usually (65%) subclinical or produces mild, nonspecific symptoms. Infection with one type of HSV may prevent or attenuate clinically apparent infection with the other type, but individuals can be infected at different times with both HSV-1 and HSV-2. Recurrent episodes are due to reactivation of latent HSV.

▶ Clinical Findings

The source of primary infection is usually an asymptomatic excreter. Most previously infected individuals shed HSV at irregular intervals. At any one time (point prevalence), more than 5% of normal seropositive adults excrete HSV-1 in the saliva; the percentage is higher in recently infected children. HSV-2 shedding in genital secretions occurs with a point prevalence exceeding 10%, depending on the method of detection (viral isolation vs PCR) and the interval since the initial infection. A history of contact with an active HSV infection is unusual.

A. Symptoms and Signs

1. Gingivostomatitis—High fever, irritability, and drooling occur in infants. Multiple oral ulcers are seen on the tongue and on the buccal and gingival mucosa, occasionally extending to the pharynx. Pharyngeal ulcers may predominate in older children and adolescents. Diffusely swollen red gums that are friable and bleed easily are typical. Cervical nodes are swollen and tender. Duration is 7–14 days. Herpangina, aphthous stomatitis, thrush, and Vincent angina should be excluded.

2. Vulvovaginitis or urethritis—Genital herpes (especially HSV-2) in a prepubertal child should suggest sexual abuse. Vesicles or painful ulcers on the vulva, vagina, or penis and tender adenopathy are seen. Systemic symptoms (fever, flulike illness, myalgia) are common with the initial episode. Painful urination may cause retention. Primary infections last 10–14 days before healing. Lesions may resemble trauma, syphilis (ulcers are painless), or chancroid (ulcers are painful and nodes are erythematous and fluctuant) in the adolescent, and bullous impetigo, trauma, and severe chemical irritation in younger children.

3. Cutaneous infections—Direct inoculation onto cuts or abrasions may produce localized vesicles or ulcers. A deep HSV infection on the fingers (called herpetic whitlow) may be mistaken for a bacterial felon or paronychia; surgical drainage is of no value and is contraindicated. HSV infection of eczematous skin may result in extensive areas of vesicles and shallow ulcers (eczema herpeticum), which may be mistaken for impetigo or varicella.

4. Recurrent mucocutaneous infection—Recurrent oral shedding is usually asymptomatic. Perioral recurrences often begin with a prodrome of tingling or burning limited to the vermilion border, followed by vesiculation, scabbing, and crusting around the lips over the next 3–5 days. Intraoral lesions rarely recur. Fever, adenopathy, and other symptoms are absent. Recurrent cutaneous herpes most closely resembles impetigo, but the latter is often outside the perinasal and perioral region, responds to antibiotics, yields a positive result on Gram stain, and *Streptococcus pyogenes* or *Staphylococcus aureus* can be isolated. Recurrent genital disease is common after the initial infection with HSV-2. It is shorter (5–7 days) and milder (mean, four lesions) than primary infection and is not associated with systemic symptoms.

5. Keratoconjunctivitis—Keratoconjunctivitis may be part of a primary infection due to spread from infected saliva. Most cases are caused by reactivation of virus latent in the ciliary ganglion. Keratoconjunctivitis produces photophobia, pain, and conjunctival irritation. With recurrences, dendritic corneal ulcers may be demonstrable with fluorescein staining. Stromal invasion may occur. Corticosteroids should never be used for unilateral keratitis without ophthalmologic consultation. Other causes of these symptoms include trauma, bacterial infections, and other viral infec-

tions (especially adenovirus if pharyngitis is present; bilateral involvement makes HSV unlikely) (see Chapter 15).

6. Encephalitis—Although unusual in infants outside the neonatal period, encephalitis may occur at any age, usually without cutaneous herpes lesions. In older children, HSV encephalitis can follow a primary infection, but often represents reactivation of latent virus. HSV is the most common cause of sporadic severe encephalitis. It is the most important because it can be treated with specific antiviral therapy. Fever, headache, behavioral changes, and neurologic deficits or focal seizures occur. Mild mononuclear pleocytosis is typically present along with an elevated protein concentration, which continues to rise on repeat lumbar punctures. In older children hypodense areas with a medial and inferior temporal lobe predilection are seen on CT scan, especially after 3–5 days, but the findings in infants may be more diffuse. Magnetic resonance imaging (MRI) is more sensitive and is positive sooner. Periodic focal epileptiform discharges are seen on electroencephalograms, but are not diagnostic of HSV infection. Viral cultures of CSF are rarely positive. The PCR assay to detect HSV DNA in CSF is a sensitive and specific rapid test. Without early antiviral therapy, the prognosis is poor. The differential diagnosis includes mumps, mosquito-borne and other viral encephalitis, parainfectious and postinfectious encephalopathy, brain abscess, acute demyelinating syndromes, and bacterial meningoencephalitis.

7. Neonatal infections—Infection is acquired by ascending spread prior to delivery (5–10% of cases) or most often at the time of vaginal delivery from a mother with genital infection. Occasionally the infection is acquired in the postpartum period from oral secretions of family members or hospital personnel. A history of genital herpes in the mother is usually absent. Within a few days and up to 4 weeks, skin vesicles appear (especially at sites of trauma, such as where scalp monitors were placed). Some infants have infections limited to the skin, eye, or mouth. Other infants are acutely ill, presenting with jaundice, shock, bleeding, or respiratory distress. Some infants appear well initially, but dissemination of the infection to the brain or other organs becomes evident during the ensuing week if it is untreated. HSV infection (and empiric therapy) should be considered in newborns with the sepsis syndrome who are unresponsive to antibiotic therapy and have negative bacterial cultures. Skin lesions may be absent at the time of presentation. Some infected infants exhibit only neurologic symptoms at 2–3 weeks after delivery: apnea, lethargy, fever, poor feeding, or persistent overt seizures. The brain infection in these children is often diffuse and is best diagnosed by MRI. The skin lesions may resemble impetigo, bacterial scalp abscesses, or miliaria; some children may fail to develop skin lesions. Skin lesions may recur over weeks or months after recovery from the acute illness. Progressive culture-negative pneumonitis is another manifestation of neonatal HSV.

B. Laboratory Findings

With multisystem disease, abnormalities in platelets, clotting factors, and liver function tests are often present. A finding of lymphocytic pleocytosis and elevated CSF protein indicates aseptic meningitis or encephalitis. Virus may be cultured from infected epithelial sites (vesicles, ulcers, or conjunctival scrapings) and from infected tissue (skin, brain) obtained by biopsy. Cultures of CSF yield positive results in about 50% of neonatal cases, but are uncommon in older children. HSV will be detected within 2 days by rapid tissue culture methods, but PCR is the preferred diagnostic method. Isolation from throat, eye, urine, or stool of a newborn is diagnostic. Vaginal culture of the mother may offer circumstantial evidence for the diagnosis, but may be negative.

Rapid diagnostic tests include immunofluorescent stains or ELISA to detect viral antigen in skin or mucosal scrapings. The PCR assay for HSV DNA is positive (> 95%) in the CSF when there is brain involvement. Serum is often positive in the presence of multisystem disease.

► Complications, Sequelae, & Prognosis

Gingivostomatitis may result in dehydration due to dysphagia; severe chronic oral disease and esophageal involvement may occur in immunosuppressed patients. Primary vulvovaginitis may be associated with aseptic meningitis, paresthesias, autonomic dysfunction due to neuritis (urinary retention, constipation), and secondary candidal infection. HIV transmission from and acquisition by individuals who are seropositive for HSV infection is increased. Extensive cutaneous disease (as in eczema) may be associated with dissemination, and with bacterial superinfection. Keratitis may result in corneal opacification or perforation. Untreated encephalitis is fatal in 70% of patients and causes severe damage in most of the remainder. When acyclovir treatment is instituted early, 20% of patients die and 40% are neurologically impaired. Disseminated neonatal infection is often fatal in spite of therapy, and survivors are often impaired.

► Treatment

A. Specific Measures

HSV is sensitive to antiviral therapy.

1. Topical antivirals—Antiviral agents are effective for corneal disease and include 1% trifluridine, 5% acyclovir, and 3% vidarabine. Trifluridine appears superior; cure rates over 95% are reported. These agents should be used with the guidance of an ophthalmologist.

2. Mucocutaneous HSV infections—These infections respond to administration of oral nucleoside analogues (acyclovir, valacyclovir, or famciclovir). The main indications are severe genital HSV infection in adolescents (see Chapter 42) and severe gingivostomatitis in young children. Antiviral therapy is beneficial for primary disease when begun early. Recurrent disease

rarely requires therapy. Frequent genital recurrences may be suppressed by oral administration of nucleoside analogues, but this approach should be used sparingly. Other forms of severe cutaneous disease, such as eczema herpeticum, respond to these antivirals. Intravenous acyclovir may be required when disease is extensive in immunocompromised children (500 mg/m² every 8 hours). Oral acyclovir, which is available in suspension, is also used within 72–96 hours for severe primary gingivostomatitis in immunocompetent young children (10 mg/kg per dose four times a day for 5–7 days). Antiviral therapy does not alter the incidence or severity of subsequent recurrences of oral or genital infection. Development of resistance to antivirals is very rare after treating immunocompetent patients, but it is reported in immunocompromised patients who receive frequent and prolonged therapy.

3. Encephalitis—Treatment consists of intravenous acyclovir, 500 mg/m² every 8 hours for 21 days.

4. Neonatal infection—Newborns receive intravenous acyclovir, 20 mg/kg every 8 hours for 21 days (14 days if infection is limited to skin, eye, or mouth).

B. General Measures

1. Gingivostomatitis—Gingivostomatitis is treated with pain relief and temperature control measures. Maintaining hydration is important because of the long duration of illness (7–14 days). Nonacidic, cool fluids are best. Topical anesthetic agents (eg, viscous lidocaine or an equal mixture of kaolin–attapulgate [Kaopectate], diphenhydramine, and viscous lidocaine) may be used as a mouthwash for older children who will not swallow it; ingested lidocaine may be toxic to infants or may lead to aspiration. Antiviral therapy is indicated in normal hosts with severe disease. Antibiotics are not helpful.

2. Genital infections—Genital infections require pain relief, assistance with voiding (warm baths, topical anesthetics, rarely catheterization), and psychological support. Lesions should be kept clean; drying may shorten the duration of symptoms. Sexual contact should be avoided during the interval from prodrome to crusting stages. Because of the frequency of asymptomatic shedding, the only effective way to prevent spread is the use of condoms.

3. Cutaneous lesions—Skin lesions should be kept clean, dry, and covered if possible to prevent spread. Systemic analgesics may be helpful. Secondary bacterial infection is uncommon in patients with lesions on the mucosa or involving small areas. Secondary infection should be considered and treated if necessary (usually with an antistaphylococcal agent) in patients with more extensive lesions. Candidal superinfection occurs in 10% of women with primary genital infections.

4. Recurrent cutaneous disease—Recurrent disease is usually milder than primary infection. Sun block lip balm helps prevent labial recurrences after intense sun exposure. There is no evidence that the many popular topical or vitamin therapies are efficacious.

5. Keratoconjunctivitis—An ophthalmologist should be consulted regarding the use of cycloplegics, anti-inflammatory agents, local debridement, and other therapies.

6. Encephalitis—Extensive support will be required for obtunded or comatose patients. Rehabilitation and psychological support are often needed for survivors.

7. Neonatal infection—The affected infant should be isolated and given acyclovir. Cesarean delivery is indicated if the mother has obvious cervical or vaginal lesions, especially if these represent primary infection (35–50% transmission rate). With infants born vaginally to mothers who have active lesions, appropriate cultures should be obtained at 24–48 hours after birth, and the infants should be observed closely. Treatment is given to infants whose culture results are positive or who have suggestive signs or symptoms. Infants born to mothers with obvious primary genital herpes should receive therapy before the culture results are known. For women with a history of genital herpes infection, but no genital lesions, vaginal delivery with peripartum cultures of maternal cervix is the standard. Clinical follow-up of the newborn is recommended when maternal culture results are positive. Repeated cervical cultures during pregnancy are not useful.

VARICELLA & HERPES ZOSTER

▶ Varicella (chickenpox):

- Exposure to varicella or herpes zoster 10–21 days previously; no prior history of varicella.
- Widely scattered red macules and papules concentrated on the face and trunk, rapidly progressing to clear vesicles on an erythematous base, pustules, and then crusting, over 5–6 days.
- Variable fever and nonspecific systemic symptoms.

▶ Herpes zoster (shingles):

- History of varicella.
- Dermatomal paresthesias and pain prior to eruption (more common in older children).
- Dermatomal distribution of grouped vesicles on an erythematous base.

► General Considerations

Primary infection with varicella-zoster virus results in varicella, which almost always confers lifelong immunity; the virus remains latent in sensory ganglia. Herpes zoster, which represents reactivation of this latent virus, occurs in 20% of individuals some time in their life. The incidence of herpes zoster is highest in elderly individuals and in immunosuppressed patients. Spread of varicella from a contact is by respiratory secretions or fomites from vesicles or pustules, with a greater than 90% infection rate in susceptible persons. Exposure to herpes zoster is about one third as likely to cause varicella in a susceptible host. Over 95% of young adults with a history of varicella are immune, as are 90% of native-born Americans who are unaware of having had varicella. Many individuals from tropical or subtropical areas never have childhood exposure and remain susceptible through early adulthood. Humans are the only reservoir.

► Clinical Findings

Exposure to varicella or herpes zoster has usually occurred 14–16 days previously (range, 10–21 days). Contact may not have been recognized, since the index case of varicella is infectious 1–2 days before rash appears. Although varicella is the most distinctive childhood exanthem, inexperienced observers may mistake other diseases for varicella. A 1- to 3-day prodrome of fever, respiratory symptoms, and headache may occur, especially in older children. The preeruptive pain of herpes zoster may last several days and be mistaken for other illnesses.

A. Symptoms and Signs

1. Varicella—The usual case consists of mild systemic symptoms followed by crops of red macules that rapidly become small vesicles with surrounding erythema (described as a “dew drop on a rose petal”), form pustules, become crusted, and then scab over and leave no scar. The rash appears predominantly on the trunk and face. Lesions occur in the scalp, and sometimes occur in the nose, mouth (where they are nonspecific ulcers), conjunctiva, and vagina. The magnitude of systemic symptoms usually parallels skin involvement. Up to five crops of lesions may be seen. New crops usually stop forming after 5–7 days. Pruritus is often intense. If varicella occurs in the first few months of life, it is often mild as a result of persisting maternal antibody. Once crusting begins, the patient is no longer contagious.

2. Herpes zoster—The eruption of shingles involves a single dermatome, usually truncal or cranial. The rash does not cross the midline. Ophthalmic zoster may be associated with corneal involvement. The closely grouped vesicles, which resemble a localized version of varicella or herpes simplex, often coalesce. Crusting occurs in 7–10 days. Postherpetic neuralgia is rare in children. A few vesicles are occasionally seen outside the involved dermatome. Herpes zoster is a

common problem in HIV-infected or other immunocompromised children. Herpes zoster is also common in children who had varicella in early infancy or whose mothers had varicella during pregnancy.

B. Laboratory Findings

Leukocyte counts are normal or low. Leukocytosis suggests secondary bacterial infection. The virus can be identified by fluorescent antibody staining of a lesion smear. Rapid culture methods take 48 hours. Diagnosis made with paired serology is not clinically useful. Serum aminotransferase levels may be modestly elevated during normal varicella.

C. Imaging

Varicella pneumonia classically produces numerous bilateral nodular densities and hyperinflation. This is very rare in immunocompetent children. Abnormal chest radiographs are seen more frequently in adults.

► Differential Diagnosis

Varicella is usually distinctive. Similar rashes include those of coxsackievirus infection (fewer lesions, lack of crusting), impetigo (fewer lesions, smaller area, no classic vesicles, positive Gram stain, perioral or peripheral lesions), papular urticaria (insect bite history, nonvesicular rash), scabies (burrows, no typical vesicles; failure to resolve), parapsoriasis (rare in children younger than age 10 years, chronic or recurrent, often a history of prior varicella), rickettsialpox (eschar where the mite bites, smaller lesions, no crusting), dermatitis herpetiformis (chronic, urticaria, residual pigmentation), and folliculitis. Herpes zoster is sometimes confused with a linear eruption of herpes simplex or a contact dermatitis (eg, *Rhus* dermatitis).

► Complications & Sequelae

A. Varicella

Secondary bacterial infection with staphylococci or group A streptococci is most common, presenting as impetigo, cellulitis or fasciitis, abscesses, scarlet fever, or sepsis. Bacterial superinfection occurs in 2–3% of children. Before a vaccine became available, hospitalization rates associated with varicella were 1:750–1:1000 cases in children and 10-fold higher in adults.

Protracted vomiting or a change in sensorium suggests Reye syndrome or encephalitis. Because Reye syndrome usually occurs in patients who are also using salicylates, these should be avoided in patients with varicella. Encephalitis occurs in less than 0.1% of cases, usually in the first week of illness, and is usually limited to cerebellitis with ataxia, which resolves completely. Diffuse encephalitis can be severe.

Varicella pneumonia usually afflicts immunocompromised children (especially those with leukemia or lymphoma or those receiving high doses of corticosteroids or chemo-

therapy) and adults; pregnant women may be at special risk. Cough, dyspnea, tachypnea, rales, and cyanosis occur several days after onset of rash. Varicella may be life-threatening in immunosuppressed patients. In addition to pneumonitis, their disease may be complicated by hepatitis and encephalitis. Varicella exposure in such patients must be evaluated immediately for postexposure prophylaxis (see Chapter 9).

Hemorrhagic varicella lesions may be seen without other complications. This is most often caused by autoimmune thrombocytopenia, but hemorrhagic lesions can occasionally represent idiopathic disseminated intravascular coagulation (purpura fulminans).

Neonates born to mothers who develop varicella from 5 days before to 2 days after delivery are at high risk for severe or fatal (5%) disease and must be given varicella-zoster immune globulin (VZIG) and followed closely (see Chapter 9).

Varicella occurring during the first 20 weeks of pregnancy may cause (2% incidence) congenital infection associated with cicatricial skin lesions, associated limb anomalies, and cortical atrophy.

Unusual complications of varicella include optic neuritis, myocarditis, transverse myelitis, orchitis, and arthritis.

B. Herpes Zoster

Complications of herpes zoster include secondary bacterial infection, motor or cranial nerve paralysis (cases in adults), encephalitis, keratitis, and dissemination in immunosuppressed patients. These complications are rare in immunocompetent children, and they do not develop prolonged pain. Postherpetic neuralgia does occur in immunocompromised children.

► Prevention

VZIG is available for postexposure prevention of varicella in high-risk susceptible persons (see Chapter 9). Postexposure prophylaxis with acyclovir is effective when it is started at 8 or 9 days after exposure and is continued for 7 days. Varicella vaccine is also useful for postexposure prophylaxis when given within 3–5 days of the exposure. Two doses of the live attenuated varicella vaccine are now part of routine childhood immunization, and “catch-up” immunization is recommended for all other susceptible children and adults.

► Treatment

A. General Measures

Supportive measures include maintenance of hydration, administration of acetaminophen for discomfort, cool soaks or antipruritics for itching (diphenhydramine, 1.25 mg/kg every 6 hours, or hydroxyzine, 0.5 mg/kg every 6 hours), and observance of general hygiene measures (keep nails trimmed and skin clean). Care must be taken to avoid overdosage with antihistaminic agents. Topical or systemic antibiotics may be needed for bacterial superinfection.

B. Specific Measures

Although acyclovir is more active against herpes simplex, it is the preferred drug for varicella and herpes zoster infections. Recommended parenteral acyclovir dosage for severe disease is 10 mg/kg (500 mg/m²) intravenously every 8 hours, each dose infused over 1 hour. Parenteral therapy should be started early in immunosuppressed patients or high-risk infected neonates. VZIG is of no value for established disease. The effect of oral acyclovir (80 mg/kg/d, divided in four doses) on varicella in immunocompetent children was modestly beneficial and nontoxic, but only when administered within 24 hour after the onset of varicella. Oral acyclovir should be used selectively in immunocompetent children (eg, when intercurrent illness is present; possibly when second attacks occur in the household or when the patient is an adolescent—both of which are associated with more severe disease) and in children with underlying chronic illnesses. Valacyclovir and famciclovir are superior antiviral agents because of better absorption; only acyclovir is available as a pediatric suspension. Herpes zoster in an immunocompromised child should be treated with intravenous acyclovir when it is severe, but oral valacyclovir or famciclovir can be used in immunocompromised children when the nature of the illness and the immune status support this decision.

► Prognosis

Except for secondary bacterial infections, serious complications are rare and recovery complete in immunocompetent hosts.

Marin M et al; Centers for Disease Control and Prevention (CDC): Prevention of varicella: Recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep* 2007;56(RR-4):1 [PMID: 17585291].

ROSEOLA INFANTUM (EXANTHEM SUBITUM)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- High fever in a child aged 6–36 months.
- Minimal toxicity.
- Rose-pink maculopapular rash appears when fever subsides.

► General Considerations

Roseola infantum is a benign illness caused by human herpesviruses 6 (HHV-6) or 7 (HHV-7). HHV-6 is a major cause of acute febrile illness in young children. Its significance is its ability to mimic more serious causes of high fever and its role in inciting febrile seizures.

► Clinical Findings

The most prominent historical feature is the abrupt onset of fever, often reaching 40.6°C, which lasts up to 8 days (mean, 4 days) in an otherwise mildly ill child. The fever then ceases abruptly, and a characteristic rash may appear. Roseola occurs predominantly in children aged 6 months to 3 years, with 90% of cases occurring before the second year. HHV-7 infection tends to occur somewhat later in childhood. These viruses are the most common recognized cause of exanthematous fever in this age group and are responsible for 20% of emergency department visits by children aged 6–12 months.

A. Symptoms and Signs

Mild lethargy and irritability may be present, but generally there is a dissociation between systemic symptoms and the febrile course. The pharynx, tonsils, and tympanic membranes may be injected. Conjunctivitis and pharyngeal exudate are notably absent. Diarrhea and vomiting occur in one third of patients. Adenopathy of the head and neck often occurs. The anterior fontanelle is bulging in one quarter of HHV-6-infected infants. If rash appears (20–30% incidence), it begins on the trunk and spreads to the face, neck, and extremities. Rose-pink macules or maculopapules, 2–3 mm in diameter, are nonpruritic, tend to coalesce, and disappear in 1–2 days without pigmentation or desquamation. Rash may occur without fever.

B. Laboratory Findings

Leukopenia and lymphocytopenia are present early. Laboratory evidence of hepatitis occurs in some patients, especially adults.

► Differential Diagnosis

The initial high fever may require exclusion of serious bacterial infection. The relative well-being of most children and the typical course and rash soon clarify the diagnosis. The erythrocyte sedimentation rate is normal. If the child has a febrile seizure, it is important to exclude bacterial meningitis. The CSF is normal in children with roseola. In children who receive antibiotics or other medication at the beginning of the fever, the rash may be attributed incorrectly to drug allergy.

► Complications & Sequelae

Febrile seizures occur in 10% of patients (even higher percentages in those with HHV-7 infections). There is evidence that HHV-6 can directly infect the central nervous system, causing meningoencephalitis or aseptic meningitis. Multiorgan disease (pneumonia, hepatitis, bone marrow suppression, encephalitis) may occur in immunocompromised patients.

► Treatment & Prognosis

Fever is managed readily with acetaminophen and sponge baths. Fever control should be a major consideration in

children with a history of febrile seizures. Roseola infantum is otherwise entirely benign.

CYTOMEGALOVIRUS INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- **Primary infection:**
 - Asymptomatic or minor illness in young children.
 - Mononucleosis-like syndrome without pharyngitis in postpubertal individuals.
- **Congenital infection:**
 - Intrauterine growth retardation.
 - Microcephaly with intracerebral calcifications and seizures.
 - Retinitis and encephalitis.
 - Hepatosplenomegaly with thrombocytopenia.
 - “Blueberry muffin” rash.
 - Sensorineural deafness.
- **Immunocompromised hosts:**
 - Retinitis and encephalitis.
 - Pneumonitis.
 - Enteritis and hepatitis.
 - Bone marrow suppression.

► General Considerations

Cytomegalovirus (CMV) is a ubiquitous herpesvirus transmitted by many routes. It can be acquired in utero following maternal viremia or postpartum from birth canal secretions or maternal milk. Young children are infected by the saliva of playmates; older individuals are infected by sexual partners (eg, from saliva, vaginal secretions, or semen). Transfused blood products and transplanted organs can be a source of CMV infection. Clinical illness is determined largely by the patient’s immune competence. Immunocompetent individuals usually develop a mild self-limited illness, whereas immunocompromised children can develop severe, progressive, often multiorgan disease. In-utero infection can be teratogenic.

1. In-Utero Cytomegalovirus Infection

Approximately 0.5–1.5% of children are born with CMV infections acquired during maternal viremia. CMV infection is

asymptomatic in over 90% of these children, who are usually born to mothers who had experienced reactivation of latent CMV infection during the pregnancy. Symptomatic infection occurs predominantly in infants born to mothers with primary CMV infection but can also result from recurrent, most likely, reinfection during pregnancy. Even when exposed to a primary maternal infection, less than 50% of fetuses are infected, and in only 10% of those infants is the infection symptomatic at birth. Primary infection in the first half of pregnancy poses the greatest risk for severe fetal damage.

► Clinical Findings

A. Symptoms and Signs

Severely affected infants are born ill; they are often small for gestational age, floppy, and lethargic. They feed poorly and have poor temperature control. Hepatosplenomegaly, jaundice, petechiae, seizures, and microcephaly are common. Characteristic signs are a distinctive chorioretinitis and periventricular calcification. A purpuric (so-called blueberry muffin) rash similar to that seen with congenital rubella may be present. The mortality rate is 10–20%. Survivors usually have significant sequelae, especially mental retardation, neurologic deficits, retinopathy, and hearing loss. Isolated hepatosplenomegaly or thrombocytopenia may occur. Even mildly affected children may subsequently manifest mental retardation and psychomotor delay. However, most infected infants (90%) are born to mothers with preexisting immunity who had a reactivation of latent CMV during pregnancy. These children have no clinical manifestations at birth. Of these, 10–15% develop sensorineural hearing loss, which is often bilateral and may appear several years after birth.

B. Laboratory Findings

In severely ill infants, anemia, thrombocytopenia, hyperbilirubinemia, and elevated aminotransferase levels are common. Lymphocytosis occurs occasionally. Pleocytosis and an elevated protein concentration are found in CSF. The diagnosis is readily confirmed by isolation of CMV from urine or saliva within 48 hours, using rapid culture methods combined with immunoassay. The presence in the infant of IgM-specific CMV antibodies suggests the diagnosis. Some commercial ELISA kits are 90% sensitive and specific for these antibodies.

C. Imaging

Head radiologic examinations may show microcephaly, periventricular calcifications, and ventricular dilation. These findings strongly correlate with neurologic sequelae and retardation. Long bone radiographs may show the “celery stalk” pattern characteristic of congenital viral infections. Interstitial pneumonia may be present.

► Differential Diagnosis

CMV infection should be considered in any newborn who is seriously ill shortly after birth, especially once bacterial

sepsis, metabolic disease, intracranial bleeding, and cardiac disease have been excluded. Other congenital infections to be considered in the differential diagnosis include toxoplasmosis (serology, more diffuse calcification of the CNS, specific type of retinitis, macrocephaly), rubella (serology, specific type of retinitis, cardiac lesions, eye abnormalities), enteroviral infections (time of year, maternal illness, severe hepatitis), herpes simplex (skin lesions, cultures, severe hepatitis), and syphilis (serology for both infant and mother, skin lesions, bone involvement).

► Prevention & Treatment

Support is rarely required for anemia and thrombocytopenia. Most children with symptoms at birth have significant neurologic, intellectual, visual, or auditory impairment. Ganciclovir, 5 mg/kg every 12 hours, is recommended for children with severe, life- or sight-threatening disease, or if end-organ disease recurs or progresses. Duration is 2–3 weeks or until symptoms resolve. This approach decreases viral shedding and limits progression of symptoms, including hearing loss, during treatment. However, the therapeutic advantage is progressively lost over time after treatment is discontinued. Children who are asymptomatic at birth have a 6–23% incidence of hearing loss. Children with positive CMV blood PCR results during the first month of life are more likely to develop hearing loss. Studies are currently ongoing to determine if early treatment prevents late-onset hearing loss.

Recent developments in the diagnosis of primary CMV infection during pregnancy using anti-CMV IgM and low-avidity IgG assays followed by quantitative CMV PCR testing of the amniotic fluid at 20–24 weeks' gestation have made possible the diagnosis of congenital CMV infection before birth. Many pregnant women elect to terminate gestation under these circumstances, but a recent study has also shown that passive immunoprophylaxis with hyperimmune CMV IgG may prevent development of congenital disease.

2. Perinatal Cytomegalovirus Infection

CMV infection can be acquired from birth canal secretions or shortly after birth from maternal milk. In some socioeconomic groups, 10–20% of infants are infected at birth and excrete CMV for many months. Infection can also be acquired in the postnatal period from unscreened transfused blood products.

► Clinical Findings

A. Symptoms and Signs

Ninety percent of immunocompetent infants infected by their mothers at birth develop subclinical illness (ie, virus excretion only) or a minor illness within 1–3 months. The remainder develop an illness lasting several weeks and characterized by hepatosplenomegaly, lymphadenopathy, and

interstitial pneumonitis in various combinations. The severity of the pneumonitis may be increased by the simultaneous presence of *Chlamydia trachomatis*. Infants who receive blood products are often premature and immunologically impaired. If they are born to CMV-negative mothers and subsequently receive CMV-containing blood, they frequently develop severe infection and pneumonia after a 2- to 6-week incubation period.

B. Laboratory Findings

Lymphocytosis, atypical lymphocytes, anemia, and thrombocytopenia may be present, especially in premature infants. Liver function is abnormal. CMV can be isolated from urine and saliva. Secretions obtained at bronchoscopy contain CMV and epithelial cells bearing CMV antigens. Serum levels of CMV antibody rise significantly.

C. Imaging

Chest radiographs show a diffuse interstitial pneumonitis in severely affected infants.

► Differential Diagnosis

CMV infection should be considered as a cause of any prolonged illness in early infancy, especially if hepatosplenomegaly, lymphadenopathy, or atypical lymphocytosis is present. This must be distinguished from granulomatous or malignant diseases and from congenital infections (syphilis, toxoplasmosis, hepatitis B) not previously diagnosed. Other viruses (Epstein-Barr virus [EBV], HIV, adenovirus) can cause this syndrome. CMV is a recognized cause of viral pneumonia in this age group. Because asymptomatic CMV excretion is common in early infancy, care must be taken to establish the diagnosis and to rule out concomitant pathogens such as *Chlamydia* and RSV. Severe CMV infection in early infancy may indicate that the child has a congenital or acquired immune deficiency.

► Prevention & Treatment

The self-limited disease of normal infants requires no therapy. Severe pneumonitis in premature infants requires oxygen administration and often intubation. Very ill infants should receive ganciclovir (6 mg/kg every 12 hours). CMV infection acquired by transfusion can be prevented by excluding CMV-seropositive blood donors. Milk donors should also be screened for prior CMV infection. It is likely that high-risk infants receiving large doses of IVIG for other reasons will be protected against severe CMV disease.

3. Cytomegalovirus Infection Acquired in Childhood & Adolescence

Young children are readily infected by playmates, especially because CMV continues to be excreted in saliva and urine for

many months after infection. The cumulative annual incidence of CMV excretion by children in day care centers exceeds 75%. In fact, young children in a family are often the source of primary CMV infection of their mothers during subsequent pregnancies. An additional peak of CMV infection takes place when adolescents become sexually active. Sporadic acquisition of CMV occurs after blood transfusion and transplantation.

► Clinical Findings

A. Symptoms and Signs

Most young children who acquire CMV are asymptomatic or have a minor febrile illness, occasionally with adenopathy. They provide an important reservoir of virus shedders that facilitates spread of CMV. Occasionally a child may have prolonged fever with hepatosplenomegaly and adenopathy. Older children and adults, many of whom are infected during sexual activity, are more likely to be symptomatic in this fashion and can present with a syndrome that mimics the infectious mononucleosis syndrome that follows EBV infection (1–2 weeks of fever, malaise, anorexia, splenomegaly, mild hepatitis, and some adenopathy; see next section). This syndrome can also occur 2–4 weeks after transfusion of CMV-infected blood.

B. Laboratory Findings

In the CMV mononucleosis syndrome, lymphocytosis and atypical lymphocytes are common, as is a mild rise in aminotransferase levels. CMV is present in saliva and urine, and CMV DNA can be uniformly detected in plasma or blood.

► Differential Diagnosis

In older children, CMV infection should be included as a possible cause of fever of unknown origin, especially when lymphocytosis and atypical lymphocytes are present. CMV infection is distinguished from EBV infection by the absence of pharyngitis, the relatively minor adenopathy, and the absence of serologic evidence of acute EBV infection. Mononucleosis syndromes also are caused by *Toxoplasma gondii*, rubella virus, adenovirus, hepatitis A virus, and HIV.

► Prevention

Screening of transfused blood or filtering blood (thus removing CMV-containing white blood cells) prevents cases related to this source.

4. Cytomegalovirus Infection in Immunocompromised Children

In addition to symptoms experienced during primary infection, immunocompromised hosts develop symptoms with reinfection or reactivation of latent CMV. This is clearly seen

in children with acquired immunodeficiency syndrome (AIDS), after transplantation, or with congenital immunodeficiencies. However, in most immunocompromised patients, primary infection is more likely to cause severe symptoms than is reactivation or reinfection. The severity of the resulting disease is generally proportionate to the degree of immunosuppression.

► Clinical Findings

A. Symptoms and Signs

A mild febrile illness with myalgia, malaise, and arthralgia may occur, especially with reactivation disease. Severe disease often includes subacute onset of dyspnea and cyanosis as manifestations of interstitial pneumonitis. Auscultation reveals only coarse breath sounds and scattered rales. A rapid respiratory rate may precede clinical or radiographic evidence of pneumonia. Hepatitis without jaundice or hepatomegaly is common. Diarrhea, which can be severe, occurs with CMV colitis, and CMV can cause esophagitis with symptoms of odynophagia or dysphagia. These enteropathies are most common in AIDS, as is the presence of a retinitis that often progresses to blindness. Encephalitis and polyradiculitis also occur in AIDS.

B. Laboratory Findings

Neutropenia and thrombocytopenia are common. Atypical lymphocytosis is infrequent. Serum aminotransferase levels are often elevated. The stools may contain occult blood if enteropathy is present. CMV is readily isolated from saliva, urine, buffy coat, and bronchial secretions. Results are available in 48 hours. Interpretation of positive cultures is made difficult by asymptomatic shedding of CMV in saliva and urine in many immunocompromised patients. CMV disease correlates more closely with the presence of CMV in the blood or lung lavage fluid. Monitoring for the appearance of CMV DNA in plasma or CMV antigen in blood mononuclear cells is used as a guide to early antiviral (“preemptive”) therapy.

C. Imaging

Bilateral interstitial pneumonitis is present on chest radiographs.

► Differential Diagnosis

The initial febrile illness must be distinguished from treatable bacterial or fungal infection. Similarly the pulmonary disease must be distinguished from intrapulmonary hemorrhage; drug-induced or radiation pneumonitis; pulmonary edema; and bacterial, fungal, parasitic, and other viruses infection in this population. CMV infection is seen bilaterally and interstitially on chest radiographs, cough is nonproductive, chest pain is absent, and the patient is not usually toxic. *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) infection may have a similar presentation. These patients may have polymy-

crobial disease. It is suspected that bacterial and fungal infections are enhanced by the neutropenia that can accompany CMV infection. Infection of the gastrointestinal tract is diagnosed by endoscopy. This will exclude candidal, adenoviral, and herpes simplex infections and allows tissue confirmation of CMV-induced mucosal ulcerations.

► Prevention & Treatment

Blood donors should be screened to exclude those with prior CMV infection, or blood should be filtered. Ideally, seronegative transplant recipients should receive organs from seronegative donors. Severe symptoms, most commonly pneumonitis, often respond to early therapy with intravenous ganciclovir (5 mg/kg every 12 hours for 14–21 days). Neutropenia is a frequent side effect of this therapy. Foscarnet and cidofovir are alternative therapeutic agents recommended for patients with ganciclovir-resistant virus. Prophylactic use of oral or intravenous ganciclovir or foscarnet may prevent CMV infections in organ transplant recipients. A new drug with an excellent safety profile, maribavir, has shown efficacy in hematopoietic stem cell recipients. Additional studies are being conducted in solid organ transplant recipients. Preemptive therapy can be used in transplant recipients by monitoring CMV blood PCR and instituting therapy when the results reach a certain threshold regardless of clinical signs or symptoms. CMV-seropositive children with AIDS and low CD4 counts (< 50/μL) should have fundoscopic examinations and plasma CMV DNA measurements every 3 months.

INFECTIOUS MONONUCLEOSIS (EPSTEIN-BARR VIRUS)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Prolonged fever.
- Exudative pharyngitis.
- Generalized adenopathy.
- Hepatosplenomegaly.
- Atypical lymphocytes.
- Heterophil antibodies.

► General Considerations

Mononucleosis is the most characteristic syndrome produced by EBV infection. Young children infected with EBV have either no symptoms or a mild nonspecific febrile illness. As the age of the host increases, EBV infection is more likely to produce the typical features of the mononucleosis syndrome in 20–25% of infected adolescents. EBV is acquired readily from asymptomatic carriers (15–20% of whom excrete the virus in saliva on any given day) and from recently ill patients, who excrete virus for many months. Young children are infected from the saliva of playmates and family members. Adolescents may be infected through sexual activity. EBV can also be transmitted by blood transfusion and organ transplantation.

► Clinical Findings

A. Symptoms and Signs

After an incubation period of 1–2 months, a 2- to 3-day prodrome of malaise and anorexia yields, abruptly or insidiously, to a febrile illness with temperatures exceeding 39°C. The major complaint is pharyngitis, which is often (50%) exudative. Lymph nodes are enlarged, firm, and mildly tender. Any area may be affected, but posterior and anterior cervical nodes are almost always enlarged. Splenomegaly is present in 50–75% of patients. Hepatomegaly is common (30%), and the liver is frequently tender. Five percent of patients have a rash, which can be macular, scarlatiniform, or urticarial. Rash is almost universal in patients taking penicillin or ampicillin. Soft palate petechiae and eyelid edema are also observed.

B. Laboratory Findings

1. Peripheral blood—Leukopenia may occur early, but an atypical lymphocytosis (comprising over 10% of the total leukocytes at some time in the illness) is most notable. Hematologic changes may not be seen until the third week of illness and may be entirely absent in some EBV syndromes (eg, neurologic ones).

2. Heterophil antibodies—These nonspecific antibodies appear in over 90% of older patients with mononucleosis but in fewer than 50% of children younger than age 5 years. They may not be detectable until the second week of illness and may persist for up to 12 months after recovery. Rapid screening tests (slide agglutination) are usually positive if the titer is significant; a positive result strongly suggests but does not prove EBV infection.

3. Anti-EBV antibodies—It may be necessary to measure specific antibody titers when heterophil antibodies fail to appear, as in young children. Acute EBV infection is established by detecting IgM antibody to the viral capsid antigen (VCA) or by detecting a fall over several weeks of IgG anti-VCA titers (IgG antibody peaks by the time symptoms appear).

4. EBV PCR—This assay detects EBV DNA. It is the method of choice for the diagnosis of CNS and ocular infections. Quantitative EBV PCR in peripheral blood mononuclear cells has been used to detect EBV-related lymphoproliferative disorders in transplant patients.

► Differential Diagnosis

Severe pharyngitis may suggest group A streptococcal infection. Enlargement of only the anterior cervical lymph nodes, a neutrophilic leukocytosis, and the absence of splenomegaly suggest bacterial infection. Although a child with a positive throat culture result for streptococcus usually requires therapy, up to 10% of children with mononucleosis are asymptomatic streptococcal carriers. In this group, penicillin therapy is unnecessary and often causes a rash. Severe primary herpes simplex pharyngitis, occurring in adolescence, may also mimic infectious mononucleosis. In this type of pharyngitis, some anterior mouth ulcerations should suggest the correct diagnosis. EBV infection should be considered in the differential diagnosis of any perplexing prolonged febrile illness. Similar illnesses that produce atypical lymphocytosis include rubella (pharyngitis not prominent, shorter illness, less adenopathy and splenomegaly), adenovirus (upper respiratory symptoms and cough, conjunctivitis, less adenopathy, fewer atypical lymphocytes), hepatitis A or B (more severe liver function abnormalities, no pharyngitis, no lymphadenopathy), and toxoplasmosis (negative heterophil test, less pharyngitis). Serum sickness-like drug reactions and leukemia (smear morphology is important) may be confused with infectious mononucleosis. CMV mononucleosis is a close mimic except for minimal pharyngitis and less adenopathy; it is much less common. Serologic tests for EBV and CMV should clarify the correct diagnosis. The acute initial manifestation of HIV infection is a mononucleosis-like syndrome in many patients.

► Complications

Splenic rupture is a rare complication, which usually follows significant trauma. Hematologic complications, including hemolytic anemia, thrombocytopenia, and neutropenia, are more common. Neurologic involvement can include aseptic meningitis, encephalitis, isolated neuropathy such as Bell palsy, and Guillain-Barré syndrome. Any of these may appear prior to or in the absence of the more typical signs and symptoms of infectious mononucleosis. Rare complications include myocarditis, pericarditis, and atypical pneumonia. Recurrence or persistence of EBV-associated symptoms for 6 months or longer characterizes chronic active EBV. This disease is due to continuous viral replication and warrants specific antiviral therapy. Rarely EBV infection becomes a progressive lymphoproliferative disorder characterized by persistent fever, multiple organ involvement, neutropenia or pancytopenia, and agammaglobulinemia. Hemocytopenia is often present in the bone marrow. An X-linked genetic defect in immune response has been inferred for some

patients (Duncan syndrome, X-linked lymphoproliferative disorder). Children with other congenital immunodeficiencies or chemotherapy-induced immunosuppression can also develop progressive EBV infection, EBV-associated lymphoproliferative disorder or lymphoma, and other malignancies.

▶ Treatment & Prognosis

Bed rest may be necessary in severe cases. Acetaminophen controls high fever. Potential airway obstruction due to swollen pharyngeal lymphoid tissue responds rapidly to systemic corticosteroids. Corticosteroids may also be given for hematologic and neurologic complications, although no controlled trials have proved their efficacy in these conditions. Fever and pharyngitis disappear by 10–14 days. Adenopathy and splenomegaly can persist several weeks longer. Some patients complain of fatigue, malaise, or lack of well-being for several months. Although corticosteroids may shorten the duration of fatigue and malaise, their long-term effects on this potentially oncogenic viral infection are unknown, and indiscriminate use is discouraged. Patients with splenic enlargement should avoid contact sports for 6–8 weeks. Acyclovir, valacyclovir, penciclovir, ganciclovir, and foscarnet are active against EBV and are indicated in the treatment of chronic active EBV.

Management of EBV-related lymphoproliferative disorders relies primarily on decreasing the immunosuppression whenever possible. Adjunctive therapy with acyclovir, ganciclovir, or another antiviral active against EBV as well as CMV hyperimmune globulin has been used without scientific evidence of efficacy.

VIRAL INFECTIONS SPREAD BY INSECT VECTORS

In the United States, mosquitoes are the most common insect vectors that spread viral infections (Table 38–4). As a consequence, these infections—and others that are spread by ticks—tend to occur as summer–fall epidemics that coincide with the seasonal breeding and feeding habits of the vector, and the etiologic agent varies by region. Thus a careful travel and exposure history is critical for correct diagnostic workup.

ENCEPHALITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Fever and headache.

- ▶ Change in mental status or behavior (or both), with or without focal neurologic deficits.
- ▶ CSF shows a mononuclear cell pleocytosis, elevated protein level, and normal glucose level.

Encephalitis is a common severe manifestation of many infections spread by insects (see Table 38–4). With many viral pathogens, the infection is most often subclinical, or mild CNS disease such as meningitis is present. These infections have some distinguishing features in terms of subclinical infection rate, unique neurologic syndromes, associated non-neurologic symptoms, and prognosis. The diagnosis is generally made clinically during recognized outbreaks and is confirmed by virus-specific serology. Prevention consists of control of mosquito vectors and precautions with proper clothing and insect repellents to minimize mosquito and tick bites.

West Nile Virus Encephalitis

This flavivirus is the most important arbovirus infection in the United States. Since it was described in 1999 in New York, it has spread to 47 states. In 2007, West Nile virus caused more than 3300 clinically apparent infections, more than 1000 nervous system infections, and 95 deaths. Its reservoir includes more than 160 species of birds whose migration explain the rapid growth of the epidemic. During summer–fall epidemics most infected individuals are asymptomatic. Approximately 20% develop West Nile fever, which is characterized by fever, headache, retro-orbital pain, nausea and vomiting, lymphadenopathy, and a maculopapular rash (20–50%). Less than 1% of infected patients develop meningitis or encephalitis, but 10% of these cases are fatal (0.1% of all infections). The major risk factor for severe disease is age older than 50 years and immune compromise, although children develop West Nile fever and occasionally have neurologic disease. The neurologic manifestations are most often those found with other encephalitides. However, distinguishing atypical features include polio-like flaccid paralysis, movement disorders (parkinsonism, tremor, myoclonus), brainstem symptoms, polyneuropathy, and optic neuritis. Muscle weakness, facial palsy, and hyporeflexia are common (20% of each finding). Diagnosis is best made by detecting IgM antibody (EIA) to the virus in CSF. This will be present by 2–3 days (95%) after onset. PCR is a specific diagnostic tool but is less sensitive than antibody detection. Antibody rise in serum can also be used for diagnosis.

Treatment is supportive, although various antivirals and specific immune globulin are being studied. The infection is not spread between contacts, but is spread by donated organs and blood and breast milk and transplacentally. The coming years will indicate if this virus will become a serious endemic problem in the United States.

Truemper EJ, Romero JR: West Nile virus. *Pediatr Ann* 2007;36:414 [PMID: 17691625].

Table 38-4. Some viral diseases spread by insects in the United States.

Disease	Natural Reservoir (Vector)	Geographic Distribution	Incubation Period	Clinical Presentations	Laboratory Findings	Complications, Sequelae	Diagnosis, Therapy, Comments
Flaviviruses							
St. Louis encephalitis (SLE)	Birds (<i>Culex</i> mosquitoes)	Southern Canada, central and southern United States, Caribbean, South America	2-5 d (up to 3 wk)	Abrupt onset of fever, chills, headache, nausea, vomiting; may develop generalized weakness, seizures, coma, ataxia, cranial nerve palsies. Aseptic meningitis is common in children.	Modest leukocytosis, neutrophilia, elevated liver enzymes. CSF: 100-200 WBCs/ μ L (PMNs predominate early).	Mortality rate 2-5% at age < 5 or > 50 years. Neurologic sequelae in 1-20%.	~35 cases/y, < 2% symptomatic. (Worse in elderly.) Therapy: supportive. Diagnosis: serology. Specific antibody often present within 5 d.
Dengue	Humans (<i>Aedes</i> mosquitoes)	Asia, Africa, Central and South America, Caribbean; observed in Texas/Mexico border area	4-7 d (range, 3-14 d)	Fever, headache, myalgia, joint and bone pain, retroocular pain, nausea and vomiting; maculopapular or petechial rash in 50%, sparing palms and soles; adenopathy. Meningoencephalitis in 5-10% of children.	Leukopenia, thrombocytopenia. CSF: 100-500 mononuclear cells/ μ L if neurologic signs are present.	Hemorrhagic fever, shock syndrome, prolonged weakness.	High infection rate. 50-150 cases occur in U.S. travelers to endemic areas. Biphasic course may occur. Therapy: supportive. Diagnosis: serology; IgM-EIA antibody by day 6.
West Nile	Birds (<i>Culex</i> mosquitoes); small mammals	North Africa, Middle East, parts of Asia, Europe, continental United States	3-12 d	Abrupt onset of fever, headache, sore throat, myalgia, retroocular pain, conjunctivitis; 20-50% with rash; adenopathy. Encephalitis may be accompanied by muscle weakness, flaccid paralysis, or movement disorders.	Mild leukocytosis; 10-15% lymphopenic; moderate CSF pleocytosis.	Mortality rate 10%, of those with CNS symptoms, especially in elderly; weakness and myalgia may persist for an extended period.	Most important mosquito-borne encephalitis in the United States. Diagnosis: IgM-EIA serology; cross-reacts with St. Louis encephalitis; positive by 2-3 d after onset of CNS symptoms. Diagnosis by PCR is less sensitive. Therapy: supportive.
Alpha toga viruses							
Eastern equine encephalitis	Birds (<i>Culiseta</i> mosquitoes)	Eastern seaboard United States, Caribbean, South America	2-5 d	Similar to that of St. Louis encephalitis but more severe. Progresses rapidly in one third to coma and death.	Leukocytosis with neutrophilia. CSF: 500-2000 WBCs/ μ L; PMNs predominate early.	Mortality rate 20-50%; neurologic sequelae in over 50% of children.	Fewer than 10 cases/y. Only 3-10% of cases are symptomatic. Therapy: supportive. Diagnosis: serology. Titers often positive in first week. Equine deaths may signal an outbreak.

(continued)

Table 38–4. Some viral diseases spread by insects in the United States. (*Continued*)

Disease	Natural Reservoir (Vector)	Geographic Distribution	Incubation Period	Clinical Presentations	Laboratory Findings	Complications, Sequelae	Diagnosis, Therapy, Comments
Western equine encephalitis	Birds (<i>Culisata</i> mosquitoes)	Canada, Mexico, and United States west of Mississippi River	2–5 d	Similar to that of St. Louis encephalitis. Most infections are subclinical.	Variable white counts. CSF: 10–300 WBCs/ μ L.	Permanent brain damage, 10% overall; most severe in older adults.	No reported cases in United States in recent years. Case/infection is 1:1000 for older adults and 1:1 for infants. Equine illness precedes human outbreaks. Diagnosis: IgM antibody in first week. Therapy: supportive.
Venezuelan equine encephalitis	Horses (10 species of mosquitoes)	South and Central America, Texas	1–6 d	Similar to that of St. Louis encephalitis.	Lymphopenia, mild thrombocytopenia, abnormal liver function tests. CSF: 50–200 mononuclear cells/ μ L.	Severe disease more common in infants; 20% fatality rate for encephalitis.	Most infections do not cause encephalitis. No cases in United States in recent years. Vaccination of horses will stop epidemic. Therapy: supportive. Diagnosis: IgM antibody (EIA).
Bunyavirus							
California encephalitis (LaCrosse, Jamestown Canyon, California)	Chipmunks and other small mammals (<i>Aedes</i> mosquitoes)	Northern and mid-central United States, southern Canada	3–7 d	Similar to that of St. Louis encephalitis; sore throat and respiratory symptoms are common; focal neurologic signs in up to 25%. Seizures prominent. Prepubertal children are most likely to have severe disease. Can mimic HSV encephalitis.	Variable white counts. CSF: 30–200 (up to 600) WBCs/ μ L; variable PMNs; protein often normal.	Mortality rate < 1%. Seizure disorder may begin during acute illness.	About 150 cases/y in United States, 5% symptomatic. > 10% with sequelae. Therapy: supportive. Diagnosis: serology. Up to 90% have specific IgM antibody in first week; 25% of population in certain regions has IgG antibody.
Coltivirus							
Colorado tick fever	Small mammals (<i>Dermacentor andersoni</i> , or wood tick)	Rocky Mountain region of United States and Canada	3–4 d (range, 2–14 d)	Fever, chills, myalgia, conjunctivitis, headache, retro-orbital pain; rash in < 10%. No respiratory symptoms. Biphasic fever in 50%.	Leukopenia (maximum at 4–6 d), mild thrombocytopenia.	Rare encephalitis, coagulopathy.	Patient may have no known tick bite. Acute illness lasts 7–10 d; prolonged fatigue in adults. Therapy: supportive. Diagnosis: serology, direct FA staining of red cells for viral antigen, PCR.

CNS, central nervous system; CSF, cerebrospinal fluid; EIA, enzyme immunoassay; FA, fluorescent antibody; HSV, herpes simplex virus; PCR, polymerase chain reaction; PMN, polymorphonuclear neutrophil; WBC, white blood cell.

DENGUE

ESSENTIALS OF DIAGNOSIS
& TYPICAL FEATURES

- ▶ Travel or residence in an endemic area.
- ▶ First infection (first episode) results in nonspecific rash and fever; retro-orbital pain, severe myalgia, and arthralgia may occur.
- ▶ Subsequent infection with a different (heterotypic) serotype of dengue results in dengue hemorrhagic fever (thrombocytopenia, bleeding, plasma leak syndrome); this may progress to shock (dengue shock syndrome).

In endemic areas 50–100 million cases of dengue occur each year, often in severe forms. In the United States, 50–150 cases are diagnosed, most often in travelers from the Caribbean or Asia and less often in those visiting Central and South America, making it the most common arboviral disease in travelers. Dengue occurs in Mexico, and Texas has sporadic indigenous outbreaks. The spread of dengue requires the requisite species of mosquito, which transmits virus from a reservoir of viremic humans in endemic areas. Most patients have mild disease, especially young children, who may have a nonspecific fever and rash. Severity is a function of age, and prior infection with other serotypes of dengue virus is a prerequisite for severe hemorrhagic complications.

▶ Clinical Findings

A. Symptoms and Signs

Dengue fever begins abruptly 4–7 days after transmission (range, 3–14 days) with fever, chills, severe retro-orbital pain, severe muscle and joint pain, nausea, and vomiting. Erythema of the face and torso may occur early. After 3–4 days a centrifugal maculopapular rash appears in half of patients. The rash can become petechial, and mild hemorrhagic signs (epistaxis, gingival bleeding, microscopic blood in stool or urine) may be noted. The illness lasts 5–7 days, although rarely fever may reappear for several additional days.

B. Laboratory Findings

Leukopenia and a mild drop in platelets are common. Liver function tests are usually normal. Diagnosis is made by viral culture of plasma (50% sensitive up to the fifth day), by detecting IgM-specific ELISA antibodies (90% sensitive at the sixth day), or by detecting a rise in type-specific antibody. PCR testing is available for diagnosis in some areas.

▶ Differential Diagnosis

This diagnosis should be considered for any traveler to an endemic area who has symptoms suggestive of a systemic viral illness, although less than 1 in 1000 travelers to these

areas develop dengue. Often the areas visited have other unique pathogens circulating (eg, malaria, typhoid fever, leptospirosis, and measles). EBV, influenza, enteroviruses, and acute HIV infection may produce a similar illness. An illness that starts 2 weeks after the trip ends or that lasts longer than 2 weeks is not dengue.

▶ Complications

Rarely dengue fever is associated with meningoencephalitis (5–10%) or hepatic damage. More common in endemic areas is the appearance of dengue hemorrhagic fever, which is defined by significant thrombocytopenia (<100,000 platelets/ μ L), bleeding, and a plasma leak syndrome [hemoconcentration = hematocrit >20% higher than baseline], hypoalbuminemia, and pleural or peritoneal effusions]. This is the consequence of circulating antibody and other immune responses acquired from a prior heterotypic dengue virus infection; thus it is rarely seen in typical travelers. Failure to recognize and treat this complication may lead to dengue shock syndrome, which is defined by signs of circulatory failure and hypotension or shock, and has a high fatality rate (10%).

▶ Prevention

Prevention of dengue fever involves avoiding high-risk areas and using conventional mosquito avoidance measures. The main vector is a daytime feeder. A vaccine to prevent dengue is being tested.

▶ Treatment

Dengue fever is treated by oral replacement of fluid lost from gastrointestinal symptoms. Analgesic therapy, which is often necessary, should not include drugs that affect platelet function. Recovery is complete without sequelae. The hemorrhagic syndrome requires prompt fluid therapy with plasma expanders and isotonic saline.

Wichmann O et al: Severe dengue virus infection in travelers: Risk factors and laboratory indicators. *J Infect Dis* 2007;195:1089 [PMID: 17357044].

COLORADO TICK FEVER

ESSENTIALS OF DIAGNOSIS
& TYPICAL FEATURES

- ▶ Travel in endemic area; tick bite.
- ▶ Fever, chills, headache, retro-orbital pain, myalgia.
- ▶ Biphasic fever curve.
- ▶ Leukopenia early in the illness.

Colorado tick fever, a tick-borne illness, is endemic in the high plains and mountains of the central and northern Rocky Mountains and northern Pacific coast of the United States. The reservoir of the virus consists of squirrels and chipmunks. Many hundreds of cases of Colorado tick fever occur each year in visitors or laborers entering this region, primarily from May through July.

► Clinical Findings

A. Symptoms and Signs

After a 3- to 4-day incubation period (maximum, 14 days) fever begins suddenly together with chills, lethargy, headache, ocular pain, myalgia, abdominal pain, and nausea and vomiting. Conjunctivitis may be present. A nondistinctive maculopapular rash occurs in 5–10% of patients. The illness lasts 7–10 days, and half of patients have a biphasic fever curve with several afebrile days in the midst of the illness.

B. Laboratory Findings

Leukopenia is characteristic early in the illness. Platelets are modestly decreased. Specific ELISA testing is available, but 3–4 weeks may elapse before seroconversion. Fluorescent antibody staining will detect virus-infected erythrocytes during the illness and for weeks after recovery.

► Differential Diagnosis

Early findings, especially if rash is present, may suggest enterovirus, measles, or rubella infection. Enteric fever may be an early consideration because of the presence of leukopenia and thrombocytopenia. A history of tick bite, which is often obtained; information about local risk; and the biphasic fever pattern will help with the diagnosis. Because of the wilderness exposure, diseases such as leptospirosis, borreliosis, tularemia, ehrlichiosis, and Rocky Mountain spotted fever will be considerations.

► Complications

Meningoencephalitis occurs in 3–7% of patients. Cardiac and pulmonary complications are rare.

► Prevention & Treatment

Prevention involves avoiding endemic areas and using conventional means to avoid tick bite. Therapy is supportive. Do not use analgesics that modify platelet function.

Gunther G, Haglund M: Tick-borne encephalopathies: Epidemiology, diagnosis, treatment and prevention. *CNS Drugs* 2005;19:1009-32 [PMID: 16332143].

OTHER MAJOR VIRAL CHILDHOOD EXANTHEMS

See the earlier section on Infections Due to Herpesvirus for a discussion of varicella and roseola, two other major childhood exanthems.

ERYTHEMA INFECTIOSUM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever and rash with “slapped-cheek” appearance, followed by a symmetrical, full-body maculopapular rash.
- Arthritis in older children.
- Profound anemia in patients with impaired erythrocyte production.
- Nonimmune hydrops fetalis following infection of pregnant women.

► General Considerations

This benign exanthematous illness of school-aged children is caused by the human parvovirus designated B19. Spread is respiratory, occurring in winter–spring epidemics. A nonspecific mild flulike illness may occur during the initial viremia at 7–10 days; the characteristic rash occurring at 10–17 days represents an immune response. The patient is viremic and contagious prior to—but not after—the onset of rash.

Approximately half of infected individuals have a subclinical illness. Most cases (60%) occur in children between ages 5 and 15 years, with an additional 40% occurring later in life. Forty percent of adults are seronegative. The disease is mildly contagious; the secondary attack rate in a school or household setting is 50% among susceptible children and 20–30% among susceptible adults.

► Clinical Findings

Owing to the nonspecific nature of the exanthem and the many subclinical cases, a history of contact with an infected individual is often absent or unreliable. Recognition of the illness is easier during outbreaks.

A. Symptoms and Signs

Typically the first sign of illness is the rash, which begins as raised, fiery red maculopapular lesions on the cheeks that coalesce to give a “slapped-cheek” appearance. The lesions are warm, nontender, and sometimes pruritic. They may be scattered on the forehead, chin, and postauricular areas, but the circumoral region is spared. Within 1–2 days, similar lesions appear on the proximal extensor surfaces of the extremities and spread distally in a symmetrical fashion. Palms and soles are usually spared. The trunk, neck, and buttocks are also commonly involved. Central clearing of confluent lesions produces a characteristic lacelike pattern. The rash fades in several days to several weeks but frequently reappears in response to local irritation, heat (bathing), sunlight, and stress. Nearly 50% of infected children have

some rash remaining (or recurring) for 10 days. Fine desquamation may be present. Mild systemic symptoms occur in up to 50% of children. These symptoms include low-grade fever, mild malaise, sore throat, and coryza. They appear for 2–3 days and are followed by a week-long asymptomatic phase before the rash appears.

Purpuric stocking-glove rashes, neurologic disease, and severe disorders resembling hemolytic-uremic syndrome have also been described in association with parvovirus B19.

B. Laboratory Findings

A mild leukopenia occurs early in some patients, followed by leukocytosis and lymphocytosis. Specific IgM and IgG serum antibody tests are available, but care must be used in choosing a reliable laboratory for this test. Nucleic acid detection tests are often definitive. The disease is not diagnosed by routine viral culture.

▶ Differential Diagnosis

In children immunized against measles and rubella, parvovirus B19 is the most frequent agent of morbilliform and rubelliform rashes. The characteristic rash and the mild nature of the illness distinguish erythema infectiosum from other childhood exanthems. It lacks the prodromal symptoms of measles and the lymphadenopathy of rubella. Systemic symptoms and pharyngitis are more prominent with enteroviral infections and scarlet fever.

▶ Complications & Sequelae

A. Arthritis

Arthritis is more common in older patients, beginning with late adolescence. Approximately 10% of children have severe joint symptoms. Girls are affected more commonly than boys. Pain and stiffness occur symmetrically in the peripheral joints. Arthritis usually follows the rash and may persist for 2–6 weeks but resolves without permanent damage.

B. Aplastic Crisis

Parvovirus B19 replicates primarily in erythroid progenitor cells. Consequently, reticulocytopenia occurs for approximately 1 week during the illness. This goes unnoticed in individuals with a normal erythrocyte half-life but results in severe anemia in patients with chronic hemolytic anemia. The rash of erythema infectiosum follows the hemolysis in these patients.

Pure red cell aplasia, leukopenia, pancytopenia, idiopathic thrombocytopenic purpura, and a hemophagocytic syndrome have also been described. Patients with AIDS and other immunosuppressive illnesses may develop prolonged anemia or pancytopenia. Patients with hemolytic anemia and aplastic crisis, or with immunosuppression, may be contagious and should be isolated while in the hospital.

C. Other End-Organ Infections

Parvovirus is under study as a potential cause of a variety of collagen-vascular diseases, neurologic syndromes, hepatitis, and myocarditis.

D. In-Utero Infections

Infection of susceptible pregnant women may produce fetal infection with hydrops fetalis. Fetal death occurs in about 6% of cases, and most fatalities occur in the first 20 weeks; this is higher than the rate of fetal loss expected in typical pregnancies. The risk of fetal infection is unknown. Congenital anomalies have not been associated with parvovirus B19 infection during pregnancy.

▶ Treatment & Prognosis

Erythema infectiosum is a benign illness for immunocompetent individuals. Patients with aplastic crisis may require blood transfusions. It is unlikely that this complication can be prevented by quarantine measures, because acute parvovirus infection in contacts is often unrecognized and is most contagious prior to the rash. Pregnant women who are exposed to erythema infectiosum or who work in a setting in which an epidemic occurs should be tested for evidence of prior infection. Susceptible pregnant women should then be followed up for evidence of parvovirus infection. Approximately 1.5% of women of childbearing age are infected during pregnancy. If maternal infection occurs, the fetus should be followed by ultrasonography for evidence of hydrops and distress. In-utero transfusion or early delivery may salvage some fetuses. Pregnancies should not be terminated because of parvovirus infection. The risk of fetal death among exposed pregnant women of unknown serologic status is less than 2.5% for homemakers and less than 1.5% for schoolteachers.

Intramuscular immune globulin is not protective. High-dose IVIG has stopped viremia and led to marrow recovery in some cases of prolonged aplasia. Its role in immunocompetent patients and pregnant women is unknown.

MEASLES (RUBEOLA)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Exposure to measles 9–14 days previously.
- ▶ Prodrome of fever, cough, conjunctivitis, and coryza.
- ▶ Koplik spots (few to many small white papules on a diffusely red base on the buccal mucosa) 1–2 days prior to and after onset of rash.

- ▶ Maculopapular rash spreading down from the face and hairline to the trunk over 3 days and later becoming confluent.
- ▶ Leukopenia.

▶ General Considerations

This childhood exanthem is rarely seen in the United States because of universal vaccination (64 cases in first half of 2008, all of which were imported or related to imported cases). Sporadic clusters of cases are the result of improper immunization more so than of vaccine failures, and are usually related to imported cases. It is recommended that all children be revaccinated on entrance into primary or secondary school (see Chapter 9). The attack rate in susceptible individuals is extremely high; spread is via respiratory droplets. Morbidity and mortality rates in the developing world are substantial because of underlying malnutrition and secondary infections. Because humans are the sole reservoir of measles, there is the potential to eliminate this disease worldwide.

▶ Clinical Findings

A history of contact with a suspected case may be absent because airborne spread is efficient and patients are contagious during the prodrome. Contact with an imported case may not be recognized. In temperate climates, epidemic measles is a winter–spring disease. Many suspected cases are misdiagnoses of other viral infections.

A. Symptoms and Signs

High fever and lethargy are prominent. Sneezing, eyelid edema, tearing, copious coryza, photophobia, and harsh cough ensue and worsen. Koplik spots are white macular lesions on the buccal mucosa, typically opposite the lower molars. These are almost pathognomonic for rubeola, although they may be absent. A discrete maculopapular rash begins when the respiratory symptoms are maximal and spreads quickly over the face and trunk, coalescing to a bright red. As it involves the extremities, it fades from the face and is completely gone within 6 days; fine desquamation may occur. Fever peaks when the rash appears and usually falls 2–3 days thereafter.

B. Laboratory Findings

Lymphopenia is characteristic. Total leukocyte counts may fall to 1500/ μL . The diagnosis is usually made by detection of measles IgM antibody in serum drawn at least 3 days after the onset of rash or later by detection of a significant rise in antibody. Direct detection of measles antigen by fluorescent antibody staining of nasopharyngeal cells is a useful rapid method. PCR testing of oropharyngeal secretions or urine is extremely sensitive and specific and can detect infection up to 5 days before symptoms.

C. Imaging

Chest radiographs often show hyperinflation, perihilar infiltrates, or parenchymal patchy, fluffy densities. Secondary consolidation or effusion may be visible.

▶ Differential Diagnosis

Table 38–3 lists other illnesses that may resemble measles.

▶ Complications & Sequelae

A. Respiratory Complications

These complications occur in up to 15% of patients. Bacterial superinfections of lung, middle ear, sinus, and cervical nodes are most common. Fever that persists after the third or fourth day of rash suggests such a complication, as does leukocytosis. Bronchospasm, severe croup, and progressive viral pneumonia or bronchiolitis (in infants) also occur. Immunosuppressed patients are at much greater risk for fatal pneumonia than are immunocompetent patients.

B. Cerebral Complications

Encephalitis occurs in 1 in 2000 cases. Onset is usually within a week after appearance of rash. Symptoms include combativeness, ataxia, vomiting, seizures, and coma. Lymphocytic pleocytosis and a mildly elevated protein concentration are usual CSF findings, but the fluid may be normal. Forty percent of patients so affected die or have severe neurologic sequelae.

Subacute sclerosing panencephalitis (SSPE) is a slow measles virus infection of the brain that becomes symptomatic years later in about 1 in 100,000 previously infected children. This progressive cerebral deterioration is associated with myoclonic jerks and a typical electroencephalographic pattern. It is fatal in 6–12 months. High titers of measles antibody are present in serum and CSF.

C. Other Complications

These include hemorrhagic measles (severe disease with multiorgan bleeding, fever, cerebral symptoms), thrombocytopenia, appendicitis, keratitis, myocarditis, and premature delivery or stillbirth. Mild liver function test elevation has been detected in up to 50% of cases in young adults; frank jaundice may also occur. Measles causes transient immunosuppression; thus, reactivation or progression of tuberculosis (including transient cutaneous anergy) occurs in untreated children.

▶ Prevention

The current two-dose active vaccination strategy is successful. Vaccine should not be withheld for concurrent mild acute illness, tuberculosis or positive tuberculin skin test, breast feeding, or exposure to an immunodeficient contact. The vaccine is recommended for HIV-infected children without severe HIV complications and adequate CD4 cells ($\geq 15\%$).

► Treatment & Prognosis

Vaccination prevents the disease in susceptible exposed individuals if given within 72 hours (see Chapter 9). Immune globulin (0.25 mL/kg intramuscularly; 0.5 mL/kg if immunocompromised) will prevent or modify measles if given within 6 days. Suspected cases should be diagnosed promptly and reported to the local health department.

Recovery generally occurs 7–10 days after onset of symptoms. Therapy is supportive: eye care, cough relief (avoid opioid suppressants in infants), and fever reduction (acetaminophen, lukewarm baths; avoid salicylates). Secondary bacterial infections should be treated promptly; antimicrobial prophylaxis is not indicated. Ribavirin is active in vitro and may be useful in infected immunocompromised children. High-dose intravenous ribavirin in combination with intrathecal interferon- α has been successfully used in the management of SSPE. In malnourished children, vitamin A supplementation should be given to attenuate the illness.

Orenstein W et al: Measles elimination in United States. *J Infect Dis* 2004;189(Suppl):S1 [PMID: 15106120].

RUBELLA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- History of rubella vaccination usually absent.
- Prodromal nonspecific respiratory symptoms and adenopathy (postauricular and occipital).
- Maculopapular rash beginning on face, rapidly spreading to the entire body, and disappearing by fourth day.
- Few systemic symptoms.
- Congenital infection.
 - Retarded growth, development.
 - Cataracts, retinopathy.
 - Purpuric “blueberry muffin” rash at birth.
 - Jaundice, thrombocytopenia.
 - Deafness.
 - Congenital heart defect.

► General Considerations

If it were not teratogenic, rubella would be of little clinical importance. Clinical diagnosis is difficult in some cases because of its variable expression. In one study, over 80% of infections were subclinical. Because of inadequate vaccina-

tion, outbreaks now occur in adolescents or adults. Rubella is transmitted by aerosolized respiratory secretions. Patients are infectious 5 days before until 5 days after the rash. Endemic rubella is absent in the US and congenital rubella, in infants both of unimmunized women and of women who have apparently been reinfected in pregnancy, is now very rare.

► Clinical Findings

The incubation period is 14–21 days. The nondistinctive signs may make exposure history unreliable. A history of immunization makes rubella unlikely but still possible. Congenital rubella usually follows maternal infection in the first trimester.

A. Symptoms and Signs

1. Infection in children—Young children may only have rash. Older patients often have a nonspecific prodrome of low-grade fever, ocular pain, sore throat, and myalgia. Postauricular and suboccipital adenopathy (sometimes generalized) is characteristic. This often precedes the rash or may occur without rash. The rash consists of erythematous discrete maculopapules beginning on the face. A “slapped-cheek” appearance or pruritus may occur. Scarletiform or morbilliform rash variants may occur. The rash spreads quickly to the trunk and extremities after it fades from the face; it is gone by the fourth day. Enanthema is usually absent.

2. Congenital infection—More than 80% of women infected in the first 4 months of gestation are delivered of affected infants; congenital disease occurs in less than 5% of women infected later in pregnancy. Later infections can result in isolated defects, such as deafness. The main manifestations are as follows:

A. GROWTH RETARDATION—Between 50% and 85% of infants are small at birth and remain so.

B. CARDIAC ANOMALIES—Pulmonary artery stenosis, patent ductus arteriosus, ventricular septal defect.

C. OCULAR ANOMALIES—Cataracts, microphthalmia, glaucoma, retinitis.

D. DEAFNESS—Sensorineural (> 50% of cases).

E. CEREBRAL DISORDERS—Chronic encephalitis; retardation.

F. HEMATOLOGIC DISORDERS—Thrombocytopenia, dermal nests of extramedullary hematopoiesis or purpura (“blueberry muffin” rash), lymphopenia.

G. OTHERS—Hepatitis, osteomyelitis, immune disorders, malabsorption, diabetes.

B. Laboratory Findings

Leukopenia is common, and platelet counts may be low. Congenital infection is associated with low platelet counts, abnormal liver function tests, hemolytic anemia, pleocytosis,

and very high rubella IgM antibody titers. Total serum IgM is elevated, and IgA and IgG levels may be depressed.

Virus may be isolated from throat or urine from 1 week before to 2 weeks after onset of rash. Children with congenital infection are infectious for months. The virus laboratory must be notified that rubella is suspected. Serologic diagnosis is best made by demonstrating a fourfold rise in antibody titer between specimens drawn 1–2 weeks apart. The first should be drawn promptly, because titers increase rapidly after onset of rash. Both specimens must be tested simultaneously by a single laboratory. Specific IgM antibody can be measured by immunoassay. Because the decision to terminate a pregnancy is usually based on serologic results, testing must be done carefully.

C. Imaging

Pneumonitis and bone metaphyseal longitudinal lucencies may be present in radiographs of children with congenital infection.

► Differential Diagnosis

Rubella may resemble infections due to enterovirus, adenovirus, measles, EBV, roseola, parvovirus, *T gondii*, and *Mycoplasma*. Drug reactions may also mimic rubella. Because public health implications are great, sporadic suspected cases should be confirmed serologically or virologically.

Congenital rubella must be differentiated from congenital CMV infection, toxoplasmosis, and syphilis.

► Complications & Sequelae

A. Arthralgia and Arthritis

Both occur more often in adult women. Polyarticular involvement (fingers, knees, wrists), lasting a few days to weeks, is typical. Frank arthritis occurs in a small percentage of patients. It may resemble acute rheumatoid arthritis.

B. Encephalitis

With an incidence of about 1:6000, this is a nonspecific parainfectious encephalitis associated with a low mortality rate. A syndrome resembling SSPE (see Measles section, earlier) has also been described in congenital rubella.

C. Rubella in Pregnancy

Infection in the mother is self-limited and not severe.

► Prevention

Rubella is one of the infections that could be eradicated. See Chapter 9 for the indication and efficacy of rubella vaccine. Standard prenatal care should include rubella antibody testing. Seropositive mothers are at no risk; seronegative mothers are vaccinated after delivery.

A pregnant woman possibly exposed to rubella should be tested immediately; if seropositive, she is immune and need

not worry. If she is seronegative, a second specimen should be drawn in 4 weeks, and both specimens should be tested simultaneously. Seroconversion in the first trimester suggests high fetal risk; such women require counseling regarding therapeutic abortion.

When pregnancy termination is not an option, some experts recommend intramuscular administration of 20 mL of immune globulin within 72 hours after exposure in an attempt to prevent infection. (This negates the value of subsequent antibody testing.) The efficacy of this practice is unknown.

► Treatment & Prognosis

Symptomatic therapy is sufficient. Arthritis may improve with administration of anti-inflammatory agents. The prognosis is excellent in all children and adults but poor in congenitally infected infants, in whom most defects are irreversible or progressive. The severe cognitive defects seem to correlate closely in these infants with the degree of growth failure.

Reef SE, Cochi SL: The evidence for elimination of rubella and congenital rubella syndrome in United States: A public health achievement. *Clin Infect Dis* 2006;43(Suppl 3):S123 [PMID: 16998770].

INFECTIONS DUE TO OTHER VIRUSES

HANTAVIRUS CARDIOPULMONARY SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Influenza-like prodrome (fever, myalgia, headache, cough).
- Rapid onset of unexplained pulmonary edema and myocardial pathology.
- Residence or travel in endemic area; exposure to aerosols from deer mouse droppings or secretions.

► General Considerations

Hantavirus cardiopulmonary syndrome is the first native bunyavirus infection endemic in the United States. This syndrome is distinctly different in mode of spread (no arthropod vector) and clinical picture from other bunyavirus diseases.

► Clinical Findings

The initial cases of hantavirus cardiopulmonary syndrome involved travel to or residence in a limited area in the southwestern United States where there was a potential for exposure to the reservoir, the deer mouse. This and many

other related rodents live in many other locales, and the disease has been confirmed in more than 30 other states, with additional cases in Canada. Epidemics occur when environmental conditions favor large increases in the rodent population and increased prevalence of virus in this reservoir.

A. Symptoms and Signs

After an incubation period of 2–3 weeks, onset is sudden, with a nonspecific virus-like prodrome: fever; back, hip, and leg pain; chills; headache; and nausea and vomiting. Abdominal pain may be present. Sore throat, conjunctivitis, rash, and adenopathy are absent, and respiratory symptoms are absent or limited to a dry cough. After 1–10 days (usually 3–7), dyspnea, tachypnea, and evidence of a pulmonary capillary leak syndrome appear. This often progresses rapidly over a period of hours. Hypotension is common not only from hypoxemia, but also from myocardial dysfunction. Copious, amber-colored, nonpurulent secretions are common. Decreased cardiac output due to cardiomyopathy and elevated systemic vascular resistance distinguish this disease from early bacterial sepsis.

B. Laboratory Findings

The hemogram shows leukocytosis with a prominent left shift and immunoblasts, thrombocytopenia, and hemoconcentration. Lactate dehydrogenase (LDH) is elevated, as are liver function tests; serum albumin is low. Creatinine is elevated in some patients, and proteinuria is common. Lactic acidosis and low venous bicarbonate are poor prognostic signs. A serum IgM ELISA test is positive early in the illness. Otherwise the diagnosis is made by specific staining of tissue or PCR, usually at autopsy.

C. Imaging

Initial chest radiographs are normal. Subsequent radiographs show bilateral interstitial infiltrates with the typical butterfly pattern of acute pulmonary edema, bibasilar airspace disease, or both. Significant pleural effusions are often present. These findings contrast with those of other causes of acute respiratory distress syndrome.

► Differential Diagnosis

In some geographic areas, plague and tularemia may be possibilities. Infections with viral respiratory pathogens and *Mycoplasma* have a slower tempo, do not elevate the LDH level, and do not cause the hematologic changes seen in this syndrome. Q fever, psittacosis, toxin exposure, legionellosis, and fungal infections are possibilities, but the history, tempo of the illness, and blood findings, as well as the exposure history, should be distinguishing features. Hantavirus cardiopulmonary syndrome is a consideration in previously healthy persons with a febrile illness associated with unexplained pulmonary edema.

► Treatment & Prognosis

Ribavirin, to which hantaviruses and other bunyaviruses are susceptible, has not been demonstrated to alter the course of the illness. Management should concentrate on oxygen therapy and mechanical ventilation as required. Because of capillary leakage, Swan-Ganz catheterization to monitor cardiac output and inotropic support—rather than fluid therapy—should be used to maintain perfusion. Venoarterial extracorporeal membrane oxygenation can provide short-term support for selected patients. The virus present in North America is not spread by person-to-person contact. No isolation is required. The case fatality rate is 30–40%. Guidelines are available for reduction of exposure to the infectious agent.

Chang B et al: Hantavirus cardiopulmonary syndrome. *Semin Respir Crit Care Med* 2007;28:193 [PMID: 17458773].

MUMPS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- No prior mumps immunization.
- Parotid gland swelling.
- Aseptic meningitis with or without parotitis.

► General Considerations

Mumps was one of the classic childhood infections; virus spread by the respiratory route attacked almost all unimmunized children (asymptotically in 30–40% of cases), and produced lifelong immunity. The vaccine is so efficacious that clinical disease is rare in immunized children. As a result of subclinical infections or childhood immunization, 95% of adults are immune. Infected patients can spread the infection from 1–2 days prior to the onset of symptoms and for 5 additional days. The incubation period is 14–21 days.

A history of exposure to a child with parotitis is not proof of mumps exposure. In an adequately immunized individual, parotitis is usually due to another cause. Currently in the United States less than 1 case is reported per 100,000 population.

► Clinical Findings

A. Symptoms and Signs

1. Salivary gland disease—Tender swelling of one or more glands, variable fever, and facial lymphedema are typical. Parotid involvement is most common; signs are bilateral in 70% of patients. The ear is displaced upward and outward; the mandibular angle is obliterated. Systemic toxicity is usually absent. Parotid stimulation with sour foods may be quite painful. The orifice of the Stensen duct may be

red and swollen; yellow secretions may be expressed, but pus is absent. Parotid swelling dissipates after 1 week.

2. Meningoencephalitis—Prior to widespread immunization, mumps was the most common cause of aseptic meningitis, which is usually manifested by mild headache or asymptomatic mononuclear pleocytosis. Fewer than 10% of patients have clinical meningitis or encephalitis. Cerebral symptoms do not correlate with parotid symptoms, which are absent in many patients with meningoencephalitis. Although neck stiffness, nausea, and vomiting can occur, encephalitic symptoms are rare (1:4000 cases of mumps); recovery in 3–10 days is the rule.

3. Pancreatitis—Abdominal pain may represent transient pancreatitis. Because salivary gland disease may elevate serum amylase, specific markers of pancreatic function (lipase, amylase isoenzymes) are required for assessing pancreatic involvement.

4. Orchitis, oophoritis—Involvement of the gonads is associated with fever, local tenderness, and swelling. Epididymitis is usually present. Orchitis is unusual in young children but occurs in up to one third of affected postpubertal males. Usually it is unilateral and resolves in 1–2 weeks. Although one third of infected testes atrophy, bilateral involvement and sterility are rare.

5. Other—Thyroiditis, mastitis (especially in adolescent females), arthritis, and presternal edema (occasionally with dysphagia or hoarseness) may be seen.

B. Laboratory Findings

Peripheral blood leukocyte count is usually normal. Up to 1000 cells/ μ L (predominantly lymphocytes) may be present in the CSF, with mildly elevated protein and normal to slightly decreased glucose. Viral culture or PCR tests of saliva, throat, urine, or spinal fluid may be positive for at least 1 week after onset. Paired sera assayed by ELISA are currently used for diagnosis. Complement-fixing antibody to the soluble antigen disappears in several months; its presence in a single specimen thus indicates recent infection.

► Differential Diagnosis

Mumps parotitis may resemble the following conditions: cervical adenitis (the jaw angle may be obliterated, but the ear does not usually protrude; the Stensen duct orifice is normal; leukocytosis and neutrophilia are observed); bacterial parotitis (pus in the Stensen duct, toxicity, exquisite tenderness); recurrent parotitis (idiopathic or associated with calculi); tumors or leukemia; and tooth infections. Many viruses, including parainfluenza, enteroviruses, EBV, CMV, and influenza virus, can cause parotitis. Parotid swelling in HIV infection is less painful and tends to be bilateral and chronic, but bacterial parotitis occurs in some children with HIV infection.

Unless parotitis is present, mumps meningitis resembles that caused by enteroviruses or early bacterial infection. An elevated amylase level is a useful clue in this situation. Isolated pancreatitis is not distinguishable from many other causes of epigastric pain and vomiting. Mumps is a classic cause of orchitis, but torsion, bacterial or chlamydial epididymitis, *Mycoplasma* infection, other viral infections, hematomas, hernias, and tumors must also be considered.

► Complications

The major neurologic complication is nerve deafness (usually unilateral), which can result in inability to hear high tones. It may occur without meningitis. Permanent damage is rare, occurring in less than 0.1% of cases of mumps. Aqueductal stenosis and hydrocephalus (especially following congenital infection), myocarditis, transverse myelitis, and facial paralysis are other rare complications.

► Treatment & Prognosis

Treatment is supportive and includes provision of fluids, analgesics, and scrotal support for orchitis. Systemic corticosteroids have been used for orchitis, but their value is anecdotal. Surgery is not recommended.

Peltola H et al: Mumps outbreaks in Canada and the United States: Time for new thinking on mumps vaccines. *Clin Infect Dis* 2007;45:459 [PMID: 17638194].

RABIES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- History of animal bite 10 days to 1 year (usually < 90 days) previously.
- Paresthesias or hyperesthesia in bite area.
- Progressive limb and facial weakness in some patients (dumb rabies; 30%).
- Irritability followed by fever, confusion, combativeness, muscle spasms (especially pharyngeal with swallowing) in all patients (furious rabies).
- Rabies antigen detected in corneal scrapings or tissue obtained by brain or skin biopsy; Negri bodies seen in brain tissue.

► General Considerations

Rabies remains a potentially serious public health problem wherever animal immunization is not widely practiced or when humans play or work in areas with sylvan rabies. Although infection does not always follow a bite by a rabid animal (about 40% infection rate following rabid dog bites),

infection is almost invariably fatal. Any warm-blooded animal may be infected, but susceptibility and transmissibility vary with different species. Bats often carry and excrete the virus in saliva or feces for prolonged periods; they are the major cause of rabies in the United States. Dogs and cats are usually clinically ill within 10 days after becoming contagious (the standard quarantine period for suspect animals). Valid quarantine periods or signs of illness are not fully known for many species. Rodents rarely transmit infection. Animal vaccines are very effective when properly administered, but a single inoculation may fail to produce immunity in up to 20% of dogs.

The risk is assessed according to the type of animal (bats always considered rabid; raccoons, skunks, foxes in many areas); wound extent and location (infection more common after head or hand bites, or if wounds have extensive salivary contamination or are not quickly and thoroughly cleaned); geographic area (urban rabies is rare to nonexistent in U.S. cities; rural rabies is possible, especially outside the United States); and animal vaccination history (risk low if documented). Most rabies in the United States is with genotypes found in bats, yet a history of bat bite is rarely obtained. Aerosolized virus in caves inhabited by bats has caused infection.

► Clinical Findings

A. Symptoms and Signs

Paresthesias at the bite site are usually the first symptoms. Nonspecific anxiety, excitability, or depression follows, then muscle spasms, drooling, hydrophobia, delirium, and lethargy. Swallowing or even the sensation of air blown on the face may cause pharyngeal spasms. Seizures, fever, cranial nerve palsies, coma, and death follow within 7–14 days after onset. In a minority of patients, the spastic components are initially absent and the symptoms are primarily flaccid paralysis and cranial nerve defects. The furious components appear subsequently.

B. Laboratory Findings

Leukocytosis is common. CSF is usually normal or may show elevation of protein and mononuclear cell pleocytosis. Cerebral imaging and electroencephalography are not diagnostic.

Infection in an animal may be determined by use of the fluorescent antibody test to examine brain tissue for antigen. Rabies virus is excreted in the saliva of infected humans, but the diagnosis is usually made by antigen detection in scrapings or tissue samples of richly innervated epithelium, such as the cornea or the hairline of the neck. Classic Negri cytoplasmic inclusion bodies in brain tissue are not always present. Seroconversion occurs after 7–10 days.

► Differential Diagnosis

Failure to elicit the bite history in areas where rabies is rare may delay diagnosis. Other disorders to be considered include parainfectious encephalopathy; encephalitis due to herpes simplex, mosquito-borne viruses, other viruses; and Guillain-Barré syndrome.

► Prevention

See Chapter 9 for information regarding vaccination and postexposure prophylaxis. Rabies immune globulin and diploid cell vaccine have made prophylaxis more effective and minimally toxic; however, rare cases of prophylaxis failure are still being reported. Because rabies is almost always fatal, presumed exposures must be managed carefully.

► Treatment & Prognosis

Survival is rare but has been reported in patients receiving meticulous intensive care. No antiviral preparations are of proved benefit. Early diagnosis is important for the protection and prophylaxis of individuals exposed to the patient.

Willoughby RE et al: Survival after treatment of rabies with induction of coma. *N Engl J Med* 2005;352:2508 [PMID: 15958806].

RICKETTSIAL INFECTIONS

Rickettsiae are pleomorphic, gram-negative coccobacilli that are obligate intracellular parasites. Rickettsial diseases are often included in the differential diagnosis of febrile rashes, although some (notably Q fever) are not characterized by rash. Severe headache is a prominent symptom. The endothelium is the primary target tissue, and the ensuing vasculitis is responsible for severe illness.

All rickettsioses except Q fever are transmitted by cutaneous arthropod contact, either by bite or contamination of skin breaks with tick feces. Evidence of such contact by history or physical examination may be completely lacking, especially in young children. The geographic distribution of the vector is often the primary determinant for suspicion of these infections. Therapy often must be empiric. Many new broad-spectrum antimicrobials are inactive against these cell wall-deficient organisms; tetracycline is usually effective.

HUMAN EHRLICHIOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Residing or travel in endemic area when ticks are active.
- Tick bite noted (~75%).
- Fever, headache, rash (~67%), gastrointestinal symptoms.
- Leukopenia, thrombocytopenia, elevated serum transaminases, hypoalbuminemia.
- Definitive diagnosis by specific serology.

Ehrlichia species are responsible for febrile pancytopenia in animals. In humans, *Ehrlichia sennetsu* is responsible for a mononucleosis-like syndrome seen in Japan and Malaysia. One agent of North American human ehrlichiosis has been identified as *Ehrlichia chaffeensis*. The reservoir hosts are probably wild rodents, deer, and sheep; ticks are the vectors. Most cases caused by this agent are reported in the south-central, southeastern, and middle Atlantic states. Arkansas, Missouri, Kentucky, Tennessee, and North Carolina are high-prevalence areas. Almost all cases occur between March and October, when ticks are active.

A second ehrlichiosis syndrome, seen in the upper Midwest and Northeast (Connecticut, Wisconsin, Minnesota, and New York) are high-prevalence areas, is caused by *Anaplasma phagocytophilum* and *E ewingii*.

E chaffeensis has a predilection for mononuclear cells, whereas *A phagocytophilum* and *E ewingii* infect and produce intracytoplasmic inclusions in granulocytes. Hence diseases caused by these agents are referred to as human monocytic ehrlichiosis or human granulocytic ehrlichiosis, respectively. Ehrlichiosis, Lyme disease, and babesiosis share some tick vectors; thus dual infections are common and should be considered in patients who fail to respond to therapy.

► Clinical Findings

In approximately 75% of patients, a history of tick bite can be elicited. The majority of the remaining patients report having been in a tick-infested area. The usual incubation period is 5–21 days.

A. Symptoms and Signs

Fever is universally present and headache is common (less so in children). Gastrointestinal symptoms (abdominal pain, anorexia, nausea and vomiting) are reported in most pediatric patients. Distal limb edema may also occur in children. Chills, photophobia, conjunctivitis, and myalgia occur in more than half of patients. Rash occurs in two thirds of children with monocytic ehrlichiosis but is less common (~50%) in granulocytic ehrlichiosis. Rash may be erythematous, macular, papular, petechial, scarlatiniform, or vasculitic. Meningitis occurs. Interstitial pneumonitis, acute respiratory distress syndrome, and renal failure occur in severe cases. Physical examination reveals rash (not usually palms and soles), mild adenopathy, and hepatomegaly. In children without a rash, infection may present as a case of fever of unknown origin.

B. Laboratory Findings

Laboratory abnormalities include leukopenia with left shift, lymphopenia, thrombocytopenia, and elevated aminotransferase levels. Hypoalbuminemia is common. Disseminated intravascular coagulation can occur in severe cases. Anemia occurs in one third of patients. The definitive diagnosis is made serologically, either by a single high titer or a fourfold

rise in titer. The Centers for Disease Control and Prevention uses appropriate antigens in an immunofluorescent antibody test in order to distinguish between the etiologic agents. Intracytoplasmic inclusions (morulae) may occasionally be observed in mononuclear cells in monocytic ehrlichiosis, and are usually observed in polymorphonuclear cells from the peripheral blood or bone marrow in granulocytic ehrlichiosis. Specific PCR testing is available for diagnosis.

► Differential Diagnosis

Ehrlichiosis should be included in the differential diagnosis of children in regions where these infections exist who present during tick season with fever, leucopenia or thrombocytopenia (or both), and increased serum transaminase levels. Patients should be treated concurrently with attempts to establish the diagnosis. The differential diagnosis includes septic or toxic shock, other rickettsial infections (especially Rocky Mountain spotted fever), Colorado tick fever, leptospirosis, Lyme borreliosis, relapsing fever, EBV, CMV, viral hepatitis and other viral infections, Kawasaki disease, systemic lupus erythematosus, and leukemia.

► Treatment & Prognosis

Asymptomatic or clinically mild and undiagnosed infections are common in some endemic areas. The disease may last several weeks if untreated. One quarter of hospitalized children require intensive care. Meningoencephalitis and persisting neurologic deficits occur in 5–10% of patients. Doxycycline, 2–4 mg/kg/d divided every 12 hours (maximum 100 mg per dose) for 7–10 days, is the treatment of choice. Response to therapy should be evident in 24–48 hours. Deaths are uncommon but do occur in children. Immune compromise is a risk factor for severe disease.

Dumler J et al: Ehrlichiosis in humans: Epidemiology, clinical presentation, diagnosis, and treatment. *Clin Infect Dis* 2007;45(Suppl 1):S45 [PMID: 17582569].

Schutze GE et al: Human monocytic ehrlichiosis in children. *Pediatr Infect Dis J* 2007;26:475 [PMID: 17529862].

ROCKY MOUNTAIN SPOTTED FEVER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Residing or travel in endemic area when ticks are active.
- Fever, rash (palms and soles), gastrointestinal symptoms, headache.
- Tick bite (50%).
- Thrombocytopenia, hyponatremia.
- Definitive diagnosis by specific serology.

Rickettsia rickettsii causes one of many similar tick-borne illnesses characterized by fever and rash that occur worldwide. Most are named for their geographic area. In all except Rocky Mountain spotted fever and murine typhus, there is a characteristic eschar at the bite site, called the *tache noire*. Dogs and rodents are reservoirs of *R. rickettsii*.

Rocky Mountain spotted fever is the most severe of these infections and the most important (500–1000 cases per year) in the United States. It occurs predominantly along the eastern seaboard; in the southeastern states; and in Arkansas, Texas, Missouri, Kansas, and Oklahoma. It is much less common in the west. Most cases occur in children exposed in rural areas from April to September. Because tick attachment lasting 6 hours or longer is needed, frequent tick removal is a preventive measure.

► Clinical Findings

A. Symptoms and Signs

After the incubation period of 3–12 days (mean, 7 days), there is high fever (> 40°C, often hectic), usually of abrupt onset, myalgia, severe and persistent headache (retro-orbital; less obvious in infants), toxicity, photophobia, vomiting, and diarrhea. A rash occurs in more than 95% of patients and appears 2–6 days after fever onset as macules and papules; most characteristic (65%) is involvement of the palms, soles, and extremities. The rash becomes petechial and spreads centrally. Conjunctivitis, splenomegaly, edema, meningismus, irritability, and confusion may occur.

B. Laboratory Findings

Laboratory findings are nonspecific and reflect diffuse vasculitis: thrombocytopenia, hyponatremia, early mild leukopenia, proteinuria, mildly abnormal liver function tests, hypoalbuminemia, and hematuria. CSF pleocytosis is common. Serologic diagnosis is achieved with indirect fluorescent or latex agglutination antibody methods, but generally only 7–10 days after onset of the illness. Skin biopsy with specific fluorescent staining may give the diagnosis within the first week of the illness.

► Differential Diagnosis

The differential diagnosis includes meningococcemia, measles, meningococcal meningitis, staphylococcal sepsis, enteroviral infection, leptospirosis, Colorado tick fever, scarlet fever, murine typhus, Kawasaki disease, and ehrlichiosis.

► Treatment & Prognosis

To be effective, therapy for Rocky Mountain spotted fever must be started early and is often based on a presumptive diagnosis in endemic areas prior to rash onset. It is important to remember that atypical presentations, such as the absence of pathognomonic rash, often lead to delay in appropriate therapy. Doxycycline is the agent of choice for children,

regardless of age. Treatment should be continued for 2 or 3 days after the temperature has returned to normal for a full day. A minimum of 10 days of therapy is recommended.

Complications and death result from severe vasculitis, especially in the brain, heart, and lung. The mortality rate is 5–7%. Persistent neurologic deficits occur. Delay in therapy is an important determinant of mortality.

ENDEMIC TYPHUS (MURINE TYPHUS)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Residing in endemic area.
- Fever for 10–14 days.
- Headache, chills, myalgia.
- Maculopapular rash spreading from trunk to extremities (not on palms and soles) 3–7 days after fever onset.
- Definitive diagnosis by serology.

Endemic typhus is present in the southern United States, mainly in southern Texas, and in Southern California. The disease is transmitted by fleas from infected rodents, from their feces in scratches, or by inhalation. Domestic cats, dogs, and opossums may play a role in the transmission of suburban cases. No eschar appears at the inoculation site, which may go unnoticed. The incubation period is 6–14 days. Headache, myalgia, and chills slowly worsen. Fever may last 10–14 days. After 3–8 days, a rash appears. Truncal macules and papules spread to the extremities; the rash is rarely petechial. The location of the rash in typhus, with sparing of the palms and soles, helps distinguish the disease from Rocky Mountain spotted fever. Rash may be absent in 20–40% of patients. Hepatomegaly may be present. Intestinal and respiratory symptoms may occur. Mild thrombocytopenia and elevated liver enzymes may be present. The illness is usually self-limited and milder than epidemic typhus. More prolonged neurologic symptoms have been described. Therapy is usually not needed. Doxycycline is the drug of choice. Therapy for 3 days is usually sufficient. Fluorescent antibody and ELISA tests are available.

Q FEVER

ESSENTIALS OF DIAGNOSIS
& TYPICAL FEATURES

- ▶ Exposure to farm animals (sheep, goats, cattle) and pets.
- ▶ Flulike illness (fever, severe headache, myalgia).
- ▶ Cough; atypical pneumonia.
- ▶ Hepatomegaly and hepatitis.
- ▶ Diagnosis by serology.

Coxiella burnetii is transmitted by inhalation rather than by an arthropod bite. The birth tissues and excreta of domestic animals and of some rodents are a major infectious source. Unpasteurized milk from infected animals may also transmit disease. Q fever is also distinguished from other rickettsial diseases by the infrequent occurrence of cutaneous manifestations and by the prominence of pulmonary disease.

▶ Clinical Findings

A. Symptoms and Signs

Many patients have a self-limited flulike syndrome of chills, fever, severe headache, and myalgia of abrupt onset occurring 10–30 days after exposure. Abdominal pain, vomiting, chest pain, and dry cough are prominent in children. Examination of the chest may produce few findings, as in other atypical pneumonias. Hepatosplenomegaly is common. The illness lasts 1–4 weeks and frequently is associated with weight loss.

B. Laboratory Findings

Leukopenia with left shift is characteristic. Thrombocytopenia is unusual and another distinction from other symptomatic rickettsial diseases. Aminotransferase and γ -glutamyl

transferase levels are elevated. Diagnosis is made by finding a complement-fixing antibody response (fourfold rise or single high titer) to the phase II organism. Chronic infection is indicated by antibody against the phase I organism. IgM ELISA and specific PCR tests are also available.

C. Imaging

Pneumonitis occurs in 50% of patients. Multiple segmental infiltrates are common, but the radiographic appearance is not pathognomonic. Consolidation and pleural effusion are rare.

▶ Differential Diagnosis

In the appropriate epidemiologic setting, Q fever should be considered in evaluating causes of atypical pneumonias such as from *M pneumoniae*, viruses, *Legionella*, and *C pneumoniae*. It should also be included among the causes of mild to moderate hepatitis without rash or adenopathy in children with exposure to farm animals.

▶ Treatment & Prognosis

Typically the illness lasts 1–2 weeks without therapy. One complication is chronic disease, which often implies myocarditis or granulomatous hepatitis. Meningoencephalitis is also a rare complication.

C burnetii is also one of the causes of so-called culture-negative endocarditis. Endocarditis is difficult to treat; mortality approaches 50%. The course of the uncomplicated illness is shortened with tetracycline; doxycycline is preferred. Therapy is continued for several days after the patient becomes afebrile. Quinolones are also effective.

Cutler SJ et al: Q fever. *J Infect* 2007;54:313 [PMID:17147957].

Human Immunodeficiency Virus Infection

Elizabeth J. McFarland, MD

39

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Children younger than age 18 months:

- ▶ Definitive diagnosis:
 - Positive results on two separate determinations on blood or tissue (excluding cord blood) for one or more of the following HIV detection tests: HIV nucleic acid detection (DNA or RNA), HIV antigen (p24), HIV culture.
 - ▶ Presumptive clinical diagnosis (in settings lacking access to HIV virologic diagnostic tests):
 - HIV-seropositive by repeatedly reactive enzyme-linked immunosorbent assay (ELISA) and confirmatory test.
- and
- Meets criteria for AIDS diagnosis based on the 1987 Centers for Disease Control and Prevention (CDC) AIDS surveillance case (see Table 39–1 and CDC case definition, *MMWR Morb Mortal Wkly Rep*, 1994) *or* has evidence of cellular and humoral immunodeficiency (without another cause) and symptoms compatible with HIV infection.

Children older than age 18 months:

- ▶ HIV-seropositive on two separate determinations on blood by ELISA and confirmatory test.
- or
- ▶ Meets any of the criteria listed for children younger than age 18 months.

▶ General Considerations

Human immunodeficiency virus (HIV) is a retrovirus that primarily infects cells of the immune system, including helper T lymphocytes (CD4 T lymphocytes), monocytes, and macrophages. The function and number of

CD4 T lymphocytes and other affected cells are diminished by HIV infection, with profound effects on both humoral and cell-mediated immunity. In the absence of treatment, HIV infection causes generalized immune incompetence, leading to conditions that meet the definition of acquired immunodeficiency syndrome (AIDS), and eventually death. The clinical diagnosis of AIDS is made when an HIV-infected child develops any of the opportunistic infections, malignancies, or conditions listed in category C of the Centers for Disease Control and Prevention (CDC) disease staging criteria (Table 39–1). In adults and adolescents, the criteria for a diagnosis of AIDS also include absolute CD4 lymphocyte counts of 200/ μ L or less.

Combination antiretroviral treatment, available in resource-rich settings since 1996, can forestall disease progression for 10 years or longer in many patients. The full duration of the favorable outcome of therapy is not yet defined, and it is not known whether adverse effects from the medications will affect mortality or limit use. Nevertheless, HIV infection can be considered a chronic rather than acutely terminal disease for people with access to treatment.

▶ Transmission & Epidemiology

HIV is transmitted by sexual contact, percutaneous exposure to contaminated blood (eg, injecting drug use or transfusion with contaminated blood products), and mother-to-child (vertical) transmission. Vertical transmission may occur in utero, at the time of delivery, or via breast feeding. Risk factors associated with mother-to-child transmission include high maternal plasma HIV RNA, advanced maternal disease stage, low CD4 lymphocyte count, premature delivery, and factors related to increased exposure to maternal blood or cervical secretions at the time of delivery (eg, duration of rupture of membranes, presence of blood in the infant's gastric secretions, and first-born twin delivery). Without intervention, 15–30% of infants born to HIV-infected women will be infected.

Table 39-1. Clinical categories of children with human immunodeficiency virus (HIV) infection.

Category N: Not symptomatic

No signs or symptoms or only one of the conditions listed in category A

Category A: Mildly symptomatic

Having two or more of the following conditions:

- Lymphadenopathy
- Hepatomegaly
- Splenomegaly
- Dermatitis
- Parotitis
- Recurrent or persistent upper respiratory infection, sinusitis, or otitis media

Category B: Moderately symptomatic

Having symptoms attributed to HIV infection other than those in category A or C

Examples:

- Anemia, neutropenia, thrombocytopenia
- Bacterial meningitis, pneumonia, sepsis (single episode)
- Candidiasis, oropharyngeal, persisting more than 2 mo
- Cardiomyopathy
- Cytomegalovirus infection with onset < age 1 mo
- Diarrhea, recurrent or chronic
- Hepatitis
- Herpes simplex virus recurrent stomatitis, bronchitis, pneumonitis, esophagitis at < 1 month of age
- Herpes zoster, two or more episodes or more than one dermatome
- Leiomyosarcoma
- Lymphoid interstitial pneumonia
- Nephropathy
- Nocardiosis
- Persistent fever
- Toxoplasmosis with onset < age 1 mo
- Varicella, complicated

Category C: Severely symptomatic

- Serious bacterial infections, multiple or recurrent
- Candidiasis, esophageal or pulmonary
- Coccidioidomycosis, disseminated
- Cryptosporidiosis or isosporiasis with diarrhea > age 1 mo
- Cytomegalovirus infection with onset > age 1 mo
- Encephalopathy
- Herpes simplex virus: persistent oral lesions, or bronchitis, pneumonitis, esophagitis at > age 1 mo
- Histoplasmosis
- Kaposi sarcoma
- Lymphoma
- Mycobacterium tuberculosis*, extrapulmonary
- Mycobacterium* infection, other species, disseminated
- Pneumocystis jiroveci* pneumonia
- Progressive multifocal leukoencephalopathy
- Salmonella* septicemia, recurrent
- Toxoplasmosis of the brain with onset > age 1 mo
- Wasting syndrome

Adapted from MMWR Recomm Rep 1994;43(RR-12):6, 8.

The rate of vertical transmission can be reduced to less than 2% by providing combination antiretroviral treatment to the mother during pregnancy and delivery, implementing recom-

mended obstetric interventions, providing additional prophylaxis to the infant during the first 6 weeks after birth, and avoidance of breast feeding. In the United States, as a result of prenatal and perinatal interventions, the number of vertically acquired AIDS cases declined 83% between 1992 (907 cases) and 2001 (150 cases). Most transmissions that occur involve women who do not receive antiretroviral therapy during pregnancy, either because the infection is undiagnosed or because of lack of prenatal care. Mother-to-child transmission rates continue to be high in resource-limited settings where access to antiretroviral therapy and safe infant formula is infrequent. Worldwide, an estimated 2.3 million children are infected with HIV, most of them in Africa, South and Southeast Asia, and parts of South America. In 2006, there were an estimated 530,000 new infections and 380,000 deaths in children younger than 15 years.

Sexual activity (both heterosexual and homosexual) is the main mode of infection after puberty, with a smaller number of cases resulting from the sharing of contaminated needles. In the United States, seroprevalence rates are highest among gay men and injecting drug users. However, the proportion of new AIDS cases in 2005 acquired by heterosexual contact exceeded the proportion acquired by injecting drug use. Youth (ages 13–24 years) and women of color are disproportionately represented among new cases. In developing nations, heterosexual contact is the most common mode of transmission among adults and the prevalence is slightly higher among women.

As a result of careful donor screening and testing of the donated blood, HIV transmission resulting from blood products is now extremely rare (1:2,000,000 transfusions). Casual, classroom, or household contact with an HIV-infected person poses no risk.

▶ Pathogenesis

Most transmission of HIV occurs via mucosal surfaces. Virus is transported to regional lymph nodes and by approximately 48 hours after infection, replicating virus is found throughout all lymphoid tissues. Nonhuman primate models using a related virus indicate that a massive loss of mature CD4 T-helper lymphocytes occurs during the first days of infection. During acute infection, high levels of HIV are detected in the bloodstream. In adults, the level of viremia declines without therapy concurrent with the appearance of an HIV-specific host immune response, and plasma viremia usually reaches a steady-state level about 6 months after primary infection. The amount of virus present in the plasma at that point and thereafter is predictive of the rate of disease progression for the individual. Despite ongoing virus replication, a period of clinical latency occurs, lasting from 1 year to more than 12 years during which the infected person is asymptomatic. The virus and anti-HIV immune responses are in a steady state, with high levels of virus production and destruction balanced against production and destruction of CD4 lymphocytes. Eventually, the balance favors the virus,

and the viral burden increases as the CD4 lymphocyte count declines.

In the pre-antiretroviral treatment era, approximately 30% of infants with vertically acquired HIV infection had virus detectable in the blood at birth, presumed to be infection acquired in utero. In-utero infection represents a larger fraction of vertical infections in populations where interventions to prevent transmission, often initiated during the second trimester or later, are common. Infants who acquire HIV during labor and delivery test negative for HIV at birth but soon have detectable virus, usually by 2–4 weeks. The level of viremia rises steeply, reaching a peak at age 1–2 months. In contrast to adults, infants have a gradual decline in plasma viremia that extends beyond 2 years. Infants generally have plasma virus levels 10 times higher than those in adults. Less is known about the viral dynamics following transmission via breast feeding.

► **Clinical Findings**

A. Symptoms and Signs

The manifestations described in this section are likely to be observed in children with untreated infection or in those unresponsive to therapy. Children given effective antiretroviral therapy usually have few symptoms, most of which stem from use of these medications.

The CDC has developed disease staging criteria for HIV-infected children (see Tables 39–1 and 39–2). The criteria incorporate clinical symptoms ranging from no symptoms to mild, moderate, and severe symptoms (categories N, A, B, and C, respectively) and age-adjusted CD4 lymphocyte counts (immunologic categories 1, 2, or 3, corresponding to none, moderate, or severe immune suppression, respectively). Each child is classified both by CD4 lymphocyte count and by clinical category. Category C diagnoses are the diseases associated with late-stage disease and confer a diagnosis of AIDS.

1. Primary acute infection—The incubation period is 2–4 weeks for primary infection acquired by adults and adolescents through high-risk behavior. Nonspecific symptoms occur in 30–90% of new infections (eg, flu- or mild mono-

nucleosis-like illness) but may not be brought to medical attention. In some U.S. cities, anonymous screening of blood samples demonstrates laboratory evidence of acute HIV infection in 1% of emergency department patients. Diagnosis requires a high index of suspicion. Infected persons may present with fever, fatigue, malaise, pharyngitis, enlarged lymph nodes, and hepatosplenomegaly. Less commonly seen signs, but more specific to HIV, are mild oral ulcerations; a diffuse macular, erythematous rash; and mild meningitis or encephalopathy. Occasionally, thrush, *Candida* esophagitis, or genital ulcers are observed. These early symptoms of primary infection resolve spontaneously within 1–2 weeks, although some persons have fatigue and depression for weeks or months.

A primary infection syndrome is rarely recognized following perinatal acquisition. Newborns with perinatal HIV infection are rarely symptomatic at birth. Size and physical features are not different from uninfected neonates. However, 75–95% will demonstrate some sign (mostly nonspecific) by age 1 year.

2. Nonspecific symptoms—These may be observed in early- or late-stage disease. Frequent illness (especially recurrent otitis media or sinusitis) is typical, in addition to poor weight gain, chronic cough, chronic diarrhea, developmental delay, unexplained fevers, night sweats, generalized lymphadenopathy, parotid swelling, or hepatosplenomegaly. Delayed growth may be observed as early as age 4 months in some infants. These common early findings may be present for years in an otherwise well child.

3. Infections related to immunodeficiency—Progressive immune dysfunction in both humoral and cell-mediated responses results in susceptibility to infections. Recurrent or serious bacterial infections are more common in children than in HIV-infected adults. Bouts of bacteremia, especially due to *Streptococcus pneumoniae*, can occur in children without suppressed CD4 T-cell counts. Infections with *Mycobacterium tuberculosis* (usually acquired from adults in the household) may be severe. Primary varicella-zoster virus (VZV) infections may be prolonged or severe. Herpes zoster (shingles), including multiple episodes, is common even in the era of combina-

Table 39–2. Immunologic categories based on age-specific CD4 lymphocyte counts and percentages of total lymphocytes.

Immunologic Category	Age of Child					
	< 12 mo		1–5 y		6–12 y	
	cells/ μ L	(%)	cells/ μ L	(%)	cells/ μ L	(%)
1. No evidence of suppression	≥ 1500	(≥ 25)	≥ 1000	(≥ 25)	≥ 500	(≥ 25)
2. Evidence of moderate suppression	750–1499	(15–24)	500–999	(15–24)	200–499	(15–24)
3. Evidence of severe suppression	< 750	(< 15)	< 500	(< 15)	< 200	(< 15)

Adapted from MMWR Recomm Rep 1994;43(RR-12):4.

tion therapy. Recurrent herpes simplex lesions may be large, painful, and persistent. Likewise, persistent aphthous ulcers may cause significant morbidity. Late-stage immunodeficiency is accompanied by susceptibility to a variety of opportunistic pathogens. Pneumonia caused by *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) is the most common AIDS-defining diagnosis in children with unrecognized HIV infection. The incidence is highest between ages 2 and 6 months and is often fatal during this period. Symptoms are difficult to distinguish from those of viral or atypical pneumonia. (See Chapter 41.) Persistent candidal mucocutaneous infections (oral, cutaneous, and vaginal) are common. Candidal esophagitis occurs with more advanced disease. In children with severe immunosuppression, cytomegalovirus (CMV) infections may result in disseminated disease, hepatitis, gastroenteritis, retinitis, and encephalitis.

Disseminated infection with *Mycobacterium avium* complex (MAC), presenting with fever, night sweats, weight loss, diarrhea, fatigue, lymphadenopathy, hepatomegaly, anemia, and granulocytopenia, occurs in infected children who have CD4 lymphocyte counts below 50–100/ μ L. A variety of diarrheal pathogens that cause mild, self-limited symptoms in healthy persons may result in severe, chronic diarrhea in HIV-infected persons. These include rotavirus, *Cryptosporidium parvum*, *Microsporidia*, *Cyclospora*, *Isospora belli*, *Giardia lamblia*, and bacterial pathogens. Chronic parvovirus infection manifested by anemia can occur. Reactivation of toxoplasmosis occurs rarely in children.

4. Organ system disease—HIV infection may cause a variety of organ system symptoms (encephalopathy, pneumonitis, hepatitis, diarrhea, hematologic suppression, nephropathy, and cardiomyopathy). The more common of these are described in this section. On average, HIV-infected children have lower than normal neuropsychological functioning; higher viral load correlates with more severe abnormalities. In many children, neuropsychological deficits do not normalize when antiretroviral therapy is started despite suppression of viremia. Studies are needed to determine if highly active antiretroviral therapy (HAART) early in life will completely prevent the central nervous system effects of HIV. Without antiretroviral therapy, encephalopathy afflicted 20% or more of HIV-infected children. Symptoms included acquired microcephaly, progressive motor deficit, ataxia, pseudobulbar palsy, and failure to attain (or loss of) developmental milestones. Children who are older may have symptoms similar to those observed in infected adults, such as gradual mental status changes initially affecting attention span and memory.

Lymphoid interstitial pneumonitis is characterized by a diffuse peribronchial and interstitial infiltrate composed of lymphocytes and plasma cells. It may be asymptomatic or associated with dry cough, hypoxemia, dyspnea or wheezing on exertion, and clubbing of the digits. Children with this disorder frequently have enlargement of the parotid glands and generalized lymphadenopathy.

Mild to moderate elevation of liver enzymes is frequently observed, and, more rarely, overt clinical hepatitis occurs due to HIV infection itself. However, patients are often taking medications with potential hepatotoxicity, and superinfection with other pathogens (CMV, Epstein-Barr virus [EBV], MAC, hepatitis C, or hepatitis B) that affect the liver is common. Thus, the diagnosis of HIV hepatitis should be one of exclusion. Chronic diarrhea may occur with HIV infection; however, as with hepatitis, it is commonly associated with other gastrointestinal infections.

5. Malignancy—Children with HIV are at increased risk of malignancy. The most commonly occurring tumors are non-Hodgkin lymphomas. Unlike non-Hodgkin lymphomas in immunocompetent persons, these tumors commonly occur at extranodal sites (central nervous system, bone, gastrointestinal tract, liver, or lungs) and are usually high-grade and of B-cell origin. Cervical infection with human papillomavirus is more likely to progress to neoplasia in adolescent females with HIV infection. Carcinoma due to anal human papillomavirus is also a concern. Kaposi sarcoma, a common malignancy among HIV-infected gay males, rarely occurs in children. There is an increased frequency of leiomyosarcomas.

B. Laboratory Findings

HIV antibody is measured by enzyme-linked immunosorbent assay (ELISA; standard or rapid antibody tests). A confirmatory test, usually a Western blot, must be performed because individuals occasionally have nonviral cross-reacting antibodies, which result in a false-positive ELISA or rapid test. Infants born to HIV-infected mothers will have HIV antibody—regardless of infection status—owing to transplacental passage of maternal antibody. Maternal HIV antibody is lost in all children by 18 months. After that age, HIV antibody testing can be used to make the diagnosis of infection. In the early weeks after acute HIV infection acquired by high-risk behaviors, HIV antibody may be absent. Most patients will seroconvert by 6 weeks, but occasionally seroconversion does not occur for 3–6 months. When acute HIV infection is suspected, tests for circulating virus (see below) should be obtained.

HIV nucleic acid, RNA (in plasma) or DNA (in blood cells), can be detected by several methods, including polymerase chain reaction (PCR), branched DNA chain assay (bDNA), and nucleic acid sequence-based amplification (NASBA). These tests are highly sensitive with a lower limit of detection of 20 copies/mL of plasma. An HIV protein (p24) can also be detected in plasma; the test is less costly, but is less sensitive. Quantitative measures of HIV RNA in plasma are valuable for predicting the rate of disease progression and are a surrogate marker of response to antiretroviral therapy.

Using nucleic acid detection, infants at risk of vertical HIV infection can be diagnosed by age 2–4 months. At birth, approximately 30% of infected infants have detectable HIV RNA and DNA. Infants acquiring HIV in the peripartum period (late gestation, labor, and delivery) will have negative results for HIV RNA and DNA at birth due to low levels of

circulating virus, but soon have detectable virus. By age 6 weeks, almost all perinatally infected infants will become positive for HIV nucleic acid. An infant who is not breast feeding and has had at least two negative HIV cultures or nucleic acid detection tests, both performed after age 1 month and at least one performed after age 2–4 months, is very unlikely to be infected. The infant should be followed up for clinical symptoms and tested for HIV antibody at ages 12, 15, and 18 months to confirm reversion to seronegative status, thereby confirming the absence of infection. Breast-fed infants may acquire HIV at any time until they are fully weaned; to confirm absence of HIV infection, HIV nucleic acid tests should be performed at least 6 weeks after the last exposure.

The hallmark of HIV disease progression is decline in the absolute number and percentage of CD4 T lymphocytes and an increasing percentage of CD8 T lymphocytes. The CD4 T-lymphocyte values are predictive of the child's risk of opportunistic infections. Healthy infants have CD4 T-lymphocyte numbers and percentages much higher than in adults; these gradually decline to adult levels by age 6 years. Hence, age-adjusted values must be used when assessing a child's CD4 T-lymphocyte parameters (see Table 39–2).

Hypergammaglobulinemia of IgG, IgA, and IgM is characteristic and may be observed as early as age 9 months. Late in the disease, some individuals may become hypogammaglobulinemic. Hematologic abnormalities (anemia, neutropenia, and thrombocytopenia) may occur due to effects of HIV disease or, more commonly, due to adverse effects of medications. With brain involvement, the cerebrospinal fluid may either be normal or the protein elevated and a mononuclear pleocytosis present.

C. Imaging

Cerebral imaging can demonstrate atrophy and calcification in the basal ganglia and frontal lobes in patients with encephalopathy. Chest radiographs of children with lymphoid interstitial pneumonitis show diffuse interstitial reticulonodular infiltrates, occasionally with hilar adenopathy. The chest radiograph in *P jiroveci* pneumonia typically demonstrates perihilar infiltrates progressing to bilateral diffuse alveolar disease.

► Differential Diagnosis

HIV infection should be in the differential diagnosis for children being evaluated for immunodeficiency. Depending on the degree of immunosuppression, the presentation in HIV infection may be similar to that in B-cell, T-cell, or combined immunodeficiencies, such as hypogammaglobulinemia and severe combined immunodeficiency. (See Chapter 31.) HIV infection should also be considered in the evaluation of children with failure to thrive or developmental delay. Children or adolescents with chronic HIV infection may present with generalized lymphadenopathy or hepatosplenomegaly resembling infections with viruses such as EBV or CMV. Because blood tests are definitive for the diagnosis of HIV infection, the diagnosis can be readily established or excluded. The

diagnosis of chronic HIV infection is made with HIV antibody testing in a child older than age 18 months. In younger infants, a negative result usually excludes HIV infection; a positive result must be confirmed by testing for viral nucleic acid. In rare cases, HIV-infected children with hypogammaglobulinemia have falsely negative antibody tests. Any child suspected of having HIV infection whose serologic test results are negative should be tested by a nucleic acid–based test. Absence of maternal risk factors or history of negative test results during pregnancy, particularly if documentation of the results is lacking, should not dissuade the provider from testing for HIV if the patient has signs consistent with the diagnosis.

The symptoms of acute primary infection in the adolescent may be similar to those of mononucleosis caused by EBV or CMV, toxoplasmosis, rubella, secondary syphilis, influenza, enterovirus, or viral hepatitis. In the first weeks of acute infection, HIV antibody tests will be negative. However, the diagnosis can be made by detection of HIV RNA in plasma. Seroconversion occurs over 2–6 weeks in symptomatic patients. Diagnosis of acute HIV infection has important public health implications, because patients are highly infectious during the first months after infection. Studies are ongoing to determine if treatment during early infection improves prognosis. Thus, HIV RNA testing is warranted if the patient has a history of high-risk behavior or an alternative diagnosis is lacking.

► Prevention

Vertical transmission can be substantially prevented by giving antiretroviral medications to the mother during pregnancy and to the newborn. Combination therapy that results in viral suppression to less than 1000 copies/mL reduces transmission rates to less than 1%. Therefore, the CDC and the American College of Obstetrics and Gynecology now recommend offering HIV testing, with an option to refuse, as a part of routine prenatal care for all pregnant women irrespective of risk factors. Women who present in labor should be tested for HIV antibody using recently approved rapid tests that give results within 60 minutes. Women found to be infected should be counseled regarding all HIV-related pregnancy care issues, including the benefits and risks of therapy with antiretroviral agents. Women in resource-rich settings generally receive three-drug combination regimens during pregnancy. Zidovudine should be incorporated into the regimen if possible because it has the greatest efficacy and safety of currently available drugs. Antiretroviral therapy begun in the last weeks of pregnancy, during labor, or even within 48 hours after birth, also reduces perinatal infection, although less profoundly. Short-course treatment can reduce transmission by 30–50% in women who are diagnosed late in pregnancy or at delivery.

Elective cesarean delivery reduces the risk of transmission by 50% and should be offered to women who are not receiving antiretroviral therapy or who have viral loads over 1000 copies/mL despite treatment. Women receiving combi-

nation therapy that suppresses viral load to below 1000 copies/mL have a very low risk of transmission. For these women, the benefit and risk of cesarean delivery should be considered on an individual basis. Because breast milk can carry the virus, breast feeding by HIV-infected mothers is contraindicated when access to safe formula can be ensured. In developing countries transmission via breast milk remains a major mode of pediatric HIV infection.

The only 100% effective method of avoiding sexual transmission of HIV infection is abstinence or limiting sexual contact to a mutually monogamous partner who is not HIV-infected. However, condoms—used consistently and correctly—are highly effective in preventing transmission between stable, sexually active couples in which only one partner is HIV-infected. In two studies, seroconversions occurred in 0–2% of discordant couples using condoms consistently compared with 10–15% of couples with inconsistent condom use. A third study reported 1.1 seroconversions per 100 person-years of observation among consistent condom users compared with 9.7 seroconversions among inconsistent users. The CDC provides detailed instructions on correct condom use. Prompt treatment of other sexually transmitted diseases, especially those associated with mucosal ulceration, also reduces the risk of sexual transmission.

Postexposure prophylaxis with antiretroviral medications begun as soon as possible is recommended for people with an occupational exposure that carries a risk of HIV transmission. Prophylaxis is also recommended for people with a nonoccupational exposure that is not likely to recur (eg, sexual assault or condom rupture) who present within 72 hours of the exposure. Detailed guidelines regarding assessment of the level of risk and selection of postexposure therapy are published by the CDC.

Horizontal transmission (ie, in the absence of sexual contact or injecting drug use) of HIV is exceedingly rare and is associated with exposure of broken skin or mucous membranes to HIV-infected blood or bloody secretions. Because undiagnosed HIV-infected infants and children might be enrolled, all schools and day care centers should have policies with simple guidelines for using universal precautions to prevent transmission of HIV infection in these settings. Saliva, tears, urine, and stool are not contagious if there is no gross blood in these fluids. A barrier protection (eg, latex or rubber gloves or thick pads of fabric or paper) should be used when possible contact with blood or bloody body fluids may occur. Objects that might be contaminated with blood, such as razors or toothbrushes, should not be shared. No special care is required for dishes, towels, toys, or bedclothes. Blood-soiled clothing may be washed routinely with hot water and detergent. Contaminated surfaces may be disinfected easily with a variety of agents, including household bleach (1:10 dilution), some commercial disinfectants (eg, Lysol), or 70% isopropyl alcohol.

▶ Treatment

HIV infection calls for specific antiretroviral treatment to prevent progressive deterioration of the immune system as

well as prophylactic measures at late stages of HIV infection to prevent opportunistic infections. Whenever possible, children should be enrolled in collaborative treatment studies. Current information on clinical trials may be obtained at:

http://aidsinfo.nih.gov/clinical_trials

Guidelines for the treatment of HIV developed by a national working group of pediatric HIV specialists are published by the U.S. Public Health System at:

<http://aidsinfo.nih.gov/guidelines>

The treatment paradigm changes frequently; therefore, prior to initiating treatment, expert consultation should be obtained.

A. Specific Measures

1. Principles of HIV treatment—Treatment of HIV is aimed at suppressing viral replication. The rate of disease progression is directly correlated with the number of HIV copies circulating in plasma. Antiretroviral treatment that reduces HIV replication is associated with increases in CD4 T-lymphocyte counts, reconstitution of immune function, and arrest of disease progression. Children have a remarkable ability to restore normal CD4 T-cell counts, even when treatment is started at an advanced disease stage. However, it is clear that even the most potent regimens fail to eradicate virus. HIV persists in long-lived resting cells and cessation of antiretroviral treatment results in resumption of viremia and decline in CD4 lymphocytes. Therefore, treatment for HIV with currently available modalities must be a lifelong endeavor. Once therapy has been initiated, the patient should be monitored every 3 months for changes in plasma virus copy number, CD4 lymphocyte count, symptoms, and adverse drug effects.

Emergence of drug-resistant HIV during therapy is a major challenge. HIV has a high spontaneous mutation rate, and emergence of drug resistance during treatment is frequent. Many antiretroviral drugs select for resistant mutations in the virus within weeks to a few months when used as monotherapy. Prevention of resistance mutations requires complete suppression such that virus is not replicating and has no opportunity to generate new mutations. Achieving potent viral suppression requires a combination of at least three antiviral agents. Treatment with a combination of drugs with different mechanisms of action provides an additional barrier to resistance as the virus must be resistant to all the drugs in the combination. Finally, strict adherence to the prescribed treatment is critical. Studies demonstrate that more than 95% of the doses must be taken in order to maintain optimal viral suppression. Therefore programs and services that enhance adherence are essential adjuncts of any HAART regimen.

Determining the best time to initiate treatment is a subject of ongoing discussion and research. Once treatment is initiated there are risks of drug toxicity as well as the risk of developing drug resistance if adherence is suboptimal,

thereby limiting future treatment options. Some children with HIV live many years without HIV-related symptoms. On the other hand, early treatment may better preserve immune function and foster normal growth and development. Thus it is important to start treatment when the risk of disease progression outweighs the risk of starting the medication. The Department of Health and Human Services publishes guidelines for the use of antiretroviral drugs for patients in the United States at the National Institutes of Health AIDSinfo web site (<http://aidsinfo.nih.gov>). These guidelines are frequently updated, and the most current online version should be consulted when treatment decisions are made.

At any age, once significant symptoms of HIV are present, the patient is likely to have ongoing disease progression. Therefore treatment is indicated for any child or adolescent with symptoms in category C or B (excluding lymphoid interstitial pneumonia or a single serious bacterial illness; see Table 39–1). For asymptomatic adults and for adolescents the guidelines for antiretroviral treatment initiation are primarily based on CD4 and some clinical conditions. Treatment is recommended for patients with absolute CD4 T-cell counts below 350 cells/mm³ and may be considered for those with CD4 counts over 350. Treatment is recommended for all patients who are pregnant or have HIV-associated nephropathy, irrespective of CD4 T-cell count.

For infants and children, the relative risk of disease progression and the predictive value of CD4 and viral load for progression vary with age. Age-specific criteria for CD4 count and viral load should be considered in the decision to treat or defer therapy. A high proportion of infants will have rapid progression during the first year of life. It is uncertain whether frequent monitoring of CD4 counts is effective in identifying infants who will have rapid progression. Viral loads do not distinguish rapid versus slow progression for individual infants in the first year of life. Therefore, current guidelines recommend treatment for any infant younger than age 12 months with CD4 levels below 25% and many experts initiate treatment for all infants younger than 12 months.

Children who have survived without treatment beyond age 12 months have a lower risk of progression. Further, at this age, CD4 parameters are more predictive of the level of risk. A large meta-analysis determined that CD4 levels of less than 20% for children aged 1–4 years and less than 15% for those older than age 4 years were associated with a 10% and 5% risk of progression to AIDS and death, respectively. Treatment is recommended for children meeting these age-based CD4 criteria, irrespective of symptoms or viral load. Studies have demonstrated that the estimated 1-year risk of death is two to three times higher in children with a plasma HIV RNA load of 100,000 copies/mL compared with 10,000 copies/mL. As a result the guidelines recommend consideration of treatment for asymptomatic or mildly symptomatic children with an HIV RNA load of 100,000 copies/mL or higher. Likewise, treatment should be considered for CD4

levels of 20–24% in children aged 1–4 years, or 15–24% in children older than 4 years. If a child is asymptomatic and has a CD4 levels above 25% and viral load of less than 100,000 copies/mL, treatment may be deferred with repeated evaluation at 3–4 month intervals.

2. Considerations in selecting antiretroviral medications—

The process of selecting a combination of medications for a particular patient has become highly complex. The U.S. Food and Drug Administration (FDA) has approved 21 drugs and several fixed drug combinations from five different drug classes for the treatment of HIV (Table 39–3). The clinician must consider the potency of the drugs, tolerability, simplicity of dosing, drug interactions, prior drug therapy, and viral resistance profiles.

Potency, the intrinsic ability of the regimen to fully suppress viral replication, is foremost because without complete suppression resistant virus will emerge. Tolerability is also critical because regimens that are poorly tolerated fail due to poor adherence. When selecting a tolerable regimen, the circumstances and priorities of each individual patient and family must be considered. Certain side effects that may be acceptable to one person may be intolerable to another. Likewise, the frequency of dosing may have a great effect on adherence of some patients to the drug regimen, whereas others may be satisfied with frequent dosing provided that the number or size of pills is reduced. Over the years, more drugs have become available that can be given once daily and require fewer total pills or liquids.

Drug interactions between different antiretroviral medications, and with other medications, are frequent and must be considered when selecting a combination of drugs. Most of the protease inhibitors and non-nucleoside reverse transcriptase inhibitors are metabolized by cytochrome P-450 (CYP-450) isotypes and therefore can induce or inhibit the metabolism of other drugs that are metabolized by that pathway. Some combinations lead to significant decreases or increases in drug levels, and combined use is contraindicated. On the other hand, the drug interactions can be advantageous, and certain combinations of protease inhibitors can be used so that therapeutic plasma levels can be achieved with lower doses (and fewer pills). Drug absorption and metabolism can vary widely between individuals, especially for the protease inhibitor class. Therefore, therapeutic drug monitoring to determine the level of drug in serum and adjust doses to achieve therapeutic levels is recommended by some experts.

The potential for viral resistance should be evaluated when selecting a combination. Optimally, an initial regimen would select viral resistance mutations that do not confer cross-resistance to a large number of other drugs. This permits an opportunity to use alternative regimens if resistance to the initial regimen develops. The process is aided by laboratory methods (genotyping and phenotyping) to determine the presence of virus with specific drug resistance mutations in the patient.

Table 39-3. Antiretroviral drugs approved by the U.S. Food and Drug Administration.

Drug Class or Drug Name	Potential Adverse Effects ^a	Mechanism of Action
Nucleoside/nucleotide reverse transcriptase inhibitors (NRTI)	Lactic acidosis (rare but potentially fatal)	Chain termination of HIV DNA
Abacavir (ABC; Ziagen)	Hypersensitivity reaction	
Didanosine (ddI; Videx)	Pancreatitis, peripheral neuropathy, nausea, diarrhea	
Emtricitabine (FTC; Emtriva)	Minimal toxicity	
Lamivudine (3TC; Epivir)	Minimal toxicity	
Stavudine (d4T; Zerit)	Peripheral neuropathy, lipodystrophy, pancreatitis	
Tenofovir (TDF; Viread)	Headache, nausea, diarrhea, bone demineralization, renal insufficiency (rare)	
Zidovudine (ZDV, AZT; Retrovir)	Anemia, neutropenia, gastrointestinal intolerance, headache	
Non-nucleoside reverse transcriptase inhibitors (NNRTI)	Rash, rarely Stevens-Johnson syndrome	Synthesis of HIV DNA inhibited
Delavirdine (DLV, Rescriptor)	Increased liver transaminases, headache	
Efavirenz (EFV, Sustiva)	Central nervous system symptoms, increased transaminases, teratogenic in monkeys	
Nevirapine (NVP, Viramune)	Hepatitis	
Protease inhibitors (PI)	Glucose intolerance, risk of bleeding in hemophiliacs, dyslipidemia, lipodystrophy, transaminase elevation	Production of noninfectious virions
Atazanavir (ATV, Reyataz)	Increased indirect bilirubin	
Darunavir (DRV, Prezista)	Rash (cross-reaction with sulfonamide), gastrointestinal intolerance	
Fosamprenavir (FPV, Lexiva)	Rash, oral paresthesia	
Indinavir (IDV, Crixivan)	Nephrolithiasis, increased indirect bilirubin	
Lopinavir/ritonavir (LPV/r, Kaletra)	Gastrointestinal intolerance	
Nelfinavir (NFV, Viracept)	Diarrhea	
Ritonavir (RTV, Norvir)	Nausea, circumoral paraesthesias, hepatitis, pancreatitis, taste perversion	
Saquinavir hard gel (SQV, Invirase)	Gastrointestinal intolerance	
Tipranavir (TPV, Aptivus)	Hepatic toxicity, rash (cross-reaction with sulfonamide)	
Integrase inhibitor		Integration of viral nucleic acid in host genome prevented
Raltegravir (Isentress)	Diarrhea, nausea, headache, and fever	
Entry inhibitors		Viral entry inhibited
Enfuvirtide (T-20, Fuzeon)	Injection site reactions, increased rate of bacterial pneumonias, hypersensitivity reactions (< 1%)	Fusion inhibited
Maraviroc (Selzentry)	Hepatic toxicity, cardiac events, postural hypotension, cough, fever, upper respiratory infections	CCR5 co-receptor antagonist
Fixed drug combinations		
Abacavir/lamivudine (Epizicom)	See individual drugs	
Tenofovir/emtricitabine (Truvada)	See individual drugs	
Tenofovir/emtricitabine/efavirenz (Atripla)	See individual drugs	
Zidovudine/lamivudine (Combivir)	See individual drugs	
Zidovudine/lamivudine/abacavir (Trizavir)	See individual drugs	

^aRelative incidence of adverse events depends on specific drug.

3. Specific antiretroviral medications

A. NUCLEOSIDE AND NUCLEOTIDE REVERSE TRANSCRIPTASE INHIBITORS (NRTIs)—The NRTIs act as nucleotide analogues, which are incorporated into HIV DNA during transcription by the HIV reverse transcriptase. The result is chain termination and failure to complete provirus, preventing incorporation of HIV genome into cellular DNA. The human mitochondrial DNA polymerase also has limited affinity for these analogues, the degree varying with the drug. Incorporation of the analogue into mitochondrial DNA is one mechanism thought to lead to adverse effects including pancreatitis, peripheral neuropathy, bone marrow suppression (anemia or neutropenia), and lipodystrophy (loss of peripheral fat and accumulation of visceral fat). Lactic acidosis with hepatic steatosis (fatty liver) is a rare but potentially fatal complication that may result from mitochondrial toxicity.

A hypersensitivity reaction (not related to mitochondrial toxicity) to abacavir occurs in approximately 10% of patients. The reaction, characterized by a flulike syndrome with or without rash, may be fatal with continued treatment or rechallenge.

B. NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NNRTIs)—NNRTIs also inhibit HIV DNA synthesis but act at a different site on the viral enzyme so that cross-resistance does not occur with NRTIs. The NNRTIs have potent antiretroviral activity, but single amino acid mutations in the viral reverse transcriptase protein often induce resistance to all three drugs in this class. The most common toxicity is rash, which may be severe. Efavirenz is associated with central nervous system symptoms (ie, dizziness and confusion), which usually resolve after the initial weeks of use. Inflammation of the liver, rarely fatal, may occur with any of the drugs in the class, but is more common with nevirapine.

C. PROTEASE INHIBITORS—Protease inhibitors (PIs) bind the HIV protease and interfere with assembly of infectious virions. Acute adverse effects are mainly gastrointestinal intolerance and rash as well as other effects specific to the particular drug (see Table 39–3). All PIs are associated with a risk of glucose intolerance, elevated transaminases, or bleeding in hemophiliacs. Most are associated with dyslipidemia (elevated cholesterol and triglycerides) and may contribute to lipodystrophy. An exception is atazanavir, which is not associated with changes in serum lipids. These drugs are highly potent and usually require multiple mutations for high-level resistance to develop. Taste and pill burden limit tolerability of these medications. The PIs are metabolized by the hepatic CYP-450 enzymes, resulting in many interactions with other drugs, including other antiretrovirals. Careful attention to drug interactions is necessary when treating a patient taking a PI. Regimens combining two PIs can take advantage of the drug interactions and improve the pharmacokinetic properties of the drugs.

D. INTEGRASE INHIBITOR—Raltegravir is the first of this class to be FDA approved. The drug inhibits the viral integrase enzyme and prevents integration of HIV-1 nucleic acid into the host genome. Studies demonstrate rapid decreases in viral load with this drug.

E. ENTRY INHIBITORS—Enfuvirtide binds to the viral envelope protein and interferes with HIV fusion with the host cell plasma membrane, thereby preventing entry of the virus into the cell. Enfuvirtide must be administered parenterally, and local reactions at the injection site are common. Maraviroc is a chemokine receptor antagonist that binds one of the co-receptor proteins (CCR5) on the host CD4 T cell. This blocks viral binding and prevents cell entry for virus that uses that receptor. The drug is approved for patients who have multi-drug-resistant virus that has been demonstrated by laboratory testing to use the particular co-receptor.

B. General Measures

1. Immunizations—Combined diphtheria-tetanus-acellular pertussis, inactivated poliovirus, conjugated *Haemophilus influenzae* type b, conjugated *Streptococcus pneumoniae*, hepatitis B, and hepatitis A vaccines should be given as recommended for healthy children. (See Chapter 9.) The conjugated meningococcal vaccine and human papillomavirus vaccine are also recommended. Studies evaluating the immunogenicity of these vaccines in HIV-infected children are underway. A dose of 23-valent polysaccharide vaccine at age 2 years and a booster after 3–5 years is recommended in addition to the conjugated pneumococcal vaccine series given in infancy. Infected children and their household contacts should receive inactivated influenza vaccine annually after age 6 months. In general, live virus vaccines should be avoided. However, the risk of measles is considered greater than the potential risk of the vaccine in asymptomatic children; thus measles-mumps-rubella vaccine should be given at age 12 months, with the second dose given 1 month later, provided the child does not have evidence of severe immunosuppression (category C or category 3). Varicella vaccine, also a live virus, should be considered after the potential risks and benefits are weighed, for asymptomatic or mildly symptomatic HIV-infected children older than age 12 months with CD4 T-lymphocyte levels of 15% or more. HIV-infected children receive two doses of varicella vaccine administered 3 months apart.

Because antibody titers to vaccines decline with time and with progression of immune deficiency, prophylaxis with immune globulin for measles exposure and tetanus immune globulin for tetanus-prone wounds should be given regardless of immunization status.

2. Prophylaxis for infections—Children with suppressed CD4 lymphocyte numbers benefit from prophylactic treatment to prevent opportunistic infections. Children who have had their CD4 counts restored to category 1 or 2 for over 2–4 months can be taken off prophylactic treatments. Antibio-

otic prophylaxis for *P jiroveci* pneumonia has been extremely effective. Because this infection has its highest incidence during the first year of life, *P jiroveci* pneumonia prophylaxis is given to all infants born to HIV-infected mothers beginning at age 4–6 weeks. When tests for HIV DNA or RNA are demonstrated negative at age 3–4 months, prophylaxis may be discontinued. HIV-infected infants should continue on prophylactic drugs until age 12 months, when further treatment is based on assessment of symptoms and age-adjusted CD4 lymphocyte counts every 3 months. Published guidelines from the CDC for *P jiroveci* pneumonia prophylaxis are summarized in Tables 39–4 and 39–5.

Children with hypogammaglobulinemia or a history of serious or multiple bacterial infections may benefit from monthly intravenous immune globulin if they are not receiving trimethoprim–sulfamethoxazole and have not responded well to antiretroviral therapy. Clarithromycin or azithromycin reduces the frequency of disseminated MAC with a survival benefit for children with very low CD4 counts.

Recurrent mucocutaneous candidiasis can be prevented with nystatin, clotrimazole, or fluconazole. Oral antiviral prophylaxis (acyclovir, valacyclovir, or famciclovir) is effective for recurrent severe herpes simplex or VZV infections.

HIV-infected children have a higher risk of progressive *M tuberculosis* infections. Because the child's infection is usually

Table 39–4. *Pneumocystis jiroveci*^a pneumonia prophylaxis for HIV-exposed and infected infants by age and HIV infection status.

Age/Infection Status	<i>P jiroveci</i> Prophylaxis
Birth to 4–6 wk	No prophylaxis
4–6 wk to 2 mo	Prophylaxis
2–12 mo	
HIV-infected or indeterminate	Prophylaxis
HIV infection reasonably excluded ^b	No prophylaxis
1–5 y, HIV-infected	Prophylaxis if CD4 count < 500/μL or CD4 < 15% ^c
6–12 y, HIV-infected	Prophylaxis if CD4 count < 200/μL or CD4 < 15% ^c

^aFormerly *Pneumocystis carinii*.

^bAmong children who have had two or more negative HIV cultures or PCR tests, at least one of which is performed after age 1 month and one of which is performed at age 2–4 months or older.

^cProphylaxis should be considered on a case-by-case basis for children who might otherwise be at risk for *Pneumocystis* pneumonia, such as those with rapidly declining CD4 counts or percentages or children with category C conditions.

Adapted from 2002 USPHS/IDSA Guidelines for the Prevention of Opportunistic Infections in Persons Infected with Human Immunodeficiency Virus. Available at: <http://www.aidsinfo.nih.gov/guidelines>.

Table 39–5. Drug regimens for *Pneumocystis jiroveci* prophylaxis for children over age 4 weeks.

Recommended regimen

Trimethoprim–sulfamethoxazole, 150 mg TMP/m²/d plus 750 mg SMX/m²/d, administered orally, divided into two doses per day 3 days a week on consecutive days

Alternative (same total daily dosages):

Single daily dose 3 days a week on consecutive days

Divided twice-daily doses 7 days a week

Divided twice-daily doses 3 days a week on alternate days

Alternative if trimethoprim–sulfamethoxazole is not tolerated^a

Dapsone, 2 mg/kg/d (not to exceed 100 mg) orally once daily or 4 mg/kg (not to exceed 200 mg) orally once weekly

Aerosolized pentamidine (children over age 5 y), 300 mg via Respigard II inhaler monthly

Atovaquone, age 1–3 mo and > 24 mos, 30 mg/kg orally once daily; age 4–24 mo, 45 mg/kg orally once daily

^aIf dapsone, aerosolized pentamidine, or atovaquone is not tolerated, some clinicians use intravenous pentamidine, 4 mg/kg every 2–4 wk.

Adapted from 2002 USPHS/IDSA Guidelines for the Prevention of Opportunistic Infections in Persons Infected with Human Immunodeficiency Virus. Available at <http://www.aidsinfo.nih.gov/guidelines>.

acquired from adult household contacts, the child and other household members should be skin-tested for tuberculosis yearly if they belong to a population with substantial risk for exposure to *M tuberculosis*.

3. Infections and other conditions—Rates of bacteremia, especially pneumococcal bacteremia, and shingles, are higher among HIV-infected children, even in the absence of severe suppression of CD4 counts. Shingles occurs 10 times more frequently among HIV infected children compared with age-matched healthy children. VZV and herpes simplex virus infections are treated with acyclovir, because symptoms may be prolonged in children with HIV. Short courses of valacyclovir or famciclovir—drugs with good bioavailability—are also effective, although not approved for children. Aphthous ulcers also occur in children, even when on suppressive antiretroviral drug therapy. Symptomatic CMV infection is treated with ganciclovir or foscarnet and requires ongoing secondary prophylaxis if CD4 lymphocyte counts remain low. MAC requires treatment with a multidrug regimen to delay the emergence of resistance. Lymphoid interstitial pneumonitis may respond to corticosteroid therapy. Chronic parvovirus as a cause of anemia should be investigated and can be treated with intravenous immune globulin. Anemia and granulocytopenia, whether drug-induced or HIV-induced, may respond to epoetin alfa (erythropoietin) and filgrastim (granulocyte colony-stimulating factor, G-CSF), respectively. Rarely transfusions are needed; CMV-seronegative blood should be used.

4. General support—Growth failure (weight and height) is one of the earliest and most sensitive markers of disease

progression. The cause is a combination of increased metabolic needs related to chronic infection and decreased caloric intake. Supplemental nutrition in the form of oral supplements may be required. Some antiretroviral drugs cause elevated cholesterol and triglycerides. A cross-sectional study found elevated serum cholesterol in 13% of children with HIV compared with 5% of uninfected pediatric controls. Although the long-term consequences of drug-induced hyperlipidemia in HIV-infected children are unknown, diet modification and exercise are recommended. Nutritional evaluation and counseling should be a part of early care and continue throughout the child's care.

Evaluation and support for psychosocial needs of HIV-affected families is imperative. As with other chronic illnesses, HIV infection affects all family members, and it also carries an additional social stigma. Emotional concerns and financial needs are more prominent than medical needs at many stages of the disease process and influence the family's ability to comply with a medical treatment regimen. HIV-infected children often have comorbid mental health conditions. Rates of attention-deficit/hyperactivity disorder range from 20–50% in various studies. Hospital admissions for mental health disorders are more frequent among HIV-infected children. In one study dual diagnosis of HIV and a mental health disorder occurred in 85% of adolescents who acquired HIV infection through high-risk behaviors. Ideally, care should be coordinated by a team of caregivers that is familiar with this disease and the newest therapies, and that has access to community resources.

5. Public health considerations—The infant or child who is well enough to attend day care or school should not be treated differently from other children. The exception may be a toddler with uncontrollable biting behavior or bleeding lesions that cannot be covered adequately; in these situations, the child may be withheld from group day care. Optimally the school health care provider and teacher will be aware of the diagnosis, but there is no legal requirement that any individual at the school or day care center be informed. The parents and child may prefer to keep the diagnosis confidential, because the stigma associated with HIV infection may be difficult to overcome. Adolescents with HIV should receive counseling on the risk of transmission through sexual activity and shared needles. Programs should be made available to encourage use of barrier protection and to develop strategies for disclosure to their partners and other friends.

► Prognosis

There is a bimodal presentation of HIV disease progression in vertically infected children. Without treatment, about 20–30% of HIV-infected infants develop an AIDS-defining illness by age 1 year and die before age 2–3 years (considered to be rapid progressors). Mortality among infants born in some developing countries is even higher and may approach

50% in the first years of life. Cohorts of infants with rapid progression have higher median peak and median average levels of viremia over the first year of life than do other HIV-infected children. Other predictors of rapid progression are low absolute counts of CD4 and suppressor-killer T (CD8) lymphocytes in the first 6 months. In the remainder of infants the disease progresses more slowly, with 5% progressing to AIDS or death per year and median survival of 10 years based on studies performed in the United States and Europe. These so-called slow progressors generally have lower levels of viremia and a more gradual decline in CD4 lymphocyte counts. In rare instances children and adults with untreated infection show no evidence of immune suppression for 8–10 years or more. Studies indicate that both viral and host genetic factors, not fully defined, play a role in determining the rate of disease progression.

The initiation of antiretroviral therapy dramatically alters the natural history by slowing disease progression and permitting restoration of most immune function. Plasma viremia and age-adjusted CD4 lymphocyte counts are used to assess the risk of progression and response to antiretroviral treatment. With the introduction of HAART, mortality rates for HIV-infected children in the United States declined 80% between 1994 and 1999. Many children, infected from birth, are entering adolescence and young adulthood. With recognition of the longer survival time in most infected children, this disease is now approached as a chronic, rather than acutely terminal, illness. The complexity of antiretroviral drug therapy requires care from a provider with HIV expertise. Primary care physicians are encouraged to participate in the care of HIV-infected children in collaboration with centers staffed by personnel with expertise in pediatric HIV issues.

Infections: Bacterial & Spirochetal

John W. Ogle, MD
Marsha S. Anderson, MD

40

BACTERIAL INFECTIONS

GROUP A STREPTOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Streptococcal pharyngitis:

- ▶ Clinical diagnosis based entirely on symptoms; signs and physical examination unreliable.
- ▶ Throat culture or rapid antigen detection test positive for group A streptococci.

Impetigo:

- ▶ Rapidly spreading, highly infectious skin rash.
- ▶ Erythematous denuded areas and honey-colored crusts.
- ▶ Group A streptococci are grown in culture from most (not all) cases.

▶ General Considerations

Group A streptococci (GAS) are common gram-positive bacteria producing a wide variety of clinical illnesses, including acute pharyngitis, impetigo, cellulitis, and scarlet fever, the generalized illness caused by strains that elaborate erythrogenic toxin. GAS can also cause pneumonia, septic arthritis, osteomyelitis, meningitis, and other less common infections. GAS infections may also produce nonsuppurative sequelae (rheumatic fever and acute glomerulonephritis).

The cell walls of streptococci contain both carbohydrate and protein antigens. The C-carbohydrate antigen determines the group, and the M- or T-protein antigens determine the specific type. In most strains, the M protein appears to confer virulence, and antibodies developed against the M protein are protective against reinfection with that type.

GAS are almost all β -hemolytic. These organisms may be carried without symptoms on the skin and in the pharynx, rectum, and vagina. Between 10% and 15% of school-aged children in some studies are asymptomatic pharyngeal carriers of GAS. Streptococcal carriers are individuals who do not mount an immune response to the organism and are therefore believed to be at low risk for nonsuppurative sequelae. All GAS are sensitive to penicillin. Resistance to erythromycin is common in some countries and has increased in the United States.

A. Clinical Findings

1. Respiratory infections

A. INFANCY AND EARLY CHILDHOOD (< AGE 3 YEARS)—The onset is insidious, with mild symptoms (low-grade fever, serous nasal discharge, and pallor). Otitis media is common. Exudative pharyngitis and cervical adenitis are uncommon in this age group.

B. CHILDHOOD TYPE—Onset is sudden, with fever and marked malaise and often with repeated vomiting. The pharynx is sore and edematous, and generally there is tonsillar exudate. Anterior cervical lymph nodes are tender and enlarged. Small petechiae are frequently seen on the soft palate. In **scarlet fever**, the skin is diffusely erythematous and appears sunburned and roughened (sandpaper rash). The rash is most intense in the axillae, groin, and on the abdomen and trunk. It blanches except in the skin folds, which do not blanch and are pigmented (Pastia's sign). The rash usually appears 24 hours after the onset of fever and rapidly spreads over the next 1–2 days. Desquamation begins on the face at the end of the first week and becomes generalized by the third week. Early in the course of infection, the surface of the tongue is coated white, with the papillae enlarged and bright red (so-called white strawberry tongue). Subsequently desquamation occurs, and the tongue appears beefy red (strawberry tongue). The face generally

shows circumoral pallor. Petechiae may be seen on all mucosal surfaces.

C. ADULT TYPE—The adult type of GAS is characterized by exudative or nonexudative tonsillitis with fewer systemic symptoms, lower fever, and no vomiting. Scarlet fever is uncommon in adults.

2. Impetigo—Streptococcal impetigo begins as a papule that vesiculates and then breaks, leaving a denuded area covered by a honey-colored crust. Both *Staphylococcus aureus* and GAS are isolated in some cases. The lesions spread readily and diffusely. Local lymph nodes may become swollen and inflamed. Although the child often lacks systemic symptoms, a high fever and toxicity may be present. If flaccid bullae are noted, the disease is called bullous impetigo and is caused by an epidermolytic toxin-producing strain of *S aureus*.

3. Cellulitis—The portal of entry is often an insect bite or superficial abrasion. A diffuse, rapidly spreading cellulitis occurs that involves the subcutaneous tissues and extends along the lymphatic pathways with only minimal local suppuration. Local acute lymphadenitis occurs. The child is usually acutely ill, with fever and malaise. In classic erysipelas, the involved area is bright red, swollen, warm, and very tender. The infection may extend rapidly from the lymphatics to the bloodstream.

Streptococcal perianal cellulitis is an entity peculiar to young children. Pain with defecation often leads to constipation, which may be the presenting complaint. The child is afebrile and otherwise well. Perianal erythema, tenderness, and painful rectal examination are the only abnormal physical findings. Scant rectal bleeding with defecation may occur. A perianal swab culture usually yields heavy growth of GAS. A variant of this syndrome is streptococcal vaginitis in prepubertal girls. Symptoms are dysuria and pain; marked erythema and tenderness of the introitus and blood-tinged discharge are seen.

4. Necrotizing fasciitis—This dangerous disease is reported sporadically and may occur as a complication of varicella infection. About 20–40% of cases are due to GAS; 30–40% are due to *S aureus*; and the rest are a result of mixed bacterial infections. The disease is characterized by extensive necrosis of superficial fasciae, undermining of surrounding tissue, and usually systemic toxicity. Initially the skin overlying the infection is tender and pale red without distinct borders, resembling cellulitis. Blisters or bullae may appear. The color deepens to a distinct purple or in some cases becomes pale. Tenderness out of proportion to the clinical appearance, skin anesthesia (due to infarction of superficial nerves), or “woody” induration suggest necrotizing fasciitis. Involved areas may develop mild to massive edema. Early recognition and aggressive debridement of necrotic tissue are essential.

5. Group A streptococcal infections in newborn nurseries—GAS epidemics occur occasionally in nurseries. The organism may be introduced into the nursery from the vaginal

tract of a mother or from the throat or nose of a mother or a staff member. The organism then spreads from infant to infant. The umbilical stump is colonized while the infant is in the nursery. Like staphylococcal infections, there may be no or few clinical manifestations while the infant is still in the nursery. Most often, a colonized infant develops a chronic, oozing omphalitis days later. The organism may spread from the infant to other family members. Serious and even fatal infections may develop, including sepsis, meningitis, empyema, septic arthritis, and peritonitis.

6. Streptococcal sepsis—Serious illness from GAS sepsis is now more common both in children and in adults. Rash and scarlet fever may be present. Prostration and shock result in high mortality rates. Pharyngitis is uncommon as an antecedent illness. Underlying disease is a predisposing factor.

7. Streptococcal toxic shock syndrome (STSS)—Toxic shock syndrome caused by GAS has been defined. Like *S aureus*–associated toxic shock, multiorgan system involvement is a prominent part of the illness. The diagnostic criteria include (1) isolation of GAS from a normally sterile site, (2) hypotension or shock, and (3) at least two of the following: renal impairment (creatinine > 2 times the upper limit of normal for age), thrombocytopenia (< 100,000/mm³), or coagulopathy, liver involvement (transaminases > 2 times normal), acute respiratory distress syndrome, generalized erythematous macular rash or soft tissue necrosis (myositis, necrotizing fasciitis, gangrene). In cases that otherwise meet clinical criteria, isolation of GAS from a nonsterile site (throat, wound, or vagina) is indicative of a probable cause.

B. Laboratory Findings

Leukocytosis with a marked shift to the left is seen early. Eosinophilia regularly appears during convalescence. β -Hemolytic streptococci are cultured from the throat. The organism may be cultured from the skin and by needle aspiration from subcutaneous tissues and other involved sites such as infected nodes. Occasionally blood cultures are positive. Newer rapid antigen detection tests such as optical immunoassays and DNA chemiluminescence probes are very specific, and in some cases are almost as sensitive as traditional throat culture. However, sensitivity varies with the type of test used and the experience level of the laboratory or office. Many experts recommend backup throat culture in patients with negative rapid strep antigen tests. Patients with positive rapid strep antigen tests do not need a confirmation by throat culture, since the specificity of antigen tests are high.

Antistreptolysin O (ASO) titers rise about 150 units within 2 weeks after acute infection. Elevated ASO and anti-DNase B titers are useful in documenting prior throat infections in cases of acute rheumatic fever. The streptozyme test detects antibodies to streptolysin O, hyaluronidase, streptokinase, DNase B, and NADase. It is somewhat more sensitive than the measurement of ASO titers.

Proteinuria, cylindruria, and minimal hematuria may be seen early in children with streptococcal infection. True post-streptococcal glomerulonephritis is seen 1–4 weeks after the respiratory or skin infection.

► Differential Diagnosis

Streptococcal infection in early childhood must be differentiated from adenovirus and other respiratory virus infections. The pharyngitis in herpangina (coxsackie A viruses) is vesicular or ulcerative. Herpes simplex also causes ulcerative lesions, which most commonly involve the anterior pharynx, tongue, and gums. In infectious mononucleosis, the pharyngitis is also exudative, but splenomegaly and generalized adenopathy are typical, and laboratory findings are often diagnostic (atypical lymphocytes, elevated liver enzymes, and a positive heterophil or other serologic test for mononucleosis). Uncomplicated streptococcal pharyngitis improves within 24–48 hours if penicillin is given and by 72–96 hours without antimicrobials.

Group G and group C streptococci are uncommon causes of pharyngitis but have been implicated in epidemics of sore throat in college students. Acute rheumatic fever does not occur following group G or group C infection, although acute glomerulonephritis is a complication. *Arcanobacterium hemolyticum* may cause pharyngitis with scarlatina-like or maculopapular truncal rash. In diphtheria, systemic symptoms, vomiting, and fever are less marked; pharyngeal pseudomembrane is confluent and adherent; the throat is less red; and cervical adenopathy is prominent. Pharyngeal tularemia causes white rather than yellow exudate. There is little erythema, and cultures for β -hemolytic streptococci are negative. A history of exposure to rabbits and a failure to respond to antimicrobials may suggest the diagnosis. Leukemia and agranulocytosis may present with pharyngitis and are diagnosed by bone marrow examination.

Scarlet fever must be differentiated from other exanthematous diseases (principally rubella), erythema due to sunburn, drug reactions, Kawasaki disease, toxic shock syndrome, and staphylococcal scalded skin syndrome (see also Table 38–3).

► Complications

Suppurative complications of GAS infections include sinusitis, otitis, mastoiditis, cervical lymphadenitis, pneumonia, empyema, septic arthritis, and meningitis. Spread of streptococcal infection from the throat to other sites—principally the skin (impetigo) and vagina—is common and should be considered in every instance of chronic vaginal discharge or chronic skin infection, such as that complicating childhood eczema. Both acute rheumatic fever and acute glomerulonephritis are nonsuppurative complications of GAS infections.

A. Acute Rheumatic Fever (See Chapter 19)

B. Acute Glomerulonephritis

Acute glomerulonephritis (AGN) can follow streptococcal infections of either the pharynx or the skin—in contrast to

rheumatic fever, which follows pharyngeal infection only. AGN may occur at any age, even infancy. In most reports of AGN, males predominate by a ratio of 2:1. Rheumatic fever occurs with equal frequency in both sexes. Certain M types are associated strongly with post-streptococcal glomerulonephritis (nephritogenic types). The serotypes producing disease on the skin often differ from those found in the pharynx.

The incidence of AGN after streptococcal infection is variable and has ranged from 0–28%. Several outbreaks of AGN in families have involved 50–75% of siblings of affected patients in 1- to 7-week periods. Second attacks of glomerulonephritis are rare. The median period between infection and the development of glomerulonephritis is 10 days. In contrast, acute rheumatic fever occurs after a median of 18 days.

C. Post-Streptococcal Reactive Arthritis

Following an episode of group A streptococcal pharyngitis, a reactive arthritis develops in some patients. This reactive arthritis is believed to be due to immune complex deposition and is seen about 1–2 weeks following the acute infection. Patients with post-streptococcal reactive arthritis do not have the full constellation of clinical and laboratory criteria needed to fulfill the Jones criteria for a diagnosis of acute rheumatic fever.

► Treatment

A. Specific Measures

Treatment is directed toward both eradication of acute infection and prevention of rheumatic fever. In patients with pharyngitis, antibiotics should be started early to relieve symptoms and should be continued for 10 days to prevent rheumatic fever. Although early therapy has not been shown to prevent AGN, it seems advisable to treat impetigo promptly in sibling contacts of patients with post-streptococcal nephritis. Neither sulfonamides nor trimethoprim-sulfamethoxazole is effective in the treatment of streptococcal infections. Although topical therapy for impetigo with antimicrobial ointments (especially mupirocin) is as effective as systemic therapy, it does not eradicate pharyngeal carriage and is less practical for extensive disease.

1. Penicillin—Except for penicillin-allergic patients, penicillin V (phenoxymethyl penicillin) is the drug of choice. Penicillin resistance has never been documented. For children weighing less than 27 kg, the regimen is 250 mg, given orally two or three times a day for 10 days. For heavier children, adolescents, or adults 500 mg two or three times a day is recommended. Giving penicillin V (250 mg) twice daily is as effective as more frequent oral administration or intramuscular therapy. Once-daily oral amoxicillin (750 mg) has been shown, in one study of children 3–18 years of age, to be as effective as penicillin V given three times a day. Another alternative for treatment of pharyngitis and impetigo is a single dose of benzathine penicillin G, given intra-

muscularly (0.6 million units for children weighing < 60 lb [27.2 kg] and 1.2 million units for children weighing > 60 lb [27.2 kg]). Intramuscular delivery ensures compliance, but is painful. Parenteral therapy is indicated if vomiting or sepsis is present. Mild cellulitis due to GAS may be treated orally or intramuscularly.

Cellulitis requiring hospitalization can be treated with aqueous penicillin G (150,000 units/kg/d, given intravenously in four to six divided doses) or cefazolin (80–100 mg/kg/d, given intravenously in three divided doses) until there is marked improvement. Penicillin V (50 mg/kg/d in four divided doses) or cephalexin (50–75 mg/kg/d in four divided doses), may then be given orally to complete a 10-day course. Acute cervical lymphadenitis may require incision and drainage. Treatment of necrotizing fasciitis requires emergency surgical debridement followed by high-dose parenteral antibiotics appropriate to the organisms cultured.

2. Other antibiotics—For penicillin-allergic patients with pharyngitis or impetigo the following alternative regimens have been used: erythromycin estolate (20–40 mg/kg/d in two to four divided doses) for 10 days; clarithromycin (15 mg/kg/d in two divided doses) for 10 days; and azithromycin (12 mg/kg/d) once daily for 5 days. Erythromycin resistance, although not currently widespread in the United States, was reported in 48% of strains tested in Pittsburgh in 2001. Penicillin-allergic patients from areas with high rates of erythromycin resistance may require an alternative antibiotic. Clindamycin, cephalexin, ceftibuten, cefdinir, cefadroxil, azithromycin, and clarithromycin are other effective oral antimicrobials. Each of these drugs should be given for 10 days, with the exception of azithromycin which is given for 5 days. The dosage of clindamycin is 10–20 mg/kg/d orally in four divided doses. Patients with immediate, anaphylactic hypersensitivity to penicillin should not receive cephalosporins, because up to 15% will also be allergic to cephalosporins. In most studies, bacteriologic failures after cephalosporin therapy are less frequent than failures following penicillin. However, cephalosporins are generally more expensive than penicillin. Additionally, there are few conclusive data on the ability of these agents to prevent rheumatic fever. Therefore, penicillin remains the agent of choice for nonallergic patients. Many strains are resistant to tetracycline.

For infections requiring intravenous therapy, aqueous penicillin G (250,000 units/kg in six divided doses) given intravenously is usually the drug of choice. Cefazolin (100–150 mg/kg/d intravenously or intramuscularly in three divided doses); clindamycin (25–40 mg/kg/d intravenously in four divided doses); and vancomycin (40 mg/kg/d intravenously in four divided doses) are alternatives in penicillin-allergic patients. Clindamycin is preferred by many experts and may be superior to penicillin for necrotizing fasciitis if the organism is susceptible to it. Clindamycin should not be used alone empirically for severe, suspected GAS infections because a small percentage of isolates in the United States are resistant to it. Some physicians use both penicillin and clindamycin in patients with necrotizing fasciitis or STSS.

3. Serious GAS disease—Serious GAS infections, such as pneumonia, osteomyelitis, septic arthritis, sepsis, endocarditis, meningitis, and STSS, require parenteral antimicrobial therapy. Penicillin G is the drug of choice for these invasive infections. Clindamycin, in addition to penicillin G, is advocated by many experts for STSS or necrotizing fasciitis. Necrotizing fasciitis requires prompt surgical debridement. In STSS, volume status and blood pressure should be monitored and patients evaluated for a focus of infection, if not readily apparent. Intravenous immune globulin (in addition to antibiotics) has been used in severe cases.

4. Treatment failure—Even when compliance is perfect, organisms will be found in cultures in 5–15% of children after cessation of therapy. Reculture is indicated only in patients with relapse or recrudescence of pharyngitis or those with a personal or family history of rheumatic fever. Repeat treatment at least once with an oral cephalosporin or clindamycin is indicated in patients with recurrent culture-positive pharyngitis.

5. Prevention of recurrences in rheumatic individuals—The preferred prophylaxis for rheumatic individuals is benzathine penicillin G, 1.2 million units intramuscularly every 4 weeks. If the risk of streptococcal exposure is high, every-3-week dosing is preferred. One of the following alternative oral prophylactic regimens may be used: sulfadiazine, 0.5 g once a day (if < 27 kg) or 1 g once a day (if > 27 kg); penicillin V, 250 mg twice daily; or erythromycin, 250 mg twice daily. Continued prophylaxis is recommended for at least 5 years or until age 21 years (whichever is longer) if carditis is absent. Prophylaxis in these individuals should be continued if the risk of contact with persons with GAS is high (eg, parents of school-aged children, pediatric nurses, and teachers). In the presence of carditis without residual heart or valvular disease, a minimum of 10 years (or well into adulthood, whichever is longer) is the minimum duration. If the patient has residual valvular heart disease, many recommend lifelong prophylaxis. These patients should be at least 10 years from their last episode of rheumatic disease and at least 40 years of age prior to considering discontinuation of prophylaxis. A similar approach to the prevention of recurrences of glomerulonephritis may be indicated during childhood when there is a suspicion that repeated streptococcal infections coincide with flare-ups of glomerulonephritis.

6. Post-streptococcal reactive arthritis—In contrast to rheumatic fever, nonsteroidal agents may not dramatically improve joint symptoms. However, like patients with rheumatic fever, some patients with post-streptococcal reactive arthritis have developed carditis several weeks to months after their arthritis symptoms began. Therefore, some experts recommend antibiotic prophylaxis of these patients for 1 year and monitoring for signs of carditis (see recommendations for prevention of recurrences of rheumatic fever, above). If carditis does not develop, prophylaxis could then be discontinued.

If carditis develops, the patient should be considered to have acute rheumatic fever and prophylaxis continued as described above.

B. General Measures

Acetaminophen is useful for pain or fever. Local treatment of impetigo may promote earlier healing. Crusts should first be soaked off. Areas beneath the crusts should then be washed with soap daily.

C. Treatment of Complications

Rheumatic fever is best prevented by early and adequate penicillin treatment of the streptococcal infection.

D. Treatment of Carriers

Identification and treatment of GAS carriers is difficult. There are no established clinical or serologic criteria for differentiating carriers from the truly infected. Some children receive multiple courses of antimicrobials, with persistence of GAS in the throat, leading to a “streptococcal neurosis” on the part of families.

In certain circumstances, eradication of carriage may be desirable: (1) when a family member has a history of rheumatic fever; (2) when an episode of STSS or necrotizing fasciitis has occurred in a household contact; (3) multiple, recurring, documented episodes of GAS in family members despite adequate therapy; and (4) during an outbreak of rheumatic fever or GAS-associated glomerulonephritis. Clindamycin (20 mg/kg/d, given orally in three divided doses, to a maximum of 150 mg/dose) or a combination of rifampin (20 mg/kg/d, given orally for 4 days) and penicillin in standard dosage given orally has been used to attempt eradication of carriage.

► Prognosis

Death is rare except in infants or young children with sepsis or pneumonia. The febrile course is shortened and complications eliminated by early and adequate treatment with penicillin.

GROUP B STREPTOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Early-onset neonatal infection:

- Newborn younger than age 7 days, with rapidly progressing overwhelming sepsis, with or without meningitis.
- Pneumonia with respiratory failure is frequent; chest radiograph resembles that seen in hyaline membrane disease.
- Leukopenia with a shift to the left.
- Blood or cerebrospinal fluid (CSF) cultures growing group B streptococci.

Late-onset Infection:

- Meningitis, sepsis, or other focal infection in a child aged 1–16 weeks with blood or CSF cultures growing group B streptococci.

► General Considerations

The incidence of perinatal group B streptococci (GBS) disease has declined dramatically since screening of pregnant mothers and provision of intrapartum chemoprophylaxis began. However, neonatal infections due to GBS still occur. Although most patients with GBS disease are infants younger than age 3 months, cases are seen in infants aged 4–5 months. Serious infection also occurs in women with puerperal sepsis, immunocompromised patients, patients with cirrhosis and spontaneous peritonitis, and diabetic patients with cellulitis. Two distinct clinical syndromes distinguished by differing perinatal events, age at onset, and serotype of the infecting strain occur in infants.

Risk factors for early-onset group GBS disease include maternal GBS colonization, gestational age less than 37 weeks, rupture of membranes more than 18 hours prior to presentation, young maternal age, history of a previous infant with invasive GBS disease, African-American or Hispanic ethnic origin, and low or absent maternal GBS anti-capsular antibodies.

► Clinical Findings

A. Early-Onset Infection

“Early-onset” illness is observed in newborns younger than 7 days old. The onset of symptoms in the majority of these infants occurs in the first 48 hours of life, and most are ill within 6 hours. Apnea is often the first sign. Sepsis, meningitis, apnea, and pneumonia are the most common clinical presentations. There is a high incidence of associated maternal obstetric complications, especially premature labor and

prolonged rupture of the membranes. Newborns with early-onset disease are severely ill at the time of diagnosis, and more than 50% die. Although most infants with early-onset infections are full-term, premature infants are at increased risk for the disease. Newborns with early-onset infection acquire GBS in utero as an ascending infection or during passage through the birth canal. When early-onset infection is complicated by meningitis, more than 80% of the bacterial isolates belong to serotype III. Postmortem examination of infants with early-onset disease usually reveals pulmonary inflammatory infiltrates and hyaline membranes containing large numbers of GBS.

B. Late-Onset Infection

“Late-onset” infection occurs in infants between ages 7 days and 4 months (median age at onset, about 4 weeks). Maternal obstetric complications are not usually associated with late-onset infection. These infants are usually not as ill at the time of diagnosis as those with early-onset disease, and the mortality rate is lower. In recent series, about 37% of patients have meningitis and 46% have sepsis. Septic arthritis and osteomyelitis, meningitis, occult bacteremia, otitis media, ethmoiditis, conjunctivitis, cellulitis (particularly of the face or submandibular area), lymphadenitis, breast abscess, empyema, and impetigo have been described. Strains of GBS possessing the capsular type III polysaccharide antigen are isolated from more than 95% of infants with late-onset disease, regardless of clinical manifestations. The exact mode of transmission of the organisms is not well defined.

C. Diagnosis

Culture of GBS from a normally sterile site such as blood, pleural fluid, or CSF provides proof of diagnosis. Frequent false-positive results limit the usefulness of testing for GBS antigen in urine and CSF.

► Prevention

Many women of childbearing age possess type-specific circulating antibody to the polysaccharide antigens for GBS. These antibodies are transferred to the newborn via the placental circulation. Carriers delivering healthy infants have significant serum levels of IgG antibody to this antigen. In contrast, women delivering infants who develop either early- or late-onset GBS disease rarely have detectable antibody in their sera.

Monovalent and bivalent vaccines with type II or III polysaccharide antigens have been studied in pregnant women, with 80–90% of vaccine recipients developing fourfold or greater increases in GBS capsular polysaccharide type-specific IgG. These reports suggest that a multivalent vaccine could be developed and given to pregnant women to prevent many cases of early-onset GBS disease.

The Centers for Disease Control and Prevention (CDC) has issued culture-based maternal guidelines for the prevention of early-onset GBS disease.

► CDC Recommendations for Prevention of Perinatal GBS Disease

- All pregnant women should be screened at 35–37 weeks’ gestation with a vaginal and rectal culture for GBS. *Exceptions:* Women with known GBS bacteriuria during the current pregnancy or women who have delivered a previous infant with GBS disease do not need screening—all these women need intrapartum prophylaxis.
- If GBS status is unknown at onset of labor or rupture of membranes, intrapartum chemoprophylaxis should be administered to women with any of the following:
 - Gestation less than 37 weeks.
 - Rupture of membranes more than 18 hours.
 - Intrapartum temperature of greater than 38°C (> 100.4°F)
- Women with GBS colonization and a planned cesarean delivery done prior to labor and rupture of membranes do not routinely need intrapartum antimicrobial prophylaxis (IAP).
- IAP recommendations (Table 40–1).
- Empiric treatment of a neonate whose mother received IAP for prevention of GBS (Figure 40–1).

► Treatment

Intravenous ampicillin and an aminoglycoside is the initial regimen of choice for newborns with presumptive invasive GBS disease. For neonates younger than 7 days of age with meningitis, the recommended ampicillin dosage is 200–300 mg/kg/d, given intravenously in three divided doses. For infants older than 7 days of age, the recommended ampicillin dosage is 300 mg/kg/d, given intravenously in four to six divided doses. Penicillin G can be used once GBS is identified and clinical and microbiologic responses have occurred. GBS are less susceptible than other streptococci to penicillin, and high doses are recommended, especially for meningitis. In infants with meningitis, the recommended dosage of penicillin G varies with age: for infants age 7 days or younger, 250,000–450,000 units/kg/d, given intravenously in three divided doses; for infants older than age 7 days, 450,000–500,000 units/kg/d, given intravenously in four to six divided doses.

A second lumbar puncture after 24–48 hours of therapy is recommended by some experts to assess efficacy. Duration of therapy is 2–3 weeks for meningitis; at least 4 weeks for osteomyelitis, cerebritis, ventriculitis, or endocarditis; and 10–14 days for most other infections. Therapy does not eradicate carriage of the organism.

Although streptococci have been universally susceptible to penicillins, increasing minimum inhibitory concentrations (MICs) have been observed in some isolates. In one U.S. study, 10 of 574 rectovaginal isolates obtained from pregnant women in South Carolina were not fully penicillin-susceptible. However, all isolates were vancomycin-susceptible. Resistance of isolates to clindamycin and erythromycin has increased significantly worldwide in the past few years.

Table 40-1. Centers for Disease Control and Prevention recommended regimens for intrapartum prophylaxis for perinatal group B streptococcal (GBS) disease.^a

Recommended	Penicillin G, 5 million units IV initial dose, then 2.5 million units IV q4h until delivery
Alternative	Ampicillin, 2 g IV initial dose, then 1 g IV q4h until delivery
If penicillin allergic ^b	
Patients not at high risk for anaphylaxis	Cefazolin, 2 g IV initial dose, then 1 g IV q8h until delivery
Patients at high risk for anaphylaxis ^c	
GBS susceptible to clindamycin and erythromycin ^d	Clindamycin, 900 mg IV q8h until delivery
GBS resistant to clindamycin or erythromycin or susceptibility unknown	Vancomycin, ^e 1 g IV q12h until delivery

^aBroader-spectrum agents, including an agent active against GBS, may be necessary for treatment of chorioamnionitis.

^bHistory of penicillin allergy should be assessed to determine whether a high risk for anaphylaxis is present. Penicillin-allergic patients at high risk for anaphylaxis are those who have experienced immediate hypersensitivity to penicillin including a history of penicillin-related anaphylaxis; other high-risk patients are those with asthma or other diseases that would make anaphylaxis more dangerous or difficult to treat, such as persons being treated with β -adrenergic-blocking agents.

^cIf laboratory facilities are adequate, clindamycin and erythromycin susceptibility testing should be performed on prenatal GBS isolates from penicillin-allergic women at high risk for anaphylaxis.

^dResistance to erythromycin is often, but not always, associated with clindamycin resistance. If a strain is resistant to erythromycin, but appears susceptible to clindamycin, it may have inducible resistance to clindamycin.

^eCefazolin is preferred over vancomycin for women with a history of penicillin allergy other than immediate hypersensitivity reactions, and pharmacologic data suggest it achieves effective intra-amniotic concentrations. Vancomycin should be reserved for penicillin-allergic women at high risk for anaphylaxis. Reprinted, with permission, from Schrag S et al: Prevention of perinatal Group B streptococcal disease. STREPTOCOCCAL INFECTIONS WITH ORGANISMS OTHER THAN GROUP A OR B

Streptococci of groups other than A and B are part of the normal flora of humans and can occasionally cause disease. Group C or group G organisms occasionally produce pharyngitis (with an ASO rise), but without risk of subsequent rheumatic fever. AGN may occasionally occur. Group D streptococci and *Enterococcus* species are normal inhabitants of the gastrointestinal tract and may produce urinary tract infections, meningitis, and sepsis in the newborn, as well as endocarditis. Nosocomial infections caused by *Enterococcus* are frequent in neonatal and oncology units and in patients with central venous catheters. Nonhemolytic aerobic streptococci and β -hemolytic streptococci are normal flora of the mouth. They are involved in the production of dental plaque and probably dental caries and are the most common cause of subacute infective endocarditis. Finally, there are numerous anaerobic and microaerophilic streptococci, normal flora of the mouth, skin, and gastrointestinal tract, which alone or in combination with other bacteria may cause sinusitis, dental abscesses, brain abscesses, and intra-abdominal or lung abscesses.

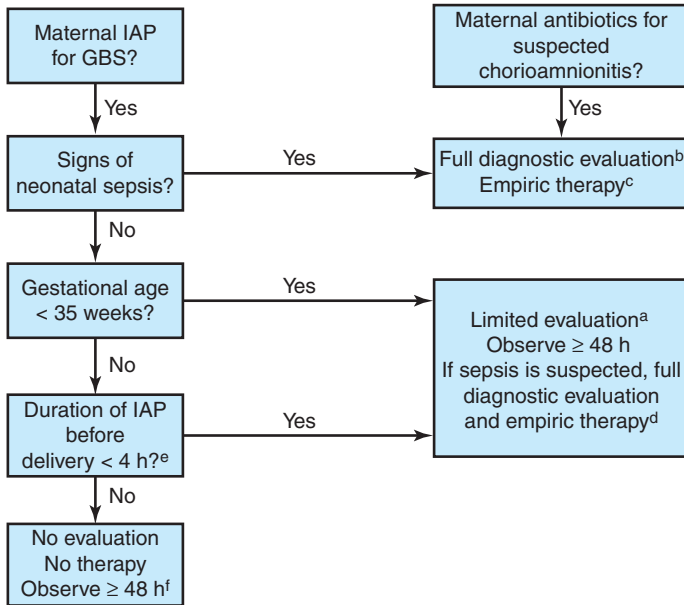

► Treatment

A. Enterococcal Infections

Enterococcus faecalis and *Enterococcus faecium* are the two most common and most important strains causing human infections. In general, *E faecalis* is more susceptible to antibiotics than *E faecium*, but antibiotic resistance is commonly seen with both species.

1. Infections with ampicillin-susceptible enterococci—

Lower tract urinary infections can be treated with oral amoxicillin. Pyelonephritis should be treated intravenously with ampicillin and gentamicin (gentamicin dosing may need to be adjusted for altered renal function). Sepsis or meningitis in the newborn should be treated intravenously with a combination of ampicillin (100–200 mg/kg/d in three divided doses) and gentamicin (3 mg/kg/d in three divided doses). Peak serum gentamicin levels of 3–5 mcg/mL are adequate as gentamicin is used as a synergistic agent. Endocarditis requires 4–6 weeks of intravenous treatment. Penicillin G (250,000 units/kg/d in six to eight divided doses) plus gentamicin (3 mg/kg/d in three divided doses) is most often used. Cephalosporins are not effective.

^a If no maternal intrapartum prophylaxis for GBS was administered despite an indication being present, data are insufficient on which to recommend a single management strategy.

^b Includes complete blood cell count and differential, blood culture, and chest radiograph if respiratory abnormalities are present. When signs of sepsis are present, a lumbar puncture, if feasible, should be performed.

^c Duration of therapy varies depending on results of blood culture, cerebrospinal fluid findings, if obtained, and the clinical course of the infant. If laboratory results and clinical course do not indicate bacterial infection, duration may be as short as 48 h.

^d CBC with differential and blood culture.

^e Applies only to penicillin, ampicillin, or celazoin and assumes recommended dosing regimens.

^f A healthy-appearing infant who was 38 weeks' gestation at delivery and whose mother received 4 h of intrapartum prophylaxis before delivery may be discharged home after 24 h if other discharge criteria have been met and a person able to comply fully with instructions for home observation will be present. If any one of these conditions is not met, the infant should be observed in the hospital for at least 48 h and until criteria for discharge are achieved.

▲ **Figure 40-1.** Algorithm for treatment of a newborn whose mother received intrapartum antimicrobial prophylaxis (IAP) for prevention of group B streptococci (GBS) or suspected chorioamnionitis. This algorithm is not an exclusive course of management. Variations that incorporate individual circumstance or institutional preferences may be appropriate. (Reproduced, with permission, from Schrag S et al: Prevention of perinatal group B streptococcal disease, revised guidelines from CDC. *MMWR Recomm Rep* 2002;51[RR-11]:1.)

2. Infections with ampicillin-resistant or vancomycin-resistant enterococci—

Ampicillin-resistant enterococci are often susceptible to vancomycin (40–60 mg/kg/d in four divided doses). Vancomycin-resistant enterococci are usually also resistant to ampicillin. Two agents are effective against vancomycin-resistant enterococci and approved for use in adults. Quinupristin–dalfopristin (Synercid) is approved for infections with vancomycin-resistant *E faecium* (not effective against *E faecalis*). Linezolid (Zyvox) is approved for vancomycin-resistant *E faecalis* and *E faecium* infections. Both agents are bacteriostatic against enterococci. Isolates resistant to these newer agents have been reported. Infectious disease consultation is recommended when use of these drugs is entertained or when vancomycin-resistant enterococcal infections are identified.

B. Viridans Streptococcal Infections (Subacute Infective Endocarditis)

It is important to determine the penicillin sensitivity of the infecting strain as early as possible in the treatment of viridans streptococcal endocarditis. Resistant organisms are most commonly seen in patients receiving penicillin prophylaxis for rheumatic heart disease. Strains sensitive to penicillin G (MIC < 0.1 mcg/mL) may be treated for 4 weeks with penicillin, 150,000–200,000 units/kg/d intravenously, with gentamicin (lower “synergy” dose of 1 mg/kg per dose every 8 hours in patients with normal renal function) added during the first 2 weeks. There is considerable experience with 2-week therapy in adult patients using penicillin and gentamicin. Similarly, excellent results have been obtained

with ceftriaxone once daily for 4 weeks. If the MIC is 0.5 mcg/mL or higher, longer therapy and higher doses of penicillin G must be used (200,000–300,000 units/kg/d intravenously in combination with gentamicin for 4–6 weeks). If the MIC is 0.1–0.5 mcg/mL, penicillin G at the higher dose for a minimum of 4 weeks is recommended, with gentamicin added for the first 2 weeks. Vancomycin, 40 mg/kg/d, is usually preferred for resistant strains and patients allergic to penicillin.

PNEUMOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Bacteremia:

- ▶ High fever (> 39.4°C).
- ▶ Leukocytosis (> 15,000/μL).
- ▶ Age 6–24 months.

Pneumonia:

- ▶ Fever, leukocytosis, and tachypnea.
- ▶ Localized chest pain.
- ▶ Localized or diffuse rales. Chest radiograph may show lobar infiltrate (with effusion).

Meningitis:

- ▶ Fever, leukocytosis.
- ▶ Bulging fontanelle, neck stiffness.
- ▶ Irritability and lethargy.

All types:

- ▶ Diagnosis confirmed by cultures of blood, CSF, pleural fluid, or other body fluid.

General Considerations

Sepsis, sinusitis, otitis media, pneumonitis, meningitis, osteomyelitis, cellulitis, arthritis, vaginitis, and peritonitis are all part of a spectrum of pneumococcal infection. Clinical findings that correlate with occult bacteremia in ambulatory patients include age (6–24 months), degree of temperature elevation (> 39.4°C), and leukocytosis (> 15,000/μL). Although each of these findings is in itself nonspecific, a combination of them should arouse suspicion. This constellation of findings in a child who has no focus of infection may be an indication for blood cultures and antibiotic therapy. The cause of most of such bacteremic episodes is pneumococci.

Streptococcus pneumoniae is a common cause of acute purulent otitis media and is the organism responsible for most cases of acute bacterial pneumonia in children. The disease is indistinguishable on clinical grounds from other bacterial pneumonias. Effusions are common, although frank empyema is less common. Abscesses also occasionally occur.

The incidence rate of pneumococcal meningitis has decreased since incorporation of the pneumococcal conjugate vaccine into the infant vaccine schedule. However, pneumococcal meningitis is still more common than *Haemophilus influenzae* type b meningitis. Pneumococcal meningitis, sometimes recurrent, may complicate serious head trauma, particularly if there is persistent leakage of CSF. This has led some physicians to recommend the prophylactic administration of penicillin or other antimicrobials in such cases.

Children with sickle cell disease, other hemoglobinopathies, congenital or acquired asplenia, and some immunoglobulin and complement deficiencies are unusually susceptible to pneumococcal sepsis and meningitis. They often have a catastrophic illness with shock and disseminated intravascular coagulation (DIC). Even with excellent supportive care, the mortality rate is 20–50%. The spleen is important in the control of pneumococcal infection by clearing organisms from the blood and producing an opsonin that enhances phagocytosis. Autosplenectomy may explain why children with sickle cell disease are at increased risk of developing serious pneumococcal infections. Children with cochlear implants are at higher risk for pneumococcal meningitis. Children who have, or who are planning to receive, a cochlear implant should receive age-appropriate pneumococcal vaccination (> 2 weeks prior to surgery if possible).

S pneumoniae rarely causes serious disease in the neonate. Although *S pneumoniae* does not normally colonize the vagina, transient colonization does occur. Serious neonatal disease—including pneumonia, sepsis, and meningitis—may occur and clinically is similar to GBS infection.

Since being introduced in clinical medicine, penicillin has been the agent of choice for pneumococcal infections. Many strains are still highly susceptible to penicillin, and in those cases, penicillin is still the drug of choice. However, pneumococci with moderately increased resistance to penicillin are found in most communities, and reports of treatment failure, particularly in meningitis, are common. The preva-

lence of these relatively penicillin-resistant strains in North America varies geographically. Pneumococci with high-level resistance to penicillin and multiple other drugs are increasingly encountered throughout the United States. Pneumococci from normally sterile body fluids should be routinely tested for susceptibility to penicillin as well as other drugs.

Pneumococci have been classified into 90 serotypes based on capsular polysaccharide antigens. The frequency distribution of serotypes varies at different times, in different geographic areas, and with different sites of infection. Serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F cause about 80–85% of invasive pneumococcal infections in young children. Similar serotypes—6B, 9V, 14, 19A, 19F, and 23F—are responsible for most of the penicillin-resistant isolates. A protein conjugate pneumococcal vaccine (Prevnar) is available for immunization of young children. It includes polysaccharide or oligosaccharide of seven different *S pneumoniae* serotypes conjugated to a protein carrier. The serotypes in the vaccine cause the bulk of pediatric invasive pneumococcal disease. The development of this vaccine is important in the prevention of pneumococcal disease because young children (< age 2 years), who are most at risk for the disease, are unable to immunologically mount a predictable response to the 23-valent polysaccharide vaccine. This vaccine is discussed further in Chapter 9. Recently, a report from Alaska described a rising incidence of invasive pneumococcal disease in Native American children caused by serotypes not represented in the conjugate vaccine. Whether serotype replacement will become more widespread remains to be seen. For older children and adults, the 23-valent pneumococcal vaccine is generally recommended.

► Clinical Findings

A. Symptoms and Signs

In pneumococcal sepsis, fever usually appears abruptly, often accompanied by chills. There may be no respiratory symptoms. In pneumococcal sinusitis, mucopurulent nasal discharge may occur. In infants and young children with pneumonia, fever and tachypnea without auscultatory changes are the usual presenting signs. Respiratory distress is manifested by nasal flaring, chest retractions, and tachypnea. Abdominal pain is common. In older children, the adult form of pneumococcal pneumonia with signs of lobar consolidation may occur, but sputum is rarely bloody. Thoracic pain (from pleural involvement) is sometimes present, but is less common in children. With involvement of the right hemidiaphragm, pain may be referred to the right lower quadrant, suggesting appendicitis. Vomiting is common at onset but seldom persists. Convulsions are relatively common at onset in infants.

Meningitis is characterized by fever, irritability, convulsions, and neck stiffness. The most important sign in very young infants is a tense, bulging anterior fontanelle. In older children, fever, chills, headache, and vomiting are common symptoms. Classic signs are nuchal rigidity associated with positive Brudzinski and Kernig signs. With progression of

untreated disease, the child may develop opisthotonos, stupor, and coma.

B. Laboratory Findings

Leukocytosis is often pronounced (20,000–45,000/ μ L), with 80–90% polymorphonuclear neutrophils. Neutropenia may be seen early in very serious infections. The presence of pneumococci in the nasopharynx is not a helpful finding, because up to 40% of normal children carry pneumococci in the upper respiratory tract. Large numbers of organisms are seen on Gram-stained smears of endotracheal aspirates from patients with pneumonia. In meningitis, CSF usually shows an elevated white blood cell (WBC) count of several thousand, chiefly polymorphonuclear neutrophils, with decreased glucose and elevated protein levels. Gram-positive diplococci may be seen on some (but not all) stained smears of CSF sediment. Antigen detection tests are not useful.

► Differential Diagnosis

There are many causes of high fever and leukocytosis in young infants; 90% of children presenting with these features have a disease other than pneumococcal bacteremia, such as human herpesvirus 6, enterovirus, or other viral infection; urinary tract infection; unrecognized focal infection elsewhere in the body; or early acute shigellosis.

Infants with upper respiratory tract infection who subsequently develop signs of lower respiratory disease are most likely to be infected with a respiratory virus. Hoarseness or wheezing is often present. A radiograph of the chest typically shows perihilar infiltrates and increased bronchovascular markings. Viral respiratory infection often precedes pneumococcal pneumonia; therefore, the clinical picture may be mixed.

Staphylococcal pneumonia may be indistinguishable early in its course from pneumococcal pneumonia. Later, pulmonary cavitation and empyema occur. Staphylococcal pneumonia is most common in infants.

In primary pulmonary tuberculosis, children do not have a toxic appearance, and radiographs show a primary focus associated with hilar adenopathy and often with pleural involvement. Miliary tuberculosis presents a classic radiographic appearance.

Pneumonia caused by *Mycoplasma pneumoniae* is most common in children aged 5 years and older. Onset is insidious, with infrequent chills, low-grade fever, prominent headache and malaise, cough, and, often, striking radiographic changes. Marked leukocytosis (> 18,000/ μ L) is unusual.

Pneumococcal meningitis is diagnosed by lumbar puncture. Without a Gram-stained smear and culture of CSF, it is not distinguishable from other types of acute bacterial meningitis.

► Complications

Complications of sepsis include meningitis and osteomyelitis; complications of pneumonia include empyema, parapneumonic effusion, and, rarely, lung abscess. Mastoiditis,

subdural empyema, and brain abscess may follow untreated pneumococcal otitis media. Both pneumococcal meningitis and peritonitis are more likely to occur independently without coexisting pneumonia. Shock, DIC, and Waterhouse-Friderichsen syndrome resembling meningococcemia are occasionally seen in pneumococcal sepsis, particularly in asplenic patients. Hemolytic-uremic syndrome may occur as a complication of pneumococcal pneumonia or sepsis.

▶ Treatment

A. Specific Measures

All *S pneumoniae* isolated from normally sterile sites should be tested for susceptibility to penicillin. Susceptible strains (MIC \leq 0.06 mcg/mL) can be treated with penicillin, ampicillin, or amoxicillin. Penicillin-intermediate (MIC 0.1–1.0 mcg/mL) or penicillin-resistant strains (MIC \geq 2.0 mcg/mL) should be tested for susceptibility to cephalosporins, vancomycin, and selected other drugs. Therapy with penicillin, amoxicillin, or cephalosporins will usually succeed in cases of bacteremia or pneumonia due to intermediate-resistant isolates because serum levels in excess of the MIC can be achieved. Therapy of meningitis, empyema, osteomyelitis, and endocarditis due to nonsusceptible *S pneumoniae* is more difficult, because penetration of antimicrobials to these sites is limited. Vancomycin and third-generation cephalosporins are indicated in these and other serious or life-threatening infections pending susceptibility test results.

1. Bacteremia—In studies done prior to immunization of young children with conjugated pneumococcal vaccine, 3–5% of blood cultures in patients younger than 2 years of age yielded *S pneumoniae*. These percentages are expected to decrease now that an effective vaccine is available. However, pneumococcal disease will not disappear, as the vaccine prevents only 85% of invasive disease. Many experts treat suspected bacteremia with ceftriaxone (50 mg/kg, given intramuscularly or intravenously). Compared with oral amoxicillin (80–90 mg/kg/d), ceftriaxone may reduce fever and the need for hospitalization. However, meningitis occurs with the same frequency despite presumptive therapy. All children with blood cultures that grow pneumococci should be reexamined as soon as possible. The child who has a focal infection, such as meningitis, or who appears septic should be admitted to the hospital to receive parenteral antimicrobials. If the child is afebrile and appears well or mildly ill, outpatient management is appropriate. If the physician is confident that close follow-up can be achieved, lumbar puncture is not mandatory. Severely ill children, in whom infection with *S pneumoniae* is suspected, should be treated with vancomycin until the susceptibilities of the organism are known.

2. Pneumonia—For infants (1 month of age or older), severely ill patients, and immunocompromised hosts with susceptible organisms appropriate regimens include aqueous

penicillin G (250,000–400,000 units/kg/d, given intravenously in four to six divided doses), cefotaxime (50 mg/kg every 8 hours), or ceftriaxone (50 mg/kg every 12–24 hours). If susceptibilities are not known and the patient is severely ill, vancomycin (10 mg/kg every 6 hours) should be used as part of the regimen to provide coverage for penicillin- or cephalosporin-resistant pneumococcus. Once results of susceptibility testing are available, the regimen can be tailored. Mild pneumonia may be treated with amoxicillin (80–90 mg/kg/d) for 7–10 days. Alternative regimens include oral macrolides and cephalosporins.

3. Otitis media—Most experts recommend oral amoxicillin (80–90 mg/kg/d, divided in two doses) as first-line therapy. The standard course of therapy is 10 days; however, many physicians have been treating uncomplicated cases in children older than 2 years for 5 days, based on recent studies. Treatment failures may be treated with amoxicillin-clavulanate (80–90 mg/kg/d of the amoxicillin component in the 14:1 formulation), intramuscular ceftriaxone, cefuroxime axetil, or cefdinir. Clarithromycin or azithromycin can also be used.

4. Meningitis—Until bacteriologic confirmation and susceptibility testing are completed, patients should receive vancomycin (60 mg/kg/d, given intravenously in four divided doses) and cefotaxime (300 mg/kg/d intravenously in four divided doses), or vancomycin (see previous dosage) and ceftriaxone (100 mg/kg/d, given intravenously in two divided doses). Corticosteroids (dexamethasone, 0.6 mg/kg/d, in four divided doses for 4 days) are recommended by many experts as adjunctive therapy for pneumococcal meningitis. However, by reducing inflammation of the meninges, steroids may reduce the entry of vancomycin into the CSF. The addition of rifampin (10 mg/kg per dose twice a day, intravenously or orally) is used by some experts if both vancomycin and steroids are given, as it penetrates CSF well and may aid in sterilization (rifampin should never be used alone for treatment of meningitis). A repeat lumbar puncture at 24–48 hours should be considered to ensure sterility of the CSF if dexamethasone is given, if resistant pneumococci are isolated, or if the patient is not demonstrating expected improvement after 24–48 hours on therapy.

If the isolate is determined to be penicillin-susceptible, aqueous penicillin G can be administered (300,000–400,000 units/kg/d, given intravenously in four to six divided doses for 10–14 days). Use of ceftriaxone or cefotaxime is acceptable alternative therapy in penicillin- and cephalosporin-susceptible isolates. Consult an infectious disease specialist or the *Red Book* (American Academy of Pediatrics, 2006) for therapeutic options for isolates that are nonsusceptible to penicillin or cephalosporins.

▶ Prognosis

In children, case fatality rates of less than 1% should be achieved except for meningitis, where rates of 5–20% still

prevail. The presence of large numbers of organisms without a prominent CSF inflammatory response or meningitis due to a penicillin-resistant strain indicates a poor prognosis. Serious neurologic sequelae, particularly hearing loss, are frequent following pneumococcal meningitis.

STAPHYLOCOCCAL INFECTIONS

Staphylococcal infections are common in childhood. Staphylococcal skin infections range from minor furuncles to the varied syndromes now collectively referred to as scalded skin syndrome. Staphylococci are the major cause of osteomyelitis and of septic arthritis and are an uncommon but important cause of bacterial pneumonia. A toxin produced by certain strains causes staphylococcal food poisoning. Staphylococci are responsible for most infections of artificial heart valves. They cause toxic shock syndrome (see later discussion). Finally, they are found in infections at all ages and in multiple sites, particularly when infection is introduced from the skin or upper respiratory tract or when closed compartments become infected (pericarditis, sinusitis, cervical adenitis, surgical wounds, abscesses in the liver or brain, and abscesses elsewhere in the body).

Staphylococci that do not produce the enzyme coagulase are termed *coagulase-negative* and are seldom speciated in the clinical microbiology laboratory. Most *S aureus* strains produce coagulase. *S aureus* and coagulase-negative staphylococci are normal flora of the skin and respiratory tract. The latter rarely cause disease except in compromised hosts, the newborn, or patients with plastic indwelling lines.

Most strains of *S aureus* elaborate β -lactamase that confers penicillin resistance. This can be overcome in clinical practice by the use of a cephalosporin or a penicillinase-resistant penicillin, such as methicillin, oxacillin, nafcillin, cloxacillin, or dicloxacillin. Methicillin-resistant strains of *S aureus* (MRSA) are found worldwide and are now common in certain hospitals and, increasingly, in community-acquired infections in some

areas of the United States. Most MRSA retain β -lactamase production, and many are resistant to other antibiotics as well. MRSA are also resistant in vivo to all of the penicillinase-resistant penicillins and cephalosporins. Strains with intermediate susceptibility to vancomycin are occurring more frequently and occasionally vancomycin-resistant strains are isolated. The existence of such strains is of concern because of the inherent virulence of most strains of *S aureus* and because of the limited choices for therapy. *S aureus* produces a variety of exotoxins, most of which are of uncertain importance. Two toxins are recognized as playing a central role in specific diseases: exfoliatin and staphylococcal enterotoxin. The former is largely responsible for the various clinical presentations of scalded skin syndrome. Most strains that elaborate exfoliatin are of phage group II. Enterotoxin causes staphylococcal food poisoning. The exoprotein toxin most commonly associated with toxic shock syndrome has been termed TSST-1. Pantone-Valentine leucocidin (PVL) is an exotoxin produced by less than 5% of clinical isolates of methicillin-susceptible *S aureus* (MSSA) and MRSA strains. PVL is a virulence factor that causes leukocyte destruction and tissue necrosis. PVL-producing *S aureus* strains are often community-acquired, and have most commonly produced boils and abscesses. However, they also have been associated with severe cellulitis, osteomyelitis, and deaths from necrotizing pneumonia in otherwise healthy children and young adults.

► Clinical Findings

A. Symptoms and Signs

1. Staphylococcal skin diseases—Dermal infection with *S aureus* causes furuncles or cellulitis. *S aureus* are often found along with streptococci in impetigo. If the strains produce exfoliatin, localized lesions become bullous (bullous impetigo).

Scalded skin syndrome is thought to be a systemic effect of exfoliatin. The initial infection may begin at any site but is in the respiratory tract in most cases. There is a prodromal phase of erythema, often beginning around the mouth, accompanied by fever and irritability. The involved skin becomes tender, and a sick infant will cry when picked up or touched. A day or so later, exfoliation begins, usually around the mouth. The inside of the mouth is red, and a peeling rash is present around the lips, often in a radial pattern. Generalized, painful peeling may follow, involving the limbs and trunk but often sparing the feet. More commonly, peeling is confined to areas around body orifices. If erythematous but unpeeled skin is rubbed sideways, superficial epidermal layers separate from deeper ones and slough (Nikolsky sign). In the newborn, the disease is termed *Ritter disease* and may be fulminant. If there is tender erythema but not exfoliation, the disease is termed *nonstreptococcal scarlet fever*. The scarlatiniform rash is sandpaper-like, but strawberry tongue is not seen, and cultures grow *S aureus* rather than streptococcus.

2. Osteomyelitis and septic arthritis—(See Chapter 24.)

3. Staphylococcal pneumonia—Staphylococcal pneumonia in infancy is characterized by abdominal distention, high fever, respiratory distress, and toxemia. It often occurs without predisposing factors or after minor skin infections. The organism is necrotizing, producing bronchoalveolar destruction. Pneumatoceles, pyopneumothorax, and empyema are frequently encountered. Rapid progression of disease is characteristic. Frequent chest radiographs to monitor the progress of disease are indicated. Presenting symptoms may be typical of paralytic ileus, suggestive of an abdominal catastrophe.

Staphylococcal pneumonia usually is peribronchial, beginning with a focal infiltrative lesion progressing to patchy consolidation. Most often only one lung is involved (80%), more often the right. Purulent pericarditis occurs by direct extension in about 10% of cases, with or without empyema.

4. Staphylococcal food poisoning—Staphylococcal food poisoning is a result of ingestion of enterotoxin produced by staphylococci growing in uncooked and poorly refrigerated food. The disease is characterized by vomiting, prostration, and diarrhea occurring 2–6 hours after ingestion of contaminated foods.

5. Staphylococcal endocarditis—*S aureus* may produce infection of normal heart valves, of valves or endocardium in children with congenital or rheumatic heart disease, or of artificial valves. About 25% of all cases of endocarditis are due to *S aureus*. The great majority of artificial heart valve infections involve either *S aureus* or coagulase-negative staphylococci. Infection usually begins in an extracardiac focus, often the skin. Involvement of the endocardium must be suspected in every case of *S aureus* bacteremia, regardless of initial signs. Suspicion must be highest in the presence of congenital heart disease, particularly ventricular septal defects with aortic insufficiency but also simple ventricular septal defect, patent ductus arteriosus, and tetralogy of Fallot.

The presenting symptoms in staphylococcal endocarditis are fever, weight loss, weakness, muscle pain or diffuse skeletal pain, poor feeding, pallor, and cardiac decompensation. Signs include splenomegaly, cardiomegaly, petechiae, hematuria, and a new or changing murmur. The course of *S aureus* endocarditis is rapid, although subacute disease occurs occasionally. Peripheral septic embolization and uncontrollable cardiac failure are common, even when optimal antibiotic therapy is administered, and may be indications for surgical intervention (see later discussion).

6. Toxic shock syndrome—Toxic shock syndrome (TSS) is characterized by fever, blanching erythroderma, diarrhea, vomiting, myalgia, prostration, hypotension, and multiorgan dysfunction. It is due to *S aureus* focal infection, usually without bacteremia. Large numbers of cases have been described in menstruating adolescents and young women

using vaginal tampons. TSS has also been reported in boys and girls with focal staphylococcal infections and in individuals with wound infections due to *S aureus*. Additional clinical features include sudden onset; conjunctival suffusion; mucosal hyperemia; desquamation of skin on the palms, soles, fingers, and toes during convalescence; DIC in severe cases; renal and hepatic functional abnormalities; and myolysis. The mortality rate with early treatment is now about 2%. Recurrences are seen during subsequent menstrual periods in as many as 60% of untreated women who continue to use tampons. Recurrences occur in up to 15% of women given antistaphylococcal antibiotics who stop using tampons. The disease is caused by strains of *S aureus* that produce TSST-1 or one of the related enterotoxins.

7. Coagulase-negative staphylococcal infections—Localized and systemic coagulase-negative staphylococcal infections occur primarily in immunocompromised patients, high-risk newborns, and patients with plastic prostheses or catheters. Coagulase-negative staphylococci are the most common nosocomial pathogen in hospitalized low-birth-weight neonates in the United States. Intravenous administration of lipid emulsions and indwelling central venous catheters are risk factors contributing to coagulase-negative staphylococcal bacteremia in newborn infants. In patients with an artificial heart valve, a Dacron patch, a ventriculoperitoneal shunt, or a central venous catheter, coagulase-negative staphylococci are a common cause of sepsis or catheter infection, often necessitating removal of the foreign material and protracted antibiotic therapy. Because blood cultures are frequently contaminated by this organism, diagnosis of genuine localized or systemic infection is often difficult.

B. Laboratory Findings

Moderate leukocytosis (15,000–20,000/ μ L) with a shift to the left is occasionally found, although normal counts are common, particularly in infants. The sedimentation rate is elevated. Blood cultures are frequently positive in systemic staphylococcal disease and should always be obtained when it is suspected. Similarly, pus from sites of infection should always be aspirated or obtained surgically, examined with Gram stain, and cultured both aerobically and anaerobically. There are no useful serologic tests for staphylococcal disease.

► Differential Diagnosis

Staphylococcal skin disease takes many forms; therefore, the differential list is long. Bullous impetigo must be differentiated from chemical or thermal burns, from drug reactions, and, in the very young, from the various congenital epidermolytic syndromes or even herpes simplex infections. Staphylococcal scalded skin syndrome may resemble scarlet fever, Kawasaki disease, Stevens-Johnson syndrome, erythema multiforme, and other drug reactions. A skin biopsy may be critical in establishing the diagnosis. Varicella lesions may

become superinfected with exfoliatin-producing staphylococci and produce a combination of the two diseases (bullous varicella).

Severe, rapidly progressing pneumonia with formation of abscesses, pneumatoceles, and empyemas is typical of *S aureus* infection and GAS but may occasionally be produced by pneumococci, *H influenzae*, and GAS.

Staphylococcal food poisoning is often epidemic. It is differentiated from other common-source gastroenteritis syndromes (*Salmonella*, *Clostridium perfringens*, and *Vibrio parahaemolyticus*) by the short incubation period (2–6 hours), the prominence of vomiting (as opposed to diarrhea), and the absence of fever.

Endocarditis must be suspected in any instance of *S aureus* bacteremia, particularly when a significant heart murmur or preexisting cardiac disease is present. (See Chapter 19.)

Newborn infections with *S aureus* can resemble infections with streptococci and a variety of gram-negative organisms. Umbilical and respiratory tract colonization occurs with many pathogenic organisms (GBS, *Escherichia coli*, and *Klebsiella*), and both skin and systemic infections occur with virtually all of these organisms.

TSS must be differentiated from Rocky Mountain spotted fever, leptospirosis, Kawasaki disease, drug reactions, adenovirus, and measles (see also Table 38–3).

▶ Treatment

A. Specific Measures

Community-acquired MRSA infections are on the rise. The incidence of community-acquired MRSA isolates varies greatly geographically, but in many communities in the United States MRSA is the most common pathogen isolated from patients with skin and soft tissue infections. If the prevalence of MRSA isolates in the community is high and if the patient is seriously ill, vancomycin should be part of the empiric coverage until culture results and susceptibility data are known. Currently, most community-acquired MRSA strains are susceptible to trimethoprim–sulfamethoxazole (TMP–SMX) and some are susceptible to clindamycin. Less serious infections in nontoxic patients may be initially treated using one of these agents while awaiting cultures and susceptibility data. Knowledge of the community MRSA susceptibility patterns is useful in guiding empiric therapy while awaiting susceptibility test results.

For MSSA strains, a β -lactamase-resistant penicillin is the drug of choice (oxacillin, nafcillin, or methicillin). In serious systemic disease, in osteomyelitis, and in the treatment of large abscesses, intravenous therapy is indicated initially (oxacillin or nafcillin, 100–150 mg/kg/d in four divided doses, or methicillin, 200–300 mg/kg/d in four divided doses). When high doses over a long period are required, it is preferable to avoid use of methicillin, because of the frequency with which interstitial nephritis occurs. In life-threatening illness, an aminoglycoside antibiotic (gentamicin or

tobramycin) or rifampin may be used in addition for its possible synergistic action.

Cephalosporins may be considered for MSSA infections in patients with a history of penicillin sensitivity unless there is a history of type 1 hypersensitivity reaction (ie, anaphylaxis, wheezing, edema, and hives). Cefazolin, 100–150 mg/kg/d, given intravenously in three divided doses, or cephalexin, 50–100 mg/kg/d, given orally in four divided doses, can be used once a child is able to take oral antibiotics. The third-generation cephalosporins should not generally be used for staphylococcal infections.

For nonmeningeal, suspected nosocomially acquired MRSA infections, vancomycin (40 mg/kg/d intravenously in three or four divided doses) should be used until results of susceptibility testing are available (frequently clindamycin- and TMP–SMX-resistant). Infections due to MRSA frequently do not respond to cephalosporins despite in-vitro testing that suggests susceptibility. For treatment of meningitis, vancomycin must be given in higher doses (60 mg/kg/d divided into four doses). The addition of rifampin is advocated by some (rifampin should not be used alone to treat this condition).

1. Skin infections—Treatment of skin and soft tissue infections depends, in part, on the extent of the lesion, immunocompetence of the host, and the toxicity of the patient. Afebrile, well-appearing patients with small abscesses may do well with incision and drainage (with or without the addition of oral antimicrobials). More serious infections or infections in immunocompromised patients should be treated more aggressively. Hospitalization and intravenous antibiotics may be required. Culture and susceptibility testing help guide therapy regardless of whether the patient initially is started on antibiotics. Results of these tests facilitate therapeutic decisions in cases in which patients do not respond to initial management or empiric intravenous antibiotic therapy was initiated.

For patients who are not sick enough to require hospitalization or intravenous therapy, selection of the best empiric antimicrobial depends on local rates of MRSA and local susceptibilities. β -Lactam antibiotics, such as penicillins and cephalosporins, can no longer be depended on as single agents for the majority of cases in communities with high MRSA rates. TMP–SMX and clindamycin (depending on local susceptibility patterns) may be used for empiric staphylococcal coverage. However, group A streptococci are generally resistant to TMP–SMX and in a small number of cases may also be resistant to clindamycin. Many clinicians empirically use a combination of TMP–SMX and cefazolin for initial treatment until susceptibilities are known. Linezolid is another option, although the cost of this drug is high.

2. Osteomyelitis and septic arthritis—Treatment should be begun intravenously, with antibiotics selected to cover the most likely organisms (staphylococci in hematogenous osteomyelitis; meningococci, pneumococci, staphylococci in chil-

dren younger than age 3 years with septic arthritis; staphylococci and gonococci in older children with septic arthritis). Knowledge of local MRSA rates will help guide empiric therapy. Antibiotic levels should be kept high at all times.

In osteomyelitis, clinical studies support the use of intravenous treatment until fever and local symptoms and signs have subsided—usually after at least 3–5 days—followed by oral therapy (for susceptible strains, dicloxacillin, 100–150 mg/kg/d in four divided doses; or cephalexin, 100–150 mg/kg/d in four divided doses) for at least 3 additional weeks. Longer treatment may be required, particularly when radiographs show extensive involvement. Treatment of community-acquired MRSA osteomyelitis should be based on susceptibility results; however, isolates are frequently susceptible to TMP–SMX or clindamycin. Vancomycin can be used as part of an empiric regimen while awaiting susceptibilities in seriously ill patients or in areas where MRSA rates are high. In arthritis, where drug diffusion into synovial fluid is good, intravenous therapy need be given only for a few days, followed by adequate oral therapy for at least 3 weeks. In all instances, oral therapy should be administered with careful attention to compliance, either in the hospital or at home. The erythrocyte sedimentation rate (ESR) is a good indicator of response to therapy. Surgical drainage of osteomyelitis or septic arthritis is often required. (See Chapter 24.)

3. Staphylococcal pneumonia—In the few areas of the country where MRSA is not prevalent, or if the isolate is known to be MSSA, nafcillin and oxacillin are the usual drugs of choice. For sick patients, vancomycin can be used empirically until results of cultures and susceptibility tests are obtained. Linezolid has recently been reported to be as efficacious as vancomycin for the treatment of resistant gram-positive pneumonia and soft tissue infections (cure rates: 95% linezolid vs 94% vancomycin).

Empyema and pyopneumothorax require drainage. The choice of chest tube versus thoracoscopic drainage depends on the practitioner's experience and skill. If staphylococcal pneumonia is treated promptly and empyema drained, resolution in children often is complete.

4. Staphylococcal food poisoning—Therapy is supportive and usually not required except in severe cases or for small infants with marked dehydration.

5. Staphylococcal endocarditis—As outlined earlier, high-dose, prolonged parenteral treatment is indicated. Methicillin-susceptible isolates are often treated with oxacillin or nafcillin. Some experts also recommend addition of gentamicin or rifampin for the first 5 days to 2 weeks. In penicillin-allergic patients (type 1 hypersensitivity or anaphylaxis) or patients with MRSA isolates, vancomycin should be used. Therapy lasts in all instances for at least 6 weeks.

Occasionally, medical treatment fails. Signs of treatment failure are (1) recurrent fever without apparent treatable other cause (eg, thrombophlebitis, respiratory or urinary

tract infection, drug fever), (2) persistently positive blood cultures, (3) intractable and progressive congestive heart failure, and (4) recurrent (septic) embolization. In such circumstances—particularly (2), (3), and (4)—valve replacement becomes necessary. Antibiotics are continued for at least another 4 weeks. Persistent or recurrent infection may require a second surgical procedure.

6. Toxic shock syndrome—Treatment is aimed at expanding blood volume, maintaining perfusion pressure with inotropic agents, ensuring prompt drainage of a focus of infection (or removal of tampons or foreign bodies), and giving intravenous antibiotics.

Vancomycin, in addition to a β -lactam antibiotic (oxacillin or nafcillin), can be used for empiric therapy. Some experts would use vancomycin and clindamycin, since clindamycin is a protein synthesis inhibitor and may turn off toxin production. Clindamycin should not be used empirically as a single agent until susceptibilities (when an isolate grows) are known; some strains of *S aureus* are clindamycin-resistant.

Intravenous immune globulin has been used as adjunctive therapy. Some experts believe that corticosteroid therapy may be effective if given to patients with severe illness early in the course of their disease. Successful antibiotic treatment reduces risk of recurrence.

7. Vancomycin-resistant *Staphylococcus aureus* infections (VRSA)—Reports of VRSA isolates are rare but are likely to increase in frequency in the future. Such isolates are sometimes susceptible to clindamycin or TMP–SMX. If not, therapeutic options are limited and include use of quinupristin–dalfopristin, linezolid, and daptomycin. Experience is very limited with daptomycin in pediatric patients. Consultation with an infectious disease specialist is recommended.

8. Coagulase-negative staphylococcal infections—Bacteremia and other serious coagulase-negative staphylococcal infections are treated initially with vancomycin. Coagulase-negative staphylococci are uncommonly resistant to vancomycin. (See Chapter 37 for dosing.) Strains susceptible to methicillin are treated with methicillin, oxacillin, or ceftazolin.

MENINGOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Fever, headache, vomiting, convulsions, shock (meningitis).
- ▶ Fever, shock, petechial or purpuric skin rash (meningococemia).
- ▶ Diagnosis confirmed by culture of normally sterile body fluids.

▶ General Considerations

Meningococci (*Neisseria meningitidis*) may be carried asymptomatically for many months in the upper respiratory tract. Less than 1% of carriers develop disease. Meningitis and sepsis are the two most common forms of illness, but septic arthritis, pericarditis, pneumonia, chronic meningococemia, otitis media, conjunctivitis, and vaginitis also occur. The incidence of invasive diseases in the United States is about 1.2 cases per 100,000 people. An estimated 2400–3000 cases occur in the United States annually. The highest attack rate for meningococcal meningitis is in the first year of life. There also is an elevated attack rate during the teen years. The development of irreversible shock with multiorgan failure is a significant factor in the fatal outcome of acute meningococcal infections.

Meningococci are gram-negative organisms containing endotoxin in their cell walls. Endotoxins cause capillary vascular injury and leak as well as DIC. Meningococci are classified serologically into groups: A, B, C, Y, and W-135 are the groups most commonly implicated in systemic disease. The serologic groups serve as markers for studying outbreaks and transmission of disease. Currently in the United States, serogroup B accounts for about one third of cases. Serogroups C and Y each cause 25% of cases, and serogroup W-135 is responsible for about 15%. Serogroup A causes periodic epidemics in developing countries, but only occasionally is associated with cases of meningococcal disease in the United States. Sulfonamide resistance is common in non-serotype-A strains. *N meningitidis* with increased MICs to penicillin G are reported from South Africa and Spain. A small number of these isolates are reported in the United States. The resistance in these strains is low-level and not due to β -lactamase. Resistant isolates are susceptible to third-generation cephalosporins. Few isolates are resistant to rifampin.

Children develop immunity from asymptomatic carriage of meningococci (usually nontypeable, nonpathogenic strains) or other cross-reacting bacteria. Patients deficient in one of the late components of complement (C6, C7, C8, or C9) are uniquely susceptible to meningococcal infection, particu-

larly group A meningococci. Deficiencies of early and alternate pathway complement components also are associated with increased susceptibility.

▶ Clinical Findings

A. Symptoms and Signs

Many children with clinical meningococemia also have meningitis, and some have other foci of infection. All children with suspected meningococemia should have a lumbar puncture.

1. Meningococemia—A prodrome of upper respiratory infection is followed by high fever, headache, nausea, marked toxicity, and hypotension. Purpura, petechiae, and occasionally bright pink, tender macules or papules over the extremities and trunk are seen. The rash usually progresses rapidly. Occasional cases lack rash. Fulminant meningococemia (Waterhouse-Friderichsen syndrome) progresses rapidly and is characterized by DIC, massive skin and mucosal hemorrhages, and shock. This syndrome also may be caused by *H influenzae*, *S pneumoniae*, or other bacteria. Chronic meningococemia is characterized by periodic bouts of fever, arthralgia or arthritis, and recurrent petechiae. Splenomegaly often is present. Patients may be free of symptoms between bouts. Chronic meningococemia occurs primarily in adults and mimics Henoch-Schönlein purpura.

2. Meningitis—In many children, meningococemia is followed within a few hours to several days by symptoms and signs of acute purulent meningitis, with severe headache, stiff neck, nausea, vomiting, and stupor. Children with meningitis generally fare better than children with meningococemia alone, probably because they have survived long enough to develop clinical signs of meningitis.

B. Laboratory Findings

The peripheral WBC count may be either low or elevated. Thrombocytopenia may be present with or without DIC. (See Chapter 28.) If petechial or hemorrhagic lesions are present, meningococci can sometimes be seen microscopically in tissue fluid expressed from a punctured lesion. CSF is generally cloudy and contains more than 1000 WBCs/ μ L, with many polymorphonuclear neutrophils and gram-negative intracellular diplococci. A total hemolytic complement assay may reveal absence of late components as an underlying cause.

▶ Differential Diagnosis

The skin lesions of *H influenzae* or pneumococci, enterovirus infection, endocarditis, leptospirosis, Rocky Mountain spotted fever, other rickettsial diseases, Henoch-Schönlein purpura, and blood dyscrasias may be similar to meningococemia. Other causes of sepsis and meningitis are distinguished by appropriate Gram stain and cultures.

► Complications

Meningitis may lead to permanent central nervous system (CNS) damage, with deafness, convulsions, paralysis, or impaired intellectual function. Hydrocephalus may develop and requires ventriculoperitoneal shunt. Subdural collections of fluid are common but usually resolve spontaneously. Extensive skin necrosis, loss of digits or extremities, intestinal hemorrhage, and late adrenal insufficiency may complicate fulminant meningococemia.

► Prevention

A. Chemoprophylaxis

Household contacts, day care center contacts, and hospital personnel directly exposed to the respiratory secretions of patients are at increased risk for developing meningococcal infection and should be given chemoprophylaxis with rifampin. The secondary attack rate among household members is 1–5% during epidemics and less than 1% in nonepidemic situations. Children between the ages of 3 months and 2 years are at greatest risk, presumably because they lack protective antibodies. Secondary cases may occur in day care centers and in classrooms. Hospital personnel are not at increased risk unless they have had contact with a patient's oral secretions, for example, during mouth-to-mouth resuscitation, intubation, or suctioning procedures. Approximately 50% of secondary cases in households have their onset within 24 hours of identification of the index case. Exposed contacts should be notified promptly. If they are febrile, they should be fully evaluated and given high doses of penicillin or another effective antimicrobial pending the results of blood cultures.

All intimate contacts should receive chemoprophylaxis for meningococcal disease. The most commonly used agent is rifampin, given orally in the following dosages twice daily for 2 days: 600 mg for adults; 10 mg/kg for children *older* than 1 month old (maximum dosage 600 mg); and 5 mg/kg for infants *younger* than 1 month. Rifampin may stain a patient's tears (and contact lenses), sweat, and urine orange; it may also affect the reliability of oral contraceptives, and alternative contraceptive measures should therefore be employed when rifampin is administered. Rifampin should not be given to pregnant women. Instead, intramuscular ceftriaxone is the preferred agent: 125 mg given as a single dose if the patient is younger than 15 years; 250 mg given as a single dose if older than 15 years. Penicillin and most other antibiotics (even with parenteral administration) are not effective chemoprophylactic agents, because they do not eradicate upper respiratory tract carriage of meningococci. Ciprofloxacin effectively eradicates nasopharyngeal carriage in adults and children but is not approved for use in children or in pregnant women. Throat cultures to identify carriers are not useful.

B. Vaccine

A quadrivalent polysaccharide vaccine prepared from purified meningococcal polysaccharides (A, C, Y, and W-135) is available in the United States for children older than 2 years of age. This vaccine has been used for controlling outbreaks. A quadrivalent meningococcal conjugate vaccine also is available. (See Chapter 9.) This vaccine is licensed for use in children and adults between the ages of 11 and 55 years, and is preferred over the polysaccharide vaccine in the age groups for which the vaccine is licensed. In general, conjugate vaccines provide longer lasting immunity and a more robust immune response than polysaccharide vaccines. Currently meningococcal conjugate vaccine is recommended for the following people:

1. All children at the age 11–12-year preadolescent visit.
2. All children prior to high school entry if they have not had a previous meningococcal vaccine.
3. College students who will be residing in dormitories for the first time.
4. Patients with functional or anatomic asplenia and patients with complement or properdin deficiency.
5. Travelers to areas where meningococcal disease is endemic.
6. Microbiologists who may be working with meningococcal strains.

Close monitoring for potential adverse events has suggested a possible association between recent meningococcal conjugate vaccine receipt and Guillain-Barré syndrome. Between June 2005, when licensure of the vaccine was granted, and March 2007, 17 cases of Guillain-Barré syndrome with onset 2–33 days after vaccine administration had been reported through the Vaccine Adverse Event Reporting System (VAERS). Researchers calculated the U.S. rate of Guillain-Barré syndrome after meningococcal vaccine administration as compared with a background U.S. incidence rate. This analysis suggested that meningococcal conjugate vaccine recipients may have a slightly higher risk of Guillain-Barré syndrome compared with the general population. However, because Guillain-Barré syndrome is such a rare event, definitive study of the association is difficult. What is known is that meningococcal disease is serious and may be fatal and that the vaccine is highly immunogenic. Thus, the Advisory Committee for Immunization Practices and the American Academy of Pediatrics continue to recommend meningococcal conjugate vaccine because the risk of Guillain-Barré syndrome, if it does exist, is small.

► Treatment

Blood cultures should be obtained for all children with fever and purpura or other signs of meningococemia, and antibiotics should be administered immediately as an emergency procedure. There is a good correlation between survival rates

and prompt initiation of antibiotic therapy. Purpura and fever should be considered a medical emergency.

Children with meningococemia or meningococcal meningitis should be treated as though shock were imminent even if their vital signs are stable when they are first seen. If hypotension already is present, supportive measures should be aggressive, because the prognosis is grave in such situations. Treatment should be started emergently and in an intensive care setting but should not be delayed for the sake of transporting the patient. Shock may worsen following antimicrobial therapy due to endotoxin release. To minimize the risk of nosocomial transmission, patients should be placed in respiratory isolation for the first 24 hours of antibiotic treatment.

A. Specific Measures

Antibiotics should be initiated promptly. Because other bacteria, such as *S pneumoniae*, *S aureus*, or other gram-negative organisms, can cause identical syndromes, initial therapy should be broad. Vancomycin and cefotaxime (or ceftriaxone) are preferred initial coverage. Once *N meningitidis* has been isolated, penicillin G, cefotaxime, or ceftriaxone intravenously for 7 days are the drugs of choice. Relative penicillin resistance is uncommon but has been reported in the United States.

B. General Measures

Most cases of invasive meningococcal disease are treated with intravenous antibiotics for 7 days.

1. Cardiovascular—(See Chapter 13 for management of septic shock.) Corticosteroids are not beneficial. Sympathetic blockade and topically applied nitroglycerin have been used locally to improve perfusion.

2. Hematologic—Adjunctive therapy with heparin is controversial. Because hypercoagulability is frequently present in patients with meningococemia, some experts believe heparin should be considered for those with DIC. A loading dose of 50 units/kg is followed by 15 units/kg/h as a continuous infusion. The patient is monitored by following the partial thromboplastin time and heparin assay. Recombinant tissue plasminogen activator, concentrated antithrombin III, and recombinant protein C infusions have been tried experimentally to reverse coagulopathy. (See Chapter 28 for the management of DIC.)

► Prognosis

Unfavorable prognostic features include shock, DIC, and extensive skin lesions. The case fatality rate in fulminant meningococemia is over 30%. In uncomplicated meningococcal meningitis, the fatality rate is much lower (10–20%).

GNOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Purulent urethral discharge with intracellular gram-negative diplococci on smear in male patients (usually adolescents).
- ▶ Purulent, edematous, sometimes hemorrhagic conjunctivitis with intracellular gram-negative diplococci in 2–4-day-old infants.
- ▶ Fever, arthritis (often polyarticular) or tenosynovitis, and maculopapular peripheral rash that may be vesiculopustular or hemorrhagic.
- ▶ Positive culture of blood, pharyngeal, or genital secretions.

► General Considerations

Neisseria gonorrhoeae is a gram-negative diplococcus. Although morphologically similar to other neisseriae, it differs in its ability to grow on selective media and to ferment carbohydrates. The cell wall of *N gonorrhoeae* contains endotoxin, which is liberated when the organism dies and is responsible for the production of a cellular exudate. The incubation period is short, usually 2–5 days.

Nearly 340,000 cases of gonorrhea were reported in the United States in 2005. Gonococcal disease in children may be transmitted sexually or nonsexually. Prepubertal gonococcal infection outside the neonatal period should be considered presumptive evidence of sexual contact or child abuse. Prepubertal girls usually manifest gonococcal vulvovaginitis because of the neutral to alkaline pH of the vagina and thin vaginal mucosa.

In the adolescent or adult, the workup of every case of gonorrhea should include a careful and accurate inquiry into the patient's sexual practices, because pharyngeal infection resulting from oral sex must be detected if present and may be difficult to eradicate. Efforts should be made to identify and provide treatment to all sexual contacts. When prepubertal children are infected, epidemiologic investigation should be thorough.

Antimicrobial-resistant gonococci are a serious problem. *N gonorrhoeae* infections resistant to tetracyclines, penicillins, and fluoroquinolones are common. Fluoroquinolone antimicrobials are no longer recommended for therapy in the United States. In some cases, clinicians will have very limited choices for therapy. Many clinical laboratories do not

routinely perform antimicrobial susceptibility tests on *N gonorrhoeae*, and many infections are documented by non-culture methods.

► Clinical Findings

A. Symptoms and Signs

1. Asymptomatic gonorrhea—The ratio of asymptomatic to symptomatic gonorrheal infections in adolescents and adults is probably 3–4:1 in women and 0.5–1:1 in men. Asymptomatic infections are as infectious as symptomatic ones.

2. Uncomplicated genital gonorrhea

A. MALE WITH URETHRITIS—Urethral discharge is sometimes painful and bloody and may be white, yellow, or green. There may be associated dysuria. The patient usually is afebrile.

B. PREPUBERTAL FEMALE WITH VAGINITIS—The only clinical findings initially may be dysuria and polymorphonuclear neutrophils in the urine. Vulvitis characterized by erythema, edema, and excoriation accompanied by a purulent discharge may follow.

C. POSTPUBERTAL FEMALE WITH CERVICITIS—Symptomatic disease is characterized by a purulent, foul-smelling vaginal discharge, dysuria, and occasionally dyspareunia. Fever and abdominal pain are absent. The cervix is frequently hyperemic and tender when touched. This tenderness is not worsened by moving the cervix, nor are the adnexa tender to palpation.

D. RECTAL GONORRHEA—Rectal gonorrhea often is asymptomatic. There may be purulent discharge, edema, and pain during evacuation.

3. Pharyngeal gonorrhea—Pharyngeal infection usually is asymptomatic. There may be some sore throat and, rarely, acute exudative tonsillitis with bilateral cervical lymphadenopathy and fever.

4. Conjunctivitis and iridocyclitis—Copious, usually purulent exudate is characteristic of gonococcal conjunctivitis. Newborns are symptomatic on days 2–4 of life. In the adolescent or adult, infection probably is spread from infected genital secretions by the fingers.

5. Pelvic inflammatory disease (salpingitis)—The interval between initiation of genital infection and its ascent to the uterine tubes is variable and may range from days to months. Menses frequently are the initiating factor. With the onset of a menstrual period, gonococci invade the endometrium, causing transient endometritis. Subsequently salpingitis may occur, resulting in pyosalpinx or hydrosalpinx. Rarely infection progresses to peritonitis or perihepatitis. Gonococcal salpingitis occurs in an acute, a subacute, or a chronic form. All three forms have in common tenderness

on gentle movement of the cervix and bilateral tubal tenderness during pelvic examination.

Gonococci or *Chlamydia trachomatis* are the cause of about 50% of cases of pelvic inflammatory disease. A mixed infection caused by enteric bacilli, *Bacteroides fragilis*, or other anaerobes occur in the other 50%.

6. Gonococcal perihepatitis (Fitz-Hugh and Curtis syndrome)—In the typical clinical pattern, the patient presents with right upper quadrant tenderness in association with signs of acute or subacute salpingitis. Pain may be pleuritic and referred to the shoulder. Hepatic friction rub is a valuable but inconstant sign.

7. Disseminated gonorrhea—Dissemination follows asymptomatic more often than symptomatic genital infection and often results from gonococcal pharyngitis or anorectal gonorrhea. The most common form of disseminated gonorrhea is polyarthritides or polytenosynovitis, with or without dermatitis. Monarticular arthritis is less common, and gonococcal endocarditis and meningitis are fortunately rare.

A. POLYARTHRITIS—Disease usually begins with the simultaneous onset of low-grade fever, polyarthralgia, and malaise. After a day or so, joint symptoms become acute. Swelling, redness, and tenderness occur, frequently over the wrists, ankles, and knees but also in the fingers, feet, and other peripheral joints. Skin lesions may be noted at the same time. Discrete, tender, maculopapular lesions 5–8 mm in diameter appear that may become vesicular, pustular, and then hemorrhagic. They are few in number and noted on the fingers, palms, feet, and other distal surfaces and may be single or multiple. In patients with this form of the disease, blood cultures are often positive, but joint fluid rarely yields organisms. Skin lesions often are positive by Gram stain but rarely by culture. Genital, rectal, and pharyngeal cultures must be performed.

B. MONARTICULAR ARTHRITIS—In this somewhat less common form of disseminated gonorrhea, fever is often absent. Arthritis evolves in a single joint. Dermatitis usually does not occur. Systemic symptoms are minimal. Blood cultures are negative, but joint aspirates may yield gonococci on smear and culture. Genital, rectal, and pharyngeal cultures must be performed.

B. Laboratory Findings

Demonstration of gram-negative, kidney-shaped diplococci in smears of urethral exudate in males is presumptive evidence of gonorrhea. Positive culture confirms the diagnosis. Negative smears do not rule out gonorrhea. Gram-stained smears of cervical or vaginal discharge in girls are more difficult to interpret because of normal gram-negative flora, but they may be useful when technical personnel are experienced. In girls with suspected gonorrhea, both the cervical os and the anus should be cultured. Gonococcal pharyngitis requires culture for diagnosis.

Cultures for *N gonorrhoeae* are plated on a selective chocolate agar containing antibiotics (eg, Thayer-Martin agar) to suppress normal flora. If bacteriologic diagnosis is critical, suspected material should be cultured on chocolate agar as well. Because gonococci are labile, agar plates should be inoculated immediately and placed without delay in an atmosphere containing CO₂ (candle jar). When transport of specimens is necessary, material should be inoculated directly into Transgrow medium prior to shipment to an appropriate laboratory. In cases of possible sexual molestation, notify the laboratory that definite speciation is needed, because nongonococcal *Neisseria* species can grow on the selective media.

Nucleic acid amplification tests on urine or genital specimens now enable detection of *N gonorrhoeae* and *C trachomatis*. These tests have excellent sensitivity and are replacing culture in many laboratories. All children or adolescents with a suspected or established diagnosis of gonorrhea should have serologic tests for syphilis and HIV.

► Differential Diagnosis

Urethritis in the male may be gonococcal or nongonococcal (NGU). NGU is a syndrome characterized by discharge (rarely painful), mild dysuria, and a subacute course. The discharge is usually scant or moderate in amount but may be profuse. *C trachomatis* is the only proven cause of NGU. Doxycycline (100 mg orally twice a day for 7 days) is efficacious. Single-dose azithromycin, 1 g orally, may achieve better compliance. *C trachomatis* has been shown to cause epididymitis in males and salpingitis in females.

Vulvovaginitis in a prepubertal female may be due to infection caused by miscellaneous bacteria, including *Shigella* and GAS, *Candida*, and herpes simplex. Discharges may be caused by trichomonads, *Enterobius vermicularis* (pinworm), or foreign bodies. Symptom-free discharge (leukorrhea) normally accompanies rising estrogen levels.

Cervicitis in a postpubertal female, alone or in association with urethritis and involvement of Skene and Bartholin glands, may be due to infection caused by *Candida*, herpes simplex, *Trichomonas*, or discharge resulting from inflammation caused by foreign bodies (usually some form of contraceptive device). Leukorrhea may be associated with birth control pills.

Salpingitis may be due to infection with other organisms. The symptoms must be differentiated from those of appendicitis, urinary tract infection, ectopic pregnancy, endometriosis, or ovarian cysts or torsion.

Disseminated gonorrhea presents a differential diagnosis that includes meningococcemia, acute rheumatic fever, Henoch-Schönlein purpura, juvenile rheumatoid arthritis, lupus erythematosus, leptospirosis, secondary syphilis, certain viral infections (particularly rubella, but also enteroviruses and parvovirus), serum sickness, type B hepatitis (in the prodromal phase), infective endocarditis, and even acute leukemia and other types of cancer. The fully evolved skin

lesions of disseminated gonorrhea are remarkably specific, and genital, rectal, or pharyngeal cultures, plus cultures of blood and joint fluid, usually yield gonococci from at least one source.

► Prevention

Prevention of gonorrhea is principally a matter of sex education, condom use, and identification and treatment of contacts.

► Treatment

A. Uncomplicated Urethral, Endocervical, or Rectal Gonococcal Infections in Adolescents

Ceftriaxone (125 mg intramuscularly in a single dose), cefixime (400 mg orally in a single dose), doxycycline (100 mg orally twice a day for 7 days), or azithromycin (1 g orally in a single dose) is recommended unless *C trachomatis* is ruled out. Ceftizoxime, cefotaxime, and cefotetan parenterally are alternative single-dose therapies. Fluoroquinolones are no longer recommended for therapy due to increasing rates of resistance. Cefpodoxime (400 mg) and cefuroxime (1 g orally) are alternatives.

Tetracyclines should be avoided in pregnancy, and repeated doses may stain the teeth of young children. Erythromycin or amoxicillin is recommended for therapy of *C trachomatis* in pregnant women; azithromycin is an alternative regimen. Repeat testing 3 weeks after completion of therapy is recommended in pregnant women.

Spectinomycin (2 g intramuscularly in a single dose) is used for penicillin- and cephalosporin-allergic patients, but is not currently available in the United States. A repeat culture after completion of therapy is not necessary in asymptomatic adolescents after the ceftriaxone-doxycycline regimen. A repeat culture after completion of therapy should be obtained from infants and children.

B. Pharyngeal Gonococcal Infection

Ceftriaxone (125 mg intramuscularly in a single dose) should be used; neither spectinomycin nor amoxicillin is recommended. A repeat culture is recommended 4–7 days after therapy.

C. Disseminated Gonorrhea

Recommended regimens include ceftriaxone (1 g intramuscularly or intravenously once daily) or cefotaxime (1 g intravenously every 8 hours). Oral therapy may follow parenteral therapy 24–48 hours after improvement. Recommended regimens include cefixime (400 mg), cefpodoxime (400 mg), or cefuroxime (1 g) twice daily to complete 7 days of therapy. Fluoroquinolones are not recommended. If concurrent infection with *Chlamydia* is present or has not been excluded, a course of doxycycline, azithromycin, or erythromycin should also be prescribed.

D. Pelvic Inflammatory Disease

Doxycycline (100 mg twice a day orally) and either cefoxitin (2 g intramuscularly or intravenously every 6 hours) or cefotetan (2 g intramuscularly or intravenously every 12 hours) are given until the patient is clinically improved, then doxycycline is administered by mouth to complete 14 days of therapy. Clindamycin and gentamicin given intravenously until the patient improves clinically may be used rather than cefoxitin. Many other regimens have been used for therapy of pelvic inflammatory disease, although comparative efficacy data are limited.

E. Prepubertal Gonococcal Infections

1. Uncomplicated genitourinary, rectal, or pharyngeal infections—These infections may be treated with ceftriaxone (25–50 mg/kg/d to a maximum of 125 mg intramuscularly in a single dose). Children older than age 8 years should also receive doxycycline (100 mg orally twice daily for 7 days). The physician should evaluate all children for evidence of sexual abuse and coinfection with syphilis, *Chlamydia*, and HIV.

2. Disseminated gonorrhea—This should be treated with ceftriaxone (50 mg/kg once daily parenterally for 7 days).

Centers for Disease Control and Prevention (CDC): Update to CDC's sexually transmitted diseases treatment guidelines 2006: Fluoroquinolones no longer recommended for treatment of gonococcal infections. MMWR Morb Mortal Wkly Rep 2007; 56:332 [PMID: 17431378].

BOTULISM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Dry mucous membranes.
- ▶ Nausea and vomiting.
- ▶ Diplopia; dilated, unreactive pupils.
- ▶ Descending paralysis.
- ▶ Difficulty in swallowing and speech occurring within 12–36 hours after ingestion of toxin-contaminated food.
- ▶ Multiple cases in a family or group.
- ▶ Hypotonia and constipation in infants.
- ▶ Diagnosis by clinical findings and identification of toxin in blood, stool, or implicated food.

▶ General Considerations

Botulism is a paralytic disease caused by *Clostridium botulinum*, an anaerobic, gram-positive, spore-forming bacillus

normally found in soil. The organism produces an extremely potent neurotoxin. Of the seven types of toxin (A–G), types A, B, and E cause most human diseases. The toxin, a polypeptide, is so potent that 0.1 mg is lethal for humans.

Food-borne botulism usually results from ingestion of toxin-containing food. Preformed toxin is absorbed from the gut and produces paralysis by preventing acetylcholine release from cholinergic fibers at myoneuronal junctions. In the United States, home-canned vegetables are usually the cause. Commercially canned foods rarely are responsible. Virtually any food will support the growth of *C botulinum* spores into vegetative toxin-producing bacilli if an anaerobic, nonacid environment is provided. The food may not appear or taste spoiled. The toxin is heat-labile, but the spores are heat-resistant. Inadequate heating during processing (temperature < 115°C) allows the spores to survive and later resume toxin production. Boiling of foods for 10 minutes or heating at 80°C for 30 minutes before eating will destroy the toxin.

Infant botulism is seen in infants younger than age 6 months (median, 10 weeks). The initial symptoms are usually constipation and progressive, often severe hypotonia. Infants younger than age 2 weeks rarely develop botulism. The toxin appears to be produced by *C botulinum* organisms residing in the gastrointestinal tract. In some instances, honey has been the source of spores. Clinical findings include constipation, weak suck and cry, pooled oral secretions, cranial nerve deficits, generalized weakness, and, on occasion, apnea. The characteristic electromyographic pattern of brief, small, abundant motor-unit action potentials (BSAPs) may help confirm the diagnosis.

Annually, 10–15 cases of wound botulism are reported. Most cases occur in drug abusers with infection in intravenous or intramuscular injection sites.

Botulism, as a result of aerosolization of botulinum toxin, also could occur as the result of a bioterrorism event. Only three such cases of botulism have been reported; the incubation period was not well-defined, but was about 72 hours in the reported cases.

▶ Clinical Findings

A. Symptoms and Signs

The incubation period for food-borne botulism is 8–36 hours. The initial symptoms are lethargy and headache. These are followed by double vision, dilated pupils, ptosis, and, within a few hours, difficulty with swallowing and speech. Pharyngeal paralysis occurs in some cases, and food may be regurgitated. The mucous membranes often are very dry. Descending skeletal muscle paralysis may be seen. Death usually results from respiratory failure.

Botulism patients present with a “classic triad”: (1) afebrile; (2) symmetrical, flaccid, descending paralysis with prominent bulbar palsies; and (3) clear sensorium. Recognition of this triad is important in making the clinical diagnosis. Botulism is caused by a toxin, thus there is no fever unless

secondary infection (eg, aspiration pneumonia) occurs. Common bulbar palsies seen include dysphonia, dysphagia, dysarthria, and diplopia (4 “Ds”).

B. Laboratory Findings

The diagnosis is made by demonstration of *C botulinum* toxin in stool, gastric aspirate or vomitus, or serum. Serum and stool samples can be sent for toxin confirmation (done by toxin neutralization mouse bioassay at CDC or state health departments). Foods that are suspected to be contaminated should be kept refrigerated and given to public health personnel for testing. Laboratory findings, including CSF examination, are usually normal. Electromyography suggests the diagnosis if the characteristic BSAP abnormalities are seen. A nondiagnostic electromyogram does not exclude the diagnosis.

► Differential Diagnosis

Guillain-Barré syndrome is characterized by ascending paralysis, sensory deficits, and elevated CSF protein without pleocytosis.

Other illnesses that should be considered include poliomyelitis, postdiphtheritic polyneuritis, certain chemical intoxications, tick paralysis, and myasthenia gravis. The history and elevated CSF protein characterize postdiphtheritic polyneuritis. Tick paralysis presents with a flaccid ascending motor paralysis. An attached tick should be sought. Myasthenia gravis usually occurs in adolescent girls. It is characterized by ocular and bulbar symptoms, normal pupils, fluctuating weakness, absence of other neurologic signs, and clinical response to cholinesterase inhibitors.

► Complications

Difficulty in swallowing leads to aspiration pneumonia. Serious respiratory paralysis may be fatal despite assisted ventilation and intensive supportive measures.

► Treatment

A. Specific Measures

Early treatment of botulism with antitoxin (food-borne or wound botulism) or passive human botulism immune globulin (infant botulism) is beneficial. Treatment should begin as soon as the clinical diagnosis is made (prior to microbiologic or toxin confirmation).

For suspected wound or food-borne botulism, equine antitoxins are available from the CDC through state health departments. Patients should be treated with the bivalent antitoxin (types A and B) and possibly also the monovalent (type E) antitoxin. The state health department or the CDC ([770] 488-7100) can be contacted for help in obtaining products and for consultation. Both preparations are given by slow intravenous infusion. All patients need to be screened for hypersensitivity to the products prior to initiating

the infusion; small challenge doses are given (see package insert). Patients who have reactions to the challenge doses are desensitized prior to receiving antitoxin infusion. In addition to the antitoxin, 24-hour diagnostic consultation, epidemic assistance, and laboratory testing services are available from the CDC through state health departments.

For treatment of infant botulism, intravenous human botulism immune globulin (Baby-BIG) is approved by the U.S. Food and Drug Administration (FDA) for use. Baby-BIG is a product containing high titers of neutralizing antibodies against type A and B toxin and is made from pooled plasma of adults who were immunized with a botulism toxoid vaccine. Results of a placebo-controlled clinical trial of use in infant botulism showed reduction in the mean hospital stay (2.5 weeks in treated patients vs 5.5 weeks in the placebo group) and decrease in mechanical ventilation time in the Baby-BIG-treated group. Although the cost of the preparation is high (\$45,000 in 2007), it still is cost-saving since there is a substantial reduction in hospital days, intensive care unit stay, and ventilator time in treated infants. Baby-BIG is not indicated for use in any form of botulism (wound, food-borne) other than infant botulism. To obtain Baby-BIG (in any state), contact the California Department of Public Health at: (510) 540-2646.

B. General Measures

General and supportive therapy consists of bed rest, ventilatory support (if necessary), fluid therapy, enteral or parenteral nutrition, and administration of purgatives and high enemas. Aminoglycoside antimicrobials and clindamycin may exacerbate neuromuscular blockage and should be avoided.

► Prognosis

The mortality rate has declined substantially in recent years and currently is at 6%. In nonfatal cases, symptoms subside over 2–3 months and recovery is usually complete.

TETANUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Nonimmunized or partially immunized patient.
- History of skin wound.
- Spasms of jaw muscles (trismus).

- ▶ Stiffness of neck, back, and abdominal muscles, with hyperirritability and hyperreflexia.
- ▶ Episodic, generalized muscle contractions.
- ▶ Diagnosis is based on clinical findings and the immunization history.

▶ General Considerations

Tetanus is caused by *Clostridium tetani*, an anaerobic, gram-positive bacillus that produces a potent neurotoxin. In unimmunized or incompletely immunized individuals, infection follows contamination of a wound by soil containing clostridial spores from animal manure. The toxin reaches the CNS by retrograde axon transport, is bound to cerebral gangliosides, and appears to increase reflex excitability in neurons of the spinal cord by blocking function of inhibitory synapses. Intense muscle spasms result. Two thirds of cases in the United States follow minor puncture wounds of the hands or feet. In many cases, no history of a wound can be obtained. Injecting substances and drug abuse may be risk factors (in individuals who are not tetanus-immune). In the newborn, usually in underdeveloped countries, infection generally results from contamination of the umbilical cord. The incubation period typically is 4–14 days but may be longer. In the United States, cases in young children are due to failure to immunize. Eighty-five percent of cases occur in adults older than 25 years.

▶ Clinical Findings

A. Symptoms and Signs

The first symptom often is mild pain at the site of the wound, followed by hypertonicity and spasm of the regional muscles. Characteristically, difficulty in opening the mouth (trismus) is evident within 48 hours. In newborns, the first signs are irritability and inability to nurse. The infant may then develop stiffness of the jaw and neck, increasing dysphagia, and generalized hyperreflexia with rigidity and spasms of all muscles of the abdomen and back (opisthotonos). The facial distortion resembles a grimace (risus sardonicus). Difficulty in swallowing and convulsions triggered by minimal stimuli such as sound, light, or movement may occur. Individual spasms may last seconds or minutes. Recurrent spasms are seen several times each hour, or they may be almost continuous. In most cases, the temperature is normal or only mildly elevated. A high or subnormal temperature is a bad prognostic sign. Patients are fully conscious and lucid. A profound circulatory disturbance associated with sympathetic overactivity may occur on the second to fourth day, which may contribute to the mortality rate. This is characterized by elevated blood pressure, increased cardiac output, tachycardia (> 20 beats/min), and arrhythmia.

B. Laboratory Findings

The diagnosis is made on clinical grounds. There may be a mild polymorphonuclear leukocytosis. The CSF is normal

with the exception of mild elevation of opening pressure. Serum muscle enzymes may be elevated. Transient electrocardiographic and electroencephalographic abnormalities may occur. Anaerobic culture and microscopic examination of pus from the wound can be helpful, but *C tetani* is difficult to grow, and the drumstick-shaped gram-positive bacilli often cannot be found.

▶ Differential Diagnosis

Poliomyelitis is characterized by asymmetrical paralysis in an incompletely immunized child. The history of an animal bite and the absence of trismus may suggest rabies. Local infections of the throat and jaw should be easily recognized. Bacterial meningitis, phenothiazine reactions, decerebrate posturing, narcotic withdrawal, spondylitis, and hypocalcemic tetany may be confused with tetanus.

▶ Complications

Complications include sepsis, malnutrition, pneumonia, atelectasis, asphyxial spasms, decubitus ulcers, and fractures of the spine due to intense contractions. They can be prevented in part by skilled supportive care.

▶ Prevention

A. Tetanus Toxoid

Active immunization with tetanus toxoid prevents tetanus. (See Chapter 9.) Immunity is almost always achieved after the third dose of vaccine. A booster at the time of injury is needed if none has been given in the past 10 years—or within 5 years for heavily contaminated wounds. Nearly all cases of tetanus (99%) in the United States are in nonimmunized or incompletely immunized individuals. Many adolescents and adults lack protective antibody.

B. Wound Care and Prophylaxis for Tetanus-Prone Wounds

Wounds that are contaminated with soil, debris, feces, or saliva are at increased risk for tetanus. Puncture wounds or wounds that contain devitalized tissue are at increased risk of infection with *C tetani*. This includes wounds that result from crush injury, frostbite, burns, or avulsion. All wounds should be adequately cleaned, foreign material removed, and debrided if necrotic or devitalized tissue is present or if residual foreign matter is present. The decision to use tetanus toxoid-containing vaccine or human tetanus immune globulin (TIG) depends on the type of injury and the tetanus immunization status of the patient. (See Chapter 9, and Table 9–5.) TIG should be used in children with fewer than three previous tetanus toxoid immunizations (DPT, DPaT, DT, Td, Tdap) who have tetanus-prone wounds, and should be administered to HIV-infected children with tetanus-prone wounds, regardless of their immunization history. When TIG is indicated for wound prophylaxis 250 units are

given intramuscularly. If tetanus immunization is incomplete, a dose of age-appropriate vaccine should be given. When both are indicated, tetanus toxoid and TIG should be administered concurrently at different sites using different syringes. (See Chapter 9.)

Prophylactic antimicrobials are useful if the child is unimmunized and TIG is not available.

► Treatment

A. Specific Measures

Serotherapy lowers the mortality rate from tetanus, but not dramatically. Human TIG in a single dose of 3000–6000 units, intramuscularly, is given to children and adults. Doses of 500 units have been used in infants. If TIG is indicated, but not available, intravenous immune globulin in a dose of 200–400 mg/kg intravenously can be used. Surgical debridement of wounds is indicated, but more extensive surgery or amputation to eliminate the site of infection is not necessary. Antibiotics are given to attempt to decrease the number of vegetative forms of the bacteria to decrease toxin production: oral metronidazole (30 mg/kg/d in four divided doses; maximum 4 g/d) for 10–14 days is the preferred agent.

B. General Measures

The patient is kept in a quiet room with minimal stimulation. Control of spasms and prevention of hypoxic episodes are crucial. Diazepam or another anxiolytic is useful (0.6–1.2 mg/kg/d intravenously in six divided doses). In the newborn, two or three divided doses should be given. Large doses (up to 25 mg/kg/d) may be required for older children. Diazepam is given intravenously until muscular spasms become infrequent and the generalized muscular rigidity much less prominent. The drug may then be given orally and the dosage reduced as the child improves. Mechanical ventilation and muscle paralysis are necessary in severe cases. Nasogastric or intravenous feedings should be used to limit stimulation of feedings and prevent aspiration.

► Prognosis

The fatality rate in newborns and heroin-addicted individuals is high. The overall mortality rate in the United States is 11%. The fatality rate depends on the quality of supportive care, the patient's age, and the patient's vaccination history. Many deaths are due to pneumonia or respiratory failure. If the patient survives 1 week, recovery is likely.

GAS GANGRENE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Contamination of a wound with soil or feces.
- Massive edema, skin discoloration, bleb formation, and pain in an area of trauma.
- Serosanguineous exudate from wound.
- Crepitation of subcutaneous tissue.
- Rapid progression of signs and symptoms.
- Clostridia cultured or seen on stained smears.

► General Considerations

Gas gangrene (clostridial myonecrosis) is a necrotizing infection that follows trauma or surgery and is caused by several anaerobic, gram-positive, spore-forming bacilli of the genus *Clostridium*. The spores are found in soil, feces, and vaginal secretions. In devitalized tissue, the spores germinate into vegetative bacilli that proliferate and produce toxins, causing thrombosis, hemolysis, and tissue necrosis. *Clostridium perfringens*, the species causing approximately 80% of cases of gas gangrene, produces at least eight such toxins. The areas involved most often are the extremities, abdomen, and uterus. *Clostridium septicum* may also cause myonecrosis and causes septicemia in patients with neutropenia. Nonclostridial infections with gas formation can mimic clostridial infections and are more common. Neutropenia is a risk factor for this severe infection.

► Clinical Findings

A. Symptoms and Signs

The onset of gas gangrene usually is sudden, often 1 day after trauma or surgery (mean, 3–4 days), but can be delayed up to 20 days. The skin around the wound becomes discolored, with hemorrhagic bullae, serosanguineous exudate, and crepitation in the subcutaneous tissues. Pain and swelling usually are intense. Systemic illness appears early and progresses rapidly to intravascular hemolysis, jaundice, shock, toxic delirium, and renal failure.

B. Laboratory Findings

Isolation of the organism requires anaerobic culture. Gram-stained smears may demonstrate many gram-positive rods and few inflammatory cells.

C. Imaging

Radiographs may demonstrate gas in tissues, but this is a late finding and is also seen in infections with other gas-forming organisms or may be due to air introduced into tissues during trauma or surgery.

D. Operative Findings

Direct visualization of the muscle at surgery may be necessary to diagnose gas gangrene. Early, the muscle is pale and edematous and does not contract normally; later, the muscle may be frankly gangrenous.

▶ Differential Diagnosis

Gangrene and cellulitis caused by other organisms and clostridial cellulitis (not myonecrosis) must be distinguished. Necrotizing fasciitis may resemble gas gangrene.

▶ Prevention

Gas gangrene can be prevented by the adequate cleansing and debridement of all wounds. It is essential that foreign bodies and dead tissue be removed. A clean wound does not provide a suitable anaerobic environment for the growth of clostridial species.

▶ Treatment

A. Specific Measures

Penicillin G (300,000–400,000 units/kg/d intravenously in six divided doses) should be given, usually combined with clindamycin or metronidazole. Clindamycin, metronidazole, meropenem, and imipenem–cilastatin are alternatives for penicillin-allergic patients. Some experts recommend a combination of penicillin and clindamycin.

B. Surgical Measures

Surgery should be prompt and extensive, with removal of all necrotic tissue.

C. Hyperbaric Oxygen

Hyperbaric oxygen therapy has been shown to be effective, but it is not a substitute for surgery. A patient may be exposed to 2–3 atm in pure oxygen for 1- to 2-hour periods for as many sessions as necessary until clinical remission occurs.

▶ Prognosis

Clostridial myonecrosis is fatal if untreated. With early diagnosis, antibiotics, and surgery, the mortality rate is 20–60%. Involvement of the abdominal wall, leukopenia, intravascular hemolysis, renal failure, and shock are ominous prognostic signs.

DIPHTHERIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Gray, adherent pseudomembrane, most often in the pharynx but also in the nasopharynx or trachea.
- ▶ Sore throat, serosanguineous nasal discharge, hoarseness, and fever in a nonimmunized child.
- ▶ Peripheral neuritis or myocarditis.
- ▶ Positive culture.
- ▶ Treatment should not be withheld pending culture results.

▶ General Considerations

Diphtheria is an acute infection of the upper respiratory tract or skin caused by toxin-producing *Corynebacterium diphtheriae*. Diphtheria in the United States is rare; five cases have been reported since 2000, and only 48 cases were reported from 1980–1997. However, significant numbers of elderly adults and unimmunized children are susceptible to infection. Diphtheria still occurs in epidemics in countries where immunization is not universal. Travelers to these areas may acquire the disease.

Corynebacteria are gram-positive, club-shaped rods with a beaded appearance on Gram stain. The capacity to produce exotoxin is conferred by a lysogenic bacteriophage and is not present in all strains of *C diphtheriae*. In immunized communities, infection probably occurs through spread of the phage among carriers of susceptible bacteria rather than through spread of phage-containing bacteria themselves. Diphtheria toxin kills susceptible cells by irreversible inhibition of protein synthesis.

The toxin is absorbed into the mucous membranes and causes destruction of epithelium and a superficial inflammatory response. The necrotic epithelium becomes embedded in exuding fibrin and red and white blood cells, forming a grayish pseudomembrane over the tonsils, pharynx, or larynx. Any attempt to remove the membrane exposes and tears the capillaries, resulting in bleeding. The diphtheria bacilli within the membrane continue to produce toxin, which is absorbed and may result in toxic injury to heart muscle, liver, kidneys, and adrenals, and is sometimes accompanied by hemorrhage. The toxin also produces neuritis, resulting in paralysis of the soft palate, eye muscles, or extremities. Death may occur as a result of respiratory obstruction or toxemia and circulatory collapse. The patient may succumb after a somewhat longer time as a result of cardiac damage. The incubation period is 2–7 days.

▶ Clinical Findings

A. Symptoms and Signs

1. Pharyngeal diphtheria—Early manifestations of diphtheritic pharyngitis are mild sore throat, moderate fever, and

malaise, followed fairly rapidly by prostration and circulatory collapse. The pulse is more rapid than the fever would seem to justify. A pharyngeal membrane forms and may spread into the nasopharynx or the trachea, producing respiratory obstruction. The membrane is tenacious and gray and is surrounded by a narrow zone of erythema and a broader zone of edema. The cervical lymph nodes become swollen, and swelling is associated with brawny edema of the neck (so-called bull neck). Laryngeal diphtheria presents with stridor, which can progress to obstruction of the airway.

2. Other forms—Cutaneous, vaginal, and wound diphtheria account for up to one third of cases and are characterized by ulcerative lesions with membrane formation.

B. Laboratory Findings

Diagnosis is clinical. Direct smears are unreliable. Material is obtained from the nose, throat, or skin lesions, if present, for culture, but specialized culture media are required. Between 16 and 48 hours is required before identification of the organism. A toxigenicity test is then performed. Cultures may be negative in individuals who have received antibiotics. The WBC count usually is normal, but hemolytic anemia and thrombocytopenia are frequent.

► Differential Diagnosis

Pharyngeal diphtheria resembles pharyngitis secondary to β -hemolytic streptococcus, Epstein-Barr virus, or other viral respiratory pathogens. A nasal foreign body or purulent sinusitis may mimic nasal diphtheria. Other causes of laryngeal obstruction include epiglottitis and viral croup. Guillain-Barré syndrome, poliomyelitis, or acute poisoning may mimic the neuropathy of diphtheria.

► Complications

A. Myocarditis

Diphtheritic myocarditis is characterized by a rapid, thready pulse; indistinct heart sounds, ST-T wave changes, conduction abnormalities, dysrhythmias, or cardiac failure; hepatomegaly; and fluid retention. Myocardial dysfunction may occur from 2–40 days after the onset of pharyngitis.

B. Polyneuritis

Neuritis of the palatal and pharyngeal nerves occurs during the first or second week. Nasal speech and regurgitation of food through the nose are seen. Diplopia and strabismus occur during the third week or later. Neuritis may also involve peripheral nerves supplying the intercostal muscles, diaphragm, and other muscle groups. Generalized paresis usually occurs after the fourth week.

C. Bronchopneumonia

Secondary pneumonia is common in fatal cases.

► Prevention

A. Immunization

Immunization with diphtheria toxoid combined with pertussis and tetanus toxoids (DTaP) should be used routinely for infants and children. (See Chapter 9.)

B. Care of Exposed Susceptibles

Children exposed to diphtheria should be examined, and nose and throat cultures obtained. If signs and symptoms of early diphtheria are found, antibiotic treatment should be instituted. Immunized asymptomatic individuals should receive diphtheria toxoid if a booster has not been received within 5 years. Unimmunized close contacts should receive either erythromycin orally (40 mg/kg/d in four divided doses) for 7 days or benzathine penicillin G intramuscularly (25,000 units/kg), active immunization with diphtheria toxoid, and observation daily.

► Treatment

A. Specific Measures

1. Antitoxin—To be effective, diphtheria antitoxin should be administered within 48 hours. (See Chapter 9.)

2. Antibiotics—Penicillin G (150,000 units/kg/d intravenously) should be given for 10 days. For penicillin-allergic patients, erythromycin (40 mg/kg/d) is given orally for 10 days.

B. General Measures

Bed rest in the hospital for 10–14 days is usually required. All patients must be strictly isolated for 1–7 days until respiratory secretions are noncontagious. Isolation may be discontinued when three successive nose and throat cultures at 24-hour intervals are negative. These cultures should not be taken until at least 24 hours have elapsed since the cessation of antibiotic treatment.

C. Treatment of Carriers

All carriers should receive treatment. Erythromycin (40 mg/kg/d orally in three or four divided doses), penicillin V potassium (50 mg/kg/d for 10 days), or benzathine penicillin G (600,000–1,200,000 units intramuscularly) should be given. All carriers must be quarantined. Before they can be released, carriers must have three negative cultures of both the nose and the throat taken 24 hours apart and obtained at least 24 hours after the cessation of antibiotic therapy.

► Prognosis

Mortality varies from 3–25% and is particularly high in the presence of early myocarditis. Neuritis is reversible; it is fatal only if an intact airway and adequate respiration cannot be maintained. Permanent heart damage from myocarditis occurs rarely.

INFECTIONS DUE TO ENTEROBACTERIACEAE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Diarrhea by several different mechanisms due to *Escherichia coli*.
- ▶ Hemorrhagic colitis and hemolytic-uremic syndrome.
- ▶ Neonatal sepsis or meningitis.
- ▶ Urinary tract infection.
- ▶ Opportunistic infections.
- ▶ Diagnosis confirmed by culture.

▶ General Considerations

Enterobacteriaceae are a family of gram-negative bacilli that are normal flora in the gastrointestinal tract and are also found in water and soil. They cause gastroenteritis, urinary tract infections, neonatal sepsis and meningitis, and opportunistic infections. *Escherichia coli* is the organism in this family that most commonly causes infection in children, but *Klebsiella*, *Morganella*, *Enterobacter*, *Serratia*, *Proteus*, and other genera are also important, particularly in the compromised host. *Shigella* and *Salmonella* are discussed in separate sections.

E coli strains capable of causing diarrhea were originally termed enteropathogenic (EPEC) and were recognized by serotype. It is now known that *E coli* may cause diarrhea by several distinct mechanisms. Classic EPEC strains cause a characteristic histologic injury in the small bowel termed adherence and effacement. Enterotoxigenic *E coli* (ETEC) causes a secretory, watery diarrhea. ETEC adheres to enterocytes and secretes one or more plasmid-encoded enterotoxins. One of these, heat-labile toxin, resembles cholera toxin in structure, function, and mechanism of action. Enteroinvasive *E coli* (EIEC) are very similar to *Shigella* in their pathogenetic mechanisms. Enterohemorrhagic *E coli* (EHEC) cause hemorrhagic colitis and the hemolytic-uremic syndrome. The most common EHEC serotype is O157:H7, although several other serotypes cause the same syndrome. These strains elaborate one of several cytotoxins, closely related to Shiga toxin produced by *Shigella dysenteriae*. Outbreaks of hemolytic-uremic syndrome associated with EHEC have followed consumption of inadequately cooked ground beef. Thorough heating to 68–71°C is

necessary. Unpasteurized fruit juice, various uncooked vegetables, and contaminated water also have caused infections and epidemics. The common source for EHEC in all of these foods and water is the feces of cattle. Person-to-person spread including spread in day care centers by the fecal-oral route has been reported.

E coli that aggregate on the surface of hep cells in tissue culture are termed enteroaggregative (EAaggEC) *E coli*. EAaggEC cause diarrhea by a distinct but unknown mechanism.

Eighty percent of *E coli* strains causing neonatal meningitis possess specific capsular polysaccharide (K1 antigen), which, alone or in association with specific somatic antigens, confers virulence. Approximately 90% of urinary tract infections in children are caused by *E coli*. *E coli* binds to the uroepithelium by P-fimbriae, which are present in more than 90% of *E coli* that cause pyelonephritis. Other bacterial cell surface structures, such as O and K antigens, and host factors are also important in the pathogenesis of urinary tract infections.

Klebsiella, *Enterobacter*, *Serratia*, and *Morganella* are normally found in the gastrointestinal tract and in soil and water. *Klebsiella* may cause a bronchopneumonia with cavity formation. *Klebsiella*, *Enterobacter*, and *Serratia* are often hospital-acquired opportunists associated with antibiotic usage, debilitated states, and chronic respiratory conditions. They frequently cause urinary tract infection or sepsis. In many newborn nurseries, nosocomial outbreaks caused by antimicrobial-resistant *Klebsiella* or *Enterobacter* species are a major problem.

Many of these infections are difficult to treat because of antibiotic resistance. Antibiotic susceptibility tests are necessary. Parenteral third-generation cephalosporins are usually more active than ampicillin, but resistance due to high-level production of chromosomal cephalosporinase may occur. *Enterobacter* and *Serratia* strains broadly resistant to cephalosporins also cause infections in hospitalized newborns and children. Aminoglycoside antibiotics are usually effective but require monitoring of serum levels to ensure therapeutic and nontoxic levels.

▶ Clinical Findings

A. Symptoms and Signs

1. *E coli* gastroenteritis—*E coli* may cause diarrhea of varying types and severity. ETEC usually produce mild, self-limiting illness without significant fever or systemic toxicity, often known as traveler's diarrhea. However, diarrhea may be severe in newborns and infants, and occasionally an older child or adult will have a cholera-like syndrome. EIEC strains cause a shigellosis-like illness, characterized by fever, systemic symptoms, blood and mucus in the stool, and leukocytosis, but currently are uncommon in the United States. EHEC strains cause hemorrhagic colitis. Diarrhea initially is watery and fever usually is absent.

Abdominal pain and cramping occur; diarrhea progresses to blood streaking or grossly bloody stools. Hemolytic-uremic syndrome occurs within a few days of diarrhea in 2–5% of children and is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. (See Chapter 22.)

2. Neonatal sepsis—Findings include jaundice, hepatosplenomegaly, fever, temperature lability, apneic spells, irritability, and poor feeding. Respiratory distress develops when pneumonia occurs; it may appear indistinguishable from respiratory distress syndrome in preterm infants. Meningitis is associated with sepsis in 25–40% of cases. Other metastatic foci of infection may be present, including pneumonia and pyelonephritis. Sepsis may lead to severe metabolic acidosis, shock, DIC, and death.

3. Neonatal meningitis—Findings include high fever, full fontanelles, vomiting, coma, convulsions, pareses or paralyses, poor or absent Moro reflex, opisthotonos, and occasionally hypertonia or hypotonia. Sepsis coexists or precedes meningitis in most cases. Thus, signs of sepsis often accompany those of meningitis. CSF usually shows a cell count of over 1000/ μ L, mostly polymorphonuclear neutrophils, and bacteria on Gram stain. CSF glucose concentration is low (usually less than half that of blood), and the protein is elevated above the levels normally seen in newborns and premature infants (> 150 mg/dL).

4. Acute urinary tract infection—Symptoms include dysuria, increased urinary frequency, and fever in the older child. Nonspecific symptoms such as anorexia, vomiting, irritability, failure to thrive, and unexplained fever are seen in children younger than age 2 years. Young infants may present with jaundice. As many as 1% of school-aged girls and 0.05% of boys have asymptomatic bacteriuria. Screening for and treatment of asymptomatic bacteriuria is not recommended.

B. Laboratory Findings

Because *E coli* are normal flora in the stool, a positive stool culture alone does not prove that the *E coli* in the stool are causing disease. Serotyping, tests for enterotoxin production or invasiveness, and tests for P-fimbriae are performed in research laboratories. MacConkey agar with sorbitol substituted for lactose (SMAC agar) is useful to screen stool for EHEC. Serotyping and testing for enterotoxin are available at many state health departments. Blood cultures are positive in neonatal sepsis. Cultures of CSF and urine should also be obtained. The diagnosis of urinary tract infections is discussed in Chapter 22.

► Differential Diagnosis

The clinical picture of EPEC infection may resemble that of salmonellosis, shigellosis, or viral gastroenteritis. Neonatal

sepsis and meningitis caused by *E coli* can be differentiated from other causes of neonatal infection only by blood and CSF culture.

► Treatment

A. Specific Measures

1. *E coli* gastroenteritis—Gastroenteritis due to EPEC seldom requires antimicrobial treatment. Fluid and electrolyte therapy, preferably given orally, may be required to avoid dehydration. Bismuth subsalicylate reduces stool volume by about one third in infants with watery diarrhea, probably including ETEC. In nursery outbreaks, *E coli* gastroenteritis has been treated with neomycin (100 mg/kg/d orally in three divided doses for 5 days). Clinical efficacy is not established. Traveler's diarrhea may be treated with TMP-SMX in children and with fluoroquinolones in adults, although resistance to these drugs is increasing. Azithromycin is an alternative. The risk of hemolytic-uremic syndrome may increase following treatment of EHEC colitis, and antimicrobials should be withheld in suspected cases.

2. *E coli* sepsis, pneumonia, or pyelonephritis—The drugs of choice are ampicillin (150–200 mg/kg/d, given intravenously or intramuscularly in divided doses every 4–6 hours), cefotaxime (150–200 mg/kg/d, given intravenously or intramuscularly in divided doses every 6–8 hours), ceftriaxone (50–100 mg/kg/d, given intramuscularly as single dose or in two divided doses), and gentamicin (5.0–7.5 mg/kg/d, given intramuscularly or intravenously in divided doses every 8 hours). Treatment is continued for 10–14 days. Amikacin or tobramycin may be used instead of gentamicin if the strain is susceptible. Third-generation cephalosporins are often an attractive alternative as single-drug therapy and do not require monitoring for toxicity.

3. *E coli* meningitis—Third-generation cephalosporins such as cefotaxime (200 mg/kg/d intravenously in four divided doses) are given for a minimum of 3 weeks. Ampicillin (200–300 mg/kg/d intravenously in four to six divided doses) and gentamicin (5.0–7.5 mg/kg/d intramuscularly or intravenously in three divided doses) also are effective. Treatment with intrathecal and intraventricular aminoglycosides does not improve outcome. Serum levels need to be monitored.

4. Acute urinary tract infection—(See Chapter 22.)

► Prognosis

Death due to gastroenteritis leading to dehydration can be prevented by early fluid and electrolyte therapy. Neonatal sepsis with meningitis is still associated with a mortality rate of over 50%. Most children with recurrent urinary tract infections do well if they have no underlying anatomic defects. The mortality rate in opportunistic infections usually depends on the severity of infection and the underlying condition.

PSEUDOMONAS INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Opportunistic infection.
- ▶ Confirmed by cultures.

▶ General Considerations

Pseudomonas aeruginosa is an aerobic gram-negative rod with versatile metabolic requirements. The organism may grow in distilled water and in commonly used disinfectants, complicating infection control in medical facilities. *P aeruginosa* is both invasive and destructive to tissue as well as toxigenic due to secreted exotoxins, all factors that contribute to virulence. Other genera previously classified as *Pseudomonas* frequently cause nosocomial infections and infections in immunocompromised children. *Stenotrophomonas maltophilia* (previously *P maltophilia*) and *Burkholderia cepacia* (previously *P cepacia*) are the most frequent.

P aeruginosa is an important cause of infection in children with cystic fibrosis, neoplastic disease, neutropenia, or extensive burns and in those receiving antibiotic therapy. Infections of the urinary and respiratory tracts, ears, mastoids, paranasal sinuses, eyes, skin, meninges, and bones are seen. *Pseudomonas* pneumonia is a common nosocomial infection in patients receiving assisted ventilation.

P aeruginosa sepsis may be accompanied by characteristic peripheral lesions called ecthyma gangrenosum. Ecthyma gangrenosum also may occur by direct invasion through intact skin in the groin, axilla, or other skinfolds. *P aeruginosa* is an infrequent cause of sepsis in previously healthy infants and may be the initial sign of underlying medical problems. *P aeruginosa* osteomyelitis often complicates puncture wounds of the feet. *P aeruginosa* is a frequent cause of malignant external otitis media and of chronic suppurative otitis media. Outbreaks of vesiculopustular skin rash have been associated

with exposure to contaminated water in whirlpool baths and hot tubs.

P aeruginosa infects the tracheobronchial tree of nearly all patients with cystic fibrosis. Mucoïd exopolysaccharide, an exuberant capsule, is characteristically overproduced by isolates from patients with cystic fibrosis. Although bacteremia seldom occurs, patients with cystic fibrosis ultimately succumb to chronic lung infection with *P aeruginosa*. Infection due to *B cepacia* has caused a rapidly progressive pulmonary disease in some colonized patients and may be spread by close contact.

Osteomyelitis of the calcaneus or other foot bones occurs after punctures such as stepping on a nail and is commonly due to *P aeruginosa*.

▶ Clinical Findings

The clinical findings depend on the site of infection and the patient's underlying disease. Sepsis with these organisms resembles gram-negative sepsis with other organisms, although the presence of ecthyma gangrenosum suggests the diagnosis. The diagnosis is made by culture. *Pseudomonas* infection should be suspected in neonates and neutropenic patients with clinical sepsis. A severe necrotizing pneumonia occurs in patients on ventilators.

Patients with cystic fibrosis have a persistent bronchitis that progresses to bronchiectasis and ultimately to respiratory failure. During exacerbations of illness, cough and sputum production increase with low-grade fever, malaise, and diminished energy.

The purulent aural drainage without fever in patients with chronic suppurative otitis media is not distinguishable from that due to other causes.

▶ Prevention

A. Infections in Debilitated Patients

Colonization of extensive second- and third-degree burns by *P aeruginosa* can lead to fatal septicemia. Aggressive debridement and topical treatment with 0.5% silver nitrate solution, 10% mafenide cream, or silver sulfadiazine will greatly inhibit *P aeruginosa* contamination of burns. (See Chapter 11 for a discussion of burn wound infections and prevention.)

B. Nosocomial Infections

Faucet aerators, communal soap dispensers, disinfectants, improperly cleaned inhalation therapy equipment, infant incubators, and many other sources that usually are associated with wet or humid conditions all have been associated with *Pseudomonas* epidemics. Infant-to-infant transmission by nursery personnel carrying *Pseudomonas* on the hands is frequent in neonatal units. Careful maintenance of equipment and enforcement of infection control procedures are essential to minimize nosocomial transmission.

C. Patients with Cystic Fibrosis

Chronic infection of the lower respiratory tract occurs in nearly all patients with cystic fibrosis. The infecting organism is seldom cleared from the respiratory tract, even with intensive antimicrobial therapy, and the resultant injury to the lung eventually leads to pulmonary insufficiency. Treatment is aimed at controlling signs and symptoms of the infection.

▶ Treatment

P. aeruginosa is inherently resistant to many antimicrobials and may develop resistance during therapy. Mortality rates in hospitalized patients exceed 50%, owing both to the severity of underlying illnesses in patients predisposed to *Pseudomonas* infection and to the limitations of therapy. Antibiotics effective against *Pseudomonas* include the aminoglycosides, ureidopenicillins (ticarcillin and piperacillin), β -lactamase inhibitor with a ureidopenicillin (ticarcillin-clavulanate and piperacillin-tazobactam), expanded-spectrum cephalosporins (ceftazidime and cefepime), imipenem, meropenem, and ciprofloxacin. Antimicrobial susceptibility patterns vary from area to area, and resistance tends to appear as new drugs become popular. Treatment of infections is best guided by clinical response and susceptibility tests.

Gentamicin or tobramycin (5.0–7.5 mg/kg/d, given intramuscularly or intravenously in three divided doses) or amikacin (15–22 mg/kg/d, given in two or three divided doses) in combination with ticarcillin (200–300 mg/kg/d, given intravenously in four to six divided doses) or with another antipseudomonal β -lactam antibiotic is recommended for treatment of serious *Pseudomonas* infections. Ceftazidime (150–200 mg/kg/d, given in four divided doses) or cefepime (150 mg/kg/d, given in three divided doses) has excellent activity against *P. aeruginosa*. Treatment should be continued for 10–14 days. Treatment with two active drugs is recommended for all serious infections.

Pseudomonas osteomyelitis due to punctures requires thorough surgical debridement and antimicrobial therapy for 2 weeks. *Pseudomonas* folliculitis does not require antibiotic therapy.

Oral or intravenous ciprofloxacin is also effective against susceptible *P. aeruginosa*, but is not approved by the FDA for use in children except in the case of urinary tract infection. Nonetheless, in some circumstances of antimicrobial resistance, or when the benefits clearly outweigh the small risks, ciprofloxacin may be used.

Chronic suppurative otitis media responds to intravenous ceftazidime (150–200 mg/kg/d in three or four divided doses) given until the drainage has ceased for 3 days. Twice-daily ceftazidime with aural debridement and cleaning given on an outpatient basis has also been successful. Swimmer's ear may be caused by *P. aeruginosa* and responds well to topical drying agents (alcohol-vinegar mix) and cleansing.

▶ Prognosis

Because debilitated patients are most frequently affected, the mortality rate is high. These infections may have a protracted course, and eradication of the organisms may be difficult.

SALMONELLA GASTROENTERITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Nausea, vomiting, headache, meningismus.
- ▶ Fever, diarrhea, abdominal pain.
- ▶ Culture or organism from stool, blood, or other specimens.

▶ General Considerations

Salmonellae are gram-negative rods that frequently cause food-borne gastroenteritis and occasionally bacteremic infection of bone, meninges, and other foci. Three species—*Salmonella typhi*, *Salmonella choleraesuis*, and *Salmonella enteritidis*—and approximately 2000 serotypes are recognized. *Salmonella typhimurium* is the most frequently isolated serotype in most parts of the world. An estimated 4 million cases of salmonellosis occur yearly in the United States, but only 40,000 are reported.

Salmonellae are able to penetrate the mucin layer of the small bowel and attach to epithelial cells. Organisms penetrate the epithelial cells and multiply in the submucosa. Infection results in fever, vomiting, and watery diarrhea; the diarrhea occasionally includes mucus and polymorphonuclear neutrophils in the stool. Although the small intestine is generally regarded as the principal site of infection, colitis also occurs. *S. typhimurium* frequently involves the large bowel.

Salmonella infections in childhood occur in two major forms: (1) gastroenteritis (including food poisoning), which may be complicated by sepsis and focal suppurative complications; and (2) enteric fever (typhoid fever and paratyphoid fever) (see next section). Although the incidence of typhoid fever has decreased in the United States, the incidence of

Salmonella gastroenteritis has greatly increased in the past 15–20 years. The highest attack rates occur in children younger than age 6 years, with a peak in the age group from 6 months to 2 years.

Salmonellae are widespread in nature, infecting domestic and wild animals. Fowl and reptiles have a particularly high carriage rate. Transmission results primarily from ingestion of contaminated food. Transmission from human to human occurs by the fecal-oral route via contaminated food, water, and fomites. Numerous foods, including meats, milk, cheese, ice cream, chocolate, contaminated egg powder, and frozen whole egg preparations used to make ice cream, custards, and mayonnaise are associated with outbreaks. Eggs with contaminated shells that are consumed raw or undercooked have been incriminated in outbreaks and sporadic cases. Animal contact also can be a source for salmonella.

Because salmonellae are susceptible to gastric acidity, the elderly, infants, and patients taking antacids or H₂-blocking drugs are at increased risk for infection. Most cases of *Salmonella* meningitis (80%) and bacteremia occur in infancy. Newborns may acquire the infection from their mothers during delivery and may precipitate outbreaks in nurseries. Newborns are at special risk for developing meningitis.

Epidemiologic studies suggest that 100 mild cases of *Salmonella* infection occur for each case detected by a positive culture. In 2005, 45,000 cases of *Salmonella* infection were reported in the United States.

► Clinical Findings

A. Symptoms and Signs

There is a very wide range of severity of infection. Infants usually develop fever, vomiting, and diarrhea. The older child also may complain of headache, nausea, and abdominal pain. Stools are often watery or may contain mucus and, in some instances, blood, suggesting shigellosis. Drowsiness and disorientation may be associated with meningismus. Convulsions occur less frequently than with shigellosis. Splenomegaly occasionally occurs. In the usual case, diarrhea is moderate and subsides after 4–5 days, but it may be protracted.

B. Laboratory Findings

Diagnosis is made by isolation of the organism from stool, blood, or, in some cases, from urine, CSF, or pus from a suppurative lesion. The WBC count usually shows a polymorphonuclear leukocytosis but may show leukopenia. *Salmonella* isolates should be reported to public health authorities for epidemiologic purposes. Stool cultures are rarely positive when obtained from children who develop diarrhea after 3 days of hospitalization.

► Differential Diagnosis

In staphylococcal food poisoning, the incubation period is shorter (2–4 hours) than in *Salmonella* food poisoning (12–

24 hours). Fever is absent, and vomiting rather than diarrhea is the main symptom. In shigellosis, many pus cells usually are seen on a stained smear of stool, and the peripheral WBC count is more likely to show a marked left shift, although some cases of salmonellosis are indistinguishable from shigellosis. *Campylobacter* gastroenteritis commonly resembles salmonellosis clinically. Culture of the stools is necessary to distinguish the causes of bacterial gastroenteritis.

► Complications

Unlike most types of infectious diarrhea, salmonellosis is frequently accompanied by bacteremia, especially in newborns and infants. Septicemia with extraintestinal infection is seen, most commonly with *Salmonella choleraesuis* but also with *S enteritidis*, *S typhimurium*, and *S paratyphi* B and C. The organism may spread to any tissue and may cause arthritis, osteomyelitis, cholecystitis, endocarditis, meningitis, pericarditis, pneumonia, or pyelonephritis. Patients with sickle cell anemia or other hemoglobinopathies have a predilection for the development of osteomyelitis. Severe dehydration and shock are more likely to occur with shigellosis but may occur with *Salmonella* gastroenteritis.

► Prevention

Measures for the prevention of *Salmonella* infections include thorough cooking of foodstuffs derived from contaminated sources, adequate refrigeration, control of infection among domestic animals, and meticulous meat and poultry inspections. Raw and undercooked fresh eggs should be avoided. Food handlers and child care workers with salmonellosis should have three negative stool cultures before resuming work. Asymptomatic children, who have recovered from *Salmonella* infection, do not need exclusion.

► Treatment

A. Specific Measures

In uncomplicated *Salmonella* gastroenteritis, antibiotic treatment does not shorten the course of the clinical illness and may prolong convalescent carriage of the organism. Colitis or secretory diarrhea due to *Salmonella* may improve with antibiotic therapy.

Because of the higher risk of sepsis and focal disease, antibiotic treatment is recommended in infants younger than age 3 months, in severely ill children, and in children with sickle cell disease, liver disease, recent gastrointestinal surgery, cancer, depressed immunity, or chronic renal or cardiac disease. Infants younger than age 3 months with positive stool cultures or suspected salmonellosis sepsis should be admitted to the hospital, evaluated for focal infection including cultures of blood and CSF, and given treatment intravenously. A third-generation cephalosporin is recommended due to frequent resistance to ampicillin and TMP-SMX. Older patients developing

bacteremia during the course of gastroenteritis should receive parenteral treatment initially, and a careful search should be made for additional foci of infection. After signs and symptoms subside, these patients should receive oral medication. Parenteral and oral treatment should last a total of 7–10 days. Longer treatment is indicated for specific complications. If susceptibility tests indicate resistance to ampicillin, third-generation cephalosporins or TMP–SMX should be given. Fluoroquinolones also are efficacious but are not approved for administration to children. Fluoroquinolones are used for strains resistant to multiple other drugs.

Salmonella meningitis is best treated with ampicillin (200–300 mg/kg/d intravenously in four to six divided doses) and a third-generation cephalosporin (cefotaxime, ceftriaxone) for 3 weeks. If the child improves rapidly and the CSF is sterile, treatment may be completed with a single drug, the choice guided by results of susceptibility tests.

Outbreaks on pediatric wards are difficult to control. Strict hand washing, cohorting of patients and personnel, and ultimately closure of the unit may be necessary.

B. Treatment of the Carrier State

About half of patients may have positive stool cultures after 4 weeks. Infants tend to remain convalescent carriers for up to a year. Antibiotic treatment of carriers is not effective.

C. General Measures

Careful attention must be given to maintaining fluid and electrolyte balance, especially in infants.

► Prognosis

In gastroenteritis, the prognosis is good. In sepsis with focal suppurative complications, the prognosis is more guarded. The case fatality rate of *Salmonella* meningitis is high in infants. There is a strong tendency to relapse if treatment is not continued for at least 14–21 days.

TYPHOID FEVER & PARATYPHOID FEVER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Insidious or acute onset of headache, anorexia, vomiting, constipation or diarrhea, ileus, and high fever.
- Meningismus, splenomegaly, and rose spots.
- Leukopenia; positive blood, stool, bone marrow, and urine cultures.

► General Considerations

Typhoid fever is caused by the gram-negative bacillus *Salmonella typhi*. Paratyphoid fevers, which are usually milder but may be clinically indistinguishable, are caused by *Salmonella paratyphi* A, *Salmonella schottmülleri*, or *Salmonella hirschfeldii* (formerly *Salmonella paratyphi* A, B, and C). Children have a shorter incubation period than do adults (usually 5–8 days instead of 8–14 days). The organism enters the body through the walls of the intestinal tract and, following a transient bacteremia, multiplies in the reticuloendothelial cells of the liver and spleen. Persistent bacteremia and symptoms then follow. Reinfection of the intestine occurs as organisms are excreted in the bile. Bacterial emboli produce the characteristic skin lesions (rose spots). Symptoms in children may be mild or severe, but children younger than age 5 years rarely have severe typhoid fever.

Typhoid fever is transmitted by the fecal-oral route and by contamination of food or water. Unlike other *Salmonella* species, there are no animal reservoirs of *S typhi*; each case is the result of direct or indirect contact with the organism or with an individual who is actively infected or a chronic carrier.

About 250 cases per year are reported in the United States, 80% of which are acquired during foreign travel.

► Clinical Findings

A. Symptoms and Signs

In children, the onset of typhoid fever usually is sudden rather than insidious, with malaise, headache, crampy abdominal pains and distention, and sometimes constipation followed within 48 hours by diarrhea, high fever, and toxemia. An encephalopathy may be seen with irritability, confusion, delirium, and stupor. Vomiting and meningismus may be prominent in infants and young children. The classic lengthy three-stage disease seen in adult patients often is shortened in children. The prodrome may last only 2–4 days, the toxic stage only 2–3 days, and the defervescence stage 1–2 weeks.

During the prodromal stage, physical findings may be absent, or there may merely be some abdominal distention

and tenderness, meningismus, mild hepatomegaly, and minimal splenomegaly. The typical typhoidal rash (rose spots) is present in 10–15% of children. It appears during the second week of the disease and may erupt in crops for the succeeding 10–14 days. Rose spots are erythematous maculopapular lesions 2–3 mm in diameter that fade on pressure. They are found principally on the trunk and chest and they generally disappear within 3–4 days. The lesions usually number fewer than 20.

B. Laboratory Findings

Typhoid bacilli can be isolated from many sites, including blood, stool, urine, and bone marrow. Blood cultures are positive in 50–80% of cases during the first week and less often later in the illness. Stool cultures are positive in about 50% of cases after the first week. Urine and bone marrow cultures also are valuable. Most patients will have negative cultures (including stool) by the end of a 6-week period. Serologic tests (Widal reaction) are not as useful as cultures because both false-positive and false-negative results occur. Leukopenia is common in the second week of the disease, but in the first week, leukocytosis may be seen. Proteinuria, mild elevation of liver enzymes, thrombocytopenia, and DIC are common.

► Differential Diagnosis

Typhoid and paratyphoid fevers must be distinguished from other serious prolonged fevers. These include typhus, brucellosis, malaria, tularemia, miliary tuberculosis, psittacosis, vasculitis, lymphoma, mononucleosis, and Kawasaki disease. The diagnosis of typhoid fever often is made clinically in developing countries, but the accuracy of clinical diagnosis is variable. In developed countries, where typhoid fever is uncommon and physicians are unfamiliar with the clinical picture, the diagnosis often is not suspected until late in the course. Positive cultures confirm the diagnosis.

► Complications

The most serious complications of typhoid fever are gastrointestinal hemorrhage (2–10%) and perforation (1–3%). They occur toward the end of the second week or during the third week of the disease.

Intestinal perforation is one of the principal causes of death. The site of perforation generally is the terminal ileum or cecum. The clinical manifestations are indistinguishable from those of acute appendicitis, with pain, tenderness, and rigidity in the right lower quadrant.

Bacterial pneumonia, meningitis, septic arthritis, abscesses, and osteomyelitis are uncommon complications, particularly if specific treatment is given promptly. Shock and electrolyte disturbances may lead to death.

About 1–3% of patients become chronic carriers of *S typhi*. Chronic carriage is defined as excretion of typhoid

bacilli for more than a year, but carriage is often lifelong. Adults with underlying biliary or urinary tract disease are much more likely than children to become chronic carriers.

► Prevention

Routine typhoid vaccine is not recommended in the United States but should be considered for foreign travel to endemic areas. An attenuated oral typhoid vaccine produced from strain Ty21a has better efficacy and causes minimal side effects but is not approved for children younger than age 6 years. A capsular polysaccharide vaccine (ViCPS) requires one intramuscular injection and may be given to children age 2 years and older. (See Chapter 9.)

► Treatment

A. Specific Measures

Third-generation cephalosporins such as cefotaxime (150 mg/kg divided in three doses), azithromycin (10 mg/kg on day 1, followed by 5 mg/kg for 7 days), or a fluoroquinolone are used for presumptive therapy. Antimicrobial susceptibility testing and local experience are used to direct subsequent therapy. Equally effective regimens for susceptible strains include the following: TMP–SMX (10 mg/kg trimethoprim and 50 mg/kg sulfamethoxazole per day orally in two or three divided doses), amoxicillin (100 mg/kg/d orally in four divided doses), and ampicillin (100–200 mg/kg/d intravenously in four divided doses). Aminoglycosides and first- and second-generation cephalosporins are clinically ineffective regardless of in-vitro susceptibility results. Ciprofloxacin or other fluoroquinolones are efficacious but not approved in children, but may be used for multiply resistant strains. Treatment duration is 14–21 days. Patients may remain febrile for 3–5 days even with appropriate therapy.

B. General Measures

General support of the patient is exceedingly important and includes rest, good nutrition, and careful observation, with particular regard to evidence of intestinal bleeding or perforation. Blood transfusions may be needed even in the absence of frank hemorrhage.

► Prognosis

A prolonged convalescent carrier stage may occur in children. Three negative cultures after all antibiotics have been stopped are required before contact precautions are stopped. With early antibiotic therapy, the prognosis is excellent, and the mortality rate is less than 1%. Relapse occurs 1–3 weeks later in 10–20% of patients despite appropriate antibiotic treatment.

SHIGELLOSIS (BACILLARY DYSENTERY)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Cramps and bloody diarrhea.
- ▶ High fever, malaise, convulsions.
- ▶ Pus and blood in diarrheal stools examined microscopically.
- ▶ Diagnosis confirmed by stool culture.

▶ General Considerations

Shigellae are nonmotile gram-negative rods of the family Enterobacteriaceae and are closely related to *E coli*. The genus *Shigella* is divided into four major groups, A–D, representing *Shigella dysenteriae*, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei*, respectively. Approximately 30,000 cases of shigellosis are reported each year in the United States. *S sonnei* followed by *S flexneri* are the most common isolates.

S dysenteriae, which causes the most severe diarrhea of all species and the greatest number of extraintestinal complications, accounts for less than 1% of all *Shigella* infections in the United States.

Shigellosis may be a serious disease, particularly in young children, and without supportive treatment an appreciable mortality rate results. In older children and adults, the disease tends to be self-limited and milder. *Shigella* is usually transmitted by the fecal-oral route. Food- and water-borne outbreaks are increasing in occurrence, but are less important overall than person-to-person transmission. The disease is very communicable—as few as 200 bacteria can produce illness in an adult. The secondary attack rate in families is high, and shigellosis is a serious problem in day care centers and custodial institutions. *Shigella* organisms produce disease by invading the colonic mucosa, causing mucosal ulcer-

ations and microabscesses. A plasmid-encoded gene is required for enterotoxin production, chromosomal genes are required for invasiveness, and smooth lipopolysaccharides are required for virulence. An experimental vaccine is under development and is safe and immunogenic in young children.

▶ Clinical Findings

A. Symptoms and Signs

The incubation period of shigellosis is usually 2–4 days. Onset is abrupt, with abdominal cramps, urgency, tenesmus, chills, fever, malaise, and diarrhea. Hallucinations and seizures sometimes accompany high fever. In severe forms, blood and mucus are seen in small stools (dysentery), and meningismus and convulsions may occur. In older children, the disease may be mild and may be characterized by watery diarrhea without blood. In young children, a fever of 39.4–40°C is common. Rarely there is rectal prolapse. Symptoms generally last 3–7 days.

B. Laboratory Findings

The total WBC count varies, but often there is a marked shift to the left. The stool may contain gross blood and mucus, and many neutrophils are seen if mucus from the stool is examined microscopically. Stool cultures are usually positive; however, they may be negative because the organism is somewhat fragile and present in small numbers late in the disease, and because laboratory techniques are suboptimal for the recovery of shigellae.

▶ Differential Diagnosis

Diarrhea due to rotavirus infection is a winter rather than a summer disease. Usually children with rotavirus infection are not as febrile or toxic as those with shigellosis, and in rotavirus infection, stool does not contain gross blood or neutrophils. Intestinal infections caused by *Salmonella* or *Campylobacter* are differentiated by culture. Grossly bloody stools in a patient without fever or stool leukocytes suggest *E coli* O157:H7 infection. Amebic dysentery is diagnosed by microscopic examination of fresh stools or sigmoidoscopy specimens. Intussusception is characterized by an abdominal mass (so-called currant jelly stools) without leukocytes, and by absence of fever. Mild shigellosis is not distinguishable clinically from other forms of infectious diarrhea.

▶ Complications

Dehydration, acidosis, shock, and renal failure are the major complications. In some cases, a chronic form of dysentery occurs, characterized by mucoid stools and poor nutrition. Bacteremia and metastatic infections are rare but serious complications. Febrile seizures are common. Fulminating fatal dysentery and hemolytic-uremic syndrome occur rarely.

► Treatment

A. Specific Measures

Resistance to TMP–SMX (10 mg/kg/d trimethoprim and 50 mg/kg/d sulfamethoxazole, given in two divided doses orally for 5 days) is now commonly encountered in many communities and limits the use of this otherwise effective drug combination to cases where results of susceptibility testing are known. Amoxicillin is not effective. Ampicillin (100 mg/kg/d, given in four divided doses) is also efficacious if the strain is sensitive. Parenteral ceftriaxone and oral cefixime are both effective; experience with other third-generation oral cephalosporins is limited. Azithromycin (12 mg/kg/d on day 1, then 6 mg/kg/d for 4 days) was superior to cefixime in one study. Ciprofloxacin (500 mg, given twice daily for 5 days) is efficacious in adults but is not approved for use in children. However, it may be used in children who remain symptomatic and in need of therapy, and when multiply resistant strains limit other preferred choices. Successful treatment reduces the duration of fever, cramping, and diarrhea and terminates fecal excretion of *Shigella*. Tetracycline and chloramphenicol are also effective, but resistance is common. Presumptive therapy should be limited to children with classic shigellosis or known outbreaks. Afebrile children with bloody diarrhea are more commonly infected with EHEC. Antimicrobial therapy of EHEC may increase the likelihood of hemolytic-uremic syndrome.

B. General Measures

In severe cases, immediate rehydration is critical. A mild form of chronic malabsorption syndrome may supervene and require prolonged dietary control.

► Prognosis

The prognosis is excellent if vascular collapse is treated promptly by adequate fluid therapy. The mortality rate is high in very young, malnourished infants who do not receive fluid and electrolyte therapy. Convalescent fecal excretion of *Shigella* lasts 1–4 weeks in patients not receiving antimicrobial therapy. Long-term carriers are rare.

CHOLERA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Sudden onset of severe watery diarrhea.
- Persistent vomiting without nausea or fever.
- Extreme and rapid dehydration and electrolyte loss, with rapid development of vascular collapse.
- Contact with a case of cholera or with shellfish, or the presence of cholera in the community.
- Diagnosis confirmed by stool culture.

► General Considerations

Cholera is an acute diarrheal disease caused by the gram-negative organism *Vibrio cholerae*. It is transmitted by contaminated water or food, especially contaminated shellfish. Typical disease is generally so dramatic that in endemic areas the diagnosis is obvious. Individuals with mild illness and young children may play an important role in transmission of the infection.

Asymptomatic infection is far more common than clinical disease. In endemic areas, rising titers of vibriocidal antibody are seen with increasing age. Infection occurs in individuals with low titers. The age-specific attack rate is highest in children younger than age 5 years and declines with age. Cholera is unusual in infancy.

Cholera toxin is a protein enterotoxin that is primarily responsible for symptoms. Cholera toxin binds to a regulatory subunit of adenyl cyclase in enterocytes, causing increased cyclic adenosine monophosphate and an outpouring of NaCl and water into the lumen of the small bowel.

Nutritional status is an important factor determining the severity of the diarrhea. Duration of diarrhea is prolonged in adults and children with severe malnutrition.

Cholera is endemic in India and southern and Southeast Asia and in parts of Africa. The most recent pandemic, caused by the El Tor biotype of *V cholerae* 01, began in 1961 in Indonesia. Epidemic cholera spread in Central and South America, with a total of 1 million cases and 9500 deaths reported through 1994. Cases in the United States occurred in the course of foreign travel or as a result of consumption of contaminated imported food. Cholera is increasingly associated with consumption of shellfish. Interstate shipment of oysters has resulted in cholera in several inland states. Cholera is now rare in the United States with fewer than 10 cases per year reported.

V cholerae is a natural inhabitant of shellfish and copepods in estuarine environments. Seasonal multiplication of *V cholerae* may provide a source of outbreaks in endemic areas. Chronic cholera carriers are rare. The incubation period is short, usually 1–3 days.

► Clinical Findings

A. Symptoms and Signs

Many patients infected with *V cholerae* have mild disease, with 1–2% developing severe diarrhea. During severe cholera, there is a sudden onset of massive, frequent, watery stools, generally light gray in color (so-called rice-water stools) and containing some mucus but no pus. Vomiting may be projectile and is not accompanied by nausea. Within 2–3 hours, the tremendous loss of fluids results in life-threatening dehydration, hypochloremia, and hypokalemia, with marked weakness and collapse. Renal failure with uremia and irreversible peripheral vascular collapse will occur if fluid therapy is not administered. The illness lasts 1–7 days and is shortened by appropriate antibiotic therapy.

B. Laboratory Findings

Markedly elevated hemoglobin (20 g/dL) and marked acidosis, hypochloremia, and hyponatremia are seen. Stool sodium concentration may range from 80–120 mEq/L. Cultural confirmation requires specific media and takes 16–18 hours for a presumptive diagnosis and 36–48 hours for a definitive bacteriologic diagnosis.

► Prevention

Cholera vaccine is available and provides 50% efficacy. Protection lasts 3–6 months. Cholera vaccine is not generally recommended for travelers. Tourists visiting endemic areas are at little risk if they exercise caution in what they eat and drink and maintain good personal hygiene. In endemic areas, all water and milk must be boiled, food protected from flies, and sanitary precautions observed. Simple filtration of water is highly effective in reducing cases. Thorough cooking of shellfish prevents transmission. All patients with cholera should be isolated.

Chemoprophylaxis is indicated for household and other close contacts of cholera patients. It should be initiated as soon as possible after the onset of the disease in the index patient. Tetracycline (500 mg/d for 5 days) is effective in preventing infection. TMP–SMX may be substituted in children.

► Treatment

Physiologic saline or lactated Ringer solution should be administered intravenously in large amounts to restore blood volume and urine output and prevent irreversible shock. Potassium supplements are required. Sodium bicarbonate, given intravenously, also may be needed initially to overcome profound metabolic acidosis from bicarbonate loss in the stool. Moderate dehydration and acidosis can be corrected in 3–6 hours by oral therapy alone, because the active glucose transport system of the small bowel is normally functional. The optimal composition of the oral solution (in mEq/L) is as follows: Na⁺, 90; Cl⁻, 80; and K⁺, 20 (with glucose, 110 mmol/L).

Treatment with tetracycline (50 mg/kg/d orally in four divided doses for 2–5 days) or azithromycin (10 mg/kg/d in one dose for 1–5 days) shortens the duration of the disease in children and prevents clinical relapse but is not as important as fluid and electrolyte therapy. Tetracycline resistance occurs in some regions, and ciprofloxacin may be used depending on local resistance patterns. TMP–SMX should be used in children younger than age 9 years.

► Prognosis

With early and rapid replacement of fluids and electrolytes, the case fatality rate is 1–2% in children. If significant symptoms appear and no treatment is given, the mortality rate is over 50%.

CAMPYLOBACTER INFECTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever, vomiting, abdominal pain, diarrhea.
- Presumptive diagnosis by darkfield or phase contrast microscopy of stool wet mount or modified Gram stain.
- Definitive diagnosis by stool culture.

► General Considerations

Campylobacter species are small gram-negative, curved or spiral bacilli that are commensals or pathogens in many animals. *Campylobacter jejuni* frequently causes acute enteritis in humans. In the 1990s, *C jejuni* was responsible for 3–11% of cases of acute gastroenteritis in North America and Europe. In many areas, enteritis due to *C jejuni* is more common than that due to *Salmonella* or *Shigella*. *Campylobacter fetus* causes bacteremia and meningitis in immunocompromised patients. *C fetus* may cause maternal fever, abortion, stillbirth, and severe neonatal infection. *Helicobacter pylori* (previously called *Campylobacter pylori*) causes gastritis and peptic ulcer disease in both adults and children. (See Chapter 20.)

Campylobacter colonizes domestic and wild animals, especially poultry. Numerous cases have been associated with sick puppies or other animal contacts. Contaminated food and water, improperly cooked poultry, and person-to-person spread by the fecal-oral route are common routes of

transmission. Outbreaks associated with day care centers, contaminated water supplies, and raw milk have been reported. Newborns may acquire the organism from their mothers at delivery.

► Clinical Findings

A. Symptoms and Signs

C jejuni enteritis can be mild or severe. In tropical countries, asymptomatic stool carriage is common. The incubation period is usually 1–7 days. The disease usually begins with sudden onset of high fever, malaise, headache, abdominal cramps, nausea, and vomiting. Diarrhea follows and may be watery or bile-stained, mucoid, and bloody. The illness is self-limiting, lasting 2–7 days, but relapses occur in 15–25% of cases. Without antimicrobial treatment, the organism remains in the stool for 1–6 weeks.

B. Laboratory Findings

The peripheral WBC count generally is elevated, with many band forms. Microscopic examination of stool reveals erythrocytes and pus cells.

Isolation of *C jejuni* from stool is not difficult but requires selective agar, incubation at 42°C rather than 35°C, and incubation in an atmosphere of about 5% oxygen and 5% CO₂ (candle jar is satisfactory).

► Differential Diagnosis

Campylobacter enteritis may resemble viral gastroenteritis, salmonellosis, shigellosis, amebiasis, or other infectious diarrheas. Because it also mimics ulcerative colitis, Crohn disease, intussusception, and appendicitis, mistaken diagnosis can lead to unnecessary surgery.

► Complications

The most common complication is dehydration. Other uncommon complications include erythema nodosum, convulsions, reactive arthritis, bacteremia, urinary tract infection, and cholecystitis. Guillain-Barré syndrome may follow *C jejuni* infection by 1–3 weeks.

► Prevention

No vaccine is available. Hand washing and adherence to basic food sanitation practices help prevent disease. Hand washing and cleaning of kitchen utensils after contact with raw poultry are important.

► Treatment

Treatment of fluid and electrolyte disturbances is important. Antimicrobial treatment with erythromycin in children (30–50 mg/kg/d orally in four divided doses for 5 days), azithromycin for 5 days, or ciprofloxacin terminates fecal excretion. Fluoroquinolone-resistant *C jejuni* are now common world-

wide. Therapy given early in the course of the illness will shorten the duration of symptoms but is unnecessary if given later. Antimicrobials used for shigellosis, such as TMP–SMX and ampicillin, are inactive against *Campylobacter*. Supportive therapy is sufficient in most cases.

► Prognosis

The outlook is excellent if dehydration is corrected and misdiagnosis does not lead to inappropriate diagnostic or surgical procedures.

TULAREMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- A cutaneous or mucous membrane lesion at the site of inoculation and regional lymph node enlargement.
- Sudden onset of fever, chills, and prostration.
- History of contact with infected animals, principally wild rabbits, or history of tick exposure.
- Positive culture or immunofluorescence from mucocutaneous ulcer or regional lymph nodes.
- High serum antibody titer.

► General Considerations

Tularemia is caused by *Francisella tularensis*, a gram-negative organism usually acquired directly from infected animals (principally wild rabbits) or by the bite of an infected tick. Occasionally infection is acquired from infected domestic dogs or cats; by contamination of the skin or mucous membranes with infected blood or tissues; by inhalation of infected material; by bites of fleas or deer flies that have been in contact with infected animals; or by ingestion of contaminated meat or water. The incubation period is short, usually 3–7 days, but may vary from 2–25 days.

Ticks are the most important vector of tularemia and rabbits are the classic vector. It is important to seek a history of rabbit hunting, skinning, or food preparation in any patient who has a febrile illness with tender lymphadenopathy, often in the region of a draining skin ulcer.

► Clinical Findings

A. Symptoms and Signs

Several clinical types of tularemia occur in children. Sixty percent of infections are of the ulceroglandular form and start as a reddened papule that may be pruritic, quickly ulcerates, and is not very painful. Soon, the regional lymph nodes become large and tender. Fluctuance quickly follows. There may be marked systemic symptoms, including high fever, chills, weakness, and vomiting. Pneumonitis occasionally accompanies the ulceroglandular form or may be seen as the sole manifestation of infection (pneumonic form). A detectable skin lesion may be absent, and localized lymphoid enlargement may exist alone (glandular form). Oculoglandular and oropharyngeal forms also occur. The latter is characterized by tonsillitis, often with membrane formation, cervical adenopathy, and high fever. In the absence of a primary ulcer or localized lymphadenitis, a prolonged febrile disease reminiscent of typhoid fever can occur (typhoidal form). Splenomegaly is common in all forms.

B. Laboratory Findings

F tularensis can be recovered from ulcers, regional lymph nodes, and sputum of patients with the pneumonic form. However, the organism grows only on an enriched medium (blood-cystine-glucose agar), and laboratory handling is dangerous owing to the risk of airborne transmission to laboratory personnel. Immunofluorescent staining of biopsy material or aspirates of involved lymph nodes is diagnostic, although it is not widely available.

The WBC count is not remarkable. Agglutinins are present after the second week of illness, and in the absence of a positive culture their development confirms the diagnosis. An agglutination titer of 1:160 or higher is considered positive.

► Differential Diagnosis

The typhoidal form of tularemia may mimic typhoid, brucellosis, miliary tuberculosis, Rocky Mountain spotted fever, and mononucleosis. Pneumonic tularemia resembles atypical or mycotic pneumonitis. The ulceroglandular type of tularemia resembles pyoderma caused by staphylococci or streptococci, plague, anthrax, and cat-scratch fever. The oropharyngeal type must be distinguished from streptococcal or diphtheritic pharyngitis, mononucleosis, herpangina, or other viral pharyngitides.

► Prevention

Children should be protected from insect bites, especially those of ticks, fleas, and deer flies, by the use of proper clothing and repellents. Because rabbits are the source of most human infections, the dressing and handling of such game should be performed with great care. If contact occurs, thorough washing with soap and water is indicated.

► Treatment

A. Specific Measures

Historically, streptomycin was the drug of choice. Gentamicin and amikacin also are efficacious, more available, and familiar to clinicians. A 10-day course is usually sufficient; although more severe infections may need longer therapy. Doxycycline is effective, but relapse rates are higher. Doxycycline is not usually recommended for children younger than 8 years of age unless benefits of use outweigh the risk of dental staining. Ciprofloxacin also can be used in patients with less severe disease. Ciprofloxacin is not approved for children younger than 18 years, and is not usually recommended in children unless benefits outweigh risks. Failures occur with ceftriaxone.

B. General Measures

Antipyretics and analgesics may be given as necessary. Skin lesions are best left open. Glandular lesions occasionally require incision and drainage.

► Prognosis

The prognosis is excellent in cases of tularemia that are recognized early and treated appropriately.

PLAGUE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Sudden onset of fever, chills, and prostration.
- Regional lymphadenitis with suppuration of nodes (bubonic form).
- Hemorrhage into skin and mucous membranes and shock (septicemia).
- Cough, dyspnea, cyanosis, and hemoptysis (pneumonia).
- History of exposure to infected animals.

► General Considerations

Plague is an extremely serious acute infection caused by a gram-negative bacillus, *Yersinia pestis*. It is a disease of

rodents that is transmitted to humans by flea bites. Plague bacilli have been isolated from rodents in 15 of the western states in the United States. Direct contact with rodents, rabbits, or domestic cats may transmit fleas infected with plague bacilli. Most cases occur from June through September. Human plague in the United States appears to occur in cycles that reflect cycles in wild animal reservoirs.

▶ Clinical Findings

A. Symptoms and Signs

Plague assumes several clinical forms; the two most common are bubonic and septicemic. Pneumonic plague, the form that occurs when organisms enter the body through the respiratory tract, is uncommon.

1. Bubonic plague—Bubonic plague begins after an incubation period of 6 days with a sudden onset of high fever, chills, headache, vomiting, and marked delirium or clouding of consciousness. A less severe form also exists, with a less precipitous onset, but with progression over several days to severe symptoms. Although the flea bite is rarely seen, the regional lymph node, usually inguinal and unilateral, is painful and tender, 1–5 cm in diameter. The node usually suppurates and drains spontaneously after 1 week. The plague bacillus produces endotoxin that causes vascular necrosis. Bacilli may overwhelm regional lymph nodes and enter the circulation to produce septicemia. Severe vascular necrosis results in widely disseminated hemorrhage in skin, mucous membranes, liver, and spleen. Myocarditis and circulatory collapse may result from damage by the endotoxin. Plague meningitis or pneumonia may occur following bacteremic spread from an infected lymph node.

2. Septicemic plague—Plague may initially present as septicemia without evidence of lymphadenopathy. In some series, 25% of cases are initially septicemic. Septicemic plague carries a worse prognosis than bubonic plague, largely because it is not recognized and treated early. Patients may present initially with a nonspecific febrile illness characterized by fever, myalgia, chills, and anorexia. Plague is frequently complicated by secondary seeding of the lung causing plague pneumonia.

3. Primary pneumonic plague—Inhalation of *Y pestis* bacilli causes primary plague pneumonia. This form of plague has been transmitted to humans from cats with pneumonic plague and would be the form of plague most likely seen after aerosolized release of *Y pestis* in a bioterrorist incident. After an incubation of 1–6 days, the patient develops fever, cough, shortness of breath, and the production of bloody, watery, or purulent sputum. Gastrointestinal symptoms are sometimes prominent. Because the initial focus of infection is the lung, buboes are usually absent; occasionally cervical buboes may be seen.

B. Laboratory Findings

Aspirate from a bubo contains bipolar-staining gram-negative bacilli. Pus, sputum, and blood all yield the organism. Rapid diagnosis can be made with fluorescent antibody detection or

polymerase chain reaction (PCR) on clinical specimens. Confirmation is made by culture or serologic testing. Laboratory infections are common enough to make bacterial isolation dangerous. Cultures are usually positive within 48 hours. Paired acute and convalescent sera may be tested for an antibody rise in those cases with negative cultures.

▶ Differential Diagnosis

The septic phase of the disease may be confused with illnesses such as meningococcemia, sepsis caused by other bacteria, and rickettsioses. The bubonic form resembles tularemia, anthrax, cat-scratch fever, streptococcal adenitis, and cellulitis. Primary gastroenteritis and appendicitis may have to be distinguished.

▶ Prevention

Proper disposal of household and commercial wastes and chemical control of rats are basic elements of plague prevention. Flea control is instituted and maintained with liberal use of insecticides. Children vacationing in remote camping areas should be warned not to handle dead or dying animals. Domestic cats that roam freely in suburban areas may contact infected wild animals and acquire infected fleas. There is no commercially available vaccine for plague.

▶ Treatment

A. Specific Measures

Streptomycin (30 mg/kg/d intramuscularly in two to three divided doses) or gentamicin (7.5 mg/kg/d intravenously in three divided doses) for 7–10 days after defervescence is effective. For patients not requiring parenteral therapy, doxycycline may be given. Doxycycline is not usually recommended for children younger than 8 years of age unless benefits of use outweigh the risk of tooth staining. Plague bacilli that are multiply resistant to antimicrobials are uncommon but of serious concern.

Mortality is extremely high in septicemic and pneumonic plague if specific antibiotic treatment is not started in the first 24 hours of the disease.

Every effort should be made to effect resolution of buboes without surgery. Pus from draining lymph nodes should be handled with gloves.

B. General Measures

Pneumonic plague is highly infectious, and droplet isolation is required until the patient has been on effective antimicrobial therapy for 48 hours. All contacts should receive prophylaxis with oral doxycycline 2.2 mg/kg per dose (maximum dose 100 mg) given twice a day for 7 days. State health officials should be notified immediately about suspected cases of plague.

C. Prophylaxis

Persons who have face-to-face contact or household exposure to a patient with plague should be instructed to closely

monitor themselves for fever or other symptoms and to seek medical attention immediately if they develop. Persons who have close personal contact (< 2 m) with a person with pneumonic plague should receive antimicrobial prophylaxis for 7 days. TMP–SMX can be used in children; doxycycline or ciprofloxacin can be used in adults.

► Prognosis

The mortality rate in untreated bubonic plague is about 50%. The mortality rate for treated pneumonic plague is 50–60%. Recent mortality rates in New Mexico were 3% for bubonic plague and 71% for the septicemic form.

HAEMOPHILUS INFLUENZAE TYPE B INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Purulent meningitis in children younger than age 4 years with direct smears of CSF showing gram-negative pleomorphic rods.
- ▶ Acute epiglottitis: high fever, drooling, dysphagia, aphonia, and stridor.
- ▶ Septic arthritis: fever, local redness, swelling, heat, and pain with active or passive motion of the involved joint in a child 4 months to 4 years of age.
- ▶ Cellulitis: sudden onset of fever and distinctive cellulitis in an infant, often involving the cheek or periorbital area.
- ▶ In all cases, a positive culture from the blood, CSF, or aspirated pus confirms the diagnosis.

► General Considerations

H influenzae type b (Hib) has become uncommon because of widespread immunization in early infancy. The 99% reduction in incidence seen in many parts of the United States is due to high rates of vaccine coverage and reduced nasopharyngeal carriage after vaccination. Forty percent of cases occur in children younger than 6 months who are too young to have completed a primary immunization series. Hib may cause meningitis, bacteremia, epiglottitis

(supraglottic croup), septic arthritis, periorbital and facial cellulitis, pneumonia, and pericarditis.

Disease due to *H influenzae* types A, C, D, E, F, or unencapsulated strains is rare, but it now accounts for a larger proportion of positive culture results. Third-generation cephalosporins are preferred for initial therapy of Hib infections. Ampicillin is adequate for culture-proved Hib susceptible strains.

Unencapsulated, nontypeable *H influenzae* frequently colonize the mucous membranes and cause otitis media, sinusitis, bronchitis, and pneumonia in children and adults. Bacteremia is uncommon. Neonatal sepsis similar to early-onset GBS is recognized. Obstetric complications of chorioamnionitis and bacteremia are usually the source of neonatal cases.

Ampicillin resistance occurs in 25–40% of nontypeable *H influenzae*.

► Clinical Findings

A. Symptoms and Signs

1. Meningitis—Infants usually present with fever, irritability, lethargy, poor feeding with or without vomiting, and a high-pitched cry.

2. Acute epiglottitis—The most useful clinical finding in the early diagnosis of Hib epiglottitis is evidence of dysphagia, characterized by a refusal to eat or swallow saliva and by drooling. This finding, plus the presence of a high fever in a toxic child—even in the absence of a cherry-red epiglottitis on direct examination—should strongly suggest the diagnosis and lead to prompt intubation. Stridor is a late sign. (See Chapter 18.)

3. Septic arthritis—Hib is a common cause of septic arthritis in unimmunized children younger than age 4 years in the United States. The child is febrile and refuses to move the involved joint and limb because of pain. Examination reveals swelling, warmth, redness, tenderness on palpation, and severe pain on attempted movement of the joint.

4. Cellulitis—Cellulitis due to Hib occurs almost exclusively in children between the ages of 3 months and 4 years but is now uncommon as a result of immunization. Fever is usually noted at the same time as the cellulitis, and many infants appear toxic. The cheek or periorbital (preseptal) area is usually involved.

B. Laboratory Findings

The WBC count in Hib infections may be high or normal with a shift to the left. Blood culture is frequently positive. Positive culture of aspirated pus or fluid from the involved site proves the diagnosis. In untreated meningitis, CSF smear may show the characteristic pleomorphic gram-negative rods.

C. Imaging

A lateral view of the neck may suggest the diagnosis in suspected acute epiglottitis, but misinterpretation is common. Intubation should not be delayed to obtain radiographs. Haziness of maxillary and ethmoid sinuses occurs with orbital cellulitis.

► Differential Diagnosis

A. Meningitis

Meningitis must be differentiated from head injury, brain abscess, tumor, lead encephalopathy, and other forms of meningoencephalitis, including mycobacterial, viral, fungal, and bacterial agents.

B. Acute Epiglottitis

In croup caused by viral agents (parainfluenza 1, 2, and 3, respiratory syncytial virus, influenza A, adenovirus), the child has more definite upper respiratory symptoms, cough, hoarseness, slower progression of obstructive signs, and lower fever. Spasmodic croup usually occurs at night in a child with a history of previous attacks. Sudden onset of choking and paroxysmal coughing suggests foreign body aspiration. Retropharyngeal abscess may have to be differentiated from epiglottitis.

C. Septic Arthritis

Differential diagnosis includes acute osteomyelitis, prepatellar bursitis, cellulitis, rheumatic fever, and fractures and sprains.

D. Cellulitis

Erysipelas, streptococcal cellulitis, insect bites, and trauma (including popsicle panniculitis or other types of freezing injury) may mimic Hib cellulitis. Periorbital cellulitis must be differentiated from paranasal sinus disease without cellulitis, allergic inflammatory disease of the lids, conjunctivitis, and herpes zoster infection.

► Complications

A. Meningitis (See Chapter 23)

B. Acute Epiglottitis

The disease may rapidly progress to complete airway obstruction with complications owing to hypoxia. Mediastinal emphysema and pneumothorax may occur.

C. Septic Arthritis

Septic arthritis may result in rapid destruction of cartilage and ankylosis if diagnosis and treatment are delayed. Even with early treatment, the incidence of residual damage and

disability after septic arthritis in weight-bearing joints may be as high as 25%.

D. Cellulitis

Bacteremia may lead to meningitis or pyarthrosis.

► Prevention

Four separate carbohydrate protein conjugate Hib vaccines are currently available. (See Chapter 9.)

The risk of invasive Hib disease is highest in unimmunized, or partially immunized, household contacts who are younger than 4 years of age. The following situations require rifampin chemoprophylaxis of all household contacts to eradicate potential nasopharyngeal colonization with Hib and limit risk of invasive disease: (1) families where at least one household contact is younger than age 4 years and either unimmunized or incompletely immunized against Hib; (2) an immunocompromised child (of any age or immunization status) resides in the household; or (3) a child younger than age 12 months resides in the home and has not received three doses of the Hib vaccine. Preschool and day care center contacts may need prophylaxis if more than one case has occurred in the center in the previous 60 days (discuss with state health officials). The index case also needs chemoprophylaxis unless treated with ceftriaxone or cefotaxime (both are effective in eradication of Hib from the nasopharynx). Household contacts and index cases younger than 1 month of age who need chemoprophylaxis should be given rifampin, 20 mg/kg per dose (maximum adult dose, 600 mg) orally, once daily for 4 successive days. Infants who are younger than 1 month of age should be given oral rifampin (10 mg/kg per dose once daily for 4 days). Rifampin should not be used in pregnant females.

► Treatment

All patients with bacteremic or potentially bacteremic Hib diseases require hospitalization for treatment. The drugs of choice in hospitalized patients are a third-generation cephalosporin (cefotaxime or ceftriaxone) until the sensitivity of the organism is known. Meropenem is an alternative choice.

Persons with invasive Hib disease should be in droplet isolation for 24 hours after initiation of parenteral antibiotic therapy.

A. Meningitis

Therapy is begun as soon as bacterial meningitis has been identified and CSF, blood, and other appropriate cultures have been obtained. Therapy is begun with cefotaxime (50 mg/kg intravenously every 6 hours) or ceftriaxone (50 mg/kg intravenously every 12 hours). If the organism is sensitive to ampicillin, it is the drug of choice. Therapy should preferably be given intravenously for the entire course. Ceftriaxone may be given intramuscularly if venous access becomes difficult.

Duration of therapy is 10 days for uncomplicated meningitis. Longer treatment is reserved for children who respond slowly or in whom complications have occurred.

Dexamethasone given immediately after diagnosis and continued for 4 days may reduce the incidence of hearing loss in children with Hib meningitis. The use of dexamethasone is controversial, but when it is used the dosage is 0.6 mg/kg/d in four divided doses for 4 days. Starting dexamethasone more than 6 hours after antibiotics have been initiated is unlikely to provide benefits.

Repeated lumbar punctures are usually not necessary in Hib meningitis. They should be obtained in the following circumstances: unsatisfactory or questionable clinical response, seizure occurring after several days of therapy, and prolonged (7 days) or recurrent fever if the neurologic examination is abnormal or difficult to evaluate.

B. Acute Epiglottitis (See Chapter 18)

C. Septic Arthritis

Initial therapy should include an effective antistaphylococcal antibiotic and cefotaxime or ceftriaxone (dosage as for meningitis). If the isolate is sensitive to ampicillin, it is given in a dosage of 200–300 mg/kg/d intravenously in four divided doses. If a child is improved following initial intravenous therapy, oral amoxicillin (75–100 mg/kg/d in four divided doses every 6 hours) may be administered under careful supervision to complete a 2-week course. Alternative oral agents for ampicillin-resistant organisms include amoxicillin–clavulanic acid or second- or third-generation cephalosporins. Ideally, susceptibility to these agents should be proved prior to use. Drainage of infected joint fluid is an essential part of treatment. In joints other than the hip, this can often be accomplished by one or more needle aspirations. In hip infections—and in arthritis of other joints when treatment is delayed or clinical response is slow—surgical drainage is advised. The joint should be immobilized.

D. Cellulitis, Including Orbital Cellulitis

Initial therapy should include an agent effective against staphylococci in combination with cefotaxime or ceftriaxone. Ampicillin may be used if the isolate is susceptible. Therapy is given parenterally for 3–7 days, followed by oral treatment as for septic arthritis, and supportive and symptomatic treatment as required. There is usually marked improvement after 72 hours of treatment. Antibiotics should be given for at least 10–14 days.

► Prognosis

The case fatality rate for Hib meningitis is less than 5%. Young infants have the highest mortality rate. One of the most common neurologic sequelae, developing in 5–10% of patients with Hib meningitis, is sensorineural hearing loss. Patients with Hib meningitis should have their hearing

checked during the course of the illness or shortly after recovery. Children in whom invasive Hib infection develops despite appropriate immunization should have tests to investigate immune function and to rule out HIV. The case fatality rate in acute epiglottitis is 2–5%. Deaths are associated with bacteremia and the rapid development of airway obstruction. The prognosis for the other diseases requiring hospitalization is good with the institution of early and adequate antibiotic therapy.

PERTUSSIS (WHOOING COUGH)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Prodromal catarrhal stage (1–3 weeks) characterized by mild cough and coryza, but without fever.
- Persistent staccato, paroxysmal cough ending with a high-pitched inspiratory “whoop.”
- Leukocytosis with absolute lymphocytosis.
- Diagnosis confirmed by PCR or culture of nasopharyngeal secretions.

► General Considerations

Pertussis is an acute, highly communicable infection of the respiratory tract caused by *Bordetella pertussis* and characterized by severe bronchitis. Children usually acquire the disease from symptomatic family contacts. Adults who have mild respiratory illness, not recognized as pertussis, frequently are the source of infection. Asymptomatic carriage of *B pertussis* is not recognized. Infectivity is greatest during the catarrhal and early paroxysmal cough stage (for about 4 weeks after onset).

Pertussis cases have increased in the United States since 1980. In 2004 and 2005, about 20,000 cases were reported. The morbidity and mortality of pertussis is greatest in young children. Fifty percent of children younger than age 1 year with a diagnosis of pertussis are hospitalized.

The duration of active immunity following natural pertussis is not known. Reinfections are usually milder. Immunity following vaccination wanes in 5–10 years. The majority of young adults in the United States are susceptible to pertussis infection, and disease is probably common but unrecognized.

Bordetella parapertussis causes a similar but milder syndrome.

B pertussis organisms attach to the ciliated respiratory epithelium and multiply there; deeper invasion does not occur. Disease is due to several bacterial toxins, the most potent of which is pertussis toxin, which is responsible for lymphocytosis and many of the symptoms of pertussis.

► Clinical Findings

A. Symptoms and Signs

The onset of pertussis is insidious, with catarrhal upper respiratory tract symptoms (rhinitis, sneezing, and an irritating cough). Slight fever may be present; temperature greater than 38.3°C suggests bacterial superinfection or another cause of respiratory tract infection. After about 2 weeks, cough becomes paroxysmal, characterized by 10–30 forceful coughs ending with a loud inspiration (the whoop). Infants and adults with otherwise typical severe pertussis often lack characteristic whooping. Vomiting commonly follows a paroxysm. Coughing is accompanied by cyanosis, sweating, prostration, and exhaustion. This stage lasts for 2–4 weeks, with gradual improvement. Cough suggestive of chronic bronchitis lasts for another 2–3 weeks. Paroxysmal coughing may continue for some months and may worsen with intercurrent viral respiratory infection. In adults, older children, and partially immunized individuals, symptoms may consist only of irritating cough lasting 1–2 weeks. Clinical pertussis is milder in immunized children.

B. Laboratory Findings

WBC counts of 20,000–30,000/μL with 70–80% lymphocytes typically appear near the end of the catarrhal stage. Severe pulmonary hypertension and hyperleukocytosis are associated with severe disease and death in young children with pertussis. Many older children and adults with mild infections never demonstrate lymphocytosis. The blood picture may resemble lymphocytic leukemia or leukemoid reactions. Identification of *B pertussis* by culture or PCR from nasopharyngeal swabs or nasal wash specimens proves the diagnosis. The organism may be found in the respiratory tract in diminishing numbers beginning in the catarrhal stage and ending about 2 weeks after the beginning of the paroxysmal stage. After 4–5 weeks of symptoms, cultures are almost always negative. Culture requires specialized media and careful attention to specimen collection and transport. PCR detection is replacing culture in most pediatric centers because of improved sensitivity, decreased time to diagnosis, and cost. Enzyme-linked immunosorbent assays (ELISAs) for detection of antibody to pertussis toxin or filamentous hemagglutinin may be useful for diagnosis but interpretation of antibody titers may be difficult in previously immunized patients. The chest radiograph reveals thickened bronchi and sometimes shows a “shaggy” heart border.

► Differential Diagnosis

The differential diagnosis of pertussis includes bacterial, tuberculous, chlamydial, and viral pneumonia. Cystic fibro-

sis and foreign body aspiration may be considerations. Adenoviruses and respiratory syncytial virus may cause paroxysmal coughing with an associated elevation of lymphocytes in the peripheral blood, mimicking pertussis.

► Complications

Bronchopneumonia due to superinfection is the most common serious complication. It is characterized by abrupt clinical deterioration during the paroxysmal stage, accompanied by high fever and sometimes a striking leukemoid reaction with a shift to predominantly polymorphonuclear neutrophils. Atelectasis is a second common pulmonary complication. Atelectasis may be patchy or extensive and may shift rapidly to involve different areas of lung. Intercurrent viral respiratory infection is also a common complication and may provoke worsening or recurrence of paroxysmal coughing. Otitis media is common. Residual chronic bronchiectasis is infrequent despite the severity of the illness. Apnea and sudden death may occur during a particularly severe paroxysm. Seizures complicate 1.5% of cases, and encephalopathy occurs in 0.1%. The encephalopathy frequently is fatal. Anoxic brain damage, cerebral hemorrhage, or pertussis neurotoxins are hypothesized, but anoxia is most likely the cause. Epistaxis and subconjunctival hemorrhages are common.

► Prevention

Active immunization (see Chapter 9) with DTaP vaccine should be given in early infancy. The recent increase in incidence of pertussis is primarily due to increased recognition of disease in adolescents and adults. A booster dose of vaccine in adolescents between the ages of 11 and 18 years is recommended. Subsequent booster doses of Tdap are recommended for adults aged 18–60 years to replace Td boosters.

Chemoprophylaxis with azithromycin or erythromycin should be given to exposed family and hospital contacts, particularly those younger than age 2 years, although data to support the efficacy of such preventive therapy are not strong. Hospitalized children with pertussis should be isolated because of the great risk of transmission to patients and staff. Several large hospital outbreaks have been reported.

► Treatment

A. Specific Measures

Antibiotics may ameliorate early infections but have no effect on clinical symptoms in the paroxysmal stage. Erythromycin is the drug of choice because it promptly terminates respiratory tract carriage of *B pertussis*. Resistance to macrolides has been rarely reported. Patients should be given erythromycin estolate (40–50 mg/kg/24 h in four divided doses for 14 days). A recent study suggests that 7 days and 14 days of treatment are equally effective. Treatment with clarithromycin for 7 days and azithromycin for 5 days was equal to erythromycin for 14

days. Ampicillin (100 mg/kg/d in four divided doses) may also be used for erythromycin-intolerant patients. Azithromycin is often preferred due to ease of compliance and decreased gastrointestinal side effects.

Corticosteroids reduce the severity of disease but may mask signs of bacterial superinfection. Albuterol (0.3–0.5 mg/kg/d in four doses) has reduced the severity of illness, but tachycardia is common when the drug is given orally, and aerosol administration may precipitate paroxysms.

B. General Measures

Nutritional support during the paroxysmal phase is important. Frequent small feedings, tube feeding, or parenteral fluid supplementation may be needed. Minimizing stimuli that trigger paroxysms is probably the best way of controlling cough. In general, cough suppressants are of little benefit.

C. Treatment of Complications

Respiratory insufficiency due to pneumonia or other pulmonary complications should be treated with oxygen and assisted ventilation if necessary. Convulsions are treated with oxygen and anticonvulsants. Bacterial pneumonia or otitis media requires additional antibiotics.

► Prognosis

The prognosis for patients with pertussis has improved in recent years because of excellent nursing care, treatment of complications, attention to nutrition, and modern intensive care. However, the disease is still very serious in infants younger than age 1 year; most deaths occur in this age group. Children with encephalopathy have a poor prognosis.

LISTERIOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Early-onset neonatal disease:

- Signs of sepsis a few hours after birth in an infant born with fetal distress and hepatosplenomegaly; maternal fever.

Late-onset neonatal disease:

- Meningitis, sometimes with monocytosis in the CSF and peripheral blood.
- Onset at age 9–30 days.

► General Considerations

Listeria monocytogenes is a gram-positive, non-spore-forming aerobic rod distributed widely in the animal kingdom and in food, dust, and soil. It causes systemic infections in newborn infants and immunosuppressed older children. In pregnant women, infection is relatively mild, with fever, aches, and chills, but is accompanied by bacteremia and sometimes results in intrauterine or perinatal infection with grave consequences for the fetus or newborn. One fourth of cases occur in pregnant women, and 20% of their pregnancies end in stillbirth or neonatal death. *Listeria* is present in the stool of approximately 10% of the healthy population. Persons in contact with animals are at greater risk. Outbreaks of listeriosis have been traced to contaminated cabbage in coleslaw, soft cheese, hot dogs, luncheon meats, and milk. *Listeria* infections have decreased since the adoption of strict regulations for ready-to-eat foods; fewer than 900 cases were reported in 2005.

Like GBS infections, *Listeria* infections in the newborn can be divided into early and late forms. Early infections are more common, leading to a severe congenital form of infection. Later infections are often characterized by meningitis.

► Clinical Findings

A. Symptoms and Signs

In the early neonatal form, symptoms of listeriosis usually appear on the first day of life and always by the third day. Fetal distress is common, and infants frequently have signs of severe disease at birth. Respiratory distress, diarrhea, and fever occur. On examination, hepatosplenomegaly and a papular rash are found. A history of maternal fever is common. Meningitis may accompany the septic course. The late neonatal form usually occurs after age 9 days and can occur as late as 5 weeks. Meningitis is common, characterized by irritability, fever, and poor feeding.

Listeria infections are rare in older children and usually are associated with immunodeficiency. Several recent cases were associated with tumor necrosis factor- α neutralizing agents. Signs and symptoms are those of meningitis, usually with insidious onset.

B. Laboratory Findings

In all patients except those receiving white cell depressant drugs, the WBC count is elevated, with 10–20% monocytes. When meningitis is found, the characteristic CSF cell count is high (> 500/ μ L) with a predominance of polymorphonuclear

clear neutrophils in 70% of cases. Monocytes may predominate in up to 30% of cases. Gram-stained smears of CSF are usually negative, but short gram-positive rods may be seen. The chief pathologic feature in severe neonatal sepsis is miliary granulomatosis with microabscesses in liver, spleen, CNS, lung, and bowel.

Culture results are frequently positive from multiple sites, including blood from the infant and the mother.

► Differential Diagnosis

Early-onset neonatal disease resembles hemolytic disease of the newborn, GBS sepsis or severe cytomegalovirus infection, rubella, or toxoplasmosis. Late-onset disease must be differentiated from meningitis due to echovirus and coxsackievirus, GBS, and gram-negative enteric bacteria.

► Prevention

Immunosuppressed, pregnant, and elderly patients can decrease the risk of *Listeria* infection by avoiding soft cheeses, by thoroughly reheating or avoiding delicatessen and ready-to-eat foods, by avoiding raw meat and milk, and by thoroughly washing fresh vegetables.

► Treatment

Ampicillin (150–300 mg/kg/d every 6 hours intravenously) is the drug of choice in most cases of listeriosis. Gentamicin (2.5 mg/kg every 8 hours intravenously) has a synergistic effect with ampicillin and should be given in serious infections and to patients with immune deficits. Vancomycin may be substituted for ampicillin when empirically treating meningitis. If ampicillin cannot be used, TMP-SMX also is effective. Cephalosporins are not effective. Treatment of severe disease should continue for at least 2 weeks.

► Prognosis

In a recent outbreak of early-onset neonatal disease, the mortality rate was 27% despite aggressive and appropriate management. Meningitis in older infants has a good prognosis. In immunosuppressed children, prognosis depends to a great extent on that of the underlying illness.

TUBERCULOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- All types: positive tuberculin test in patient or members of household, suggestive chest radiograph, history of contact, and demonstration of organism by stain and culture.
- Pulmonary: fatigue, irritability, and undernutrition, with or without fever and cough.
- Glandular: chronic cervical adenitis.
- Miliary: classic snowstorm appearance of chest radiograph.
- Meningitis: fever and manifestations of meningeal irritation and increased intracranial pressure. Characteristic CSF.

► General Considerations

Tuberculosis is a granulomatous disease caused by *Mycobacterium tuberculosis*. It is a leading cause of death throughout the world. Children younger than age 3 years are most susceptible. Lymphohematogenous dissemination through the lungs to extrapulmonary sites, including the brain and meninges, eyes, bones and joints, lymph nodes, kidneys, intestines, larynx, and skin, is more likely to occur in infants. Increased susceptibility occurs again in adolescence, particularly in girls within 2 years of menarche. Following substantial increases in disease during the 1980s, tuberculosis incidence has decreased since 1992 due to increased control measures. More than 10,000 new cases were reported in 2005. High-risk groups include ethnic minorities, foreign-born persons, prisoners, residents of nursing homes, indigents, migrant workers, and health care providers. However, 50% of cases occurred in U.S.-born persons. HIV infection is an important risk factor for both development and spread of disease. Pediatric tuberculosis incidence mirrors the trends seen in adults.

Exposure to an infected adult is the most common risk factor in children. The primary complex in infancy and childhood consists of a small parenchymal lesion in any area of the lung with caseation of regional nodes and calcification. Post-primary tuberculosis in adolescents and adults commonly occurs in the apices of the lungs and is likely to cause chronic progressive cavitary pulmonary disease with less tendency for hematogenous dissemination. *Mycobacterium bovis* infection is clinically identical to *M tuberculosis*. *M bovis* may be acquired from unpasteurized dairy products obtained outside the United States.

► Clinical Findings

A. Symptoms and Signs

1. Pulmonary—(See Chapter 18.)

2. Miliary—Diagnosis is usually based on the classic “snowstorm” or “millet seed” appearance of lung fields on radiograph, although early in the course of disseminated tuberculosis the chest radiograph may show no or only subtle abnormalities. Choroidal tubercles are sometimes seen on fundoscopic examination. Other lesions may be present and produce osteomyelitis, arthritis, meningitis, tuberculomas of the brain, enteritis, or infection of the kidneys and liver.

3. Meningitis—Symptoms include fever, vomiting, headache, lethargy, and irritability, with signs of meningeal irritation and increased intracranial pressure, cranial nerve palsies, convulsions, and coma.

4. Lymphatic—The primary complex may be associated with a skin lesion drained by regional nodes or chronic cervical node enlargement or infection of the tonsils. Involved nodes may become fixed to the overlying skin, suppurate, and drain.

B. Laboratory Findings

The Mantoux test (0.1 mL of intermediate-strength purified protein derivative [PPD] [5 TU] inoculated intradermally) is positive at 48–72 hours if there is significant induration (Table 40–2). Parental reporting of skin test results is often inaccurate. All tests should be read by professionals trained to interpret Mantoux tests. False-negative results occur in malnourished patients, in those with overwhelming disease, and in 10% of children with isolated pulmonary disease. Temporary suppression of tuberculin reactivity may be seen with viral infections (eg, measles, influenza, varicella, and mumps), after live virus immunization, and during corticosteroid or other immunosuppressive drug therapy. For these reasons, a negative Mantoux test does not exclude the diagnosis of tuberculosis. When tuberculosis is suspected in a child, household members and adult contacts (eg, teachers and caregivers) also should be tested immediately. Multiple puncture tests (tine tests) should not be used because they are associated with false-negative and false-positive reactions, and because standards for interpretation of positive results do not exist. γ -Interferon release assays are approved to replace Mantoux skin tests in adults. These assays have much higher specificity due to less common false-positive results from nontuberculosis mycobacteria and BCG. They are done on blood obtained by venipuncture and are further advantageous in requiring only a single visit; however, these tests are not yet sufficiently studied in children.

The ESR is usually elevated. Cultures of pooled early morning gastric aspirates from three successive days will yield *M tuberculosis* in about 40% of cases. Biopsy may be necessary to establish the diagnosis. Therapy should not be delayed in sus-

Table 40–2. Interpretation of tuberculin skin test reactions.^a

Degree of Risk	Risk Factors	Positive Reaction
High	Recent close contact with a case of active tuberculosis Chest radiograph compatible with tuberculosis Immunocompromise HIV infection	≥ 5 mm induration
Medium	Current or previous residence in high-prevalence area (Asia, Africa, Latin America) Skin test converters within past 2 y Intravenous drug use Homelessness or residence in a correctional institution Recent weight loss or malnutrition Leukemia, Hodgkin disease, or diabetes mellitus Age < 4 y	≥ 10 mm induration
Low	Children ≥ 4 y without any risk factor	≥ 15 mm induration

^aStandard intradermal Mantoux test, 5 test units.

pected cases. The CSF in tuberculous meningitis shows slight to moderate pleocytosis (50–300 WBCs/ μ L, predominantly lymphocytes), decreased glucose, and increased protein.

The direct detection of mycobacteria in body fluids or discharges is best done by staining specimens with auramine-rhodamine and examining them with fluorescence microscopy; this method is superior to the Ziehl-Neelsen method.

C. Imaging

Chest radiograph should be obtained in all children with suspicion of tuberculosis at any site or with a positive skin test. Segmental consolidation with some volume loss and hilar adenopathy are common findings in children. Pleural effusion also occurs with primary infection. Cavities and apical disease are unusual in children but are common in adolescents and adults.

► Differential Diagnosis

Pulmonary tuberculosis must be differentiated from fungal, parasitic, mycoplasmal, and bacterial pneumonias; lung abscess; foreign body aspiration; lipoid pneumonia; sarcoidosis; and mediastinal cancer. Cervical lymphadenitis is most likely due to streptococcal or staphylococcal infections. Cat-scratch fever and infection with atypical mycobacteria may need to be distinguished from tuberculous lymphade-

nitis. Viral meningoencephalitis, head trauma (child abuse), lead poisoning, brain abscess, acute bacterial meningitis, brain tumor, and disseminated fungal infections must be excluded in tuberculous meningitis. The skin test in the patient or family contacts is frequently valuable in differentiating these conditions from tuberculosis.

▶ Prevention

A. BCG Vaccine

Bacille Calmette–Guérin (BCG) vaccines are live-attenuated strains of *M bovis*. Although neonatal and childhood administration of BCG is carried out in countries with a high prevalence of tuberculosis, protective efficacy varies greatly with vaccine potency and method of delivery. Because the great majority of children who have received BCG still have negative Mantoux tests, the past history of BCG vaccination should be ignored in interpreting the skin test. In the United States, BCG vaccination is not recommended.

B. Isoniazid Chemoprophylaxis

Daily administration of isoniazid (10 mg/kg/d orally; maximum 300 mg) is advised for children who are exposed by prolonged close or household contact with adolescents or adults with active disease. Isoniazid is given until 2 months after last contact. At the end of this time, a Mantoux test should be done, and therapy should be continued for an additional 7 months if the test is positive.

C. Other Measures

Tuberculosis in infants and young children is evidence of recent exposure to active infection in an adult, usually a family member or household contact. The source contact (index case) should be identified, isolated, and given treatment to prevent other secondary cases. Reporting cases to local health departments is essential for contact tracing. Exposed tuberculin-negative children should usually receive isoniazid chemoprophylaxis. If a repeated skin test is negative 2–3 months following the last exposure, isoniazid may be stopped. Routine tuberculin skin testing is not recommended for children without risk factors who reside in communities with a low incidence of tuberculosis. Children with no personal risk for tuberculosis but who reside in communities with a high incidence of tuberculosis should be given a skin test at school entry and then again at age 11–16 years. Children with a risk factor for acquiring tuberculosis should be tested every 2–3 years. Incarcerated adolescents and children living in a household with HIV-infected persons should have annual skin tests.

Children who immigrate into the United States from a country with a high incidence of infection should receive a skin test on entry to the United States or upon presentation to health care providers. A past history of BCG vaccine should not delay skin testing.

▶ Treatment

A. Specific Measures

Most children with tuberculosis in the United States are hospitalized initially. If the infecting organism has not been isolated from the presumed contact for susceptibility testing, reasonable attempts should be made to obtain it from the child using morning gastric aspirates, sputum, bronchoscopy, thoracentesis, or biopsy when appropriate. Unfortunately, cultures are frequently negative in children, and the risk of these procedures must be weighed against the yield. Therapy is given daily for 14 days and then reduced to 2–3 times per week for the duration of the course. Directly observed administration of all doses of antituberculosis therapy by a trained health care professional is essential to ensure compliance with therapy.

Children with positive skin tests (see Table 40–2) without evidence of active disease have latent tuberculosis and should receive 9 months of isoniazid (10 mg/kg/d orally; maximum 300 mg) therapy. In children with active pulmonary disease, therapy for 6 months using isoniazid (10 mg/kg/d), rifampin (15 mg/kg/d), and pyrazinamide (25–30 mg/kg/d) in a single daily oral dose for 2 months, followed by isoniazid plus rifampin (either in a daily or twice-weekly regimen) for 4 months appears effective for eliminating isoniazid-susceptible organisms. For more severe disease, such as miliary or CNS infection, duration is increased to 12 months or more, and a fourth drug (streptomycin or ethambutol) is added for the first 2 months. In communities with resistance rates greater than 4%, initial therapy should usually include four drugs.

1. Isoniazid—The hepatotoxicity from isoniazid seen in adults and some adolescents is rare in children. Transient elevation of aminotransferases (up to three times normal) may be seen at 6–12 weeks, but therapy is continued unless clinical illness occurs. Routine monitoring of liver function tests is unnecessary unless prior hepatic disease is known or the child is severely ill. Peripheral neuropathy associated with pyridoxine deficiency is rare in children, and it is not necessary to add pyridoxine unless significant malnutrition coexists.

2. Rifampin—Although it is an excellent bactericidal agent, rifampin is never used alone owing to rapid development of resistance. Hepatotoxicity may occur but rarely with recommended doses. The orange discoloration of secretions is benign but may stain contact lenses or clothes.

3. Pyrazinamide—This excellent sterilizing agent is most effective during the first 2 months of therapy. With the recommended duration and dosing, it is well tolerated. Although pyrazinamide elevates the uric acid level, it rarely causes symptoms of hyperuricemia in children. Use of this drug is now common for tuberculous disease in children, and resistance is almost unknown. Oral acceptance and CNS penetration are good.

4. Ethambutol—Because optic neuritis is the major side effect in adults, ethambutol has usually been given only to children whose vision can be reliably tested for loss of color differentiation. Optic neuritis is rare and usually occurs in those receiving more than the recommended dosage of 25 mg/kg/d. Documentation of optic toxicity in children is lacking despite considerable worldwide experience. Therefore, many four-drug regimens for children now include ethambutol.

5. Streptomycin—Streptomycin (20–30 mg/kg/d, given intramuscularly in one or two doses) should be given for 1 or 2 months in severe disease. The child's hearing should be tested periodically during use as ototoxicity is common.

B. Chemotherapy for Drug-Resistant Tuberculosis

The incidence of drug resistance is increasing and reaches 10–20% in some areas of the United States. Transmission of multiply drug-resistant and extensively drug-resistant strains to contacts has occurred in some epidemics. Consultation with local experts in treating tuberculosis is important in these difficult cases. Therapy should continue for 12 months or longer. Often, four to six first- and second-line medications are needed.

C. General Measures

Corticosteroids may be used for suppressing inflammatory reactions in meningeal, pleural, and pericardial tuberculosis and for the relief of bronchial obstruction due to hilar adenopathy. Prednisone is given orally, 1 mg/kg/d for 6–8 weeks, with gradual withdrawal at the end of that time. The use of corticosteroids may mask progression of disease. Accordingly, the clinician needs to be sure that an effective regimen is being used.

► Prognosis

If bacteria are sensitive and treatment is completed, most children are cured with minimal sequelae. Repeat treatment is more difficult and less successful. With antituberculosis chemotherapy (especially isoniazid), there should now be nearly 100% recovery in miliary tuberculosis. Without treatment, the mortality rate in both miliary tuberculosis and tuberculous meningitis is almost 100%. In the latter form, about two thirds of patients receiving treatment survive. There may be a high incidence of neurologic abnormalities among survivors if treatment is started late.

INFECTIONS WITH NONTUBERCULOUS MYCOBACTERIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Chronic unilateral cervical lymphadenitis.
- Granulomas of the skin.
- Chronic bone lesion with draining sinus (chronic osteomyelitis).
- Reaction to PPD-S (standard) of 5–8 mm, negative chest radiograph, and negative history of contact with tuberculosis.
- Diagnosis by positive acid-fast stain or culture.
- Disseminated infection in patients with AIDS.

► General Considerations

Various species of acid-fast mycobacteria other than *M tuberculosis* may cause subclinical infections and occasionally clinical disease resembling tuberculosis. Strains of nontuberculous mycobacteria are common in soil, food, and water. Organisms enter the host by small abrasions in skin, oral mucosa, or gastrointestinal mucosa. Strain cross-reactivity with *M tuberculosis* can be demonstrated by simultaneous skin testing (Mantoux) with PPD-S (standard) and PPD prepared from one of the atypical antigens. Unfortunately, reagents prepared for routine nontuberculosis skin testing are not available to clinicians.

The Runyon classification of mycobacteria includes the following:

Group I. Photochromogens (PPD-Y): (*Mycobacterium kansasii*, *M marinum*) Yellow color develops on exposure to light in previously white colony grown 2–4 weeks in the dark.

Group II. Scotochromogens (PPD-G): (*Mycobacterium scrofulaceum*) Colonies are definitely yellow-orange after incubation in the dark. Organisms may be found in small numbers in the normal flora of some human saliva and gastric contents. Subclinical infection is widespread in the United States, but clinical disease appears rarely.

Group III. Nonphotochromogens (PPD-B): “Battey avian-swine group” grows as small white colonies after incubation in the dark, with no significant development of pigment on exposure to light. Infection with *Mycobacterium*

avium complex (MAC) is prevalent on the East Coast of the United States, particularly the Southeast, and in patients with AIDS.

Group IV. “Rapid growers”: (*Mycobacterium fortuitum*, *M chelonae*) Within 1 week after inoculation they form colonies closely resembling *M tuberculosis* morphologically.

▶ Clinical Findings

A. Symptoms and Signs

1. Lymphadenitis—In children, the most common form of infection due to mycobacteria other than *M tuberculosis* is cervical lymphadenitis. MAC is the most common organism. A submandibular or cervical node swells slowly and is firm and initially somewhat tender. Low-grade fever may occur. Over time, the node suppurates and may drain chronically. Nodes in other areas of the head and neck and elsewhere are sometimes involved.

2. Pulmonary disease—In the western United States, pulmonary disease is usually due to *M kansasii*. In the eastern United States, it may be due to MAC. In other countries, disease is usually caused by MAC. In adults, there is usually underlying chronic pulmonary disease. Immunologic deficiency may be present. Presentation is clinically indistinguishable from that of tuberculosis. Adolescents with cystic fibrosis may be infected with nontuberculous mycobacteria.

3. Swimming pool granuloma—This is due to *M marinum*. A solitary chronic granulomatous lesion with satellite lesions develops after minor trauma in infected swimming pools. Minor trauma in home aquariums or other aquatic environments also may lead to infection.

4. Chronic osteomyelitis—Osteomyelitis is caused by *M kansasii*, *M fortuitum*, or other rapid growers. Findings include swelling and pain over a distal extremity, radiolucent defects in bone, fever, and clinical and radiographic evidence of bronchopneumonia. Such cases are rare.

5. Meningitis—Disease is due to *M kansasii* and may be indistinguishable from tuberculous meningitis.

6. Disseminated infection—Rarely, apparently immunologically normal children develop disseminated infection due to nontuberculous mycobacteria. Children are ill, with fever and hepatosplenomegaly, and organisms are demonstrated in bone lesions, lymph nodes, or liver. Chest radiographs are usually normal. Between 60% and 80% of patients with AIDS will acquire MAC infection, characterized by fever, night sweats, weight loss, and diarrhea. Infection usually indicates severe immune dysfunction and is associated with CD4 lymphocyte counts less than 50/ μ L.

B. Laboratory Findings

In most cases, there is a small reaction (< 10 mm) when Mantoux testing is done. Larger reactions may be seen. The

chest radiograph is negative, and there is no history of contact with a case of tuberculosis. Needle aspiration of the node excludes bacterial infection and may yield acid-fast bacilli on stain or culture. Fistulization should not be a problem because total excision is usually recommended for infection due to atypical mycobacteria. Cultures of any normally sterile body site will yield MAC in immunocompromised patients with disseminated disease. Blood cultures are positive, with a large density of bacteria.

▶ Differential Diagnosis

See section on differential diagnosis in the previous discussion of tuberculosis and in Chapter 18.

▶ Treatment

A. Specific Measures

The usual treatment of lymphadenitis is complete surgical excision. Occasionally excision is impossible because of proximity to branches of the facial nerve. Chemotherapy may then be necessary. Response of extensive adenopathy or other forms of infection varies according to the infecting species and susceptibility. Usually, combinations of two to four medications administered for months are required. Isoniazid, rifampin, and ethambutol (depending on sensitivity to isoniazid) will result in a favorable response in almost all patients with *M kansasii* infection. Chemotherapeutic treatment of MAC is much less satisfactory because resistance to isoniazid, rifampin, and pyrazinamide is common. Susceptibility testing is necessary to optimize therapy. Most clinicians favor surgical excision of involved tissue if possible and treatment with at least three drugs to which the organism has been shown to be sensitive. Disseminated disease in patients with AIDS calls for a combination of three or more active drugs. Clarithromycin or azithromycin and ethambutol is started, in addition to one or more of the following drugs: ethionamide, capreomycin, amikacin, rifabutin, or ciprofloxacin. *M fortuitum* and *M chelonae* are usually susceptible to amikacin plus cefoxitin followed by erythromycin, clarithromycin, azithromycin, or doxycycline, and may be successfully treated with such combinations. Swimming pool granuloma due to *M marinum* is usually treated with doxycycline (in children older than age 9 years) or rifampin, plus ethambutol, clarithromycin, or TMP-SMX for a minimum of 3 months. Surgery may also be beneficial.

B. General Measures

Isolation of the patient is usually not necessary. General supportive care is indicated for the child with disseminated disease.

▶ Prognosis

The prognosis is good for patients with localized disease, although fatalities occur in immunocompromised children who have disseminated disease.

LEGIONELLA INFECTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Severe progressive pneumonia in a child with compromised immunity.
- ▶ Diarrhea and neurologic signs are common.
- ▶ Positive culture requires buffered charcoal yeast extract media and proves infection.
- ▶ Direct fluorescent antibody staining of respiratory secretions proves infection.

▶ General Considerations

Legionella pneumophila is a ubiquitous gram-negative bacillus that causes two distinct clinical syndromes: Legionnaire disease and Pontiac fever. Usually Legionnaire disease is an acute, severe pneumonia that is frequently fatal in immunocompromised patients. Pontiac fever is a mild, flulike illness that spares the lungs and is characterized by fever, headache, myalgia, and arthralgia. The disease is self-limited and is described in outbreaks in otherwise healthy adults.

Over 40 species of *Legionella* have been discovered, but not all cause disease in humans. *L pneumophila* causes most infections. *Legionella* is present in many natural water sources as well as domestic water supplies (faucets and showers). Contaminated cooling towers and heat exchangers have been implicated in several large institutional outbreaks. Person-to-person transmission has not been documented.

Few cases of Legionnaire disease have been reported in children. Most were in children with compromised cellular immunity. In adults, risk factors include smoking, underlying cardiopulmonary or renal disease, alcoholism, and diabetes.

L pneumophila is thought to be acquired by inhalation of a contaminated aerosol. The bacteria are phagocytosed but proliferate within macrophages. Cell-mediated immunity is necessary to activate macrophages to kill intracellular bacteria.

▶ Clinical Findings

A. Symptoms and Signs

Onset of fever, chills, anorexia, and headache is abrupt. Pulmonary symptoms appear within 2–3 days and progress

rapidly. The cough is nonproductive early. Purulent sputum occurs late. Hemoptysis, diarrhea, and neurologic signs (including lethargy, irritability, tremors, and delirium) are seen.

B. Laboratory Findings

The WBC count is usually elevated. Chest radiographs show rapidly progressive patchy consolidation. Cavitation and large pleural effusions are uncommon. Cultures from sputum, tracheal aspirates, or bronchoscopic specimens, when grown on specialized media are positive in 70–80% of patients at 3–7 days. Direct fluorescent antibody staining of sputum or other respiratory specimens is only 50–70% sensitive but 95% specific. A negative result on culture or direct fluorescent antibody staining of sputum or tracheal secretions does not rule out disease due to *Legionella*. PCR detection of respiratory secretions for *Legionella* is available at some centers. A urine immunoassay for *Legionella* antigen is more sensitive than the immunoassay using respiratory secretions and is highly specific. Serologic tests are available, but a maximum rise in titer may require 6–8 weeks.

▶ Differential Diagnosis

Legionnaire disease is usually a rapidly progressive pneumonia in a patient who appears very ill with unremitting fevers. Other bacterial pneumonias, viral pneumonias, *Mycoplasma pneumoniae*, and fungal disease are all possibilities and may be difficult to differentiate clinically in an immunocompromised patient.

▶ Complications

In sporadic untreated cases, mortality rates are 5–25%. In immunocompromised patients with untreated disease, mortality approaches 80%. Hematogenous dissemination may result in extrapulmonary foci of infection, including pericardium, myocardium, and kidneys. *Legionella* may be the cause of culture-negative endocarditis.

▶ Prevention

No vaccine is available. Hyperchlorination and periodic superheating of water supplies in hospitals have been shown to reduce the number of organisms and the risk of infection.

▶ Treatment

Intravenous azithromycin, 10 mg/kg/d given as a once-daily dose (maximum dose 500 mg), is the drug of choice. Rifampin (20 mg/kg/d divided in two doses) may be added to the regimen in gravely ill patients. Ciprofloxacin and levofloxacin are effective in adults but are not approved for use in children. Duration of therapy is 5–10 days if azithromycin is used; for other antibiotics a 14–21-day course is recommended. Oral therapy may be substituted for intravenous therapy as the patient's condition improves.

► Prognosis

Mortality rate is high if treatment is delayed. Malaise, problems with memory, and fatigue are common after recovery.

PSITTACOSIS (ORNITHOSIS) & CHLAMYDIA PNEUMONIAE INFECTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever, cough, malaise, chills, headache.
- Diffuse rales; no consolidation.
- Long-lasting radiographic findings of bronchopneumonia.
- Isolation of the organism or rising titer of complement-fixing antibodies.
- Exposure to infected birds (ornithosis).

► General Considerations

Psittacosis is caused by *Chlamydia psittaci*. When the agent is transmitted to humans from psittacine birds (parrots, parakeets, cockatoos, and budgerigars), the disease is called psittacosis or parrot fever. However, other avian genera (eg, pigeons and turkeys) are common sources of infection in the United States, and the general term *ornithosis* often is used. The agent is an obligate intracellular parasite. Human-to-human spread rarely occurs. The incubation period is 5–14 days. The bird from which the disease was transmitted may not be clinically ill.

Chlamydia pneumoniae may cause atypical pneumonia similar to that due to *M pneumoniae*. Transmission is by respiratory spread. Infection appears to be most prevalent during the second decade; half of surveyed adults are seropositive. Only a small percentage of infections result in clinical pneumonia. The disease may be more common than atypical pneumonia due to *M pneumoniae*. Lower respiratory tract infection due to *C pneumoniae* is uncommon in infants and young children.

► Clinical Findings

A. Symptoms and Signs

1. *C psittaci*—The disease is extremely variable but tends to be mild in children. The onset is rapid or insidious, with fever, chills, headache, backache, malaise, myalgia, and dry cough. Signs include pneumonitis, altered percussion notes and breath sounds, and rales. Pulmonary findings may be

absent early. Dyspnea and cyanosis may occur later. Splenomegaly, epistaxis, prostration, and meningismus are occasionally seen. Delirium, constipation or diarrhea, and abdominal distress may occur.

2. *C pneumoniae*—Clinically, *C pneumoniae* infection is similar to *M pneumoniae* infection. Most patients have mild upper respiratory infections. Lower respiratory tract infection is characterized by fever, sore throat (perhaps more severe with *C pneumoniae*), cough, and bilateral pulmonary findings and infiltrates.

B. Laboratory Findings

1. *C psittaci*—In psittacosis, the WBC count is normal or decreased, often with a shift to the left. Proteinuria is common. *C psittaci* is present in the blood and sputum during the first 2 weeks of illness and can be isolated by inoculation of specimens into mice or embryonated eggs, but culture is available only in research laboratories. A fourfold rise in complement fixation titers in specimens obtained at least 2 weeks apart or a single titer above 1:32 is considered evidence of infection. The titer rise may be blunted or delayed by therapy. Infection with *C pneumoniae* may lead to diagnostic confusion because cross-reactive antibody may cause falsely positive *C psittaci* titers. Microimmunofluorescence and PCR assays are specific but usually not available for *C psittaci*.

2. *C pneumoniae*—A fourfold rise in IgG titer (microimmunofluorescence antibody test) or an IgM titer above 1:16 is evidence of infection. IgG antibody peaks 6–8 weeks after infection. *C pneumoniae* can be isolated from nasal wash or throat swab specimens after inoculation into cell culture. A PCR assay also is available.

C. Imaging

The radiographic findings in psittacosis are those of central pneumonia that later becomes widespread or migratory. Psittacosis is indistinguishable from viral pneumonias by radiograph. Signs of pneumonitis may appear on radiograph in the absence of clinical suspicion of pulmonary involvement.

► Differential Diagnosis

Psittacosis can be differentiated from viral or mycoplasmal pneumonias only by the history of contact with potentially infected birds. In severe or prolonged cases with extrapulmonary involvement the differential diagnosis is broad, including typhoid fever, brucellosis, and rheumatic fever.

► Complications

Complications of psittacosis include myocarditis, endocarditis, hepatitis, pancreatitis, and secondary bacterial pneumonia. *C pneumoniae* infection may be prolonged or may recur.

▶ Treatment

Doxycycline should be given for 14 days after defervescence to patients older than age 8 years with psittacosis. Alternatively, erythromycin, azithromycin, or clarithromycin may be used in younger children. Supportive oxygen may be needed. The patient should be kept in isolation. *C pneumoniae* responds to macrolides or doxycycline: a 14-day course is recommended.

Tsai MH et al: Chlamydial pneumonia in children requiring hospitalization: Effect of mixed infection on clinical outcome. J Microbiol Immunol Infect 2005;38:117 [PMID: 15843856].

CAT-SCRATCH DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ History of a cat scratch or cat contact.
- ▶ Primary lesion (papule, pustule, or conjunctivitis) at site of inoculation.
- ▶ Acute or subacute regional lymphadenopathy.
- ▶ Aspiration of sterile pus from a node.
- ▶ Laboratory studies excluding other causes.
- ▶ Biopsy of node or papule showing histopathologic findings consistent with cat-scratch disease and occasionally characteristic bacilli on Warthin-Starry stain.
- ▶ Positive cat-scratch serology (antibody to *Bartonella henselae*).

▶ General Considerations

The causative agent of cat-scratch disease is *Bartonella henselae*, a gram-negative bacillus that also causes bacillary angiomatosis. Cat-scratch disease is a benign, self-limited form of lymphadenitis. Patients often report a cat scratch (67%) or contact with a cat or kitten (90%). The cat almost invariably is healthy. The clinical picture is that of a regional lymphadenitis associated with an erythematous papular skin lesion without intervening lymphangitis. The disease occurs worldwide and is more common in the fall and winter. It is estimated that more than 20,000 cases per year occur in the United States. The most common systemic complication is encephalitis.

▶ Clinical Findings

A. Symptoms and Signs

About 50% of patients with cat-scratch disease develop a primary lesion at the site of the wound. The lesion usually is a papule or pustule that appears 3–10 days after injury and is located most often on the arm or hand (50%), head or leg

(30%), or trunk or neck (10%). The lesion may be conjunctival (10%). Regional lymphadenopathy appears 10–50 days later and may be accompanied by mild malaise, lassitude, headache, and fever. Multiple sites are seen in about 10% of cases. Involved nodes may be hard or soft and 1–6 cm in diameter. They are usually tender, and 10–20% of them suppurate. The overlying skin may be inflamed. Lymphadenopathy usually resolves in about 2 months but may persist for up to 8 months.

Unusual manifestations include erythema nodosum, thrombocytopenic purpura, conjunctivitis (Parinaud oculoglandular fever), parotid swelling, pneumonia, osteolytic lesions, mesenteric and mediastinal adenitis, neuroretinitis, peripheral neuritis, hepatitis, granulomata of the liver and spleen, and encephalitis.

Immunocompetent patients may develop an atypical systemic form of cat-scratch disease. These patients have prolonged fever, fatigue, and malaise. Lymphadenopathy may be present. Hepatosplenomegaly or low-density hepatic or splenic lesions visualized by ultrasound or computed tomography scan are seen in some patients.

Infection in immunocompromised individuals may take the form of bacillary angiomatosis, presenting as vascular tumors of the skin and subcutaneous tissues. Immunocompromised patients may also have bacteremia or infection of the liver (peliosis hepatis).

B. Laboratory Findings

Serologic evidence of *Bartonella* infection by indirect fluorescent antibody or ELISA with a titer above 1:64 is supportive of the diagnosis. PCR assays are available. Cat-scratch skin test antigens are not recommended.

Histopathologic examination of involved tissue may show pyogenic granulomas or bacillary forms demonstrated by Warthin-Starry silver stain. There usually is some elevation in the ESR. In patients with CNS involvement, the CSF is usually normal but may show a slight pleocytosis and modest elevation of protein.

▶ Differential Diagnosis

Cat-scratch disease must be distinguished from pyogenic adenitis, tuberculosis (typical and atypical), tularemia, plague, brucellosis, lymphoma, primary toxoplasmosis, infectious mononucleosis, lymphogranuloma venereum, and fungal infections.

▶ Treatment

Treatment of cat-scratch disease adenopathy is controversial because the disease usually resolves without therapy and the patient is typically not exceedingly ill. Treatment of typical cat-scratch disease with a 5-day course of azithromycin has been shown to speed resolution of lymphadenopathy in some patients. The best therapy is reassurance that the adenopathy is benign and will subside spontaneously with time (mean duration of illness is 14 weeks). In cases of nodal suppuration, needle aspiration under local anesthesia relieves the pain. Excision of the

involved node is indicated in cases of chronic adenitis. In some reports, azithromycin, gentamicin, ciprofloxacin, rifampin, or TMP-SMX have been useful. Azithromycin is used by many experts if treatment of adenopathy is desired because it is given once a day, is reasonably priced, and was studied in one randomized placebo-controlled trial. In that trial, lymph node volume decreased faster than placebo by 1 month; there was no difference in long-term resolution in the azithromycin and placebo groups.

Immunocompromised patients with evidence of infection should be treated with antibiotics: long-term therapy (months) in these patients with azithromycin, erythromycin, or doxycycline often is needed to prevent relapses. Immunocompetent patients with more severe disease or evidence of systemic infection should also be treated with antibiotics.

▶ Prognosis

The prognosis is good if complications do not occur.

SPIROCHETAL INFECTIONS

SYPHILIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Congenital:

- ▶ All types: history of untreated maternal syphilis, a positive serologic test, and a positive darkfield examination.
- ▶ Newborn: hepatosplenomegaly, characteristic radiographic bone changes, anemia, increased nucleated red cells, thrombocytopenia, abnormal spinal fluid, jaundice, edema.
- ▶ Young infant (3–12 weeks): snuffles, maculopapular skin rash, mucocutaneous lesions, pseudoparalysis (in addition to radiographic bone changes).
- ▶ Children: stigmata of early congenital syphilis, interstitial keratitis, saber shins, gummas of nose and palate.

Acquired:

- ▶ Chancre of genitals, lip, or anus in child or adolescent.
- ▶ History of sexual contact.

▶ General Considerations

Syphilis is a chronic, generalized infectious disease caused by a spirochete, *Treponema pallidum*. In the acquired form, the disease is transmitted by sexual contact. Primary syphilis is characterized by the presence of an indurated painless chancre, which heals in 7–10 days. A secondary eruption involving the skin and mucous membranes appears in 4–6 weeks. After a long latency period, late lesions of tertiary syphilis involve the eyes, skin, bones, viscera, CNS, and cardiovascular system.

Congenital syphilis results from transplacental infection. Infection may result in stillbirth or produce illness in the newborn, in early infancy, or later in childhood. Syphilis occurring in the newborn and young infant is comparable to secondary disease in the adult but is more severe and life-threatening. Late congenital syphilis (developing in childhood) is comparable to tertiary disease.

Congenital syphilis is increasing in the United States due to increasing primary and secondary syphilis in women of childbearing age, and perhaps due to inadequate diagnosis and treatment of syphilis in prenatal care programs.

▶ Clinical Findings

A. Symptoms and Signs

1. Congenital Syphilis

A. NEWBORNS—Most newborns with congenital syphilis are asymptomatic. If infection is not detected and treated, symptoms develop within weeks to months. When clinical signs are present, they usually consist of jaundice, anemia with or without thrombocytopenia, increase in nucleated red blood cells, hepatosplenomegaly, and edema. Overt signs of meningitis (bulging fontanelle or opisthotonos) may be present, but subclinical infection with CSF abnormalities is more likely.

B. YOUNG INFANTS (3–12 WEEKS)—The infant may appear normal for the first few weeks of life only to develop mucocutaneous lesions and pseudoparalysis of the arms or legs. Shotty lymphadenopathy may be felt. Hepatomegaly is universal, with splenomegaly in 50% of patients. Other signs of disease similar to those seen in the newborn may be present. Anemia has been reported as the only presenting manifestation of congenital syphilis in this age group. “Snuffles” (syphilitic rhinitis), characterized by a profuse mucopurulent discharge, are present in 25% of patients. A syphilitic rash is common on the palms and soles but may occur anywhere on the body. The rash consists of bright red, raised maculopapular lesions that gradually fade. Moist lesions occur at the mucocutaneous junctions (nose, mouth, anus, and genitals) and lead to fissuring and bleeding.

Syphilis in the young infant may lead to stigmata recognizable in later childhood, such as rhagades (scars) around the mouth or nose, a depressed bridge of the nose (saddle nose), and a high forehead (secondary to mild hydroceph-

alus associated with low-grade meningitis and frontal periostitis). The permanent upper central incisors may be peg-shaped with a central notch (Hutchinson teeth), and the cusps of the sixth-year molars may have a lobulated mulberry appearance.

C. CHILDREN—Bilateral interstitial keratitis (at age 6–12 years) is characterized by photophobia, increased lacrimation, and vascularization of the cornea associated with exudation. Chorioretinitis and optic atrophy may also be seen. Meningovascular syphilis (at age 2–10 years) is usually slowly progressive, with mental retardation, spasticity, abnormal pupillary response, speech defects, and abnormal CSF. Deafness sometimes occurs. Thickening of the periosteum of the anterior tibiae produces saber shins. A bilateral effusion in the knee joints may occur but is not associated with sequelae. Soft inflammatory growths called gummas may develop in the nasal septum, palate, long bones, and subcutaneous tissues.

2. Acquired syphilis—The primary chancre of the genitals, mouth, or anus may occur from genital, anal, or oral sexual contact. If the chancre is missed, signs of secondary syphilis, such as rash, fever, headache, and malaise, may be the first manifestations.

B. Laboratory Findings

1. Darkfield microscopy—Treponemes can be seen in scrapings from a chancre and from moist lesions.

2. Serologic tests for syphilis—There are two general types of serologic tests for syphilis: treponemal and nontreponemal. The latter (Venereal Disease Research Laboratory, or VDRL) is useful for screening and follow-up of known cases. A rapid test (the rapid plasma reagin, or RPR) is useful for screening, but positive sera should be examined further by quantitative nontreponemal and treponemal tests. Positive nontreponemal tests are confirmed with the more specific fluorescent treponemal antibody absorbed (FTA-ABS) test. False-positive FTA-ABS tests are uncommon except with other spirochetal disease.

One or 2 weeks after the onset of primary syphilis (chancre), the FTA-ABS test becomes positive. The VDRL or a similar nontreponemal test usually turns positive a few days later. By the time the secondary stage has been reached, virtually all patients show both positive FTA-ABS and positive nontreponemal tests. During latent and tertiary syphilis, the VDRL may become negative, but the FTA-ABS test usually remains positive. The quantitative VDRL or a similar nontreponemal test should be used to follow-up treated cases (see following discussion).

Positive serologic tests in cord sera may represent passively transferred antibody rather than congenital infection and therefore must be supplemented by a combination of clinical and laboratory data. Elevated total cord IgM is a helpful but nonspecific finding. A specific IgM-FTA-ABS is available, but negative results are not conclusive and should

not be relied on. Demonstration of characteristic treponemes by darkfield examination of material from a moist lesion (skin; nasal or other mucous membranes) is definitive. Serial measurement of quantitative VDRL is also very useful, because passively transferred antibody in the absence of active infection should decay with a normal half-life of about 18 days.

In one study, 15% of infants with congenital syphilis had negative cord blood serology, presumably due to maternal infection late in pregnancy.

C. Imaging

Radiographic abnormalities are present in 90% of infants with symptoms of congenital syphilis and in 20% of asymptomatic infants. Metaphyseal lucent bands, periostitis, and a widened zone of provisional calcification may be present. Bilateral symmetrical osteomyelitis with pathologic fractures of the medial tibial metaphyses (Wimberger sign) is almost pathognomonic.

► Differential Diagnosis

A. Congenital Syphilis

1. Newborns—Sepsis, congestive heart failure, congenital rubella, toxoplasmosis, disseminated herpes simplex, cytomegalovirus infection, and hemolytic disease of the newborn have to be differentiated. A positive Coombs test and blood group incompatibility distinguish hemolytic disease.

2. Young infants—Injury to the brachial plexus, poliomyelitis, acute osteomyelitis, and septic arthritis must be differentiated from pseudoparalysis. Coryza due to viral infection often responds to symptomatic treatment. Rash (ammoniacal diaper rash) and scabies may be confused with a syphilitic eruption.

3. Children—Interstitial keratitis and bone lesions of tuberculosis are distinguished by positive tuberculin reaction and chest radiograph. Arthritis associated with syphilis is unaccompanied by systemic signs, and joints are nontender. Mental retardation, spasticity, and hyperactivity are shown to be of syphilitic origin by strongly positive serologic tests.

B. Acquired Syphilis

Herpes genitalis, traumatic lesions, and other venereal diseases must be differentiated.

► Prevention

A serologic test for syphilis should be performed at the initiation of prenatal care and repeated at delivery. In mothers at high risk for syphilis, repeated tests may be necessary. Serologic tests may be negative on both the mother and infant at the time of birth if the mother acquires syphilis near term. Adequate treatment of mothers with secondary syphilis before the last month of pregnancy reduces the incidence of congenital

syphilis from 90% to less than 2%. Examination and serologic testing of sexual partners and siblings should also be done.

▶ Treatment

A. Specific Measures

Penicillin is the drug of choice for *T pallidum* infection. If the patient is allergic to penicillin, erythromycin or one of the tetracyclines may be used.

1. Congenital syphilis

A. INITIAL EVALUATION AND TREATMENT—Infants born to seropositive mothers require careful examination and quantitative antitreponemal (VDRL, RPR) syphilis testing. The same quantitative antitreponemal test used in evaluating the mother should be used in the infant so the titers can be compared. Maternal records regarding the diagnosis of syphilis, treatment, and follow-up titers should be reviewed. Infants should be further evaluated for congenital syphilis in any of the following circumstances:

- The maternal titer has increased fourfold.
- The infant's titer is at least fourfold greater than the maternal titer.
- Signs of syphilis are found on examination.
- Maternal syphilis was not treated or was inadequately treated during pregnancy.
- Maternal syphilis was treated with a nonpenicillin regimen, or the regimen or dose of medication is undocumented.
- Maternal syphilis was treated during pregnancy, but therapy was completed less than 4 weeks prior to delivery.
- Maternal syphilis was treated appropriately during pregnancy, but without the appropriate decrease in maternal nontreponemal titers after treatment.

The complete evaluation of an infant for possible congenital syphilis includes complete blood count, liver function tests, long bone radiographs, CSF examination (cell counts, glucose, and protein), CSF VDRL, and quantitative serologic tests. In addition, the placenta and umbilical cord should be examined pathologically using fluorescent antitreponemal antibody, if available. An ophthalmologic examination may also be done.

Treatment for congenital syphilis is indicated for infants with physical signs, umbilical cord or placenta positive for DFA-TP staining or darkfield examination, abnormal radiographs, elevated CSF protein or cell counts, reactive CSF VDRL, or serum quantitative nontreponemal titer that is more than fourfold higher than the maternal titer (using same test). Infants with proved or suspected congenital syphilis should receive either (1) aqueous crystalline penicillin G, 50,000 units/kg per dose intravenously every 12 hours (if < 1 week old) or (2) every 8 hours (if 1–4 weeks old) for 10 days. All infants diagnosed after age 4 weeks should receive 50,000–60,000 units/kg per dose aqueous crystalline penicillin intravenously every 6 hours for 10 days.

Additionally, treatment should be given to infants whose mothers have inadequately treated syphilis, to those whose mothers received treatment less than 1 month before delivery, to those whose mothers have undocumented or inadequate serologic response to therapy, and to those whose mothers were given nonpenicillin drugs to treat syphilis. In these instances, if the infant is asymptomatic, has a normal physical examination, normal CSF parameters, nonreactive CSF VDRL, normal bone films, quantitative nontreponemal titer less than fourfold of the mother's titer, and good follow-up is certain, some experts would give a single dose of penicillin G benzathine, 50,000 units/kg intramuscularly. If there is any abnormality in the preceding evaluation or if the CSF testing is not interpretable, the full 10 days of intravenous penicillin should be given. Close clinical and serologic monthly follow-up is necessary.

Asymptomatic, seropositive infants with normal physical examinations born to mothers who received adequate syphilis treatment (completed > 4 weeks prior to delivery) and whose mothers have an appropriate serologic response (fourfold or greater decrease in titer) to treatment may be at lower risk for congenital syphilis. Some experts believe complete laboratory and radiographic evaluation in these infants (CSF and long bone films) is not necessary. Infants who meet the preceding criteria, who have nontreponemal titers less than fourfold higher than maternal titers, and for whom follow-up is certain can be given benzathine penicillin G, 50,000 units/kg, administered intramuscularly in a single dose. Infants should be followed with quantitative serologic tests and physical examinations until the nontreponemal serologic test is negative (see discussion of follow-up, below). Rising titers or clinical signs usually occur within 4 months in infected infants, requiring a full evaluation (including CSF studies and long bone radiographs) and institution of intravenous penicillin therapy.

B. FOLLOW-UP FOR CONGENITAL SYPHILIS—Children treated for congenital syphilis need physical examinations at 1 and 2 months after completion of therapy, and both physical examinations and quantitative VDRL or RPR tests should be performed at 4, 6, and 12 months after the end of therapy or until the tests become nonreactive. Repeat CSF examination, including a CSF VDRL test, every 6 months until normal is indicated for infants with a positive CSF VDRL reaction or with abnormal cell counts or protein in the CSF. A reactive CSF VDRL test at the 6-month interval is an indication for retreatment. Titers decline with treatment and are usually negative by 6 months. Repeat treatment is indicated for children with rising titers or stable titers that do not decline.

2. Acquired syphilis of less than 1 year's duration—Benzathine penicillin G (50,000 units/kg, given intramuscularly, to a maximum of 2.4 million units) is given to adolescents with primary, secondary, or latent disease of less than 1 year's duration. All children should have a CSF examination (with CSF VDRL) prior to commencing therapy, to exclude neurosyphilis. Adolescents and adults need a CSF examination

if clinical signs or symptoms suggest neurologic involvement or if they are HIV-infected.

3. Syphilis of more than 1 year's duration (late latent disease)—Syphilis of more than 1 year's duration (without evidence of neurosyphilis) requires weekly intramuscular benzathine penicillin G therapy for 3 weeks. CSF examination and VDRL test should be done on all children and patients with coexisting HIV infection or neurologic symptoms. In addition, patients who have failed treatment or who were previously treated with an agent other than penicillin need a CSF examination and CSF VDRL.

4. Neurosyphilis—Aqueous crystalline penicillin G is recommended, 200,000–300,000 units/kg/d in four to six divided doses, given intravenously for 10–14 days. The maximum adult dose is 4 million units per dose. This regimen should possibly be followed by an intramuscular course of benzathine G penicillin, 50,000 units/kg given once a week for 3 consecutive weeks, to a maximum dose of 2.4 million units.

B. General Measures

Penicillin treatment of early congenital or secondary syphilis may result in a dramatic systemic febrile illness termed the Jarisch-Herxheimer reaction. Treatment is symptomatic, with careful follow-up. Transfusion may be necessary in infants with severe hemolytic anemia.

► Prognosis

Severe disease, if undiagnosed, may be fatal in the newborn. Complete cure can be expected if the young infant is given penicillin. Serologic reversal usually occurs within 1 year. Treatment of primary syphilis with penicillin is curative. Permanent neurologic sequelae may occur in meningovascular syphilis.

RELAPSING FEVER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Episodes of fever, chills, malaise.
- Occasional rash, arthritis, cough, hepatosplenomegaly, conjunctivitis.

- Diagnosis confirmed by direct microscopic identification of spirochetes in smears of peripheral blood.

► General Considerations

Relapsing fever is a vector-borne disease caused by spirochetes of the genus *Borrelia*. Epidemic relapsing fever is transmitted to humans by body lice (*Pediculus humanus*) and endemic relapsing fever by soft-bodied ticks (genus *Ornithodoros*). Tick-borne relapsing fever is endemic in the western United States. Although several hundred cases are reported per year, substantial underdiagnosis occurs. Transmission usually takes place during the warm months, when ticks are active and recreation or work brings people into contact with *Ornithodoros* ticks. Infection is often acquired in mountain camping areas and cabins. The ticks are nocturnal feeders and remain attached for only 5–20 minutes. Consequently, the patient seldom remembers a tick bite. Rarely, neonatal relapsing fever results from transplacental transmission of *Borrelia*. Both louse-borne and tick-borne relapsing fever may be acquired during foreign travel.

► Clinical Findings

A. Symptoms and Signs

The incubation period is 4–18 days. The attack is sudden, with high fever, chills, tachycardia, nausea and vomiting, headache, myalgia, arthralgia, bronchitis, and a dry, nonproductive cough. Hepatomegaly and splenomegaly appear later. Meningeal irritation may be present. An erythematous rash may be seen over the trunk and extremities, and petechiae may be present. After 3–10 days, the fever falls. Jaundice, iritis, conjunctivitis, cranial nerve palsies, and hemorrhage occur more commonly during relapses.

The disease is characterized by relapses at intervals of 1–2 weeks and lasting 3–5 days. The relapses duplicate the initial attack but become progressively less severe. In louse-borne relapsing fever, there is usually a single relapse. In tick-borne infection, two to six relapses occur.

B. Laboratory Findings

During febrile episodes, the patient's urine contains protein, casts, and occasionally erythrocytes; a marked polymorphonuclear leukocytosis is present; and about 25% of patients have a false-positive serologic test for syphilis. Examination of the peripheral blood smear is the diagnostic test of choice. Spirochetes can be found in the peripheral blood by direct microscopy in approximately 70% of cases by darkfield examination or by Wright, Giemsa, or acridine orange staining of thick and thin smears. Spirochetes are not found during afebrile periods. Immunofluorescent antibody (or ELISA confirmed by Western blot) can sometimes help establish the diagnosis serologically. However, high titers of *Borrelia hermsii* can cross-react with *Borrelia burgdorferi* (the

agent in Lyme disease) in immunofluorescent antibody assay, ELISA, and Western blots. Serologic specimens can be sent to the Division of Vector-Borne Infectious Diseases, Centers for Disease Control and Prevention, Fort Collins, CO 80522.

► Differential Diagnosis

Relapsing fever may be confused with malaria, leptospirosis, dengue, typhus, rat-bite fever, Colorado tick fever, Rocky Mountain spotted fever, collagen-vascular disease, or any fever of unknown origin.

► Complications

Complications include facial paralysis, iridocyclitis, optic atrophy, hypochromic anemia, pneumonia, nephritis, myocarditis, endocarditis, and seizures. CNS involvement occurs in 10–30% of patients.

► Treatment

For children younger than age 8 years who have tick-borne relapsing fever, standard dosages of penicillin or erythromycin should be given for 10 days. Older children may be given doxycycline. Chloramphenicol is also efficacious and was often used in the past.

Severely ill patients should be hospitalized. Patients may experience a Jarisch-Herxheimer reaction (usually noted in the first few hours after commencing antibiotics). Isolation precautions are not necessary for relapsing fever. Contact precautions are recommended for patients with louse infestations.

► Prognosis

The mortality rate in treated cases of relapsing fever is very low, except in debilitated or very young children. With treatment, the initial attack is shortened and relapses prevented. The response to antimicrobial therapy is dramatic.

LEPTOSPIROSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Biphasic course lasting 2–3 weeks.
- Initial phase: high fever, headache, myalgia, and conjunctivitis.
- Apparent recovery for 2–3 days.

- Return of fever associated with meningitis.
- Jaundice, hemorrhages, and renal insufficiency (severe cases).
- Culture of organism from blood and CSF (early) and from urine (later), or direct microscopy of urine or CSF.
- Positive leptospiral agglutination test.

► General Considerations

Leptospirosis is a zoonosis caused by many antigenically distinct but morphologically similar spirochetes. The organism enters through the skin or respiratory tract. Classically the severe form (Weil disease), with jaundice and a high mortality rate, was associated with infection with *Leptospira icterohaemorrhagiae* after immersion in water contaminated with rat urine. It is now known that a variety of animals (eg, dogs, rats, and cattle) may serve as reservoirs for pathogenic *Leptospira*, that a given serogroup may have multiple animal species as hosts, and that severe disease may be caused by many different serogroups.

In the United States, leptospirosis usually occurs after contact with dogs. Cattle, swine, or rodents may transmit the organism. Sewer workers, farmers, abattoir workers, animal handlers, and soldiers are at risk for occupational exposure. Outbreaks have resulted from swimming in contaminated streams and harvesting field crops. In the United States, about 100 cases are reported yearly, about one third of them in children.

► Clinical Findings

A. Symptoms and Signs

1. Initial phase—The incubation period is 4–19 days (mean, 10 days). Chills, fever, headache, myalgia, conjunctivitis (episcleral injection), photophobia, cervical lymphadenopathy, and pharyngitis commonly occur. The initial leptospiremic phase lasts for 3–7 days.

2. Phase of apparent recovery—Symptoms typically (but not always) subside for 2–3 days.

3. Systemic phase—Fever reappears and is associated with headache, muscular pain and tenderness in the abdomen and back, and nausea and vomiting. Lung, heart, and joint involvement occasionally occurs. These manifestations are due to extensive vasculitis.

A. CENTRAL NERVOUS SYSTEM INVOLVEMENT—The CNS is involved in 50–90% of cases. Severe headache and mild nuchal rigidity are usual, but delirium, coma, and focal neurologic signs may be seen.

B. RENAL AND HEPATIC INVOLVEMENT—In about 50% of cases, the kidney or liver is affected. Gross hematuria and oliguria or anuria is sometimes seen. Jaundice may be associated with an enlarged and tender liver.

C. GALLBLADDER INVOLVEMENT—Leptospirosis may cause acalculous cholecystitis in children, demonstrable by abdominal ultrasound as a dilated, nonfunctioning gallbladder. Pancreatitis is unusual.

D. HEMORRHAGE—Petechiae, ecchymoses, and gastrointestinal bleeding may be severe.

E. RASH—A rash is seen in 10–30% of cases. It may be maculopapular and generalized or may be petechial or purpuric. Occasionally erythema nodosum is seen. Peripheral desquamation of the rash may occur. Gangrenous areas are sometimes noted over the distal extremities. In such cases, skin biopsy demonstrates the presence of severe vasculitis involving both the arterial and the venous circulations.

B. Laboratory Findings

Leptospire are present in the blood and CSF only during the first 10 days of illness. They appear in the urine during the second week, where they may persist for 30 days or longer. Culture is difficult and requires specialized media and conditions. The WBC count often is elevated, especially when there is liver involvement. Serum bilirubin levels usually remain below 20 mg/dL. Other liver function tests may be abnormal, although the aspartate transaminase usually is elevated only slightly. An elevated serum creatine kinase is frequently found. CSF shows moderate pleocytosis (< 500/ μ L)—predominantly mononuclear cells—increased protein (50–100 mg/dL), and normal glucose. Urine often shows microscopic pyuria, hematuria, and, less often, moderate proteinuria (++ or greater). The ESR is elevated markedly. Chest radiograph may show pneumonitis.

Serologic antibodies measured by enzyme immunoassay may be demonstrated during or after the second week of illness. The serologic test of choice is a microscopic agglutination test using live organisms (performed at the CDC). Leptospiral agglutinins generally reach peak levels by the third to fourth week. A 1:100 titer is considered suspicious; a fourfold or greater rise is diagnostic. A PCR assay may be available at specialized research centers or through the CDC.

► Differential Diagnosis

Fever and myalgia associated with the characteristic episcleral injection should suggest leptospirosis. During the prodrome, malaria, typhoid fever, typhus, rheumatoid arthritis, brucellosis, and influenza may be suspected. Later, depending on the organ systems involved, a variety of other diseases need to be distinguished, including encephalitis, viral or tuberculous meningitis, viral hepatitis, glomerulonephritis, viral or bacterial pneumonia, rheumatic fever, subacute infective endocarditis, acute surgical abdomen, and Kawasaki disease (see Table 38–3).

► Prevention

Preventive measures include avoidance of contaminated water and soil, rodent control, immunization of dogs and other domestic animals, and good sanitation. Immunization

or antimicrobial prophylaxis with doxycycline may be of value to certain high-risk occupational groups.

► Treatment

A. Specific Measures

Aqueous penicillin G (150,000 units/kg/d, given in four to six divided doses intravenously for 7–10 days) should be given when the diagnosis is suspected. Studies in severely ill patients indicate a benefit even if treatment is started 4 days after onset. A Jarisch-Herxheimer reaction may occur. Oral doxycycline may be used for mildly ill patients.

B. General Measures

Symptomatic and supportive care is indicated, particularly for renal and hepatic failure and hemorrhage. Contact isolation is recommended, due to potential transmission from contact with urine.

► Prognosis

Leptospirosis is usually self-limiting and not characterized by jaundice. The disease usually lasts 1–3 weeks but may be more prolonged. Relapse may occur. There are usually no permanent sequelae associated with CNS infection, although headache may persist. The mortality rate in the United States is 5%, usually from renal failure. The mortality rate may reach 20% or more in elderly patients who have severe kidney and hepatic involvement.

LYME DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Characteristic skin lesion (erythema migrans) 3–30 days after tick bite.
- Arthritis, usually pauciarticular, occurring about 4 weeks after appearance of skin lesion. Headache, chills, and fever.
- Residence or travel in an endemic area during the late spring to early fall.

► General Considerations

Lyme disease is a subacute or chronic spirochetal infection caused by *Borrelia burgdorferi* and transmitted by the bite of an

infected deer tick (*Ixodes* species). The disease was known in Europe for many years as tick-borne encephalomyelitis, often associated with a characteristic rash (erythema migrans). Discovery of the agent and vector followed investigation of an outbreak of pauciarticular arthritis in Lyme, Connecticut, in 1977.

Although cases are reported from many countries, the most prominent endemic areas in the United States include the Northeast, upper Midwest, and West Coast. The northern European countries also have high rates of infection. More than 20,000 cases were reported in the United States in 2005. The disease is spreading as a result of increased infection in and distribution of the tick vector. Most cases with rash are recognized in spring and summer, when most tick bites occur; however, because the incubation period for joint and neurologic disease may be months, cases may present at any time. *Ixodes* ticks are very small, and their bite often is unrecognized.

► Clinical Findings

A. Symptoms and Signs

Erythema chronicum migrans, the most characteristic feature of Lyme disease, develops in 60–80% of patients. Between 3 and 30 days after the bite, a ring of erythema develops at the site and spreads over days. It may attain a diameter of 20 cm. The center of the lesion may clear (resembling tinea corporis), remain red, or become raised (suggesting a chemical or infectious cellulitis). Many patients are otherwise asymptomatic. Some have fever (usually low-grade), headache, and myalgias. Multiple satellite skin lesions, urticaria, or diffuse erythema may occur. Untreated, the rash lasts days to 3 weeks.

In up to 50% of patients, arthritis develops several weeks to months after the bite. Recurrent attacks of migratory, monarticular, or pauciarticular arthritis involving the knees and other large joints occur. Each attack lasts for days to a few weeks. Fever is common and may be high. Complete resolution between attacks is typical. Chronic arthritis develops in less than 10% of patients, more often in those with the DR4 haplotype.

Neurologic manifestations develop in up to 20% of patients and usually consist of Bell palsy, aseptic meningitis (which may be indistinguishable from viral meningitis), or polyradiculitis. Peripheral neuritis, Guillain-Barré syndrome, encephalitis, ataxia, chorea, and other cranial neuropathies are less common. Seizures suggest another diagnosis. Untreated, the neurologic symptoms are usually self-limited but may be chronic or permanent. Although fatigue and nonspecific neurologic symptoms may be prolonged in a few patients, Lyme disease is not a cause of chronic fatigue syndrome. Self-limited heart block or myocardial dysfunction occurs in about 5% of patients.

B. Laboratory Findings

Most patients with only rash have normal laboratory tests. Children with arthritis may have moderately elevated ESRs

and WBC counts; the antinuclear antibodies and rheumatoid factor tests are negative or nonspecific; streptococcal antibodies are not elevated. Circulating IgM cryoglobulins may be present. Joint fluid may show up to 100,000 cells with a polymorphonuclear predominance, normal glucose, and elevated protein and immune complexes; Gram stain and culture are negative. In patients with CNS involvement, the CSF may show lymphocytic pleocytosis and elevated protein; the glucose and all cultures and stains are normal or negative. Abnormal nerve conduction may be present with peripheral neuropathy.

C. Diagnosis

Lyme disease is a clinical diagnosis. History, physical examination, and laboratory features are important to consider. The causative organism is difficult to culture. Serologic testing may support the clinical diagnosis. Antibody testing should be performed in experienced laboratories. Serologic diagnosis of Lyme disease is based on a two-test approach: an ELISA and an immunoblot to confirm a positive or indeterminate ELISA. Antibodies may not be detectable until several weeks after infection has occurred; therefore, serologic testing in children with a typical rash is not recommended. Therapy early in disease may blunt antibody titers. Recent studies have shown considerable intralaboratory and interlaboratory variability in titers reported. Overdiagnosis of Lyme disease based on atypical symptoms and positive serology appears to be common. Sera from patients with syphilis, HIV, and leptospirosis may give false-positive results. Patients who receive appropriate treatment for Lyme disease may remain seropositive for years. Diagnosis of CNS disease requires objective abnormalities of the neurologic examination, laboratory or radiographic studies, and consistent positive serology.

► Differential Diagnosis

Aside from the disorders already mentioned, the rash may resemble pityriasis, erythema multiforme, a drug eruption, or erythema nodosum. Erythema chronicum migrans is nonscaly, minimally tender or nontender, and persists longer in the same place than many of the more common childhood erythematous rashes. The arthritis may resemble juvenile rheumatoid arthritis, reactive arthritis, septic arthritis, reactive effusion from a contiguous osteomyelitis, rheumatic fever, leukemic arthritis, systemic lupus erythematosus, and Henoch-Schönlein purpura. Spontaneous resolution in a few days to weeks helps differentiate Lyme disease from juvenile rheumatoid arthritis, in which arthritis lasting a minimum of 6 weeks is required for diagnosis. The neurologic signs may suggest idiopathic Bell palsy, viral or parainfectious meningitis or meningoencephalitis, lead poisoning, psychosomatic illness, and many other conditions.

► Prevention

Prevention consists of avoidance of endemic areas, wearing long sleeves and pants, frequent checks for ticks, and appli-

cation of tick repellents. Ticks usually are attached for 24–48 hours before transmission of Lyme disease occurs. Ticks should be removed with a tweezer by pulling gently without twisting or excessive squeezing of the tick. Permethrin sprayed on clothing decreases tick attachment. Repellents containing high concentrations of DEET may be neurotoxic and should be used cautiously and washed off when tick exposure ends. The CDC does not recommend prophylactic antibiotics for tick bites in asymptomatic individuals.

► Treatment

Antimicrobial therapy is beneficial in most cases of Lyme disease. It is most effective if started early. Prolonged treatment is important for all forms. Relapses occur in some patients on all regimens.

A. Rash, Early Infections

Amoxicillin, 25–50 mg/kg/d orally in two divided doses (to a maximum of 2 g/d) for 14–21 days can be used for children of all ages. Doxycycline (100 mg orally twice a day) for 14–21 days may be used for children older than age 8 years. Erythromycin (30 mg/kg/d) or cefuroxime is used in penicillin-allergic children, although erythromycin may be less effective than amoxicillin.

B. Arthritis

The amoxicillin or doxycycline regimen (same dosage as for the rash) should be used, but treatment should continue for 4 weeks. Parenteral ceftriaxone (75–100 mg/kg/d) or penicillin G (300,000 units/kg/d, given intravenously in four divided doses for 2–4 weeks) is used for persistent arthritis.

C. Bell Palsy

The same oral drug regimens may be used for 3–4 weeks.

D. Other Neurologic Disease or Cardiac Disease

Parenteral therapy for 2–3 weeks is recommended with either ceftriaxone (75–100 mg/kg/d in one daily dose) or penicillin G (300,000 units/kg/d intravenously in four divided doses).

Infections: Parasitic & Mycotic

Samuel R. Dominguez, MD, PhD
Adriana Weinberg, MD
Myron J. Levin, MD

41

PARASITIC INFECTIONS

Parasitic diseases are common and may present clinically in a variety of ways (Table 41–1). Although travel to endemic areas suggests particular infections, many are transmitted through fomites or acquired from contact with human carriers and can occur anywhere. Some of the less common parasitic infections and those seen primarily in the developing world are presented in abbreviated form in Table 41–2.

Selection of Patients for Evaluation

The incidence of parasitic infections varies greatly with geographic area. Children who have traveled or lived in areas where parasitic infections are endemic are at risk for infection with a variety of intestinal and tissue parasites. Children who have resided only in developed countries are usually free of tissue parasites (except *Toxoplasma*). Searching for intestinal parasites is expensive for the patient and time-consuming for the laboratory. More than 90% of ova and parasite examinations performed in most hospital laboratories in the United States are negative; many have been ordered inappropriately. An approach to determining which children with diarrhea need such examinations is presented in Figure 41–1. It can be more cost-effective to treat symptomatic U.S. immigrants with albendazole or nitazoxanide, broad-spectrum anti-parasitic drugs, and to investigate only those whose symptoms persist.

Immunodeficient children are very susceptible to protozoal intestinal infections. Multiple opportunists are frequently identified, and the threshold for ordering tests should be low for these children.

Specimen Processing

For tissue parasites, contact the laboratory for proper collection procedures. Diarrheal stools may contain trophozoites that die rapidly during transport. The specimen should be either examined immediately or placed in a stool fixative such as polyvinyl alcohol. Fixative vials for home collection of stool are available. They may contain toxic compounds, so they should be stored safely. Fixed specimens are stable at room temperature. Formed stools usually contain cysts that are more stable. It is also best to fix these after collection, although they may be reliably examined after transport at room temperature.

Eosinophilia & Parasitic Infections

Although some parasites commonly cause eosinophilia, in developed countries other causes are much more common and include allergies, drugs, and other infections. Heavy intestinal nematode infections cause eosinophilia; they are easily detected on a single ova and parasite examination. Light nematode infections and common protozoal infections—giardiasis, cryptosporidiosis, and amebiasis—rarely cause eosinophilia. Eosinophilia is also unusual or minimal in more serious infections such as amebic liver abscess and malaria.

The most common parasitic infection in the United States that causes significant eosinophilia with negative stool examination is toxocariasis. In a young child with unexplained eosinophilia and a negative stool examination, a serologic test for *Toxocara* may be the next appropriate test. Trichinosis is a rare cause of marked eosinophilia; strongyloidiasis is a cause of eosinophilia that may be difficult to diagnose with stool examinations. The differential diagnosis of eosinophilia is broad for patients who have been in developing countries (see Table 41–1).

Table 41-1. Signs and symptoms of parasitic infection.

Sign/Symptom	Agent	Comments ^a
Abdominal pain	<i>Anisakis</i>	Shortly after raw fish ingestion.
	<i>Ascaris</i>	Heavy infection may obstruct bowel, biliary tract.
	<i>Clonorchis</i>	Heavy, early infection. Hepatomegaly later.
	<i>Entamoeba histolytica</i>	Hematochezia, variable fever, diarrhea.
	<i>Fasciola hepatica</i>	Diarrhea, vomiting.
	Hookworm	Iron deficiency anemia with heavy infection.
	<i>Strongyloides</i>	Eosinophilia, pruritus. May resemble peptic disease.
	<i>Trichinella</i> <i>Trichuris</i>	Myalgia, periorbital edema, eosinophilia. Diarrhea, dysentery with heavy infection.
Cough	<i>Ascaris</i>	Wheezing, eosinophilia during migration phase.
	<i>Paragonimus westermani</i>	Hemoptysis; chronic. May mimic tuberculosis.
	<i>Strongyloides</i>	Wheezing, pruritus, eosinophilia during migration or dissemination.
	<i>Toxocara</i>	Affects ages 1-5 y; hepatosplenomegaly; eosinophilia.
	Tropical eosinophilia	Pulmonary infiltrates, eosinophilia.
Diarrhea	<i>Blastocystis</i>	Possibly with heavy infection in immunosuppressed or immunocompetent individuals.
	<i>Cyclospora</i>	Watery; severe in immunosuppressed individuals
	<i>Cryptosporidium</i>	Watery; prolonged in normals, chronic in immunosuppressed individuals.
	<i>Dientamoeba fragilis</i>	Only with heavy infection.
	<i>Entamoeba histolytica</i>	Hematochezia, variable fever; no eosinophilia.
	<i>Giardia</i>	Afebrile, chronic; anorexia
	<i>Schistosoma</i>	Chronic; hepatosplenomegaly (some types).
	<i>Strongyloides</i>	Abdominal pain; eosinophilia.
	<i>Trichinella</i> <i>Trichuris</i>	Myalgia, periorbital edema, eosinophilia. With heavy infection.
Dysentery	<i>Balantidium coli</i>	Swine contact.
	<i>Entamoeba histolytica</i>	Few to no leukocytes in stool; fever; hematochezia.
	<i>Schistosoma</i>	During acute infection.
	<i>Trichuris</i>	With heavy infection.
Dysuria	<i>Enterobius</i>	Usually girls with worms in urethra, bladder; nocturnal, perianal pruritus.
	<i>Schistosoma</i>	Hematuria. Exclude bacteriuria, stones (some types).
Headache (and other cerebral symptoms)	<i>Angiostrongylus</i>	Eosinophilic meningitis.
	<i>Naegleria</i>	Fresh-water swimming; rapidly progressive meningoencephalitis.
	<i>Plasmodium</i>	Fever, chills, jaundice, splenomegaly. Cerebral ischemia (with <i>P falciparum</i>).
	<i>Taenia solium</i>	Cysticercosis. Focal seizures, deficits; hydrocephalus, aseptic meningitis.
	<i>Toxoplasma</i>	Meningoencephalitis (especially in infants and the immunosuppressed); hydrocephalus in infants.
	<i>Trypanosoma</i>	African forms. Chronic lethargy (sleeping sickness).
Pruritus	<i>Ancylostoma braziliense</i>	Creeping eruption; dermal serpiginous burrow.
	<i>Enterobius</i>	Perianal, nocturnal.
	Filaria	Variable; seen in many filarial diseases.
	Hookworm	Local at penetration site in heavy exposure.
	<i>Strongyloides</i>	Diffuse with migration; may be recurrent.
	<i>Trypanosoma</i>	African forms; one of many nonspecific symptoms.

(continued)

Table 41-1. Signs and symptoms of parasitic infection. (Continued)

Sign/Symptom	Agent	Comments ^a
Fever	<i>Entamoeba histolytica</i> <i>Leishmania donovani</i> <i>Plasmodium</i> <i>Toxocara</i> <i>Toxoplasma</i> <i>Trichinella</i> <i>Trypanosoma</i>	With acute dysentery or liver abscess. Hepatosplenomegaly, anemia, leukopenia. Chills, headache, jaundice; periodic. Cough, hepatosplenomegaly, eosinophilia. Generalized adenopathy; splenomegaly. Myalgia, periorbital edema, eosinophilia. Early stage, African forms; lymphadenopathy.
Anemia	<i>Diphyllobothrium</i> Hookworm <i>Leishmania donovani</i> <i>Plasmodium</i> <i>Trichuris</i>	Megaloblastic due to B ₁₂ deficiency; rare. Iron deficiency. Fever, hepatosplenomegaly, leukopenia (kala-azar). Hemolysis. Heavy infection; due to iron loss.
Eosinophilia	<i>Angiostrongylus</i> <i>Fasciola</i> Filaria <i>Onchocerca</i> <i>Schistosoma</i> <i>Strongyloides</i> <i>Toxocara</i> <i>Trichinella</i> Tropical pulmonary eosinophilia	Eosinophilic meningitis. Abdominal pain. Microfilariae in blood; lymphadenopathy. Skin nodules, keratitis. Chronic; intestinal or genitourinary symptoms. Abdominal pain, diarrhea. Hepatosplenomegaly, cough; affects ages 1-5 y. Myalgia, periorbital edema. Cough.
Hematuria	<i>Schistosoma</i>	<i>S haematobium</i> . Bladder, urethral granulomas. Exclude stones, bacteriuria.
Hemoptysis	<i>Paragonimus westermani</i>	Lung fluke. Variable chest pain; chronic.
Hepatomegaly	<i>Clonorchis</i> <i>Echinococcus</i> <i>Entamoeba histolytica</i> <i>Leishmania donovani</i> <i>Schistosoma</i> <i>Toxocara</i>	Heavy infection. Tenderness early; cirrhosis late. Chronic; cysts. Toxic hepatitis or abscess. No eosinophilia. Splenomegaly, fever, pancytopenia. Chronic; hepatic fibrosis, splenomegaly (some types). Splenomegaly, eosinophilia, cough; no adenopathy.
Splenomegaly	<i>Leishmania donovani</i> <i>Plasmodium</i> <i>Schistosoma</i> <i>Toxocara</i> <i>Toxoplasma</i>	Hepatomegaly, fever, anemia. Fever, chills, jaundice, headache. Hepatomegaly. Eosinophilia, hepatomegaly. Lymphadenopathy, other symptoms.
Lymphadenopathy	Filaria <i>Leishmania donovani</i> <i>Schistosoma</i> <i>Toxoplasma</i> <i>Trypanosoma</i>	Inguinal typical; chronic. Hepatosplenomegaly, pancytopenia, fever. Acute infection; fever, rash, arthralgia, hepatosplenomegaly. Cervical common; may involve single site; splenomegaly. Localized near bite or generalized; hepatosplenomegaly (Chagas disease); generalized (especially posterior cervical) in African forms.

^aSymptoms usually related to degree of infestation. Infestation with small numbers of organisms is often asymptomatic.

Table 41-2. Some parasitic infections seen less commonly in developed regions.

Agent (Disease)	Geographic Region	Vector	Symptoms and Signs	Laboratory Findings	Diagnosis	Therapy and Comments
<i>Angiostrongylus cantonensis</i> (eosinophilic meningitis)	Hawaii, Asia, Pacific Islands	Snails, slugs	Ingestion (usually inadvertent) followed in 1-4 wk by meningitis of variable severity. Paresthesias.	Eosinophils in CSF and blood	Positive serology. Larvae may be present in CSF.	Fever absent or low. No focal lesions on CNS imaging. No specific therapy. Steroids may be beneficial. Mebendazole may help.
<i>Clonorchis sinensis</i> (liver fluke infection)	Asia	Raw fish	Adult flukes obstruct biliary tree. Acute: hepatomegaly, fever, jaundice, urticaria. Late: cirrhosis, carcinoma.	Variable liver function abnormalities	Ova in feces.	Praziquantel. Advanced disease not treatable. Liver transplant.
<i>Leishmania braziliensis</i> , <i>L. mexicana</i> (chiclero ulcer)	South America	Sandfly	Painful mucocutaneous ulcers or granulomas. Nasolabial lesions common.	—	Skin biopsy. Positive skin test, serology.	Same as for <i>L. donovani</i> ; ketoconazole.
<i>Leishmania donovani</i> (kala-azar)	Mideast, India, Mediterranean, South and Central America	Sandfly	Fever, generalized adenopathy, hepatosplenomegaly weeks to months after infection.	Pancytopenia, hypergammaglobulinemia	Organisms in skin biopsy. Positive skin test, serology.	Sodium stibogluconate, meglumine antimonate, pentamidine, amphotericin B.
<i>Leishmania tropica</i> (Oriental sore)	Asia, India, North Africa	Sandfly	Papule at bite site (usually on face, limbs) develops after weeks to months, then ulcerates and scars.	—	Organisms in skin biopsy. Positive skin test, serology.	Same as for <i>L. donovani</i> .
<i>Paragonimus westermani</i> (lung fluke infection)	Asia, South America, Africa	Raw crabs, crustaceans	Cough, hemoptysis. Rarely seizures, other CNS signs if migration to brain occurs.	—	Large ova in concentrated specimens, feces. Cystic nodular lesions on chest radiograph or CNS imaging.	Resembles pulmonary tuberculosis. Praziquantel very effective.
<i>Trypanosoma brucei</i> (sleeping sickness)	Africa	Tsetse fly	Hepatosplenomegaly, adenopathy. Nodule at bite site (resolves). Recurrent fever, headache, myalgia, progressive encephalitis.	Elevated ESR, anemia, CSF pleocytosis	Organisms in marrow, nodes, spleen. Positive serology.	Suramin, eflornithine, pentamidine, melarsoprol.
<i>Trypanosoma cruzi</i> (Chagas disease)	South and Central America, Mexico	Reduviid bug	Acute: painful red nodule at bite site, conjunctivitis, periorbital edema (Romaña sign), fever, local ± generalized adenitis. Late: myocarditis, megaesophagus, megacolon.	Mononuclear leukocytosis	Organisms in peripheral blood. Positive serology.	Nifurtimox or benznidazole may help early. No therapy for late disease. May be transmitted by blood transfusion or congenitally.
<i>Wuchereria</i> , <i>Brugia</i> (filariasis)	Tropics, subtropics	Mosquito	Chronic adenopathy, often inguinal. Obstructive lymphedema.	Eosinophilia	Concentrated blood smears for larvae. Positive serology.	Diethylcarbamazine kills larvae. Surgery for lymphatic obstruction.

CNS, central nervous system; CSF, cerebrospinal fluid; ESR, erythrocyte sedimentation rate.

O + P = Ova and parasite examination.

^a*Shigella*, *Salmonella*, *Campylobacter*, *E coli* (*Escherichia coli*) O 157, *Yersinia*: assay for *Clostridium difficile* toxin if recent antimicrobial use.

^bUnless critically ill, from endemic area for amebiasis, or unresponsive to standard therapy.

^cInclude examination for *Cryptosporidium* and *Cyclospora*; immediate stool fixation needed if stool is diarrheal.

▲ **Figure 41-1.** Parasitologic evaluation of acute diarrhea.

PROTOZOAL INFECTIONS

SYSTEMIC INFECTIONS

1. Malaria

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Residence in or travel to an endemic area.
- ▶ Cyclic paroxysms of chills, fever, and intense sweating.
- ▶ Headache, backache, cough, abdominal pain, nausea, vomiting, diarrhea.
- ▶ Coma, seizures.
- ▶ Splenomegaly, anemia.
- ▶ Malaria parasites in peripheral blood smear.

▶ General Considerations

Malaria kills a million children worldwide each year and is undergoing a resurgence in areas where it was previously controlled. Approximately 1000 imported cases are diagnosed

in the United States each year; local transmission may also occasionally take place from imported cases. The female anopheline mosquito transmits the parasites—*Plasmodium vivax* (most common), *P falciparum* (most virulent), *P ovale* (similar to *P vivax*), and *P malariae*. The gametocytes ingested from an infected human form sporozoites in the mosquito; when these are inoculated into a susceptible host, they infect hepatocytes. The preerythrocytic phase (hepatic) is about 1–2 weeks for all but *P malariae* infection (3–5 weeks), but the initial symptoms may be delayed for up to a year in *P falciparum*, 4 years in *P vivax*, and decades in *P malariae* infections. Merozoites released into the circulation from hepatocytes infect red cells (young cells by *P vivax* and *P ovale*, old cells by *P malariae*, and all cells by *P falciparum*) and begin the synchronous erythrocytic cycles, rupturing the infected cells at regular 48- or 72-hour intervals. Asynchronous cycles causing daily fevers are most common in early stages of infection. Survival is associated with a progressive decrease in intensity of cycles; relapses years later may occur from persistent hepatic infection, which occurs in *P vivax*, *P ovale* and *P malariae* infections. Infection acquired congenitally or from transfusions or needlesticks does not result in a hepatic phase.

Susceptibility varies genetically; certain red cell phenotypes are partially resistant to *P falciparum* infection (hemo-

globin S, hemoglobin F, thalassemia, and possibly glucose-6-phosphate dehydrogenase [G6PD] deficiency). The worldwide distribution of the four species is determined to some extent by host genetic factors. The absence of *P vivax* from Africa reflects the lack of specific Duffy blood group substances among most native Africans. Recurrent infections result in some natural species-specific immunity; this does not prevent infection but does decrease parasitemia and symptoms. Normal splenic function is an important factor because of the immunologic and filter function of the spleen. Asplenic persons develop rapidly progressive malaria with many circulating infected erythrocytes (including mature forms of *P falciparum*). Maternal immunity protects the neonate.

► Clinical Findings

A. Symptoms and Signs

Clinical manifestations vary according to species, strain, and host immunity. The infant presents with recurrent bouts of fever, irritability, poor feeding, vomiting, jaundice, and splenomegaly. Rash is usually absent, which helps distinguish malaria from viral infections in patients presenting with similar symptoms. In older children, the pathognomonic constellation of headache, backache, chills, myalgia, and fatigue is more easily elicited. Fever may be cyclic (every 48 hours for all but *P malariae* infection, in which it occurs every 72 hours) or irregular (most commonly observed with *P falciparum*). Between attacks, patients may look quite well. If the disease is untreated, relapses cease within a year in *P falciparum* and within several years in *P vivax* infections, but may recur decades later with *P malariae* infection. Infection during pregnancy often causes intrauterine growth restriction or premature delivery, but rarely true fetal infection.

Physical examination in patients with uncomplicated cases may show only mild splenomegaly and anemia.

B. Laboratory Findings

The diagnosis of malaria relies on detection of one or more of the four human plasmodia in blood smears. Most acute infections are caused by *P vivax*, *P ovale*, or *P falciparum*, although 5–7% are due to multiple species. Giemsa-stained thick smears offer the highest diagnostic accuracy for malaria parasites. Identification of the *Plasmodium* species relies on morphologic criteria (Table 41–3) and requires an experienced observer.

Alternative techniques of similar or higher diagnostic accuracy for *P falciparum* include enzyme-linked immunosorbent assay (ELISA), DNA hybridization, and polymerase chain reaction (PCR). Rapid antigen detection tests (RDTs) have recently been developed and are starting to be used in malaria endemic areas in Africa. A unique feature of the microscopic examination is the semiquantitative estimate of the parasitemia, which is best done on thin smears. This information is particularly useful in the management of

Table 41–3. Differentiation of malaria parasites on blood smears.

	<i>Plasmodium falciparum</i>	<i>P vivax</i> , <i>P ovale</i>
Multiple infected erythrocytes	Common	Rare
Mature trophozoites or schizonts	Absent ^a	Common
Schüffner dots	Absent	Common
Enlarged erythrocytes	Absent	Common
Banana-shaped gametocytes	Common	Absent

^aUsually sequestered in the microcirculation. Rare cases with circulating forms have extremely high parasitemia and a poor prognosis.

infections caused by *P falciparum*, in which high parasitemia (more than 10% infected erythrocytes or more than 500,000 infected erythrocytes/ μ L) is associated with high morbidity and mortality and requires hospitalization. Treatment response of *P falciparum* and chloroquine-resistant *P vivax* infections is best monitored by daily parasitemia assays. Constant or increased number of infected erythrocytes after 48 hours of treatment or after the second hemolytic crisis suggests an inadequate therapeutic response. Other laboratory findings that reflect the severity of the hemolysis include decreased hematocrit, hemoglobin, and haptoglobin levels; increased reticulocyte count; and hyperbilirubinemia and increased lactate dehydrogenase. Thrombocytopenia is common, but the incidence of leukocytosis is variable.

► Differential Diagnosis

Relapsing fever may be associated with borreliosis, brucellosis, sequential common infections, Hodgkin disease, juvenile rheumatoid arthritis, rat-bite fever, or one of the idiopathic periodic fevers. Other common causes of high fever and headache include influenza, *Mycoplasma pneumoniae* or enteroviral infection, sinusitis, meningitis, enteric fever, tuberculosis, occult pneumonia, or bacteremia. Fever, headache, and jaundice in a patient returning from tropical areas indicate that leptospirosis and yellow fever should be included in the differential diagnosis. Malaria may also coexist with other diseases.

► Complications & Sequelae

Severe complications are limited to *P falciparum* infection and result from microvascular obstruction and tissue ischemia. Impaired consciousness and seizures are the most common complications of malaria in children. In addition, respiratory failure, renal impairment, severe bleeding, and shock are associated with a poor prognosis. Among the laboratory abnormalities, hypoglycemia, acidosis, elevated

aminotransferases, and parasitemia greater than 10% characterize severe malaria.

► Prevention

Malaria chemoprophylaxis should be instituted 2 weeks (weekly regimens) to 2 days (daily regimens) before traveling to an area of endemic infection to permit changes if the drug is not tolerated. Because the antimalarial drugs recommended for prophylaxis do not kill sporozoites, therapy should be continued for 1 week (atovaquone–proguanil) or 4 weeks (all other regimens) after returning from an endemic area to cover infection acquired at departure.

Chloroquine is the drug of choice for prophylaxis of *P vivax*, *P ovale*, *P malariae*, and chloroquine-sensitive *P falciparum* (Table 41–4). Chloroquine is safe for all ages and during pregnancy. Side effects (dizziness, blurred vision, and headache) can be reduced by administering half of the weekly dose twice per week. Effects of chloroquine on heart rhythm are infrequent and are typically associated with rapid intravenous infusion or overdosage. Chloroquine has immunosuppressive properties and has been reported to impair immunization against rabies but not against yellow fever.

For chloroquine-resistant *P falciparum*, the regimens of choice are weekly mefloquine, daily doxycycline, or daily atovaquone–proguanil. The side effects of mefloquine are headache, dizziness, and blurred vision. This drug is now considered safe during pregnancy, but is not used in children weighing less than 5 kg. Daily doxycycline is recommended for patients older than age 8 years who are unable to tolerate mefloquine. Women on prolonged doxycycline therapy tend to develop yeast vaginitis, and it is advisable to supply them with nystatin suppositories. Atovaquone–proguanil is better tolerated than mefloquine. For optimal absorption, this drug should be administered with food or no later than 45 minutes after a meal. Daily primaquine is also effective. Primaquine is also used to prevent relapse of *P vivax* or *P ovale* infections. Primaquine is contraindicated for patients with G6PD deficiency, in whom it induces hemolysis. Less effective alternatives include chloroquine plus proguanil or chloroquine alone, with one therapeutic dose of pyrimethamine–sulfadoxine made available for self-treatment in the advent of potential breakthrough, signaled by fever while in areas where medical attention is not readily available.

No drug regimen guarantees protection against malaria. If fever develops within 1 year (particularly within 2 months) after travel to an endemic area, patients should be advised to seek medical attention. Insect repellents, insecticide-impregnated bed nets, and proper clothing are important adjuncts for malaria prophylaxis.

► Treatment

Treatment for malaria includes a variety of supportive strategies in addition to the antimalarial drugs. It is advisable to hospitalize nonimmune patients infected with *P falciparum*

Table 41–4. Chemoprophylaxis of malaria.^a

Drug	Dosage
Chloroquine-sensitive areas^b	
Chloroquine	5 mg base/kg/wk up to 300 mg (adult dose)
Chloroquine-resistant areas	
Mefloquine	0.125 tablet (31.25 mg) once a week (5–10 kg) 0.25 tablet (62.5 mg) once a week (11–20 kg) 0.5 tablet (125 mg) (21–30 kg) 0.75 tablet (187.5 mg) (31–45 kg) 1 tablet (250 mg) (> 45 kg)
Doxycycline	2 mg/kg/daily (age > 8 y) up to 100 mg (adult dose)
Atovaquone–proguanil	11–20 kg: 62.5 mg/25 mg daily (1 pediatric tablet) 21–30 kg: 125 mg/50 mg (2 pediatric tablets) 31–40 kg: 187.5 mg/75 mg (3 pediatric tablets) > 40 kg: 250 mg/100 mg (1 adult tablet)
Primaquine	0.6 mg/kg base daily up to 30 mg (adult dose)
Chloroquine Plus Proguanil	As above
Proguanil	50 mg daily (age < 2 y) 100 mg (age 2–6 y) 150 mg (age 7–10 y) 200 mg (age > 10 y)
Self-presumptive therapy	
Atovaquone–proguanil (carry a course for self-treatment of febrile illness when medical care is not immediately available)	< 5 kg: not indicated 5–8 kg: 2 pediatric tablets daily × 3 d > 8–10 kg: 3 pediatric tablets daily × 3 d > 10–20 kg: 1 adult tablet daily × 3 d > 20–30 kg: 2 adult tablets daily × 3 d > 30–40 kg: 3 adult tablets daily × 3 d > 40 kg: 4 adult tablets daily × 3 d
Relapse of <i>P vivax</i> or <i>P ovale</i>^c	
Primaquine	0.3 mg base/kg/d up to 15 mg (adult dose) during the last 2 wk of prophylaxis

^aUpdated malaria chemoprophylaxis information may be obtained by calling the Centers for Disease Control and Prevention Hot Line at (404) 332-4555 or on the web at <http://www.cdc.gov>.

^bChloroquine-resistant *Plasmodium falciparum* has not yet been identified in Central America west of the Panama Canal zone, Haiti, Dominican Republic, Mexico, and most of the Middle East.

^cOptional. Observation and prompt initiation of treatment when relapse occurs is sufficient.

until a decrease in parasitemia is demonstrated, indicating that treatment is effective and severe complications are unlikely to occur.

Partially immune patients with uncomplicated *P falciparum* infection and nonimmune persons infected with *P vivax*, *P ovale*, or *P malariae* can receive treatment as outpatients if follow-up is reliable. For children, hydration and treatment of hypoglycemia are of utmost importance. Anemia, seizures, pulmonary edema, and renal failure require conventional management. Corticosteroids are contraindicated for cerebral malaria because of increased mortality. In severe malaria, exchange transfusion can be lifesaving, particularly in nonimmune persons with parasitemia greater than 15%.

Choice of antimalarial treatment depends on the immune status of the person, plasmodium species, degree of parasitemia, and geographical region of acquisition. An algorithm for the treatment of malaria is shown in Figure 41–2 and a description of the recommended antimalarial drugs available in the United States is provided in Table 41–5. Artemisinin derivatives clear parasites very rapidly and are now widely used as key components in malaria treatment worldwide, but currently they are not available in the United States.

Griffith KS et al: Treatment of malaria in the United States. *JAMA* 2007;297:2264 [PMID: 17519416].

2. Babesiosis

Babesia microti is a malaria-like protozoan that infects and lyses erythrocytes of wild and domestic animals in North America and Europe. In the United States, human babesiosis has been identified in the coastal areas of New England, northern California and Washington State, and in the lakes region of the upper Midwest. Humans accidentally enter the cycle when bitten by *Ixodes scapularis* (deer tick), one of the intermediate hosts and vectors of *B microti*. After inoculation, the protozoan penetrates the erythrocytes and starts an asynchronous cycle that causes hemolysis.

► Clinical Findings

A. Symptoms and Signs

The incubation period is 1–3 weeks but may extend up to 6 weeks. Many times the tick bite is unnoticed. Symptoms are nonspecific and include sustained or cyclic fever up to 40°C, shaking chills, malaise, myalgias, headache, and dark urine. Hepatosplenomegaly is an uncommon finding. The disease is usually self-limited, but severe cases have been described in asplenic patients and immunocompromised hosts. Because they share a common vector, physicians should consider the

possibility of coinfection with *Borrelia burgdorferi* or *Anaplasma phagocytophilum* in any patient diagnosed with *Babesia* infection.

B. Laboratory Findings

The presence of viral infection-like symptoms and identification of babesial parasites in blood by microscopic evaluation of thin or thick blood smears or by PCR amplification of babesial DNA is required to make the diagnosis. *Babesia* parasites are intraerythrocytic organisms that resemble *P falciparum* ring forms. Specific serologic tests are also available through the Centers for Disease Control and Prevention.

► Treatment

Clindamycin (7–10 mg/kg, up to 600 mg, every 8 hours) in combination with quinine (8 mg/kg, up to 650 mg, every 8 hours) or azithromycin (10 mg/kg up to 500 mg on the first day, followed by 5 mg/kg up to 250 mg/day) and atovaquone (20 mg/kg, up to 750 mg, twice a day) for 7–10 days is the treatment of choice. Other antimalarial drugs, including chloroquine, have been unsuccessful. Partial or complete RBC exchange transfusion is indicated for persons with severe babesiosis, as indicated by high grade parasitemia ($\geq 10\%$), significant hemolysis, or renal, hepatic, or pulmonary compromise.

Wormser GP et al: The clinical assessment, treatment, and prevention of Lyme disease, human granulocytic anaplasmosis, and babesiosis: Clinical practice guidelines by the Infectious Disease Society of America. *Clin Infect Dis* 2006;43:1089 [PMID: 17029130].

3. Toxoplasmosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Congenital toxoplasmosis: chorioretinitis, microphthalmia, strabismus, microcephaly, hydrocephaly, convulsions, psychomotor retardation, intracranial calcifications, jaundice, hepatosplenomegaly, abnormal blood cell counts.
- Acquired toxoplasmosis in an immunocompetent host: lymphadenopathy, hepatosplenomegaly, rash.
- Acquired or reactivated toxoplasmosis in an immunocompromised host: encephalitis, chorioretinitis, myocarditis, and pneumonitis.
- Ocular toxoplasmosis: chorioretinitis.
- Serologic evidence of infection with *Toxoplasma gondii* or demonstration of the agent in tissue or body fluids.

► General Considerations

Toxoplasma gondii is a worldwide parasite of animals and birds. Felines, the definitive hosts, excrete oocysts in their

*If species not yet identified is subsequently diagnosed as a non-falciparum infection, then complete treatment as per the identified species recommendations. G6PD indicates glucose-6-phosphate dehydrogenase. †Central America west of the Panama Canal, Mexico, Hispaniola, parts of China, and the Middle East. ‡All malaria-endemic countries except those listed in second footnote. §Contraindicated in pregnant women and children younger than 8 years of age. ¶Drug options for chloroquine-resistant *P falciparum* may also be used if chloroquine or hydroxychloroquine cannot be used.

Table 41-5. Antimalarial drugs available in the United States recommended for use in the treatment of malaria.

Drug	Indication	Adult Dosage	Pediatric Dosage ^a	Potential Adverse Effects	Comments
Atovaquone-proguanil (oral)	<i>Plasmodium falciparum</i> from chloroquine-resistant areas	Adult tablet = 250 mg atovaquone/100 mg proguanil 4 adult tablets orally per day × 3 d	Pediatric tablet = 62.5 mg atovaquone/25 mg proguanil 5-8 kg: 2 pediatric tablets orally per day × 3 d > 8-10 kg: 3 pediatric tablets orally per day × 3 d > 10-20 kg: 1 adult tablet orally per day × 3 d > 20-30 kg: 2 adult tablets orally per day × 3 d > 30-40 kg: 3 adult tablets orally per day × 3 d > 40 kg: 4 adult tablets orally per day × 3 d	Abdominal pain, nausea, vomiting, diarrhea, headache, rash, mild reversible elevations in liver aminotransferase levels	Not indicated for use in pregnant women due to limited data Contraindicated if hypersensitivity to atovaquone or proguanil; severe renal impairment (creatinine clearance < 30 mL/min) Should be taken with food to increase absorption of atovaquone
Chloroquine phosphate	<i>P falciparum</i> from chloroquine-sensitive areas <i>P vivax</i> from chloroquine-sensitive areas All <i>P ovale</i> ; all <i>P malariae</i>	600-mg base (= 1000 mg salt) orally immediately, followed by 300-mg base (= 500 mg salt) orally at 5, 24, and 48 h Total dose: 1500-mg base (= 2500 mg salt)	10-mg base/kg orally immediately, followed by 6-mg base/kg orally at 6, 24, and 48 h Total dose: 25-mg base/kg	Nausea, vomiting, rash, headache, dizziness, urticaria, abdominal pain, pruritus	Safe in children and pregnant women Give for chemoprophylaxis (500 mg salt orally every week) in pregnant women with chloroquine-sensitive <i>P vivax</i> Contraindicated if retinal or visual field change; hypersensitivity to 4-aminoquinolines Use with caution in those with impaired liver function since the drug is concentrated in the liver
Clindamycin (oral or IV)	<i>P falciparum</i> from chloroquine-resistant areas <i>P vivax</i> from chloroquine-resistant areas (in combination with quinine-quinidine)	Oral: 20-mg base/kg/d orally divided 3 times daily × 7 d IV: 10-mg base/kg loading dose IV followed by 5-mg base/kg IV every 8 h; switch to oral clindamycin (oral dose as above) as soon as patient can take oral medication; treatment course = 7 d	Oral: 20-mg base/kg/d orally divided 3 times daily × 7 d IV: 10-mg base/kg loading dose IV followed by 5-mg base/kg IV every 8 h; switch to oral clindamycin (oral dose as above) as soon as patient can take oral medication; treatment course = 7 d	Diarrhea, nausea, rash	Always use in combination with quinine-quinidine Safe in children and pregnant women

Doxycycline (oral or IV)	<p><i>P falciparum</i> from chloroquine-resistant areas</p> <p><i>P vivax</i> from chloroquine-resistant areas (in combination with quinine-quinidine)</p>	<p>Oral: 100 mg orally twice daily \times 7 d</p> <p>IV: 100 mg IV every 12 h and then switch to oral doxycycline (as above) as soon as patient can take oral medication; treatment course = 7 d</p>	<p>Oral: 2.2 mg/kg orally every 12 h \times 7 d</p> <p>IV: IV only if patient is not able to take oral medication; for children < 45 kg, give 2.2 mg/kg IV every 12 h and then switch to oral doxycycline (dose as above) as soon as patient can take oral medication; for children \geq 45 kg, use same dosing as for adults; treatment course = 7 d</p>	<p>Nausea, vomiting, diarrhea, abdominal pain, dizziness, photosensitivity, headache, esophagitis, odynophagia</p> <p>Rarely, hepatotoxicity, pancreatitis, and benign intracranial hypertension seen with tetracycline class of drugs</p>	<p>Always use in combination with quinine-quinidine</p> <p>Contraindicated in children < 8 y, pregnant women, and persons with hypersensitivity to tetracyclines</p> <p>While food, milk, and divalent and trivalent cations decrease the absorption of tetracycline, doxycycline can be taken with food, including milk products, which helps to decrease gastrointestinal disturbances</p> <p>To prevent esophagitis, the tetracyclines should be taken with large amounts of fluids, and patients should not lie down for 1 h after taking the drugs</p> <p>Concurrent treatment with barbiturates, carbamazepine, or phenytoin may cause a reduction in serum concentrations of doxycycline</p>
Hydroxychloroquine (oral)	<p>Second-line alternative for treatment of:</p> <p><i>P falciparum</i> from chloroquine-sensitive areas</p> <p><i>P vivax</i> from chloroquine-sensitive areas</p> <p>All <i>P ovale</i>; all <i>P malariae</i></p>	<p>620-mg base (= 800 mg salt) orally immediately, followed by 310-mg base (= 400 mg salt) orally at 6, 24, and 48 h</p> <p>Total dose: 1550-mg base (= 2000 mg salt)</p>	<p>10-mg base/kg orally immediately, followed by 5-mg base/kg orally at 6, 24, and 48 h</p> <p>Total dose: 25-mg base/kg</p>	<p>Nausea, vomiting, rash, headache, dizziness, urticaria, abdominal pain, pruritus^b</p>	<p>Safe in children and pregnant women</p> <p>Give for chemoprophylaxis (310-mg base orally every week) in pregnant women with chloroquine-sensitive <i>P vivax</i></p> <p>Contraindicated if retinal or visual field change; hypersensitivity to 4-aminoquinolines</p> <p>Use with caution in those with impaired liver function</p>

(continued)

Table 41-5. Antimalarial drugs available in the United States recommended for use in the treatment of malaria. (Continued)

Drug	Indication	Adult Dosage	Pediatric Dosage ^a	Potential Adverse Effects	Comments
Mefloquine ^c	<i>P falciparum</i> from chloroquine-resistant areas, except Thailand-Burmese and Thailand-Cambodian border regions <i>P vivax</i> from chloroquine-resistant areas	684-mg base (= 750 mg salt) orally as initial dose, followed by 456-mg base (= 500 mg salt) orally given 6–12 h after initial dose Total dose = 1250 mg salt	13.7-mg base/kg (= 15 mg salt/kg) orally as initial dose, followed by 9.1-mg base/kg (= 10 mg salt/kg) orally given 6–12 h after initial dose Total dose = 25 mg salt/kg	Gastrointestinal complaints (nausea, vomiting, diarrhea, abdominal pain), mild neuropsychiatric complaints (dizziness, headache, somnolence, sleep disorders), myalgia, mild skin rash, and fatigue; moderate to severe neuropsychiatric reactions, electrocardiographic changes, including sinus arrhythmia, sinus bradycardia, first degree atrioventricular block, prolongation of QTc interval, and abnormal T waves	Contraindicated if hypersensitive to the drug or to related compounds; cardiac conduction abnormalities; psychiatric disorders; and seizure disorders Do not administer if patient has received related drugs (chloroquine, quinine, quinidine) < 12 h earlier May be used for chemoprophylaxis (250 mg salt orally every week) in pregnant women with chloroquine-resistant <i>P vivax</i>
Primaquine phosphate	Radical cure of <i>P vivax</i> and <i>P ovale</i> (to eliminate hypnozoites)	30-mg base orally per day × 14 d	0.5-mg base/kg orally per day × 14 d	Gastrointestinal disturbances, methemoglobinemia (self-limited), hemolysis in persons with G6PD deficiency	Must screen for G6PD deficiency prior to use Contraindicated in persons with G6PD deficiency; pregnant women Should be taken with food to minimize gastrointestinal adverse effects
Quinine sulfate (oral)	<i>P falciparum</i> from chloroquine-resistant areas <i>P vivax</i> from chloroquine-resistant areas	542-mg base (= 650 mg salt) ^d orally 3 times daily × 3 d (infections acquired outside Southeast Asia) to 7 d (infections acquired in Southeast Asia)	8.3-mg base/kg (= 10 mg salt/kg) orally 3 times daily × 3 d (infections acquired outside Southeast Asia) to 7 d (infections acquired in Southeast Asia)	Cinchonism, ^e sinus arrhythmia, junctional rhythms, atrioventricular block, prolonged QT interval ventricular tachycardia, ventricular tachycardia, ventricular fibrillation (these are rare and more commonly seen with quinidine), hypoglycemia	Combine with tetracycline, doxycycline, or clindamycin, except for <i>P vivax</i> infections in children < 8 y or pregnant women Contraindicated in hypersensitivity including history of blackwater fever, thrombocytopenic purpura, or thrombocytopenia associated with quinine or quinidine use; many cardiac conduction defects and arrhythmias ^f ; myasthenia gravis; optic neuritis

<p>Quinidine gluconate (IV)</p>	<p>Severe malaria (all species, independently of chloroquine resistance) Patient unable to take oral medication Parasitemia > 10%</p>	<p>6.25-mg base/kg (= 10 mg salt/kg) loading dose IV over 1-2 h, then 0.0125-mg base/kg/min (= 0.02 mg salt/kg/min) continuous infusion for at least 24 h Alternative regimen: 15-mg base/kg (= 24 mg salt/kg) loading dose IV infused over 4 h, followed by 7.5 mg base/kg (= 12 mg salt/kg) infused over 4 h every 8 h, starting 8 h after the loading dose (see package insert); once parasite density < 1% and patient can take oral medication, complete treatment with oral quinine, dose as above Quinidine-quinine course = 7 d in Southeast Asia (3 d in Africa or South America)</p>	<p>Same as adult</p>	<p>Cinchonism, tachycardia, prolongation QRS and QTc intervals, flattening of T-wave (effects are often transient) Ventricular arrhythmias, hypotension, hypoglycemia</p>	<p>Combine with tetracycline, doxycycline, or clindamycin Contraindicated in hypersensitivity; thrombocytopenic purpura or thrombocytopenia associated with quinine or quinidine use; many cardiac conduction defects and arrhythmias⁹; myasthenia gravis; optic neuritis</p>
<p>Tetracycline (oral or IV)</p>	<p><i>P falciparum</i> from chloroquine-resistant areas <i>P vivax</i> from chloroquine-resistant areas (in combination with quinine-quinidine)</p>	<p>Oral: 250 mg orally 4 times daily × 7 d IV: dosage same as for oral</p>	<p>25 mg/kg/d orally divided 4 times daily × 7 d IV: dosage same as for oral</p>	<p>See doxycycline</p>	<p>See doxycycline</p>

^aPediatric dosage should never exceed adult dosage.

^bExtrapolated from chloroquine literature.

^cMefloquine should not be used to treat *P falciparum* infections acquired in the following areas: borders of Thailand with Burma (Myanmar) and Cambodia, western provinces of Cambodia, eastern states of Burma (Myanmar), border between Burma and China, Laos along borders of Laos and Burma (and adjacent parts of Thailand-Cambodia border), and southern Vietnam due to resistant strains.

^dQuinine sulfate capsule manufactured in the United States is in a 324-mg dose; therefore, 2 capsules should be sufficient for adult dosing.

^eNausea, vomiting, headache, tinnitus, deafness, dizziness, and visual disturbances.

^fRefer to quinine sulfate, package insert (Mutual Pharmaceutical Inc, Philadelphia, Pa, August 2005).

^gRefer to quinidine gluconate, package insert (Eli Lilly Co, Indianapolis, Ind, February 2002).

feces. Ingested mature oocysts or tissue cysts lead to tachyzoite invasion of the intestinal cells. Intracellular replication of the tachyzoites causes cell lysis and spread of the infection to adjacent cells or to other tissues via the bloodstream. In chronic infection, *T gondii* appears as bradyzoite-containing tissue cysts that do not trigger an inflammatory reaction. In immunocompromised hosts, tachyzoites are released from the cysts and begin a new cycle of infection.

The two major routes of *Toxoplasma* transmission to humans are oral and congenital. Oocysts survive for up to 18 months in moist soil. Oral infection occurs after ingestion of cysts on contaminated surfaces (including pica) and in undercooked meat or other food products. Oocyst survival is limited in dry, very cold, or very hot conditions, and at high altitude, which probably accounts for the lower incidence of toxoplasmosis in these climatic regions. In the United States, less than 1% of cattle and 25% of sheep and pigs are infected with toxoplasmosis. In humans, depending on geographic area, seropositivity increases with age from nil to 10% in children younger than age 10 years, to 3–70% in adults.

Congenital transmission occurs during acute infection of pregnant women; this occurs in 0.2–1% of all pregnancies in the United States. Rarely, fetal infection has been documented in immunocompromised mothers who have chronic toxoplasmosis. The rate of vertical transmission in patients with untreated toxoplasmosis increases from 10% in the first trimester to 60% in the third. Symptomatic disease, however, is more likely to follow infection in early gestation (20–25%) compared with late gestation (< 11%). Treatment during pregnancy decreases transmission by 60%.

► Clinical Findings

A. Congenital Toxoplasmosis

Congenital toxoplasmosis has a variety of manifestations, including miscarriage, prematurity, and stillbirth. Most frequently, symptomatic infants present with a combination of fever, microcephaly or hydrocephaly, hepatosplenomegaly, jaundice, chorioretinitis, convulsions, abnormal cerebrospinal fluid (xanthochromia and mononuclear pleocytosis), and cerebral calcifications. Other findings include strabismus, eye palsy, maculopapular rash, pneumonitis, myocarditis, thrombocytopenia, lymphocytosis and monocytosis, and an erythroblastosis-like syndrome. The overall mortality rate for congenital toxoplasmosis, which is approximately 10%, is higher in neonates who are symptomatic at birth.

B. Acquired *Toxoplasma* Infection in the Immunocompetent Host

Only 10–20% of acute *Toxoplasma* infections produce symptoms. Patients usually present with lymphadenopathy without fever. The nodes are discrete, variably tender, and do not suppurate. Cervical lymph nodes are most frequently involved, but any nodes may be enlarged. Less common

findings include fever, malaise, myalgias, fatigue, hepatosplenomegaly, low lymphocyte counts (usually < 10%), and liver enzyme elevations. Unilateral chorioretinitis may occur. The disease is self-limited, although lymph node enlargement may persist or may wax and wane for a few months to 1 or even more years. Rarely, an apparently healthy child may develop severe disseminated disease associated with myocarditis, pneumonitis, or encephalitis.

Toxoplasmic lymphadenitis must be distinguished from other causes of infectious mononucleosis-like syndromes (< 1% are caused by *Toxoplasma*).

C. Acute Toxoplasmosis in the Immunodeficient Host

Patients infected with human immunodeficiency virus (HIV), and those with lymphoma, leukemia, or transplantation, are at high risk for developing severe disease (encephalitis, chorioretinitis, myocarditis, or pneumonitis) following acute infection or reactivation. Children born to HIV- and *Toxoplasma*-infected mothers may acquire both pathogens in utero.

D. Ocular Toxoplasmosis

In active congenital toxoplasmosis, chorioretinitis is usually bilateral and shows acute inflammatory foci on funduscopic examination. This generally resolves, leaving depigmented scars of the retina surrounded by areas of hyperpigmentation. Chorioretinitis may reactivate in a single eye later in life. The appearance of the ocular lesion is not specific and mimics other granulomatous ocular diseases.

E. Diagnostic Findings

Active infection is diagnosed by demonstration of *T gondii* or its DNA in blood or body fluids; by visualization of tachyzoites in histologic sections or cytology preparations, or cysts in placenta or fetal tissues; by characteristic lymph node histology; or serologically (most commonly used). IgG antibodies, measured by the Sabin-Feldman dye test, immunofluorescence, ELISA, or particle agglutination, become detectable 1–2 weeks after infection, peak at 1–2 months, and after decreasing at variable speed, persist for life. IgM antibodies, measured by ELISA or particle agglutination, appear earlier and decline faster than IgG antibodies. Absence of both serum IgG and IgM virtually rules out the diagnosis of toxoplasmosis. Acute toxoplasmosis in an immunocompetent host is best documented by analyzing IgG and IgM in paired blood samples drawn 3 weeks apart. Because high antibody titers (IgM or IgG) can persist for several months after acute infection, a single high-titer determination is nonspecific. However, seroconversion or a fourfold increase in titer confirms the diagnosis. In the immunocompromised host, serologic tests are not sensitive, and active infection is documented by PCR or finding tachyzoites by histologic examination.

Patients with *Toxoplasma* chorioretinitis typically have low levels of specific IgG and absent IgM. The diagnosis can be confirmed by demonstrating high antibody titers in aqueous fluid.

Congenital infection is documented by anti-*Toxoplasma* IgM or IgA antibodies in the blood of the neonate. Prenatal diagnosis of congenital infection requires a combination of ultrasonography (to detect ventricle enlargement) and amniotic fluid PCR or cord blood serology. Amniotic fluid PCR is highly sensitive and carries fewer risks than cord puncture.

► Differential Diagnosis

Congenital toxoplasmosis must be differentiated from cytomegalovirus infection, rubella, herpes simplex infection, syphilis, Lyme disease, listeriosis, erythroblastosis, and the encephalopathies that accompany degenerative diseases. Acquired infection mimics viral, bacterial, or lymphoproliferative disorders.

► Prevention

Pregnant women and immunocompromised patients should wash hands thoroughly after handling raw meat, cook meat to 66°C or greater, wash fruits and vegetables before consumption, and avoid contact with cat feces. Serologic screening of pregnant women is warranted in areas of high prevalence. A first test should be performed by 10–12 weeks of pregnancy. Seronegative patients should be retested at 20–22 weeks' gestation and near term. Seroconverters require specific therapy.

► Treatment

Treatment does not reverse central nervous system (CNS) damage in neonates, but does markedly decrease late sequelae. A year of treatment is recommended for all congenitally infected infants; symptomatic patients receive 6 months of pyrimethamine and sulfadiazine, followed by alternating spiramycin and pyrimethamine–sulfadiazine monthly for the next 6 months. Subclinical infection is treated with pyrimethamine and sulfadiazine for 6 weeks, followed by alternating spiramycin for 6 weeks with pyrimethamine–sulfadiazine for 4 weeks.

Oral pyrimethamine at 1 mg/kg/d (maximum, 25 mg) causes gastrointestinal upset, leukopenia, thrombocytopenia, and rarely, agranulocytosis. Frequent blood counts should be performed to guide therapy. Leucovorin calcium (folinic acid), 5 mg given intramuscularly every 3 days, decreases myelotoxicity. The dosage of sulfadiazine is 40–45 mg/kg twice a day orally (maximum, 8 g/d). Clindamycin can be substituted for sulfadiazine in patients who cannot tolerate sulfonamides. Spiramycin and trimethoprim–sulfamethoxazole are less active.

Since acquired infection is usually self-limited, the potentially toxic therapy should be prescribed with discretion when the illness is uncomplicated.

In chorioretinitis, antimicrobial therapy (pyrimethamine and sulfadiazine) is used for 4 weeks. A course of corticosteroids (prednisone, 1.5 mg/kg up to 75 mg) is recommended when lesions involve the macula or the optic nerve. Lesions tend to improve after 10 days of therapy.

In primary infection during pregnancy, spiramycin is started immediately. Pyrimethamine plus sulfadiazine, alternating every 3 weeks with spiramycin, are used when fetal infection has been documented.

GASTROINTESTINAL INFECTIONS

1. Amebiasis

- Acute dysentery: diarrhea with blood and mucus, abdominal pain, tenesmus.
or
- Chronic nondysenteric diarrhea.
or
- Hepatic abscess.
- Amebas or cysts in stool or abscesses; amebic antigen in stool.
- Serologic evidence of amebic infection.

► General Considerations

Amebiasis, caused by *Entamoeba histolytica*, is a common problem in areas with poor sanitation. An estimated 10% of the world's population is infected with *E histolytica* or *Entamoeba dispar*, and an estimated 100,000 people die of amebic infection each year. Amebiasis should be suspected in patients with a history of travel to, or contact with individuals who may be asymptomatic carriers from, endemic areas. In the United States, amebiasis may occur in homes for the handicapped, where poor hygiene fosters the spread of enteric pathogens. *E histolytica* has been found in the stools of as many as 30% of homosexual men. Individuals of any age may be infected. Transmission is usually fecal-oral, often from asymptomatic carriers who pass cysts. Trophozoites are killed by stomach acid and are not infectious. Infection with *E dispar*, which is morphologically identical to *E histolytica* but results only in asymptomatic carriage, is ten times more common than infection with *E histolytica*. Furthermore, only 10% of *E histolytica* infections result in gastrointestinal or other symptoms.

► Clinical Findings

A. Symptoms and Signs

Patients with intestinal amebiasis can have asymptomatic cyst passage, or be symptomatic with acute amebic proctocolitis, chronic nondysenteric colitis, or ameboma. Because all *E dispar* infections and up to 90% of *E histolytica* infections are asymptomatic, carriage is the most common manifestation of amebiasis. Patients with acute amebic colitis typically have a 1- to 2-week history of watery stools containing blood and mucus, abdominal pain, and tenesmus. A minority of patients are febrile or dehydrated. Abdominal examination may reveal pain over the lower abdominal quadrants. Fulminant colitis is an unusual complication of amebic dysentery and is associated with a grave prognosis (> 50% mortality). Patients with fulminant colitis present with severe bloody diarrhea, fever, and diffuse abdominal pain. Children younger than age 2 years appear to be at increased risk for this condition. Chronic amebic colitis is clinically indistinguishable from idiopathic inflammatory bowel disease; patients present with recurrent episodes of bloody diarrhea over a period of years. Ameboma is a localized amebic infection, usually in the cecum or ascending colon, which presents as a painful abdominal mass.

The most common complication of intestinal amebiasis is intestinal perforation and peritonitis. Perianal ulcers, a less common complication, are painful, punched-out lesions that usually respond to medical therapy. Infrequently, colonic strictures may develop following colitis.

Extraintestinal amebiasis can result in liver, lung, and cerebral abscesses, and rarely genitourinary disease. Patients with amebic liver abscess, the most common form of extraintestinal amebiasis, present with recent-onset fever and right upper quadrant tenderness. The pain may be dull or pleuritic or referred to the right shoulder. Physical examination reveals liver enlargement in less than 50% of affected patients. Some patients have a subacute presentation lasting 2 weeks to 6 months. In these patients, hepatomegaly, anemia, and weight loss are common findings, and fever is less common. Jaundice and diarrhea are rarely associated with an amebic liver abscess.

The most common complication of amebic liver abscess is pleuropulmonary amebiasis due to rupture of a right liver lobe. Lung abscesses may occur from hematogenous spread. Cough, dyspnea, and pleuritic pain can also be caused by the serous pleural effusions and atelectasis that frequently accompany amebic liver abscesses. Rupture of hepatic abscesses can lead to peritonitis and more rarely to pericarditis. Cerebral amebiasis is an infrequent manifestation. Genitourinary amebiasis, which is also uncommon, results from rupture of a liver abscess, hematogenous dissemination, or lymphatic spread.

B. Diagnostic Findings

Intestinal amebiasis is diagnosed by detecting the parasite on stool examination or mucosal biopsy. The clinical differential

diagnosis of acute amebic colitis includes bacillary diarrhea and perhaps infection with *Balantidium coli* and *Dientamoeba fragilis*, which have occasionally been associated with acute diarrhea, but whose pathogenic role remains controversial. Chronic amebic colitis has to be distinguished from inflammatory bowel disease, *Cyclospora*, and perhaps *B coli*. Occult blood is present in virtually all cases of amebic colitis and can be used as an inexpensive screening test. Fecal leukocytes are uncommon. The presence of hematophagous trophozoites in feces indicates pathogenic *E histolytica* infection.

Ideally, a wet mount preparation of the stool should be examined within 20 minutes after collection to detect motile trophozoites. Otherwise, specimens should be fixed with polyvinyl alcohol or refrigerated to avoid disintegration of the trophozoites. Examination of three separate stool specimens has 90% sensitivity for the diagnosis of amebic dysentery. However, infection of the ascending colon, amebomas, and extraintestinal infections frequently yield negative stool examinations. The antigen detection test for stool is very sensitive and more specific, because it detects *E histolytica*-specific antigens that do not cross-react with *E dispar*. Colonoscopy and biopsy are most helpful in diagnosing amebic colitis when stool samples lack ova or parasites. Barium studies are contraindicated for patients with suspected acute amebic colitis because of the risk of perforation.

The presence of antibodies against *E histolytica* can differentiate *E histolytica* from *E dispar* infections. The antibody response follows both intestinal and extraintestinal invasive amebiasis and can be used for diagnostic purposes. ELISA and indirect hemagglutination assays are positive in 85–95% of invasive *E histolytica* colitis or amebic abscess. However, these antibodies persist for years, and a positive result does not distinguish between acute and past infection. Noninvasive imaging studies have greatly improved the diagnosis of hepatic abscesses. Ultrasonographic examination and computed tomography (CT) are sensitive techniques that can guide fine-needle aspiration to obtain specimens for definitive diagnosis. Because an amebic abscess may take up to 2 years to completely resolve on CT scans, imaging techniques are not recommended for therapeutic evaluation.

► Prevention & Treatment

Travelers to endemic areas need to follow the precautions for preventing enteric infections—drink bottled or boiled water and eat cooked or peeled vegetables and fruits.

Treatment of amebic infection is complex because different agents are required for eradicating the parasite from the bowel or tissue (Table 41–6). Whether treatment of asymptomatic cyst passers is indicated is a controversial issue. The prevalent opinion is that asymptomatic infection with *E histolytica*, as evidenced by amebic cysts in the stool and a positive serologic test, should be treated in nonendemic areas. If serologic tests are negative, the cysts are more likely to represent infection with the nonpathogenic *E dispar*, which does not require treatment. Noninvasive infections

Table 41-6. Treatment of amebiasis.

Type of Infection	Drug of Choice	Dosage
Asymptomatic	Paromomycin	25–35 mg/kg/d in three doses for 7 d
	or Iodoquinol	30–40 mg/kg/d (maximum, 2 g) in 3 doses for 20 days
	or Diloxanide furoate ^a	20 mg/kg/d up to 1.5 g/d in three doses for 10 d
Intestinal disease and hepatic abscess ^b	Metronidazole	35–50 mg/kg/d up to 2.25 g/d in three doses for 10 d
	or Tinidazole ^c	50 or 60 mg/kg up to 2 g/d for 3 d

^aDiloxanide furoate is available from the CDC Drug Service: (404) 639-3670.

^bTreatment should be followed by iodoquinol or another intraluminal cysticidal agent.

^cNot marketed in the United States; higher dosage is for hepatic abscess.

may be treated with paromomycin. Paromomycin, a nonabsorbable aminoglycoside, can be used safely during pregnancy and has only mild intestinal side effects, including flatulence and increased number of stools. Diloxanide furoate is relatively nontoxic and used widely outside the United States. The treatment of invasive amebiasis requires metronidazole. Metronidazole has a disulfiram-like effect and should be avoided in patients receiving ethanol-containing medications. Tinidazole, a more potent nitroimidazole against amebic infection, can be used for shorter treatment courses and is well tolerated in children.

In patients who cannot tolerate metronidazole or tinidazole, erythromycin and tetracycline are active against intestinal trophozoites, but are inactive against trophozoites in liver abscesses. Conversely, chloroquine is active only against hepatic amebiasis. Treatment of invasive amebiasis should always be followed with an intraluminal cysticidal agent, even if the stool examination is negative. Metronidazole and paromomycin should not be given concurrently, because the diarrhea that is a common side effect of paromomycin may make it difficult to assess response to therapy. Patients with large, thin-walled hepatic abscesses may need therapeutic aspiration to avoid abscess rupture. Patients with amebiasis should be placed under enteric precautions.

2. Giardiasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Chronic relapsing diarrhea, flatulence, bloating, anorexia, poor weight gain.
- ▶ Absence of fever and hematochezia.
- ▶ Detection of trophozoites, cysts, or *Giardia* antigens in stool.

▶ General Considerations

Giardiasis, caused by *Giardia lamblia*, is the most common intestinal protozoal infection in children in the United States and in most of the world. Endemic worldwide, the infection is classically associated with drinking contaminated water, either in rural areas or in areas with faulty purification systems. But even ostensibly clean urban water supplies can be contaminated intermittently. Persons have acquired the infection in swimming pools. Fecal-oral contamination allows person-to-person spread. Day care centers have become a major source of infection, with an incidence of up to 50% reported in some centers. No symptoms occur in 25% of infected persons, facilitating spread to household contacts. Food-borne outbreaks also occur. Although infection is rare in neonates, giardiasis may occur at any age.

▶ Clinical Findings

A. Symptoms and Signs

Giardia infection is followed by asymptomatic cyst passage, acute self-limited diarrhea, or a chronic syndrome of diarrhea, malabsorption, and weight loss. Acute diarrhea occurs 1–2 weeks after infection and is characterized by abrupt onset of diarrhea with greasy, malodorous stools; malaise; flatulence; bloating; and nausea. Fever and vomiting occur in a minority of patients. Urticaria, reactive arthritis, biliary tract disease, gastric infection, and constipation have occasionally been reported. The disease has a protracted course (> 1 week) and frequently leads to weight loss. Patients who develop chronic diarrhea complain of profound malaise, lassitude, headache, and diffuse abdominal pain in association with bouts of diarrhea—most typically foul-smelling, greasy stools—intercalated with periods of constipation or normal bowel habits. This syndrome can persist for months until specific therapy is administered or until it subsides spontaneously. Chronic diarrhea frequently leads to malabsorption, steatorrhea, vitamin A and vitamin B₁₂ deficiencies, and disaccharidase depletion. Lactose intolerance, which develops in 20–40% of patients, can persist for several weeks

after treatment and needs to be differentiated from relapsing giardiasis or reinfection.

B. Laboratory Findings

The diagnosis of giardiasis relies on finding the parasite in stool or duodenal aspirates or detecting *Giardia* antigen in feces. For ova and parasite examination, a fresh stool provides the best results. Liquid stools have the highest yield of trophozoites, which are more readily found on wet mounts. With semifformed stools, the examiner should look for cysts in fresh or fixed specimens, preferably using a concentration technique. When these techniques are applied carefully, one examination has a sensitivity of 50–70%; three examinations increase the sensitivity to 90%. *Giardia* antigen detection by means of immunofluorescence ELISAs, nonenzymatic immunoassays, and direct fluorescence antibody tests are becoming the standard diagnostic tests in the United States. They are comparable in cost to a stool ova and parasite examination, have a more rapid return of results, and are 85–90% sensitive and 95–100% specific. With a careful stool ova and parasite examination or with the use of a new antigen test, direct sampling of the duodenal contents should be restricted to particularly difficult cases. Three methods are currently available: the string test (Entero-Test), duodenal aspiration, and duodenal biopsy.

▶ Prevention

The prevention of giardiasis requires proper treatment of water supplies and interruption of person-to-person transmission. Travelers to developing countries or wilderness areas should halogenate or boil (for over 10 minutes) drinking water and avoid uncooked foods that might have been washed with contaminated water. Sexual transmission is prevented by avoiding oral-anal and oral-genital sex. Interrupting fecal-oral transmission requires strict hand washing. However, outbreaks of diarrhea in day care centers might be particularly difficult to eradicate, and reinforcing hand-washing and treating the disease in both symptomatic and asymptomatic carriers may be necessary.

▶ Treatment

Metronidazole, tinidazole, and nitazoxanide are the drugs of choice for treatment of giardiasis. When given at 5 mg/kg (up to 250 mg) three times a day for 5 days, metronidazole has 80–95% efficacy. The drug is well tolerated in children. It has a disulfiram-like effect and should be avoided in patients receiving ethanol-containing medication. Metronidazole can be administered safely during pregnancy. Tinidazole has an efficacy approaching 90% when given as a single dose of 50 mg/kg (up to 2 g). Nitazoxanide is available in liquid formulation and requires only 3 days of treatment. Recommended doses are 100 mg (5 mL) every 12 hours for children 12–47 months of age and 200 mg (10 mL) for 4- to 11-year-olds. Furazolidone is sometimes used in children because it is

available in suspension. Administered at 1.5 mg/kg (up to 100 mg) four times daily for 7–10 days, it has only 80% efficacy. Furazolidone may cause gastrointestinal side effects, turn urine red, and cause mild hemolysis in patients with G6PD deficiency. For patients who do not respond to therapy, or who suffer relapse, a second course with the same drug or switching to another drug is equally effective. In cases of repeated treatment failure, albendazole (400 mg/d for 5–10 days), although not specifically recommended in the United States for the treatment of giardiasis, is an effective option.

Huang DB et al: An updated review on *Cryptosporidium* and *Giardia*. *Gastroenterol Clin North Am* 2006;35:291 [PMID: 16880067].

3. Cryptosporidiosis

Cryptosporidium parvum is an intracellular protozoan that has gained importance because it causes severe diarrhea in patients with acquired immunodeficiency syndrome (AIDS) and in other immunodeficient persons. The parasite is ubiquitous and infects and reproduces in the epithelial cell lining of the digestive and respiratory tracts of humans and most other vertebrate animals. Humans acquire the infection from contaminated water supplies, including swimming pools and lake water, or from close contact with infected humans or animals.

▶ Clinical Findings

A. Symptoms and Signs

Immunocompetent persons infected with *Cryptosporidium* usually develop self-limited diarrhea (2–26 days) with or without abdominal cramps. Diarrhea is intermittent and scant or continuous, watery, and voluminous. Low-grade fever, nausea, vomiting, loss of appetite, and malaise may accompany the diarrhea. Children younger than age 2 years appear more susceptible to infection than older children. Immunocompromised patients (either cellular or humoral deficiency) tend to develop prolonged disease, which usually subsides only after the immunodeficiency is corrected. Other clinical manifestations associated with cryptosporidiosis in immunocompromised hosts include cholecystitis, pancreatitis, hepatitis, and respiratory symptoms.

B. Laboratory Findings

Cryptosporidiosis has no characteristic laboratory features other than identification of the microorganism in feces or on biopsy. ELISA and PCR tests are more sensitive than staining of stool specimens or concentrates.

▶ Prevention & Treatment

Prevention of *Cryptosporidium* infection is limited by oocyst resistance to some of the standard water purification proce-

dures and to common disinfectants. Enteric precautions are recommended for infected persons. Boiled or bottled drinking water may be considered for those at high risk for developing chronic infection (eg, inadequately treated patients with AIDS).

Immunocompetent patients and those with temporary immunodeficiencies respond to treatment with nitazoxanide, antidiarrheal agents, and hydration. Immunocompromised patients usually require more intense supportive care with parenteral nutrition in addition to hydration and nonspecific antidiarrheal agents. Octreotide acetate, a synthetic analogue of somatostatin that inhibits secretory diarrhea, has been associated with symptomatic improvement, but not with parasitologic cure. Among the antiparasitic agents, nitazoxanide, paromomycin–azithromycin, rifabutin, and hyperimmune bovine colostrum, in that order, have met with success. For patients with AIDS, institution of effective antiretroviral therapy eliminates symptomatic cryptosporidiosis.

Chen X et al: Cryptosporidiosis. *N Engl J Med* 2002;346:1723 [PMID: 12037153].

Huang DB et al: An updated review on Cryptosporidium and Giardia. *Gastroenterol Clin North Am* 2006;35:291 [PMID: 16880067].

4. Cyclosporiasis

Cyclospora is a coccidian that infects both humans and animals with worldwide distribution. It causes food-associated outbreaks, characterized by an incubation period of 2–11 days followed by watery diarrhea in relapsing patterns, sometimes alternating with constipation. Other symptoms include profound fatigue, vomiting, and myalgias. The infection can be unusually severe in immunocompromised patients. Although the illness is self-limited, it may last for several weeks. Diagnosis is based on finding oocysts 8–10 mm in diameter on examination of stool specimens stained with acid-fast stain. The treatment of choice is trimethoprim–sulfamethoxazole for 7 days.

Lewthwaite P: Gastrointestinal parasites in the immunocompromised. *Curr Opin Infect Dis* 18:427 [PMID: 16148530].

5. Free-Living Amebas

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Acute meningoencephalitis: fever, headache, meningismus, acute mental deterioration.
- ▶ Swimming in warm, fresh water in an endemic area.
- ▶ Chronic granulomatous encephalitis: insidious onset of focal neurologic deficits.
- ▶ Keratitis: pain, photophobia, conjunctivitis, blurred vision.

▶ General Considerations

Infections with free-living amebas are uncommon. *Naegleria* species, *Acanthamoeba* species, and *Balamuthia* (previously called leptomyxid) amebas have been associated with human disease.

Acute meningoencephalitis, caused by *Naegleria fowleri*, occurs mostly in children and young adults. Patients present with abrupt fever, headache, nausea and vomiting, meningismus, and decreased mental status a few days to 2 weeks after swimming in warm freshwater lakes. Swimming history may be absent. CNS invasion occurs after nasal inoculation of *N fowleri*. The disease is rapidly progressive, and death ensues within 1 week of onset.

Chronic granulomatous encephalitis, caused by *Acanthamoeba* or *Balamuthia*, occurs most commonly in patients who are immunocompromised from corticosteroid use, chemotherapy, or AIDS. There is no association with freshwater swimming. This disease has an insidious onset of focal neurologic deficits, and approximately 50% of patients present with headache. Skin, sinus, or lung infections with *Acanthamoeba* precede many of the CNS infections and may still be present at the onset of neurologic disease. The granulomatous encephalitis progresses to fatal outcome over a period of weeks to months (average 6 weeks).

Acanthamoeba keratitis is a corneal infection associated with minor trauma or use of soft contact lenses in otherwise healthy persons. Frequently misdiagnosed as herpes simplex or bacterial keratitis, *Acanthamoeba* keratitis has a characteristic dendritiform epithelial pattern that suggests the diagnosis.

▶ Clinical Findings & Differential Diagnosis

Amebic encephalitis should be included in the differential diagnosis of acute meningoencephalitis in children with a history of recent freshwater swimming. The cerebrospinal fluid (CSF) is usually hemorrhagic, with leukocyte counts that may be normal early in the disease, but later range from 400–2600/μL with neutrophil predominance, low to normal glucose, and elevated protein. The etiologic diagnosis relies on finding trophozoites on a wet mount of the CSF.

Granulomatous encephalitis is diagnosed by brain biopsy of CT-identified nonenhancing lucent areas. The CSF of these patients is usually nondiagnostic with intermediate white blood cell counts, elevated protein, and decreased glucose. *Acanthamoeba* or leptomyxid amebas have not been found in the CSF; however, they can be visualized in biopsies or grown from brain or other infected tissues.

Acanthamoeba keratitis is diagnosed by finding the trophozoites in corneal scrapings or by isolating the parasite from corneal specimens or contact lens cultures.

▶ Prevention

Because primary amebic meningitis occurs infrequently, active surveillance of lakes for *N fowleri* is not warranted.

However, in the presence of a documented case, it is advisable to close the implicated lake to swimming. *Acanthamoeba* keratitis can be prevented by heat disinfection of contact lenses, by storage of lenses in sterile solutions, and by not wearing lenses when swimming in fresh water.

▶ Treatment

The few patients who have survived acute amebic meningoencephalitis received high-dose intravenous and intrathecal amphotericin B, accompanied by miconazole, rifampin, and sulfisoxazole in some cases. The first two cases of successful treatment of *Balamuthia* encephalitis were reported after combination therapy with flucytosine, pentamidine, fluconazole, sulfadiazine, and a macrolide.

Acanthamoeba keratitis responds well to surgical debridement followed by 3–4 weeks of topical 1% miconazole; 0.1% propamidine isethionate; and polymyxin B sulfate, neomycin, and bacitracin (Neosporin).

TRICHOMONIASIS

Trichomonas vaginalis infection is discussed in Chapter 42.

METAZOAL INFECTIONS

NEMATODE INFECTIONS

1. Enterobiasis (Pinworms)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Anal pruritus.
- ▶ Worms in the stool or eggs on perianal skin.

▶ General Considerations

This worldwide infection is caused by *Enterobius vermicularis*. The adult worms are about 5–10 mm long and lives in the colon; females deposit eggs on the perianal area, primarily at night, which cause intense pruritus. Scratching contaminates the fingers and allows transmission back to the host (autoinfection) or to contacts.

▶ Clinical Findings

A. Symptoms and Signs

Although blamed for myriad symptoms, pinworms are definitely associated only with localized pruritus. Adult worms may migrate within the colon or up the urethra or vagina in girls. They can be found within the bowel wall, in the lumen of the appendix (usually an incidental finding by the pathologist), in the bladder, and even in the peritoneal cavity of girls. The granulomatous reaction that may be present around these ectopic worms is usually asymptomatic. Worm eradication may correspond with the cure of recurrent urinary tract infections in some young girls.

B. Laboratory Findings

The usual diagnostic test consists of pressing a piece of transparent tape on the child's anus in the morning prior to bathing, then placing it on a drop of xylene on a slide. Microscopic examination under low power usually demonstrates the ova. Occasionally eggs or adult worms are seen in fecal specimens. Parents may also notice adult worms.

▶ Differential Diagnosis

Nonspecific irritation or vaginitis, streptococcal perianal cellulitis (usually painful with marked erythema), and vaginal or urinary bacterial infections may at times resemble pinworm infection, although the symptoms of pinworms are often so suggestive that a therapeutic trial is justified without a confirmed diagnosis.

▶ Treatment

A. Specific Measures

Treat all household members at the same time to prevent reinfections. Because the drugs are not active against the eggs, therapy should be repeated after 2 weeks to kill the recently hatched adults.

Pyrantel pamoate is given as a single dose (11 mg/kg; maximum, 1 g); it is safe and very effective. Mebendazole (100 mg) and albendazole (400 mg) in a single dose are highly effective for this infection at all ages.

B. General Measures

Personal hygiene must be emphasized. Nails should be kept short and clean. Children should wear undergarments to bed to diminish contamination of fingers; bedclothes should be laundered frequently. Although eggs may be widely dispersed in the house and multiple family members infected, the disease is mild and treatable.

Brown MD: *Enterobius vermicularis*. *N Engl J Med* 2006;354:e12 [PMID: 16571876].

St Georgiev V: Chemotherapy of enterobiasis (oxyuriasis). *Expert Opin Pharmacother* 2001;2:267 [PMID: 11336585].

2. Ascariasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Abdominal cramps and discomfort.
- ▶ Large, white or reddish, round worms, or ova in the feces.

▶ General Considerations

Together with the whipworm and hookworms (see below), *Ascaris* comprises the group of so-called “soil-transmitted helminths.” This group of parasites causes human infection through contact with eggs or larvae that thrive in the moist soil of the tropics and subtropics. Worldwide more than a billion people are infected with one species of these parasites, and especially in less developed countries, it is not uncommon for children to be chronically infected with all three worms. Children infected with these worms are at increased risk for malnutrition, stunted growth, intellectual retardation, and cognitive and education deficits. Together, the soil-transmitted helminths are one of the world’s most important causes of physical and intellectual growth retardation.

Ascaris lumbricoides is a worldwide human parasite. Ova passed by carriers may remain viable for months under the proper soil conditions. The ova contaminate food or fingers and are subsequently ingested by a new host. The larvae hatch, penetrate the intestinal wall, enter the venous system, reach the alveoli, are coughed up, and return to the small intestine, where they mature. The female lays thousands of eggs daily.

▶ Clinical Findings

A. Symptoms and Signs

Infections usually remain asymptomatic; severe cases, however, can be associated with pain, weight loss, anorexia, diarrhea, or vomiting. Adult worms may be seen in feces or vomitus. Rarely, they perforate or obstruct the small bowel, biliary system, or appendix. Large numbers of larvae migrating through the lungs may cause an acute, transient eosinophilic pneumonia (Löfller syndrome).

B. Laboratory Findings

The diagnosis is made by observing the large roundworms (1.5–4 cm) in the stool or by microscopic detection of the ova.

▶ Treatment

Because the adult worms live less than a year, asymptomatic infection need not be treated. Mebendazole (100 mg twice a day for 3 days or 500 mg once), pyrantel pamoate (a single dose of 11 mg/kg; maximum, 1 g), and albendazole (400 mg

in a single dose, or 200 mg in children 1–2 years of age) are highly and equally effective. In cases of intestinal or biliary obstruction, piperazine (150 mg/kg initially, followed by six doses of 65 mg/kg every 12 hours by nasogastric tube) is recommended because it narcotizes the worms and helps relieve obstruction. However, surgical removal is occasionally required.

Bethony J et al: Soil-transmitted helminth infections: Ascariasis, trichuriasis, and hookworm. *Lancet* 2006;367:1521 [PMID: 16679166].

3. Trichuriasis (Whipworm)

Trichuris trichiura is a widespread human and animal parasite common in children living in warm, humid areas conducive to survival of the ova. The adult worms live in the cecum and colon; the ova are passed and become infectious after several weeks in the soil. Ingested infective eggs hatch in the upper small intestine. Unlike *Ascaris*, *Trichuris* does not have a migratory tissue phase. Symptoms are not present unless the infection is severe, in which case pain, diarrhea, and mild abdominal distention are present. Massive infections may also cause rectal prolapse and dysentery. Detection of the characteristic barrel-shaped ova in the feces confirms the diagnosis. Adult worms may be seen in the prolapsed rectum or at proctoscopy; their thin heads are buried in the mucosa, and the thicker posterior portions protrude. Mild to moderate eosinophilia may be present.

Mebendazole (100 mg orally twice a day for 3 days or 500 mg once) or albendazole (400 mg in a single dose for 3 days, or 200 mg in children 1–2 years of age) improves gastrointestinal symptoms and terminates constitutional symptoms.

Bethony J et al: Soil-transmitted helminth infections: Ascariasis, trichuriasis, and hookworm. *Lancet* 2006;367:1521 [PMID: 16679166].

4. Hookworm

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Iron deficiency anemia.
- ▶ Abdominal discomfort, weight loss.
- ▶ Ova in the feces.

▶ General Considerations

The common human hookworms are *Ancylostoma duodenale* and *Necator americanus*. Both are widespread in the tropics and subtropics. The larger *A duodenale* is more pathogenic because it consumes more blood, up to 0.5 mL per worm per day.

The adults live in the jejunum. Eggs are passed in the feces and develop and hatch into infective larvae in warm, damp soil within 2 weeks. The larvae penetrate human skin on contact, enter the blood, reach the alveoli, are coughed up and swallowed, and develop into adults in the intestine. The adult worms attach with their mouth parts to the mucosa, from which they suck blood. Blood loss is the major sequela of infection. Infection rates reach 90% in areas without sanitation.

A separate species, *A. braziliense* (dog or cat hookworm), causes creeping eruption (cutaneous larva migrans). This disease occurs mainly on the warm-water American coasts.

▶ Clinical Findings

A. Symptoms and Signs

The larvae usually penetrate the skin of the feet and cause intense local itching (ground itch). This subsides as the larvae continue their migration. Löffler syndrome may supervene during lung migration. In creeping eruption, the nonhuman *Ancylostoma* larvae migrate blindly in the skin before dying, creating serpiginous burrows.

Mild intestinal infections produce no symptoms. Severe infections cause iron deficiency anemia and malnutrition. Occasionally abdominal pain and diarrhea may be observed.

B. Laboratory Findings

The large ova of both species of hookworm are found in feces and are indistinguishable. Microcytic anemia, hypoalbuminemia, eosinophilia, and hematochezia occur in severe cases.

▶ Prevention

Fecal contamination of soil and skin contact with potentially contaminated soil should be avoided.

▶ Treatment

A. Specific Measures

Albendazole (400 mg orally in a single dose, or 200 mg in children 1–2 years of age), mebendazole (100 mg orally twice a day for 3 days), and pyrantel pamoate (11 mg/kg, to a maximum of 1 g, daily for 3 days) are the drugs of choice. Topical thiabendazole or albendazole or oral thiabendazole are useful for creeping eruption.

B. General Measures

Iron therapy may be as important as worm eradication.

▶ Prognosis

The outcome is usually excellent.

Bethony J et al: Soil-transmitted helminth infections: Ascariasis, trichuriasis, and hookworm. *Lancet* 2006;367:1521 [PMID: 16679166].

5. Strongyloidiasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Abdominal pain, diarrhea.
- ▶ Eosinophilia.
- ▶ Larvae in stools and duodenal aspirates.
- ▶ Serum antibodies.

▶ General Considerations

Strongyloides stercoralis is unique in having both parasitic and free-living forms; the latter can survive in the soil for several generations. The parasite is found in most tropical and subtropical regions of the world. The adults live in the submucosal tissue of the duodenum and occasionally elsewhere in the intestines. Eggs deposited in the mucosa hatch rapidly; the first-stage (rhabditiform) larvae, therefore, are the predominant form found in duodenal aspirates and feces. The larvae mature rapidly to the tissue-penetrating filariform stage and initiate internal autoinfection. The filariform larvae also inhabit the soil and can penetrate the skin of another host, subsequently migrating into veins and pulmonary alveoli, reaching the intestine when coughed up and swallowed.

Older children and adults are infected more often than are young children. Even low worm burden can result in significant clinical symptoms. Infestations due to poor sanitation and hygiene are noteworthy. Immunosuppressed patients may develop fatal disseminated strongyloidiasis, known as the hyperinfection syndrome.

▶ Clinical Findings

A. Symptoms and Signs

At the site of skin penetration, a pruritic rash may occur. Large numbers of migrating larvae can cause wheezing, cough, and hemoptysis. Although one third of intestinal infections are asymptomatic, the most prominent features of strongyloidiasis include abdominal pain, distention, diarrhea, vomiting, and occasionally malabsorption.

Patients with cellular immunodeficiencies and those on corticosteroid therapy may develop disseminated infection involving the intestine, the lungs, and the meninges. Gram-negative sepsis may complicate disseminated strongyloidiasis.

B. Laboratory Findings

Finding larvae in the feces, in duodenal aspirates, on a string test (Enterio-Test), or in sputum is diagnostic. IgG antibodies measured by ELISA or immunoblot are sensitive and specific for *Strongyloides*. These persist after successful therapy. Marked eosinophilia is common.

► Differential Diagnosis

Strongyloidiasis should be differentiated from peptic disease, celiac disease, regional or tuberculous enteritis, hookworm infection, and other causes of intestinal symptoms or malabsorption. The pulmonary phase may mimic asthma or bronchopneumonia. Patients with severe infection can present with an acute abdomen.

► Prevention & Treatment

Thiabendazole (50 mg/kg/d in two doses for 2 days; maximum, 3 g/d) and ivermectin (0.2 mg/kg/d for 1 or 2 days) are the drugs of choice. Relapses are common. In the hyperinfection syndrome, 2–3 weeks of therapy may be necessary. Patients from endemic areas should be tested for specific antibodies and receive treatment before undergoing immunosuppression.

Keiser PB et al: *Strongyloides stercoralis* in the immunocompromised population. *Clin Microbiol Rev* 2004;17:208 [PMID: 14726461].

6. Visceral Larva Migrans (Toxocariasis)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Visceral involvement including hepatomegaly, marked eosinophilia, and anemia.
- Posterior or peripheral ocular inflammatory mass.
- Elevated antibody titers in serum or aqueous fluid; demonstration of *Toxocara* larvae in biopsy specimen.

► General Considerations

Visceral larva migrans is a worldwide disease. The agent is the cosmopolitan intestinal ascarid of dogs and cats, *Toxocara canis* or *Toxocara cati*. The eggs passed by infected animals contaminate parks and other areas that young children frequent. Children with pica are at increased risk. In the United States, seropositivity ranges from 2.8% in unselected populations to 23% in southern states to 54% in rural areas. Ingested eggs hatch and penetrate the intestinal wall, then migrate to the liver, lungs, eyes, and other organs, where they die and incite a granulomatous inflammatory reaction.

► Clinical Findings

A. Visceral Larva Migrans

Toxocariasis is usually asymptomatic, but young children (aged 1–5 years) sometimes present with anorexia, fever, fatigue, pallor, abdominal distention, abdominal pain, nausea, vomiting, and cough. Hepatomegaly is common, sple-

nomegaly is unusual, and adenopathy is absent. Lung involvement, usually asymptomatic, can be demonstrated readily by radiologic examination. Seizures are common, but more severe neurologic abnormalities are infrequent. Eosinophilia with leukocytosis, anemia, and elevated liver function tests are typical laboratory findings. ELISA is sensitive, specific, and useful in confirming the clinical diagnosis. Most patients recover spontaneously, but disease may last up to 6 months.

B. Ocular Larva Migrans

This condition occurs in older children and adults who present with a unilateral posterior or peripheral inflammatory mass. History of visceral larva migrans and eosinophilia are typically absent. Anti-*Toxocara* antibody titers are low in the serum and high in vitreous and aqueous fluids.

C. Diagnostic Findings

Hypergammaglobulinemia and elevated isohemagglutinins sometimes result from cross-reactivity between *Toxocara* antigens and human group A and B blood antigens. The diagnosis is confirmed by finding larvae in granulomatous lesions. Positive serology in high titers and the exclusion of other causes of hypereosinophilia allow a presumptive diagnosis to be made in typical cases.

► Differential Diagnosis

Diseases associated with hypereosinophilia must be considered. These include trichinosis (enlarged liver not common; muscle tenderness common), eosinophilic leukemia (rare in children; eosinophils are abnormal in appearance), collagen-vascular disease (those associated with eosinophilia are rare in young children), strongyloidiasis (no organomegaly; enteric symptoms are common), early ascariasis, tropical eosinophilia (occurring mainly in India), allergies, and hypersensitivity syndromes.

► Prevention & Treatment

A. Specific Measures

The clinical benefit of specific anthelmintic therapy is not defined. Treatment with albendazole (400 mg twice a day for 5 days) or mebendazole (100–200 mg twice a day for 5 days) is indicated for severe complications of brain, lung, or heart.

B. General Measures

Treating any cause of pica, such as iron deficiency, is important. Corticosteroids are used to treat marked inflammation of lung, eye, or other organs. Pets should be dewormed routinely. Other children in the household may be infected. Mild eosinophilia and positive serologic tests may be the only clue to their infection. Therapy is not necessary for these individuals.

7. Trichinosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Vomiting, diarrhea, and pain within 1 week of eating infected meat.
- ▶ Fever, periorbital edema, myalgia, and marked eosinophilia.

▶ General Considerations

Trichinella spiralis is a small roundworm that inhabits hogs and several other meat-eating animals. The human cycle begins with ingestion of viable larvae in undercooked meat. In the intestine, the larvae develop into adult worms that mate and produce hundreds of larvae. The larvae enter the bloodstream and migrate to the striated muscle where they continue to grow and eventually encyst. Symptoms are caused by the inflammatory response in the intestines or muscle.

▶ Clinical Findings

A. Symptoms and Signs

Most infections are asymptomatic. The initial bowel penetration may cause nausea, vomiting, diarrhea, and cramps within 1 week after ingestion of contaminated meat. This may progress to the classic myopathic form, which consists of fever, periorbital edema, myalgia, and weakness. Many organs may be infected by the migrating larvae: diaphragm, heart, lungs, kidneys, spleen, skin, and brain. Severe cerebral involvement may be fatal. Myocarditis may also be severe or fatal. Symptoms usually peak after 2–3 weeks, but may last months. Children typically have milder clinical and laboratory findings than adults.

B. Laboratory Findings

Marked eosinophilia is the rule. Serology confirms the diagnosis. Muscle biopsy is rarely necessary.

▶ Differential Diagnosis

The classic symptoms are pathognomonic if one is aware of this disease. It has to be distinguished from dermatomyositis, typhoid fever, sinusitis, influenza with myopathy, and angio-neurotic edema.

▶ Prevention

Because a microscopic examination must be performed, meat in the United States is not inspected for trichinosis. Although all states require the cooking of hog swill, hog-to-hog or hog-to-rat cycles may continue. All pork and sylvatic

meat (eg, bear or walrus) should be heated to at least 65°C. Freezing meat to at least –15°C for 3 weeks may also prevent transmission. Animals used for food should not be fed or allowed access to raw meat.

▶ Treatment

Mebendazole has activity against the intestinal, circulating, and tissue stages of infection. The adult dose is 200–400 mg three times a day for 3 days followed by 400–500 mg three times a day for 10 days. Pediatric dosing has not been standardized and recommendations range from 5–25 mg/kg/d divided in three doses for 14 days. Concurrent corticosteroids are used in an attempt to prevent the Herxheimer reaction associated with treatment.

▶ Prognosis

Death may occur within the first weeks, but most infections are self-limited.

Ozdemir D et al: Acute trichinellosis in children compared with adults. *Pediatr Infect Dis J* 2005;24:897 [PMID: 16220088].

8. Raccoon Roundworm Infections

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Eosinophilic meningoencephalitis or encephalopathy.
- ▶ Ocular larva migrans.
- ▶ Contact with raccoons or raccoon feces.

▶ General Considerations

Human infections with *Baylisascaris procyonis*, the raccoon roundworm, have been increasingly recognized, particularly in children. The definitive host of this ascarid is the raccoon. Humans who ingest the eggs excreted in raccoon feces become intermediate hosts when the larvae penetrate the gut and disseminate via the bloodstream to the brain, eyes, viscera, and muscles. Young age, pica, and exposure to raccoon feces (eg, while camping) represent the main risk factors for this infection. Most of the infections are asymptomatic, but cases of severe encephalitis (neural larva migrans) and endophthalmitis (ocular larva migrans) occur. Symptoms typically begin 2–4 weeks after inoculation. CNS infections characteristically present as acute, rapidly progressive encephalitis with eosinophilic pleocytosis of the CSF. Both CNS and ocular infections resemble other larva migrans infections such as toxocarasis; therefore *B procyonis* should be considered in the differential diagnosis of these infections when *Toxocara* serology is negative. The diagnosis of *B procyonis* is established by

observing the larvae on examination of tissue biopsies or by serology. Treatment consists of anthelmintics and corticosteroid anti-inflammatory drugs. Prognosis is reserved, since complete resolution of symptoms has not been achieved thus far.

Gavin PJ et al: Baylisascariasis. Clin Microbiol Rev 2005;18:703 [PMID: 16223954].

CESTODE INFECTIONS (FLUKES)

1. Taeniasis & Cysticercosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Mild abdominal pain; passage of worm segments (taeniasis).
- ▶ Focal seizures, headaches (neurocysticercosis).
- ▶ Cysticerci present in biopsy specimens, on plain films (as calcified masses), or on CT scan or magnetic resonance imaging.
- ▶ Proglottids and eggs in feces; specific antibodies in serum or CSF.

▶ General Considerations

Both the beef tapeworm (*Taenia saginata*) and the pork tapeworm (*Taenia solium*) cause taeniasis. The adults live in the intestines of humans; the egg-laden distal segments, or proglottids, break off and are passed in feces, disintegrating and releasing the ova in the soil. After ingestion in food or water by cattle or pigs, the eggs hatch and the larvae migrate to and encyst in skeletal muscle. Encysted larvae in meat ingested by humans mature into adult tapeworms.

Humans can be an intermediate host for *T solium* (but not *T saginata*), and the larvae released from ingested eggs encyst in a variety of tissues, especially muscle and brain. Full larval maturation occurs in 2 months, but the cysts cause little inflammation until they die months to years later. Inflammatory edema ensues with calcification or disappearance of the cyst. A slowly expanding mass of sterile cysts at the base of the brain may cause obstructive hydrocephalus (racemose cysticercosis).

Both parasites are distributed worldwide. Contamination of foods by eggs in human feces allows infection without exposure to meat or travel to endemic areas. Asymptomatic cases are common, but neurocysticercosis is a leading cause of seizures in endemic areas.

Person-to-person spread may occur, resulting in infection of individuals with no exposure to infected meat.

▶ Clinical Findings

A. Symptoms and Signs

1. Taeniasis—In most tapeworm infections, the only clinical manifestation is the passage of fecal proglottids, which are white, motile bodies 1–2 cm in size. They occasionally crawl out onto the skin and down the leg, especially the larger *T saginata*. Children may harbor the adult worm for years and complain of abdominal pain, anorexia, and diarrhea.

2. Cysticercosis—Most cases are asymptomatic. Subcutaneous nodules of 1–2 cm may be the only sign. After several years, the cysticerci calcify and appear as radiographic opacities. Brain cysts may remain silent or cause seizures, headache, hydrocephalus, and basilar meningitis. Rarely, the spinal cord is involved. Neurocysticercosis manifests an average of 5 years after exposure, but may cause symptoms in the first year of life. In the eye, cysts cause bleeding, retinal detachment, and uveitis. Definitive diagnosis requires histologic demonstration of larvae or cyst membrane. Presumptive diagnosis is often made by the characteristics of the cysts seen on CT scan or magnetic resonance imaging; the differential diagnosis may include tuberculoma, brain abscess, arachnoid cyst, and tumor. The presence of *T solium* eggs in feces is uncommon, but supports the diagnosis.

B. Laboratory Findings

Eggs or proglottids may be found in feces or on the perianal skin (using the tape method employed for pinworms). Eggs of both *Taenia* species are identical. The species are identified by examination of proglottids.

Peripheral eosinophilia is minimal or absent. CSF eosinophilia is seen in 10–75% of cases of neurocysticercosis; its presence supports an otherwise presumptive diagnosis.

ELISA antibody titers are eventually positive in up to 98% of serum specimens and over 75% of CSF specimens from patients with neurocysticercosis. Solitary cysts are associated with seropositivity less often than are multiple cysts. High titers tend to correlate with more severe disease. CSF titers are higher if cysts are near the meninges.

▶ Treatment

A. Taeniasis

Praziquantel (5–10 mg/kg once) and albendazole are equally effective. Feces free of segments or ova for 3 months suggest cure.

B. Cysticercosis

Specific treatment is reserved for patients with meningitis, or enhancing or cystic parenchymal lesions. In contrast, those with inactive disease require only symptomatic treatment (anticonvulsants). Albendazole, 15 mg/kg/d (maximum, 800 mg

divided in two doses daily for 8 days, is the treatment of choice. Larval death may result in clinical worsening because of inflammatory edema. A short course of dexamethasone may decrease these symptoms. Giant subarachnoid cysts may require more than one cycle of therapy or surgery (or both). Follow-up scans every several months help assess the response to therapy. Treatment of patients with calcified lesions and seizure disorder results in a decrease of generalized seizures.

▶ Prevention

The incidence in the United States is low because beef and pork are inspected for taeniasis. Prevention requires proper cooking of meat, careful washing of raw vegetables and fruits, treatment of intestinal carriers, avoiding the use of human excrement for fertilizer, and providing proper sanitary facilities.

▶ Prognosis

The prognosis is good in intestinal taeniasis. Symptoms associated with a few cerebral cysts may disappear in a few months; heavy brain infections may cause death or chronic neurologic impairment.

Del Brutto OH et al: Meta-analysis: Cysticidal drugs for neurocysticercosis: Albendazole and praziquantel. *Ann Intern Med* 2006; 145:43 [PMID: 16818928].

Garcia HH et al: A trial of antiparasitic treatment to reduce the rate of seizures due to cerebral cysticercosis. *N Engl J Med* 2004; 350:249 [PMID: 14724304].

Nash TE et al: Treatment of neurocysticercosis: Current status and future research needs. *Neurology* 2006;67:1120 [PMID: 17030744].

2. Hymenolepiasis

Hymenolepis nana, the cosmopolitan human tapeworm, is a common parasite of children; *Hymenolepis diminuta*, the rat tapeworm, is rare. The former is capable of causing autoinfection. Larvae hatched from ingested eggs penetrate the intestinal wall and then reenter the lumen to mature into adults. Their eggs are immediately infectious for the same or a new host. The adult is only a few centimeters long. Finding the characteristic eggs in feces is diagnostic.

H. diminuta has an intermediate stage in rat fleas and other insects; children are infected when they ingest these insects.

Light infections with either tapeworm are usually asymptomatic; heavy infection can cause diarrhea and abdominal pain. Therapy is with praziquantel (25 mg/kg once).

3. Echinococcosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Cystic tumors of liver, lung, kidney, bone, brain, and other organs.
- ▶ Eosinophilia.

- ▶ Urticaria and pruritus if cysts rupture.
- ▶ Protoscoleces or daughter cysts in the primary cyst.
- ▶ Positive serology.
- ▶ Epidemiologic evidence of exposure

▶ General Considerations

Dogs, cats, and other carnivores are the hosts for *Echinococcus granulosus*. Cystic and alveolar echinococcosis (hydatid disease) cause significant morbidity and mortality worldwide. Endemic areas include Australia, New Zealand, and the southwestern United States, including Native American reservations where shepherding is practiced. The adult tapeworm lives in sheep intestines, and eggs are passed in the feces. When ingested by humans, the eggs hatch, and the larvae penetrate the intestinal mucosa and disseminate in the bloodstream to produce cysts; the primary sites of involvement are the liver (60–70%) and the lungs (20–25%). A unilocular cyst is most common. Over years, the cyst may reach 25 cm in diameter, although most are much smaller. The cysts of *Echinococcus multilocularis* are multilocular and demonstrate more rapid growth.

▶ Clinical Findings

A. Symptoms and Signs

Clinical disease is due to pressure from the enlarging cysts, vessel erosion, and sensitization to cyst or worm antigens. Liver cysts present as slowly expanding tumors that may cause biliary obstruction. Most are in the right lobe and extend inferiorly; 25% are on the upper surface and may be asymptomatic for years. Omental torsion or hemorrhage from vessel erosion may occur.

Rupture of a pulmonary cyst causes coughing, dyspnea, wheezing, urticaria, chest pain, and hemoptysis; cyst and worm remnants are found in sputum. Brain cysts may cause focal neurologic signs and convulsions; renal cysts cause pain and hematuria; bone cysts cause pain.

B. Laboratory Findings

Presumptive diagnosis is made by a combination of radiographic or ultrasonographic and serologic findings. ELISA, which is the method most widely used for antibody testing, is highly sensitive, but has limited specificity.

Confirmation may be obtained by ultrasonography-guided fine-needle aspiration coupled with parasitologic examination for protoscoleces, rostellar hooks, antigens, or DNA. Eosinophilia is variable and may be absent. Serologic tests are useful for diagnosis and follow-up of therapy.

C. Imaging

Pulmonary or bone cysts may be visible on plain films. Other imaging techniques are preferred for cysts in other

organs. Visualization of daughter cysts is highly suggestive of echinococcosis.

▶ Differential Diagnosis

Tumors, bacterial or amebic abscess, and tuberculosis (pulmonary) must be considered.

▶ Complications

Sudden cyst rupture with anaphylaxis and death is the worst complication. If the patient survives, secondary infections from seeding of daughter cysts may occur. Segmental lung collapse, secondary bacterial infections, effects of increased intracranial pressure, and severe renal damage due to renal cysts are other potential complications.

▶ Treatment

Definitive therapy of *E multilocularis* requires meticulous surgical removal of the cysts, preceded by careful injection of the cyst with formalin, iodine, or 95% alcohol solution to sterilize infectious protoscoleces, freezing the cyst wall and injecting silver nitrate prior to its removal, or puncture-aspiration/injection-reaspiration technique, which is best suited for treatment of multiple cysts. A surgeon familiar with this disease should be consulted. Medical therapy may be of additional benefit, particularly in disseminated disease. Albendazole (15 mg/kg/d for 28 days with repeat courses as necessary following a 14-day rest period) is effective in many cases of *E granulosus* infection (hydatid disease). If the cyst leaks or ruptures, the allergic symptoms must be managed immediately.

▶ Prognosis

Patients with large liver cysts may be asymptomatic for years. Surgery is often curative for lung and liver cysts, but not always for cysts in other locations. Secondary disease has a much worse prognosis; about 15% of patients with this disease die.

TREMATODE INFECTIONS

Schistosomiasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Transient pruritic rash after exposure to fresh water.
- ▶ Fever, urticaria, arthralgias, cough, lymphadenitis, and eosinophilia.
- ▶ Weight loss, anorexia, hepatosplenomegaly.

- ▶ Hematuria, dysuria.
- ▶ Eggs in stool, urine, or rectal biopsy specimens.

▶ General Considerations

One of the most common serious parasitic diseases, schistosomiasis, is caused by several species of *Schistosoma* flukes. *Schistosoma japonicum*, *S mekongi*, and *S mansoni* involve the intestines and *S haematobium*, the urinary tract. The first two species are found in eastern and southeastern Asia; *S mansoni* in tropical Africa, the Caribbean, and parts of South America; and *S haematobium* in northern Africa.

Infection is caused by free-swimming larvae (cercariae), which emerge from the intermediate hosts, certain species of freshwater snails. The cercariae penetrate human skin, migrate to the liver, and mature into adults, which then migrate through the portal vein to lodge in the bladder veins (*S haematobium*), superior mesenteric veins (*S mekongi* and *S japonicum*), or inferior mesenteric veins (*S mansoni*). Clinical disease results primarily from inflammation caused by the many eggs that are laid in the perivascular tissues or that embolize to the liver. Escape of ova into bowel or bladder lumen allows microscopic visualization and diagnosis from stool or urine specimens, as well as contamination of fresh water and infection of the snail hosts that ingest them.

▶ Clinical Findings

Much of the population in endemic areas is infected but asymptomatic. Only heavy infections produce symptoms.

A. Symptoms and Signs

The cercarial penetration may cause a pruritic rash; larval migration may cause fever, urticaria, and cough; the maturation phase may cause tender hepatosplenomegaly followed by days to weeks of fever and malaise as the worms migrate to their final destination. Bladder infection results in dysuria, hematuria, reflux, stones, and incontinence. Secondary pyelonephritis and ureteral obstruction may occur. Intestinal infection is usually asymptomatic. The final stages of disease caused by the parasite in mesenteric veins are characterized by hepatic fibrosis, portal hypertension, splenomegaly, ascites, and bleeding from esophageal varices. The chronic inflammation in the urinary tract associated with *S haematobium* infections may result in obstructive uropathy, stones, infection, bladder cancer, fistulas, and anemia due to chronic hematuria. Spinal cord granulomas and paraplegia due to egg embolization into the Batson plexus have been reported.

B. Laboratory Findings

The diagnosis is made by finding the species-specific eggs in feces (*S japonicum*, *S mekongi*, *S mansoni*, and occasionally *S haematobium*) or urine (*S haematobium* and occasionally *S mansoni*). If no eggs are found, concentration methods should be used. A rectal biopsy may reveal *S mansoni* and should be

done if other specimens are negative. Peripheral eosinophilia is common, and eosinophils may be seen in urine.

► Prevention

The best prevention is to avoid contact with contaminated fresh water in endemic areas. Efforts to destroy the snail hosts have been successful in areas of accelerated economic development.

► Treatment

A. Specific Measures

Praziquantel is the treatment of choice for schistosomiasis. A dosage of 40 mg/kg/d in two divided doses (*S mansoni* or *S haematobium*) or 20 mg/kg three times in 1 day (*S japonicum* or *S mekongi*) is very effective and nontoxic. Praziquantel has no effect on eggs and immature worms and therefore a repeat dose 4–6 weeks later is sometimes needed. Oxamniquine (20 mg/kg/d in two doses once per day) is an alternative regimen for treatment of *S mansoni* infection. Artemether (6 mg/kg every 3 weeks) may prevent new infections or reinfection after curative treatment.

B. General Measures

Therapy of nutritional deficiency or secondary bacterial infections may be needed. The patient's urinary tract should be

evaluated carefully in *S haematobium* infection; reconstructive surgery may be needed. Hepatic fibrosis requires careful evaluation of the portal venous system and surgical management of portal hypertension when appropriate.

► Prognosis

Therapy decreases the worm burden and liver size, despite continued exposure in endemic areas. Early disease responds well to therapy, but once significant scarring or severe inflammation has occurred, eradication of the parasites is of little benefit.

Gryseels B et al: Human schistosomiasis. *Lancet* 2006;368:1106 [PMID: 16997665].

MYCOTIC INFECTIONS

Fungi can be classified as yeasts, which are unicellular and reproduce by budding; as molds, which are multicellular and consist of tubular structures (hyphae) and grow by elongation and branching; or as dimorphic fungi, which can exist either as yeasts or molds depending on environmental conditions. Fungal infections can be categorized as shown in Table 41–7.

Table 41–7. Pediatric fungal infections.

Type	Agents	Incidence	Diagnosis	Diagnostic Tests	Therapy	Prognosis
Superficial	<i>Candida</i> Dermatophytes <i>Malassezia</i>	Very common	Simple	KOH prep	Topical	Good
Subcutaneous	<i>Sporothrix</i> ^a	Uncommon	Simple ^b	Culture	Oral	Good
Systemic: normal host	<i>Coccidioides</i> <i>Histoplasma</i> <i>Blastomyces</i>	Common: regional	Often presumptive	Chest radiograph; serology, antigen detection (histoplasmosis; blastomycosis); histology; culture of body fluids or tissue	None ^c or systemic	Good
Systemic: opportunistic infection	<i>Candida</i> ^a <i>Pneumocystis</i> ^d <i>Aspergillus</i> Mucorales <i>Malassezia</i> <i>Pseudallescheria</i> <i>Cryptococcus</i>	Uncommon	Difficult ^e	Tissue biopsy, culture, antigen detection (cryptococcosis)	Systemic, prolonged	Poor if therapy is delayed and in severely immunocompromised patients

^a*Candida* and *Sporothrix* in immunocompromised patients may cause severe, rapidly progressive disease and require systemic therapy.

^bSporotrichosis may require biopsy for diagnosis.

^cOften self-limited in normal host.

^dNow reclassified as a fungus. Asymptomatically infects many normal hosts.

^eExcept *Cryptococcus*, which is often diagnosed by antigen detection.

KOH, potassium hydroxide.

In the United States, systemic disease in normal hosts is commonly caused by three organisms—*Coccidioides*, *Histoplasma*, and *Blastomyces*—which are restricted to certain geographic areas. Prior residence in or travel to these areas, even for a brief time, is a prerequisite for inclusion in a differential diagnosis. Of these three, *Histoplasma* most often relapses years later in patients who are immunosuppressed.

Immunosuppression, foreign bodies (eg, central catheters), ulceration of gastrointestinal and respiratory mucosa, broad-spectrum antimicrobial therapy, malnutrition, HIV infection, and neutrophil defects or depletion are major risk factors for opportunistic fungal disease.

Laboratory diagnosis may be difficult because of the small number of fungi present in some lesions, slow growth of some organisms, and difficulty in distinguishing normal colonization of mucosal surfaces from infection. A tissue biopsy with fungal stains and culture is the best method for diagnosing systemic disease with some fungi. Repeat blood cultures may be negative even in the presence of intravascular infections. Serologic tests are useful for diagnosing coccidioidomycosis and histoplasmosis, and antigen detection is useful for diagnosing histoplasmosis and cryptococcosis.

The common superficial fungal infections of the hair and skin are discussed in Chapter 14.

BLASTOMYCOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Residence in or travel to an endemic area.
- ▶ In immunocompetent patients, most often a self-limited flulike illness; acute pneumonia occurs in a minority of cases.
- ▶ Complications include progressive pneumonia and disseminated disease (CNS, skin, bone and joints, genitourinary tract).
- ▶ Diagnosis by culture of specimens from bronchoscopy, skin, or other tissue.

▶ General Considerations

The causative fungus, *Blastomyces dermatitidis*, is found in soil primarily in the Mississippi and Ohio River valleys, additional southeastern and south central states, and the states bordering the Great Lakes. Transmission is by inhalation of spores. Subclinical disease is common. Severe disease is much more common in adults and males. In children, infection rates are similar in both sexes.

▶ Clinical Findings

A. Symptoms and Signs

Primary infection is unrecognized or produces pneumonia. Acute symptoms include cough, chest pain, headache,

weight loss, and fever occurring several weeks to months after inoculation. Infection is usually self-limited in immunocompetent patients. In some patients an indolent progressive pulmonary disease occurs after an incubation period of 30–45 days. Cutaneous lesions usually represent disseminated disease; local primary inoculation is rare. Slowly progressive ulcerating lesions with a sharp, heaped-up border or verrucous lesions occur. Bone disease resembles other forms of chronic osteomyelitis. Lytic skull lesions in children are typical, but long bones, vertebrae, and the pelvis may be involved. Extrapulmonary disease occurs in 25–40% of patients with progressive disease. A total body radiographic examination is advisable when blastomycosis is diagnosed in the skin or another nonpulmonary site. The genitourinary tract involvement characteristic of dissemination in adults is rare in prepubertal children. Lymph nodes, brain, and kidneys may be involved.

B. Laboratory Findings

Diagnosis requires isolation or visualization of the fungus. Pulmonary specimens (sputum, tracheal aspirates, or lung biopsy) may be positive with conventional stains or fungal cell wall stains. An initial suppurative response is followed by an increase in the number of mononuclear cells, and then formation of noncaseating granulomas. The budding yeasts are thick-walled, have refractile walls, and are very large and distinctive. Sputum specimens are positive in 50–80% of cases and skin lesions are positive in 80–100%. The fungus can be grown readily in most laboratories, but 1–2 weeks are required. Serologic tests are generally not helpful for diagnosis. An ELISA antigen detection method, similar to that used for histoplasmosis, is useful for detecting *Blastomyces* antigen in urine and other body fluids.

C. Imaging

Radiographic consolidation and fibronodular interstitial and alveolar infiltrates are typical; effusions, hilar nodes, and cavities are less common. The paucity of cavitation distinguishes acute blastomycosis from histoplasmosis and tuberculosis. Miliary patterns also occur with acute infection. Chronic disease can develop in the upper lobes, with cavities and fibronodular infiltrations similar to those seen in tuberculosis, but unlike in tuberculosis or histoplasmosis, these lesions rarely caseate or calcify.

▶ Differential Diagnosis

Primary pulmonary infection resembles acute viral, bacterial, or mycoplasmal infections. Blastomycosis should be considered when a significant pulmonary infection in an endemic area fails to respond to antibiotic therapy. Subacute infection mimics tuberculosis, histoplasmosis, and coccidioidomycosis. Chronic pulmonary or disseminated disease must be differentiated from cancer, tuberculosis, or other fungal infections.

▶ Treatment

Mild pulmonary blastomycosis does not require treatment; indeed, it is rarely recognized. Recommended therapy for life-threatening (especially in the immunocompromised patient) or CNS infections is amphotericin B (0.7–1.0 mg/kg intravenously for a total of 1.5–2.0 g). Itraconazole (6–8 mg/kg/d for 6 months) is preferred for other forms of blastomycosis. Bone disease may require a full year of itraconazole therapy. Surgical debridement is required for devitalized bone, drainage of large abscesses, and pulmonary lesions not responding to medical therapy.

CANDIDIASIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ In normal or immunosuppressed individuals: superficial infections (oral thrush or ulcerations; vulvovaginitis; erythematous intertriginous rash with satellite lesions); fungemia related to intravascular devices.
- ▶ In immunosuppressed individuals: systemic infections (renal, hepatic, splenic, pulmonary, or cerebral abscesses); cotton-wool retinal lesions; cutaneous nodules.
- ▶ In either patient population: budding yeast and pseudohyphae are seen in biopsy specimens, body fluids, or scrapings of lesions; positive culture.

▶ General Considerations

Disease due to *Candida* is caused by *Candida albicans* in 60–80% of cases; similar systemic infection may be due to *C. tropicalis*, *C. parapsilosis*, *C. glabrata*, and a few other *Candida* species. Speciation is important because of differences in pathogenicity and response to azole therapy. In tissue, pseudohyphae or budding yeast (or both) are seen. *Candida* grows on routine media more slowly than bacteria; growth is usually evident on agar after 2–3 days and in blood culture media in 2–7 days.

C. albicans is ubiquitous and often present in small numbers on skin, mucous membranes, or in the intestinal tract. Normal bacterial flora, intact epithelial barriers, neutrophils and macrophages in conjunction with antibody and complement, and normal lymphocyte function by skin test reactivity are factors in preventing invasion. Disseminated infection is almost always preceded by prolonged broad-spectrum

antibiotic therapy, instrumentation (including intravascular catheters), or immunosuppression. Patients with diabetes mellitus are especially prone to superficial *Candida* infection; thrush and vaginitis are most common. *Candida* is the third most common blood isolate in hospitals in the United States and is a common cause of catheter-related urinary tract infection.

▶ Clinical Findings

A. Symptoms and Signs

1. Oral candidiasis (thrush)—Adherent creamy white plaques on the buccal, gingival, or lingual mucosa are seen. These may be painful. Lesions may be few and asymptomatic, or they may be extensive, extending into the esophagus. Thrush is very common in otherwise normal infants in the first weeks of life; it may last weeks despite topical therapy. Spontaneous thrush in older children is unusual unless they have recently received antimicrobials. Corticosteroid inhalation for asthma predisposes patients to thrush. HIV infection should be considered if there is no other reason for oral thrush, or if it is persistent or recurrent. Angular cheilitis is the name given to painful erythematous fissures caused by *Candida* at the corners of the mouth, often in association with a vitamin or iron deficiency.

2. Vaginal infection—Vulvovaginitis occurs in sexually active girls, in diabetic patients, and in girls receiving antibiotics. Thick, odorless, cheesy discharge with intense pruritus is typical. The vagina and labia are usually erythematous and swollen. Outbreaks are more frequent before menses.

3. Skin infection

A. DIAPER DERMATITIS—Diaper dermatitis is often due entirely or partly to *Candida*. Pronounced erythema with a sharply defined margin and satellite lesions is typical. Pustules, vesicles, papules, or scales may be seen. Weeping, eroded lesions with a scalloped border are common. Any moist area, such as axillae or neck folds, may be involved.

B. CONGENITAL SKIN LESIONS—These lesions may be seen in infants born to women with *Candida* amnionitis. A red maculopapular or pustular rash is seen. Dissemination may occur in premature infants, or in term infants after prolonged rupture of membranes.

C. SCATTERED RED PAPULES OR NODULES—Such findings may represent cutaneous dissemination.

D. PARONYCHIA AND ONYCHOMYCOSIS—These conditions occur in immunocompetent children but are often associated with immunosuppression, hypoparathyroidism, or adrenal insufficiency (*Candida* endocrinopathy syndrome). The selective absence of specific T-cell responses to *Candida* can lead to marked, chronic skin and nail infections called chronic mucocutaneous candidiasis.

E. CHRONIC DRAINING OTITIS MEDIA—This problem may occur in patients who have received multiple courses of antibiotics and are superinfected with *Candida*.

4. Enteric infection—Esophageal involvement in immunosuppressed patients is the most common enteric manifestation. It is manifested by substernal pain, dysphagia, painful swallowing, and anorexia. Nausea and vomiting are common in young children. Most patients do not have thrush. Stomach or intestinal ulcers also occur. A syndrome of mild diarrhea in normal individuals who have predominant *Candida* on stool culture has also been described, although *Candida* is not considered a true enteric pathogen. Its presence more often reflects recent antimicrobial therapy.

5. Pulmonary infection—Because the organism frequently colonizes the respiratory tract, it is commonly isolated from respiratory secretions. Thus demonstration of tissue invasion is needed to diagnose *Candida* pneumonia or tracheitis. It is rare, being seen in immunosuppressed patients and patients intubated for long periods, usually while taking antibiotics. The infection may cause fever, cough, abscesses, nodular infiltrates, and effusion.

6. Renal infection—Candiduria may be the only manifestation of disseminated disease. More often, candiduria is associated with instrumentation, an indwelling catheter, or anatomic abnormality of the urinary tract. Symptoms of cystitis may be present. Masses of *Candida* may obstruct ureters and cause obstructive nephropathy. *Candida* casts in the urine suggest renal tissue infection.

7. Other infections—Endocarditis, myocarditis, meningitis, and osteomyelitis usually occur only in immunocompromised patients or neonates.

8. Disseminated candidiasis—Skin and mucosal colonization precedes, but does not predict dissemination. Too often, dissemination is confused with bacterial sepsis. This occurs in neonates—especially premature infants—in an intensive care unit setting, and is recognized when the infant fails to respond to antibiotics or when candidemia is documented. These infants often have unexplained feeding intolerance, cardiovascular instability, apnea, new or worsening respiratory failure, glucose intolerance, thrombocytopenia, or hyperbilirubinemia. A careful search should be carried out for lesions suggestive of disseminated *Candida* (retinal cotton-wool spots or nodular dermal abscesses). If these findings are absent, diagnosis is often based presumptively on the presence of a compatible illness in an immunocompromised patient, a burn patient, or a patient with prolonged postsurgical or intensive care unit course who has no other cause for the symptoms; who fails to respond to antimicrobials; and who usually has *Candida* colonization of mucosal surfaces. Treatment for presumptive infection is often undertaken because candidemia is not identified antemortem in many such patients.

Hepatosplenic candidiasis occurs in immunosuppressed patients. The typical case consists of a severely neutropenic patient who develops chronic fever, variable abdominal pain, and abnormal liver function tests. No bacteria are isolated, and there is no response to antimicrobials. Symptoms persist even when neutrophils return. Ultrasound or CT scan of the liver and spleen demonstrates multiple round lesions. Biopsy is needed to confirm the diagnosis.

B. Laboratory Findings

Budding yeast cells are easily seen in scrapings or other samples. A wet mount preparation of vaginal secretions is 40–50% sensitive; this is increased to 50–70% with the addition of 10% potassium hydroxide. The use of a Gram-stained smear is 70–100% sensitive. The presence of pseudohyphae suggests tissue invasion. Culture is definitive. Ninety-five percent of positive blood cultures will be detected within 3 days, but cultures may remain negative (10–40%) even with disseminated disease or endocarditis. *Candida* should never be considered a contaminant in cultures from normally sterile sites. *Candida* in any number in appropriately collected urine suggests true infection. Antigen tests are not sensitive or specific enough for clinical use. Antibody tests are not useful. The ability of yeast to form germ tubes when incubated in human serum gives a presumptive speciation for *C. albicans*.

► Differential Diagnosis

Thrush may resemble formula (which can be easily wiped away with a tongue blade or swab, revealing normal mucosa without underlying erythema or erosion), other types of ulcers (including herpes), burns, or oral changes induced by chemotherapy. Skin lesions may resemble contact, allergic, chemical, or bacterial dermatitis; miliaria; folliculitis; or eczema. Candidemia and systemic infection should be considered in any seriously ill patient with the risk factors previously mentioned.

► Complications

Failure to recognize disseminated disease early is the greatest complication. Arthritis and meningitis occur more often in neonates than in older children. Blindness from retinitis, massive emboli from large vegetations of endocarditis, and abscesses in any organ are other complications; the greater the length or degree of immunosuppression and the longer the delay before therapy, the more complications are seen.

► Treatment

A. Oral Candidiasis

In infants, oral nystatin suspension (100,000 units four to six times a day in the buccal fold after feeding until resolution) usually suffices. Nystatin must come in contact with the lesions because it is not absorbed systemically. Older children may use

it as a mouthwash (200,000–500,000 units four times a day), although it is poorly tolerated because of its taste. Clotrimazole troches (10 mg) four times a day are an alternative in older children. Prolonged therapy with either agent or more frequent dosing may be needed. Painting the lesions with a cotton swab dipped in gentian violet (0.5–1%) is visually dramatic and messy, but may help refractory cases. Eradication of *Candida* from pacifiers, bottle nipples, toys, or the mother's breasts (if the infant is breast feeding and there is candidal infection of the nipples) may be helpful.

Oral azoles, such as fluconazole (6 mg/kg/d), are effective in older children with candidal infection refractory to nystatin. Discontinuation of antibiotics or corticosteroids is advised when possible.

B. Skin Infection

Cutaneous infection usually responds to a cream or lotion containing nystatin, amphotericin B, or an azole. Associated inflammation, such as severe diaper dermatitis, is also helped by concurrent use of a topical mild corticosteroid cream, such as 1% hydrocortisone. One approach is to keep the involved area dry; a heat lamp and nystatin powder may be used. Suppression of intestinal *Candida* with nystatin and eradicating thrush may speed recovery and prevent recurrence of the diaper dermatitis.

C. Vaginal Infections

Vulvovaginal candidiasis (see Chapter 42) is treated with clotrimazole, miconazole, triazoles, or nystatin (cheapest if generic is used) suppositories or creams, usually applied once nightly for 3–7 days. In general, nystatin is less effective and longer therapy is required. A high-dose clotrimazole formulation need be given for only a single night. *Candida* balanitis in sexual partners should be treated. Oral azole therapy is equally effective. A single 150-mg oral dose of fluconazole is effective for vaginitis. It is more expensive, but very convenient. No controlled study has shown that treating colonization of male sexual partners prevents recurrence in females. Frequent recurrent infections may require elimination of risk factors, the use of oral therapy, or some prophylactic antifungal therapy, such as a single dose of fluconazole weekly.

D. Renal Infection

Candiduria is treated with a 7- to 14-day course of fluconazole, which is concentrated in the urine. Renal abscesses or ureteral fungus balls require intravenous antifungal therapy. Surgical debridement may be required. Removal of an indwelling catheter is imperative. Amphotericin B may improve poor renal function caused by renal candidiasis, even though the drug is nephrotoxic.

E. Systemic Infection

Systemic infection is dangerous and resistant to therapy. Surgical drainage of abscesses and removal of all infected

tissue (eg, a heart valve) are required for cure. Hepatosplenic candidiasis should be treated until all lesions have disappeared or are calcified on imaging studies. Treatment of systemic infection has traditionally utilized amphotericin B. Lipid forms of amphotericin B retain the antifungal potency of the free drug, but are much better tolerated. Although they are much more expensive than amphotericin B, they are indicated for patients who are intolerant of conventional therapy and for those whose infection is refractory to treatment or who have a high likelihood of developing renal toxicity from such therapy. Fluconazole and the newer azole drugs, such as itraconazole (best absorbed from the liquid solution), voriconazole, and a new class of drugs, echinocandins, are used interchangeably with amphotericin; in general these are less toxic. These new drugs also are often effective against fluconazole-resistant candidal infection.

Correction of predisposing factors is important (eg, discontinuing antibiotics and immunosuppressives, and improving control of diabetes). Flucytosine (50–75 mg/kg/d orally in four doses; keep serum levels below 75 mcg/mL) may be additive or synergistic to amphotericin B. Flucytosine is frequently added to treat neonatal infections, but clinical outcome seems to be similar when amphotericin B is used alone. Unlike amphotericin B, flucytosine penetrates tissues well. It should not be used as a single agent in serious infections because resistance develops rapidly.

Fluconazole, itraconazole, and voriconazole are acceptable alternatives for serious *C. albicans* infections in non-neutropenic patients and are often effective as first-line therapy in immunocompromised patients. The decision to use systemic azole therapy should include consideration of the local experience with azole-resistant *Candida*. Susceptibility testing for *Candida* species is now available to guide this decision. *C. glabrata* and *C. krusei* are common isolates that may be resistant to fluconazole; these are often susceptible to the newer azoles and echinocandins. Infected central venous lines must be removed immediately; this alone often is curative. Persistent fever and candidemia suggest infected thrombus, endocarditis, or tissue infection. If the infection is considered limited to the line and environs, a 14-day course (after the last positive culture) of a systemic antifungal agent following line removal is recommended for immunocompromised patients. Systemic azole therapy should also be considered for immunocompetent patients with candidemia, because of the late occurrence of focal *Candida* infection in some cases.

Fluconazole is well absorbed (oral and intravenous therapy are equivalent), reasonably nontoxic, and effective for a variety of *Candida* infections. Fluconazole dosage is 8–12 mg/kg/d in a single daily dose for initial therapy of severely ill children. Selected patients with prolonged immunosuppression (eg, after bone marrow transplantation) should receive fluconazole, itraconazole, or intermittent amphotericin B prophylaxis. These drugs are less expensive than the lipid formulations of amphotericin.

► Prognosis

Superficial disease in normal hosts has a good prognosis; in abnormal hosts, it may be refractory to therapy. Early therapy of systemic disease is often curative if the underlying immune response is adequate. The outcome is poor when therapy is delayed or when host response is inadequate.

COCCIDIOIDOMYCOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Residence in or travel to an endemic area.
- Primary pulmonary form: fever, chest pain, cough, anorexia, weight loss, and often a macular rash or erythema nodosum or multiforme.
- Primary cutaneous form: skin trauma followed in 1–3 weeks by an ulcer and regional adenopathy.
- Spherules seen in pus, sputum, CSF, joint fluid; positive culture.
- Appearance of precipitating (early) and complement-fixing antibodies (late).

► General Considerations

Coccidioidomycosis is caused by the dimorphic fungus *Coccidioides immitis*, which is endemic in the Sonoran Desert areas of western parts of Texas, southern New Mexico and Arizona, southern California, northern Mexico, and South America. Infection results from inhalation or inoculation of arthrospores (highly contagious and readily airborne in the dry climate). Even brief travel in or through an endemic area, especially during windy seasons, may allow infection. Human-to-human transmission does not occur. More than half of all infections are asymptomatic, and less than 5–10% are associated with significant pulmonary disease. Chronic pulmonary disease or dissemination occurs in less than 1% of cases.

► Clinical Findings

A. Symptoms and Signs

1. Primary disease—The incubation period is 10–16 days (range, 7–28 days). Symptoms vary from those of a mild fever and arthralgia to severe influenza-like illness with high fever, nonproductive cough, pleurisy, myalgias, arthralgias, headache, night sweats, and anorexia. Upper respiratory tract signs are not common. Severe pleuritic chest pain suggests this diagnosis. Signs vary from none to rash, rales, pleural rubs, and signs of pulmonary consolidation. Weight loss may occur.

2. Skin disease—Up to 10% of children develop erythema nodosum or multiforme. These manifestations imply a favorable host response to the organism. Less specific maculopapular eruptions occur in a larger number of children. Skin lesions can occur following fungemia. Primary skin inoculation sites develop indurated ulcers with local adenopathy. Contiguous involvement of skin from deep infection in nodes or bone also occurs. The presence of chronic skin lesions with this fungus should lead to a search for other areas of infection (eg, lung).

3. Chronic pulmonary disease—This is uncommon in children. Chronic disease is manifested by chronic cough (occasionally with hemoptysis), weight loss, pulmonary consolidation, effusion, cavitation, or pneumothorax.

4. Disseminated disease—This is less common in children than adults. It is more common in infants, neonates, pregnant women (especially during the third trimester), blacks, Filipinos, American Indians, and patients with HIV or other types of immunosuppression. One or more organs may be involved. The most common sites involved are bone or joint (usually a single bone or joint; subacute or chronic swelling, pain, redness), nodes, meninges (slowly progressive meningeal signs, ataxia, vomiting, headache, and cranial neuropathies), and kidney (dysuria and urinary frequency). As with most fungal diseases, the evolution of the illness is usually slow.

B. Laboratory Findings

Direct examination of respiratory secretions, pus, CSF, or tissue may reveal large spherules (30–60 μm) containing endospores. These are the product of coccidioidal spores germinating in tissue. Phase-contrast microscopy is useful for demonstrating these refractile bodies; Gram or methylene blue stains are not helpful, but periodic acid–Schiff reagent, methenamine silver, and calcofluor stains are. Fluffy, gray-white colonies grow within 2–5 days on routine fungal and many other media. CSF cultures are often negative.

Routine laboratory tests are nonspecific. The sedimentation rate is usually elevated. Eosinophilia may occur, particularly prior to dissemination, and is more common in

coccidioidomycosis than in many other conditions with similar symptoms. Meningitis causes a mononuclear pleocytosis (70% with eosinophils) with elevated protein and mild hypoglycorrhachia.

Within 2–21 days, most patients develop a delayed hypersensitivity reaction to coccidioidin skin test antigen (Spherulin, 0.1 mL intradermally, should produce 5-mm induration at 48 hours). Erythema nodosum predicts strong reactivity; when this reaction is present the antigen should be diluted 10–100 times before use. The skin test may be negative in immunocompromised patients or in those with disseminated disease. Positive reactions may remain for years and do not prove active infection.

Antibodies consist of precipitins (usually measurable by 2–3 weeks in 90% of cases and gone by 12 weeks) and complement-fixing antibodies (delayed for several weeks; appear as the precipitins are falling and disappear by 8 months, unless dissemination or chronic infection occurs). The extent of the complement-fixing antibody response reflects the severity of infection. Persistent high levels suggest dissemination. Serum precipitins usually indicate acute infection. Excellent ELISA assays are now available to detect IgM and IgG antibodies against the precipitin and complement-fixing antigens. The presence of antibody in CSF indicates CNS infection.

C. Imaging

Approximately half of symptomatic infections are associated with abnormal chest radiographs—usually infiltrates with hilar adenopathy. Pulmonary consolidation, effusion, and thin-walled cavities may be seen. About 5% of infected patients have asymptomatic nodules or cysts after recovery. Unlike reactivation tuberculosis, apical disease is not prominent. Bone infection causes osteolysis that enhances with technetium. Cerebral imaging may show hydrocephalus and meningitis; intracranial abscesses and calcifications are unusual. Radiographic evolution of all lesions is slow.

► Differential Diagnosis

Primary pulmonary infection resembles acute viral, bacterial, or mycoplasmal infections; subacute presentation mimics tuberculosis, histoplasmosis, and blastomycosis. Chronic pulmonary or disseminated disease must be differentiated from cancer, tuberculosis, or other fungal infections.

► Complications

Dissemination of primary pulmonary disease is associated with ethnic background, prolonged fever (> 1 month), a negative skin test, high complement-fixation antibody titer, and marked hilar adenopathy. Local pulmonary complications include effusion, empyema, and pneumothorax. Cerebral infection can cause noncommunicating hydrocephalus due to basilar meningitis.

► Treatment

A. Specific Measures

Mild pulmonary infections in most normal hosts require no therapy. These patients should be assessed for 1–2 years to document resolution and to identify any complications. Antifungal therapy is used for prolonged fever, weight loss (> 10%), prolonged duration of night sweats, severe pneumonitis (especially if persisting for 4–6 weeks), or any form of disseminated disease. Neonates, pregnant women, and patients with high antibody titer also receive treatment. Therapy is often utilized for pregnant women and subjects with high-risk racial origins.

Amphotericin B is used to treat severe disease (1 mg/kg/d until improvement, then reduce dose; total duration, 2–3 months). Lipid formulations are used at 2–5 mg/kg/d. In general, the more rapidly progressive the infection, the more compelling the case for amphotericin B therapy. However, posaconazole and voriconazole appear to be effective and their role as first-line therapy is being determined. For less severe disease and for meningeal disease, fluconazole or itraconazole are preferred (duration of therapy is > 6 months, and is indefinite for meningeal disease). Measurement of serum levels is suggested to monitor therapy. Chronic fibrocavitary pneumonia is treated for at least 12 months. Lifelong suppressive therapy is recommended after treating coccidioid meningitis. Itraconazole may be superior to fluconazole. Refractory meningitis may require prolonged intrathecal or intraventricular amphotericin B therapy. Pregnant patients should not receive azoles.

B. General Measures

Most pulmonary infections require only symptomatic therapy, self-limited activity, and good nutrition. They are not contagious.

C. Surgical Measures

Excision of chronic pulmonary cavities or abscesses may be needed. Infected nodes, sinus tracts, and bone are other operable lesions. Azole therapy should be given prior to surgery to prevent dissemination, and should be continued for 4 weeks arbitrarily or until other criteria for cure are met.

► Prognosis

Most patients recover. Even with amphotericin B, however, disseminated disease may be fatal, especially in those racially predisposed to severe disease. Reversion of the skin test to negative or a rising complement-fixing antibody titer are ominous signs. Individuals who later in life undergo immunosuppressive therapy or develop HIV may experience reactivation of dormant disease. Thus, some transplant and oncology programs determine prior infection by serology and either provide prophylaxis or observe patients closely during periods of intense immune suppression.

CRYPTOCOCCOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Acute pneumonitis in immunocompetent individuals.
- ▶ Immunosuppressed patients especially vulnerable to CNS infection (headache, vomiting, cranial nerve palsies, meningeal signs; mononuclear cell pleocytosis).
- ▶ Cryptococcal antigen detected in CSF; also in serum and urine in some patients.
- ▶ Readily isolated on routine media.

▶ General Considerations

Cryptococcus neoformans is a ubiquitous soil yeast. It appears to survive better in soil contaminated with bird excrement, especially that of pigeons. However, most infections in humans are not associated with a history of significant contact with birds. Inhalation is the presumed route of inoculation. Infections in children are rare, even in heavily immunocompromised patients such as those with HIV infection. Immunocompetent individuals can also be infected. Asymptomatic carriage does not occur.

▶ Clinical Findings

A. Symptoms and Signs

1. Pulmonary disease—Pulmonary infection precedes dissemination to other organs. It is frequently asymptomatic (ie, many older children and adults have serologic evidence of prior infection) and less often clinically apparent than cryptococcal meningitis. Pneumonia is the primary manifestation in one third of patients and CNS disease in 50%; cryptococcal pneumonia may coexist with cerebral involvement. Symptoms are nonspecific and subacute—cough, weight loss, and fatigue.

2. Meningitis—The most common clinical disease is meningitis, which follows hematogenous spread from a pulmonary focus. Symptoms of headache, vomiting, and fever occur over days to months. Meningeal signs and papilledema are common. Cranial nerve dysfunction and seizures may occur.

3. Other forms—Cutaneous forms are usually secondary to dissemination. Papules, pustules, and ulcerating nodules are typical. Bones (rarely joints) may be infected; osteolytic areas are seen, and the process may resemble osteosarcoma. Many other organs, especially the eye, can be involved with dissemination.

B. Laboratory Findings

The CSF usually has a lymphocytic pleocytosis; it may be completely normal in immunosuppressed patients who have cryptococcal meningitis. Direct microscopy may reveal organisms in sputum, CSF, or other specimens. The capsular antigen can be detected by latex agglutination or ELISA, which are both sensitive (> 90%) and specific. Serum, CSF, and urine may be tested. The serum may be negative if the only organ infected is the lung. False-negative CSF tests have been reported. The organism grows well after several days on many routine media; for optimal culture, collecting and concentrating a large amount of CSF (10 mL) is recommended, because the number of organisms may be low.

C. Imaging

Radiographic findings are usually lower lobe infiltrates or nodular densities; less often effusions; and rarely cavitation, hilar adenopathy, or calcification. Single or multiple focal mass lesions (cryptococcoma) may be detected in the CNS on CT or magnetic resonance imaging scan.

▶ Differential Diagnosis

Cryptococcal meningitis may mimic tuberculosis, viral meningoencephalitis, meningitis due to other fungi, or a space-occupying CNS lesion. Lung infection is difficult to differentiate from many causes of pneumonia.

▶ Complications

Hydrocephalus may be caused by chronic basilar meningitis. Symptomatic intracranial hypertension is common. Significant pulmonary or osseous disease may accompany the primary infection or dissemination.

▶ Treatment

Patients with symptomatic pulmonary disease should receive fluconazole for 3–6 months. All immunocompromised patients should have a lumbar puncture to rule out CNS infection; this should also be done for immunocompetent patients with cryptococcal antigen in the serum. Severely ill patients should receive amphotericin B (0.7 mg/kg/d). Meningitis is treated with amphotericin B and flucytosine (100 mg/kg/d). This combination is synergistic and allows lower doses of amphotericin B to be used. Therapy is usually 6 weeks for CNS infections (or for 1 month after sterilization) and 8 weeks for osteomyelitis. An alternative is to substitute

fluconazole after 2 weeks of the combination therapy and continue fluconazole alone for 8–10 weeks. Fluconazole is the preferred maintenance therapy to prevent relapses in high-risk (HIV) patients. CSF antigen levels should be checked after 2 weeks of therapy. Intracranial hypertension is treated by frequent spinal taps or a lumbar drain.

► Prognosis

Treatment failure, including death, is common in immunosuppressed patients, especially those with AIDS. Lifelong maintenance therapy may be required in these patients. Poor prognostic signs are the presence of extrameningeal disease; fewer than 20 cells/ μL of initial CSF; and initial CSF antigen titer greater than 1:32.

HISTOPLASMOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Residence in or travel to an endemic area.
- Pneumonia with flulike illness.
- Hepatosplenomegaly, anemia, leukopenia if disseminated.
- Histoplasmal antigen in urine, blood, or CSF.
- Detection of the organism in smears or tissue or by culture.

► General Considerations

The dimorphic fungus *Histoplasma capsulatum* is found in the central and eastern United States (Ohio and Mississippi River valleys), Mexico, and most of South America. Soil contamination is enhanced by the presence of bat or bird feces. The small yeast form (2–4 μm) is seen in tissue, especially within macrophages. Infection is acquired by inhaling spores that transform into the pathogenic yeast phase. Infections in endemic areas are very common at all ages and are usually asymptomatic. Over two thirds of children are infected in these areas. Reactivation is very rare in children; it may occur years later, usually owing to significant immunosuppression. Reinfection also occurs.

The extent of symptoms with primary or reinfection is influenced by the size of the infecting inoculum.

► Clinical Findings

Because human-to-human transmission does not occur, infection requires exposure in the endemic area—usually within prior weeks or months. Congenital infection does not occur.

A. Symptoms and Signs

1. Asymptomatic infection (90% of infections)—Asymptomatic histoplasmosis is usually diagnosed by the presence of scattered calcifications in lungs or spleen and a positive skin test. The calcification may resemble that caused by tuberculosis but may be more extensive than the usual Ghon complex.

2. Pneumonia—Approximately 5% of patients have mild to moderate disease. Most of these patients are not recognized as having a histoplasmal infection. Acute pulmonary disease may resemble influenza, with fever, myalgia, arthralgia, and cough occurring 1–3 weeks after exposure; the subacute form resembles infections such as tuberculosis, with cough, weight loss, night sweats, and pleurisy. Chronic disease is unusual in children. Physical examination may be normal, or rales may be heard. A small number of patients may have immune-mediated signs such as arthritis, pericarditis, and erythema nodosum. The usual duration of the disease is less than 2 weeks, followed by complete resolution. Symptoms may last several months and still resolve without antifungal therapy.

3. Disseminated infection (5% of infections)—Fungemia during primary infection probably occurs in the first 2 weeks of all infections, including those with minimal symptoms. Transient hepatosplenomegaly may occur, but resolution is the rule in immunocompetent individuals. Heavy exposure, severe underlying pulmonary disease, and immunosuppression are risk factors for progressive reticuloendothelial cell infection, with anemia, fever, weight loss, organomegaly, bone marrow involvement, and death. Dissemination may occur in otherwise immunocompetent children; usually they are younger than age 2 years.

4. Other forms—Ocular involvement consists of multifocal choroiditis. This usually occurs in immunocompetent adults who exhibit other evidence of disseminated disease. Brain, pericardium, intestine, and skin (oral ulcers and nodules) are other involved sites. Adrenal gland involvement is common with systemic disease.

B. Laboratory Findings

Routine tests are normal or nonspecific in the benign forms. Pancytopenia is present in many patients with disseminated disease. The diagnosis can be made by demonstrating the

organism by histology or culture. Tissue yeast forms are small and may be mistaken for artifact. They are usually found in macrophages, occasionally in peripheral blood leukocytes in severe disease, but rarely in sputum, urine, or CSF. Cultures of infected fluids or tissues may yield the organism after 1–6 weeks of incubation on fungal media, but even cultures of bronchoalveolar lavage or transbronchial biopsy specimens in immunocompromised patients are often negative (15%). Thus bone marrow and tissue specimens are needed. Detection of histoplasmal antigen in blood, urine, CSF, and bronchoalveolar lavage fluid is the most sensitive diagnostic test (90% positive in the urine with disseminated disease; 75% positive with acute pneumonia). The level of antigen correlates with the extent of the infection, and antigen levels can be used to follow the response to therapy and to indicate low-grade infection persisting after completion of therapy (eg, in a child with HIV infection).

Antibodies may be detected by immunodiffusion and complement fixation; the latter rises in the first 2–6 weeks of illness and fall unless dissemination occurs. Cross-reactions occur with some other endemic fungi. A single high titer or rising titer indicates a high likelihood of disease. Antigen detection has replaced serology as a rapid diagnostic test.

C. Imaging

Scattered pulmonary calcifications in a well child are typical of past infection. Bronchopneumonia (focal midlung infiltrates) occurs with acute disease, often with hilar and mediastinal adenopathy, occasionally with nodules, but seldom with effusion. Apical cavitation occurs with chronic infection, often on the background of preexisting pulmonary infection.

► Differential Diagnosis

Pulmonary disease resembles viral infection, tuberculosis, coccidioidomycosis, and blastomycosis. Systemic disease resembles disseminated fungal or mycobacterial infection, leukemia, histiocytosis, or cancer.

► Treatment

Mild infections do not require therapy. Treatment is indicated for severe pulmonary disease (diffuse radiographic involvement); disseminated disease; when endovascular, CNS, or chronic pulmonary disease is present; and for children younger than age 1 year. Treatment should also be considered for patients who do not improve after 1 month. Disseminated disease in infants may respond to as few as 10 days of amphotericin B, although 4–6 weeks (or 30 mg/kg total dosage) is usually recommended. Amphotericin B is the preferred therapy for moderately severe forms of the disease. Patients with severe disease may benefit from a short course of corticosteroid therapy (see also later section on *Pneumocystis jirovecii*). Surgical excision of chronic pulmonary lesions is rarely required. Itraconazole (3–5 mg/kg/d for 6–12 weeks;

achieve peak serum level of >1.0 mcg/mL) appears to be equivalent to amphotericin B therapy for mild disease and can be substituted for amphotericin B in severe disease after a favorable initial response. With chronic pulmonary, CNS, or disseminated disease, prolonged therapy may be required.

Quantitation of fungal antigen is useful for directing therapy. Histoplasmosis can reactivate in previously infected individuals who subsequently become immunosuppressed. Chronically immunosuppressed patients (eg, those with HIV) may require lifelong maintenance therapy with an azole.

► Prognosis

Patients with mild and moderately severe infections have a good prognosis. With early diagnosis and treatment, infants with disseminated disease usually recover; the prognosis worsens if the immune response is poor.

SPOROTRICHOSIS

- Subacute cutaneous ulcers.
- New lesions appearing proximal to existing lesions along a draining lymphatic.
- Absence of systemic symptoms.
- Isolation of *Sporothrix schenckii* from wound drainage or biopsy.

► General Considerations

Sporotrichosis is caused by *Sporothrix schenckii*, a dimorphic fungus present as a mold in soil, plants, and plant products from most areas of North and South America. Spores of the fungus can cause infection when they breach the skin at areas of minor trauma. Sporotrichosis has been transmitted from cutaneous lesions of pets.

► Clinical Findings

Cutaneous disease is by far the most common manifestation. Typically at the site of inapparent skin injury an initial papular lesion will slowly become nodular and ulcerate. Subsequent new lesions develop in a similar fashion proximally along lymphatics draining the primary lesion. This sequence of developing painless, chronic ulcers in a linear pattern is strongly suggestive of the diagnosis. Solitary

lesions may exist and some lesions may develop a verrucous character. Systemic symptoms are absent and laboratory evaluations are normal, except for acute phase reactants. The fungus rarely disseminates in immunocompetent hosts, but bone and joint infections have been described. Cavitory pneumonia is an uncommon manifestation when patients inhale the spores. Immunocompromised patients, especially those with HIV infection, may develop disseminated skin lesions and multiorgan disease with extensive pneumonia.

► Differential Diagnosis

The differential diagnosis of nodular lymphangitis (sporotrichoid infection) includes other endemic fungi and some bacteria, especially atypical mycobacteria. Diagnosis is made by culture. Biopsy of skin lesions will demonstrate a suppurative response with granulomas and provides the best source for laboratory isolation. Occasionally the characteristic yeast will be seen in the biopsy.

► Treatment & Prognosis

Treatment is with itraconazole (100 mg/d or 5 mg/kg/d) for 3–6 months. Prognosis is excellent with lymphocutaneous disease in immunocompetent children. Pulmonary or osteoarticular disease, especially in immunocompromised individuals, requires longer therapy, and surgical debridement may be required.

Kauffmann CA et al: Clinical practice guidelines for the management of sporotrichosis. *Clin Infect Dis* 2007;45:1255 [PMID: 17968818].

OPPORTUNISTIC FUNGAL INFECTIONS

These infections occur most commonly when patients are treated with corticosteroids, antineoplastic drugs, or radiation, thereby reducing the number or function of neutrophils and competent lymphocytes. Inborn errors in immune function (combined immune deficiency or chronic granulomatous disease) may also be complicated by these fungal infections. Infection is also facilitated by altering the normal flora with antibiotics and by disruption of mucous membranes with antineoplastic therapy or skin and with indwelling lines and tubes.

Table 41–8 indicates that filamentous fungi are prominent causes of severe systemic fungal disease in immunocompromised patients. *Aspergillus* species (usually *fumigatus*) and Zygomycetes (usually Mucorales) cause subacute pneumonia and sinusitis and should be considered when these conditions do not respond to antibiotics in immunocompromised patients. *Aspergillus* species are common invasive organisms in patients with chronic granulomatous disease. Mucormycosis is especially likely to produce severe sinusitis in patients with chronic acidosis, usually because of poorly controlled diabetes.

This fungus may invade the orbit and cause brain infection. Mucormycosis also occurs in patients receiving iron chelation therapy. These fungal infections may disseminate widely. Imaging procedures may suggest the etiology, but they are best diagnosed by aspiration or biopsy of infected tissues. *Cryptococcus*, which can cause disease in the immunocompetent host, is more likely to be clinically apparent and severe in immunocompromised patients. This yeast causes pneumonia and is a prominent cause of fungal meningitis. *Candida* species in these patients cause fungemia and multiorgan disease, with lung, esophagus, liver, and spleen frequently affected.

Malassezia furfur is a yeast that normally causes the superficial skin infection known as tinea versicolor (see Chapter 14). This organism is considered an opportunist when it is associated with prolonged intravenous therapy, especially central lines used for hyperalimentation. The yeast, which requires skin lipids for its growth, can infect lines when lipids are present in the infusate. Some species will grow in the absence of lipids. Unexplained fever and thrombocytopenia are common. Pulmonary infiltrates may be present. The diagnosis is facilitated by alerting the bacteriology laboratory to add olive oil to culture media. The infection will respond to removal of the line or the lipid supplement. Amphotericin B may hasten resolution.

Opportunistic fungal infections are always included in the differential diagnosis for immunocompromised patients with unexplained fever or pulmonary infiltrates. These pathogens should be aggressively pursued with imaging studies and with tissue sampling when clues are available. These infections are difficult to treat. Amphotericin B and appropriate triazole drugs are usually indicated. The echinocandins and voriconazole are now used to treat *Candida* and *Aspergillus* infections. Combinations of current antifungal drugs are being tested to improve the outcome. Many children who will have depressed phagocytic and T-cell-mediated immune function for long periods should receive antifungal prophylaxis, most often itraconazole.

PNEUMOCYSTIS JIROVECI INFECTION

- Significant immunosuppression.
- Fever, tachypnea, cough, dyspnea.
- Hypoxemia; diffuse interstitial infiltrates.

Table 41-8. Unusual fungal infections in children.

Organism	Predisposing Factors	Route of Infection	Clinical Disease	Diagnostic Tests	Therapy and Comments
<i>Aspergillus</i> species	None	Inhalation of spores	Allergic bronchopulmonary aspergillosis; wheezing, cough, migratory infiltrates, eosinophilia.	Organisms in sputum; positive skin test; specific IgE antibody; elevated IgE levels.	Hypersensitivity to fungal antigens. Use steroids. Antifungals may not be needed.
	Immunosuppression	Inhalation of spores	Progressive pulmonary disease: consolidation, nodules, abscesses. Sinusitis. Disseminated disease: usually lung, brain; occasionally intestine, kidney, heart, bone. Invades blood vessels.	Demonstrate fungus in tissues by stain or culture; septate hyphae branching at 45-degree angle.	Amphotericin B, voriconazole, and oral caspofungin are equally effective; these can be used in combination.
<i>Malassezia furfur</i> , <i>M pachydermatis</i>	Central venous catheter, usually lipid infusion (can occur in the absence of lipid)	Line infection from skin colonization	Sepsis; pneumonitis, thrombocytopenia.	Culture of catheter or blood on lipid-enriched media (for <i>M furfur</i> ; <i>M pachydermatis</i> does not need lipid). Fungus may be seen in buffy coat.	Discontinuation of lipid may be sufficient. Remove catheter. Short-term amphotericin B may be added. Organism ubiquitous on normal skin; requires long-chain fatty acids for growth.
Mucorales (<i>Mucor</i> , <i>Rhizopus</i> , <i>Absidia</i>)	Immunosuppression, diabetic acidosis, iron chelation therapy	Inhalation, mucosal colonization	Rhinocerebral: sinus, nose, necrotizing vasculitis; central nervous system spread. Pulmonary. Disseminated: any organ.	Broad aseptate hyphae branching at 90-degree angles demonstrates fungus in tissues by stain. Culture: rapidly growing, fluffy fungus.	Amphotericin B, surgical debridement; voriconazole and posaconazole may also be effective or can be used as a second agent for combined therapy. Poor prognosis.
<i>Pseudallescheria boydii</i>	Immunosuppression	Inhalation	Disseminated abscesses (lung, brain, liver, spleen, other).	Culture of pus or tissue.	Surgical drainage; voriconazole or caspofungin.
	Minor trauma	Cutaneous	Mycetoma (most common).	Yellow-white granules in pus. Culture.	Aggressive surgery. Amputation may be needed.
<i>Sporothrix schenckii</i>	Minor trauma (thorns, splinters)	Cutaneous	Chronic skin ulcers, subcutaneous nodules along lymphatics. Rarely pneumonia, osteomyelitis, arthritis in immunocompromised host.	Gram or fungal stain of pus or tissue may show "hockey stick" organisms. Culture of pus, tissue.	Itraconazole, drainage, débridement.

► General Considerations

Although classified as a fungus on the basis of structural and nucleic acid characteristics, *Pneumocystis* responds readily to antiprotozoal drugs and antifols. It is a ubiquitous pathogen. Initial infection is presumed to occur asymptotically via inhalation, usually in early childhood, and to become a clinical problem upon reactivation during immune suppression. There

is evidence that person-to-person transmission may contribute to symptomatic disease. Nevertheless, it appears that in the normal host clinical disease rarely occurs. A syndrome of afebrile pneumonia similar to that caused by *Chlamydia trachomatis* in normal infants has been described, but its etiology is rarely appreciated. Whether by reactivation or new exposure, severe signs and symptoms occur chiefly in patients with abnormal T-cell function such as occurs with HIV infection, hemato-

logic malignancies, and organ transplantation. Prolonged, high-dose corticosteroid therapy for any condition is a risk factor; onset of illness as steroids are tapered is a typical presentation. Severely malnourished infants with no underlying illness may also develop this infection, as can those with congenital humoral or cellular immunodeficiency. The incubation period is usually at least 1 month after onset of immunosuppression.

Pneumocystis pneumonia is a common complication of advanced HIV infection and is one of the diseases that defines AIDS. Prophylaxis usually prevents this infection (see Chapter 39).

Infection is generally limited to the lower respiratory tract. In advanced disease, spread to other organs occurs.

► Clinical Findings

A. Symptoms and Signs

In most patients, a gradual onset of fever, tachypnea, dyspnea, and mild, nonproductive cough occurs over 1–4 weeks. Initially the chest is clear, although retractions and nasal flaring are present. At this stage the illness is nonspecific. Hypoxemia out of proportion to the clinical and radiographic signs is an early finding; however, even minimally decreased arterial oxygen pressure values should suggest this diagnosis in immunosuppressed children. Tachypnea, nonproductive cough, and dyspnea progress. Respiratory failure and death occur without treatment. In some children with AIDS or severe immunosuppression from chemotherapy or organ transplantation, the onset may be abrupt and progression more rapid. Acute dyspnea with pleuritic pain may indicate the related complication of pneumothorax.

The general examination is unremarkable except for tachypnea and tachycardia; rales may be absent. There are no upper respiratory signs, conjunctivitis, organomegaly, enanthem, or rash.

B. Laboratory Findings

Laboratory findings reflect the individual child's underlying illness and are not specific. Serum lactate dehydrogenase levels may be elevated markedly as a result of pulmonary damage. In moderately severe cases, the arterial oxygen pressure is less than 70 mm Hg or the alveolar-arterial gradient is less than 35 mm Hg.

C. Imaging

Early chest radiographs are normal. The classic pattern in later films is that of bilateral, interstitial, lower lobe alveolar disease starting in the perihilar regions, without effusion, consolidation, or hilar adenopathy. High-resolution CT scanning may reveal extensive ground-glass attenuation or cystic lesions. Older HIV-infected patients present with other patterns, including nodular infiltrates, lobar pneumonia, cavities, and upper lobe infiltrates.

D. Diagnostic Findings

Diagnosis requires finding characteristic round (6–8 mm) cysts in a lung biopsy specimen, bronchial brushings, alveolar washings, induced sputum, or tracheal aspirates. The latter specimens are less sensitive but are more rapidly and easily obtained. They are more often negative in children with leukemia compared with those with HIV infection; presumably, greater immunosuppression results in larger numbers of organisms. Because pneumonia in immunosuppressed patients may have many causes, negative results from tracheal secretions should prompt more aggressive diagnostic attempts. Bronchial washing using fiberoptic bronchoscopy is usually well tolerated and rapidly performed.

Several rapid stains—as well as the standard methenamine silver stain—are useful. The indirect fluorescent antibody method is most sensitive. These methods require competent laboratory evaluation, because few organisms may be present and many artifacts may be found.

► Differential Diagnosis

In immunocompetent infants, *C trachomatis* pneumonia is the most common cause of the afebrile pneumonia syndrome described for *Pneumocystis*. In older immunocompromised children, the differential diagnosis includes influenza, respiratory syncytial virus, cytomegalovirus, adenovirus, and other viral infections; bacterial and fungal pneumonia; pulmonary emboli or hemorrhage; congestive heart failure; and *Chlamydia pneumoniae* and *Mycoplasma pneumoniae* infections. Lymphoid interstitial pneumonitis, which occurs in older infants with HIV infection, is more indolent and the patient's lactate dehydrogenase level is normal (see Chapter 39). *Pneumocystis* pneumonia is uncommon in children who are complying with prophylactic regimens.

► Prevention

Children at high risk for developing *Pneumocystis* infection should receive prophylactic therapy. Children at risk include those with hematologic malignancies, children who for other reasons are receiving intensive chemotherapy or high-dose corticosteroids, and children with organ transplants or advanced HIV infection. All children born to HIV-infected mothers should receive prophylaxis against *Pneumocystis* starting at age 6 weeks until HIV infection has been ruled out, or if the infant is infected, until the patient's immunologic status has been clarified (see Chapter 39). The prophylaxis of choice is trimethoprim-sulfamethoxazole (150 mg/m²/d of trimethoprim and 750 mg/m²/d of sulfamethoxazole) for 3 consecutive days of each week. Alternatives to this prophylaxis regimen are described in Chapter 39.

► Treatment

A. General Measures

Supplemental oxygen and nutritional support may be needed. The patient should be in respiratory isolation.

B. Specific Measures

Trimethoprim–sulfamethoxazole (20 mg/kg/d of trimethoprim and 100 mg/kg/d of sulfamethoxazole in four divided doses intravenously or orally if well tolerated) is the treatment of choice. Improvement may not be seen for 3–5 days. Duration of treatment is 3 weeks in HIV-infected children. Methylprednisolone (2–4 mg/kg/d in four divided doses intravenously) should also be given to HIV-infected patients with moderate to severe infection (partial oxygen pressure < 70 mm Hg or alveolar-arterial gradient > 35) for the first 5 days of treatment. The dosage is reduced 50% for the next 5 days, and further reduced by 50% until antibiotic treatment is completed. If trimethoprim–sulfamethoxazole is not tolerated or there is no clinical response in 5 days, pentamidine isethionate (4 mg/kg once daily by slow intravenous infusion) should be given. There is growing concern that antimicrobial resistance may be developing in some locations. Clinical efficacy is similar with pentamidine, but adverse reactions are more common. These reactions include dysglycemia, pancreatitis, nephrotoxicity, and leukopenia. Other effective alternatives in adults include atovaquone, trimethoprim plus dapsone, and primaquine plus clindamycin.

► Prognosis

The mortality rate is high in immunosuppressed patients who receive treatment late in the illness.

Sexually Transmitted Infections

Ann-Christine Nyquist, MD, MSPH
Eric J. Sigel, MD

The rate of sexually transmitted infections (STIs) acquired during adolescence remains high despite widespread educational programs and increased access to health care. The highest age-specific rates for gonorrhea, chlamydia, and human papillomavirus (HPV) infection occur in adolescents and young adults. By age 18 years, half of youth will have had sexual intercourse. One quarter of those having intercourse will develop an STI—an estimated 3 million teenagers per year. Adolescents contract STIs at a higher rate than adults because of sexual risk-taking, age-related biologic factors, and barriers to health care access. Providers need to comply with state-sanctioned confidentiality laws covering STI-related services, while recognizing the importance of confidentiality to adolescents. Except in a few states, adolescents can provide consent for the diagnosis and confidential treatment of STIs without parental consent or knowledge. In many states, adolescents can also provide consent for human immunodeficiency virus (HIV) counseling and testing.

Providers should screen sexually experienced adolescents for STIs and use this opportunity to discuss risk reduction. Health education counseling should be nonjudgmental and appropriate for the developmental level, yet sufficiently thorough to identify risk behaviors because many adolescents may not readily acknowledge engaging in these behaviors.

ADOLESCENT SEXUALITY

The spectrum of sexual behavior includes holding hands and kissing; touching, expanding to mutual masturbation; oral-genital contact; and vaginal and anal intercourse. Each has its associated risks. A small, but statistically significant, trend has occurred in the epidemiology of sexual risk-taking toward less sexual involvement and later onset of vaginal intercourse. The most recent Youth Risk Behavior Survey (2005) reports that 47% of high school students have had vaginal intercourse during their lifetime; unchanged from the 2003 survey. Six percent of teenagers have initiated sex by age 13. Significant racial and gender differences exist, with 16% of black students

(27% of males and 7% of females), 7% of Hispanics, and 4% of whites initiating sex by age 13. Thirty-four percent of students have had sex in the prior 3 months—49% of twelfth-graders and 22% of ninth-graders. Condom use has increased, with 63% of youth reporting that either they or their partner had used a condom during their last sexual intercourse, compared with 42% in 1999. Paradoxically, condom use decreases with age—75% of ninth-graders report condom use at last intercourse compared with 55% of twelfth-graders.

Oral sex has not been as well studied. A recent study reports that 38% of boys and 42% of girls in the tenth grade engaged in oral sex, with only 17% using any protection. A significant number of teenagers exhibit higher-risk sexual behavior; 14% overall have had four or more sexual partners in their lifetime—21% of high school seniors and 9% of freshman. Racial and ethnic differences exist as well: having four or more sexual partners is more common among black males (39%) than among Hispanic males (22%) or white males (12%). One million teenagers become pregnant annually. Almost 8% of students have been physically forced to have sexual intercourse when they did not want to—10% of females and 5% of males. Anal intercourse occurs in both heterosexual and homosexual populations.

Adolescents may not yet identify themselves as gay, lesbian, or bisexual, but continue to question and to engage in high-risk behaviors with multiple partners. Anywhere from 10% to 30% of males experiment with same-sex partners in some fashion, with 4–10% practicing anal sex. Frequently teenage males have their first same-sex experience with partners who are significantly older, which puts them at higher risk for STIs. Lesbians often experiment with male partners during their teen years as they sort out their sexual orientation, placing them at increased risk for pregnancy and STIs.

Impaired judgment related to alcohol or drug use creates an environment for unsafe sexual experimentation. Eighty-two percent of high school students have experimented with alcohol; 50% of high school senior boys have been drunk in the last 30 days. Nationwide, among students who were

currently having sexual intercourse, 25% used alcohol or drugs the last time they had sex. This additional barrier to decision-making results in decreased condom use and an increased incidence of forced sex.

RISK FACTORS

Certain behaviors and experiences put the adolescent at higher risk for developing STIs. These include early age at sexual debut, lack of condom use, multiple partners, prior STI, history of STI in a partner, and sex with a partner who is 3 or more years older. The type of sex affects risk as well, with intercourse being riskier than oral sex. Other risk-taking behaviors associated with STIs in adolescents are smoking, alcohol use, drug use, dropping out of school, pregnancy, and watching X-rated movies.

The adolescent female is especially predisposed to chlamydia, gonorrhea, and HPV infection because the cervix during adolescence has an exposed squamocolumnar junction. The rapidly dividing cells in this area are especially susceptible to microorganism attachment and infection. During early to mid puberty this junction slowly invaginates as the uterus and cervix mature, and by the late teens to early 20s the squamocolumnar junction is inside the cervix.

PREVENTION OF SEXUALLY TRANSMITTED INFECTIONS

Efforts to reduce STI risk behavior should begin before the onset of sexual experimentation: first by helping youth personalize their risk for STIs and encouraging positive behaviors that minimize these risks, and then by enhancing communication skills with sexual partners about STI prevention, abstinence, and condom use.

Primary prevention focuses largely on education and risk-reduction techniques. It is essential to recognize that a key task

of adolescence is developing sexual identity. Teenagers are sexual beings and will decide if, when, and how they are going to initiate sexual involvement. Health care providers should routinely address sexuality as part of well adolescent checkups. Being open and frank about the risks and benefits of each specific type of sexual activity will help youth think about their decision and the consequences. Although more than 90% of students have been taught about HIV infection and other STIs in school, adolescents still have a difficult time personalizing risk. Discussing prevalence, symptoms, and sequelae of STIs can raise awareness and help teenagers make informed decisions about initiating sexual activity and the use of safer sex techniques. Making condoms available reiterates the message that safer sex is vital to health. Discussing condoms, dental dams, and the proper use of lubrication also facilitates safer sex practices. Condoms prevent infections with HIV, HPV, gonorrhea, *Chlamydia*, and herpes simplex virus (HSV). They are probably effective in preventing other STIs as well.

Secondary prevention requires identifying and treating STIs (see next section on Screening) before infected individuals transmit infection to others. Access to medical care is critical to this objective. Identifying and treating STIs in partners are essential in limiting the spread of these infections. Cooperation with the state or county health department is valuable, because these agencies assume the responsibility for locating the contacts of infected persons and ensuring appropriate treatment.

Tertiary prevention is directed toward complications of a specific illness. Examples of tertiary prevention would be treating pelvic inflammatory disease (PID) before infertility develops; following the serologic response to syphilis to prevent late-stage syphilis; treating cervicitis to prevent PID; or treating a chlamydial infection before epididymitis ensues.

Finally, preexposure vaccination against hepatitis B or hepatitis A reduces the risk for these preventable STIs. All adolescents should have prior or current immunization against hepatitis B. (See Chapter 9.) However, because hepatitis B infection is frequently sexually transmitted, this vaccine is especially critical for all unvaccinated patients being evaluated for an STI. Hepatitis A vaccination is recommended for males who have sex with men and for injection drug users. Preexposure vaccination for HPV in females can decrease risk for cervical dysplasia and cervical cancer as well as decrease risk for genital warts. (See Chapter 9.)

DiClemente RJ et al: A programmatic and methodologic review and synthesis of clinic-based risk-reduction interventions for sexually transmitted infections: Research and practice implications. *Semin Pediatr Infect Dis* 2005;16:199 [PMID: 16044394].

SCREENING FOR SEXUALLY TRANSMITTED INFECTIONS

An essential part of screening is by history. Teenagers should be asked open-ended questions about their sexual experiences to assess their risk for STIs. The ability of the health

care provider to obtain an accurate sexual history is crucial in prevention and control efforts. Questions must be explicit and understandable to the youth. If the adolescent has ever engaged in sexual activity, the provider needs to determine what kind of sexual activity (mutual masturbation or oral, anal, or vaginal sex); whether it has been heterosexual, homosexual, or both; whether birth control and condoms were used; and whether it has been consensual or forced. During the interview the clinician should take the opportunity to discuss risk-reduction techniques regardless of the history obtained from the youth. Importantly, female health care providers are twice as likely as male providers to screen female teenagers for STIs, so male health care providers need to better use screening opportunities.

A routine laboratory screening process is warranted if the patient has engaged in intercourse, presents with STI symptoms, or reports a partner with an STI. The availability of nucleic acid amplification tests (NAATs), primarily for *Chlamydia* and *Neisseria gonorrhoeae*, has changed the nature of STI screening and intervention. These amplification tests are more than 95% sensitive and more than 99% specific, using either urine or cervical/urethral swabs. Annual screening of all sexually active females aged 25 years or younger is recommended for *Chlamydia trachomatis*. Routine chlamydial testing should be considered for all adolescent males and, in particular, males who have sex with men, have new or multiple sex partners, or are in correctional facilities.

Initial screening for urethritis in males begins with a physical examination. A first-catch urine sample (the first 10–40 mL of voided urine collected after not voiding for 2 hours) should be sent for *Chlamydia* and *N gonorrhoeae* testing if there are no signs (urethral discharge or lesions) or symptoms. With signs or symptoms, a urethral swab should be sent to test for both *N gonorrhoeae* and *Chlamydia*. A wet mount preparation should then be done on a spun urine sample or from urethral discharge, evaluating for the presence of *Trichomonas vaginalis*.

Screening asymptomatic females has become more complicated because a variety of approaches are available. Generally, either a first-void urine specimen or a cervical swab is used to screen for *Chlamydia* and *N gonorrhoeae* by NAAT. When screening for *N gonorrhoeae*, it is important to recognize that certain NAATs are less sensitive when using urine compared with a cervical swab and may not be approved for urine screening. A wet preparation of the vaginal secretions should be performed annually to check for bacterial vaginosis and trichomoniasis, and a potassium hydroxide (KOH) preparation done to screen for yeast infections. The Papanicolaou (Pap) smear serves to evaluate the cervix for the presence of HPV. The first Pap smear should be performed 3 years after the initiation of sexual intercourse, and then annually. HPV typing is no longer recommended.

For both sexes if high-risk behavior is present (three or more partners in the last 6 months or more than two partners per year for several years), then screening for hepatitis B

surface antigen is warranted if the individual was not fully immunized prior to initiation of sexual intercourse. The presence of hepatitis B surface antigen indicates either the carrier state or active infection. Presence of only hepatitis B surface antibody identifies vaccinated individuals, whereas presence of hepatitis B core antibody and hepatitis B surface antibody identifies individuals with past infection (see Chapter 21).

In urban areas with a relatively high rate of syphilis or in males who have sex with men, an RPR/VDRL (rapid plasma reagin/Venereal Disease Research Laboratory) test should be drawn yearly. RPR and HIV antibody tests should be done in all individuals in whom a concomitant STI is present.

SIGNS & SYMPTOMS

For males, the most common symptoms are dysuria and penile discharge resulting from urethral inflammation. Less common symptoms are scrotal pain, hematuria, proctitis, and pruritus in the pubic region. Signs include epididymitis, orchitis, and urethral discharge. Rarely do males develop systemic symptoms. For females, the most common symptoms are vaginal discharge and dysuria. Vaginal itching and irregular menses or spotting are also common. Abdominal pain, fever, and vomiting, although less common, are signs of PID. Pain in the genital region and dyspareunia may be present.

Signs that can be found in both males and females with an STI include genital ulcerations, adenopathy, and genital warts.

THE MOST COMMON ANTIBIOTIC-RESPONSIVE SEXUALLY TRANSMITTED INFECTIONS

C trachomatis and *N gonorrhoeae* are STIs that are epidemic in the United States and are readily treated when appropriate antibiotics are administered in a timely fashion.

CHLAMYDIA TRACHOMATIS INFECTION

▶ General Considerations

C trachomatis is the most common bacterial cause of STIs in the United States. Three million cases are estimated to occur annually in adolescents and young adults. *C trachomatis* is an obligate intracellular bacterium that replicates within the cytoplasm of host cells. Destruction of *Chlamydia*-infected cells is mediated by host immune responses.

► Clinical Findings

A. Symptoms and Signs

Clinical infection in females manifests as dysuria, urethritis, vaginal discharge, cervicitis, or PID. The presence of mucopus at the cervical os (mucopurulent cervicitis) is a sign of *Chlamydia* infection or gonorrhea. *Chlamydia* infection is asymptomatic in 75% of females.

Chlamydial infection may be asymptomatic in 70% of males or manifest as dysuria, urethritis, or epididymitis. Some patients complain of urethral discharge. On clinical examination a clear white discharge may be found after milking the penis. Proctitis or proctocolitis from *Chlamydia* may occur in adolescents practicing receptive anal intercourse.

B. Laboratory Findings

NAAT (polymerase or ligase chain reaction) is the most sensitive (92–99%) way to detect *Chlamydia*. Enzyme-linked immunosorbent assay or direct fluorescent antibody tests are less sensitive, but may be the only testing option in some centers. Culture is mandated for sexual abuse cases.

A cervical swab, using the manufacturer's swab provided with the specific test, or first-void urine specimen should be obtained. Often a single swab can be used to collect both the *Chlamydia* and *N gonorrhoeae* specimen. To optimize detection of *Chlamydia* from the cervix, columnar cells need to be collected by inserting the swab in the os and rotating it 360 degrees. If rectal symptoms are present, a rectal specimen should be obtained.

The first-void urine test for leukocyte esterase was previously used for screening asymptomatic, sexually active males. Due to the high false-positive rate this screening technique is now less commonly used. In symptomatic males, examination of the urine sediment for white blood cells (WBCs) can provide evidence of urethritis, although it is often impractical to perform in a clinical setting. In general, a first-void urine sample, or urethral swab for NAAT should be obtained at least annually. Some studies suggest that more frequent screenings—every 6 months—in higher-prevalence populations can decrease the rate of chlamydial infection. Evaluation of the symptomatic male patient or an asymptomatic contact for *Chlamydia* is the same.

For both males and females, testing urine allows for more frequent screening and simplifies screening in settings such as schools and correctional facilities, or among the military and other groups.

► Complications

Epididymitis is a complication in males. Reiter syndrome occurs in association with chlamydial urethritis. This should be suspected in male patients who are sexually active and present with low back pain (sacroiliitis), arthritis (polyarticular), characteristic mucocutaneous lesions, and conjunctivitis. PID is an important complication in females.

► Treatment

Infected patients and their contacts, regardless of the extent of signs or symptoms, need to receive treatment (Table 42–1). Because adolescents have a high risk of acquiring a repeat *Chlamydia* infection within several months of the first infection, all infected females should be retested 3–4 months after treatment. Retesting for *Chlamydia* in males previously infected 3 months after treatment is suggested although there is limited evidence as to the benefit.

Meyers DS et al: Screening for chlamydial infection: An evidence update for the U.S. Preventive Services Task Force. *Ann Intern Med* 2007;147:135 [PMID: 17576995].

NEISSERIA GONORRHOEAE INFECTION

► General Considerations

Gonorrhea is the second most prevalent bacterial STI in the United States, where an estimated 600,000 new *N gonorrhoeae* infections occur each year. In the United States the rate of reported gonorrhea was 115.6 cases per 100,000 population in 2005, representing the first increase in this rate since 1999. Gonorrhea rates continued to be highest among adolescents and young adults. The overall gonorrhea rate was highest for 20- to 24-year-olds (506.8), which is over four times higher than the national gonorrhea rate. Among females in 2005, 15- to 19-year-olds and 20- to 24-year-olds had the highest rates of gonorrhea (624.7 and 581.2, respectively); among males, 20- to 24-year-olds had the highest rate (436.8).

Sites of infection include the cervix, urethra, rectum, and pharynx. In addition, gonorrhea is a cause of PID. Humans are the natural reservoir. Gonococci are present in the exudate and secretions of infected mucous membranes.

► Clinical Findings

A. Symptoms and Signs

In uncomplicated gonococcal cervicitis, females may be symptomatic 23–57% of the time, presenting with vaginal discharge and dysuria. Urethritis and pyuria may also be present. Mucopurulent cervicitis with a yellowish discharge may be found, and the cervix may be edematous and friable. Other symptoms include abnormal menstrual periods and dyspareunia. Approximately 15% of females with endocervical gonorrhea have signs of involvement of the upper genital tract. Compared with *Chlamydia* infection, pelvic inflammation with gonorrhea often has a shorter duration, but an increased intensity of symptoms, and is more often associated with fever. Symptomatic males usually have a yellowish-green urethral discharge and burning on urination, but most

Table 42-1. Treatment regimens for sexually transmitted infections.

	Recommended Regimens	Pregnancy ^a [Category]
Pelvic inflammatory disease (PID)		
Parenteral therapy regimen A <i>Note:</i> Therapy should be continued for 24–48 h after patient has improved; therapy can then be switched to either oral regimen to complete a 14-d course.	Cefotetan, 2 g IV q 12 h	Safe [B]
	or	
	Cefoxitin, 2 g IV q 6 h	Safe [B]
Parenteral therapy regimen B <i>Note:</i> Once clinically improved for 48 h, patients can continue doxycycline, 100 mg PO bid for 14 d total. ^b	Doxycycline, 100 mg IV or PO q 12 h	Contraindicated [D]
	plus	
Alternative parenteral regimens	Clindamycin, 900 mg IV q 8 h	Safe [B]
	plus	
Recommended oral regimen <i>Note:</i> Pregnant patients with PID and women with tubo-ovarian abscesses should be hospitalized and given parenteral antibiotics. ^b	Gentamicin, 2 mg/kg IV loading dose, then 1.5 mg/kg IV q 8 h	Safe [B]
	plus	
Alternative parenteral regimens	Ampicillin/sulbactam, 3 g IV q 6 h	Safe [A]
	plus	
Recommended oral regimen <i>Note:</i> Pregnant patients with PID and women with tubo-ovarian abscesses should be hospitalized and given parenteral antibiotics. ^b	Doxycycline, 100 mg IV or PO q 12 h	Contraindicated [D]
	Ceftriaxone, 250 mg IM once	Safe [B]
	plus	
	Doxycycline, 100 mg, PO bid for 14 d with or without	Contraindicated [D]
	Metronidazole, 500 mg PO bid for 14 d	Safe [B]
	or	
	Cefoxitin, 2 g IM once plus probenecid, 1 g PO	Safe [B]
	plus	
	Doxycycline, 100 mg, PO bid for 14 d with or without	Contraindicated [D]
	Metronidazole, 500 mg PO bid for 14 d	Safe [B]
or		
Other parenteral third-generation cephalosporin (eg, ceftizoxime or cefotaxime)	Safe [B]	
plus		
Doxycycline, 100 mg, PO bid for 14 d with or without	Contraindicated [D]	
Metronidazole, 500 mg PO bid for 14 d	Safe [B]	
Cervicitis		
	Azithromycin, 1 g PO as single dose	Safe [B]
	or	
	Doxycycline, 100 mg PO bid for 7 d	Contraindicated [D]
Gonorrhea, uncomplicated		
Cervicitis, urethritis, rectal <i>Note:</i> Empiric treatment for <i>Chlamydia trachomatis</i> with azithromycin or doxycycline is recommended due to coexisting infection in 20–40% of patients with gonorrhea infection if chlamydial infection is not ruled out. ^c	Ceftriaxone, 125 mg IM as single dose	Safe [B]
	or	
	Cefixime, 400 mg PO as single dose	Safe [B]
Alternative regimen	Spectinomycin, 2 g in a single IM dose	Safe [B]
	or	
	Cephalosporins single-dose regimens ^c	Safe [B]
Pharyngitis	Ceftriaxone, 125 mg IM once	Safe [B]
Gonorrhea, disseminated		
<i>Note:</i> Treat IV until clinically improved (usually 48 h; then switch to PO); complete at least a 7-d course. ^d	Ceftriaxone, 1 g IV or IM q 24 h	Safe [B]

(continued)

Table 42-1. Treatment regimens for sexually transmitted infections. (Continued)

	Recommended Regimens	Pregnancy ^a [Category]
Alternative regimens	Cefotaxime, 1 g IV q 8 h	Safe [B]
	or	
	Ceftizoxime, 1 g IV q 8 h	Safe [B]
Oral regimen ^d	Spectinomycin, 2 g IM q 12 h	Safe [B]
	Cefixime, 400 mg PO bid	Safe [B]
	or	
	Cefixime suspension, 400 mg by suspension (200 mg/5 mL) PO bid	Safe [B]
Nongonococcal, nonchlamydial urethritis	or	
	Cefpodoxime, 400 mg PO bid	Safe [B]
Alternative regimens	Azithromycin, 1 g PO as single dose	Safe [B]
	or	
	Doxycycline, 100 mg PO bid for 7 d	Contraindicated [D]
	Erythromycin base, 500 mg PO qid for 7 d	Safe [B]
	or	
Alternative regimens	Erythromycin ethylsuccinate, 800 mg PO qid for 7 d	Safe [B]
	or	
	Ofloxacin, 300 mg PO bid for 7 d ^d	Contraindicated [C]
	or	
Recurrent or persistent urethritis	Levofloxacin, 500 mg PO once daily for 7 d ^d	Contraindicated [C]
	Metronidazole, 2 g PO as single dose	Safe [B]
	or	
Recurrent or persistent urethritis	Tinidazole, 2 g PO as single dose	Contraindicated [C]
	plus	
	Azithromycin, 1 g PO as single dose (if not used for initial episode)	Safe [B]
Proctitis, proctocolitis, and enteritis		
	Ceftriaxone 125 mg IM	Safe [B]
	plus	
	Doxycycline, 100 mg PO bid for 7 d	Contraindicated [D]
Trichomonas vaginalis vaginitis or urethritis		
	Metronidazole, 2 g PO as single dose	Safe [B]
	or	
	Tinidazole, 2 g PO as single dose	Contraindicated [C]
Alternative regimen	Metronidazole, 500 mg PO bid for 7d	Safe [B]
Bacterial vaginosis		
	Metronidazole, 500 mg PO bid for 7 d	Safe [B]
	or	
	Metronidazole, 0.75% gel, 5 g intravaginally once daily for 5 d	Safe [B]
	or	
Alternative regimen	Clindamycin cream, 2%, one applicator intravaginally at bedtime for 7 d	Safe [B]
	Clindamycin, 300 mg PO bid for 7 d	Safe [B]
	or	
	Clindamycin ovule, 100 mg intravaginally once at bedtime for 3 d	Safe [B]

(continued)

Table 42-1. Treatment regimens for sexually transmitted infections. (Continued)

	Recommended Regimens	Pregnancy ^a [Category]
Vulvovaginal candidiasis		
	Butoconazole, clotrimazole, miconazole, terconazole or tioconazole, intravaginally for 1, 3, or 7 d	Safe [B]
	or	
	Butoconazole sustained-release, 5 g once intravaginally	Safe [B]
	or	
	Fluconazole, 150 mg oral tablet, in single dose	Contraindicated [C]
Syphilis		
Early (primary, secondary, or latent < 1 y)	Benzathine penicillin G, 2.4 million units IM (for patients > 40 kg)	Safe [B]
	or	
	Benzathine penicillin G, 50,000 units/kg IM (for patients < 40 kg); up to 2.4 million units in one dose	Safe [B]
	or	
	Doxycycline, 100 mg PO bid for 14 d	Contraindicated [D]
Late (> 1 y duration or of unknown duration)	Benzathine penicillin G, 7.2 million units total, administered as 3 doses of 2.4 million units IM each at 1-week intervals	Safe [B]
	or	
	Benzathine penicillin G, 50,000 units/kg IM (for patients < 40 kg) once a week for 3 consecutive weeks; up to 2.4 million units in one dose	Safe [B]
	or	
	Doxycycline, 100 mg PO bid for 28 d	Contraindicated [D]
Neurosyphilis		
	Aqueous crystalline penicillin G, 18–24 million units/d, administered as 3–4 million units IV q 4 h or continuous infusion for 10–14 d	Safe [B]
Alternative regimen (if compliance can be assured)	Procaine penicillin, 2.4 million units IM once daily	Safe [B]
	plus	
	Probenicid, 500 mg PO qid for 10–14 d	Safe [B]
Epididymitis		
Most likely caused by gonococcal or chlamydial infection	Ceftriaxone, 250 mg IM as single dose	
	plus	
	Doxycycline, 100 mg PO bid for 10 d	
Most likely caused by enteric organisms; patient older than 35 y or allergies to cephalosporins or tetracyclines (or both)	Ofloxacin, 300 mg PO bid for 10 d	
	or	
	Levofloxacin, 500 mg PO once daily for 10 d	
Chlamydia trachomatis infection		
Cervicitis or urethritis	Azithromycin, 1 g PO as single dose	Safe [B]
	or	
	Doxycycline, 100 mg PO bid for 7 d	Contraindicated [D]
Alternative regimen^b	Erythromycin, 500 mg PO qid for 7 d	Safe [B]
	or	
	Erythromycin ethylsuccinate, 800 mg PO qid for 7 d	Safe [B]
	or	
	Ofloxacin, 300 mg PO bid for 7 d	Contraindicated [C]
	or	
	Levofloxacin 500 mg PO once daily for 7 d	Contraindicated [C]

(continued)

Table 42-1. Treatment regimens for sexually transmitted infections. (Continued)

	Recommended Regimens	Pregnancy ^a [Category]
Granuloma inguinale		
	Doxycycline, 100 mg PO bid for 3 weeks or longer	Contraindicated [D]
Alternative regimen	Ciprofloxacin, 750 mg PO bid for at least 3 weeks	Contraindicated [C]
	or	
	Erythromycin base, 500 mg PO qid for at least 3 weeks	Safe [B]
	or	
	Azithromycin, 1 g PO once per week for at least 3 weeks	Safe [B]
	or	
	Trimethoprim-sulfamethoxazole, one double-strength tablet PO bid for 3 weeks or longer	Contraindicated [C]
Lymphogranuloma venereum		
	Doxycycline, 100 mg PO bid for 21 d	Contraindicated [C]
Alternative regimen	Erythromycin, 500 mg PO qid for 21 d	Safe [B]
Herpes simplex infection		
First episode, genital	Acyclovir, 400 mg PO tid for 7-10 d	Safe [B]
	or	
	Famciclovir, 250 mg PO tid for 7-10 d	Safe [B]
	or	
	Valacyclovir, 1 g PO bid for 7-10 d	Safe [B]
Episodic therapy for recurrent genital herpes	Acyclovir, 400 mg PO tid for 5 d	Safe [B]
	or	
	Acyclovir, 800 mg PO bid for 5 d	Safe [B]
	or	
	Acyclovir, 800 mg PO tid for 2 d	Safe [B]
	or	
	Famciclovir, 125 mg PO bid for 5 d	Safe [B]
	or	
Famciclovir, 1000 mg PO bid for 1 d	Safe [B]	
	or	
	Valacyclovir, 500 mg PO bid for 3 d	Safe [B]
	or	
	Valacyclovir, 1 g PO once daily for 5 d	Safe [B]
Suppressive therapy for recurrent genital herpes	Acyclovir, 400 mg PO bid	Safe [B]
	or	
	Famciclovir, 250 mg PO bid	Safe [B]
	or	
	Valacyclovir, 500 mg PO daily (if < 10 recurrences per year; if ≥ 10 recurrences use 1 g daily)	Safe [B]
Chancroid		
	Azithromycin, 1 g PO as single dose	Safe [B]
	or	
	Ceftriaxone 250 mg IM once	Safe [B]
	or	
	Ciprofloxacin, 500 mg PO bid for 3 d	Contraindicated [D]
	or	
	Erythromycin base, 500 mg PO tid for 7 d	Safe [B]

(continued)

Table 42-1. Treatment regimens for sexually transmitted infections. (Continued)

	Recommended Regimens	Pregnancy ^a [Category]
Human papillomavirus infection		
External lesions	Podophyllin, 25% in benzoin tincture applied directly to warts; wash off in 1-4 h [contraindicated for urethral or intravaginal lesions]	Contraindicated [X]
Note: Topical therapies usually require weekly treatments for 4 consecutive weeks	or Trichloroacetic acid (85%); apply directly to warts; wash off in 6-8 h	Safe
	or Podofilox, 0.5% solution; apply bid for 3 d; used by patient at home; practitioner needs to demonstrate how compound is applied (to be used only on external lesions)	Contraindicated [C]
	or Imiquimod 5% cream, applied 3 times per week overnight (maximum of 16 weeks)	Contraindicated [C]
	or Cryotherapy: liquid nitrogen, cryoprobe Safe Laser surgery	Safe
Ectoparasitic infections		
Pubic lice^e	Permethrin 1% creme rinse: wash off after 10 min	Safe [B]
Alternative regimen	or Pyrethins with piperonyl butoxide: apply, wash off after 10 min	Safe [B]
	Malathion 0.5% lotion: wash off after 8-12 h	Safe [B]
Scabies	or Ivermectin, 250 mcg/kg repeated in 2 weeks	Contraindicated [C]
	Permethrin cream 5%: apply to entire body from the neck down, wash off after 8-14 h	Safe [B]
Alternative regimen	or Ivermectin, 200 mcg/kg PO, repeat in 2 weeks	Contraindicated [C]
	Lindane (1%): apply to entire body from neck down, wash off after 8 h	Contraindicated [C]

^aFDA use in pregnancy ratings: [A] *Controlled studies show no risk.* Adequate, well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester of pregnancy. [B] *No evidence of risk in humans.* Adequate, well-controlled studies in pregnant women have not shown increased risk of fetal abnormalities despite adverse findings in animals, in the absence of adequate human studies, animal studies show no fetal risk. The chance of fetal harm is remote but remains a possibility. [C] *Risk cannot be ruled out.* Adequate, well-controlled human studies are lacking, and animal studies have shown a risk to the fetus or are lacking as well. There is a chance of fetal harm if the drug is administered during pregnancy; but the potential benefits outweigh the potential risk. [D] *Positive evidence of risk.* Studies in humans, or investigational or postmarketing data, have demonstrated fetal risk. Nevertheless, potential benefits from the use of the drug may outweigh the potential risk. For example, the drug may be acceptable if needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective. [X] *Contraindicated in pregnancy.* Studies in animals or humans, or despite adverse findings in animals, or investigational or postmarketing reports have demonstrated positive evidence of fetal abnormalities or risk that clearly outweighs any possible benefit to the patient.

^bDoxycycline is contraindicated in pregnancy. Alternative therapies during pregnancy which include erythromycin, azithromycin, and amoxicillin are not as effective, but are clinically useful if the recommended regimens cannot be used due to allergy or pregnancy.

^cSingle-dose cephalosporin regimens include ceftizoxime (500 mg IM) or cefoxitin (2 g IM) administered with probenecid (1 g PO) or cefotaxime (500 mg IM). Some evidence indicates that cefpodoxime (400 mg) and cefuroxime axetil (1 g) might be oral alternatives.

^dIf parenteral cephalosporin therapy is not feasible, use of fluoroquinolones (levofloxacin, 500 mg PO once daily, or ofloxacin, 400 mg PO bid for 14 d) with or without metronidazole (500 mg PO bid for 14 d) may be considered if community prevalence and individual risk of gonorrhea is low. Tests for gonorrhea must be performed prior to instituting therapy and if NAAT test is positive, parenteral cephalosporin is recommended. If culture for gonorrhea is positive, treatment should be based on results of antimicrobial susceptibility.

^eBedding and clothing need to be decontaminated by washing in hot water or by dry cleaning. Regimen may be repeated in 1 week if complete response is not achieved.

bid, twice daily; IM, intramuscular; IV, intravenous; NAAT, nucleic acid amplification test; PO, orally (by mouth); qid, 4 times daily; tid, 3 times daily.

males (55–67%) with *N gonorrhoeae* are asymptomatic. Both males and females can develop gonococcal proctitis and pharyngitis after appropriate exposure.

B. Laboratory Findings

A cervical swab from females should be sent for NAAT or cultured on Thayer-Martin agar. Obtaining specimens from the rectum or pharynx when clinically indicated will increase the likelihood of positive results. Pharyngeal infection requires more intensive therapy. Nongonococcal *Neisseria* species reside in the vagina, thereby negating the value of the Gram stain in a female. NAAT screening of female urine can be used; however, polymerase chain reaction (PCR) testing is less sensitive (83%) compared with ligase chain reaction (99%).

Culture or NAAT for *N gonorrhoeae* in males can be achieved with a swab of the urethra or first-void urine. Urethral culture is less sensitive (85%) compared with the 95–99% sensitivity using NAAT methods on either urethral or urine specimens. Gram stain of urethral discharge showing gram-negative intracellular diplococci indicates gonorrhea in a male.

If proctitis is present, appropriate cultures should be obtained and treatment for both gonorrhea and *Chlamydia* infection given. If oral exposure to gonorrhea is suspected, cultures should be taken and the patient given empiric treatment.

► Differential Diagnosis

Gonococcal pharyngitis needs to be differentiated from streptococcal infection, herpes simplex pharyngitis, and infectious mononucleosis. *Chlamydia* infection needs to be differentiated from gonococcal infection.

► Complications

Disseminated gonococcal infection occurs in a minority (0.5–3%) of patients with untreated gonorrhea. Hematogenous spread most commonly causes arthritis and dermatitis. The joints most frequently involved are the wrist, metacarpophalangeal joints, knee, and ankle. Skin lesions are typically tender, with hemorrhagic or necrotic pustules or bullae on an erythematous base occurring on the distal extremities. Disseminated disease occurs more frequently in females than in males. Risk factors include pregnancy and gonococcal pharyngitis. Gonorrhea is complicated occasionally by perihepatitis and very rarely by endocarditis or meningitis.

► Treatment

Historically, patients diagnosed with gonorrhea were treated for chlamydia as well. As chlamydia testing has become more sensitive, the Centers for Disease Control and Prevention suggests that treatment for coinfection is not necessary if testing for chlamydia has been done by NAAT. Their guidelines also state that *N gonorrhoeae* and *C trachomatis* do not require tests of cure when they are treated with first-line

medications, unless the patient remains symptomatic. If retesting is indicated it should be delayed for 1 month after completion of therapy if NAATs are used to document a test of cure. Retesting might also be considered for sexually active adolescents likely to be reinfected. Patients should be advised to abstain from sexual intercourse until both they and their partners have completed a course of treatment. Treatment for disseminated disease may require hospitalization (see Table 42–1). Quinolones should no longer be used to treat gonorrhea due to high levels of quinolone resistance in all populations in the United States. Failure of initial treatment should prompt reevaluation of the patient and consideration of retreatment with ceftriaxone.

Centers for Disease Control and Prevention: Update to CDC's sexually transmitted diseases treatment guidelines, 2006: Fluoroquinolones no longer recommended for treatment of gonococcal infections. MMWR Morb Mortal Wkly Rep 2007;56:332 [PMID: 17431378].

Newman LM et al: Update on the management of gonorrhea in adults in the United States. Clin Infect D 2007;44:S84 [PMID: 17342672].

THE SPECTRUM OF SEXUALLY TRANSMITTED INFECTIONS

The patient presenting with an STI usually has one or more of the signs or symptoms described in this section. Management considerations for STIs include assessing the patient's adherence to therapy and ensuring follow-up, treating STIs in partners, and determining pregnancy risk. Treatment of each STI is detailed in Table 42–1.

CERVICITIS

► General Considerations

Cervicitis is caused by *C trachomatis* or *N gonorrhoeae* approximately 30% of the time. HSV, *T vaginalis*, and *Mycoplasma genitalium* are less common causes. Bacterial vaginosis has emerged as a new condition associated with cervicitis. Cervicitis can also be present without an STI.

► Clinical Findings

A. Symptoms and Signs

Cervicitis is often asymptomatic, but many females have an abnormal vaginal discharge or postcoital bleeding. Purulent or mucopurulent endocervical exudate visible in the endocervical canal or on an endocervical swab specimen is characteristic of cervicitis. The cervix is often friable with easily induced bleeding.

B. Laboratory Findings

Although endocervical Gram stain may show an increased number of polymorphonuclear leukocytes, this finding has a

low positive predictive value and is not recommended for diagnosis. Patients with cervicitis should be tested for *C trachomatis*, *N gonorrhoeae*, and trichomoniasis by using the most sensitive and specific tests available at the site.

► Complications

Persistent cervicitis is difficult to manage and requires reassessment of the initial diagnosis. Cervicitis can persist despite repeated courses of antimicrobial therapy. Presence of a large ectropion can contribute to persistent cervicitis.

► Treatment

Empiric treatment for both gonorrhea and chlamydial infection is recommended when the prospect of follow-up is questionable or the patient is part of a high-risk population. If the patient is asymptomatic except for cervicitis, then treatment may wait until diagnostic test results are available (see Table 42–1). Follow-up is recommended if symptoms persist. Patients should be instructed to abstain from sexual intercourse until they and their sex partners are cured and treatment is completed.

Marrazzo JM, Martin DH: Management of women with cervicitis. *Clin Infect D* 2007;44:S102 [PMID: 17342663].

PELVIC INFLAMMATORY DISEASE

► General Considerations

Pelvic inflammatory disease (PID) is defined as inflammation of the upper female genital tract and may include endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. It is the most common gynecologic disorder necessitating hospitalization for female patients of reproductive age in the United States. Over 1 million females develop PID annually, and 275,000 are hospitalized. The incidence is highest in the teen population. Teenage girls who are sexually active have a high risk (1 in 8) of developing PID, whereas women in their 20s have one-tenth the risk. Predisposing risk factors include multiple sexual partners, younger age of initiating sexual intercourse, prior history of PID, and lack of condom use. Lack of protective antibody from previous exposure to sexually transmitted organisms and cervical ectopy contribute to the development of PID. Many adolescents with subacute or asymptomatic disease are never identified.

PID is a polymicrobial infection. Causative agents include *N gonorrhoeae*, *Chlamydia*, anaerobic bacteria that reside in the vagina, and genital mycoplasmas. Vaginal douching and other mechanical factors such as an intrauterine device or prior gynecologic surgery increase the risk of PID by providing access of lower genital tract organisms to pelvic organs. Recent menses and bacterial vaginosis have been associated with the development of PID.

► Clinical Findings

A. Symptoms and Signs

Acute PID is difficult to diagnose because of the wide variation in the symptoms and signs. No single historical, clinical, or laboratory finding has both high sensitivity and specificity for the diagnosis. Diagnosis of PID is usually made clinically (Table 42–2). Typical patients have lower abdominal pain, nausea, vomiting, and fever. However, the patient may be afebrile. Vaginal discharge is variable. Cervical motion tenderness, uterine or adnexal tenderness, or signs of peritonitis are often present. Mucopurulent cervicitis is present in 50% of patients. Tubo-ovarian abscesses can often be detected by careful physical examination (feeling a mass or fullness in the adnexa).

B. Laboratory Findings

Laboratory findings include elevated WBCs with a left shift and elevated acute phase reactants (erythrocyte sedimentation rate or C-reactive protein). A positive test for *N gonorrhoeae* or *C trachomatis* is supportive, although 25% of the time neither of these bacteria is detected. Pregnancy needs to be ruled out, because patients with an ectopic pregnancy can present with abdominal pain. All female patients with acute PID should be offered HIV testing.

C. Diagnostic Studies

Laparoscopy is the gold standard for detecting salpingitis; it can be used if the diagnosis is in question or to help differen-

Table 42–2. Diagnostic criteria for pelvic inflammatory disease (PID).

Minimum criteria

Empiric treatment of PID should be initiated in sexually active young women and others at risk for sexually transmitted infections if one or more of the following minimum criteria are present:

- They are experiencing pelvic or lower abdominal pain and no other cause(s) for the illness can be identified
- Cervical motion tenderness or uterine tenderness or adnexal tenderness

Additional supportive criteria

Oral temperature > 38.3°C (101°F)

Abnormal cervical or vaginal mucopurulent discharge

Presence of white blood cells on saline microscopy of vaginal secretions

Elevated erythrocyte sedimentation rate or elevated C-reactive protein

Laboratory documentation of infection with *Neisseria gonorrhoeae*

or *Chlamydia trachomatis*

Definitive criteria (selected cases)

Histopathologic evidence of endometritis on endometrial biopsy

Tubo-ovarian abscess on sonography or other radiologic tests

Laparoscopic abnormalities consistent with PID

Adapted, with permission, from Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines 2006. *MMWR Recomm Rep* 2006;55(RR-11).

tiate PID from an ectopic pregnancy, ovarian cysts, or adnexal torsion. The clinical diagnosis of PID has a positive predictive value for salpingitis of 65–90% in comparison with laparoscopy. Pelvic ultrasonography also is helpful in detecting tubo-ovarian abscesses, which are found in almost 20% of teens with PID. Transvaginal ultrasound is more sensitive than abdominal ultrasound.

► Differential Diagnosis

Differential diagnosis includes other gynecologic illnesses (ectopic pregnancy, threatened or septic abortion, adnexal torsion, ruptured and hemorrhagic ovarian cysts, dysmenorrhea, endometriosis, or mittelschmerz); gastrointestinal illnesses (appendicitis, cholecystitis, hepatitis, gastroenteritis, or inflammatory bowel disease); and genitourinary illnesses (cystitis, pyelonephritis, or urinary calculi).

► Complications

Scarring of the fallopian tubes is one of the major sequelae of PID. After one episode of PID, 17% of patients become infertile, 17% develop chronic pelvic pain, and 10% will have an ectopic pregnancy. Infertility rates increase with each episode of PID; three episodes of PID result in a 73% infertility rate. Duration of symptoms appears to be the largest determinant of infertility. Fitz-Hugh-Curtis syndrome is inflammation of the liver capsule (perihepatitis) from either hematogenous or lymphatic spread of organisms from the fallopian tubes. This results in right upper quadrant pain and elevation of liver function tests.

► Treatment

The objective of treatment is both to achieve a clinical cure and to prevent long-term sequelae. Recent data have demonstrated no differences in short-term and long-term clinical and microbiologic response rates between parenteral and oral therapy. PID is frequently managed at the outpatient level, although some clinicians argue that all adolescents with PID should be hospitalized because of the rate of complications. Severe systemic symptoms and toxicity, signs of peritonitis, inability to take fluids, pregnancy, nonresponse or intolerance of oral antimicrobial therapy, and tubo-ovarian abscess support hospitalization. In addition, if the health care provider believes that the patient will not adhere to treatment, hospitalization is warranted. Surgical drainage may be required to ensure adequate treatment of tubo-ovarian abscesses.

The treatment regimens described in Table 42–1 are broad spectrum to cover the numerous microorganisms associated with PID. All treatment regimens should be effective against *N gonorrhoeae* and *C trachomatis* because negative endocervical screening tests do not rule out upper reproductive tract infection with these organisms. Outpatient treatment should be reserved for compliant patients who have classic signs of PID without systemic symptoms. Patients with PID who

receive outpatient treatment should be reexamined within 24–48 hours, with phone contact in the interim, to detect persistent disease or treatment failure. Patients should have substantial improvement within 48–72 hours. An adolescent should be reexamined 7–10 days after the completion of therapy to ensure the resolution of symptoms.

URETHRITIS

► General Considerations

The most common bacterial causes of urethritis in males are *N gonorrhoeae* and *C trachomatis*. Additionally, *T vaginalis*, HSV, *Ureaplasma urealyticum*, and *M genitalium* cause urethritis. Approximately 20% of nongonococcal, nonchlamydial urethritis can be attributed both to *M genitalium* and *U urealyticum*. Coliforms may cause urethritis in males practicing insertive anal intercourse. Mechanical manipulation or contact with irritants can also cause transient urethritis. It is important to recognize that urethritis in both males and females is frequently asymptomatic.

Females often present with symptoms of a urinary tract infection from which no enteric bacterial pathogens are isolated, and often have urethritis caused by the organisms just described.

► Clinical Findings

A. Symptoms and Signs

If symptomatic, males present most commonly with a clear or purulent discharge from the urethra, dysuria, or urethral pruritus. Hematuria and inguinal adenopathy can occur. Most infections caused by *C trachomatis* and *T vaginalis* are asymptomatic, while 70% of males with *M genitalium* and 23–90% with gonococcal urethritis are symptomatic.

B. Laboratory Findings

In a symptomatic male a positive leukocyte esterase test on first-void urine, or microscopic examination of first-void urine demonstrating more than 10 WBCs per high-power field, is suggestive of urethritis. Gram stain of urethral secretions demonstrating more than 5 WBCs per high-power field

is also suggestive. Gonococcal urethritis is established by documenting the presence of WBCs containing intracellular gram-negative diplococci. Urethral swab or first-void urine for culture or NAAT should be sent to the laboratory to detect *N gonorrhoeae* and *C trachomatis*. Evaluation for *T vaginalis* by a wet preparation of either urethral discharge or spun urine should be considered when the other test results are negative. Additionally, PCR testing is more sensitive for *T vaginalis* than culture or direct microscopy. Specific PCR testing of urine is available for *Mycoplasma* and *Ureaplasma*, though it is not often clinically utilized.

► Complications

Complications include recurrent or persistent urethritis, epididymitis, prostatitis, or Reiter syndrome.

► Treatment

See Table 42–1 for treatment recommendations. Patients with objective evidence of urethritis should receive empiric treatment for gonorrhea and *Chlamydia* infection, ideally directly observed in the office. If the infection is unresponsive to initial treatment, and the infection is NAAT-negative, trichomoniasis should be ruled out, and nongonococcal, nonchlamydial urethritis should be suspected and treated appropriately. Patients should be instructed to return for evaluation if symptoms persist or recur after completion of initial empiric therapy. Symptoms alone, without documentation of signs or laboratory evidence of urethral inflammation, are not a sufficient basis for retreatment (see Table 42–1). Sexual partners should either be evaluated or treated as well for gonorrhea and *Chlamydia* infection.

Falk L et al: Symptomatic urethritis is more prevalent in men infected with *Mycoplasma genitalium* than with *Chlamydia trachomatis*. *Sexually Transm Infect* 2004;80:289 [PMID: 15295128].
Simpson T, Oh MK: Urethritis and cervicitis in adolescents. *Adolesc Med Clin* 2004;15:253 [PMID: 15449844].

EPIDIDYMITIS

► General Considerations

Epididymitis is most often caused by *C trachomatis* or *N gonorrhoeae*. Epididymitis caused by *Escherichia coli* occurs among males who are the insertive partners during anal intercourse and in males who have urinary tract abnormalities.

► Clinical Findings

A. Symptoms and Signs

Epididymitis is associated with unilateral testicular pain and tenderness. Palpable, tender swelling of the epididymis is usually present. The spermatic cord may also be tender and swollen. Often these symptoms are accompanied by asymptomatic urethritis.

B. Laboratory and Diagnostic Studies

Diagnosis is generally made clinically. Color Doppler ultrasound can help make the diagnosis. Although often not available, radionuclide scanning of the scrotum is the most accurate method of diagnosis. Laboratory evaluation is identical to evaluation for suspected urethritis.

► Differential Diagnosis

Acute epididymitis associated with sexual activity must be distinguished from orchitis due to infarct, testicular torsion, viral infection, testicular cancer, tuberculosis, or fungal infection.

► Complications

Infertility is rare, and chronic local pain is uncommon.

► Treatment

Empiric therapy is indicated before culture results are available. As an adjunct to therapy, bed rest, scrotal elevation, and analgesics are recommended until fever and local inflammation subside. Lack of improvement of swelling and tenderness within 3 days requires reevaluation of both the diagnosis and therapy (see Table 42–1). Sex partners should be evaluated and treated as well for gonorrhea and *Chlamydia* infections.

PROCTITIS, PROCTOCOLITIS, & ENTERITIS

► General Considerations

Proctitis occurs predominantly among persons who participate in anal intercourse. Enteritis occurs among those whose sexual practices include oral-fecal contact. Proctocolitis can be acquired by either route depending on the pathogen. Common sexually transmitted pathogens causing proctitis or proctocolitis include *C trachomatis* (including lymphogranuloma venereum serovars), *Treponema pallidum*, HSV, *N gonorrhoeae*, *Giardia lamblia*, and enteric organisms.

► Clinical Findings

A. Symptoms and Signs

Proctitis, defined as inflammation limited to the distal 10–12 cm of the rectum, is associated with anorectal pain, tenesmus, and rectal discharge. Acute proctitis among persons who have recently practiced receptive anal intercourse is most often sexually transmitted. The symptoms of proctocolitis combine those of proctitis, plus diarrhea or abdominal cramps (or both), because of inflamed colonic mucosa more than 12 cm from the anus. Enteritis usually results in diarrhea and abdominal cramping without signs of proctitis or proctocolitis.

B. Laboratory and Diagnostic Studies

Evaluation may include anoscopy or sigmoidoscopy, stool examination, culture for appropriate organisms, and serology for syphilis.

► Treatment

Management will be determined by the etiologic agent. (See Table 42–1 and Chapter 40). Reinfection may be difficult to distinguish from treatment failure.

Hamlyn E, Taylor C: Sexually transmitted proctitis. *Postgrad Med J* 2006;82:733 [PMID:17099092].

VAGINAL DISCHARGE

Adolescent girls may have a normal physiologic leukorrhea, secondary to turnover of vaginal epithelium. Infectious causes of discharge include *T vaginalis*, *C trachomatis*, *N gonorrhoeae*, and bacterial vaginosis pathogens. Candidiasis is a yeast infection that produces vaginal discharge, but is not usually sexually transmitted. Vaginitis is characterized by vaginal discharge, vulvar itching, and irritation, and by possible vaginal odor. Discharge may be white, gray, or yellow. Physiologic leukorrhea is usually white, homogeneous, and not associated with itching, irritation, or foul odor. Mechanical, chemical, allergic, or other noninfectious irritants of the vagina may cause vaginal discharge.

1. Bacterial Vaginosis

► General Considerations

Bacterial vaginosis is a polymicrobial infection of the vagina caused by an imbalance of the normal bacterial vaginal flora. The altered flora has a paucity of hydrogen peroxide–producing lactobacilli and increased concentrations of *Mycoplasma hominis* and anaerobes, such as *Gardnerella vaginalis* and *Mobiluncus*. It is unclear whether bacterial vaginosis is sexually transmitted, but it is associated with having multiple sex partners.

► Clinical Findings

A. Symptoms and Signs

The most common symptom is a heavy, malodorous, homogeneous gray-white vaginal discharge. Patients may report vaginal itching or dysuria. The fishy odor may be more noticeable after intercourse or during menses, when the high pH of blood or semen volatilizes the amines.

B. Laboratory Findings

Bacterial vaginosis is most often diagnosed by the use of clinical criteria, which include (1) presence of gray-white discharge, (2) fishy (amine) odor before or after the addition of 10% KOH (whiff test), (3) pH of vaginal fluid greater than 4.5 determined with narrow-range pH paper, and (4) presence of “clue cells” on microscopic examination. Clue cells are squamous epithelial cells that have multiple bacteria adhering to them, making their borders irregular and giving them a speckled appearance. Diagnosis requires three out of four criteria, although many female patients who fulfill these criteria have no discharge or other symptoms.

► Complications

Bacterial vaginosis during pregnancy is associated with adverse outcomes such as premature labor, preterm delivery, intra-amniotic infection, and postpartum endometritis. In the nonpregnant individual, it may be associated with PID and urinary tract infections.

► Treatment

All female patients who have symptomatic disease should receive treatment to relieve vaginal symptoms and signs of infection (see Table 42–1). Pregnant patients should receive treatment to prevent adverse outcomes of pregnancy. Treatment for patients who do not complain of vaginal discharge or itching, but who demonstrate bacterial vaginosis on routine pelvic examination, is unclear. Because some studies associate bacterial vaginosis and PID, the recommendation is to have a low threshold for treating asymptomatic bacterial vaginosis. Follow-up visits are unnecessary if symptoms resolve. Recurrence of bacterial vaginosis is not unusual. Follow-up examination 1 month after treatment for high-risk pregnant patients is recommended.

Males do not develop infection equivalent to bacterial vaginosis. Treatment of male partners has no effect on the course of infection in females.

Brotnan RM et al: Findings associated with recurrence of bacterial vaginosis among adolescents attending sexually transmitted diseases clinics. *J Pediatr Adolesc Gynecol* 2007;20:225 [PMID: 17673134].

O'Brien RF: Bacterial vaginosis: many questions—any answers? *Curr Opin Pediatr* 2005;17:473 [PMID: 16012258].

Walker CK, Wiesenfeld HC: Antibiotic therapy for acute pelvic inflammatory disease: The 2006 Centers for Disease Control and Prevention sexually transmitted diseases treatment guidelines. *Clin Infect Dis* 2007;44: S111 [PMID: 17342664].

2. Trichomoniasis

► General Considerations

Trichomoniasis is caused by *T vaginalis*, a flagellated protozoan that infects 5–7 million people annually in the United States.

► Clinical Findings

A. Symptoms and Signs

Fifty percent of females with trichomoniasis develop a symptomatic vaginitis with vaginal itching, a green-gray malodorous frothy discharge, and dysuria. Occasionally postcoital bleeding and dyspareunia may be present. The vulva may be erythematous and the cervix friable.

B. Laboratory Findings

Mixing the discharge with normal saline facilitates detection of the flagellated protozoan on microscopic examination

(wet preparation). The infection may be detected by the pathologist when reviewing the Pap smear. Culture and PCR testing are available when the diagnosis is unclear. PCR tests are sensitive, but expensive and not readily available. Two FDA-approved, point-of-care antigen-based detection assays for *T vaginalis* are now available. Both are performed on vaginal secretions and have a sensitivity greater than 83.3% and a specificity greater than 97%. Trichomonal urethritis frequently causes a positive urine leukocyte esterase test and WBCs on urethral smear.

► Complications

Male partners of females diagnosed with trichomoniasis have a 22% chance of having trichomoniasis. Half of males with trichomoniasis will have urethritis. *Trichomonas* infection in females has been associated with adverse pregnancy outcomes.

► Treatment

See Table 42–1 for treatment recommendations.

Schwebke JR, Burgess D: Trichomoniasis. *Clin Microbiol Rev* 2004;17:794 [PMID: 15489349].

3. Vulvovaginal Candidiasis

► General Considerations

Vulvovaginal candidiasis is caused by *Candida albicans* in 85–90% of cases. Most females will have at least one episode of vulvovaginal candidiasis in their lifetime, and almost half will have two or more episodes. The highest incidence is between ages 16 and 30 years. Predisposing factors include recent use of antibiotics, diabetes, pregnancy, and HIV. Risk factors include vaginal intercourse, use of oral contraceptives, and use of spermicide. This is rarely a sexually transmitted infection. Recurrences generally reflect reactivation of colonization.

► Clinical Findings

A. Symptoms and Signs

Typical symptoms include pruritus and a white, cottage cheese–like vaginal discharge without odor. The itching is more common midcycle and shortly after menses. Other symptoms include vaginal soreness, vulvar burning, vulvar edema and redness, dyspareunia, and dysuria (especially after intercourse).

B. Laboratory Findings

The diagnosis is usually made by visualizing yeast or pseudohyphae with 10% KOH (90% sensitive) or Gram stain (77% sensitive) in the vaginal discharge. Fungal culture can be used if symptoms and microscopy are not definitive or if disease is unresponsive or recurrent. However, culture is not very specific as colonization is common in asymptomatic females. Vaginal pH is normal with yeast infections.

► Complications

The only complication of vulvovaginal candidiasis is recurrent infections (ie, four or more episodes annually). Most females with recurrent infection have no apparent predisposing or underlying conditions.

► Treatment

Short-course topical formulations effectively treat uncomplicated vaginal yeast infections (see Table 42–1). The topically applied azole drugs are more effective than nystatin. Treatment with azoles results in relief of symptoms and negative cultures in 80–90% of patients who complete therapy. Oral fluconazole as a one-time dose is an effective oral medication. Patients should be instructed to return for follow-up visits only if symptoms persist or recur. Six-month prophylaxis regimens have been effective in many female patients with persistent or recurrent yeast infection. Recurrent disease is usually due to *C albicans* that remains susceptible to azoles, and should be treated for 14 days with oral azoles. Some non-*albicans Candida* will respond to itraconazole or boric acid gelatin capsules (600 mg daily for 14 days) intravaginally. Treatment of sex partners is not recommended, but may be considered for females who have recurrent infection.

GENITAL ULCERATIONS

In the United States, young, sexually active patients who have genital ulcers have genital herpes, syphilis, or chancroid. The relative frequency of each disease differs by geographic area and patient population; however, in most areas, genital herpes is the most prevalent of these diseases. More than one of these diseases could be present in a patient with genital ulcers. All ulcerative diseases are associated with an increased risk for HIV infection. The acute retroviral syndrome of HIV infection may be accompanied by oral and genital ulcers.

Ulcers are vaginal, vulvar, or cervical in females, and on any part of the penis in males. Oral lesions may occur concomitantly with genital ulcerations in HSV infection and syphilis. Each etiologic agent has specific characteristics that are described in the following sections. Lesion pain, inguinal lymphadenopathy, and urethritis may be found in association with the ulcers.

1. Herpes Simplex Virus Infection

► General Considerations

HSV is the most common cause of visible genital ulcers. At least 50 million people are infected with genital herpes in the United States. Approximately 0.5–1.5 million new cases occur each year. Approximately 30% of primary herpetic genital lesions are caused by HSV type 1 (HSV-1), and the rest by type 2 (HSV-2). As with oral HSV infections, many primary genital infections are asymptomatic (60–80%) or not recognized as herpetic in origin.

► Clinical Findings

A. Symptoms and Signs

Symptomatic initial HSV infection causes vesicles of the vulva, vagina, cervix, penis, rectum, or urethra, which are quickly followed by shallow, painful ulcerations. Atypical presentation of HSV infection includes vulvar erythema and fissures. Urethritis may occur. Initial infection can be severe, lasting up to 3 weeks, and be associated with fever and malaise, as well as localized tender adenopathy. The pain and dysuria can be extremely uncomfortable, requiring sitz baths, topical anesthetics, and occasionally catheterization for urinary retention.

Symptoms tend to be more severe in females. Recurrence in the genital area with HSV-2 is likely (65–90%). Recurrent genital herpes is of shorter duration (5–7 days), with fewer lesions and usually no systemic symptoms. Prodromal pain in the genital, buttock, or pelvic region is common prior to recurrences. First-episode genital herpes infection caused by HSV-1 is usually the consequence of oral-genital sex. Primary HSV-1 infection is as severe as HSV-2 infection, and treatment is the same. Recurrence of HSV-1 happens in less than 50% of patients, and the frequency of recurrences is much less than in those patients with prior HSV-2 infection.

B. Laboratory Findings

Diagnosis of genital HSV infection is often made presumptively, but in one large series this diagnosis was incorrect for 20% of cases. Culture or antigen testing of the vesicles can confirm the diagnosis, but sensitivity decreases with advancing age of the ulcer. Several serologic tests with sensitivities between 80% and 90% are available and can distinguish between HSV-1 and HSV-2, which is important for prognosis. Recurrent genital ulceration is suggestive of HSV infection.

► Differential Diagnosis

Any genital ulcer should be cultured for HSV and differentiated from syphilis and chancroid ulcers. The character of the ulcers and inguinal nodes differs in these diseases. (See next sections on Syphilis and Chancroid.)

► Complications

Complications, usually with the first episode of genital HSV infection, include viral meningitis, urinary retention, transmission to newborns at birth, and pharyngitis. Infection with genital HSV, whether active or not, greatly increases the likelihood of transmitting or acquiring HIV infection within couples discordant for HIV.

► Prevention

All patients with active lesions should be counseled to abstain from sexual contact. Almost all patients have very frequent periodic asymptomatic shedding of HSV, and most cases of

genital HSV infection re transmitted by persons who are unaware that they have the infection or are asymptomatic when transmission occurs. Reactivation can occur in individuals who never had symptomatic disease. Individuals with prior HSV infection should be encouraged to always use condoms to protect susceptible partners. Antiviral prophylaxis of infected individuals reduces shedding and significantly reduces the chance of transmission to their sexual partners.

► Treatment

Antiviral drugs administered within the first 5 days of primary infection decrease the duration and severity of HSV infection (see Table 42–1). The effect of antivirals on the severity or duration of recurrent disease is limited. For best results, therapy should be started with the prodrome or during the first day of the attack. Patients should have a prescription at home to initiate treatment. If recurrences are frequent and cause significant physical or emotional discomfort, patients may elect to take antiviral prophylaxis on a daily basis to reduce the frequency (70–80% decrease) and duration of recurrences. Treatment of first or subsequent attacks will not prevent future attacks, but recurrence frequency decreases in many individuals over time.

Patel R et al: Managing patients with genital herpes and their sexual partners. *Infect Dis Clin N Am* 2005;19:427 [PMID:15963881].

2. Syphilis

► General Considerations

Syphilis is an acute and chronic STI caused by infection with *T pallidum*. The national rate of syphilis has increased annually after reaching an all time low in 2000. Increases have been observed in both genders, but predominantly in males who have sex with men. In 2005, the rate of syphilis was highest among women in the 20- to 24-year-old age group (3.0 cases per 100,000 population) and among men in the 35- to 39-year-old age group (13.2 cases per 100,000 population).

► Clinical Findings

A. Symptoms and Signs

Skin and mucous membrane lesions characterize the acute phase of primary and secondary syphilis. Lesions of the bone, viscera, aorta, and central nervous system predominate in the chronic phase (tertiary syphilis) (see Chapter 40). Prevention of syphilis is also important because syphilitic mucosal lesions facilitate transmission of HIV.

Primary syphilis usually presents as a solitary chancre—a painless ulcer with an indurated base and associated nontender, firm adenopathy. The chancre appears 10–90 days after exposure and resolves spontaneously 4–8 weeks later. Because it is painless, it may go undetected, especially if the

lesion is within the vagina. Chancres may occur on the genitalia, lips, or anus. Secondary syphilis occurs 4–10 weeks after the chancre appears, with generalized malaise, adenopathy, and a nonpruritic maculopapular rash that often includes the palms and soles. Secondary syphilis resolves in 1–3 months, but can recur. Verrucous lesions known as condylomata lata may develop on the genitalia. These must be distinguished from genital warts.

B. Laboratory Findings

If the patient has a suspect primary lesion, is at high risk, is a contact, or may have secondary syphilis, a nontreponemal serum screen—either RPR or VDRL—should be performed. If the nontreponemal test is positive, then a specific treponemal test, a fluorescent treponemal antibody-absorbed (FTA-ABS) or microhemagglutination–*Treponema pallidum* (MHA-TP) test, is done to confirm the diagnosis. An additional diagnostic tool is darkfield microscopy, which can be used to detect spirochetes in scrapings of the chancre base. Darkfield examinations and direct fluorescent antibody tests of lesion exudate or tissue are the definitive methods for diagnosing early syphilis.

If a patient is engaging in high-risk sexual behavior or is living in an area in which syphilis is endemic, RPRs should be drawn yearly to screen for asymptomatic infection. Syphilis is reportable to state health departments, and all contacts need to be evaluated. Patients also need to be evaluated for other STIs, especially HIV, because HIV-infected patients have increased rates of failure with some treatment regimens.

► Complications

Untreated syphilis can lead to tertiary complications with serious multiorgan involvement, including aortitis and neurosyphilis. Transmission to the fetus can occur from an untreated pregnant individual (see Chapters 1 and 40).

► Treatment

See Table 42–1 for treatment recommendations. Patients should be reexamined clinically and serologically with nontreponemal tests at 6 and 12 months after treatment. If signs or symptoms persist or recur, or patients do not have a fourfold decrease in their nontreponemal test titer, they should be considered to have failed treatment or be reinfectured and need retreatment.

French P: Syphilis. *BMJ* 2007;334:143 [PMID:17235095].

Stoner BP: Current controversies in the management of adult syphilis. *Clin Infect Dis* 2007;44:S130 [PMID:17342666].

3. Chancroid

► General Considerations

Chancroid is caused by *Haemophilus ducreyi*. It is relatively rare, but is endemic in some urban areas, and has been

associated with HIV infection, drug use, and prostitution. Ten percent of patients with chancroid acquired in the United States are coinfectured with HSV or syphilis.

► Clinical Findings

A. Symptoms and Signs

The typical lesion begins as a papule that erodes after 24–48 hours into an ulcer. The ulcer has ragged, sharply demarcated edges and a purulent base, is painful (unlike syphilis), solitary, and somewhat deeper than HSV infection. Tender, fluctuant (unlike syphilis and HSV) inguinal adenopathy is present in one third of patients. A painful ulcer in combination with suppurative inguinal adenopathy is very often chancroid.

B. Laboratory Findings

Gram stain shows gram-positive cocci arranged in a boxcar formation. Culture, which has a sensitivity of less than 80%, can be performed on a special medium that is available in academic centers. Some clinical laboratories have developed their own PCR testing.

► Differential Diagnosis

Chancroid is distinguished from syphilis by the painful nature of the ulcer and the associated tender suppurative adenopathy. HSV vesicles often produce painful ulcers, but these are multiple, smaller, and shallower than chancroid ulcers. Adenopathy associated with initial HSV infection does not suppurate. A presumptive diagnosis of chancroid should be considered in a patient with typical painful genital ulcers and regional adenopathy, if the test results for syphilis and HSV are negative.

► Treatment

Symptoms improve within 3 days after therapy (see Table 42–1). Most ulcers resolve in 7 days, although large ulcers may take 2 weeks to heal. All sexual contacts need to be examined and given treatment, even if asymptomatic.

Lewis DA: Chancroid: Clinical manifestations, diagnosis, and management. *Sex Transm Infect* 2003;79:68 [PMID:12576620].

4. Other Ulcerations

Lymphogranuloma venereum (LGV), caused by *Chlamydia trachomatis* serovars L1, L2, or L3, is rare in the United States, with the exception of communities of males who have sex with men where prevalence of LGV is increasing. Patients with LGV present with a painless vesicle or ulcer that heals spontaneously, followed by development of tender adenopathy, either unilateral or bilateral. A classic finding is the groove sign—an inguinal crease created by concomitant involvement of inguinal and femoral nodes. These nodes

become matted and fluctuant and may rupture. LGV can cause proctocolitis with rectal ulceration, purulent anal discharge, fever, tenesmus, and lower abdominal pain, primarily in communities of males who have sex with men. Diagnosis can be made by culturing a node aspirate for *Chlamydia* or by serology. Differential diagnosis during the adenopathy phase includes bacterial adenitis, lymphoma, and cat-scratch disease. Differential diagnosis during the ulcerative phase encompasses all causes of genital ulcers. See Table 42–1 for treatment recommendations.

Granuloma inguinale, or donovanosis, is caused by *Klebsiella granulomatis*, a gram-negative bacillus that is rare in the United States. An indurated subcutaneous nodule erodes to form a painless, friable ulcer with granulation tissue. Diagnosis is based on clinical suspicion and supported by a Wright or Giemsa stain of the granulation tissue that reveals intracytoplasmic rods (Donovan bodies) in mononuclear cells. See Table 42–1 for treatment recommendations.

GENITAL WARTS & HUMAN PAPILLOMAVIRUS

▶ General Considerations

Condylomata acuminata, or genital warts, are caused by HPV, which can also cause cervical dysplasia and cervical cancer. An estimated 20 million people are infected annually with HPV, including approximately more than 9 million sexually active adolescents and young adults 15–24 years of age. The majority (74%) of new HPV infections occurs among those 15–24 years of age; in females younger than age 25 years, the prevalence ranges between 28% and 46%. Estimates suggest that 32–50% of adolescent females having sexual intercourse in the United States have HPV infections, though only 1% may have visible lesions. HPV is transmitted sexually: 30–60% of males whose partners have HPV have evidence of condylomata on examination. An estimated 1 million new cases of genital warts occur every year in the United States.

Up to 100 serotypes of HPV have been identified. HPV types 6 and 11 cause approximately 90% of genital warts, whereas HPV types 16 and 18 cause more than 70% of cervical dysplasia. The infection is more common in persons with multiple partners and in those who initiate sexual intercourse at an early age.

The American Cancer Society indicates that there is little risk of missing an important cervical lesion until 3–5 years after initiation of intercourse. Pap smears should be obtained after this time or by age 21. Thereafter, annual cervical screening should be performed using conventional Pap smears.

▶ Clinical Findings

A. Symptoms and Signs

For males, verrucous lesions are found on the shaft or corona of the penis. Lesions also may develop in the urethra or rectum. Lesions do not produce discomfort. They may be single or found in clusters. Females develop verrucous lesions on any genital mucosal surface, either internally or externally.

B. Laboratory Findings

External, visible lesions have unique characteristics that make the diagnosis straightforward. Condylomata acuminata can be distinguished from condylomata lata (syphilis), skin tags, and molluscum contagiosum by application of 5% acetic acid solution. Acetowhitening is used to indicate the extent of cervical infection.

Pap smears detect cervical abnormalities. HPV infection is the most frequent cause of an abnormal smear. Pap smear findings are graded by the atypical nature of the cervical cells. These changes range from atypical squamous cells of undetermined significance (ASCUS) to low-grade squamous intraepithelial lesions (LSIL) and high-grade squamous intraepithelial lesions (HSIL). LSIL encompasses cellular changes associated with HPV and mild dysplasia. HSIL includes moderate dysplasia, severe dysplasia, and carcinoma in situ.

Follow-up for ASCUS is controversial, as only 25% progress to dysplasia, and the remainder are unchanged or regress. If ASCUS is present, options for follow-up management include (1) immediate colposcopy, (2) repeat Pap smears at 6-month intervals for three intervals, or (3) an HPV DNA test for oncogenic HPV types. If high-risk HPV DNA is positive or if HSIL is found, colposcopy should be performed. If LSIL is detected, colposcopy is not needed, but a repeat Pap smear should be done in 1 year and if LSIL or HSIL are subsequently detected, the patient should be referred for colposcopy for direct visualization or biopsy of the cervix (or both). If a Pap smear shows signs of inflammation only, and concomitant infection such as vaginitis or cervicitis is present, the smear should be repeated after the infection has cleared.

▶ Differential Diagnosis

The differential diagnosis includes normal anatomic structures (pearly penile papules, vestibular papillae, and sebaceous glands), molluscum contagiosum, seborrheic keratosis, and syphilis.

▶ Complications

Because genital warts can proliferate and become friable during pregnancy, many experts advocate their removal during pregnancy. HPV types 6 and 11 can cause laryngeal papillomatosis in infants and children. Complications of appropriate treatment include scarring with changes in skin pigmentation or chronic pain at the treatment site. Cervical cancer is the most common and important sequel of HPV.

▶ Prevention

The use of condoms may reduce, but does not eliminate, the risk for transmission to uninfected partners. The quadrivalent HPV vaccine is 96–100% effective in preventing HPV 6 and 11–related genital warts and HPV 16 and 18–related cervical dysplasia. It is recommended for girls and women aged 9–26 years. (See Chapter 9.)

▶ Treatment

All penile and external vaginal or vulvar lesions can be treated topically. Treatment may need to occur weekly for 4–6 weeks. An experienced practitioner should treat internal and cervical lesions (see Table 42–1). Treatment may clear the visible lesions but may not reduce the presence of virus, nor is it clear whether transmission of HPV is reduced.

Warts may resolve or remain unchanged if left untreated or they may increase in size or number. Treatment can induce wart-free periods in most patients. Most recurrences occur within the 3 months following completion of a treatment regimen. Appropriate follow-up of abnormal Pap smears is essential to detect any progression to malignancy.

OTHER VIRAL INFECTIONS

1. Hepatitis (See also Chapter 21)

▶ General Considerations

Hepatitis B and hepatitis C are often STIs. Hepatitis B is at least 10 times more common than HIV in the adolescent population. Since 1998, sexual transmission has accounted for approximately 50% of the estimated 181,000 new hepatitis B infections that occur annually in the United States. Heterosexuals who have unprotected sex with multiple partners and males who have sex with men are the groups at highest risk for sexual transmission.

Hepatitis C generally is transmitted through blood products and shared intravenous needles, although about 10% of hepatitis C infections have been linked to sexual transmis-

sion. Hepatitis C needs to be considered in teenagers who are symptomatic and engage in high-risk sexual behavior or intravenous drug use. Outbreaks of sexually transmitted hepatitis A infection have occurred among males who have sex with men, although the efficiency of sexual transmission is low.

2. Human Immunodeficiency Virus (See also Chapter 39)

▶ General Considerations

Half of the 40,000 new HIV-infected cases occurring yearly in the United States are in youth and young adults aged 13–24 years. Because of the long latency period between infection with HIV and progression to AIDS, it is felt that many HIV-positive young adults contracted HIV during adolescence. The number of females who become HIV-positive has increased dramatically, representing almost half of teenagers with HIV infection.

Risk factors for contracting HIV include a prior STI, infrequent condom use, practicing insertive or receptive anal sex (both males and females), prior genital HSV infection, practicing survival sex (ie, trading sex for money or drugs), intravenous drug or crack cocaine use, crystal methamphetamine use, homelessness, and being the victim of sexual abuse (males). HIV infection should be considered in all sexually active youth, whether they have sex with males, females or both.

▶ Clinical Findings

A. Symptoms and Signs

Adolescents may be asymptomatic with recent HIV infection or may present with the acute retroviral syndrome, which is evident 2–6 weeks after exposure. Fever, malaise, lymphadenopathy, rash, upper respiratory symptoms, oral and genital ulcerations, aseptic meningitis, and thrush may occur. If HIV infection is suspected, diagnosis is made in the acute period (before seroconversion) by HIV RNA PCR testing or HIV p24 antigen detection.

B. Laboratory Findings

All persons with an STI should be screened for HIV by serology. Adolescents may also present to the office requesting an HIV test. In either case, a careful history of sexual behavior should be obtained to assess risk and intervene with risk-reduction counseling. It is also necessary to determine how teens may respond to being told they are HIV-positive and what support systems they have in place. If an adolescent is homeless; does not have emotional support from family, friends, or a counselor; or threatens suicide or homicide in response to the idea of being HIV-positive, then testing should be deferred until the health care provider is confident that the youth will be safe if the test result is positive.

► Treatment

Many experts recommend aggressive antiretroviral treatment of patients diagnosed with acute retroviral syndrome.

National Institutes of Health–sponsored AIDS information site: <http://aidsinfo.nih.gov/>

3. HIV Post-Sexual Exposure Prophylaxis

The risk of acquiring HIV infection through sexual assault or abuse is low but present. The risk for HIV transmission per episode of receptive penile-anal sexual exposure is estimated at 0.5–3%; the risk per episode of receptive vaginal exposure is estimated at less than 0.1–0.2%. HIV transmission also occurs from receptive oral exposure, but the risk is unknown. Specific circumstances of an assault might increase risk for HIV transmission (eg, trauma, including bleeding) with vaginal, anal, or oral penetration; site of exposure to ejaculate; HIV viral load in ejaculate; duration of HIV infection in the assailant; and presence of an STI, prior genital HSV infection, or genital lesions in the assailant or survivor.

Health care providers who consider offering postexposure therapy should take into account the likelihood that exposure to HIV occurred, the potential benefits and risks of such therapy, and the interval between the exposure and initiation of therapy. It will be helpful to know the HIV status of the sexual contact. In general, postexposure therapy is not recommended when more than 72 hours has passed since exposure. If the patient decides to take postexposure therapy, clinical management should be implemented according to published Centers for Disease Control and Prevention guidelines.

Centers for Disease Control and Prevention: Antiretroviral postexposure prophylaxis after sexual, injection-drug use, or other nonoccupational exposure to HIV in the United States: Recommendations from the U.S. Department of Health and Human Services. *MMWR Recomm Rep* 2005;54(RR-2) [PMID: 15660015].

ECTOPARASITIC INFECTIONS

1. Pubic Lice

Phthirus pubis, the pubic louse, lives in pubic hair. The louse or the nits can be transmitted by close contact from person

to person. Patients complain of itching and they may report having seen the insect. Examination of the pubic hair may reveal the louse crawling around or attached to the hair. Closer inspection may reveal the nit or sac of eggs, which is a gelatinous material (1–2 mm) stuck to the hair shaft. See Table 42–1 for treatment recommendations.

2. Scabies

Sarcoptes scabiei, the causative organism in scabies, is smaller than the louse. It can be identified by the classic burrow, which is created by the organism laying eggs and traveling just below the skin surface. Scabies can be sexually transmitted by close skin-to-skin contact and can be found in the pubic region, groin, lower abdomen, or upper thighs. The rash is intensely pruritic, especially at night, erythematous, and scaly.

See Table 42–1 for treatment options. Ivermectin represents a new oral therapeutic option for scabies and may hold particular promise in the treatment of severe infestations or in epidemic situations. When treating with lotion or shampoo, the entire area needs to be covered for the time specified by the manufacturer. One treatment usually clears the infestation, although a second treatment may be necessary. Bed sheets and clothes must be washed in hot water. Both sexual and close personal or household contacts within the preceding month should be examined and treated.

Leone PA: Scabies and pediculosis pubis: An update of treatment regimens and general review. *Clin Infect Dis* 2007;44:S153 [PMID: 17342668].

EVALUATION OF SEXUALLY TRANSMITTED INFECTIONS IN SEXUAL ABUSE & ASSAULT

Sexual abuse and sexual violence are common. Half of rape victims are younger than age 18 years. Rape is both a medical and a psychological emergency. Evaluation and treatment after sexual abuse or assault depends on the patient's age, his or her ability to communicate what occurred, and the timing of the abuse.

Teenagers usually can describe the kind of abuse (eg, oral, anal, vaginal; receptive or insertive), and evaluation needs to be directed accordingly. If the abuse has occurred in the preceding 72 hours, most states require for legal purposes that a rape kit be used. All practitioners should have access to a rape kit, which guides the practitioner through a stepwise collection of evidence and cultures. A thorough physical examination is indicated to evaluate for other signs of trauma.

Beyond 72 hours, evaluation is tailored to the history provided. The involved orifices should be cultured for *N gonorrhoeae* and *C trachomatis* (NAAT is not admissible in court), and vaginal secretions evaluated for *Trichomonas*. RPR, hepatitis B, and HIV serology should be drawn at baseline and repeated in 2–3 months. Pregnancy testing should be done as indicated.

Trichomoniasis, bacterial vaginosis, chlamydia, and gonorrhea are the most frequently diagnosed infections among women and girls who have been sexually assaulted. Because the prevalence of these STIs is substantial among sexually experienced females, their presence after an assault does not necessarily signify acquisition during the assault.

Prophylactic therapy using ceftriaxone (125 mg IM in a single dose), metronidazole (2 g orally in a single dose), and either azithromycin (1 g orally in a single dose) or doxycycline (100 mg orally twice a day for 7 days) should be offered when patients present for evaluation. Hepatitis B vaccination should be administered to patients if they have not been previously vaccinated. No effective prophylaxis is available for hepatitis C. Evaluating the perpetrator for STI, if possible, can help determine risk exposure and guide prophylaxis. HIV prophylaxis should be considered in certain circumstances (discussed earlier). Emergency contraception should be given if the abuse occurred within 72 hours. Psychological assessment at the time of presentation, as well as over the next several months, is a top priority. Any suspected abuse must be reported to the local authorities.

All younger children should be referred to child abuse multidisciplinary teams, which can help with the psychologi-

cal aspects of the abuse and are well versed in helping children communicate what may have occurred. Colposcopic examination is critical in determining the extent of the damage and provides documentation for the legal system.

Although it is often difficult for persons to comply with follow-up examinations weeks after an assault, such examinations are essential to detect new infections, complete immunization with hepatitis B vaccination if needed, and continue psychological support.

Fluid, Electrolyte, & Acid-Base Disorders & Therapy

Douglas M. Ford, MD

43

REGULATION OF BODY FLUIDS, ELECTROLYTES, & TONICITY

Total body water (TBW) constitutes 50–75% of the total body mass, depending on age, sex, and fat content. After an initial postnatal diuresis, the TBW slowly decreases to the adult range near puberty (Figure 43–1). TBW is divided into the intracellular and extracellular spaces. Intracellular fluid (ICF) accounts for two thirds of the TBW and extracellular fluid (ECF), for one third. The ECF is further compartmentalized into plasma (intravascular) volume and interstitial fluid (ISF).

The principal constituents of plasma are sodium, chloride, bicarbonate, and protein (primarily albumin). The ISF is similar to plasma but lacks significant amounts of protein (Figure 43–2). Conversely, the ICF is rich in potassium, magnesium, phosphates, sulfates, and protein.

An understanding of osmotic shifts between the ECF and ICF is fundamental to understanding disorders of fluid balance. Iso-osmolality is generally maintained between fluid compartments. Because the cell membrane is water-permeable, abnormal fluid shifts occur if the concentration of solutes that cannot permeate the cell membrane in the ECF does not equal the concentration of such solutes in the ICF. Thus NaCl, mannitol, and glucose (in the setting of hyperglycemia) remain restricted to the ECF space and contribute effective osmoles by obligating water to remain in the ECF compartment. In contrast, a freely permeable solute such as urea does not contribute effective osmoles because it is not restricted to the ECF and readily crosses cell membranes. Tonicity, or effective osmolality, differs from measured osmolality in that it accounts only for osmotically active impermeable solutes rather than all osmotically active solutes, including those that are permeable to cell membranes. Osmolality may be estimated by the following formula:

$$\text{mOsm/kg} = 2\left(\text{Na}^+, \text{mEq/L}\right) + \frac{\text{Glucose, mg/dL}}{18} + \frac{\text{BUN, mg/dL}}{2.8}$$

Although osmolality and osmolarity differ, the former being an expression of osmotic activity per weight (kg) and the latter per volume (L) of solution, for clinical purposes they are similar and occasionally used interchangeably. Oncotic pressure represents the osmotic activity of macromolecular constituents such as albumin in the plasma and body fluids.

The principal mechanisms that regulate ECF volume and tonicity are antidiuretic hormone (ADH), thirst, aldosterone, and atrial natriuretic factor (ANF).

Antidiuretic Hormone

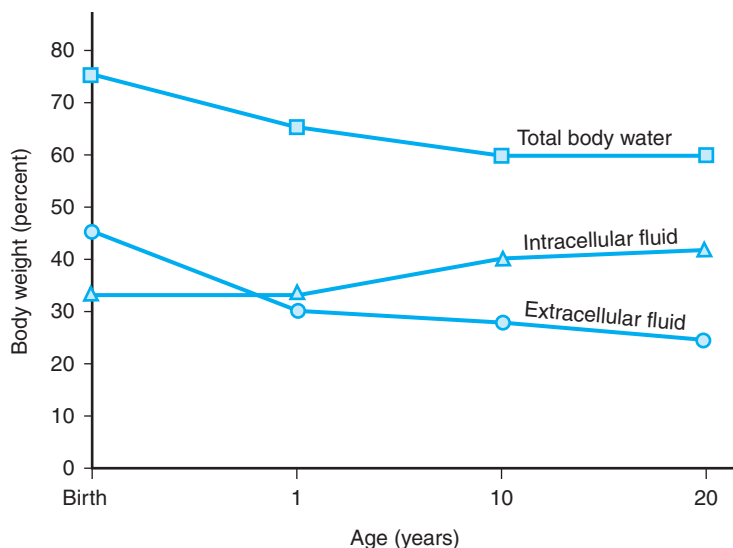

In the kidney, ADH increases water reabsorption in the cortical and medullary collecting ducts, leading to formation of concentrated urine. In the absence of ADH, dilute urine is produced. Under normal conditions, ADH secretion is regulated by the tonicity of body fluids rather than the fluid volume and becomes detectable at a plasma osmolality of 280 mOsm/kg or greater. However, tonicity may be sacrificed to preserve ECF volume, as in the case of hyponatremic dehydration, wherein ADH secretion and renal water retention are maximal.

Thirst

Water intake is commonly determined by cultural factors rather than by thirst. Thirst is not physiologically stimulated until plasma osmolality reaches 290 mOsm/kg, a level at which ADH levels are sufficient to induce maximal antidiuresis. Thirst provides control over a wide range of fluid volumes and can even be a response to an absence of or lack of responsiveness to ADH, with attendant production of copious and dilute urine, as in diabetes insipidus. One who cannot perceive thirst develops profound problems with fluid balance.

Aldosterone

Aldosterone—released from the adrenal cortex in response to decreased effective circulating volume and stimulation of the renin-angiotensin-aldosterone axis or in response to

▲ **Figure 43-1.** Body water compartments related to age. (Modified, with permission, from Friis-Hansen B: Body water compartments in children: Changes during growth and related changes in body composition. *Pediatrics* 1961;28:169.)

increasing plasma K^+ —enhances renal tubular reabsorption of Na^+ in exchange for K^+ and to a lesser degree, H^+ . At a constant osmolality, retention of Na^+ leads to expansion of ECF volume and suppression of aldosterone release.

Atrial Natriuretic Factor

ANF, a polypeptide hormone secreted principally by the cardiac atria in response to atrial dilation, plays an important role in regulation of blood volume and blood pressure. ANF inhibits renin secretion and aldosterone synthesis and causes an increase in glomerular filtration rate and renal sodium excretion. ANF also guards against excessive plasma volume expansion in the face of increased ECF volume by shifting fluid from the vascular to the interstitial compartment. ANF inhibits angiotensin II- and norepinephrine-induced vasoconstriction and acts in the brain to decrease the desire for salt and inhibit the release of ADH. Thus the net effect of ANF is a decrease in blood volume and blood pressure associated with natriuresis and diuresis.

ACID-BASE BALANCE

The pH of arterial blood is maintained between 7.38 and 7.42 to ensure that pH-sensitive enzyme systems function normally. Acid-base balance is maintained by interaction of the lungs, kidneys, and systemic buffering systems. Over 50% of the blood's buffering capacity is provided by the carbonic acid–bicarbonate system, roughly 30% by hemoglobin, and the remainder by phosphates and ammonium. The carbonic acid–bicarbonate system, depicted chemically as:

interacts with the lungs, kidneys, and nonbicarbonate systems to stabilize systemic pH. The concentration of dissolved CO_2 in blood is established by the respiratory system and that of HCO_3^- by the kidneys. Disturbances in acid-base balance are initially stabilized by chemical buffering, compensated for by pulmonary or renal regulation of CO_2 or HCO_3^- , and ultimately corrected when the primary cause of the acid-base disturbance is eliminated.

Renal regulation of acid-base balance is accomplished by the reabsorption of filtered HCO_3^- and the excretion of H^+ or HCO_3^- to match the net input of acid or base. When urine is alkalinized, HCO_3^- enters the kidney and is ultimately lost in the urine. Alkalinization of the urine may occur when an absolute or relative excess of bicarbonate exists. However, urinary alkalinization will not occur if there is a deficiency of Na^+ or K^+ , because HCO_3^- must also be retained to maintain electroneutrality. In contrast, the urine may be acidified if an absolute or relative decrease occurs in systemic HCO_3^- . In this setting, proximal tubular HCO_3^- reabsorption and distal tubular H^+ excretion are maximal. A “paradoxical aciduria” with low urinary pH may also be seen in the setting of hypokalemic metabolic alkalosis and systemic K^+ depletion when H^+ is exchanged in preference to K^+ in response to mineralocorticoid. Some of the processes involved in acid-base regulation are shown in Figure 43–3.

FLUID & ELECTROLYTE MANAGEMENT

Therapy of fluid and electrolyte disorders is directed toward providing maintenance fluid and electrolyte requirements, replenishing prior losses, and replacing persistent abnormal

▲ **Figure 43-2.** Composition of body fluids. ECF, extracellular fluid; ICF, intracellular fluid; ISF, interstitial fluid.

losses. Therapy should be phased to (1) rapidly expand the ECF volume and restore tissue perfusion, (2) replenish fluid and electrolyte deficits while correcting attendant acid-base abnormalities, (3) meet the patient’s nutritional needs, and (4) replace ongoing losses.

The cornerstone of therapy involves an understanding of maintenance fluid and electrolyte requirements. Maintenance requirements call for provision of enough water, glucose, and electrolytes to prevent deterioration of body stores. During short-term parenteral therapy, sufficient glucose is provided to prevent ketosis and limit protein catabolism, although this is usually little more than 20% of the patient’s true caloric needs. Prior to the administration of maintenance fluids, it is important to consider the patient’s volume status and to determine whether intravenous fluids are needed at all.

Various models have been devised to facilitate calculation of maintenance requirements based on body surface area, weight, and caloric expenditure. A system based on caloric expenditure is most helpful, because 1 mL of water is needed for each kilocalorie expended. The system presented in Table 43-1 is based on caloric needs and is applicable to children weighing more than 3 kg.

As depicted in Table 43-1, a child weighing 30 kg would need 1700 kcal and 1700 mL of water daily. If the child received parenteral fluids for 2 days, the fluid would usually contain 5% glucose, which would provide 340 kcal/d, or 20% of the maintenance caloric needs. Maintenance fluid requirements take into account normal insensible water losses and water lost in sweat, urine, and stool, and assume the patient to

be afebrile and relatively inactive. Thus if excessive losses occur standard “maintenance fluids” will be inadequate. In contrast, if losses are reduced for any reason standard “maintenance fluid” administration would be excessive. Maintenance requirements are greater for low-birth-weight and pre-term infants. Table 43-2 lists other factors that commonly alter fluid and caloric needs.

Electrolyte losses occur primarily through the urinary tract and to a lesser degree via the skin and stool. Although maintenance electrolyte estimates vary, reasonable approximations for maintenance needs are 3 mEq Na⁺/100 kcal and 2 mEq K⁺/100 kcal or 30 mEq Na⁺/L and 20 mEq K⁺/L, respectively, of intravenous fluid.

It is helpful to monitor the patient’s daily weight, urinary output, fluid input, and urine specific gravity. If fluid or electrolyte balance is abnormal, serial determination of electrolyte concentrations, blood urea nitrogen, and creatinine may be necessary. In patients with significant burns, anuria, oliguria, or persistent abnormal losses (eg, from a stoma, or polyuria secondary to a renal concentrating defect), it is important to measure output, and if needed its components, so appropriate replacement can be provided.

DEHYDRATION

Depletion of body fluids is one of the most commonly encountered problems in clinical pediatrics. Children have a high incidence of gastrointestinal diseases, including gastroenteritis, and may demonstrate gastrointestinal symptoms in

▲ **Figure 43-3.** Maintaining metabolic stability via compensatory mechanisms.

nongastrointestinal conditions. Infants and young children often decrease their oral intake when ill, and their high ratio of surface area to weight promotes significant evaporative losses. Renal concentrating mechanisms do not maximally conserve water in early life, and fever may significantly increase fluid needs. Dehydration decreases ECF volume, leading to decreased tissue perfusion, impaired renal function, compensatory tachycardia, and lactic acidosis. The clinical effects of dehydration relate to the degree of dehydration and to the relative amounts of salt and water lost. Caregivers must be particularly aware of dehydration occurring in breast-fed newborn infants who go home soon after birth and whose mothers fail to produce enough milk. This problem is more common in the hot summer months and has been associated with severe dehydration, brain damage, and death.

The clinical evaluation of a child with dehydration should focus on the composition and volume of fluid intake; the frequency and amount of vomiting, diarrhea, and urine output; the degree and duration of fever; the nature of any administered medications; and the existence of underlying medical conditions. A recently recorded weight, if known, can be very helpful in calculating the magnitude of dehydration. Important clinical features in estimating the degree of dehydration include the capillary refill time, postural blood pressure, and heart rate changes; dryness of the lips and mucous membranes; lack of tears; lack of external jugular venous filling when supine; a sunken fontanelle in an infant;

Table 43-1. Caloric and water needs per unit of body weight.

Body Weight (kg)	kcal/kg	ml of Water/kg
3-10	100	100
11-20	1000 kcal + 50 kcal/kg for each kg > 10 kg	1000 mL + 50 mL/kg for each kg > 10 kg
> 20	1500 kcal + 20 kcal/kg for each kg > 20 kg	1500 mL + 20 mL/kg for each kg > 20 kg

Data from Holliday MA, Segar WE: The maintenance need for water in parenteral fluid therapy. *Pediatrics* 1957;19:823.

oliguria; and altered mental status (Table 43-3). Children generally respond to a decrease in circulating volume with a compensatory increase in pulse rate and may maintain their blood pressure in the face of severe dehydration. A low or falling blood pressure is, therefore, a late sign of shock in children, and when present should prompt emergent treatment. Salient laboratory parameters include a high urine specific gravity (in the absence of an underlying renal concentrating defect), a relatively greater elevation in blood urea nitrogen than in creatinine, a low urinary $[\text{Na}^+]$ excretion ($< 15 \text{ mEq/L}$), and an elevated hematocrit or serum albumin level secondary to hemoconcentration.

Emergent intravenous therapy is indicated when there is evidence of compromised perfusion (inadequate capillary refill, tachycardia, poor color, oliguria, or hypotension). The initial goal is to rapidly expand the plasma volume and to prevent circulatory collapse. A 20 mL/kg bolus of isotonic fluid should be given intravenously as rapidly as possible. Either colloid (5% albumin) or crystalloid (normal saline or Ringer lactate) may be used. Colloid is particularly useful in hypernatremic patients in shock, in malnourished infants, and in neonates. If no intravenous site is available, fluid may be administered intraosseously through the marrow row space of the tibia. If there is no response to the first fluid bolus, a second bolus may be given. When adequate tissue

Table 43-2. Alterations of maintenance fluid requirements.

Factor	Altered Requirement
Fever	12% per degree C^{a}
Hyperventilation	10-60 mL/100 kcal

Specific gravity	> 1.020 →		Anuria
Urine [Na ⁺]	< 20 mEq/L →		Anuria

perfusion is demonstrated by improved capillary refill, decreased pulse rate and urine output, and improved mental status, deficit replacement may be instituted. If adequate perfusion is not restored after 40 mL/kg of isotonic fluids, other pathologic processes must be considered such as sepsis, occult hemorrhage, or cardiogenic shock. Isotonic dehydration may be treated by providing half of the remaining fluid deficit over 8 hours and the second half over the ensuing 16 hours in the form of 5% dextrose with 0.2–0.45% saline containing 20 mEq/L KCl. In the presence of metabolic acidosis, potassium acetate may be considered. Maintenance fluids and replacement of ongoing losses should also be provided. Typical electrolyte compositions of various body fluids are depicted in Table 43-4, although it may be necessary to measure the specific constituents of a patient’s fluid losses to guide therapy. If the patient is unable to eat for a prolonged period, nutritional needs must be met through hyperalimentation or enteral tube feedings.

Oral rehydration may be provided to children with mild to moderate dehydration. Clear liquid beverages found in the home, such as broth, soda, juice, and tea, are inappropriate for the treatment of dehydration. Commercially available solutions provide 45–75 mEq/L of Na⁺, 20–25 mEq/L of K⁺, 30–34 mEq/L of citrate or bicarbonate, and 2–2.5% glucose. Frequent small aliquots (5–15 mL) should be given to provide approximately 50 mL/kg over 4 hours for mild dehydration and up to 100 mL/kg over 6 hours for moderate dehydration. Oral rehydration is contraindicated in children

with altered levels of consciousness or respiratory distress who cannot drink freely; in children suspected of having an acute surgical abdomen; in infants with greater than 10% volume depletion; in children with hemodynamic instability; and in the setting of severe hyponatremia ([Na⁺] < 120 mEq/L) or hypernatremia ([Na⁺] > 160 mEq/L). Failure of oral rehydration due to persistent vomiting or inability to keep up with losses mandates intravenous therapy. Successful oral rehydration requires explicit instructions to caregivers.

The type of dehydration is characterized by the serum [Na⁺]. If relatively more solute is lost than water, the [Na⁺] falls, and hyponatremic dehydration ([Na⁺] < 130 mEq/L) ensues. This is important clinically because hypotonicity of the plasma contributes to further volume loss from the ECF

Table 43-4. Typical electrolyte compositions of various body fluids.

	Na ⁺ (mEq/L)	K ⁺ (mEq/L)	HCO ₃ ⁻ (mEq/L)
Diarrhea	10-90	10-80	40
Gastric	20-80	5-20	0
Small intestine	100-140	5-15	40
Ileostomy	45-135	3-15	40

into the intracellular space. Thus tissue perfusion is more significantly impaired for a given degree of hyponatremic dehydration than for a comparable degree of isotonic or hypertonic dehydration. It is important to note, however, that significant solute losses also occur in hypernatremic dehydration. Furthermore, because plasma volume is somewhat protected in hypernatremic dehydration, it poses the risk of underestimating the severity of dehydration. Typical fluid and electrolyte losses associated with each form of dehydration are shown in Table 43–5.

HYPONATREMIA

Hyponatremia may be factitious in the presence of high plasma lipids or proteins, which decrease the percentage of plasma volume that is water. Hyponatremia in the absence of hypotonicity also occurs when an osmotically active solute, such as glucose or mannitol, is added to the ECF. Water drawn from the ICF dilutes the serum $[\text{Na}^+]$ despite isotonicity or hypertonicity.

Patients with hyponatremic dehydration generally demonstrate typical signs and symptoms of dehydration (see Table 43–3), because the vascular space is compromised as water leaves the ECF to maintain osmotic neutrality. The treatment of hyponatremic dehydration is fairly straightforward. The magnitude of the sodium deficit may be calculated by the following formula:

$$\begin{aligned} \text{Na}^+ \text{ deficit} = \\ (\text{Na}^+ \text{ desired} - \text{Na}^+ \text{ observed}) \times \\ \text{Bodyweight (kg)} \times 0.6 \end{aligned}$$

Half of the deficit is replenished in the first 8 hours of therapy, and the remainder is given over the following 16 hours. Maintenance and replacement fluids should also be provided. The deficit plus maintenance calculations generally approximate 5% dextrose with 0.45% saline. The rise in serum $[\text{Na}^+]$ should not exceed 2 mEq/L/h. The dangers of too rapid correction of hyponatremia include cerebral dehydration and injury due to fluid shifts from the ICF compartment.

Hypovolemic hyponatremia also occurs in cerebral salt wasting associated with central nervous system (CNS) insults,

a condition characterized by high urine output and elevated urinary $[\text{Na}^+]$ (> 80 mEq/L) due to an increase in ANF. This must be distinguished from the syndrome of inappropriate secretion of ADH (SIADH), which may also become manifest in CNS conditions and certain pulmonary disorders. In contrast to cerebral salt wasting, SIADH is characterized by euvolemia or mild volume expansion and relatively low urine output due to ADH-induced water retention. Urinary $[\text{Na}^+]$ is high in both conditions, though generally not as high as in SIADH. It is important to distinguish between these two conditions, because the treatment of the former involves replacement of urinary salt and water losses, whereas the treatment of SIADH involves water restriction.

In cases of severe hyponatremia (serum $[\text{Na}^+] < 120$ mEq/L) with CNS symptoms, intravenous 3% NaCl may be given over 1 hour to raise the $[\text{Na}^+]$ to 120 mEq/L, to alleviate CNS manifestations and sequelae. In general, 6 mL/kg of 3% NaCl will raise the serum $[\text{Na}^+]$ by 5 mEq/L. If 3% NaCl is administered, estimated Na^+ and fluid deficits should be adjusted accordingly. Further correction should proceed slowly, as outlined earlier.

Hypovolemic hyponatremia may occur in edematous disorders such as nephrotic syndrome, congestive heart failure, and cirrhosis, wherein water is retained in excess of salt. Treatment involves restriction of Na^+ and water and correction of the underlying disorder. Hypervolemic hyponatremia due to water intoxication is characterized by a maximally dilute urine (specific gravity < 1.003) and is also treated with water restriction.

HYPERNATREMIA

Although diarrhea is commonly associated with hyponatremic or isonatremic dehydration, hypernatremia may develop in the presence of persistent fever or decreased fluid intake or in response to improperly mixed rehydration solutions. Extreme care is required to treat hypernatremic dehydration appropriately. If the serum $[\text{Na}^+]$ falls precipitously, the osmolality of the ECF drops more rapidly than that of the CNS. Water shifts from the ECF compartment into the CNS to maintain osmotic neutrality. If hypertonicity is corrected too rapidly (a drop in $[\text{Na}^+]$ of greater than 0.5–1 mEq/L/h), cerebral edema, seizures, and CNS injury may occur. Thus following the initial restoration of adequate tissue perfusion using isotonic fluids, a gradual decrease in serum $[\text{Na}^+]$ is desired (10–15 mEq/L/d). This is commonly achieved using 5% dextrose with 0.2% saline to replace the calculated fluid deficit over 48 hours. Maintenance and replacement fluids should also be provided. If the serum $[\text{Na}^+]$ is not correcting appropriately, the free water deficit may be estimated as 4 mL/kg of free water for each milliequivalent of serum $[\text{Na}^+]$ above 145 and provided as 5% dextrose over 48 hours. If metabolic acidosis is also present, it must be corrected slowly to avoid CNS irritability. Potassium is provided as indicated—as the acetate salt if necessary. Electrolyte concentra-

Table 43–5. Estimated water and electrolyte deficits in dehydration (moderate to severe).

Type of Dehydration	H ₂ O (mL/kg)	Na ⁺ (mEq/kg)	K ⁺ (mEq/kg)	Cl ⁻ and HCO ₃ ⁻ (mEq/kg)
Isotonic	100–150	8–10	8–10	16–20
Hypotonic	50–100	10–14	10–14	20–28
Hypertonic	120–180	2–5	2–5	4–10

tions should be assessed every 2 hours in order to control the decline in serum $[\text{Na}^+]$. Elevations of blood glucose and blood urea nitrogen may worsen the hyperosmolar state in hypernatremic dehydration and should also be monitored closely. Hyperglycemia is often associated with hypernatremic dehydration and may necessitate lower intravenous glucose concentrations (eg, 2.5%).

Patients with diabetes insipidus, whether nephrogenic or central in origin, are prone to develop profound hypernatremic dehydration as a result of unremitting urinary free water losses (urine specific gravity < 1.010), particularly during superimposed gastrointestinal illnesses associated with vomiting or diarrhea. Treatment involves restoration of fluid and electrolyte deficits as described earlier as well as replacement of excessive water losses, with subsequent water deprivation testing during daylight hours to distinguish responsiveness to ADH. The evaluation and treatment of nephrogenic and central diabetes insipidus are discussed in detail in Chapters 22 and 32, respectively.

Hypervolemic hypernatremia (salt poisoning), associated with excess total body salt and water, may occur as a consequence of providing improperly mixed formula, excessive NaCl or NaHCO_3 administration, or as a feature of primary hyperaldosteronism. Treatment includes the use of diuretics, and potentially, concomitant water replacement or even dialysis.

POTASSIUM DISORDERS

The predominantly intracellular distribution of potassium is maintained by the actions of Na^+/K^+ -ATPase in the cell membranes. Potassium is shifted into the ECF and plasma by acidemia and into the ICF in the setting of alkalosis, hypochloremia, or in conjunction with insulin-induced cellular glucose uptake. The ratio of intracellular to extracellular K^+ is the major determinant of the cellular resting membrane potential and contributes to the action potential in neural and muscular tissue. Abnormalities of K^+ balance are potentially life-threatening. In the kidney, K^+ is filtered at the glomerulus, reabsorbed in the proximal tubule, and excreted in the distal tubule. Distal tubular K^+ excretion is regulated primarily by aldosterone. Renal K^+ excretion continues for significant periods even after the intake of K^+ is decreased. Thus by the time urinary $[\text{K}^+]$ decreases, the systemic K^+ pool has been depleted significantly.

The causes of net K^+ loss are primarily renal in origin. Gastrointestinal losses through nasogastric suction or vomiting reduce total body K^+ to some degree. However, the attendant volume depletion results in an increase in plasma aldosterone, promoting renal excretion of K^+ in exchange for Na^+ . Diuretics (especially thiazides), mineralocorticoids, and intrinsic renal tubular diseases (eg, Bartter syndrome) enhance the renal excretion of K^+ . Clinically, hypokalemia is associated with neuromuscular excitability, decreased peristalsis or ileus, hyporeflexia, paralysis, rhabdomyolysis, and arrhythmias. Electrocardiographic changes include flattened

T waves, a shortened PR interval, and the appearance of U waves. Arrhythmias associated with hypokalemia include premature ventricular contractions; atrial, nodal, or ventricular tachycardia; and ventricular fibrillation. Hypokalemia increases responsiveness to digitalis and may precipitate overt digitalis toxicity. In the presence of arrhythmias, extreme muscle weakness, or respiratory compromise, intravenous K^+ should be given. If the patient is hypophosphatemic ($[\text{PO}_4^{-3}] < 2 \text{ mg/dL}$), a phosphate salt may be used. The first priority in the treatment of hypokalemia is the restoration of an adequate serum $[\text{K}^+]$. Providing maintenance amounts of K^+ is usually sufficient; however, when the serum $[\text{K}^+]$ is dangerously low and K^+ must be administered intravenously, it is imperative that the patient have a cardiac monitor. Intravenous K^+ should generally not be given faster than at a rate of 0.5 mEq/kg/h. Oral K^+ supplements may be needed for weeks to replenish depleted body stores.

Hyperkalemia—due to decreased renal K^+ excretion, mineralocorticoid deficiency or unresponsiveness, or K^+ release from the ICF compartment—is characterized by muscle weakness, paresthesias, and tetany; ascending paralysis; and arrhythmias. Electrocardiographic changes associated with hyperkalemia include peaked T waves, widening of the QRS complex, and arrhythmias such as sinus bradycardia or sinus arrest, atrioventricular block, nodal or idioventricular rhythms, and ventricular tachycardia or fibrillation. The severity of hyperkalemia depends on the electrocardiographic changes, the status of the other electrolytes, and the stability of the underlying disorder. A rhythm strip should be obtained when significant hyperkalemia is suspected. If the serum $[\text{K}^+]$ is less than 6.5 mEq/L, discontinuing K^+ supplementation is usually sufficient. If the serum $[\text{K}^+]$ is greater than 7 mEq/L or if potentiating factors such as hyponatremia, digitalis toxicity, and renal failure are present, more aggressive therapy is needed. If electrocardiographic changes or arrhythmias are present, treatment must be initiated promptly. Intravenous 10% calcium gluconate (0.2–0.5 mL/kg over 2–10 minutes) will rapidly ameliorate depolarization and may be repeated after 5 minutes if electrocardiographic changes persist. Calcium should be given only with a cardiac monitor in place and should be discontinued if bradycardia develops. The intravenous administration of a diuretic that acts in the loop of Henle, such as furosemide (1–2 mg/kg), will augment renal K^+ excretion and can be very helpful in lowering serum and total body $[\text{K}^+]$. Administering Na^+ and increasing systemic pH with bicarbonate therapy (1–2 mEq/kg) will shift K^+ from the ECF to the ICF compartment, as will therapy with a β -agonist such as albuterol. In nondiabetic patients, 0.5 g/kg of glucose over 1–2 hours will enhance endogenous insulin secretion, lowering serum $[\text{K}^+]$ 1–2 mEq/L. Administration of intravenous glucose and insulin may be needed as a simultaneous drip (0.5–1 g/kg glucose and 0.3 units of regular insulin per gram of glucose) given over 2 hours with monitoring of the serum glucose level every 15 minutes.

The therapies outlined above provide transient benefits. Ultimately, K^+ must be reduced to normal levels by reestablishing adequate renal excretion using diuretics or optimizing urinary flow, using ion exchange resins such as sodium polystyrene sulfonate orally or as a retention enema (0.2–0.5 g/kg orally or 1 g/kg as an enema), or by dialysis.

ACID-BASE DISTURBANCES

When evaluating a disturbance in acid-base balance, the systemic pH, partial carbon dioxide pressure (P_{CO_2}), serum $[HCO_3^-]$, and anion gap must be considered. The anion gap, $Na^+ - (Cl^- + HCO_3^-)$, is an expression of the unmeasured anions in the plasma and is normally 12 ± 4 mEq/L. An increase above normal suggests the presence of an unmeasured anion, such as occurs in diabetic ketoacidosis, lactic acidosis, salicylate intoxication, and so on. Although the base excess (or deficit) is also used clinically, it is important to recall that this expression of acid-base balance is influenced by the renal response to respiratory disorders and cannot be interpreted independently (as in a compensated respiratory acidosis, wherein the base excess may be quite large). Recently, there has been greater interest in the Stewart approach to acid-base disturbances and the calculation of the “strong ion difference,” which is beyond the scope of the present discussion. The interested reader is referred to the review by Gunnerson and Kellum listed in the references at the end of this chapter.

METABOLIC ACIDOSIS

Metabolic acidosis is characterized by a primary decrease in serum $[HCO_3^-]$ and systemic pH due to the loss of HCO_3^- from the kidneys or gastrointestinal tract, the addition of an acid (from external sources or via altered metabolic processes), or the rapid dilution of the ECF with non-bicarbonate-containing solution (usually normal saline). When HCO_3^- is lost through the kidneys or gastrointestinal tract, Cl^- must be reabsorbed with Na^+ disproportionately, resulting in a hyperchloremic acidosis with a normal anion gap. Thus a normal anion gap acidosis in the absence of diarrhea or other bicarbonate-rich gastrointestinal losses suggests the possibility of renal tubular acidosis and should be evaluated appropriately. (See Chapter 22.) In contrast, acidosis that results from addition of an unmeasured acid is associated with a widened anion gap. Examples are diabetic ketoacidosis, lactic acidosis, starvation, uremia, toxin ingestion (salicylates, ethylene glycol, or methanol), and certain inborn errors of organic or amino acid metabolism. Dehydration may also result in a widened anion gap acidosis as a result of inadequate tissue perfusion, decreased O_2 delivery, and subsequent lactic and keto acid production. Respiratory compensation is accomplished through an increase in minute ventilation and a decrease in P_{CO_2} . The patient's history, physical findings, and laboratory features should lead to the appropriate diagnosis.

The ingestion of unknown toxins or the possibility of an inborn error of metabolism (see Chapter 34) must be considered in children without an obvious cause for a widened anion gap acidosis. Unfortunately, some hospital laboratories fail to include ethylene glycol or methanol in their standard toxicology screens, so that these toxins must be requested specifically. This is of critical importance when therapy with fomepizole (4-methylpyrazole) must be considered for either ingestion—and instituted quickly to head off profound toxicity. Ethylene glycol (eg, antifreeze) is particularly worrisome because of its sweet taste and accounts for a significant number of toxin ingestions. Screening by fluorescence of urine under a Wood's lamp is relatively simple but does not replace specific laboratory assessment. Salicylate intoxication has a stimulatory effect on the respiratory center of the CNS; thus patients may initially present with respiratory alkalosis or mixed respiratory alkalosis and widened anion gap acidosis.

Most types of metabolic acidosis will resolve with correction of the underlying disorder, improved renal perfusion, and acid excretion. Intravenous $NaHCO_3$ administration may be considered in the setting of metabolic acidosis when the pH is less than 7.0 or the $[HCO_3^-]$ is less than 5 mEq/L, but only if adequate ventilation is ensured. The dose (in milliequivalents) of $NaHCO_3$ may be calculated as:

$$\text{Weight (kg)} \times \text{Base deficit} \times 0.3$$

and given as a continuous infusion over 1 hour. The effect of $NaHCO_3$ in lowering serum potassium and ionized calcium concentrations must also be considered and monitored.

METABOLIC ALKALOSIS

Metabolic alkalosis is characterized by a primary increase in $[HCO_3^-]$ and pH resulting from a loss of strong acid or gain of buffer base. The most common cause for a metabolic alkalosis is the loss of gastric juice via nasogastric suction or vomiting. This results in a Cl^- -responsive alkalosis, characterized by a low urinary $[Cl^-]$ (< 20 mEq/L) indicative of a volume-contracted state that will be responsive to the provision of adequate Cl^- salt (usually in the form of normal saline). Cystic fibrosis may also be associated with a Cl^- -responsive alkalosis due to the high losses of $NaCl$ through the sweat, whereas congenital Cl^- -losing diarrhea is a rare cause of Cl^- -responsive alkalosis. Chloride-resistant alkaloses are characterized by a urinary $[Cl^-]$ greater than 20 mEq/L and include Bartter syndrome, Cushing syndrome, and primary hyperaldosteronism, conditions associated with primary increases in urinary $[Cl^-]$, or volume-expanded states lacking stimuli for Cl^- reabsorption. Thus the urinary $[Cl^-]$ is helpful in distinguishing the nature of a metabolic alkalosis, but must be specifically requested in many laboratories because it is not routinely included in urine electrolyte screens. The serum $[K^+]$ is also low in these settings (hypokalemic metabolic alkalosis) owing to a combination of increased mineralocorticoid activity associated with volume contraction, the shift of K^+ to the ICF compart-

ment, preferential reabsorption of Na^+ rather than K^+ to preserve intravascular volume, or primary mineralocorticoid excess.

RESPIRATORY ACIDOSIS

Respiratory acidosis develops when alveolar ventilation is decreased, increasing PCO_2 and lowering systemic pH. The kidneys compensate for respiratory acidosis by increasing HCO_3^- reabsorption, a process that takes several days to manifest. Patients with acute respiratory acidosis frequently demonstrate air hunger with retractions and the use of accessory respiratory muscles. Respiratory acidosis occurs in upper or lower airway obstruction, ventilation-perfusion disturbances, CNS depression, and neuromuscular defects. Hypercapnia is not as detrimental as the hypoxia that usually accompanies these disorders. The goal of therapy is to correct or compensate for the underlying pathologic process, to improve alveolar ventilation. Bicarbonate therapy is not indicated in a pure respiratory acidosis, because it will worsen the acidosis by shifting the equilibrium of the carbonic acid-bicarbonate buffer system to increase PCO_2 .

RESPIRATORY ALKALOSIS

Respiratory alkalosis occurs when hyperventilation results in a decrease in PCO_2 and an increase in pH. Patients may experience tingling, paresthesias, dizziness, palpitations, syncope, or even tetany and seizures due to the associated decrease in ionized calcium. Causes of respiratory alkalosis include psychobehavioral disturbances, CNS irritation from meningitis or encephalitis, and salicylate intoxication. Therapy is directed toward the causal process. Rebreathing into a

paper bag will decrease the severity of symptoms in acute hyperventilation.

Pediatric Laboratory Medicine & Reference Ranges

Georgette Siparsky, PhD
Frank J. Accurso, MD

Laboratory tests provide valuable information necessary to evaluate a patient's condition and to monitor recommended treatment. Chemistry and hematology test results are compared with those of healthy individuals or those undergoing similar therapeutic treatment to determine clinical status and progress. In the past, the term *normal ranges* relayed some ambiguity because statistically, the term *normal* also implied a specific (gaussian or normal) distribution and epidemiologically it implied the state of the majority, which is not necessarily the desirable or targeted population. This is most apparent in cholesterol levels, where values greater than 200 mg/dL are common, but not desirable. Use of the term *reference range* or *reference interval* is therefore recommended by the International Federation of Clinical Chemistry (IFCC) and the Clinical and Laboratory Standards Institute (CLSI, formerly the National Committee for Clinical Laboratory Standards, NCCLS) to indicate that the values relate to a reference population and clinical condition.

Reference ranges are established for a specific age (eg, α -fetoprotein), sex, and sexual maturity (eg, luteinizing hormone and testosterone); they are also defined for a specific pharmacologic status (eg, taking cyclosporine), dietary restrictions (eg, phenylalanine) and stimulation protocol (eg, growth hormone). Similarly, diurnal variation is a factor (eg, cortisol), as is degree of obesity (eg, insulin). Some reference ranges are particularly meaningful when combined with other results (eg, parathyroid hormone and calcium), or when an entire set of analytes is evaluated (eg, lipid profile: triglyceride, cholesterol, high-density lipoprotein, and low-density lipoprotein).

Laboratory tests are becoming more specific and measure much lower concentrations than ever before. Therefore reference ranges should reflect the analytical procedure, as well as reagents and instrumentation used for a specific analysis. As test methodology continues to evolve, reference ranges are modified and updated.

CHALLENGES IN DETERMINING & INTERPRETING PEDIATRIC REFERENCE INTERVALS

The pediatric environment is particularly challenging for the determination of reference intervals since growth and developmental stages do not have a distinct and finite boundary by which test results can be tabulated. Reference ranges may overlap and, in many cases, complicate diagnosis and treatment. Collection and allocation of test results by age for the purpose of establishing a reference range is a convenient and manageable way to report them, but caution is needed in their interpretation and clinical correlation.

A particular difficulty lies in establishing reference ranges for analytes whose levels are changed under scheduled stimulation conditions. The common glucose tolerance test is such an example, but more complex endocrinology tests (eg, stimulation by clonidine and cosyntropin) require skill and extensive experience to interpret. Reference ranges for these serial tests are established over a long period of time and are not easily transferable between test methodologies. Changing analytical technologies adds a new dimension to the challenges of establishing pediatric reference ranges.

GUIDELINES FOR USE OF DATA IN A REFERENCE RANGE STUDY

The College of American Pathologists provides guidelines for the adoption of reference ranges used in hospitals and commercial clinical laboratories. It recognizes the enormous task of establishing a laboratory's own reference ranges, and recommends alternatives to the process. A laboratory may acquire reference ranges by:

1. Conducting its own study to evaluate a statistically significant number of "healthy" volunteers. It is a monumental task for a laboratory to develop its own pediatric reference ranges, because parental consent and

procedural approval by review boards need to be addressed. The numerous age categories to be evaluated also add to the complexity and size of the study.

- Adopting ranges established by the manufacturer of a particular analytical instrument. The laboratory must validate the data by analyzing a sample of 20 “reference” subjects (patients representing that specific population) to confirm that the adopted range is truly representative of that group.
- Using reference data in the general medical literature and conferring with physicians to make sure the data agree with their clinical experience. A validation study is also recommended.
- Analyzing hospital patient data. Laboratory test results from hospital patients have been used to compute reference ranges provided they fulfill stated clinical criteria. Patient records need to indicate that the patient’s specific medical condition does not influence the analyte whose reference range is being determined. For example, a child undergoing surgery for bone fracture repair is expected to have normal electrolytes and thyroid function, whereas a child examined for precocious puberty should not be included in a reference range study for luteinizing hormone. In the REALAB Project, Grossi et al chose the “inclusion criterion,” whereby tests that have a single laboratory measurement were used; justification was based on the fact that persons with repeated testing had a higher probability of being diseased and their results should be excluded from the study.

Statistically, the sample size of a hospital patient study should be considerably larger than that of a healthy group. A study from a healthy population may require 20 subjects to be statistically significant, whereas a hospital population should evaluate a minimum of 120 patients. At Children’s Hospital in Denver, the free thyroxine reference range was recently established using 1480 clinic and hospital patient results in this manner.

STATISTICAL COMPUTATION OF REFERENCE INTERVALS

The establishment of reference intervals is based on a statistical distribution of test results obtained from a representative population. The CLSI recommendation for data collection and statistical analysis provides guidelines for managing the data. For clinicians, it is not important that they can reproduce the calculation. It is far more critical to understand the benefits and restrictions provided by the described statistical approaches, and to evaluate patient results with these limitations in mind.

In reviewing the statistics, 95% of all results will be inherently included in the reference range. Note that 5% of that population will have “abnormal” results, when in fact they are “healthy” and an integral part of the reference group

study. Similarly an equivalent 5% of the “ill” population will have laboratory results within the reference range. These are inherent features of the statistical computation. Taking that analysis one step further, the probability of a healthy patient having a test result within a calculated reference range is

$$P = 0.95$$

When multiple tests or panels of tests are used, the combined probability of all the test results falling in their respective reference ranges drops dramatically. For example, the probability of all results from 10 tests in the complete metabolic panel being in the reference range is

$$P = (0.95)^{10} = 0.60$$

Therefore, about one third of healthy patients will have one test result in the panel that is outside the reference range.

A. Parametric Method of Computation

The parametric method of establishing reference intervals is simple, though not always representative, since it is based on the assumption that the data have a gaussian distribution. A mean (\bar{x}) and standard deviation (s) are calculated; test results of 95% of that specific population will fall within the mean $\pm 1.96s$, as shown in Figure 44–1.

Where the distribution is not gaussian, a mathematical manipulation of the values (eg, plotting the log of the value, instead of the value itself) may give a gaussian distribution. The mean and standard deviation are then converted back to give a usable reference range.

B. Nonparametric Method of Computation

The nonparametric method of establishing reference ranges is currently recommended by CLSI since it defines outliers as those in the extreme 2.5 percentile of the upper and lower limits of data respectively. The number of data points excluded at the limits depends on the skew of the curve, and

▲ **Figure 44–1.** Gaussian distribution and parametric calculation using $\bar{x} \pm 1.96s$ to define the range.

▲ **Figure 44-2.** Histogram of free thyroxine (FT4) using clinic and hospital patients at Children’s Hospital in Denver.

so the computation accommodates a nongaussian distribution. A histogram depicting the nongaussian distribution of data from a free thyroxine reference range study conducted at Children’s Hospital in Denver is shown in Figure 44-2.

WHY REFERENCE INTERVALS VARY

Recent modifications to reference ranges are due to the introduction of new and improved analytical procedures, advanced automated instrumentation, and standardization of reagents and reference materials. Reference ranges are also affected by preanalytical variations that can occur during sample collection, processing, and storage.

Preanalytical variations of biological origin can occur when specimens are drawn in the morning versus in the evening, or from hospitalized recumbent patients versus ambulatory outpatients. Variations may also be caused by metabolic and hemodynamic factors. Preanalytical factors may be a product of the socioeconomic environment or ethnic background (eg, genetic or dietary).

Analytical variations are caused by differences in analytical measurements and depend on the analytical tools as well as an inherent variability in obtaining a quantitative value. Furthermore, scientific progress is constantly introducing new reagents, instruments, and improved testing procedures to the clinical laboratory, and each tool adds an element of variability between tests.

1. **Antigen-antibody reactions** have revolutionized clinical chemistry, but have also added a degree of variability because biologically derived reagents have different specificity and sensitivity. In addition to the targeted analyte, some of its metabolites are also measured, and these may or may not be biologically active.
2. **Reference materials** continue to be reviewed and evaluated by organizations such as the World Health Organization and the National Institute for Standards and

Technology. A new standard was recently established for troponin I, and reference ranges were modified to reflect the new standard.

3. **Analytical instrumentation** with advanced electronics and robotics has improved accuracy of results and increased throughput. However, they have added an element of variability between instruments from different manufacturers.
4. **Analytical detection methods** have also made big strides as they have expanded from simple ultraviolet–visible spectrophotometry, to fluorescence, nephelometry, radioimmunoassay, and chemiluminescence. For example, the third-generation thyroid-stimulating hormone assays can now measure concentrations as low as 0.001 $\mu\text{IU}/\text{mL}$, and the reference range was recently modified to reflect the improved sensitivity of the assay.

SENSITIVITY & SPECIFICITY

Despite its statistical derivation, a reference interval does not necessarily provide a finite and clear-cut guideline as to whether a patient has a disease. There will always be a segment of the population with test values that fall within the reference interval, but clinical manifestations that indicate disease is present. Similarly, a segment of the population will have test values outside the reference interval, but no clinical signs of disease. The ability of a test and corresponding reference interval to detect individuals with disease is defined by the diagnostic sensitivity of the test. Similarly, the ability of a test to detect individuals without disease is described by the diagnostic specificity. These characteristics are governed by the analytical quality of the test, as well as the numerical parameters (reference interval) that define the presence of disease. The tolerance level for the desired sensitivity and specificity of a test requires significant input from clinicians.

Generally, specificity increases as sensitivity decreases. A typical reference range frequency distribution, shown in Figure 44-3 (solid line), provides information on the test results of a number of healthy subjects, or individuals without the disease. A second curve (dashed line) shows test results for individuals with the disease. As with most tests, there is an overlap area. A patient with a test result of 1 is likely healthy, and the result indicates a true negative (TN) for the presence of disease. A patient with a test result of 9 is likely to have the disease and the test result is a true positive (TP). There is a small, but significant population with a test result of 2–5 in whom the test is not 100% conclusive. A statistical analysis may determine the most likely cutoff for healthy individuals, but the clinically acceptable cutoff depends on the test as well as clinical correlation. Where the treatment is aggressive and has serious side effects, a clinician may choose to err on the side of caution and hold treatment for anyone with a test value of less than 6.

▲ **Figure 44-3.** Frequency distribution of test results for patients with and without disease. FN, false negative; FP, false positive; TN, true negative; TP, true positive.

If cutoff values for the reference interval are such that a test result indicates that a healthy patient has the disease, the result is a false positive (FP). Conversely if a test result indicates that a patient is well when in fact he or she has the disease, the result is a false negative (FN). To define the ability of the test and reference interval to identify a disease state, the diagnostic sensitivity and specificity are measured.

$$\text{Diagnostic sensitivity} = \frac{TP}{(TP + FN)}$$

$$\text{Diagnostic specificity} = \frac{TN}{(TN + FP)}$$

In the example shown in Figure 44-3, a reference interval of 0.5-3 will provide more TN results and minimize FP results. Alternatively, a reference interval of 0.5-4 will increase the rate of FN. Thus an increase in sensitivity leads to a decrease in specificity. A medical condition that requires aggressive treatment may necessitate a test and corresponding reference interval with a high sensitivity, which is a measure of the TP rate. This is accomplished at the expense of lowering specificity.

A reference interval is a statistical representation of test results from a finite population, but it is by no means inclusive of every member of the group. It is merely one component in the measure of a patient’s status, to be viewed in relation to the sensitivity and specificity of the test.

Clinical laboratory data are frequently interpreted using a dynamic approach rather than from the perspective of a static state, so that each value is compared with another, instead of a strict reference range. In this case, time series analysis of relative values may provide more important information than comparison against a reference range. Examples include the evaluation of enzyme activity over time and various stimulation studies for endocrine assessment. Drug monitoring is also a dynamic process.

PEDIATRIC REFERENCE INTERVALS

The establishment of reference ranges is a complex process. Assumptions are made in the management of data processes, regardless of whether “healthy” individuals or hospital patients are used for the accumulation of test results. Analytical instrument manufacturers conduct large studies to identify reference intervals for each specific analyte, and pediatric values have always been the most challenging. Some of the manufacturers’ recommended reference intervals are listed in Table 44-1 for general chemistry, Table 44-2 for endocrinology, and Table 44-3 for hematology. The interpretation of chemistry and hematology laboratory results is equally complex and forms a continuous challenge for physicians and the medical community at large.

Table 44-1. General chemistry.

Index

NOTE: A *t* following a page number indicates tabular material, and *f* following a page number indicates a figure.
Drugs are listed under their generic names. When a drug trade name is listed, the reader is referred to the generic name.

- Abdomen, 6
 - pain, 602
- Abdominal surgical conditions
 - intestinal obstruction, 44*t*
 - newborn, 43–46
- Abdominal wall defects, 45
- Abetalipoproteinemia, 605
- ABG. *See* Arterial blood gas
- Abnormal head size, 711–713
- Abnormalities in female pubertal development, ovarian function, 934–938
- Abnormalities in male pubertal development, testicular function, 938–940
- Abnormalities of platelet number, function, 831
- ABO blood group incompatibility, 12
- ABRS. *See* Acute bacterial rhinosinusitis
- Abscess, 384
- Absorption, prevention, poisoning, 315–317
- Abstinence, 130
- Abuse, 209–215
 - child, 211–213
 - emotional, 210–211
 - forms, 209–210
 - historical features, 210*t*
 - history, 210–211
 - management, 213–214
 - medical care neglect, 210
 - medical emergencies, 212*t*
 - physical, 211–213
 - physical abuse, 209
 - physical findings, 211–213
 - physical neglect, 210
 - prevention, 214
 - radiologic, laboratory findings, 213
 - recognition of, 210–213
 - reporting, 213–214
 - sexual, 211–213
 - presentations of, 210*t*
 - sexual abuse, 209
- Acetabular labral tears, 782
- Acetaminophen, 374
- Acetylcysteine administration, intravenous, 319*t*–320*t*
- Achalasia of esophagus, 579
- Achondroplasia, 753–754, 1005–1008
- Acid-base balance, 1246
- Acid-base disorders, 1245–1253
 - acid-base balance, 1246
 - acid-base disturbances, 1252–1253
 - fluid, electrolyte management, 1246–1252
 - regulation of body fluids, electrolytes tonicity, 1245–1246
 - and tonicity, 1245–1246
- Acid-base disturbances, 1252–1253
- Acidosis, 959
 - correction of, 955
- Acne, 381, 383
 - treatment, 382*t*
- Acoustic reflectometry, 441
- Acquired aplastic anemia, 805
- Acquired bleeding disorders, 839–841
- Acquired growth hormone deficiency, pattern of growth, 918*f*
- Acquired hearing loss, 451
- Acquired heart disease, 554–566
 - infective endocarditis, antibiotic prophylaxis, 561*t*
 - Kawasaki disease
 - long-term management, 557*t*
 - noncardiac manifestations, 556*t*
 - rheumatic fever, Jones diagnostic criteria, 554*t*
- Acquired hemolytic anemia, 822–824
- Acquired hypogammaglobulinemia, 898
- Acquired hypothyroidism, 922
- Acquired immunodeficiency syndrome, ocular manifestations, 414–415
- Acquired melanocytic nevi, 378–379
- Acquired syphilis, 1176–1178
- Acquired *Toxoplasma* infection, immunocompetent host, 1196
- Acrocentric, 984
- Acrodermatitis enteropathica, 605
- Acromioclavicular separation, 779
- ACTH, 945. *See also* Adrenocorticotropic hormone
- ACTH stimulation test, 941
- Actions, 947
- Activity, stress factors, 359*t*
- Activity patterns, assessment of, 285*t*
- Acute abdomen, 600
 - causes, 600*t*
- Acute appendicitis, 586–587
- Acute asthma, 1032–1034
- Acute bacterial pharyngitis, 460–463
- Acute bacterial rhinosinusitis, 453–455, 456*f*
- Acute bilirubin encephalopathy, 14
- Acute-care visits, 229
- Acute cerebellar ataxia, 717–721
- Acute cervical adenitis, 464–465
- Acute diarrhea, 593–594
- Acute epiglottitis, 1162–1164
- Acute febrile illness, 1082
- Acute flaccid paralysis, 734–735*t*
 - syndromes presenting as, 733
- Acute glomerulonephritis, 1125
- Acute hypertensive emergencies, 665
- Acute insufficiency, 942
- Acute interstitial nephritis, 658
- Acute intracranial hypertension, 306–307
- Acute liver failure, 627
- Acute lymphoblastic leukemia, 853–856
- Acute lymphonodular pharyngitis, 1082
- Acute myeloid leukemia, 856
 - FAB subtypes of, 857*t*
