Strabismus is misalignment of the visual axes of the two eyes. Its prevalence in childhood is about 2–3%. Strabismus is categorized by the direction of the deviation and its frequency. Early diagnosis of strabismus and amblyopia, which often coexist, provides the best chance of reaching full visual potential. Strabismus may cause or be due to amblyopia.

An infant whose eyes are destined to be well aligned may appear intermittently esotropic, but this should occur less frequently over the first few months of life. By age 5 or 6 months, the eyes should be constantly well aligned.

Besides its effect on visual development, strabismus may be a marker of other ocular or systemic disease. Twenty percent of patients with retinoblastoma exhibit strabismus. Patients with CNS disorders such as hydrocephalus, space-occupying lesions, and an amaurotic (blind) eye can also exhibit strabismus. In children younger than age 3 or 4 years, blind eyes tend to assume a position of esodeviation, but after about age 4 years an amaurotic eye tends to show an exotropic shift.

Misdiagnosis of strabismus when the eyes are well-aligned—pseudostabismus—can occur when relying on the gross observation of the appearance of the two eyes. If the child has prominent epicanthal folds, pseudoesotropia may be diagnosed erroneously. Observation of the reflection of a penlight on the cornea, the corneal light reflex, is a more accurate means of determining if the eyes are straight. If strabismus is present, the corneal light reflex will not be centered in both eyes. Observation of eye move-

ments may reveal restriction of eye movements in certain positions of gaze.

1. Esotropia

▶ Pathogenesis & Clinical Findings

In esotropia the eyes cross. Congenital esotropia (infantile esotropia) has its onset in the first year of life in healthy infants. The deviation is large and obvious. Esotropia beginning in the first year also occurs in premature infants or in children with a complicated perinatal history associated with CNS problems such as intracranial hemorrhage and periventricular leukomalacia. The most frequent type of acquired esotropia is the accommodative type (Figure 15–26). Onset is usually between ages 2 and 5 years. The deviation is variable in magnitude and constancy and is often accompanied by amblyopia. One type of accommodative esotropia is associated with a high hyperopic refraction. In another type,

A

B

C

▲ **Figure 15–26.** Accommodative esotropia. Without glasses, esotropic (A). With glasses, well-aligned at distance (B), and at near with bifocal correction (C).

the deviation is worse with near than with distant vision. This type of esodeviation is usually associated with lower refractive errors.

Esotropia is associated with certain syndromes. In Möbius syndrome (congenital facial diplegia), a sixth nerve palsy causing esotropia is associated with palsies of the seventh and 12th cranial nerves and limb deformities. Duane syndrome can affect the medial or lateral rectus muscles (or both). It may be an isolated defect or may be associated with a multitude of systemic defects (eg, Goldenhar syndrome). Duane syndrome is often misdiagnosed as a sixth (abducens) nerve palsy. The left eye is involved more commonly than the right, but both eyes can be involved. Girls are affected more frequently than boys. Children with unilateral paretic or restrictive causes of esotropia may develop face turns toward the affected eye to maintain binocularity.

After age 5 years, any esotropia of recent onset should arouse suspicion of CNS disease. Infratentorial masses, hydrocephalus, demyelinating diseases, and idiopathic intracranial hypertension are causes of abducens palsy, which appears as an esotropia, lateral rectus paralysis or paresis, and face turn. The face turn is an attempt to maintain binocularity away from the field of action of the paretic muscle. Papilledema is often, but not invariably, present with increased intracranial pressure. Besides the vulnerability of the abducens nerve to increased intracranial pressure, it is susceptible to infection and inflammation. Otitis media and Gradenigo syndrome (inflammatory disease of the petrous bone) can cause sixth nerve palsy. Less commonly, migraine and diabetes mellitus are considerations in children with sixth nerve palsy.

Evaluation of esotropia requires examination by an ophthalmologist. Motility, cycloplegic refraction and a dilated fundusoscopic examination are necessary to determine the etiology of esotropia. Some children require imaging studies and neurologic consultation.

▶ Treatment

Surgery is the mainstay of treatment for congenital esotropia. Controversy exists as to how young the child should be when surgery is performed so that the child can obtain an optimal binocular result. The age range is from younger than 6 months to 2 years.

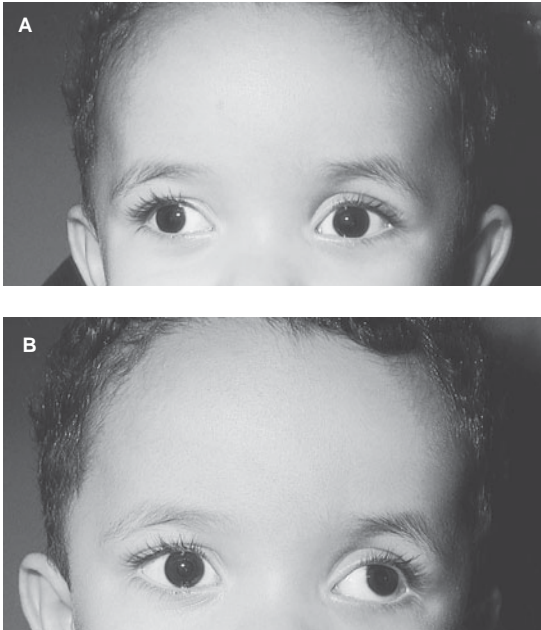

Management of accommodative esotropia includes glasses with or without bifocals, amblyopia treatment, and in some cases surgery.

Underlying neurologic disease should be referred to the appropriate specialists for further management.

2. Exotropia

▶ Pathogenesis & Clinical Findings

Exotropia is a type of strabismus in which the eyes are divergent. The patient appears wall-eyed with the visual axes of the eyes deviated in a divergent position (Figure 15–27).

▲ **Figure 15-27.** Exotropia. **A:** Fixation with left eye. **B:** Fixation with right eye.

The deviation most often begins intermittently and occurs after age 2 years. Congenital (infantile) exotropia is extremely rare in an otherwise healthy infant. Early-onset exotropia may occur in infants and children with severe neurologic problems.

Evaluation of the corneal light reflex reveals nasal decentration of the penlight's reflection in the deviated eye. All children with constant, congenital exotropia require CNS neuroimaging. Referral to an ophthalmologist is indicated.

► Treatment

Treatment of exotropia is with surgery, orthoptic exercises, patching, and occasionally glasses.

UNEXPLAINED DECREASED VISION IN INFANTS & CHILDREN

Some infants with delayed visual development during the first few months of life who are otherwise normal neurologically will reach an appropriate level of visual maturation.

Occult causes of poor vision and blindness in children are those for which there are no obvious ocular defects: they

include Leber congenital amaurosis, a childhood form of retinitis pigmentosa; achromatopsia, the absence of functioning cones in the retina; and optic nerve abnormalities, including optic nerve hypoplasia and atrophy.

Cerebral visual impairment, also known as cortical blindness, is manifested as decreased visual attentiveness of varying degree. Cerebral visual impairment can be congenital or acquired. Insults to the optic pathways and higher cortical visual centers are responsible. Asphyxia, trauma, intracranial hemorrhage, and periventricular leukomalacia are some of the causes of cerebral visual impairment.

Besides an ophthalmologic workup, electroretinogram and visual evoked response testing may be required in children with decreased vision of unexplained etiology. Imaging studies of the brain and a pediatric neurologic evaluation may be useful.

► Treatment

A low-vision assessment may be indicated. Low-vision aids enhance remaining vision. Devices used include magnifiers for both distance and near vision, closed-circuit television, and large-print reading materials.

THE BLIND CHILD

A child's development is affected profoundly by blindness or low vision. There are psychological consequences for the child blind from birth, as well as for the family. It can be devastating to a young family to find out that their newborn is blind. Although acquired blindness may give an individual time to grow as a sighted person and make preparations for life as a nonsighted person if loss of vision is slow and predicted, psychological consequences for the child and family must be addressed.

The child who is blind from birth or from very early childhood has had little or no opportunity to form visual impressions of the physical world. Blind infants reach developmental landmarks on a different schedule from that of sighted children. In addition, some blind children are multiply handicapped. For example, the premature child who is blind from retinopathy of prematurity may also have cerebral palsy. Children with Usher syndrome become both deaf and blind.

Leading causes of blindness in the pediatric age group differ among regions of the world and between industrialized nations and developing countries. The most common causes of blindness in the pediatric age group are thought to be cerebral visual impairment, retinopathy of prematurity, and optic nerve hypoplasia. Albinism, optic atrophy, cataract, retinitis pigmentosa, microphthalmia or anophthalmia, aniridia, and glaucoma are other diseases causing blindness.

► Clinical Findings

Children with low vision will not fixate on visual targets and often have roving eye movements. Ophthalmic referral is

necessary to determine if the etiology of the low vision is due to an ocular or neurologic disorder. Neuroimaging or specific ocular tests such as an electroretinogram may be necessary.

▶ Treatment

Blind children and their families should receive the benefit of knowledgeable therapists and support groups.

Edmond JC, Foroozan R: Cortical visual impairment in children. *Curr Opin Ophthalmol* 2006;17:509 [PMID: 17065917].

LEARNING DISABILITIES & DYSLEXIA

Visits to the physician because of educational difficulties are common. Children often have vague complaints of ocular fatigue, headaches, and difficulty reading. Learning disabilities and dyslexia result in poor reading comprehension and writing.

Evaluation of the child with learning disabilities and dyslexia should include ophthalmologic examination to identify any ocular disorders that could cause or contribute to poor school performance. Most children with learning

difficulties have no demonstrable problems on ophthalmic examination.

▶ Treatment

A multidisciplinary approach as suggested by the American Academy of Pediatrics, the American Association for Pediatric Ophthalmology and Strabismus, and the American Academy of Ophthalmology is recommended in evaluating children with learning disabilities. Although many therapies directed at “training the eyes” exist, scientific support for such approaches is weak.

ISSUES IN PEDIATRIC ORAL HEALTH

Concept of the Dental Home

Analogous to the American Academy of Pediatrics' (AAP) concept of a "medical home," the American Academy of Pediatric Dentistry (AAPD) supports the concept of a "dental home." This refers to a specialized primary dental care provider within the philosophical complex of the medical home and includes all aspects of oral health, involving interaction among the patient, parents, and dental and nondental professionals. A dental home is established by referring a child for an oral health examination to a dentist who provides care for infants and young children (ie, pediatric dentist) 6 months after the first tooth erupts or by 12 months of age. The intent is to implement preventive dental health habits with the goal of keeping the child free from dental and oral disease. Expectations include development of an individualized preventive health program derived from an accurate risk assessment for dental disease, anticipatory guidance about growth and development, education about proper nutrition, provision of comprehensive dental care, and referral to other dental specialists as needed.

Infant Oral Health Care

Infant oral health care is the foundation on which preventive education and dental care is built. Ideally, it begins before caries develop when preventive measures can be implemented to give the child an opportunity to grow up free from preventable oral disease. Oral evaluation of a child consists of risk assessment, anticipatory guidance, and health supervision. This approach advances dental care beyond tooth monitoring toward true health promotion. Risk assessment determines a child's risk of developing oral disease. Anticipatory guidance is proactive counseling of the parents directed toward enlisting them as allies in preventing oral health problems. Because pediatricians are far more likely to encounter new mothers and infants than are dentists, it is

essential that they be aware of the infectious pathophysiology and risk factors for early childhood caries in order to guide and intervene effectively. The most important risk factor for childhood oral disease is poverty.

The primary goals for an infant oral health program are (1) to establish with parents the goals of oral health, (2) to inform parents of their role in reaching these goals, (3) to motivate parents to learn and practice good preventive dental care, and (4) to initiate a long-term dental care relationship with parents. Such an alliance is necessary to prevent early childhood caries by preventing acquisition of harmful oral bacteria, modifying "nonnutritive sucking habits" before they become deleterious, and implementing optimal fluoride protection. Pediatricians should incorporate oral health into anticipatory guidance by providing information in their offices or by referring the child to a pediatric dental colleague.

Oral Health Risk Assessment

By 6 months of age, every child should have an oral health risk assessment by a pediatric health care provider. The Caries Risk Assessment Tool developed by the AAPD is an important component of later clinical decision making. Because the etiology of caries is multifactorial, risk assessment evaluates several contributing factors such as diet, host susceptibility, presence of aciduric oral microflora, and cultural and behavioral factors. Although the best predictor of future caries is previous caries incidence, this finding is not a practical preventative tool. Other risk factors include parental education, socioeconomic status, and age of colonization with *Streptococcus mutans* and *Lactobacillus* spp (the earlier colonization occurs, the greater the risk of severe decay). Indicators that place a patient automatically into the high-risk group are special health care needs, high maternal caries rate, nighttime breast or bottle feeding, and low socioeconomic status. High-risk individuals should be referred to a dentist as early as 6 months of age and no later than 6

months after the first tooth erupts or 12 months of age (whichever comes first) for establishment of a dental home.

Early Childhood Caries

Formerly termed “baby bottle tooth decay” or “nursing bottle caries,” early childhood caries (ECC) is a particularly aggressive and rapidly progressing form of caries that begins on the smooth surfaces soon after tooth eruption. The main cause is the frequent consumption of liquids containing fermentable carbohydrates through a nursing bottle or frequent sipping from a no-spill sippy cup. Children who take a bottle to bed and those who nurse at will and fall asleep nursing are at high risk for ECC. ECC typically involves the maxillary incisors but any other teeth may be affected. When a child sucks a bottle while supine, milk pools between the backs of the front teeth and the tongue. Acid produced in this stagnant area by oral bacteria cannot dissipate, and damage to the teeth occurs.

ECC is defined as one or more decayed (d), missing (m), or filled (f) tooth surfaces (s) in any primary tooth in a child younger than 71 months of age. Any sign of smooth-surface caries in a child younger than 3 years is termed *severe ECC* (S-ECC). From 3–5 years, one or more decayed, missing, or filled smooth surfaces in maxillary front teeth or a total dmfs score of 4 or higher must be present to make a diagnosis of S-ECC. By age 5 years, a dmfs score of 6 or higher must be present to constitute S-ECC. Children with S-ECC are at higher risk for new carious lesions, more frequent hospitalizations, and emergency department visits. They are absent more often from school, may have below-normal height and weight gain, and have a diminished oral health-related quality of life. Although S-ECC can affect all children, it is 32 times more likely in children who consume sugary foods and whose mothers are of low socioeconomic status and education level.

Parents should be counseled not to put infants to sleep with a bottle containing fermentable carbohydrates. After eruption of the first tooth, ad libitum breast feeding should be discontinued and regular oral hygiene measures implemented. Infants should be weaned from the bottle at about 1 year and encouraged to drink from a cup. Frequent consumption of cariogenic liquids from a bottle or no-spill training cup should be avoided.

ORAL EXAMINATION OF THE NEWBORN & INFANT

The mouth of the normal newborn is lined with an intact, smooth, moist, shiny mucosa (Figure 16–1). The alveolar ridges are continuous and relatively smooth. Within the alveolar bone are numerous tooth buds, which at birth are mostly primary teeth.

Teeth

Hard tissue formation of primary teeth begins at approximately 4 months' gestation. At birth, all 20 primary teeth are

▲ **Figure 16-1.** Normal anatomy of the newborn mouth.

calcified. The central maxillary incisors are almost completely calcified while only the cusp tips of the maxillary and mandibular second molars are calcified. There is a trace of enamel on the first four permanent molars at birth.

The primary teeth usually begin to erupt at 6–7 months of age. On rare occasions (1:3000), natal teeth are present at birth or neonatal teeth erupt within the first month. These are most commonly (85%) mandibular primary incisors. They can be “real” primary teeth (90%) or supernumerary teeth (10%) and should be differentiated radiographically. Although the preferred approach is to leave the tooth in place, supernumerary and hypermobile immature primary teeth should be extracted. On occasion, such teeth must be smoothed or removed if their sharp incisal edge causes laceration of the tongue (Riga-Fede disease). If such teeth cause difficulties with breast feeding, pumping and bottling the milk is initially recommended while the infant is conditioned not to “bite” during suckling.

Frena

Noticeable but small maxillary and mandibular labial frena should be present (Figure 16–2). Several small accessory frena may also be present farther posteriorly. In rare cases, as in oro-facial-digital syndrome, there are multiple thick tightly bound frena. Decisions about surgical correction should be based on the ability to maintain the child’s gingival health and are best left until the late preteen years. Many thick frena do not require correction.

The tongue is connected to the floor of the mouth by the lingual frenum (Figures 16–1 and 16–3). This connection should not impede the free movement of the tongue. If the

▲ Figure 16-2. The frena.

attachment is tight and high up on the alveolar ridge (Figure 16-4), it may restrict movement and interfere with the child's ability to produce "t," "d," and "l" sounds. This condition is called ankyloglossia (tongue-tie). Surgical correction may be indicated if the tongue cannot touch the maxillary incisors or the roof of the mouth. Earlier intervention (at age 3-4 years) is better than later, but there is usually no urgency for surgery in the neonatal period.

Cleft Lip & Palate

The palate of the newborn should be intact and continuous from the alveolar ridge anteriorly to the uvula (see Figure 16-1). Cleft lip and palate are common defects with an incidence of 0.28-3.74 in 1000 live births globally. Incidence varies widely among races and ranges from 1 in 500 among Navaho Native Americans and Japanese to more than 1 in 800 in whites and 1 in 2000 in blacks. The cleft of the palate can be

▲ Figure 16-3. Normal position of lingual frenum.

▲ Figure 16-4. Ankyloglossia (tongue-tie).

unilateral or bilateral (Figure 16-5). It can involve only the alveolar ridge, or the ridge and entire palate. Cleft palate may also present as an isolated submucous cleft, which may be detected by passing a finger posteriorly along the midline of the palate. Normally the posterior nasal spine is detectable, but if a submucous cleft is present, a bony notch will be found. Affected children sometimes have a bifid uvula. Although clefts present superficially as a cosmetic problem, they cause complex functional problems such as oro-antral communication and disruption of the maxillary alveolar ridge with a large number of associated dental problems. They disturb the muscle arrangement of the perioral and the soft palate muscles by interrupting their continuity across the midline. As a result,

▲ Figure 16-5. Types of clefts.

feeding, swallowing, speech, and ventilation of the middle ear are negatively affected.

Children with cleft lip and palate should be referred as soon as possible to a multidisciplinary cleft palate team. Team members assess the patient's medical status, feeding difficulties, general and dental development, hearing, facial esthetics, and overall well-being. Dental involvement in children with cleft palate is extensive and treatment may begin immediately after birth with fabrication of a palatal obturator as a feeding aid. This appliance, used by approximately 32% of cleft teams in the United States and Canada, may also provide cross-arch stability after surgical closure of the lip and maxillary orthopedic molding before primary alveolar cleft bone grafting. Nasoalveolar molding can be used to guide the protruding premaxilla back into the oral cavity, thus making surgical lip closure easier when it is performed (usually by 10 weeks of age). However, opinions on its effectiveness, potential growth disturbances, and additional costs differ among surgeons. Palate closure to facilitate the acquisition of normal speech without nasality follows at 12–18 months of age. The associated scar formation causes significant dentofacial growth disturbance. Orthodontic treatment addresses the sagittal and transverse maxillary growth deficits as well as irregularities in tooth eruption and position. Between 7 and 10 years of age, an alveolar bone graft is often necessary to promote proper eruption of the permanent teeth adjacent to the cleft. In some patients, a combined orthodontic-surgical repositioning of the permanent dentition is needed to complete a successful rehabilitation of the patient.

Other Soft Tissue Variations

Minor oral soft tissue variations can occur in newborns. Small (1–2 mm), round, smooth, white or grayish lesions are sometimes noted on the buccal and lingual aspects of the alveolar ridges or the midpalatine raphe. The latter, called Epstein pearls are considered remnants of epithelial tissue that were trapped along the raphe during fetal growth. The former, Bohn nodules, are remnants of mucous gland tissue. Both are benign, require no treatment, and usually disappear a few weeks after birth.

Some newborns may have small intraoral lymphangiomas on the alveolar ridge or the floor of the mouth. These and any other soft tissue variations that are more noticeable or larger than those just described should be evaluated by a dentist familiar with neonates.

ERUPTION OF THE TEETH

Normal Eruption

Primary teeth generally begin to erupt at about 6 months of age. The mandibular incisors usually erupt before the maxillary incisors. The first teeth may appear as early as age 3–4 months or as late as age 12–16 months. Many symptoms are

ascribed to teething, but any association with fever, upper respiratory infection, or systemic illness is probably coincidental rather than related to the eruption process. Attributing fever to teething without thorough diagnostic evaluation for other sources has resulted in missing serious organic disease.

Common treatment for teething pain is the application of topical anesthetics or teething gels, available over the counter. Most of these agents contain benzocaine or, less commonly, lidocaine. If improperly used, they can cause numbness of the entire oral cavity and pharynx. Suppression of the gag reflex can be a serious side effect. Systemic analgesics such as acetaminophen or ibuprofen are safer and more effective. Chewing on a teething object can be beneficial, if only for distraction purposes.

Occasionally, swelling of the alveolar mucosa overlying an erupting tooth is seen during teething. This condition appears as localized red to purple, round, raised, smooth lesions that may be symptomatic but usually are not. No treatment is necessary as these so-called eruption cysts or eruption hematomas resolve with tooth eruption.

Delayed Eruption

Premature loss of a primary tooth can either accelerate or delay eruption of the underlying secondary tooth. Early eruption occurs when the permanent tooth is beginning its active eruption and the overlying primary tooth is removed. This generally occurs when the primary tooth is lost within 1 year of its normal exfoliation. If loss of the primary tooth occurs more than 1 year before expected exfoliation, the permanent tooth will probably be delayed in eruption owing to healing that results in filling in of bone and gingiva over the permanent tooth. The loss of a primary tooth may cause adjacent teeth to tip into the space and lead to impaction of the underlying permanent tooth. A space maintainer should be placed by a dentist to avoid impaction.

Other local factors delaying or preventing eruption include supernumerary teeth, cysts, tumors, overretained primary teeth, ankylosed primary teeth, and impaction. A generalized delay in eruption may be associated with global developmental delays, endocrinopathies (hypothyroidism or hypopituitarism), or other systemic conditions (cleidocranial dysplasia, rickets, or trisomy 21).

Ectopic Eruption

If the dental arch provides insufficient room, permanent teeth may erupt ectopically and cause a usually painless root resorption in the adjacent primary tooth. This phenomenon is more common in the maxilla, with ectopic eruption of the maxillary first permanent molar being the most frequent. In the mandible, lower incisors may erupt lingually and thus the primary predecessor may be retained. Parental concern about a “double row of teeth” may be the reason for the child's first dental visit. If the primary teeth are not loose,

they should be removed by the dentist to allow their successors to drift into proper position.

Impaction

Impaction occurs when a permanent tooth is prevented from erupting. Although crowding is the most frequent reason, overretained primary or supernumerary teeth are other causes. The teeth most often affected in the developing dentition are the maxillary canines. Generally, they are brought into correct alignment through surgical exposure and orthodontic treatment.

Variations in Tooth Number

Failure of teeth to develop—a condition called hypodontia—is rare in the primary dentition. However, it occurs about 5% of the time in the permanent dentition. The most frequently missing teeth are the third molars followed by the lateral maxillary incisors and mandibular second premolars. Oligodontia, a condition in which only a few teeth develop, occurs in patients with ectodermal dysplasias. Partial dentures should be considered as early as 3 years of age to improve the patient's ability to chew.

Occasionally, supernumerary teeth are present, most typically in the maxillary incisor area, distal to the maxillary molars, or in the mandibular bicuspid region. Mesiodentes are peg-shaped supernumerary teeth situated at the maxillary midline that occur in about 5% of individuals. If they hinder eruption of adjacent permanent incisors, their timely removal is recommended.

DENTAL CARIES

► General Considerations

Dental caries is biofilm-mediated acid demineralization of dental enamel or dentin. It is the most common chronic childhood disease and the most prevalent unmet health need of U.S. children. Caries is largely a disease of poverty; the 29 million children and adolescents in low-income families account for 80% of patients with tooth decay.

► Pathogenesis

Development of caries requires the interaction of four factors: (1) a host (tooth in the oral environment), (2) a suitable

dietary substrate (fermentable carbohydrates), (3) cariogenic microorganisms that can adhere to the tooth, and (4) time, measured as the frequency of exposure to fermentable carbohydrates and the duration of the acid attack. Demineralization of the dental enamel occurs below a pH of 5.5, therefore flow and buffering capacity of saliva is an important modifier.

The main bacteria implicated in the initiation of caries are *Streptococcus mutans* and *S sobrinus*; *Lactobacillus acidophilus* and *L casei* are linked to progression of caries. *S mutans* is most commonly transmitted from mother to child. A “window of infectivity” between 19 and 33 months of age has been described, but colonization can occur as early as 3 months of age. Earlier colonization increases the risk of caries. The greatest impact physicians can have on this disease is through early referral of high-risk children to dental practitioners.

Dental plaque is an adherent film on the tooth surface that harbors bacteria in close proximity to the tooth enamel. As the bacteria metabolize sucrose, they produce lactic acid. The acidic environment causes the enamel of the teeth to decalcify. This is the first step in production of caries. After the carious process has penetrated the enamel, it advances through the dentin towards the pulp of the tooth. In response, blood vessels in the pulp dilate and inflammatory cells begin to infiltrate (pulpitis). If the carious lesion is left untreated, a frank pulp exposure will occur, triggering invasion of more inflammatory cells and the eventual formation of a small abscess in the pulp. If the abscess can drain into the oral cavity, the apical tooth tissue may remain vital. However, if the radical pulp becomes necrotic, a periapical abscess develops (Figure 16–6). Although this process is not always symptomatic, it often leads to severe pain, fever, and swelling.

► Clinical Findings & Treatment

The diagnosis of caries is usually made by a visual-tactile oral examination using a dental explorer supplemented by radiographs. Radiographs are used to visualize caries on the surfaces between teeth that cannot be reached with the dental explorer. The earliest sign of caries is a white spot lesion—a white, chalky, decalcified area along the gingival margin or on approximated tooth surfaces. Frank carious lesions are light to dark brown spots or cavities of varying size on a tooth. A lighter shade of brown indicates more rampant decay, whereas arrested caries are almost black in

▲ **Figure 16–6.** Tooth anatomy and progression of caries.

color. In the early stages of decay, the tooth may be sensitive to temperature changes or sweets. At this point, the tooth can be repaired by removing the carious tooth structure and filling the defect with a restorative material. As decay progresses deeper into the pulp pain increases as more of the still-vital pulp becomes necrotic. Once the entire pulp is necrotic and nonvital, a choice must be made between root canal therapy (pulpectomy) or removal of the tooth. In the presence of cellulitis or facial space abscess, extraction with antibiotic therapy is the treatment of choice.

Because cavitation is a late stage of the disease, filling cavities does nothing to address the underlying pathologic process. Unlike other infections, dental caries cannot be treated by a simple course of antibiotics. The disease can only be cured through treatment of the pervasive oral infection, a sustained reduction in the number of cariogenic bacteria, and the creation of a favorable oral environment. To achieve this, a patient's (and ideally a family's) diet must be changed to avoid the frequent intake of fermentable carbohydrates in solid and liquid form. All active cavities must be restored to eliminate sources of reinfection and meticulous oral hygiene practices embraced to prevent plaque buildup and reduce the number of bacteria. Regular dental visits must be maintained to monitor and reinforce good oral health practices. The concept of prevention through timely parent education, early diagnosis, and prompt intervention offers greater efficiency, better health outcomes, and lower costs than repeated restoration of diseased teeth.

► Caries Prevention

To prevent dental caries, it is necessary to remove plaque and its resident cariogenic bacteria on a regular basis.

A. Oral Hygiene

Oral hygiene should start at birth. The gums can be cleaned gently with a moist, soft cloth. Once the teeth begin to erupt, oral hygiene must be practiced in earnest. A small, soft toothbrush designed for infants should be used. Toothpaste is not necessary but should be added by age 2 years. Prior to age 8 years parents need to be involved daily in brushing and flossing. Brushing with fluoride-containing toothpaste at least twice daily and regular flossing will help to reduce the count of cariogenic bacteria in the oral flora. A second step is to decrease the amount of substrate available to the bacteria. Limiting the frequent ingestion of refined carbohydrates is most effective because each exposure produces an acidic environment for up to 30 minutes. This explains the particularly deleterious effects of frequent consumption of sugar-containing juices, sodas, and infant formulas through a nursing bottle. The primary care physician plays an invaluable role in disseminating this information and reinforcing these ideas.

Children with special health care needs require dental advice and care more frequently. Children with serious medi-

Table 16–1. Dietary fluoride supplementation schedule.

Age	Concentration of Fluoride in Water		
	< 0.3 ppm F	0.3–0.6 ppm F	> 0.6 ppm F
Birth–6 mo	0	0	0
6 mo–3 y	0.25 mg	0	0
3–6 y	0.50 mg	0.25 mg	0
6–at least 16 y	1.00 mg	0.50 mg	0

cal problems or disabilities should be referred to a pediatric dentist as early as possible, usually before 1 year of age.

B. Fluoride

Fluorides are safe and effective for caries control and prevention. Fluoride can be applied professionally or by the patient under supervision. Although more than half the U.S. population has access to fluoridated community water, an increasing number of families consume processed water with unknown fluoride content. The cariostatic mechanisms of fluoride include increased resistance to demineralization, enhanced remineralization, and inhibition of bacterial colonization of dental plaque. Fluoride affects the dentin and enamel of both erupted and unerupted teeth. Systemic effects are achieved by oral ingestion from sources such as fluoridated drinking water or fluoride supplements. Fluoridated toothpaste and mouth rinses deliver topical benefits. Table 16–1 shows the current AAP and AAPD recommendations for dietary fluoride supplementation in children drinking fluoride deficient water. The patient's true exposure to fluoride must be judiciously evaluated before supplements are prescribed to avoid dental fluorosis. Because children younger than 6 years of age cannot expectorate reliably, the use of fluoridated toothpaste must be monitored by their parents and the recommendation to use only a "pea-sized" amount of toothpaste should be followed. Higher risk individuals with orthodontic appliances, reduced salivary function, or gastroesophageal reflux disease, or those who are unable to clean their teeth properly, are at dietary risk, have mothers or siblings with caries, or have active caries should be considered for additional topical fluoride therapy to supplement oral hygiene measures.

PERIODONTAL DISEASE

Periodontal disease involves a tooth's supporting structures: bone, gingiva, and periodontal ligaments (Figure 16–7). It begins as inflammation of the gingival tissue adjacent to a tooth. Bacterial accumulation in the gingival sulcus causes irritation and inflammation. This beginning phase is called dental plaque–induced gingivitis, and it is found almost universally in children and adolescents. Alterations in hormone

▲ Figure 16-7. Periodontal disease.

levels (insulin, gonadotropin) can intensify the inflammatory response to plaque. Generally, this condition responds well to removal of bacterial deposits and improved oral hygiene.

Periodontitis is characterized by loss of attachment and destruction of bone. Patients with localized aggressive periodontitis typically have severe alveolar bone loss around permanent first molars and incisors, whereas the generalized form involves other teeth as well. The prevalence is 0.2% in Caucasians, but much higher (2.5%) in African Americans. Familial aggregation and functional defects such as anomalies of neutrophil chemotaxis, phagocytosis, and bacterial activity increase the risk of periodontitis. *Actinobacillus actinomycetemcomitans* in combination with *Bacteroides*-like species are implicated in this disease. An association between maternal periodontal disease and preterm birth has been established. It is currently unclear whether this association involves causation or it is a marker for another etiology.

Treatment consists of combined surgical and nonsurgical root debridement plus antibiotic therapy. Isolated chronic periodontitis is rare in children and adolescents but may complicate conditions such as Papillon-Lefèvre and Down syndromes, cyclic neutropenia, hypophosphatasia, agranulocytosis, and leukocyte adherence defects.

The incidence of necrotizing periodontal disease is lower (1%) in North America than in developing countries (2–5%). Necrotizing periodontal disease is characterized by interproximal ulceration and necrosis of the dental papillae, rapid onset of dental pain, and often fever. Predisposing factors include viral infections (including HIV), malnutrition, emotional stress, and systemic disease. The condition usually responds rapidly to treatment consisting of mechanical debridement with ultrasonic scalers, improved oral hygiene, and metronidazole and penicillin for febrile patients.

OROFACIAL TRAUMA

Orofacial trauma often consists only of abrasions or lacerations of the lips, gingiva, tongue, or oral mucosa (including the frena), without damage to the teeth. Lacerations should be cleansed, inspected for foreign bodies, and sutured if necessary. Occasionally, radiographs of the tongue, lips, or cheeks are needed to detect tooth fragments or other foreign bodies. All patients with facial trauma should be evaluated for jaw fractures. Blows to the chin are among the most

▲ Figure 16-8. Patterns of luxation injuries.

common childhood orofacial traumas. They are also a leading cause of condylar fracture in the pediatric population. Condylar fracture should be suspected if pain or deviation occurs when the jaw is opened.

Tooth-related trauma affects any or all of the dental hard tissues and the pulp, the alveolar process, and the periodontal tissues. The range of luxation injuries includes concussion; subluxation; intrusive, extrusive, and lateral luxation; and avulsion. Figure 16-8 demonstrates the different luxation injuries, and Figure 16-9 shows the different degrees of tooth fracture.

The least problematic luxation injuries are concussion (no mobility) and subluxation (mobility without displacement). Unless mobility is extensive, this condition can be followed without active intervention. Pulp vitality should be periodically assessed.

Primary Teeth

The peak age for injuries to primary teeth is toddlerhood. Any treatment must include measures to ensure the integrity

▲ Figure 16-9. Patterns of crown fractures.

of the permanent teeth. Parents should be advised of any permanent tooth complications such as enamel hypocalcifications or crown-root dilacerations caused by intrusion injuries of primary maxillary front teeth. An intrusive luxation is usually observed for a period of time to discern whether the tooth or teeth will spontaneously re-erupt (see Figure 16–8). Severe luxations in any direction are treated with extraction. Avulsed primary teeth are not replanted. In a root fracture, the crown and apical fragment are generally extracted. The latter should be left for physiologic resorption if its retrieval would result in potential damage to the permanent tooth.

Permanent Teeth

Because the prognosis for viability worsens rapidly as time outside the mouth increases, avulsed permanent teeth should be replanted at or near the site of injury following gentle rinsing with clean water. The patient should seek emergency dental care immediately thereafter. Hank's Balanced Salt Solution is the best storage and transport medium for avulsed teeth that are to be replanted. The next best storage media in decreasing order are milk, saline, saliva (buccal vestibule), or water. The commercially available Food and Drug Administration–approved Save-a-Tooth kit should be part of first-aid kits in schools and sports facilities (see references).

Intrusions of permanent teeth are corrected with surgical or orthodontic repositioning. Lateral and extrusive luxations are generally repositioned and splinted for a minimum of 3–4 weeks. Root canal treatment is necessary in the majority of injuries. Factors to consider during treatment planning are root development (open or closed apex) and the extent of the luxation. Pulp necrosis; surface, inflammatory, and replacement resorption; or ankylosis may occur at any time during the healing process and determine the long-term outcome. All luxated and replanted teeth need to be followed regularly by a dentist.

DENTAL EMERGENCIES

Dental emergencies other than trauma are usually associated with pain or swelling due to advanced caries. Odontogenic pain usually responds to acetaminophen or ibuprofen. Topical medications are of limited value.

A localized small swelling confined to the gingival tissue associated with a tooth is usually not an urgent situation. This “gumboil” or parulis represents infection that has spread outward from the root of the tooth through the bone and periosteum. Usually it will drain and leave a fistulous tract. Facial cellulitis results if the infection invades the facial spaces. Elevated temperature ($> 38.8^{\circ}\text{C}$), difficulty swallowing, and difficulty breathing are signs of more serious infection. Swelling of the midface—especially the bridge of the nose and the lower eyelid—should be urgently evaluated as a potential dental infection. Extraction of teeth or root canal therapy

combined with antibiotics is the usual treatment. Hospitalization is a prudent choice for younger children with severe facial cellulitis especially if other risk factors are present—dehydration, airway compromise, or possible noncompliance. Inpatient treatment consists of intravenous antibiotics such as clindamycin or ampicillin-sulbactam (Unasyn) with incision, drainage, and removal of the source of infection.

ANTIBIOTICS IN PEDIATRIC DENTISTRY

The antibiotics of choice for odontogenic infection are clindamycin and penicillin. Several patient groups require prophylactic antibiotic coverage prior to invasive dental manipulation. These include children with artificial heart valves, previous infectious endocarditis, certain congenital heart conditions, immunodeficiency, or central venous catheters. Revised guidelines for infective endocarditis prophylaxis were published by the American Heart Association in April 2007.

SPECIAL PATIENT POPULATIONS

Children with Cancer

The most common source of systemic sepsis in the immunosuppressed patient with cancer is the oral cavity. Therefore, children with cancer should be evaluated by a dentist knowledgeable about pediatric oncology soon after diagnosis. The aim is to educate the patient and caregivers about the importance of good oral hygiene and to eliminate all existing and potential sources of infection before the child becomes neutropenic as a consequence of chemotherapy. Younger patients have more oral problems than adults. Sources of infection include abscessed teeth, extensive caries, teeth that will soon exfoliate, ragged or broken teeth, uneven fillings, and orthodontic appliances. After an initial evaluation and before the initiation of cancer therapy, a dental treatment plan should be developed in discussion with the medical team. Preventive strategies include reduction of refined sugars, fluoride therapy, lip care, and patient education. Chemotherapeutic drugs and local irradiation are cytotoxic to the oral mucosa, which becomes atrophic and develops mucositis. Oral pain may be severe and often leads to inadequate food and fluid intake, infections in the oral cavity, and an increased risk of septicemia. Meticulous oral hygiene reduces the risk of severe mucositis.

The pediatric oncology patient should be monitored throughout therapy to screen for infection, manage oral bleeding, and control oral pain. These patients can experience spontaneous oral hemorrhage, especially when the platelet count is less than 20,000/mL. Poor oral hygiene or areas of irritation can increase the chances of bleeding.

Children receiving radiation therapy to the head and neck may develop salivary dysfunction (xerostomia) if salivary glands are in the path of the beam of radiation. Xerostomia should be managed aggressively to avoid rapid and

extensive destruction of the teeth. Customized fluoride applicators are used in this situation in combination with close follow-up.

Children receiving hematopoietic cell transplantation may require long periods of immunosuppression. During the neutropenic phase of pretransplant conditioning, mucositis, xerostomia, oral pain, oral bleeding, and opportunistic infections may occur. Oral graft-versus-host disease as well as oral fungal and herpes simplex virus infections can be seen during the subsequent initial engraftment and hematopoietic reconstitution period. Long-term dental follow-up includes management of salivary dysfunction and craniofacial growth abnormalities from total body radiation and treatment of oral graft-versus-host disease.

Pediatric oncology patients need regular care by a dentist familiar with young children and their growth and development. Oral and maxillofacial growth disturbances can occur after therapy. Late effects of therapy include such morphologic changes as microdontia, hypocalcification, short and blunted roots, delayed eruption, and alterations in facial bone growth.

Children with Hematologic Disorders

The child with hemophilia requires appropriate clotting factors before and after any invasive dental procedures, including local block anesthesia. Patients with factor VIII inhibitors who require oral surgical procedures should be admitted to a hospital. Some patients with very mild factor VIII deficiency or von Willebrand disease type 1 may respond to DDAVP (1-deamino-8-D-arginine vasopressin). Antifibrinolytic medications such as ϵ -aminocaproic and tranexamic acid are used successfully after dental treatment. Topical medications such as Gelfoam and thrombin can be used to control postoperative bleeding. Patients receiving anticoagulant therapy should generally not undergo dosage adjustment before surgical dental treatment because the risk of embolic complications is much higher than bleeding complications in those whose anticoagulant therapy is continued. However, the dentist is advised to consult with the hematologist to obtain the most recent INR (international normalized ratio) results and to discuss the most appropriate level of anticoagulation.

Children with Diabetes

Children who are insulin-dependent have significantly higher incidence of plaque, gingival inflammation, and attachment loss. They are, therefore, at high risk for periodontal disease. However, only those who are in poor metabolic control have an increased rate of caries. Care must be taken not to disturb the regular cycle of eating and insulin dosage. Anxiety associated with dental appointments can cause a major upset in the diabetic child's glycemic control. Postoperative pain or pain from dental abscess can prevent routine oral intake, necessitating adjustment of insulin doses.

MATERNAL-FETAL RELATIONSHIP

Childhood caries is an infectious disease transmitted by bacteria from the mother to the child. Infants whose mothers have high levels of *S mutans* are at greater risk for acquiring the organism. Dental treatment of their mothers or primary caregivers can delay or prevent the inoculation of the infant. A significant association between maternal periodontitis at 21–24 weeks' gestation and preterm birth has been reported. However, according to a more recent study, periodontal treatment of expectant mothers does not improve the incidence of preterm delivery or significantly improve birth weight. The risk of preterm birth is elevated if a mother smokes and is of low socioeconomic status, both of which also increase the risk for periodontitis. Secondhand or passive smoke increases the risk of caries in children. This association is independent of age, family income, geographic region, and frequency of dental visits. It is important to advise expectant mothers about these risk factors.

There is a higher risk of oral developmental anomalies in preterm and low birth weight infants than in full-term infants. These developmental anomalies include enamel hypoplasia of the primary dentition, crown dilaceration of the permanent maxillary incisors, and a narrow palate caused by laryngoscopy or prolonged endotracheal intubation. The role of palatal protection plates to prevent "grooving" remains unclear. It is difficult to distinguish delayed dental development of preterm infants from that associated with global developmental delays.

DENTAL & ORTHODONTIC REFERRAL

Orthodontic referral is usually made by the dentist. Early referral is indicated for any child with a craniofacial growth disorder. Other children may be referred at any time between ages 6 and 12 years, depending on their growth and oral development. Orthodontists differ about when to begin treatment. Many pediatric dentists provide early orthodontic management as a part of their practices.

THE EAR

INFECTIONS OF THE EAR

The spectrum of infectious ear diseases includes the structures of the outer ear (otitis externa), the middle ear (acute otitis media), the mastoid bone (mastoiditis), and the inner ear (labyrinthitis).

1. Otitis Externa

Otitis externa is inflammation of the skin lining the ear canal and surrounding soft tissue. The most common cause is loss of the protective function of cerumen, leading to maceration of the underlying skin such as occurs with swimming. Other causes are trauma to the ear canal from using cotton-tipped applicators for cleaning or from using poorly fitted ear plugs while swimming; contact dermatitis due to hair sprays, perfumes, or self-administered ear drops; secondary infection of the canal from otitis media with a patent tympanostomy tube; and chronic drainage from a perforated tympanic membrane (TM). Infections due to *Staphylococcus aureus* or *Pseudomonas aeruginosa* are the most common.

Symptoms include pain and itching in the ear, especially with chewing or pressure on the tragus. Movement of the pinna or tragus causes considerable pain. Drainage may be minimal unless the otitis externa is from a draining pressure equalization tube or TM perforation. The ear canal is typically grossly swollen, and the patient may resist any attempt to insert an ear speculum. Debris is noticeable in the canal. It is often impossible to visualize the TM. Hearing is normal unless complete occlusion has occurred.

► Treatment

Topical treatment usually suffices. Fluoroquinolone drops may be more effective than traditional combination drops and are safer to use. If the TM cannot be seen, then a perforation should be presumed to exist. Children with otitis

externa secondary to draining tubes or perforations should be treated with topical therapy only in the absence of systemic symptoms. The topical therapy chosen must be safe for the inner ear because the perforation or the patent tube allows the drops access to the middle and inner ear. If the ear canal is open, ototopical antibiotics are placed and prescribed for 5–7 days as indicated. If the canal is too edematous to allow the ear drop to get in, a Pope ear wick (expandable sponge) is needed for the first few days to assure antibiotic delivery. Oral antibiotics are indicated if any signs of invasive infection, such as fever, cellulitis of the auricles, or tender postauricular lymph nodes, are present. In such cases, prescribe an antistaphylococcal antibiotic while awaiting the results of the cultured ear canal discharge. Systemic antibiotics alone without topical treatment will not successfully treat otitis externa. Narcotic analgesics may be required until the infection begins to resolve in 2–3 days.

During the acute phase, the patient should avoid swimming. A cotton ear plug is not helpful and may prolong the infection. Schedule a follow-up visit in 1 week to document an intact TM (Figure 17–1). Children who have intact TMs and are predisposed to external otitis should receive 2 or 3 drops of a 1:1 solution of white vinegar and 70% ethyl alcohol into the ears before and after swimming.

2. Acute Otitis Media

► Classification & Clinical Findings

Otitis media is an infection associated with middle ear effusion (a collection of fluid in the middle ear space) or with otorrhea (a discharge from the ear through a perforation in the TM or

▲ **Figure 17-1.** Tympanic membrane.

a ventilating tube). Otitis media can be further classified by its associated clinical symptoms, otoscopic findings, duration, frequency, and complications. These more specific classifications are acute otitis media (AOM), otitis media with effusion (OME), and chronic suppurative otitis media.

AOM is commonly defined as inflammation of the middle ear resulting in an effusion and associated with rapid onset of symptoms such as otalgia, fever, irritability, anorexia, or vomiting. The 2004 Guidelines from the American Academy of Pediatrics and of the American Academy of Family Physicians specified three criteria which must be present (Table 17-1). The presence of an ear effusion is best determined by either pneumatic otoscopy or tympanometry. To distinguish

AOM from OME, signs of inflammation of the TM and symptoms of acute infection must be present. Otosopic findings specific for AOM are a bulging TM, impaired visibility of the ossicular landmarks, a yellow or white color, opacification of the eardrum, and squamous exudate or bullae on the eardrum. OME is associated with a nonbulging TM, which may be retracted or neutral, but always has decreased mobility, may have opacification, and may have white or amber discoloration. Children with OME may develop superimposed acute infection, but they will then exhibit inflammation of the eardrum as described for AOM.

A. Predisposing Factors

Factors that make otitis media more common in children than in adults include bacterial nasopharyngeal colonization in the absence of antibody, frequent upper respiratory infections, exposure to parental cigarette smoke, unfavorable eustachian tube function, and allergies.

1. Bacterial colonization—Nasopharyngeal colonization with *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Moraxella catarrhalis* increases the risk of otitis media, whereas colonization with normal flora such as viridans streptococci may prevent otitis episodes by inhibiting the growth of these pathogens. Colonization usually occurs sequentially with different pathogen serotypes present for about 2 months, and there is a risk of AOM with each new serotype acquired. Infants in day care acquire these serotypes at a younger age than those in home care. Since younger children are at higher risk of AOM, the increased number of children in day care over the past three decades has undoubtedly played a major role in the increase in AOM in the United States.

2. Viral upper respiratory infections—These infections increase the colonization of the nasopharynx with otitis

Table 17-1. Definition of acute otitis media (AOM).

A diagnosis of AOM requires (1) a history of acute onset of signs and symptoms, (2) the presence of MEE, and (3) signs and symptoms of middle-ear inflammation.

Elements of the definition of AOM are all of the following:

1. Recent, usually abrupt, onset of signs and symptoms of middle-ear inflammation and MEE
2. The presence of MEE that is indicated by any of the following:
 - a. Bulging of the tympanic membrane
 - b. Limited or absent mobility of the tympanic membrane
 - c. Air-fluid level behind the tympanic membrane
 - d. Otorrhea
3. Signs or symptoms of middle ear inflammation as indicated by either
 - a. Distinct erythema of the tympanic membrane or
 - b. Distinct otalgia (discomfort clearly referable to the ear[s]) that results in interference with or precludes normal activity or sleep

MEE, middle ear effusion.

pathogens. Viral infection also impairs eustachian tube function by causing both adenoidal swelling and edema of the tube. Therefore, factors that increase the frequency of viral respiratory infections, such as child care attendance, smoke exposure, later birth order, and absence of breast feeding, promote colonization with otitis pathogens and predispose to otitis media.

3. Smoke exposure—Passive smoking increases the risk of persistent middle ear effusion by enhancing colonization, prolonging the inflammatory response, and impeding drainage through the eustachian tube. For infants aged 12–18 months, exposure to each additional pack of cigarettes smoked at home is associated with an 11% increase in the duration of a middle ear effusion.

4. Eustachian tube dysfunction—Infants born with craniofacial disorders, such as Down syndrome or a cleft palate, are often affected by AOM and OME. The patency of the tube allows aeration of the middle ear. When the tube is obstructed, a vacuum develops in the middle ear, which can pull nasopharyngeal secretions and pathogens into the middle ear or can pull serous fluid from the middle ear lining cells. Either way, the fluid is then prone to infection.

5. Impaired host immune defenses—Immunocompromised children such as those with selective IgA deficiency usually experience recurrent AOM, rhinosinusitis, and pneumonia. However, most children who experience recurrent or persistent otitis only have selective impairments of immune defenses against specific otitis pathogens. For example, a recent study showed some children have low-to-absent IgG2 or IgA pneumococcal polysaccharide antibody responses (or both) after vaccination, despite normal serum levels of total IgG₂ and IgA.

6. Bottle feeding—Breast feeding reduces the incidence of acute respiratory infections, provides IgA antibodies that reduce colonization with otitis pathogens, and decreases the aspiration of contaminated secretions into the middle ear space when a bottle is propped in the crib.

7. Genetic susceptibility—Although AOM is known to be multifactorial, and no gene for susceptibility has yet been identified, recent studies of twins and triplets suggest that as much as 70% of the risk is genetically determined. This has implications for the subsequent offspring of parents with a child experiencing recurrent AOM. These families might wish to consider breast feeding and home child care for later children.

B. Microbiology of Acute Otitis Media

The role of respiratory viral infection in precipitating otitis media is unquestionable, yet fewer than 12% of ear effusions culture positive for viruses. Recent studies with sensitive viral antigen or nucleic acid tests have detected virus in over 40% of infected ears. The viral infection usually precedes the

bacterial otitis media by 3–14 days and presumably causes adenoid hypertrophy and eustachian tube dysfunction. The two viruses most clearly shown to precipitate otitis media are respiratory syncytial virus and influenza, accounting for the annual surge in otitis media cases from January to May in temperate climates.

Historically, over 50% of AOM cases in the midwestern and northeastern United States were due to *S pneumoniae*, while the hotter, drier climates of southern Israel and Denver, Colorado, reported a preponderance of nontypeable *H influenzae* (Table 17–2). However, since widespread use of the pneumococcal conjugate vaccine (Prevnam; PCV7) in children younger than 2 years of age, the incidence of *H influenzae* may be on the rise and that of *S pneumoniae* may be declining. The pattern of infection in Kentucky now resembles that seen before PCV7 in Colorado. (No data are available for Denver in the post-Prevnam era.) More importantly, Prevnam has increased the percentage of cases due to non-PCV serotypes nationally from 12% in 1999 to 32% in 2002. The clinical significance of this change is to decrease the overall percentage of drug-resistant pneumococci, since the serotypes included in the vaccine are the most multiply resistant.

The third most common pathogen in some studies is *M catarrhalis*, which causes up to 25% of AOM cases in the United States. The fourth organism found is *Streptococcus pyogenes*, which is more common in school-aged children than in infants. This organism and *S pneumoniae* are the predominant causes of mastoiditis. Contrary to earlier teaching, the etiology of AOM in early infancy differs little from that in adult life. The only difference is that the risk of gram-negative enteric infection is slightly increased in infants younger than age 4 weeks who are or have been hospitalized in a neonatal intensive care nursery.

Table 17–2. Bacteriology of acute otitis media.

	Denver (Author)	Kentucky ^a Pre-PCV7 (Prevnam)	Kentucky ^a Post-PCV7

PCV7, seven-valent pneumococcal vaccine.

^aData used, with permission, from Block SL et al: Community-wide vaccination with the heptavalent pneumococcal conjugate significantly alters the microbiology of acute otitis media. *Pediatr Infect Dis J* 2004;23:829.

Drug-resistant *S pneumoniae* is a common pathogen in AOM and strains may be resistant to only one drug (ie, penicillin or macrolides) or to multiple classes. Children with resistant strains tend to be younger and to have had more unresponsive infections. Antibiotic treatment in the preceding 3 months also increases the risk of harboring resistant pathogens. Penicillin resistance develops through stepwise mutations in the structure of the three penicillin-binding proteins. Strains for which minimum inhibitory concentrations of penicillin range between 0.12 and 1.0 mcg/mL are said to exhibit “intermediate” resistance. Strains for which minimum inhibitory concentrations are equal to or higher than 2 mcg/mL are said to have “high-level resistance.” The prevalence of resistant strains no longer varies significantly among geographic areas within the United States, but it does vary worldwide. Lower incidences are found in countries using fewer courses of antibiotic per person. These strains are also resistant to many other drug classes. Nationwide resistance rates include 63% for trimethoprim-sulfamethoxazole, 32% for macrolides, and 2% for amoxicillin (dosed at 90 mg/kg/d). Oral cephalosporins vary widely in efficacy, with the highest resistance rates for cefixime and cefaclor and lowest rates (about 35%) for cefuroxime, cefprozil, cefpodoxime, and cefdinir. Over 90% of highly penicillin-resistant strains are still susceptible to clindamycin, rifampin, and fluoroquinolones. Fluoroquinolones are not yet approved for children younger than 16 years; however, studies are under way to assess their safety and efficacy in this age group.

C. Examination Techniques and Procedures

1. Pneumatic otoscopy—AOM is overdiagnosed. Contributing to errors in diagnosis are the temptation to accept the diagnosis without removing enough cerumen to adequately visualize the eardrum, and the mistaken belief that a red eardrum establishes the diagnosis. In fact, redness of the eardrum is often a vascular flush caused by fever, crying, or even efforts to remove cerumen. Failure to achieve an adequate seal with the otoscope, poor visualization due to low light intensity, and mistaking the ear canal wall for the membrane can make it impossible to assess eardrum mobility.

A pneumatic otoscope with a rubber suction bulb and tube is used to assess mobility of the TM. The speculum inserted into the patient’s ear canal must be large enough to provide an airtight seal. Placing a piece of rubber tubing 0.25–0.5 cm wide near the end of the ear speculum helps to create an adequate pneumatic seal. The tubing should fit snugly on the speculum at a distance about 0.5 cm from its end. The largest possible speculum (usually 3 or 4 mm) should be used to maximize the field of view. When the rubber bulb is squeezed, the TM will move freely to and fro if no fluid is present with a snapping motion; if fluid is present in the middle ear space, the mobility of the TM will be absent or resemble a fluid wave. The ability to assess mobility is compromised by low light intensity; a halogen

source is necessary. These bulbs dim but rarely ever burn out, so they must be replaced on a schedule.

Disposable ear specula have become popular but are not needed for infection control, because reusable specula can be easily disinfected. The disposable specula are sharp at the tip and often cause pain when pushed to get an airtight seal. It is advisable to consider using a smaller speculum to assess the entire TM and then place a larger speculum to stay within the outer cartilaginous ear canal when assessing mobility.

2. Cerumen removal—Cerumen removal is an essential skill for anyone who cares for children. Impacted cerumen pushed against the TM can cause itching, otalgia, or hearing loss. Parents should be advised that ear wax protects the ear (cerumen contains lysozymes and immunoglobulins that inhibit infection) and usually comes out by itself; therefore, parents should never put anything solid into the ear canal to remove the ear wax.

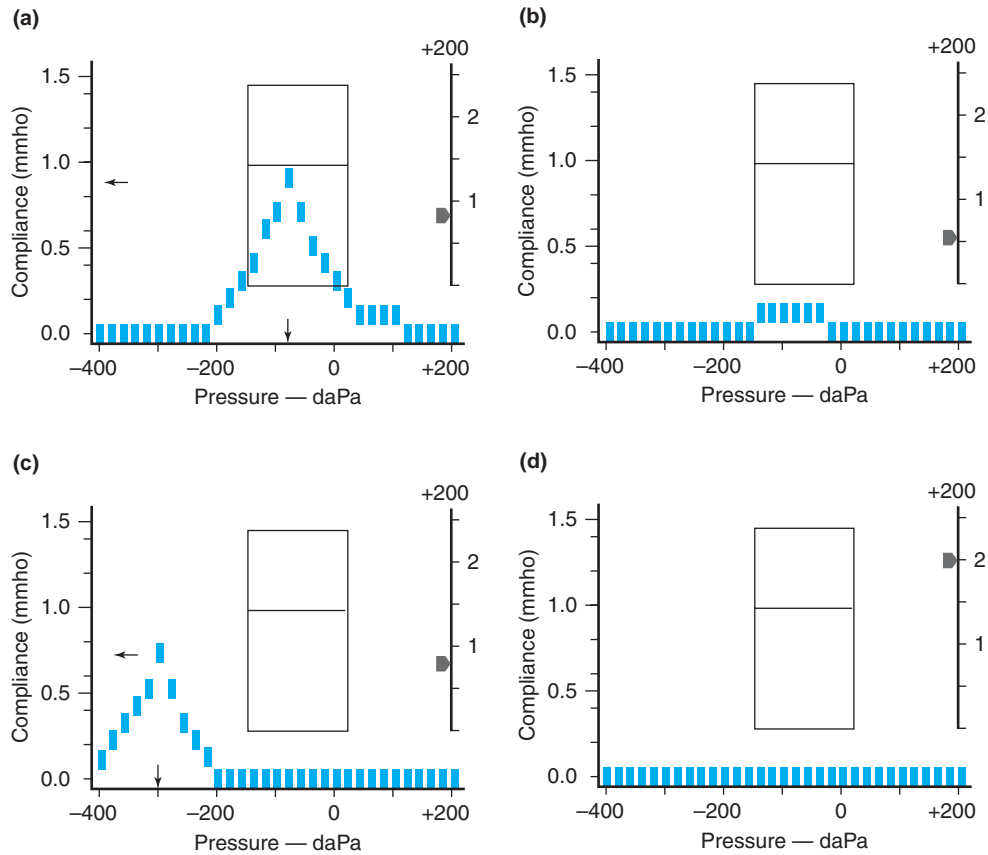

The physician may safely remove cerumen under direct visualization through the operating head of an otoscope, provided two adults are present to hold the child. A plastic disposable ear size 0 curette may be used. Any curette used should not be pointed or sharp.

Irrigation can also be used to remove hard or flaky cerumen. Asian children may have an ear wax variant that is flaky, called “rice bran wax.” This type of wax can be softened with 1% sodium docusate solution, carbamyl peroxide solutions, mineral oil, or a few drops of detergent before irrigation is attempted. After 20 minutes, irrigation with a soft bulb syringe can be started with water warmed to 35–38°C to prevent vertigo. A commercial jet tooth cleanser (eg, Water Pik) is also an excellent device for removing cerumen, but it is important to set it at low power (2 or less) to prevent damage to the TM. A perforated TM or patent tympanostomy tube is a contraindication to any form of irrigation.

A good home remedy for recurrent cerumen impaction is a few drops of oil such as mineral or olive oil a couple of times a week warmed to body temperature to prevent dizziness.

3. Tympanometry—Tympanometry can rapidly identify an effusion in infants over about 6 months, and it requires little training. It should be preceded by pneumatic otoscopy to assure that 50% or more of the canal is wax-free. Because it does not identify inflammation, it cannot differentiate AOM and OME. Tympanometry measures TM compliance and displays it in graphic form (along the y axis, expressed in mm H₂O). Compliance is determined as air pressures are varied from +200 to –400 mm H₂O in the sealed external ear canal.

Tympanograms can be classified into four major patterns, as shown in Figure 17–2. The pattern shown in Figure 17–2A, characterized by maximum compliance at normal atmospheric pressure, indicates a normal TM, good eustachian tube function, and absence of effusion. The height and sharpness of the peak is not important when using the Welch-Allyn tympanometer. The pattern shown in Figure 17–2B identifies a nonmobile TM, which indicates middle

▲ **Figure 17-2.** Four types of tympanograms obtained with Welch-Allyn MicroTympan 2. **A:** Normal middle ear. **B:** Otitis media with effusion or acute otitis media. **C:** Negative middle ear pressure due to eustachian tube dysfunction. **D:** Patent tympanostomy tube or perforation in the tympanic membrane. Same as B except for a very large middle ear volume.

ear effusion. The pattern shown in Figure 17-2C indicates an intact mobile TM with poor eustachian tube function and excessive negative pressure (worse than -300 mm H₂O air pressure) in the middle ear. Figure 17-2D shows a flat tracing, which would have a very large middle ear volume on the printout, due to a patent tube or large perforation.

4. Acoustic reflectometry—Acoustic reflectometry measures the spectral gradient of the TM using a handheld instrument, without requiring an airtight seal. However, recent data suggest that this method cannot reliably distinguish negative middle ear pressure from effusion. The instrument is not commercially available at present.

► Treatment

A. Pain Management

Children with pain related to AOM may obtain relief from acetaminophen or ibuprofen, accompanied by a topical

anesthetic drop. In a randomized controlled trial, Auralgan (benzocaine and antipyrine) ear drops were superior to olive oil in reducing pain. When severe pain is present, tympanocentesis should be considered for pain relief and to diagnose the causative pathogen.

B. The Observation Option (Watchful Waiting)

Few issues are as controversial as the necessity of immediate antibiotic treatment of otitis media. Doctors must balance the desire of the parents for symptom relief against the risk of selecting for drug resistance by overuse of antibiotics. In two recent editorials, Dr. Ellen Wald has pointed out that the major overuse of antibiotics is for the treatment of viral colds and viral pharyngitis, not otitis media. The second reason for antibiotic overuse is overdiagnosis of AOM by providers. The natural history of untreated AOM is to improve through host defenses or by perforation of the TM; but mastoiditis was not an infrequent complication before the use of antibiotics.

In Dr. Howie's classic studies in the 1970s, in which he randomized children to placebo or various antibiotics, bacteriologic cure rates determined by a second tympanocentesis while on therapy were only 32% in the placebo group. The spontaneous cure rate varied greatly by organism: 16% for *S pneumoniae*, 50% for nontypeable *H influenzae*, and about 84% for *M catarrhalis*, which he considered a contaminant. Several authors have correlated clinical cure rates at the end of therapy with bacteriologic cure on days 4–6, and clinical cure rates are always higher than bacteriologic cure rates. However, the children who are bacteriologic failures at the end of treatment have an extremely high likelihood of also experiencing clinical failure. This has important implications for study design, which has led the Food and Drug Administration (FDA) to start requiring new antibiotics to be studied for proof of bacteriologic cure in a subset of patients.

In 2004 the two academies (Family Physicians and Pediatricians) issued a clinical practice guideline that suggested nontreatment of limited groups of children with AOM (Table 17–3). Key points are that children older than age 2 years with nonsevere disease were recommended for nontreatment for the first 48–72 hours after onset of symptoms. Those younger than age 2 years and older children with severe pain or fever were always recommended to receive immediate antibiotics. Children failing observation were to begin antibiotics after 48–72 hours. Although, not mentioned, a prescription can be given at the first visit, with instructions to fill if no improvement is seen after the specified observation period.

The guidelines offer different recommendations for “certain” versus “uncertain” diagnosis, but clinicians should be able to see the eardrum and make a correct diagnosis if they master cerumen removal and pneumatic otoscopy. An “uncertain” diagnosis should only occur when pus, blood, or cerumen obscures the eardrum. For infants younger than age 6 months, antibiotics are always recommended on the first visit, regardless of the certainty of diagnosis. The guidelines also emphasize the importance of using pneumatic otoscopy or tympanometry to establish the presence of effusion, and the importance of differentiating OME from AOM by the absence of acute signs and symptoms of inflammation (see Table 17–3).

Everyone agrees that overtreatment of OME by well-meaning providers has led to overuse of antibiotics for no discernible benefit. AOM requires the recent onset of otalgia, which may be harder to diagnose in infants, but often manifests as night awakening, ear tugging, anorexia due to pain on swallowing, and unexplained crying. Although most clinicians routinely treat acute otitis with antibiotics, it is also reasonable to involve parents in the decision. There is a trade-off for the individual child between the risks of antibiotic treatment (cost, allergic reactions, side effects, and colonization with an antibiotic-resistant pathogen) and the benefit of a possibly more rapid clinical response and avoidance of potential complications. More rapid pain relief alone may justify treatment in older children. Children younger

Table 17-3. Criteria for initial antibiotic treatment in children with acute otitis media.

Age	Certain Diagnosis	Uncertain Diagnosis
< 6 mo	Antibacterial therapy	Antibacterial therapy
6 mo-2 y	Antibacterial therapy	Antibacterial therapy if severe illness; observation option ^a if nonsevere illness
≥ 2 y	Antibacterial therapy if severe illness; observation option ^a if nonsevere illness	Observation option ^a

^aNonsevere illness is mild otalgia and fever < 39°C in the past 24 h.

than age 2 years should be immediately treated with antibiotics because studies show an advantage over placebo, and they are more likely to develop complications.

C. Antibiotic Therapy

Amoxicillin remains the first-line antibiotic for treating otitis media, even with a high prevalence of drug-resistant *S pneumoniae*, because resistance to β -lactam antibiotics, such as amoxicillin, develops as a stepwise process over many years. A bacterial strain resistant to low levels of amoxicillin usually is eradicated by a higher dosage. Amoxicillin dosage may be raised considerably without toxicity; for example, a dosage of 200 mg/kg/d has been used to treat meningitis in children, and a maximum daily dose of 4 g has been used in adults. Studies have shown that increasing the dosage from 40 mg/kg to 90 mg/kg yields a drug concentration in middle ear fluid that surpasses the minimal level needed to inhibit 98% of all pneumococcal otitis media. A second advantage is that dosing amoxicillin at these higher levels may help delay stepwise emergence of resistance. In recognition of this new pharmacodynamic data, the federal government in June 1999 doubled the minimum inhibitory concentration used to define resistance to amoxicillin to 8 mcg/mL or greater. Because otitis media is not a life-threatening disease, it is not necessary for a first-line antibiotic to achieve 100% cure. High-dose amoxicillin will usually eradicate the most invasive pathogen, *S pneumoniae*, and if no improvement occurs, a second-line antibiotic may be chosen to cover *M catarrhalis* and β -lactamase-producing *H influenzae*.

Amoxicillin-clavulanate enhanced-strength, with 90 mg/kg/d of amoxicillin dosing (14:1 ratio of amoxicillin to clavulanate), is an appropriate choice when a child is clinically failing after 48–72 hours on amoxicillin (Table 17–4). In this situation, the most likely pathogen is *H influenzae*, and the addition of clavulanate to amoxicillin will broaden the coverage while retaining efficacy against *S pneumoniae*. The older 200- and 400-mg-per-teaspoon formulations of amoxicillin-clavulanate (7:1 ratio) should never be doubled in dosage, because the amount of clavulanate will be so high as to cause diarrhea.

Table 17-4. Treatment of acute otitis media in an era of drug resistance.

First-line therapy

1. Amoxicillin, 90 mg/kg/d, up to 4 g/d. For children over age 2 y, give for 5 d; under age 2 y, for 10 d.
2. If amoxicillin has caused a rash, give cefuroxime (Ceftin), cefdinir (Omnicef), or cefpodoxime (Vantin).
3. If urticaria or other IgE-mediated events have occurred, give trimethoprim-sulfamethoxazole or azithromycin (Zithromax).
4. If child is unable to take oral medication, give single IM dose of ceftriaxone (Rocephin).

Second-line therapy^a

1. Amoxicillin-clavulanate (Augmentin ES-600), given so that patient receives amoxicillin at 90 mg/kg/d.
2. If amoxicillin has caused allergic symptoms, see recommendations above.

Third-line therapy

1. Tympanocentesis is recommended to determine the cause.
2. Ceftriaxone (Rocephin), two doses given IM, 48 h apart, with option of a third dose.

Recurrences > 4 wk after first episode

1. A new pathogen is likely, so restart first-line therapy.
2. Be sure diagnosis is not OME, which may be observed for 3-6 mos without treatment.

^aFor clinical failure after 48-72 h of treatment, or for recurrences within 4 wk. IM, intramuscular; OME, otitis media with effusion.

Three oral cephalosporins (cefuroxime, cefpodoxime, and cefdinir) are more β -lactamase-stable and these are alternative choices for antibiotic therapy in children who develop papular rashes with amoxicillin (see Table 17-4). Unfortunately, the coverage of highly penicillin-resistant pneumococci with these agents is poor and only the intermediate-resistance classes are covered. Of these three drugs, cefdinir is quite palatable in the liquid form while the other two drugs have a bitter aftertaste which is difficult, but not impossible, to conceal. Newer flavoring agents may be helpful here. A second-line antibiotic is indicated when a child experiences symptomatic infection within 1 month of stopping amoxicillin; however, repeat use of high-dose amoxicillin is indicated if more than 4 weeks have passed without symptoms, because a new pathogen is usually present. Macrolides such as azithromycin and clarithromycin are not recommended as second-line agents for two reasons. First, the national *S pneumoniae* resistance rate to macrolides is approximately 30% in respiratory isolates. Second, double tympanocentesis studies have demonstrated eradication of *H influenzae*, regardless of β -lactamase production. Virtually all strains of *H influenzae* have an intrinsic macrolide efflux pump, which pumps antibiotic out of the bacterial cell. In a recent double tympanocentesis study, the on-therapy eradication rate of all pathogens was 94.2% for high-dose amoxicillin-clavulanate and 70.3% for azithromycin ($P < .001$).

If a child remains symptomatic longer than 3 days while taking a second-line agent, a tympanocentesis is useful to

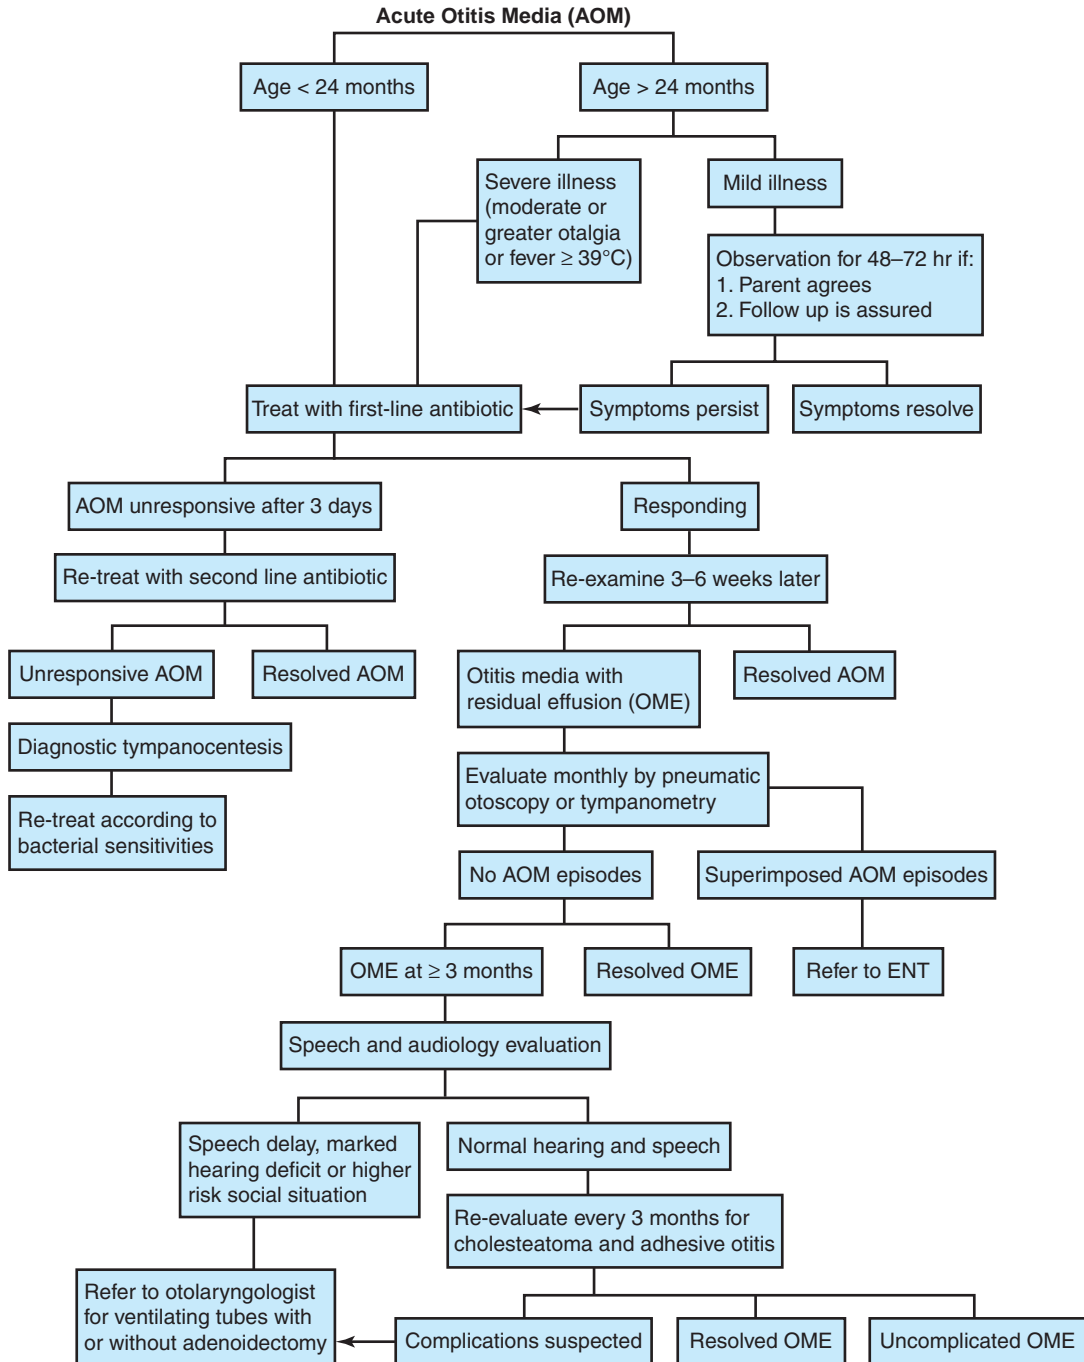

identify the causative pathogen. The tap may be sterile or the organism may be sensitive. Reasons for failure to eradicate a sensitive pathogen may be nonadherence, poor drug absorption, or vomiting of drug. If a highly resistant pneumococcus is found or if tympanocentesis is not feasible, intramuscular ceftriaxone at 50 mg/kg/d for 3 consecutive days is probably the best choice based on a study performed in Israel. In addition to listing the steps of therapy, Table 17-4 also lists specific cephalosporins that may be used as alternative drugs in penicillin-allergic children. If the child has experienced anaphylaxis to amoxicillin, cephalosporins should not be substituted. However, the maculopapular rash frequently seen with amoxicillin is not IgE-mediated, and cephalosporins may be used.

With the emergence of *S pneumoniae* with minimum inhibitory concentration values of 4 mcg/mL, high-dose amoxicillin will undoubtedly fail to cure. Therefore, two new classes of antibiotics are in active clinical trials for AOM: fluoroquinolones and ketolides. Recently, however, ketolides were removed from the market. Fluoroquinolones are divided into two classes; the older class includes ciprofloxacin, ofloxacin, and levofloxacin. The newer class is the 8-methoxy-fluoroquinolones, which include gatifloxacin and moxifloxacin. The difference between the two classes is that the newer drugs have a lower tendency to select resistant *S pneumoniae*, because two mutations are required. Pneumococcal resistance has been seen in countries where fluoroquinolones were widely used in adults. Levofloxacin was evaluated in a double tympanocentesis trial and found to be highly efficacious, but the manufacturers have chosen not to apply to the FDA for use in AOM at this time. In a double tympanocentesis study of high-risk children, gatifloxacin was shown to eradicate 96% of pathogens. Cartilage toxicity has been seen only in juvenile laboratory animals, and no increased incidence of arthropathy has been seen during the compassionate use of any fluoroquinolone.

Figure 17-3 shows the recommended follow-up of AOM that resolves with a residual effusion at 3-4 weeks. Children, particularly those young enough to still be developing language skills, should be seen monthly for otoscopic examinations to determine if the effusion is persistent or occurs only with symptomatic infections. Prophylactic antibiotics and corticosteroids are no longer recommended for OME. An audiology evaluation should be performed after approximately 3 months of continuous bilateral effusion in children younger than 3 years and those at risk of language delay due to poverty or craniofacial anomalies or other risk factors. Children with hearing loss or speech delay should be referred to an otolaryngologist for possible ventilation tubes. Older children may have periodic hearing testing in the primary provider's office (see later section on Management of OME).

D. Duration of Therapy

The duration of antibiotic treatment is controversial. Only three recent trials have used stringent entry and outcome

▲ **Figure 17-3.** Algorithm for acute otitis media. ENT, ear, nose, and throat consult.

criteria. Success rates were higher following 10 days of therapy in all three studies, particularly for children younger than 2 years of age, and for those in day care. At

this time, short-course (5-day) therapy can only be recommended for children older than 2 years and not in day care.

One side effect of using amoxicillin or penicillin is the eradication of the normal nasopharyngeal and oral flora. A recent study of preschoolers demonstrated that drug-resistant pneumococcal carriage at day 28 post-therapy was lower in a short-course high-dose amoxicillin group compared with a group given a standard course of therapy. This is an important finding, because it is now known that the nasopharyngeal flora influence the pathogen in the next episode of AOM. Normal flora resist colonization by disease-causing flora such as *S pneumoniae*.

E. Tympanocentesis

Tympanocentesis is performed by placing a needle through the TM and aspirating the middle ear fluid. Indications for tympanocentesis are (1) AOM in a patient with compromised host resistance, (2) research studies, (3) evaluation for presumed sepsis or meningitis, such as in a neonate, (4) unresponsive otitis media despite courses of two appropriate antibiotics, and (5) acute mastoiditis or other suppurative complications. The technique of tympanocentesis is as follows:

1. Premedication—In the conditions mentioned, the pain associated with tympanocentesis is only slightly greater than the pain of existing acute inflammation of the TM. Therefore, no premedication is used, but the provider should perform the procedure rapidly and return the child immediately to the parent's arms.

2. Restraint—A papoose board or a sheet can be used to immobilize the patient's body, and an extra attendant is required to hold the child's head steady. It is helpful to have the parent remain in sight of the child for reassurance.

3. Site selection—With an open-headed operating otoscope (Figure 17-4), the operator carefully selects a target. This is best done in the anteroinferior quadrant, although the posteroinferior quadrant is a safe but shallower alternative. These sites avoid damage to the ossicles, which are in the posterior superior quadrant, during the procedure.

4. Aspiration—An 8.8-cm spinal needle (No. 18 or 20) with a short bevel is attached to a 3-mL syringe. Alternatively, either an Alden-Senturia trap (Storz Instrument Co., St. Louis, MO) or the Tymp-Tap aspirator (Xomed Surgical Products, Jackson, FL) is attached to a suction pump. The operator then aspirates the middle ear effusion from the anterior inferior quadrant. Aspirate should be placed directly onto culture plates for maximum recovery, and chocolate agar is adequate to grow all common pathogens.

F. Prevention of Acute Otitis Media

1. Antibiotic prophylaxis—Prolonged use of low doses of antibiotics, for periods of 6–12 months, has been the primary method of prophylaxis. However, as the health care community tries to avoid using low doses of antibiotics (or drugs present for long time periods after therapy such as azithro-

▲ **Figure 17-4.** Operating head and Alden-Senturia trap for tympanocentesis. 18-gauge spinal needle is attached and bent.

mycin), this method should be reserved for unusual situations. Amoxicillin is the drug most studied. A situation in which prophylaxis might still be recommended is a child being considered for tympanostomy tube placement for recurrent infections who presents in late spring. A 1–2 month course of amoxicillin might prevent infection until the low-risk summer season when AOM is uncommon. Another recommendation for prophylaxis is in the child with patent tympanostomy tubes who experiences recurrent AOM and has been found to have an immune deficiency on more than one occasion. Antibiotic prophylaxis is not recommended for children with OME, despite earlier guidelines that made such a recommendation.

2. Lifestyle modifications—Parental education plays a major role in decreasing AOM, and the National Association of Daycare Providers has prepared educational materials for its centers and its parents. Here are some counseling topics to consider in children with frequent recurrences:

- Smoking is a risk factor both for upper respiratory infection and for AOM, and primary care physicians can provide literature on smoking cessation programs and on nicotine-containing gums or patches.

- Breast feeding protects children from AOM, but the mechanism is unknown. Also, propping a bottle of milk in the crib increases AOM risk.
- Removing pacifiers from infants was shown in Finland to reduce episodes of AOM by about one third compared with a control group. The mechanism is uncertain but is likely to be related to effects on the eustachian tube.
- Day care is clearly a risk factor for AOM, but working parents may have few alternatives. Suggestions include care by relatives or care of the child in a home care setting with fewer children.
- Xylitol, also known as birch sugar, is found in plums, strawberries, and raspberries. It was first studied in Europe as a chewing gum to reduce dental caries, and proved effective. Unfortunately, to prevent a single AOM episode would require a group of children to chew 4100 pieces of gum per year.

3. Surgery—Tympanostomy tubes are an effective treatment of recurrent otitis media as well as OME, which will be discussed in the next section.

4. Immunologic evaluation and allergy testing—Parents often ask if an immune deficiency may be causing their child's frequent otitis episodes. While it is known that immunoglobulin subclass deficiencies are more common in immune-deficient children, the relationship is not straightforward. Furthermore, there is no practical immune therapy. More serious immunodeficiencies such as selective IgA deficiency should be sought in children with a combination of recurrent AOM, rhinosinusitis, and pneumonia. Parents may also inquire about the role of allergy, since a generation ago many children with recurrent AOM were placed on milk elimination diets. No benefits were seen in the large group, but for certain individuals eliminating all milk and milk-containing foods can eliminate ear infections. In the school-aged child or the preschooler with an atopic background, skin testing may be beneficial in identifying allergens that predispose to AOM.

5. Vaccines—With the increasing problems of antibiotic therapy and prophylaxis, vaccines are increasingly important. The seven-valent pneumococcal vaccine (PCV7) was designed to prevent meningitis and sepsis, not AOM. However, it did produce a 55% reduction in AOM resulting from the seven serotypes found in the vaccine, and these strains include the serotypes most likely to be penicillin- and macrolide-resistant. Overall PCV7 reduced AOM by 6% in a group of children in California, compared with a control group. More impressively, it reduced pressure equalization tube placements by 20% and greatly reduced AOM incidence in children having six or more episodes per year. Furthermore, studies are showing a herd immunity effect on the older siblings of vaccinated children, which may further reduce drug-resistant serotype circulation. The vaccine

should be used as a single dose for children aged 2–5 years with a history of either recurrent AOM or OME with superimposed AOM episodes.

In recent studies, intranasal influenza vaccine reduced the number of influenza-associated cases of AOM by 92%. For children older than 6 months with recurrent AOM, it seems prudent to recommend yearly influenza vaccine, although this is not yet an official recommendation.

Vaccines currently being studied in animals that hold promise for AOM prevention include a respiratory syncytial virus vaccine and a nontypeable *H influenzae* vaccine. Studies of pregnant women in the third trimester have shown that their pneumococcal antibody levels are raised by a heptavalent pneumococcal vaccine, which may also raise antibody levels in the offspring. A recent study showed that low cord blood pneumococcal antibody is a risk factor for AOM and OME, so passive transfer from the mother is a logical next step to study.

G. Management of Otitis Media with Residual and Persistent Effusions

OME is treated to avoid the consequences of prolonged negative pressure on the TM and chronic conductive hearing loss. Available data show a causal relationship between severe sensorineural hearing loss and language delay, but not between conductive hearing loss due to OME and language delay. Studies looking at middle ear effusion (MEE) and its effects on language development in normal children of English-speaking middle- and upper-class society do not show differences at ages 5–7 years. This, however, eliminates many if not most of the children with high risk factors for otitis media. Two thirds of children with AOM have an MEE or high negative middle ear pressure 2 weeks after diagnosis and one third at 1 month after diagnosis regardless of antibiotic therapy. The management options for otitis media with residual effusion at 6 weeks to 4 months include observation. Nasal and oral corticosteroids have not been found in large studies to decrease MEE over several months but may be helpful in certain patients with nasal obstruction from adenoid hypertrophy or allergic rhinitis.

If the patient clears the persistent MEE unilaterally or bilaterally, the physician should follow the patient monthly. Because of the increase in antibiotic resistance, the use of prophylaxis, even intermittently, must be restricted to carefully selected patients. The guideline recommendation developed by the Agency for Healthcare Research and Quality for the management of OME is that ventilating tubes should be placed after the effusion has persisted for 4 months and is accompanied by a bilateral hearing impairment of 20 dB or greater. Earlier placement of ventilating tubes should depend on the child's developmental and behavioral status as well as on parental preference. The value of ventilating tubes for

treating unilateral effusions in otherwise healthy children is focused on preventing middle ear sequelae often seen as a retracted or atelectatic drum.

Children who have otitis media and persistent effusion have an increased incidence of cholesteatoma, adhesive otitis, retraction pockets, membrane atrophy, and persistent membrane perforation. As there is no way to identify the small proportion of candidate children for whom insertion of ventilating tubes will prevent the damage, close follow-up of children with abnormal ears may be best accomplished by an otolaryngologist. This approach is discussed further below.

3. Mastoiditis

Mastoiditis is a spectrum of disease that ranges from inflammation of the mastoid periosteum to bony destruction of the mastoid air system (coalescent mastoiditis) or abscess development. Infection of the periosteum of the mastoid bone is a rare complication of AOM in the postantibiotic era. In a recent article Rosenfeld and colleagues noted a 0.01% rate of mastoiditis in a large group of children not receiving antibiotic therapy. Mastoiditis can occur in any age group, but more than 60% of the patients are younger than age 2 years. Many children do not have a prior history of recurrent AOM. The most common pathogens are *Streptococcus pneumoniae* and *S pyogenes*, with *Staphylococcus aureus* and *H influenzae* occasionally seen. Rarely gram-negative bacilli and anaerobes are isolated. Antibiotics may affect the incidence and morbidity of acute mastoiditis. However, acute mastoiditis does occur in children who are on antibiotics for an acute ear infection. In the Netherlands, where only 31% of AOM patients receive antibiotics, the incidence of acute mastoiditis is 4.2 per 100,000 person-years. In the United States, where more than 96% of patients with AOM receive antibiotics, the incidence of acute mastoiditis is 2 per 100,000 person-years. The higher antibiotic usage in the United States correlates with a higher rate of resistant organisms and more adverse drug interactions. Moreover, despite the routine use of antibiotics, the incidence of acute mastoiditis has been rising in some cities. The pattern change may be secondary to the emergence of resistant *S pneumoniae*.

Rosenfeld RM et al: Implications of the AHRQ evidence report on acute otitis media. *Otolaryngol Head Neck Surg* 2001;125:440 [PMID: 11700439].

► Clinical Findings

The principal complaints of patients with mastoiditis are usually postauricular pain, fever, and an outwardly displaced pinna. On examination, the mastoid area often appears

swollen and reddened. With disease progression it may become fluctuant. The earliest finding is severe tenderness on mastoid palpation.

AOM, by otoscopy, is almost always present. Late findings are a pinna that is pushed forward by postauricular swelling and an ear canal that is narrowed in the posterosuperior wall because of pressure from the mastoid abscess. In infants younger than age 1 year, the swelling occurs superior to the ear and pushes the pinna downward rather than outward. In the acute phase, diffuse inflammatory clouding of the mastoid cells occurs, as in every case of AOM. In more severe cases, bony destruction and resorption of the mastoid air cells may occur. The best way to determine the extent of disease is by computed tomography (CT) scan.

Meningitis is a complication of acute mastoiditis and should be suspected when a child has associated high fever, stiff neck, severe headache, or other meningeal signs. Lumbar puncture should be performed for diagnosis. Brain abscess occurs in 2% of patients and may be associated with persistent headaches, recurring fever, or changes in sensorium. Facial palsy, cavernous sinus thrombosis, and thrombophlebitis may be encountered.

► Treatment

Treatment for mastoiditis without a posterior abscess is typically myringotomy, with or without tube placement, in order to obtain material for culture. Hospitalization for intravenous therapy follows. Reasonable initial therapy is ceftriaxone plus nafcillin or clindamycin until culture results are returned. If clinical improvement does not occur after 24–48 hours of intravenous or intramuscular therapy, or if any signs or symptoms of intracranial complications exist, immediate surgery to drain the mastoid abscess is indicated. The primary management for coalescent mastoiditis (with abscess formation and breakdown of the mastoid air cells) is a cortical mastoidectomy. A recent review from the University of Texas–Southwestern revealed that 39% of patients with mastoiditis required a mastoidectomy. After significant clinical improvement is achieved with parenteral therapy, oral antibiotics are begun and should be continued for 3 weeks. If the child has an isolated subperiosteal abscess and not coalescent mastoiditis, either needle aspiration or incision and drainage with an associated myringotomy has produced good clinical outcomes.

4. Otitis Media with Complications

Complications of otitis media may involve damage to the middle ear structures, such as tympanosclerosis, retraction pockets, adhesions, ossicular erosion, cholesteatoma, perforations, and intratemporal and intracranial injury.

A. Tympanosclerosis

A white plaquelike appearance on the TM is caused by chronic inflammation or trauma that produces granulation

tissue and hyalinization. The appearance of a small defect in the posterosuperior area of the pars tensa or in the pars flaccida suggests a retraction pocket. Retraction pockets occur when chronic inflammation and negative pressure in the middle ear space produce atrophy and atelectasis of the TM.

Continued inflammation can cause adhesions between the retraction pocket and the ossicles. This condition, referred to as adhesive otitis, predisposes to formation of a cholesteatoma or fixation and erosion of the ossicles (Figure 17–5). Erosion of the ossicles results from osteitis and compromise of the blood supply to the ossicles. Ossicular discontinuity may produce a maximal hearing loss with a 50-dB threshold. A tympanogram with very high compliance suggests ossicular discontinuity.

B. Cholesteatoma

A greasy-looking mass or pearly white mass seen in a retraction pocket or perforation suggests a cholesteatoma, whether or not there is discharge (see Figure 17–5). A perforation is usually painless. If infection is absent, the middle ear cavity generally contains normal mucosa. If infection is superimposed, serous or purulent drainage will be seen, and the middle ear cavity may contain granulation tissue or even polyps. Persistent or recurrent otorrhea following appropriate medical management should make one suspect a cholesteatoma. Foul smelling otorrhea at any time should raise suspicion of potential cholesteatoma.

C. Tympanic Membrane Perforation

Occasionally, an episode of AOM is associated with otorrhea. An aural discharge indicates that the TM has perforated. Most likely the perforation will heal spontaneously. If the perforation has not healed within 3 months, surgical intervention will be necessary. A conductive hearing loss is usually

▲ **Figure 17-5.** Attic cholesteatoma, formed from an inward drawing of an attic retraction pocket.

present, depending on the size and location of the perforation. The site of perforation is important for both cholesteatoma formation and amount of hearing loss expected. Central perforations surrounded by intact TM are usually relatively safe from cholesteatoma formation. With a peripheral perforation, especially in the pars flaccida, the perforation extends to the canal wall without any intervening TM. Peripheral perforations create a risk for cholesteatoma because the ear canal epithelium may invade the perforation. Perforations over the round window membrane in the posterior part of the TM result in more hearing loss than a perforation in either the inferior or anterior TM.

Most perforations secondary to AOM heal within 2 weeks. When perforations fail to heal after 3–6 months, surgical repair may be needed. Repair of the defect in the TM is generally delayed until the child is older and eustachian tube function has improved. Procedures include paper patch, fat myringoplasty, and tympanoplasty. Tympanoplasty is generally deferred until age 7–9 years. In otherwise healthy children without any craniofacial anomalies, some surgeons repair the perforated TM earlier if the contralateral nonperforated drum remains free of infection and effusion for 1 year. This policy does not guarantee success. The age of the child when repair is performed is the more probable indicator of success. Occasionally, a perforation is closed in a child of younger age if recurrent otorrhea is thought to be secondary to water contamination or nasopharyngeal reflux. Earlier closure of the perforation will seal the middle ear space and reestablish the air cushion provided by the mastoid air system. An older child is more likely to have a successful outcome from closure of the perforation. Water activities should be limited to surface swimming, preferably with the use of an ear mold. Diving, jumping into the water, and underwater swimming should be prohibited for 6 weeks following the reparative surgery.

D. Facial Nerve Paralysis

The facial nerve crosses the middle ear as it courses through the temporal bone to its exit at the stylomastoid foramen. Occasionally, the nerve is incompletely encased in bone, which makes it susceptible to inflammation during an episode of AOM. The acute onset of a facial nerve paralysis should not be deemed idiopathic Bell palsy until all other causes have been excluded. If middle ear fluid is present, a prompt myringotomy is indicated. Placement of a ventilation tube will allow for prolonged ventilation. CT is indicated if a cholesteatoma is suspected or acute coalescent mastoiditis is present.

E. Chronic Suppurative Otitis Media

Chronic suppurative otitis media is present when persistent otorrhea occurs in a child with tympanostomy tubes or TM perforations. Occasionally, it is an accompanying sign of cholesteatoma. Visualization of the TM, meticulous cleaning

with culture of the drainage, and appropriate antimicrobial therapy are keys to management of cases not related to cholesteatoma. The successful treatment of chronic suppurative otitis usually requires therapy with an antibiotic that covers *Pseudomonas* and anaerobes. Oral quinolone antibiotics effective against *Pseudomonas* infection are not yet approved for use in growing children. Recent studies suggest that topical quinolones for 14 days may be effective. It is very important to clean the ear canal by suction to allow penetration of drops, and it is often useful to culture the secretions. A Pope ear wick should be inserted and drops placed on the wick several times daily. The child should be seen in 7 days, the wick removed, and suction repeated if necessary. When a cholesteatoma (see Figure 17–5) is associated with chronic suppurative otitis media, medical therapy is not effective. If the discharge does not respond to 2 weeks of aggressive therapy, mastoiditis, cholesteatoma, tuberculosis, or fungal infection should be suspected. Serious central nervous system (CNS) complications such as extradural abscess, subdural abscess, brain abscess, meningitis, labyrinthitis, or lateral sinus thrombophlebitis can occur with extension of this process. Therefore, patients with facial palsy, vertigo, or other CNS signs should be referred immediately to an otolaryngologist.

ACUTE TRAUMA TO THE MIDDLE EAR

Head injuries, a blow to the ear canal, sudden impact with water, blast injuries, or the insertion of pointed instruments into the ear canal can lead to perforation of the TM or hematoma of the middle ear. One study reported that 50% of serious penetrating wounds of the TM were due to parental use of a cotton-tipped swab.

Treatment of middle ear hematomas consists mainly of watchful waiting. Antibiotics are not necessary unless signs

of infection appear. The prognosis for unimpaired hearing depends on whether the ossicles are dislocated or fractured in the process. The patient needs to be followed with audiometry or by an otolaryngologist until hearing has returned to normal, which is expected within 6–8 weeks.

Traumatic perforations of the TM often do not heal spontaneously, in which case the patient should be referred to an otolaryngologist. Perforations caused by a foreign body should be attended to urgently, especially if accompanied by vertigo.

EAR CANAL FOREIGN BODY

Numerous objects can be inserted into the ear canal by a child. If the object is large, wedged into place, or difficult to remove with available instruments, the patient should be referred to an otolaryngologist early rather than risk traumatizing the child or the ear canal or causing edema that will require removal under anesthesia. An emergency condition exists if the foreign body is a disk-type battery used in clocks, watches, and hearing aids. An electric current is generated in the moist canal, and a severe burn with resulting scarring can occur in less than 4 hours.

Lin VY et al: Button batteries in the ear, nose and upper aerodigestive tract. *Int J Pediatr Otorhinolaryngol* 2004;68:473 [PMID: 15013616].

HEMATOMA OF THE PINNA

Trauma to the ear can result in a hematoma between the perichondrium and cartilage. The hematoma appears as a boggy purple swelling of the upper half of the ear. If this is not treated, it can cause pressure necrosis of the underlying cartilage and result in “cauliflower ear.” To prevent this cosmetic deformity, physicians should urgently refer patients to an otolaryngologist for aspiration and application of a carefully molded pressure dressing. Recurrent or persistent hematoma of the ear may require surgical drainage.

CONGENITAL EAR MALFORMATIONS

Agenesis, known as atresia, of the external ear canal results in conductive hearing loss that requires evaluation in the first month of life by hearing specialists and an otolaryngologist.

“Lop ears,” folded down or protruding ears (so-called “Dumbo” ears), are a source of much teasing and ridicule. In the past, surgical correction at age 5 or 6 years was offered. Taping the ears into a correct anatomic position is very effective if performed in the first 72–96 hours of life. Tape is applied over a molding of wax and continued for 2 weeks. Another alternative for the ear that can be molded solely by finger pressure into a normal configuration is an incisionless otoplasty, which can be performed at a much earlier age than 5–6 years and is associated with little postoperative morbidity. Because no cartilage destruction is associated with this technique, future growth is unaffected.

An ear is low-set if the upper pole is below eyebrow level. This condition is often associated with renal malformations (eg, Potter syndrome), and renal ultrasound examination is suggested.

Preauricular tags, ectopic cartilage, fistulas, sinuses, and cysts require surgical correction, mainly for cosmetic reasons. Children exhibiting any of these findings should have their hearing tested. Most preauricular pits cause no symptoms. If one should become infected, the patient should receive antibiotic therapy and be referred to an otolaryngologist for eventual excision.

IDENTIFICATION & MANAGEMENT OF HEARING LOSS

Hearing loss is classified as being conductive, sensorineural, or mixed in nature. Conductive hearing loss occurs when there is a blockage of sound transmission between the opening of the external ear and the cochlear receptor cells. The most common cause of conductive hearing loss in children is fluid in the middle ear. Sensorineural hearing loss is due to a defect in the neural transmission of sound, arising from a defect in the cochlear hair cells or the auditory nerve. Mixed hearing loss is characterized by elements of both conductive and sensorineural loss.

Hearing is measured in decibels (dB). The threshold, or 0 dB, refers to the level at which a sound is perceived in normal subjects 50% of the time. Hearing is considered normal if an individual’s thresholds are within 15 dB of normal. In children, severity of hearing loss is commonly graded as follows: 5–30 dB mild, 31–60 dB moderate, 61–90 dB severe, and 91+ dB profound.

Hearing loss can significantly impair a child’s ability to communicate, and hinder academic, social, and emotional development. Studies suggest that periods of auditory deprivation may have enduring effects on auditory processing, even after normal hearing is restored. In the past, the effects of unilateral hearing loss were thought to be of little consequence, but studies have shown that even a unilateral loss may be associated with difficulties in school and behavioral issues. Early identification and management of any hearing impairment is therefore critical.

Conductive Hearing Loss

The most common cause of childhood conductive hearing loss is otitis media and related conditions such as middle ear effusion (MEE) and eustachian tube dysfunction. Other causes of conductive hearing loss may include external auditory canal atresia or stenosis, TM perforation, cerumen impaction, cholesteatoma, and middle ear abnormalities,

such as ossicular fixation or discontinuity. Often, a conductive loss may be corrected with surgery.

MEE may be serous, mucoid, or purulent, as in AOM. Effusions are generally associated with a mild conductive hearing loss that normalizes once the effusion is gone. The American Academy of Pediatrics recommends that hearing and language skills be assessed in children who have recurrent AOM or MEE lasting longer than 3 months.

Sensorineural Hearing Loss

Sensorineural hearing loss (SNHL) arises due to a defect in the cochlear receptor cells or the auditory nerve (cranial nerve VIII). The loss may be congenital (present at birth) or acquired. In both the congenital and acquired categories, the hearing loss may be either hereditary (due to a genetic mutation) or nonhereditary. It is estimated that SNHL affects 2–3 out of every 1000 live births, making this the most common congenital sensory impairment. The incidence is thought to be considerably higher among the neonatal intensive care unit population. Well-recognized risk factors for SNHL in neonates include positive family history of childhood SNHL, birthweight less than 1500 g, low Apgar scores (0–4 at 1 minute or 0–6 at 5 minutes), craniofacial anomalies, hypoxia, in utero infections (eg, TORCH syndrome), hyperbilirubinemia requiring exchange transfusion, and mechanical ventilation for more than 5 days.

A. Congenital Hearing Loss

Nonhereditary causes account for approximately 50% of congenital hearing loss. These include prenatal infections, teratogenic drugs, and perinatal injuries. The other 50% is attributed to genetic factors. Among children with hereditary hearing loss, approximately one third of cases are thought to be due to a known syndrome, while the other two thirds are considered nonsyndromic.

Syndromic hearing impairment is associated with malformations of the external ear or other organs, or with medical problems involving other organ systems. Over 400 genetic syndromes that include hearing loss have been described. All patients being evaluated for hearing loss should also be evaluated for features commonly associated with these syndromes. These include branchial cleft cysts or sinuses, preauricular pits, ocular abnormalities, white forelock, café-au-lait spots, and craniofacial anomalies. Some of the more frequently mentioned syndromes associated with congenital hearing loss include the following: Waardenberg, branchio-oto-renal, Usher, Pendred, Jervell and Lange-Nielsen, and Alport.

Over 70% of hereditary hearing loss is nonsyndromic (ie, there are no associated visible abnormalities or related medical problems). The most common mutation associated with nonsyndromic hearing loss is in the *GJB2* gene, which encodes the protein connexin 26. The *GJB2* mutation has a carrier rate of about 3% in the general population. Most

nonsyndromic hearing loss, including that due to the *GJB2* mutation, is autosomal recessive, but gene loci for autosomal dominant and X-linked hearing loss have also been identified.

B. Acquired Hearing Loss

Hereditary hearing loss may be delayed in onset, as in Alport syndrome and most types of autosomal dominant nonsyndromic hearing loss. Vulnerability to aminoglycoside-induced hearing loss has also been linked to a mitochondrial gene defect.

Nongenetic etiologies for delayed-onset SNHL include exposure to ototoxic medications, meningitis, autoimmune or neoplastic conditions, noise exposure, and trauma. Infections such as syphilis or Lyme disease have been associated with hearing impairment. Hearing loss associated with congenital cytomegalovirus infection may be present at birth, or may have a delayed onset. The loss is progressive in approximately half of all patients with congenital cytomegalovirus-associated hearing loss. Other risk factors for delayed-onset, progressive loss include a history of persistent pulmonary hypertension and extracorporeal membrane oxygenation therapy.

Identification of Hearing Loss

A. Office Clinical Assessment

In the past, the parents' report of their infant's behavior was considered an adequate assessment of hearing. However, a deaf infant's behavior can appear normal and mislead parents as well as professionals, especially if the infant has autosomal recessive deafness and is the first-born child of carrier parents. The following office screening techniques may identify only gross hearing losses, and may not detect less severe hearing loss, such as due to otitis media.

1. Birth to 4 months—In response to a sudden loud sound (70 dB or more) produced by a horn, clacker, or special electronic device, the infant should show a startle reflex or blink the eyes.

2. Four months to 2 years—While the infant is distracted with a toy or bright object, a noisemaker is sounded softly outside the field of vision at the child's waist level. Normal responses are as follows: at 4 months, there is widening of the eyes, interruption of other activity, and perhaps a slight turning of the head in the direction of the sound; at 6 months, the head turns toward the sound; at 9 months or older, the child is usually able to locate a sound originating from below as well as turn to the appropriate side; after 1 year, the child is able to locate sound whether it comes from below or above.

After responses to soft sounds are noted, a loud horn or clacker should be used to produce an eye blink or startle reflex. This latter maneuver is necessary because deaf children are often visually alert and able to scan the environment so actively that their scanning can be mistaken for an appropriate response to the softer noise test. A deaf child will

not blink in response to the loud sound. Consonant sounds such as “mama,” “dada,” and “baba” should be present in speech by age 11 months. Children who fail to respond appropriately should be referred for audiologic assessment.

B. Newborn Hearing Screening

Prior to the institution of universal screening programs, the average age at identification of hearing loss was 30 months. Recognizing the importance of early detection, in 1993, a National Institutes of Health Consensus Panel recommended that all newborns be screened for hearing impairment prior to hospital discharge. Today, universal newborn hearing screening is mandated in a majority of states, with a goal of hearing loss identification by 3 months of age, and appropriate intervention by the age of 6 months. Subjective testing is not reliable in infants, and therefore objective, physiologic methods are used for screening. Auditory brainstem response and otoacoustic emission testing are the two commonly employed screening modalities.

C. Audiologic Evaluation of Infants and Children

Audiometry subjectively evaluates hearing. There are several different methods used, based on patient age:

- Behavioral observational audiometry: Birth to 6 months. Sounds are presented at various intensity levels, and the audiologist watches closely for a reaction, such as change in respiratory rate, starting or stopping of activity, startle, head turn, or muscle tensing. This method is highly tester-dependent and error-prone.
- Visual reinforcement audiometry: 6 months to 2.5 years. Auditory stimulus is paired with positive reinforcement. For example, when a child reacts appropriately by turning toward a sound source, the behavior is rewarded by activation of a toy that lights up. After a brief conditioning period, the child localizes toward the tone, if audible, in anticipation of the lighted toy.
- Conditioned play audiometry: 2.5 to 5 years. The child responds to sound stimulus by performing an activity, such as putting a peg into a board.
- Conventional audiometry: Age 5 and up. The child indicates when he or she hears a sound.

Objective methods such as auditory brainstem response and otoacoustic emission testing may be used if a child cannot be reliably tested using the above methods.

Referral

A child who fails newborn hearing screening or has a suspected hearing loss should be referred for further audiologic evaluation, and any child with hearing loss should be referred to an otolaryngologist for further workup and treatment. In addition to the infants who fall into the high-risk categories for SNHL as outlined above, hearing should be tested in children with a history of developmental delay,

bacterial meningitis, ototoxic medication exposure, neurodegenerative disorders, or a history of infection such as mumps or measles. Even if a newborn screening was passed, all infants who fall into a high-risk category for progressive or delayed-onset hearing loss should receive ongoing audiologic monitoring for 3 years and at appropriate intervals thereafter to avoid a missed diagnosis.

Prevention

Appropriate care may treat or prevent conditions causing hearing deficits. Aminoglycosides and diuretics, particularly in combination, are potentially ototoxic and should be used judiciously and monitored carefully. Given the association of a mitochondrial gene defect and aminoglycoside ototoxicity, use should be avoided, if possible, in patients with a known family history of aminoglycoside-related hearing loss. Reduction of repeated exposure to loud noises may help prevent high-frequency hearing loss associated with acoustic trauma. Any patient with sudden-onset sensorineural hearing loss should be seen by an otolaryngologist immediately, as in some cases, steroid therapy may reverse the loss if initiated right away.

Management of Hearing Loss

If hearing impairment is suspected, the child should be referred to an audiologist for testing, and to an otolaryngologist for further evaluation and treatment. The management of hearing loss depends on the type and severity of impairment. Conductive hearing loss is typically correctable by addressing the point in sound transmission at which efficiency is compromised. For example, hearing loss due to chronic effusions usually normalizes once the fluid has cleared, whether by natural means or by the placement of tympanostomy tubes. Conductive loss due to TM perforation may be corrected by performing a tympanoplasty. As of yet, SNHL is not reversible, although cochlear hair cell regeneration is an area of very active research. Most sensorineural loss is managed with amplification. Cochlear implantation is an option for some children with severe-profound loss, and at the time of this writing, is FDA approved down to the age of 12 months. Unlike hearing aids, the cochlear implant does not amplify sound, but works by directly stimulating the cochlea with electrical impulses. Children with hearing loss should receive ongoing audiologic monitoring.

THE NOSE & PARANASAL SINUSES

ACUTE VIRAL RHINITIS (COMMON COLD; SEE ALSO CHAPTER 38)

The common cold (viral upper respiratory infection) is the most common pediatric infectious disease, and the incidence is higher in early childhood than in any other period of life. Children younger than age 5 years typically have 6–12 colds per year. Approximately 30–40% of these are caused by rhinoviruses. Other culprits include adenoviruses, coronaviruses, enteroviruses, influenza and parainfluenza viruses, and respiratory syncytial virus.

Clinical Findings

The patient usually experiences a sudden onset of clear or mucoid rhinorrhea, nasal congestion, sneezing, and sore throat. Cough or fever may develop. Although fever is usually not a prominent feature in older children and adults, in the first 5 or 6 years of life it can be as high as 40.6°C without superinfection. The nose, throat, and tympanic membranes may appear red and inflamed. Figure 17–6 shows the duration of cough, sore throat, and rhinorrhea in adults with rhinovirus-proven infections. The average duration of symptoms is about 1 week. Nasal secretions tend to become thicker and more purulent after day 2 of infection due to shedding of epithelial cells and influx of neutrophils. This discoloration should not be assumed to be a sign of bacterial rhinosinusitis, unless it persists beyond 10–14 days, by which time the patient should be experiencing significant symptomatic improvement.

Treatment

Treatment for the common cold should be symptomatic (Figure 17–7). Acetaminophen or ibuprofen is helpful for fever and pain. Nasal congestion can be treated with nasal saline drops and bulb suctioning for an infant or child unable to blow his or her nose. A topical decongestant such as oxymetazoline may provide some relief, but should be discontinued within 3 days to prevent severe rebound nasal congestion or chemical rhinitis. A cool mist vaporizer or humidifier may help the cough, but antimicrobial solution should be added to the water or the device should be cleaned at least every 3 days.

Available scientific data suggest that cold and cough medications are generally not effective in children, and may be associated with serious adverse effects. Antihistamines have not proven effective in relieving cold symptoms. In rhinoviral colds, increased levels of histamine are not observed. There is

▲ **Figure 17-6.** Duration of symptoms in the common cold in adults. (Reproduced, with permission, from Gwaltney JM: Rhinovirus infections in an industrial population. II. Characteristics of illness and antibody response. *JAMA* 1967;202:494.)

insufficient evidence of benefit to warrant the use of antibiotics for common cold symptoms. Oral decongestants have been found to provide some symptomatic relief in adults but have not been well-studied in children. Cough suppression at night is the number one goal of many parents; however, the effectiveness of dextromethorphan is unclear. It is believed by most experts to be effective in adults and adolescents, but benefit has not been proven in younger children. Use of narcotic antitussives is discouraged, as these have been associated with severe respiratory depression.

Education and reassurance may be the most important “therapy” for the common cold. Parents should be informed about the expected nature and duration of symptoms, efficacy and potential side effects of medications, and the signs and symptoms of complications of the common cold, such as bacterial rhinosinusitis, bronchiolitis or pneumonia.

RHINOSINUSITIS

The use of the term *rhinosinusitis* has replaced sinusitis. Rhinosinusitis acknowledges that the nasal and sinus mucosa are involved in similar and concurrent inflammatory processes.

1. Acute Bacterial Rhinosinusitis

Acute bacterial rhinosinusitis (ABRS) is a bacterial infection of the paranasal sinuses which lasts less than 30 days and in

▲ **Figure 17-7.** Algorithm for acute nasal congestion and rhinosinusitis.

which the symptoms resolve completely. It is almost always preceded by a viral upper respiratory infection (cold). Other predisposing conditions include allergies, trauma, or other situations that lead to inflammation of sinonasal mucosa and obstruction of sinus drainage. The diagnosis of ABRS is made when a child with a cold does not improve by 10–14 days or worsens after 5–7 days. The maxillary and ethmoid sinuses are most commonly involved. These sinuses are present at birth, forming in the third to fourth gestational month. The sphenoid sinuses form by the age of 5 years, and the frontal sinuses form by about age 7–8 years. Frontal sinusitis is unusual before age 10 years.

A combination of anatomic, mucosal, microbial, and immune pathogenic processes is believed to underlie the development of rhinosinusitis in children. Both viral and bacterial infections play integral roles in the pathogenesis. Viral upper respiratory infections may cause sinus mucosal injury and swelling, resulting in osteomeatal obstruction, loss of ciliary activity, and mucus hypersecretion. The bacterial pathogens that commonly cause acute rhinosinusitis are

S pneumoniae, *H influenzae* (nontypeable), *M catarrhalis*, and β -hemolytic streptococci.

► Clinical Findings

The onset of symptoms in ABRS may be gradual or sudden, and may commonly include nasal drainage, nasal congestion, facial pressure or pain, postnasal drainage, hyposmia or anosmia, fever, cough, fatigue, maxillary dental pain, and ear pressure or fullness. The physical examination is rarely helpful in making the diagnosis, as the findings are essentially the same as those in a child with an uncomplicated cold. Occasionally, sinuses may be tender to percussion, but this is typically seen only in older children and is of questionable reliability. Transillumination of the sinuses is difficult to perform and not very helpful unless the sinuses are grossly asymmetrical.

In complicated or immunocompromised patients, sinus aspiration and culture by an otolaryngologist should be considered for diagnostic purposes and to facilitate culture-

directed antibiotic therapy. Gram stain or culture of nasal discharge does not necessarily correlate with cultures of sinus aspirates. If the patient is hospitalized because of rhinosinusitis-related complications, blood cultures should also be obtained.

Imaging of the sinuses during acute illness is not indicated except when evaluating for possible complications, or for patients with persistent symptoms which do not respond to medical therapy. As with the physical examination, the radiographic findings of ABRs, such as sinus opacification, fluid, and mucosal thickening, are also seen in viral upper respiratory infections.

► Complications

Complications of ABRs occur when infection spreads to adjacent structures—the overlying tissues, the eye, or the brain. Orbital complications are the most common, arising from the ethmoid sinuses. These complications usually begin as a preseptal cellulitis, but can progress to postseptal cellulitis, subperiosteal abscess, orbital abscess, and cavernous sinus thrombosis. Associated signs and symptoms include eyelid edema, restricted extraocular movements, proptosis, chemosis, and altered visual acuity (see Chapter 15).

The most common complication of frontal sinusitis is osteitis of the frontal bone, also known as Pott's puffy tumor. Intracranial extension can lead to meningitis and to epidural, subdural, and brain abscesses. The most common maxillary complication is overlying cheek cellulites. Rarely, osteomyelitis of the maxilla can develop. For reasons that are unclear, male adolescents seem to be at higher risk for intracranial spread. Frequently, children with complicated rhinosinusitis have no prior history of sinus infection. No information is available on the rate of complications in ambulatory patients with rhinosinusitis, but the severity of the complications suggests that patients should be carefully followed while receiving treatment.

► Treatment

For children who are not improving by 10 days, or who have more severe symptoms, with fever of at least 39°C and purulent nasal drainage for at least 3–4 consecutive days, antibiotic therapy is recommended. Although some discrepancy exists, antibiotics are generally thought to decrease duration and severity of symptoms.

To minimize the number of children who receive antimicrobial therapy for uncomplicated viral upper respiratory infections, and to help combat antibiotic resistance, the American Academy of Pediatrics in 2001 issued guidelines for treatment. This algorithm is presented in Figure 17–8. Key decision points include severity of disease and risk factors for resistant organisms

For patients with mild-moderate symptoms, who are not in day care, and have not been on recent antibiotic therapy, amoxicillin is considered first-line therapy. For those with

severe symptoms, in day care, or who were on antibiotics within the past 1–3 months, high-dose amoxicillin–clavulanate is recommended as first-line therapy. Cefuroxime, cefpodoxime, and cefdinir are recommended for patients with a non–type I hypersensitivity to penicillin. Macrolides should be reserved for patients with an anaphylactic reaction to penicillin. Other options for these patients include clindamycin or trimethoprim–sulfamethoxazole. However, it should be remembered that clindamycin is not effective against gram-negative organisms such as *H influenzae*.

Failure to improve after 48–72 hours suggests a resistant organism or potential complication. Second-line therapies should be initiated at this point, or, if the patient is already on amoxicillin–clavulanate or cephalosporin, intravenous antibiotic therapy should be considered. Imaging and referral for sinus aspiration should be strongly considered as well.

Patients who are toxic, or who have evidence of invasive infection or CNS complications, should be hospitalized immediately. Intravenous therapy with nafcillin or clindamycin plus a third-generation cephalosporin such as cefotaxime should be initiated until culture results become available.

Topical decongestants and oral combinations are frequently used in acute rhinosinusitis to promote drainage. Their effectiveness has not been proven, and concern has been raised about potential adverse effects related to impaired ciliary function, decreased blood flow to the mucosa, and reduced diffusion of antibiotic into the sinuses. Patients with underlying allergic rhinitis may benefit from intranasal cromolyn or corticosteroid nasal spray. Topical nasal decongestants should not be used for more than 3 days due to risk of rebound edema.

Sinus and Allergy Health Partnership: Antimicrobial treatment guidelines for acute bacterial rhinosinusitis. *Otolaryngol Head Neck Surg* 2004;13:1 [PMID: 14726904].

2. Recurrent or Chronic Rhinosinusitis

Recurrent rhinosinusitis occurs when episodes of ABRs clear with antibiotic therapy but recur with each or most upper respiratory infections. Chronic rhinosinusitis is diagnosed when the child has not cleared the infection in the expected time but has not developed acute complications. Both symptoms and physical findings are required to support the diagnosis, and CT scan may be a useful adjuvant in making the diagnosis. Although recent meta-analysis evaluations have resulted in recommendations for ABRs, there is a paucity of data for the treatment of recurrent or chronic rhinosinusitis. Important factors to consider include allergies, anatomic variations, and disorders in host immunity. Mucosal inflammation leading to obstruction is most com-

▲ **Figure 17-8.** Management of children with uncomplicated acute bacterial rhinosinusitis (ABRS). (Reproduced, with permission, from the American Academy of Pediatrics: Clinical practice guidelines: Management of sinusitis. Pediatrics 2001;108:798.)

monly caused by allergic rhinitis and occasionally by nonallergic rhinitis. Gastroesophageal reflux has also been found to be associated with chronic rhinosinusitis. Less commonly, chronic rhinosinusitis is caused by anatomic variations, such as septal deviation, polyp, or foreign body. Allergic polyps are unusual in children younger than age 10 years and should prompt a workup for cystic fibrosis. In cases of chronic or recurrent pyogenic pansinusitis, poor host resistance (eg, an immune defect, Kartagener syndrome, or cystic fibrosis)—though rare—must be ruled out by immunoglobulin studies, microscopic studies of respiratory cilia, and a sweat chloride test. Anaerobic and staphylococcal organisms are often responsible for chronic rhinosinusitis. Evaluation by an allergist and an otolaryngologist may be useful in determining the underlying causes.

► Treatment

A. Medical Therapy

Antibiotic therapy is similar to that used for ABRS, but the duration is longer, typically 3–4 weeks. Antimicrobial choice should include drugs effective against staphylococcal organisms. Adjuvant therapies such as saline nasal irrigation, decongestants, antihistamines, or topical intranasal steroids may be helpful depending on the underlying cause. A small percentage of children do not respond to medical therapy and will require surgery.

B. Surgical Therapy

1. Antral lavage—Antral lavage, generally regarded as a diagnostic procedure, may have some therapeutic value. An aspirate or a sample irrigated from the maxillary sinus is retrieved under anesthesia, either with a spinal needle or a curved-tip instrument. In the very young child, this may be the only procedure that should be performed.

2. Adenoidectomy—Adenoidectomy has been shown to be effective in 50–75% of children with chronic rhinosinusitis. The role of the adenoids in this disease is not completely understood, but it is thought that the adenoids serve as a reservoir of pathogenic bacteria, and that the adenoids may also interfere with mucociliary clearance and drainage. Biofilms have been reported in the adenoids of children with chronic rhinosinusitis, and may explain the resistance of these infections to standard antibiotic therapy.

3. Endoscopic sinus surgery—Endoscopic sinus surgery in children was controversial because of concern about alteration of developing sinuses and impairment of midface growth. However, recent studies have not supported this concern. Endoscopic sinus surgery has been shown to be effective in children, and may be indicated in addition to adenoidectomy.

4. External drainage—External drainage procedures are reserved for complications arising from ethmoid and frontal sinusitis.

CHOANAL ATRESIA

Choanal atresia occurs in approximately 1 in 7000 live births. The female-to-male ratio is 2:1, as is the unilateral-to-bilateral ratio. Bilateral atresia results in severe respiratory distress at birth and requires immediate placement of an oral airway, and otolaryngology consultation for a more permanent surgical solution. Unilateral atresia usually appears later as a unilateral chronic nasal discharge that may be mistaken for chronic rhinosinusitis. Diagnosis may be suspected if a 6F catheter cannot be passed through the nose and is confirmed by axial CT scan. Approximately 50% of patients with bilateral choanal atresia have CHARGE association (Coloboma, Heart disease, Atresia of the choanae, Retarded growth and retarded development or CNS anomalies, Genital hypoplasia, and Ear anomalies or deafness) (see Chapter 35) or other congenital anomalies.

Keller JL, Kacker A: Choanal atresia, CHARGE association, and congenital nasal stenosis. *Otolaryngol Clin North Am* 2000; 33:1343 [PMID: 11449791].

RECURRENT RHINITIS

Recurrent rhinitis is frequently seen in the office practice of pediatrics. The child is brought in with the chief complaint of having “one cold after another,” “constant colds,” or “always being sick.” Approximately two thirds of these children have recurrent colds; the rest have either allergic rhinitis or recurrent rhinosinusitis.

1. Allergic Rhinitis

Allergic rhinitis has significant morbidity and may contribute to the development of rhinosinusitis and asthma exacerbations. Symptoms include nasal congestion, frequent sneezing, rubbing of the nose, and clear rhinorrhea. On physical examination the nasal turbinates are swollen and may be red or pale pink. Treatment with nasal corticosteroids is effective in decreasing the airway obstruction and rhinorrhea. Sneezing and clear drainage are controlled with non-sedating antihistamines. Montelukast, a leukotriene antagonist, has been shown to be effective in reducing nasal congestion, but it is less likely to improve the symptoms of itching, sneezing, and rhinorrhea, which are related to histamine release. Ipratropium can be used as an adjunctive therapy.

Pullerits T et al: Comparison of a nasal glucocorticoid, antileukotriene, and a combination of antileukotriene and antihistamine in the treatment of seasonal allergic rhinitis. *J Allergy Clin Immunol* 2002;109:949 [PMID: 12063523].

American Academy of Allergy, Asthma, and Immunology: http://www.aaaai.org/patients/allergic_conditions/rhinitis.stm

2. Vasomotor Rhinitis

Some children react to sudden changes in environmental temperature with prolonged congestion and rhinorrhea. Air pollution (especially tobacco smoke) may be a factor. Oral decongestants or nasal corticosteroids can be used to give symptomatic relief.

EPISTAXIS

The nose is an extremely vascular structure. In most cases, epistaxis (nosebleed) arises from the anterior portion of the nasal septum (Kiesselbach area), and is often due to dryness, or vigorous nose rubbing, nose blowing, or nose picking. If a patient has been using a nasal corticosteroid spray, check the patient's technique to make sure he or she is directing the nozzle laterally, away from the septum. If this does not reduce the nosebleeds, then the steroid spray should be discontinued. Examination of the anterior septum usually reveals a red, raw surface with fresh clots or old crusts. Also look for telangiectasias, hemangiomas, or varicosities.

In fewer than 5% of cases epistaxis is caused by a bleeding disorder such as von Willebrand disease. Patients need a hematologic workup if any of the following is present: a family history of a bleeding disorder; a medical history of easy bleeding, particularly with circumcision or dental extraction; spontaneous bleeding at any site; bleeding that lasts for more than 30 minutes or blood that will not clot with direct pressure by the physician; onset before age 2 years; or a drop in hematocrit due to epistaxis. High blood pressure may rarely predispose to prolonged nosebleeds in children.

A nasopharyngeal angiofibroma may be manifested by recurrent epistaxis. Adolescent boys are affected almost exclusively. CT scan of the nasal cavity and nasopharynx is diagnostic.

► Treatment

The following approach can be carried out in the office or offered as phone advice: The patient should sit up and lean forward so as not to swallow the blood. Swallowed blood may cause nausea and hematemesis. The nasal cavity should be cleared of clots by gentle blowing. The soft part of the nose below the nasal bones is pinched firmly enough to prevent arterial blood flow, with pressure over the bleeding site (anterior septum) being maintained for 5 minutes by the clock. For persistent bleeding, a one time only application of oxymetazoline (Afrin) into the nasal cavity may be helpful. If bleeding

continues, the bleeding site needs to be visualized. A small piece of gelatin sponge (Gelfoam) or collagen sponge (Sur-gicel) can be inserted over the bleeding site and held in place.

Friability of the nasal vessels can be decreased by increasing nasal moisture. This can be accomplished by daily application of a water-based ointment to the nose. A pea-sized amount of ointment is placed just inside the nose and the lubricant is spread by gently squeezing the nostrils. Twice-daily nasal saline irrigation and humidification of the patient's bedroom may also be helpful. Aspirin and ibuprofen should be avoided, as should nose picking and vigorous nose blowing. Cautery of the nasal vessels is reserved for treatment failures.

NASAL INFECTION

A nasal furuncle is an infection of a hair follicle in the anterior nares. Hair plucking or nose picking can provide a route of entry. The most common organism is *S aureus*. The diagnosis is made by finding an exquisitely tender, firm, red lump in the anterior nares. Treatment includes dicloxacillin or cephalexin orally for 5 days to prevent spread. The lesion should be gently incised and drained as soon as it points, usually with a needle. Topical bacitracin ointment may be of additional value. Because this lesion is in the drainage area of the cavernous sinus, the patient should be followed closely until healing is complete. Parents should be advised never to pick or squeeze a furuncle in this location—and neither should the physician. Associated cellulitis or spread requires hospitalization for administration of intravenous antibiotics.

A nasal septal abscess usually follows nasal trauma or a nasal furuncle. Examination reveals a fluctuant gray septal swelling, which is usually bilateral. The possible complications are the same as for nasal septum hematoma (see following discussion). In addition, spread of the infection to the CNS is possible. Treatment consists of immediate hospitalization and incision and drainage by an otolaryngologist.

NASAL TRAUMA

Newborn infants rarely present with subluxation of the quadrangular cartilage of the septum. In this disorder, the top of the nose deviates to one side, the inferior septal border deviates to the other side, the columella leans, and the nasal tip is unstable. This disorder must be distinguished from the more common transient flattening of the nose caused by the birth process. In the past, physicians were encouraged to reduce all subluxations in the nursery. Otolaryngologists are more likely to perform the reduction under anesthesia for more difficult cases.

Most blows to the nose result in swallowing of blood and hematoma formation without fracture. A persistent nose-bleed after trauma, crepitus, instability of the bones in the nasal bridge, and deviation of the nose to one side indicate fracture. However, septal injury cannot be ruled out by

radiography, and can only be ruled out by careful intranasal examination. Patients with suspected nasal fractures should be referred to an otolaryngologist for definitive therapy. Since the nasal bones begin healing within 7 days, the child must be seen by an otolaryngologist within 48–72 hours of the injury.

After nasal trauma, it is essential to examine the inside of the nose with a nasal speculum. Hematoma of the nasal septum imposes a considerable risk of pressure necrosis and resorption of the cartilage, leading to permanent nasal deformity that is very difficult to correct. This diagnosis is confirmed by the abrupt onset of nasal obstruction following trauma and the presence of a boggy, widened nasal septum. The normal nasal septum is only 2–4 mm thick. A cotton swab can be used to palpate the septum. Treatment consists of immediate referral to an otolaryngologist for evacuation of the hematoma and packing of the nose.

FOREIGN BODIES IN THE NOSE

The most common foreign bodies in the nose are seeds or beads. If the diagnosis is delayed, unilateral rhinorrhea, foul smell, halitosis, bleeding, or nasal obstruction may occur. The leading cause of halitosis in children is a nasal foreign body, and not dental disease as in adults.

There are many ways to remove nasal foreign bodies. The obvious first maneuver is vigorous nose blowing if the child is old enough. The next step in removal requires topical anesthesia, nasal decongestion, good lighting, correct instrumentation, and physical restraint. Topical tetracaine or lidocaine can be used in young children. Nasal decongestion can be achieved by topical pseudoephedrine or oxymetazoline. When the child is properly restrained, most nasal foreign bodies can be removed using a pair of alligator forceps through an operating head otoscope. If the object seems unlikely to be removed on the first attempt, is wedged in, or is quite large, the patient should be referred to an otolaryngologist rather than worsening the situation through futile attempts at removal.

Because the nose is a moist cavity, the electrical current generated by disk-type batteries—such as those used in clocks, watches, and hearing aids—can cause necrosis of mucosa and cartilage destruction in less than 4 hours. This constitutes a true foreign body emergency.

THE THROAT & ORAL CAVITY

ACUTE STOMATITIS

1. Recurrent Aphthous Stomatitis

Also referred to as canker sores, these small ulcers (3–10 mm) are usually found on the inner aspect of the lips or on

the tongue; rarely they may appear on the tonsils or palate. There is usually no associated fever and no cervical adenopathy. The ulcers may be painful and last 1–2 weeks. They may recur numerous times throughout life. The cause is unknown, although an allergic or autoimmune basis is suspected.

Treatment consists of coating the lesions with betamethasone valerate ointment twice daily, because unlike other topical corticosteroids, it adheres to the mucosa. Pain can also be reduced by eating a bland diet, avoiding salty or acidic foods and juices, and giving acetaminophen or ibuprofen.

Other less common causes of recurrent oral ulcers include Behçet disease, familial Mediterranean fever, and the FAPA syndrome (Fever, Aphthous stomatitis, Pharyngitis, and cervical Adenopathy). FAPA syndrome was first described in 1987, and its cause is unknown. It usually begins before a child is 5 years of age and continues through adolescence, then resolves. It recurs at 4- to 6-week intervals, and an episode may be dramatically improved with prednisone bursts, but recurrences continue. In one case report it resolved totally with a 6-month course of cimetidine, suggesting an immune etiology. FAPA may also resolve with tonsillectomy (see later section on tonsillectomy), and an otolaryngology referral is appropriate. The ulcers in all of these syndromes respond to betamethasone valerate application. A diagnosis of Behçet disease requires two of the following: genital ulcers, uveitis, and erythema nodosum-like lesions. Patients with Mediterranean fever usually have a positive family history, serosal involvement, and recurrent fever.

Dahn KA et al: Periodic fever and pharyngitis in young children: A new disease for the otolaryngologist? *Arch Otolaryngol Head Neck Surg* 2000;126:1146 [PMID: 10979131].

2. Herpes Simplex Gingivostomatitis (See also Chapter 38)

Children having their first infection with the herpes simplex virus develop 10 or more small ulcers (1–3 mm) of the buccal mucosa, anterior pillars, inner lips, tongue, and especially the gingiva. The ulcers do not affect the posterior pharynx. The lesions are often associated with fever, tender cervical nodes, and generalized inflammation of the mouth, which precedes the development of the ulcers. Typically, exposure to the virus occurs 3–50 days prior to the onset of symptoms. Affected children are commonly younger than 3 years of age. Gingivostomatitis lasts 7–10 days. Treatment is symptomatic, as described earlier for recurrent aphthous stomatitis, with the exception that corticosteroids are contraindicated because they may cause spread of the infection. If the patient is seen early in the course, the physician should prescribe oral acyclovir suspension (200 mg/5 mL), 20 mg/kg per dose, four times daily for 5 days. The patient must be followed closely because dehydration occasionally develops, requiring hospitalization. Herpetic laryngotracheitis is a rare complication.

3. Thrush (See also Chapter 41)

Oral candidiasis mainly affects infants and occasionally older children in a debilitated state. *Candida albicans* is a saprophyte that normally is not invasive unless the mouth is abraded or the patient is immunocompromised. The use of broad-spectrum antibiotics and systemic or inhaled corticosteroids may be contributing factors. The symptoms include soreness of the mouth and refusal of feedings. Lesions consist of white curdlike plaques, predominantly on the buccal mucosa, which cannot be washed away after a feeding. Another less common variation of oral candidal infection is erythematous candidiasis, which produces erythematous patches on the palate and dorsum of the tongue. This condition is associated primarily with patients who are taking broad-spectrum antibiotics or corticosteroids, or are HIV-positive.

Specific treatment consists of nystatin oral suspension. Treatment may begin by removing large plaques with a moistened cotton-tipped applicator, and half the nystatin may be rubbed on the lesions with an applicator. Gentian violet is probably also effective, but it can severely stain clothing and skin. Patients who do not respond to oral therapy or who are immunocompromised may require systemic antifungal agents. The parents should be advised to replace any items, such as a pacifier, that may have become contaminated with *Candida*.

4. Traumatic Oral Ulcers

Mechanical trauma most commonly occurs on the buccal mucosa secondary to accidentally biting with the molars. Thermal trauma, from very hot foods, can also cause ulcerative lesions. Chemical ulcers can be produced by mucosal contact with aspirin, caustics, and the like. Oral ulcers can also occur with leukemia or on a recurrent basis with cyclic neutropenia.

PHARYNGITIS

Figure 17-9 is an algorithm for the management of a sore throat.

1. Acute Viral Pharyngitis & Tonsillitis

Over 90% of cases of sore throat and fever in children are due to viral infections. The findings seldom give any clue to the particular viral agent, but four types of viral pharyngitis are sufficiently distinctive to support an educated guess about the specific cause and are listed below.

► Clinical Findings

A. Infectious Mononucleosis

The findings are exudative tonsillitis, generalized cervical adenitis, and fever, usually in a patient older than 5 years of age. A palpable spleen or axillary adenopathy increases the

likelihood of the diagnosis. The presence of more than 10% atypical lymphocytes on a peripheral blood smear or a positive mononucleosis spot test supports the diagnosis, although these tests are often falsely negative in children younger than age 5 years. Epstein-Barr virus serology showing an elevated IgM-capsid antibody is definitive. Clinicians should not prescribe amoxicillin for patients suspected of having mononucleosis because the drug often precipitates a rash and, in those with a viral infection, would be ineffective.

B. Herpangina

Herpangina ulcers are classically 3 mm in size and surrounded by a halo, and are found on the anterior pillars, the soft palate, and the uvula, but not the anterior mouth or tonsils. Herpangina is caused by several members of the coxsackie A group of viruses, and a patient may have several bouts of the ulcers. Enteroviral polymerase chain reaction testing, although now widely available, is not necessary as herpangina is a self-limiting illness.

C. Hand, Foot, and Mouth Disease

This entity is caused by several enteroviruses, only one of which (enterovirus 71) can rarely cause encephalitis. Ulcers occur anywhere in the mouth. Vesicles, pustules, or papules may be found on the palms, soles, interdigital areas, and buttocks. In younger children lesions may be seen on the distal extremities and even the face.

D. Pharyngoconjunctival Fever

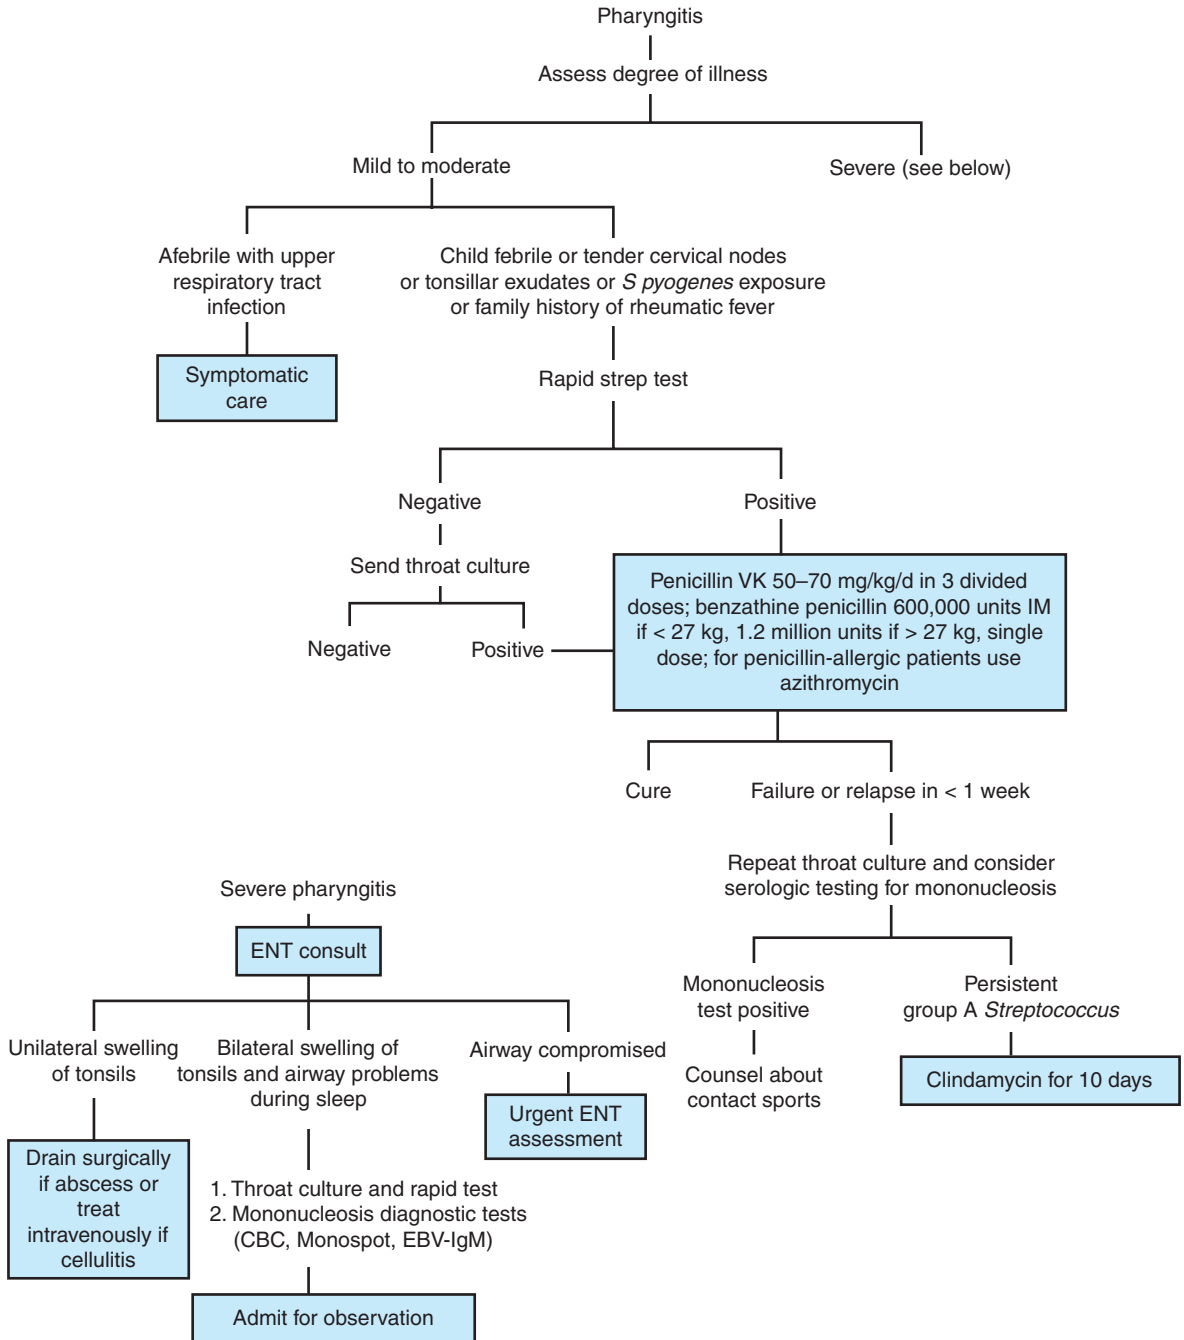

This disorder is caused by an adenovirus and often is epidemic. Exudative tonsillitis, conjunctivitis, lymphadenopathy, and fever are the main findings, and treatment is symptomatic.

2. Acute Bacterial Pharyngitis

Approximately 10% of children with sore throat and fever have a group A streptococcal infection. Less common causes of bacterial pharyngitis are *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, groups C and G streptococci, and *Arcanobacterium hemolyticum*. Of the five, *M pneumoniae* is by far the most common and may cause over one third of all pharyngitis cases in adolescents and adults.

► Clinical Findings

Untreated streptococcal pharyngitis can result in acute rheumatic fever, glomerulonephritis, and suppurative complications (eg, cervical adenitis, peritonsillar abscess, otitis media, cellulitis, and septicemia). Anterior cervical nodes, palatal petechiae, a beefy-red uvula, and a tonsillar exudate suggest streptococcal infection; however, the only way to make a definitive diagnosis is by throat culture or rapid antigen test. Rapid antigen tests are very specific, but have a sensitivity of

▲ **Figure 17-9.** Algorithm for pharyngitis. CBC, computed tomography; EBV, Epstein-Barr virus; ENT, ear, nose, and throat.

only 85–95%. Therefore, a positive test indicates *S pyogenes* infection, but a negative result requires confirmation by performing a culture. The presence of conjunctivitis, cough, hoarseness, symptoms of upper respiratory infection, ante-

rior stomatitis, discrete ulcerative lesions, viral rash, and diarrhea should raise suspicion of a viral cause.

Occasionally, a child with group A streptococcal infection develops scarlet fever within 24–48 hours after the onset of

symptoms. Scarlet fever is a diffuse, finely papular, erythematous eruption producing a bright red discoloration of the skin, which blanches on pressure. The rash is more intense in the skin creases. The tongue has a strawberry appearance.

► Treatment

The physician should treat cases of suspected or proven group A streptococcal infection with a 10-day course of oral penicillin V potassium, a cephalosporin, or intramuscularly injected penicillin G benzathine LA (Table 17-5). Penicillin VK is equally effective if given in two or three divided doses in school-aged children. However, in adolescents, three doses are recommended. Amoxicillin and azithromycin may be used once daily if compliance is a concern; however, both are broad-spectrum drugs that select for resistant nasopharyngeal flora.

The American Heart Association guidelines continue to recommend penicillin, with erythromycin for penicillin-allergic patients. A recent meta-analysis of trials of oral cephalosporins for streptococcal pharyngitis has concluded that penicillin should no longer be used. Just as in the case of otitis media meta-analyses, the quality of the trials included biases the results. In this case, inclusion of children who are carriers may bias certain of these trials. For further analysis of this controversy, the 2005 review by Gerber is highly recommended.

The treatment failure rate after 10 days of penicillin VK administered three times daily varies from 6–23%. However, over 50 years of treatment with penicillin, no group A streptococcal species have developed resistance to either penicillin or cephalosporins, so the cause of failure lies elsewhere. Patient compliance with 20 doses of medication is a large

factor in failures, and intramuscular benzathine penicillin should be considered strongly in children who fail during or immediately after treatment. It has been suggested that the presence of β -lactamase-producing organisms in the pharynx may inactivate penicillin, but this has not been proven.

Children who fail to respond to treatment may be given amoxicillin-clavulanate or azithromycin. Approximately 5% of *S pyogenes* organisms are resistant to erythromycin, and trimethoprim-sulfamethoxazole is ineffective against group A streptococci. Further, because trimethoprim-sulfamethoxazole is ineffective in the eradication of pharyngeal organisms and is ineffective in the prevention of acute rheumatic fever when used as therapy for acute pharyngeal infections, it is not recommended. Routine culturing after treatment is not recommended, since children may be carriers.

In general, the carrier state is harmless, self-limited (2–6 months), and not contagious. An attempt to eradicate the carrier state is warranted only if the patient or another family member has frequent streptococcal infections or when a family member or patient has a history of rheumatic fever or glomerulonephritis. If eradication is chosen, a course of clindamycin for 10 days or of rifampin for 5 days should be used.

In the past, daily penicillin prophylaxis was occasionally recommended; however, to prevent development of drug resistance, tonsillectomy is now preferred.

Bisno AL: Are cephalosporins superior to penicillin for treatment of acute streptococcal pharyngitis? *Clin Infect Dis* 2004;38:1535 [PMID: 15156438].

Bisno AL et al: Practice guidelines for the diagnosis and management of group A streptococcal pharyngitis. *Clin Infect Dis* 2002;35:113 [PMID: 12087516].

Table 17-5. Treatment of group A streptococcal pharyngitis.

Drug	Duration of Therapy	Dose	Clinical Cure Rate
Treatment of acute pharyngitis			
Penicillin	10 d	Penicillin V 50-75 mg/kg/d in 3 divided doses Benzathine penicillin 600,000 units IM if < 27 kg, 1.2 million units if > 27 kg, single dose	63-64%
Amoxicillin	10 d	50 mg/kg/d once daily	86%
Azithromycin	5 d	12 mg/kg once daily	82%
Cephalexin	10 d	25-50 mg/kg/d in divided doses	94%
Eradication of carrier state			
Clindamycin	10 d	20 mg/kg/d in 3 divided doses	92% for carrier state
Penicillin + rifampin	10 d (rifampin final 4 d)	Penicillin V 50-75 mg/kg/d in 3 divided doses Benzathine penicillin 600,000 units IM if < 27 kg, 1.2 million units if > 27 kg, single dose Rifampin 20 mg/kg/d twice daily for 4 d	55%

PERITONSILLAR CELLULITIS OR ABSCESS (QUINSY)

Tonsillar infection occasionally penetrates the tonsillar capsule, spreads to the surrounding tissues, and causes peritonsillar cellulitis. If untreated, necrosis occurs and a tonsillar abscess forms. This can occur at any age. The most common cause is β -hemolytic streptococcal infection. Other pathogens are group D streptococci, β -hemolytic streptococci, *S pneumoniae*, and anaerobes.

The patient complains of a severe sore throat even before the physical findings become marked. A high fever is usually present, and the process is almost always unilateral. The tonsil bulges medially, and the anterior tonsillar pillar is prominent. The soft palate and uvula on the involved side are edematous and displaced toward the uninvolved side. In cases of abscess formation, trismus, ear pain, dysphagia, and eventually drooling occur. The most serious complication of inadequately treated peritonsillar abscess is a lateral pharyngeal abscess. This causes fullness and tenderness of the lateral neck as well as torticollis. Without intervention, the lateral pharyngeal abscess threatens life by airway obstruction or carotid artery erosion. If airway symptoms are present, an immediate otolaryngology consultation is indicated.

It is often difficult to differentiate peritonsillar cellulitis from abscess. In some children, it is possible to aspirate the peritonsillar space to diagnose and treat an abscess. However, it is reasonable to admit a child for 12–24 hours of intravenous antimicrobial therapy, because aggressive treatment in early cases of peritonsillar cellulitis usually prevents suppuration. Therapy with penicillin or clindamycin is appropriate. Failure to respond to therapy during the first 12–24 hours indicates a high probability of abscess formation. An otolaryngologist should be consulted for incision and drainage or for aspiration under local or general anesthesia. Prompt referral is indicated if the child is having respiratory difficulty.

Recurrent peritonsillar abscesses are so uncommon (7%) that routine tonsillectomy for a single bout is not indicated unless other tonsillectomy indications exist. Hospitalized patients can be discharged on oral antibiotics when fever has resolved for 24 hours and dysphagia has improved.

Schraff S et al: Peritonsillar abscess in children: a 10-year review of diagnosis and management. *Int J Pediatr Otorhinolaryngol* 2001;57:213 [PMID: 11223453].

RETROPHARYNGEAL ABSCESS

Retropharyngeal nodes drain the adenoids, nasopharynx, and paranasal sinuses and can become infected. The most common causes are β -hemolytic streptococci and *S aureus*. If this pyogenic adenitis goes untreated, a retropharyngeal abscess forms. The process occurs most commonly during the first 2 years of life. Beyond this age, retropharyngeal abscess usually results from superinfection of a penetrating injury of the posterior wall of the oropharynx.

The diagnosis of retropharyngeal abscess should be strongly suspected in an infant with fever, respiratory symptoms, and neck hyperextension. Dysphagia, drooling, dyspnea, and gurgling respirations are also found and are due to impingement by the abscess. Prominent swelling on one side of the posterior pharyngeal wall confirms the diagnosis. Swelling usually stops at the midline because a medial raphe divides the prevertebral space. Lateral neck soft tissue films show the retropharyngeal space to be wider than the C4 vertebral body.

Although retropharyngeal abscess is a surgical emergency, frequently it cannot be distinguished from retropharyngeal adenitis. Immediate hospitalization and intravenous antimicrobial therapy with a semisynthetic penicillin or clindamycin is the first step for most cases. Immediate surgical drainage is required when a definite abscess is seen radiographically or when the airway is compromised markedly. In most instances, a period of 12–24 hours of antimicrobial therapy will help to differentiate the two entities. In the child with adenitis, fever will decrease and oral intake will increase. A child with retropharyngeal abscess will continue to deteriorate. A surgeon should incise and drain the abscess under general anesthesia to prevent its extension.

LUDWIG ANGINA

Ludwig angina is a rapidly progressive cellulitis of the submandibular space that can cause airway obstruction and death. The submandibular space extends from the mucous membrane of the floor of the mouth to the muscular and fascial attachments of the hyoid bone. This infection is encountered infrequently in infants and children. The initiating factor in over 50% of cases is dental disease, including abscesses and extraction. Some patients have a history of lacerations and injuries to the floor of the mouth. Group A streptococci are the most common organism identified, but other pathogens cause the infection.

The manifestations are fever and tender swelling of the floor of the mouth. The tongue can become enlarged as well as tender and erythematous. Upward displacement of the tongue may cause dysphagia, drooling, and airway obstruction.

Treatment consists of giving high doses of intravenous clindamycin or ampicillin plus nafcillin until the results of cultures and sensitivity tests are available. Because the most common cause of death in Ludwig angina is sudden airway

obstruction, the patient must be monitored closely in the intensive care unit and intubation provided for progressive respiratory distress. An otolaryngologist should be consulted to identify and perform a drainage procedure.

Britt JC et al: Ludwig's angina in the pediatric population: Report of a case and review of the literature. *Int J Pediatr Otorhinolaryngol* 2000;52:79 [PMID: 10699244].

ACUTE CERVICAL ADENITIS

Local infections of the ear, nose, and throat can involve a regional node and form an abscess. The typical case involves a unilateral, solitary, anterior cervical node. About 70% of these cases are due to β -hemolytic streptococcal infection, 20% to staphylococci, and the remainder to viruses, atypical mycobacteria, and *Bartonella henselae*. Methicillin-resistant *S aureus* (MRSA) must also be considered.

The initial evaluation of cervical adenitis should generally include a rapid group A streptococcal test, a complete blood count with differential looking for atypical lymphocytes, and a purified protein derivative skin test, looking for nontuberculous mycobacteria. If multiple enlarged nodes are found in addition to the sentinel node, a rapid mononucleosis test is useful. Early treatment with antibiotics prevents many cases of adenitis from progressing to suppuration. However, once fluctuation occurs, antibiotic therapy alone is often insufficient and needle aspiration may promote resolution. Depending on abscess size, an incision and drainage procedure may be necessary. Because of the increase in community acquired MRSA, it is a prudent to send a specimen for culture and sensitivity.

Cat-scratch disease is caused by *B henselae* and is the most frequent cause of indolent ("cold") adenopathy. The diagnosis is aided by the finding of a primary papule at the scratch site on the face. In over 90% of patients, there is a history of contact with kittens. The node is usually only mildly tender but may, over a month or more, suppurate and drain. About one third of children have fever and malaise, and rarely neurologic sequelae and prolonged fever occur. Cat-scratch disease can be diagnosed by serologic testing available at commercial laboratories, but testing is not always confirmatory. Blood should be drawn 2–8 weeks after onset of symptoms. Because most nodes caused by this pathogen spontaneously resorb within 1–3 months, the benefit of antibiotics is controversial. In a placebo-controlled trial, azithromycin for 5 days caused a more rapid decrease in node size. Other drugs likely to be effective include rifampin, trimethoprim–sulfamethoxazole, erythromycin, clarithromycin, doxycycline, ciprofloxacin, and gentamicin.

Cervical lymphadenitis can be caused by nontuberculous mycobacterial species or *Mycobacterium avium* complex. Mycobacterial disease is unilateral and may involve several matted nodes, and poor dentition may provide an entry portal. A characteristic violaceous appearance may develop over a prolonged period of time without systemic signs or much local pain. Atypical mycobacterial infections are often associated with positive purified protein derivative skin test

reactions less than 10 mm in diameter, and a second-strength (250-test-unit) purified protein derivative skin test is virtually always positive.

► Differential Diagnosis

A. Neoplasms and Cervical Nodes

Malignant tumors usually are not suspected until the adenopathy persists despite antibiotic treatment. Classically, the nodes are painless, nontender, and firm to hard in consistency. They may be fixed to underlying tissues. These nodes may occur as a single node, as unilateral nodes in a chain, bilateral cervical nodes, or generalized adenopathy. Common malignancies that may manifest in the neck include Hodgkin disease, non-Hodgkin lymphoma, rhabdomyosarcoma, and thyroid carcinoma.

B. Imitators of Adenitis

Several structures in the neck can become infected and resemble a node. The first three masses are of congenital origin and are listed in order of frequency.

1. Thyroglossal duct cyst—When superinfected, this congenital malformation can become acutely swollen. Helpful findings are the fact that it is in the midline, located between the hyoid bone and suprasternal notch, and moves upward when the tongue is stuck out or during swallowing. Occasionally, the cyst develops a sinus tract and opening just lateral to the midline.

2. Branchial cleft cyst—When superinfected, this malformation can become a tender mass 3–5 cm in diameter. Aids to diagnosis are the fact that the mass is located along the anterior border of the sternocleidomastoid muscle and is smooth and fluctuant. Occasionally it is attached to the overlying skin by a small dimple or a draining sinus tract.

3. Lymphatic malformation—Most of these lymphatic cysts are located in the posterior triangle just above the clavicle. The mass is soft and compressible and can be transilluminated. Over 60% of lymphatic malformations are noted at birth; the remaining malformations are usually seen by the time the child is age 2 years. If cysts become large enough, they can compromise the patient's ability to swallow and breathe.

4. Parotitis—The most common pitfall is mistaking parotitis for cervical adenitis. However, a swollen parotid crosses the angle of the jaw, is associated with preauricular percussion tenderness, and is bilateral in 70% of cases. There may be a history of exposure to mumps, but in the United States viruses such as parainfluenza are now the main cause. An amylase level will be elevated in parotitis.

5. Ranula—A ranula is a cyst in the floor of the mouth caused by obstruction of the ducts of the sublingual gland. A plunging ranula extends below the mylohyoid muscle and can appear as a neck mass.

6. Sternocleidomastoid muscle hematoma—This cervical mass is noted at age 2–4 weeks. On close examination, it is found to be part of the muscle body and not movable. An associated torticollis usually confirms the diagnosis.

SNORING, MOUTH BREATHING, & UPPER AIRWAY OBSTRUCTION

In April 2002, the American Academy of Pediatrics published a clinical practice guideline for the diagnosis and management of uncomplicated childhood obstructive sleep apnea syndrome. Currently, OSA is considered just one component of a broader spectrum of disease known as sleep-disordered breathing (SDB) that ranges from primary snoring (isolated snoring without apnea, arousals, or gas-exchange abnormalities) to upper airway resistance syndrome (UARS) to OSA. Historically, primary snoring (PS) had not been considered to be pathologic so surgery was felt to be unnecessary. The guideline emphasizes that pediatricians should screen all children for snoring and that complex high-risk patients should be referred to a specialist.

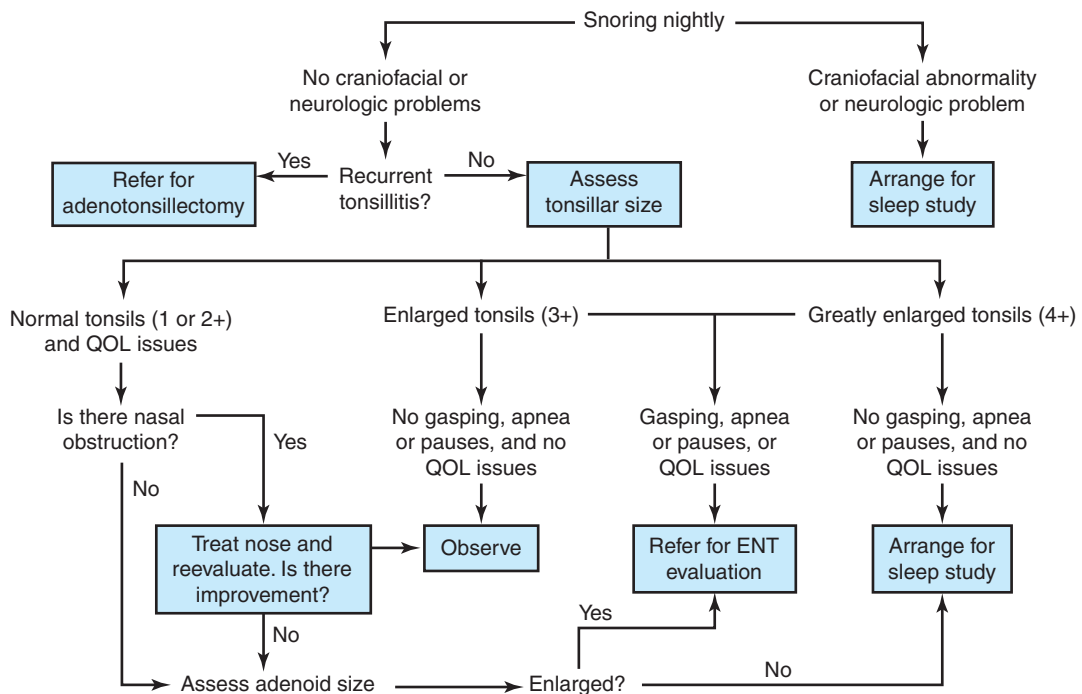

Clinical Evaluation & Management

When parents report that their child has nightly snoring and is a mouth breather even during the day, one should be suspicious of OSA. In a healthy child, evaluation of three symptoms and signs can help determine the need for polysomnography or surgery.

1. Nighttime symptoms: habitual snoring along with gasping, pauses, or struggling to breathe.
2. Daytime symptoms: unrefreshed sleep, attention deficit, hyperactivity, emotional lability, temperamental behavior, poor weight gain, and daytime fatigue.
3. Enlarged tonsils.

If all three findings are present, some clinicians would consider proceeding with surgery without polysomnography. If the three findings cannot be confirmed but the child has other indications for an adenotonsillectomy—ie, recurrent tonsillitis, markedly enlarged (4+) tonsils with dysphagia—surgery is also scheduled.

Figure 17–10 is an algorithm for management of these complaints. The pathway relies on clinical symptoms and tonsil size. Low muscle tone also contributes to an individual’s propensity to experience SDB. However, measurement of muscle tone is not straightforward. Although the pathway states that an asymptomatic child with markedly enlarged tonsils (4+) should undergo an overnight poly-

▲ **Figure 17-10.** Algorithm for snoring. ENT, ear, nose and throat; QOL, quality of life.

somnographic study, a period of observation is reasonable. One's clinical suspicion of SDB should be heightened in the presence of enlarged tonsils, especially if the parents cannot provide a reliable history. If the child has no clinical symptoms and the tonsils are only moderately enlarged (3+), observation is appropriate. Educating the parents about the risks of SDB and what to look for is paramount.

A polysomnographic study is recommended for a child who has no adenotonsillar hypertrophy with a patent nose but significant daytime symptoms of SDB. Other conditions, especially a periodic limb movement disorder, may mimic SDB. If the polysomnogram does detect SDB in a child with no adenotonsillar hypertrophy, a complete evaluation of the upper airway by flexible laryngoscopy should be performed to look for other possible sites of obstruction: base of tongue, lingual tonsils, hypopharynx or larynx.

The adenoids can also be assessed by radiographic studies. Either adenoid hypertrophy or nasal obstruction can be assumed when a child has hyponasal speech. The consonants "m," "n," and "ng" rely on the palate not touching the posterior pharyngeal wall. By having a child repeat the word "banana" or "ninety-nine" with the nose open or pinched closed, one may assess the nasal and nasopharyngeal airways. If the voice does not change with occlusion of the nostrils, then either adenoid or nasal obstruction is present.

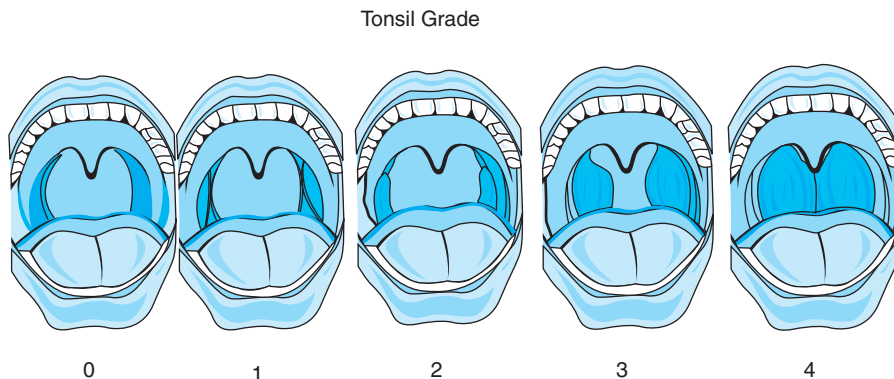

Although nasal obstruction is usually due to allergic rhinitis and can be diagnosed by a careful allergy history, there are other less common causes. Nasal polyps appear as glistening, gray to pink, jelly-like masses that are prominent just inside the anterior nares and occur singly or in clusters. They occur in cystic fibrosis and severe allergic rhinitis. Persistent mouth breathing may also rarely be due to a nasopharyngeal tumor, or to a meningocele herniated into the nasal cavity. For male patients, if unilateral nasal obstruction and epistaxis occur frequently, juvenile angiofibroma

should be suspected. If allergic rhinitis is the suspected cause of snoring, a trial of intranasal corticosteroid spray is indicated. If enlarged tonsils (Figure 17–11) or adenoids are present, a referral to an otolaryngologist or a pediatric sleep laboratory is in order.

Polysomnography

The gold standard for diagnosis of OSA is a polysomnogram. A patient's history and clinical examination cannot predict the presence or severity of OSA. Similarly, an overnight oximetry study is a poor screening test for OSA; it may detect patients with severe disease but miss those with milder forms, such as upper airway resistance syndrome. Patients with this syndrome have an otherwise normal polysomnogram with the only evidence of obstruction being increased respiratory effort.

The criteria for diagnosing OSA differ between children and adults. An obstructive event occurs when airflow stops despite persistence of respiratory effort. A hypopnea episode is counted when airflow and respiratory effort decrease with an associated oxygen desaturation or arousal. Normative values are just being established. The revised edition of the *International Classification of Sleep Disorders*, published by the American Academy of Sleep Medicine (AASM), states that for children, the occurrence of more than one apneic or hypopneic event per hour with duration of at least two respiratory cycles is abnormal. However, the diagnostic committee of the AASM qualified its recommendation, stating that the criteria may be modified once more comprehensive data become available. An investigation of SDB in children between the ages of 6 and 11 years was the first study to evaluate clinical relevance using full polysomnograms. The study demonstrated that a respiratory disturbance index of at least one event per hour, when associated with a 3% oxygen desaturation, was associated with daytime sleepiness

▲ **Figure 17-11.** A grading scale for tonsil size that ranges from 0 to 4. With grade 0 the tonsils are small and contained within the tonsillar fossa; in grade 4 the tonsils are so large they almost touch ("kissing"). (Reprinted, with permission, from Brodsky L: Modern assessment of tonsils and adenoids. *Pediatr Clin North Am* 1989;36:1551.)

and learning problems. If oxygen desaturations were absent, a respiratory disturbance index of five events per hour was associated with clinical symptoms.

Although an obstructive apnea index of greater than one event may be statistically significant, whether it is clinically relevant remains unclear. Any child with an apnea-plus-hypopnea index of greater than five events per hour appears to have clinically significant SDB. The dilemma is how to manage children with an apnea-plus-hypopnea index of more than one but fewer than five events per hour as some of these children do experience neurocognitive symptoms.

Complications & Sequelae

The importance of diagnosing OSA and SDB in children cannot be underestimated. Recent studies have shown that teenagers who are loud snorers exhibit impaired school performance, and that behavioral problems are associated with OSA. Likewise, a recent comprehensive review of the literature by Beebe provides a strong argument that SDB affects neurocognition and behavior.

TONSILLECTOMY & ADENOIDECTOMY

Tonsillectomy

A tonsillectomy with or without adenoidectomy is typically performed for either hypertrophy or recurrent infections.

Nowadays, the most common indication for an adenotonsillectomy is adenotonsillar hypertrophy that is associated with an obstructed breathing pattern at night (see earlier discussion of OSA and SDB). Besides producing airway obstruction, adenotonsillar hypertrophy may produce dysphagia or dental malocclusion. Rarely, hypertrophied tonsils may produce pulmonary hypertension or cor pulmonale. Recurrent infections are present when a child has seven or more documented *S pyogenes* infections in 1 year, five per year for 2 years, or three per year for 3 years. A tonsillectomy is reasonable if fewer infections are present but the child has missed multiple school days or has a complicated course. Recurrent peritonsillar abscesses and persistent streptococcal carrier state are other indications, as well as unilateral tonsillar hypertrophy that appears neoplastic.

A possible new indication is FAPA syndrome (see section on Recurrent Aphthous Stomatitis, earlier), in which the fever is predictable and commonly occurs every 4–8 weeks. Removal of the tonsils was shown to relieve the symptoms in five children in one recent study.

Recently, a proliferation of new surgical techniques has occurred that can potentially reduce the morbidity associated with an adenotonsillectomy.

Adenoidectomy

The adenoids, composed of lymphoid tissue in the nasopharynx, are a component of the Waldeyer ring of lymphoid tissue, which also includes the palatine tonsils and lingual tonsils. Enlargement of the adenoids with or without infection can obstruct the upper airway, alter normal orofacial growth, and interfere with speech, swallowing, or eustachian tube function. Most children with prolonged mouth breathing eventually develop dental malocclusion and what has been termed an adenoidal facies. The face is pinched and the maxilla narrowed because the molding pressures of the orbicularis oris and buccinator muscles are unopposed by the tongue. The role of hypertrophy and chronic infection in the pathogenesis of rhinosinusitis is unclear, but adenoidectomy has been shown to be effective in some patients with chronic rhinosinusitis.

Indications for adenoidectomy with or without tonsillectomy include pulmonary conditions such as chronic hypoxia related to upper airway obstruction; orofacial conditions such as mandibular growth abnormalities and dental malocclusion; speech abnormalities; persistent middle ear effusion; recurrent and chronic otitis media; and chronic rhinosinusitis.

Complications of Tonsillectomy & Adenoidectomy

The reported mortality rates associated with tonsillectomy and adenoidectomy now approximate that of general anesthesia alone. The rate of hemorrhage varies between 0.1% and 8.1% depending on the definition of hemorrhage; the rate of postoperative transfusion is 0.04%. Other complications include hypernasal speech (< 0.01%), and more rarely nasopharyngeal stenosis, atlantoaxial subluxation, mandible condyle fracture, and psychological trauma.

Contraindications to Tonsillectomy & Adenoidectomy

A. Short Palate

Adenoids should not be removed completely in a child with a cleft palate or submucous cleft palate because of the risk of aggravating the velopharyngeal incompetence and causing hypernasal speech and nasal regurgitation. A superior or partial adenoidectomy can be performed in a child with marked OSA who has a submucous cleft palate or ongoing conductive hearing loss from middle ear effusion.

B. Bleeding Disorder

If a chronic bleeding disorder is present, it must be diagnosed and treated before tonsillectomy and adenoidectomy.

C. Acute Tonsillitis

An elective tonsillectomy and adenoidectomy can often be postponed until acute tonsillitis is resolved. Urgent tonsillectomy may be required for tonsillitis unresponsive to medical therapy.

DISORDERS OF THE LIPS

1. Labial Sucking Tubercle

A young infant may present with a small callus in the mid-upper lip. It usually is asymptomatic and disappears after cup feeding is initiated.

2. Cheilitis

Dry, cracked, scaling lips are usually caused by sun or wind exposure. Contact dermatitis from mouthpieces or various woodwind or brass instruments has also been reported. Licking the lips accentuates the process, and the patient should be warned of this. Liberal use of lip balms gives excellent results.

3. Inclusion Cyst

Inclusion (retention) cysts are due to the obstruction of mucous glands or other mucous membrane structures. In the newborn, they occur on the hard palate or gums and are called Epstein pearls. These small cysts resolve spontaneously in 1–2 months. In older children, inclusion cysts usually occur on the palate, uvula, or tonsillar pillars. They appear as taut yellow sacs varying in size from 2–10 mm. Inclusion cysts that do not resolve spontaneously may undergo incision and drainage. Occasionally a mucous cyst on the lower lip (mucocele) requires excision for cosmetic reasons. Mucoceles pathologically are a blocked minor salivary gland.

DISORDERS OF THE TONGUE

1. Geographic Tongue (Benign Migratory Glossitis)

This condition of unknown cause occurs in 1–2% of the population with no age, sex, or racial predilection and is characterized by irregularly shaped areas on the tongue that are devoid of papillae and surrounded by parakeratotic reddish borders. The pattern changes as alternating regeneration and desquamation occurs. The lesions are generally asymptomatic and require no treatment.

2. Fissured Tongue (Scrotal Tongue)

This condition is marked by numerous irregular fissures on the dorsum of the tongue. It occurs in approximately 1% of the population and is usually a dominant trait. It is also frequently seen in children with trisomy 21 and other developmentally delayed patients who have the habit of chewing on a protruded tongue.

3. Coated Tongue (Furry Tongue)

The tongue normally becomes coated if mastication is impaired and the patient is taking a liquid or soft diet. Mouth breathing, fever, or dehydration can accentuate the process.

4. Macroglossia

Tongue hypertrophy and protrusion may be a clue to trisomy 21, Beckwith-Wiedemann syndrome, glycogen storage disease, cretinism, mucopolysaccharide storage disease, lymphangioma, or hemangioma. Tongue reduction procedures should be considered in otherwise healthy subjects when macroglossia affects airway patency.

HALITOSIS

Bad breath is usually due to acute stomatitis, pharyngitis, rhinosinusitis, a nasal foreign body, or dental hygiene problems. In older children and adolescents, halitosis can be a manifestation of chronic rhinosinusitis, gastric bezoar, bron-

chiectasis, or lung abscess. The presence of orthodontic devices or dentures can cause halitosis if good dental hygiene is not maintained. Halitosis can also be caused by decaying food particles embedded in cryptic tonsils. In adolescents, tobacco use is a common cause. Mouthwashes and chewable breath fresheners give limited improvement. Treatment of the underlying cause is indicated, and a dental referral may be in order.

Cicek Y et al: Effect of tongue brushing on oral malodor in adolescents. *Pediatr Int* 2003;45:719 [PMID: 14651548].

SALIVARY GLAND DISORDERS

1. Parotitis

A first episode of parotitis may safely be considered to be of viral origin, unless fluctuance is present. The leading cause was mumps until adoption of vaccination; now the leading viruses are parainfluenza and Epstein-Barr virus. HIV infection should be considered if the child is known to be at risk.

2. Suppurative Parotitis

Suppurative parotitis is an uncommon clinical disorder occurring chiefly in newborns and debilitated elderly patients. The parotid gland is swollen, tender, and often reddened, usually unilaterally. The diagnosis is made by expression of purulent material from the Stensen duct. The material should be smeared and cultured. Fever and leukocytosis may be present.

Treatment includes hospitalization and intravenous nafcillin because the most common causative organism is *S aureus*.

3. Recurrent Idiopathic Parotitis

Some children experience repeated episodes of parotid swelling that last 1–2 weeks and then resolve spontaneously, or can become infected and require antibiotics for resolution. There is usually pain and often no fever. The process is most often unilateral, suggesting some sort of obstructive process, but can be associated with Sjögren syndrome, another autoimmune process, HIV infection, or a calculus in the parotid duct. Serum amylase levels are normal, which speaks against a diagnosis of viral parotitis. Recently increased IgA levels have been found in these children. Many episodes occur from age 2 years on. The problem often resolves spontaneously at puberty.

Treatment includes analgesics if pain is present and an antistaphylococcal antibiotic for prophylaxis of infection and quicker resolution at the onset of symptoms. A second attack of parotid swelling without fever should result in referral to an otolaryngologist to make the diagnosis.

Fazekas T: Selective IgA deficiency in children with recurrent parotitis of childhood. *Pediatr Infect Dis J* 2005;24:461 [PMID: 15876950].

4. Tumors of the Parotid Gland

Mixed tumors, hemangiomas, sarcoidosis, and leukemia can be manifested in the parotid gland as a hard or persistent mass. A cystic mass or multiple cystic masses may represent an HIV infection. Workup may require consultation with oncology, infectious diseases, hematology, and otolaryngology.

5. Ranula

A ranula is a retention cyst of a sublingual salivary gland. It occurs on the floor of the mouth to one side of the lingual frenulum. Ranula has been described as resembling a frog's belly because it is thin-walled and contains a clear bluish fluid. Referral to an otolaryngologist for excision of the cyst and associated sublingual gland is the treatment of choice.

CONGENITAL ORAL MALFORMATIONS

1. Tongue-Tie (Ankyloglossia)

The tightness of the lingual frenulum varies greatly among normal people. A short frenulum prevents both protrusion and elevation of the tongue. Puckering of the midline of the tongue occurring with tongue movement is noted on physical examination.

When mild, treatment consists of reassurance. If the tongue cannot protrude past the teeth or alveolar ridge or move between the gums and cheek, referral to an otolaryngologist or dentist for evaluation is indicated. Frenulectomy may be recommended if there is a question of suckling difficulties, dental health (related to the inability to clear food from around the teeth), or articulation problems. A frenulectomy should be performed in the neonatal period if the infant is having difficulty latching onto the breast. In our practice, a neonatal frenulectomy is performed in clinic.

Messner AH, Lalakea ML: Ankyloglossia: Controversies in management. *Int J Pediatr Otorhinolaryngol* 2000;54:123 [PMID: 10967382].

Messner AH, Lalakea ML: The effect of ankyloglossia on speech in children. *Otolaryngol Head Neck Surg* 2002;127:539 [PMID: 12501105].

2. Torus Palatini

Hard midline masses on the palate are called torus palatini. They are bony protrusions that form at suture lines of bone. Usually they are asymptomatic and require no therapy. They can be surgically reduced if necessary.

3. Cleft Lip & Cleft Palate (See Chapter 35)

A. Submucous Cleft Palate

A bifid uvula is present in 3% of healthy children. However, a close association exists (as high as 75%) between bifid uvula and submucous cleft palate. A submucous cleft can be

diagnosed by noting a translucent zone in the middle of the soft palate (zona pellucida). Palpation of the hard palate reveals absence of the posterior bony protrusion. Affected children have a 40% risk of developing persistent middle ear effusion. They are at risk also of incomplete closure of the palate, resulting in hypernasal speech. During feeding, some of these infants experience nasal regurgitation of food. Children with submucous cleft palate causing abnormal speech or nasal regurgitation of food require referral for surgical repair.

B. High-Arched Palate

A high-arched palate is usually a genetic trait of no consequence. It also occurs in children who are chronic mouth breathers and in premature infants who undergo prolonged oral intubation. Some rare causes of high-arched palate are congenital disorders such as Marfan syndrome, Treacher Collins syndrome, and Ehlers-Danlos syndrome.

C. Pierre Robin Sequence

This group of congenital malformations is characterized by the triad of micrognathia, cleft palate, and glossoptosis. Affected children present as emergencies in the newborn period because of infringement on the airway by the tongue. The main objective of treatment is to prevent asphyxia until the mandible becomes large enough to accommodate the tongue. In some cases, this objective can be achieved by leaving the child in a prone position while unattended. Other airway manipulations such as a nasal trumpet may be necessary. Recently distraction osteogenesis has been used to avoid tracheostomy. In severe cases, a tracheostomy is required. The child requires close observation and careful feeding until the problem is outgrown.

RESPIRATORY TRACT

Pediatric pulmonary diseases account for almost 50% of deaths in children younger than age 1 year and about 20% of all hospitalizations of children younger than age 15 years. Approximately 7% of children have a chronic disorder of the lower respiratory system. Understanding the pathophysiology of many pediatric pulmonary diseases requires an appreciation of the normal growth and development of the lung.

GROWTH & DEVELOPMENT

The lung has its origins from an outpouching of the foregut during the fourth week of gestation. The development of the lung is divided into five overlapping stages.

1. *Embryonic stage* (3–7 weeks' gestation). During this stage, the primitive lung bud undergoes asymmetrical branching and then subsequent dichotomous branching, leading to the development of the conducting airways. This stage of lung development is dependent on a complex interaction of various growth factors originating in both the pulmonary epithelium and the splanchnic mesenchyme. It also sees the development of the large pulmonary arteries from the sixth aortic arch and the pulmonary veins as outgrowths of the left atrium. Abnormalities during this stage result in congenital abnormalities such as lung aplasia, tracheoesophageal fistula, and congenital pulmonary cysts.
2. *Pseudoglandular stage* (5–17 weeks' gestation). During this stage, which overlaps with the embryonic stage, the lung has a glandular appearance and witnesses the completion of the conducting airways (bronchi and bronchioles). The respiratory epithelium of these airways begins to differentiate, and the presence of cartilage, smooth muscle cells, and mucus glands are first seen. In addition, the pleuroperitoneal cavity divides into two distinct compartments. Abnormalities during this stage lead to

pulmonary sequestration, cystic adenomatoid malformation, and congenital diaphragmatic hernia.

3. *Canalicular stage* (16–26 weeks' gestation). This stage witnesses the delineation of the pulmonary acinus. The alveolar type II cells differentiate into type I cells, the pulmonary capillary network develops, and the alveolar type I cells closely approximate with the developing capillary network. Abnormalities of development during this stage include neonatal respiratory distress syndrome and lung hypoplasia.
4. *Saccular stage* (26–36 weeks' gestation). During this stage further branching of the terminal saccules takes place as well as a thinning of the interstitium and fusion of the type I cell and capillary basement membrane in preparation for the lungs' function as a gas-exchange organ.
5. *Alveolar stage* (36 weeks' gestation to 3–8 years of age). Controversy surrounds the length of this stage of lung development. This stage witnesses secondary septal formation, further sprouting of the capillary network, and the development of true alveoli. Abnormalities during this stage lead to lung hypoplasia and can result in the development of bronchopulmonary dysplasia.

At birth, the lung assumes the gas-exchanging function served by the placenta in utero, placing immediate stress on all components of the respiratory system. Abnormalities in the lung, respiratory muscles, chest wall, airway, respiratory controller, or pulmonary circulation may therefore be present at birth. Survival after delivery depends, for example, on the development of the surfactant system to maintain airspace stability and allow gas exchange. Immaturity of the surfactant system, often seen in infants born before 35 weeks' gestational age, can result in severe respiratory morbidity in the immediate neonatal period as well as subsequent chronic lung disease. A lethal form of lung disease has been recognized in infants homozygous for abnormalities in the gene for surfactant protein B. Persistent pulmonary hypertension of the newborn (failure of the normal transition to a low-

resistance pulmonary circulation at birth) can complicate several neonatal respiratory diseases. There is mounting evidence that abnormalities during fetal and neonatal growth and development of the lung have long-standing effects into adulthood, such as reduced gas exchange, exercise intolerance, asthma, and an increased risk of chronic obstructive pulmonary disease.

DIAGNOSTIC AIDS

PHYSICAL EXAMINATION OF THE RESPIRATORY TRACT

The four components of a complete pulmonary examination include: inspection, palpation, auscultation, and percussion. *Inspection* of respiratory rate, depth, ease, symmetry, and rhythm of respiration is critical to the detection of pulmonary disease. In young children, an elevated respiratory rate may be an initial indicator of pneumonia or hypoxemia. In a study of children with respiratory illnesses, abnormalities of attentiveness, consolability, respiratory effort, color, and movement had a good diagnostic accuracy in detecting hypoxemia. *Palpation* of tracheal position, symmetry of chest wall movement, and vibration with vocalization can help in identifying intrathoracic abnormalities. A shift in tracheal position can suggest pneumothorax or significant atelectasis. Tactile fremitus may change with the presence of consolidation or air in the pleural space. Other helpful noise transmission tests include whispered pectoriloquy, bronchophony, and egophony. Although chest radiography has replaced the utility of these tests, they can be helpful when imaging is not available. *Auscultation* should assess the quality of breath sounds and detect the presence of abnormal sounds such as fine or coarse crackles, wheezing, or rhonchi. It is important to know the lung anatomy in order to identify the location of abnormal findings (Figure 18–1). In older patients, unilateral crackles are the most valuable examination finding in pneumonia. *Percussion* may identify tympanic or dull sounds that can help define an intrathoracic process. (This component of the examination can prove challenging in young children, who may not cooperate.) Extrapulmonary manifestations of pulmonary disease include growth failure, altered mental status (from hypoxemia or hypercapnia), cyanosis, clubbing, and osteoarthropathy. Evidence of cor pulmonale (loud pulmonic

▲ **Figure 18–1.** Projections of the pulmonary lobes on the chest surface. The upper lobes are white, the right-middle lobe is the darker color, and the lower lobes are the lighter color.

component of the second heart sound, hepatomegaly, elevated neck veins, and rarely, peripheral edema) signifies advanced lung disease.

Respiratory disorders can be secondary to disease in other systems. It is therefore important to look for other conditions such as congenital heart disease (murmur or gallop), neuromuscular disease (muscle wasting or scoliosis), immunodeficiency (rash or diarrhea), and autoimmune disease or occult malignancy (arthritis or hepatosplenomegaly).

PULMONARY FUNCTION TESTS

Lung function tests can help to differentiate obstructive from restrictive lung diseases, measure disease severity, define precipitants of symptoms, and evaluate response to therapy. They can help define the risks of anesthesia and surgery and assist in the planning of respiratory care in the postoperative period. However, the range of normal values for a test may be wide, and the predicted normal values change dramatically with growth. For this reason, serial determinations of lung function are often more informative than a single determination. Patient cooperation is essential for almost all physiologic assessments.

Some children are not able to perform the necessary maneuvers before age 5 years and benefit from a well-trained technician, visual incentives, and interactive computer-animated systems. Lung functions in infants and toddlers are available at specialized centers. Despite these limitations, tests of lung function are valuable in the care of children.

Spirometers are available on which forced vital capacity can be recorded either as a volume-time tracing (spirogram) or a flow-volume curve. The patient inhales maximally, holds his or her breath for a short period, and then exhales as fast as possible for at least 3 seconds. The tracing produced by the exhalation shows forced vital capacity (FVC), which is the total amount of air that is exhaled from maximum inspiration, and the forced expiratory volume in the first second of the exhalation (FEV₁). The maximum midexpiratory flow rate is the mean flow rate during the middle portion of the FVC maneuver and is also referred to as the forced expiratory flow at 25–75% of FVC (FEF_{25–75}). The FEV₁:FVC ratio is calculated from these absolute values; a ratio greater than 0.85 in children and young adults shows unlimited normal airflow.

These basic tests of lung function differentiate obstructive from restrictive processes (Table 18–1). Examples of obstructive processes include asthma, chronic bronchitis, and cystic fibrosis (CF); restrictive problems include chest wall deformities that limit lung expansion and interstitial processes due to collagen-vascular diseases, hypersensitivity pneumonitis, and interstitial fibrosis. Classically, diseases that obstruct airflow decrease the FEV₁ more than the FVC, so that the FEV₁:FVC ratio is low. In restrictive problems, however, the decreases in the FEV₁ and FVC are proportionate; thus, the ratio of FEV₁ to FVC is either normal or high. Clinical suspicion of a restrictive disease is usually an indication for referral to a specialist for evaluation.

The peak expiratory flow rate, the maximal flow recorded during an FVC maneuver, can be assessed by handheld devices. The records of the peak expiratory flow rate can be helpful in following the course of pulmonary disorders that are difficult to control and require multiple medications (eg, asthma). These devices can also be used to give patients with poor perception of their disease an awareness of a decrease in lung function, thus facilitating earlier treatment.

ASSESSMENT OF OXYGENATION & VENTILATION

Arterial blood gas determination defines the balance between respiration at the tissue level and that in the lungs.

Table 18–1. Classification of lung function abnormalities.

	Type of Lung Disease	
	Obstructive ^a	Restrictive ^b
FVC	Normal or decreased	Decreased
FEV ₁	Decreased	Decreased
FEV ₁ :FVC ratio	Decreased	Normal or increased
FEF _{25–75}	Decreased	Normal, increased, or decreased

^aExamples include asthma, chronic bronchitis, and cystic fibrosis.

^bExamples include chest wall deformities, interstitial processes due to collagen-vascular disease, hypersensitivity pneumonitis, and interstitial fibrosis.

FEF_{25–75}, forced expiratory flow at 25–75% of forced vital capacity; FEV₁, forced expiratory volume in the first second of exhalation; FVC, forced vital capacity.

Assessment of blood gases is essential in critically ill children and may be used also for determining the severity of lung involvement in chronic conditions. Blood gas measurements are affected by abnormalities of respiratory control, gas exchange, respiratory mechanics, and the circulation. In pediatrics, hypoxemia (low partial pressure of arterial oxygen [PaO₂]) most commonly results from mismatching of ventilation and perfusion. Hypercapnia (elevated partial pressure of arterial carbon dioxide [PaCO₂]) results from inadequate alveolar ventilation (ie, inability to clear the CO₂ produced). This is termed *hypoventilation*. Causes include decreased central respiratory drive, paralysis of respiratory muscles, and low-tidal-volume breathing as seen in restrictive lung diseases, severe scoliosis, or chest wall trauma. Table 18–2 gives normal values for arterial pH, PaO₂, and PaCO₂ at sea level and at 5000 feet.

Exhaled or end-tidal CO₂ monitoring can be used to estimate arterial CO₂ content. It is used to monitor alveolar ventilation and is most accurate in patients without significant lung disease, particularly those with a good match of ventilation and perfusion and without airway obstruction. Monitoring of exhaled or end-tidal CO₂ is increasingly being used to confirm endotracheal tube placement and ensure endotracheal rather than esophageal intubation. This assessment is accurate in children who weigh more than 2 kg and

Table 18–2. Normal arterial blood gas values on room air.

	pH	PaO ₂ (mm Hg)	PaCO ₂ (mm Hg)
Sea level	7.38–7.42	85–95	36–42
5000 ft	7.36–7.40	65–75	35–40

PaCO₂, partial pressure of arterial carbon dioxide; PaO₂, partial pressure of arterial oxygen.

have a perfusing rhythm. Exhaled CO₂ can be monitored by attaching a CO₂ detector to an endotracheal tube or to a nasal cannula. Qualitative CO₂ monitors use a chemical detector in a strip of paper that changes color when CO₂ is present. Capnography devices are quantitative and measure the concentration of CO₂ by infrared absorption detectors. These display continuous exhaled CO₂ concentration as a waveform and with a digital display of end-tidal CO₂.

Transcutaneous gas monitoring is a noninvasive assessment of PaO₂ and PaCO₂ using electrodes that measure gas tension at the skin surface. Transcutaneous monitoring can underestimate the PaO₂ and overestimate the PaCO₂ unless skin perfusion is maximal. Thus heating of the skin site is required, and cardiac function should be stable.

Pulse oximetry (measuring light absorption by transilluminating the skin) is the most reliable and easiest form of noninvasive monitoring of oxygenation. Oxygenated hemoglobin absorbs red light at certain wavelengths. Measurement during a systolic pulse allows estimation of arterial oxygen saturation as the machine corrects for the light absorbed at the tissue level between pulses. No heating of the skin is necessary. Values of oxygen saturation are reliable as low as 80%. The pulse oximeter has reduced reliability during conditions causing reduced arterial pulsation such as hypothermia, hypotension, or infusion of vasoconstrictor drugs. Carbon monoxide bound by hemoglobin results in falsely high oxygen saturation readings.

CULTURE OF MATERIAL FROM THE RESPIRATORY TRACT

Sources of respiratory tract secretions for culture include expectorated and induced sputum, oropharyngeal swabs, endolaryngeal suction, and bronchoalveolar lavage fluid. Spontaneously expectorated sputum is the easiest and most convenient sample to culture though it is rarely available from patients younger than age 6 years. Sputum induction, performed by inhaling aerosolized hypertonic saline, is a relatively safe noninvasive means of obtaining lower airway secretions and is generally successful in children older than age 10 years. Oropharyngeal swabs are widely used as a surrogate for lower airway cultures in nonexpectorating patients, particularly children with cystic fibrosis. Cultures from the lower respiratory tract can be obtained invasively by tracheal aspiration through an endotracheal tube or rigid bronchoscope, or by performing a bronchoalveolar lavage through a flexible bronchoscope. Other less commonly

employed means of obtaining lung specimens include computed tomography (CT)-guided needle aspiration and lung biopsy, either open or thoracoscopic. Thoracentesis should be considered when pleural fluid is present.

Ho SA et al: Clinical value of obtaining sputum and cough swab samples following inhaled hypertonic saline in children with cystic fibrosis. *Pediatr Pulmonol* 2004;38:82 [PMID: 15170878].

IMAGING OF THE RESPIRATORY TRACT

The plain chest radiograph remains the foundation for investigating the pediatric thorax. Both frontal and lateral views should be obtained. The radiograph is useful for evaluating air trapping caused by airway obstruction, opacification caused by pneumonia, and interstitial problems such as pulmonary edema. Hyperinflation is best demonstrated in lateral views as flattening of the diaphragm. It is often seen because young children commonly develop small-airway obstruction and asthma. Parenchymal changes may cause increased interstitial markings, consolidation, air bronchograms, or loss of diaphragm or heart contours. When pleural fluid is suspected, lateral decubitus radiographs may be helpful in determining the extent and mobility of the fluid. When a foreign body is suspected, forced expiratory radiographs may show focal air trapping and shift of the mediastinum to the contralateral side. Lateral neck radiographs can be useful in assessing the size of adenoids and tonsils and also in differentiating croup from epiglottitis, the latter being associated with the “thumbprint” sign.

Barium swallow is indicated for patients with suspected aspiration to detect swallowing dysfunction, tracheoesophageal fistula, gastroesophageal reflux, and achalasia. This technique is also important in detecting vascular rings and slings, because most of these abnormalities compress the esophagus. Airway fluoroscopy is another important tool for assessing both fixed airway obstruction (eg, tracheal stenosis) and dynamic airway obstruction (eg, tracheomalacia). Fluoroscopy or ultrasound of the diaphragm can detect paralysis by demonstrating paradoxical movement of the involved hemidiaphragm.

High-resolution CT scanning is useful to evaluate parenchymal changes caused by interstitial lung disease and airway abnormalities including bronchiectasis. Characteristic patterns seen in interstitial lung disease (eg, ground-glass opacification) or airway disease (eg, bronchiectasis) are often missed on chest radiographs. Magnetic resonance imaging (MRI) is useful for defining subtle or complex abnormalities and vascular rings. Ventilation-perfusion scans can provide information about regional ventilation and perfusion and can help detect vascular malformations and pulmonary emboli (rare in children). Pulmonary angiography is occasionally necessary to define the pulmonary vascular bed more precisely.

Long FR: Imaging evolution of airway disorders in children. *Radiol Clin North Am* 2005;43:371 [PMID: 15737374].

LARYNGOSCOPY & BRONCHOSCOPY

The indications for laryngoscopy include undiagnosed hoarseness, stridor, symptoms of obstructive sleep apnea, and laryngeal wheezing consistent with a diagnosis of vocal cord dysfunction; indications for bronchoscopy include wheezing, suspected foreign body, pneumonia, atelectasis, chronic cough, hemoptysis, placement of an endotracheal tube, and assessment of its patency. In general, the more specific the indication, the higher the diagnostic yield.

Pediatric bronchoscopy instruments are of either the flexible fiberoptic or the rigid open tube type. Flexible bronchoscopy has the following advantages:

1. With conscious sedation and topical anesthetics, the procedure can be done at the bedside.
2. Evaluation of the upper airway can be done with little risk in patients who are awake.
3. The distal airways of intubated patients can be examined without removing the endotracheal tube.
4. The instrument can be used as an obturator to intubate a patient with a difficult upper airway.
5. Endotracheal tube placement and patency can be checked.
6. Assessment of airway dynamics is generally better.
7. It is possible to examine more distal airways.

Improvements in digital optics have greatly enhanced the image quality. The advantages of using a rigid instrument are (1) easier removal of foreign bodies (thus rigid bronchoscopy is preferred for suspected foreign body aspiration); and (2) better airway control, allowing the patient to be ventilated through the bronchoscope. In addition, this approach to the airway allows better assessment of the subglottic space for stenosis. The choice of procedures depends largely on the expertise available.

Bronchoalveolar lavage through a flexible bronchoscope is used to detect infection. Aspiration and hemorrhage can be suspected in the presence of lipid- and hemosiderin-laden macrophages, respectively, though lipid-laden macrophages can also be found in other conditions. Analysis of lavage fluid can also be completed for cell counts, surfactant proteins, and inflammatory mediators. Transbronchial biopsy in children is limited to evaluation for infection and rejection in transplant patients due to poor diagnostic yield in most conditions. Transbronchial biopsy may have a role in diagnosing diffuse lung diseases such as sarcoidosis.

GENERAL THERAPY OF PEDIATRIC LUNG DISEASES

OXYGEN THERAPY

Oxygen therapy in children with respiratory disease can reduce the work of breathing, resulting in fewer respiratory symptoms; relax the pulmonary vasculature, lessening the potential for pulmonary hypertension and congestive heart failure; and improve feeding. Patients breathing spontaneously can be treated by nasal cannula, head hood, or mask (including simple, rebreathing, nonrebreathing, or Venturi masks). The general goal of oxygen therapy is to achieve an arterial oxygen tension of 65–90 mm Hg or an oxygen saturation above 92%. The actual oxygen concentration achieved by nasal cannula or mask depends on the flow rate, the type of mask used, and the patient's age. Small changes in flow rate during oxygen administration by nasal cannula can lead to substantial changes in inspired oxygen concentration in young infants. The amount of oxygen required to correct hypoxemia may vary according to the child's activity. It is not unusual, for example, for an infant with chronic lung disease to require 0.75 L/min while awake but 1 L/min while asleep or feeding.

Although the head hood is an efficient device for delivery of oxygen in young infants, the nasal cannula is used more often because it allows the infant greater mobility. The cannula has nasal prongs that are inserted in the nares. Flow through the nasal cannula should generally not exceed 3 L/min to avoid excessive drying of the mucosa. Even at high flow rates, oxygen by nasal cannula rarely delivers inspired oxygen concentrations greater than 40–45%. In contrast, partial rebreathing and nonrebreathing masks or head hoods achieve inspired oxygen concentrations as high as 90–100%.

Because the physical findings of hypoxemia are subtle, the adequacy of oxygenation should be measured as the arterial oxygen tension, or oxygen saturation can be determined by oximetry. The advantages of the latter noninvasive method include the ability to obtain continuous measurements during various normal activities and to avoid artifacts caused by crying or breath-holding during attempts at arterial puncture. For children with chronic cardiopulmonary disorders that may require supplemental oxygen therapy (eg, bronchopulmonary dysplasia or CF), frequent noninvasive assessments are essential to ensure the safety and adequacy of treatment.

Ralston M et al (editors): *Pediatric Advanced Life Support Provider Manual*. American Heart Association and American Academy of Pediatrics, 2006.

INHALATION OF MEDICATIONS

Airway obstruction that is at least partially reversed by an inhaled bronchodilator can be seen in CF, bronchiolitis, and bronchopulmonary dysplasia, as well as in acute and chronic asthma. Inhaled medications can be used to deliver anti-

inflammatory medications, mucolytics, or antibiotics in patients with a variety of lung diseases.

The inhaled β -adrenergic agonists may be delivered by metered-dose inhaler, dry powder inhaler, or nebulizer. Metered-dose inhalers are convenient and best combined with valved holding chambers, especially for children who lack the ability to coordinate actuation of the metered-dose inhaler with inhalation. In contrast, the nebulizer is an effective method of delivering medication to infants and young children. Long-acting inhaled β_2 -adrenergic agents that are relatively selective for the respiratory tract are described in Chapter 36. Inhaled bronchodilators are as effective as injected agents for treating acute episodes of airway obstruction and have fewer side effects. These drugs can be safely administered at home as long as both the physician and the family realize that a poor response may signify the need for corticosteroids to help restore β -adrenergic responsiveness.

Anticholinergic agents may also acutely decrease airway obstruction. Furthermore, they may yield a longer duration of bronchodilation than do many adrenergic agents. Selected patients may benefit from receiving both β -adrenergic and anticholinergic agents. In general, this class of drugs is most effective in the treatment of chronic bronchitis.

Chronic use of inhaled medications is common in children with chronic lung diseases. Inhaled corticosteroids are standard of care for persistent asthma and may be delivered by metered-dose inhaler, dry powder inhaler, or nebulizer. Dornase alfa is used as a mucolytic in CF and other disorders of mucous clearance. Hypertonic saline is used to induce sputum production and as a chronic medication for mucous clearance in CF. Inhaled antibiotics may be used acutely or chronically in patients with lung disease that predispose them to chronic airway infections.

Rubin BK, Fink JB: The delivery of inhaled medication to the young child. *Pediatr Clin North Am* 2003;50:717 [PMID: 12877243].

AIRWAY CLEARANCE THERAPY

Chest physical therapy, with postural drainage, percussion, and forced expiratory maneuvers, has been widely used to improve the clearance of lower airway secretions even though there are limited data on the efficacy of these techniques. Children with CF have been shown to benefit from routine airway clearance. Many airway clearance techniques exist, but only a few long-term studies have compared the various options. The various techniques currently available include chest physiotherapy, autogenic drainage, positive expiratory pressure (Flutter or Acapella), intrapulmonary percussive ventilation, or high-frequency chest compression. The decision about which technique to use should be based on the patient's age and preference after trying different approaches. Often bronchodilators or mucolytic medications are given prior to or during airway clearance therapy. Inhaled corticosteroids and inhaled antibiotics should be given after airway clearance

therapy so that the airways are first cleared of secretions, allowing the medications to maximally penetrate into the lung.

Marks JH: Airway clearance devices in cystic fibrosis. *Paediatr Respir Rev* 2007;8:17 [PMID: 17419974].

AVOIDANCE OF ENVIRONMENTAL HAZARDS

All parents or other caregivers should be counseled about environmental hazards to the lung. The list of potential hazards includes small objects that may be aspirated, allergens that can precipitate respiratory symptoms in atopic children, and tobacco smoke. The harmful effects of smoking in the home deserve special emphasis. Children from families where the parents and others smoke have decreased lung growth as well as decreased pulmonary function in comparison with children raised in smoke-free homes. Exposure of children to tobacco smoke also leads to an increased frequency of lower respiratory tract infections and an increased incidence of respiratory symptoms, including recurrent wheezing. Health care providers must increase their efforts to educate patients and their families about the hazards of smoking.

Bradley JP et al: Severity of respiratory syncytial virus bronchiolitis is affected by cigarette smoke exposure and atopy. *Pediatrics* 2005;115:e7 [PMID: 15629968].

DiFranza JR et al: Prenatal and postnatal environmental tobacco smoke exposure and children's health. *Pediatrics* 2004;113:1007 [PMID: 15060193].

DISORDERS OF THE CONDUCTING AIRWAYS

The conducting airways (the nose, mouth, pharynx, larynx, trachea, bronchi, and bronchioles) direct inspired air to the gas-exchange units of the lung; they do not participate in gas exchange themselves. Airflow obstruction in the conducting airways occurs by (1) external compression (eg, vascular ring or tumor), (2) abnormalities of the airway structure itself (eg, congenital defects or thickening of an airway wall due to inflammation), or (3) material in the airway lumen (eg, foreign body or mucus).

Airway obstruction can be fixed (airflow limited in both the inspiratory and the expiratory phases) or variable (airflow limited more in one phase of respiration than in the other). Variable obstruction is common in children because their airways are more compliant and susceptible to dynamic compression. With variable extrathoracic airway obstruction (eg, croup), airflow limitation is greater during inspiration, leading to inspiratory stridor. With variable intrathoracic obstruction (eg, bronchomalacia), limitation is greater during expiration, producing expiratory wheezing. Thus determining the phase of respiration in which obstruction is greatest may be helpful in localizing the site of obstruction.

EXTRATHORACIC AIRWAY OBSTRUCTION

Patients with abnormalities of the extrathoracic airway may present with snoring and other symptoms of obstructive apnea, hoarseness, brassy cough, or stridor. The course of the illness may be acute (eg, infectious croup), recurrent (eg, spasmodic croup), chronic (eg, subglottic stenosis), or progressive (eg, laryngeal papillomatosis). Significant risk factors are difficult delivery, ductal ligation, and intubation. Examination should determine if obstructive symptoms are present at rest or with agitation, if they are positional, or if they are related to sleep. The presence of agitation, air hunger, severe retractions, cyanosis, lethargy, or coma should alert the physician to a potentially life-threatening condition that may require immediate airway intervention. Helpful diagnostic studies in the evaluation of upper airway obstruction include chest and lateral neck radiographs, airway fluoroscopy, and barium swallow. In patients who have symptoms of severe chronic obstruction, an electrocardiogram should be obtained to evaluate for right ventricular hypertrophy and pulmonary hypertension. Patients with obstructive sleep apnea should have polysomnography (measurements during sleep of the motion of the chest wall, airflow at the nose and mouth, heart rate, oxygen saturation, and selected electroencephalographic leads to stage sleep) to determine severity and to evaluate the need for tonsillectomy and adenoidectomy, oxygen, or continuous or biphasic positive airway pressure. In older children, pulmonary function tests can differentiate fixed from variable airflow obstruction and identify the site of variable obstruction. If noninvasive studies are unable to establish the cause, direct laryngoscopy and bronchoscopy remain the procedures of choice to establish the precise diagnosis. Treatment should be directed at relieving airway obstruction and correcting the underlying condition if possible.

INTRATHORACIC AIRWAY OBSTRUCTION

Intrathoracic airway obstruction usually causes expiratory wheezing. The history should include the following:

1. Age at onset
2. Precipitating factors (eg, exercise, upper respiratory illnesses, allergens, or choking while eating)
3. Course—acute (bronchiolitis or foreign body), chronic (tracheomalacia or vascular ring), recurrent (asthma), or progressive (CF or bronchiolitis obliterans)
4. Presence and nature of cough
5. Production of sputum
6. Previous response to bronchodilators
7. Symptoms with positional changes (vascular rings)
8. Involvement of other organ systems (malabsorption in CF)

Physical examination should include growth measurements and vital signs. The examiner should look for cyanosis or pallor, barrel-shaped chest, retractions and use of acces-

sory muscles, and clubbing. Auscultation should define the pattern and timing of respiration, detect the presence of crackles and wheezing, and determine whether findings are localized or generalized.

Routine tests include plain chest radiographs, a sweat test, and pulmonary function tests in older children. Other diagnostic studies are dictated by the history and physical findings. Treatment should be directed toward the primary cause of the obstruction, but generally includes a trial of bronchodilators.

STRIDOR & NOISY BREATHING FROM CONGENITAL DISORDERS OF THE EXTRATHORACIC AIRWAY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Presentation from birth or within the first few months of life.
- ▶ Inspiratory sounds usually of a high-pitched (“croup”) nature but can be variable depending on diagnosis.
- ▶ Moderate to severe symptoms require visualization of the airway.

LARYNGOMALACIA

Laryngomalacia is a benign congenital disorder in which the cartilaginous support for the supraglottic structures is underdeveloped. It is the most common cause of persistent stridor in infants and usually is seen in the first 6 weeks of life. Stridor has been reported to be worse in the supine position, with increased activity, with upper respiratory infections, and during feeding; however, the clinical presentation can be variable. Patients may have slight oxygen desaturation during sleep. Gastroesophageal reflux may also be associated with laryngomalacia requiring treatment. The condition usually improves with age and resolves by age 2 years, but in some cases symptoms persist for years. The diagnosis is established by direct laryngoscopy, which shows inspiratory collapse of an omega-shaped epiglottis (with or without long, redundant arytenoids). In mildly affected patients with a typical presentation (those without stridor at rest or retractions), this procedure may not be necessary. No treatment is usually needed. However, in patients with severe symptoms of airway obstruction associated with feeding difficulties, failure to thrive, obstructive sleep apnea, respiratory insufficiency, or severe dyspnea, surgical epiglottoplasty may be necessary.

Vicencui AG et al: Laryngomalacia and tracheomalacia: Common dynamic airway lesions. *Pediatr Rev* 2006;27:e33 [PMID: 16581951].

Zoumalan R et al: Etiology of stridor in infants. *Ann Otol Rhinol Laryngol* 2007;116:329 [PMID: 17561760].

OTHER CONGENITAL PROBLEMS

Other rare congenital lesions of the larynx (laryngeal atresia, laryngeal web, laryngocele and cyst of the larynx, subglottic hemangioma, and laryngeal cleft) are best evaluated by direct laryngoscopy. Laryngeal atresia presents immediately after birth with severe respiratory distress and is usually fatal. Laryngeal web, representing fusion of the anterior portion of the true vocal cords, is associated with hoarseness, aphonia, and stridor. Surgical correction may be necessary depending on the degree of airway obstruction.

Congenital cysts and laryngoceles are believed to have similar origin. Cysts are more superficial, whereas laryngoceles communicate with the interior of the larynx. Cysts are generally fluid-filled, whereas laryngoceles may be air- or fluid-filled. Airway obstruction is usually prominent and requires surgery or laser therapy.

Subglottic hemangiomas are seen in infancy with signs of upper airway obstruction and can be associated with similar lesions of the skin (but not always). Although these lesions tend to regress spontaneously, airway obstruction may require surgical treatment or even tracheostomy.

Laryngeal cleft is a very rare condition resulting from failure of posterior cricoid fusion. Patients with this condition may have stridor but always aspirate severely, resulting in recurrent or chronic pneumonia and failure to thrive. Barium swallow is always positive for severe aspiration, but diagnosis can be very difficult even with direct laryngoscopy. Patients often require tracheostomy and gastrostomy, because success with surgical correction can be mixed.

Vijayasekaran S et al: Open excision of subglottic hemangiomas to avoid tracheostomy. *Arch Otolaryngol Head Neck Surg* 2006;132:159 [PMID: 16490873].

Watson GJ et al: Acquired paediatric subglottic cysts: A series from Manchester. *Int J Pediatr Otorhinolaryngol* 2007;71:533 [PMID: 17239962].

STRIDOR & NOISY BREATHING FROM ACQUIRED DISORDERS OF THE EXTRATHORACIC AIRWAY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Presentation with acute or subacute symptoms.
- ▶ Inspiratory sounds usually of a high-pitched (“croup”) nature but can be variable depending on diagnosis.
- ▶ Life-threatening condition can occur, requiring careful patient assessment.

CROUP SYNDROME

Croup describes acute inflammatory diseases of the larynx, including viral croup (laryngotracheobronchitis), epiglottitis

(supraglottitis), and bacterial tracheitis. These are the main entities in the differential diagnosis for patients presenting with acute stridor, although spasmodic croup, angioneurotic edema, laryngeal or esophageal foreign body, and retropharyngeal abscess should be considered as well.

1. Viral Croup

Viral croup generally affects younger children in the fall and early winter months and is most often caused by parainfluenza virus serotypes. Other organisms causing croup include respiratory syncytial virus (RSV), human metapneumovirus, influenza virus, rubeola virus, adenovirus, and *Mycoplasma pneumoniae*. Although inflammation of the entire airway is usually present, edema formation in the subglottic space accounts for the predominant signs of upper airway obstruction.

▶ Clinical Findings

A. Symptoms and Signs

Usually a prodrome of upper respiratory tract symptoms is followed by a barking cough and stridor. Fever is usually absent or low-grade but may on occasion be high-grade. Patients with mild disease may have stridor when agitated. As obstruction worsens, stridor occurs at rest, accompanied in severe cases by retractions, air hunger, and cyanosis. On examination, the presence of cough and the absence of drooling favor the diagnosis of viral croup over epiglottitis.

B. Imaging

Lateral neck radiographs in patients with classic presentations are not required but can be diagnostically supportive by showing subglottic narrowing without the irregularities seen in tracheitis and a normal epiglottis.

▶ Treatment

Treatment of viral croup is based on the symptoms. Mild croup, signified by a barking cough and no stridor at rest, requires supportive therapy with oral hydration and minimal handling. Mist therapy has historically been used but clinical studies do not demonstrate effectiveness. Conversely, patients with stridor at rest require active intervention. Oxygen should be administered to patients with oxygen desaturation. Nebulized racemic epinephrine (2.25% solution; 0.05 mL/kg to a maximum of 1.5 mL diluted in sterile saline) is commonly used because it has a rapid onset of action within 10–30 minutes. Both racemic epinephrine and epinephrine hydrochloride are effective in alleviating symptoms and decreasing the need for intubation.

Once controversial, the efficacy of glucocorticoids in croup is now more firmly established. Dexamethasone, 0.6 mg/kg intramuscularly as one dose, improves symptoms, reduces the duration of hospitalizations and frequency of intubations, and permits earlier discharge from the emergency department. Oral dexamethasone (0.15 mg/kg) appears equally effective.

Inhaled budesonide (2–4 mg) also improves symptoms and decreases hospital stay. Onset of action occurs within 2 hours, and this agent may be as effective as dexamethasone; however, dexamethasone is still the most cost-effective steroid of choice. Dexamethasone has also been shown to be more effective than prednisolone in equivalent doses.

If symptoms resolve within 3 hours of glucocorticoids and nebulized epinephrine, patients can safely be discharged without fear of a sudden rebound in symptoms. If, however, recurrent nebulized epinephrine treatments are required or if respiratory distress persists, patients require hospitalization for close observation, supportive care, and nebulization treatments as needed. In patients with impending respiratory failure, an airway must be established. Hospitalized patients with persistent symptoms over 3–4 days despite treatment should initiate consideration of another underlying cause.

Patients with impending respiratory failure require an artificial airway. Intubation with an endotracheal tube of slightly smaller diameter than would ordinarily be used is reasonably safe. Extubation should be accomplished within 2–3 days to minimize the risk of laryngeal injury. If the patient fails extubation, tracheostomy may be required.

► Prognosis

Most children with viral croup have an uneventful course and improve within a few days. Some evidence suggests that patients with a history of croup associated with wheezing may have airway hyperreactivity. It is not clear if this was present prior to the croup episode or if the croup episode itself altered airway function.

Duman M et al: Nebulised L-epinephrine and steroid combination in the treatment of moderate to severe croup. *Clin Drug Investig* 2005;25:183 [PMID: 17523767].

Moore M et al: Humidified air inhalation for treating croup. *Cochrane Database Syst Rev* 2006;(3):CD002870 [PMID: 16855994].

Sparrow A et al: Prednisolone versus dexamethasone in croup: A randomised equivalence trial. *Arch Dis Child* 2006;91:580 [PMID: 16624882].

2. Epiglottitis

With the introduction of the *Haemophilus influenzae* conjugate vaccine the incidence of epiglottitis has dramatically decreased and is now rare in countries with immunization programs. If disease occurs it is likely to be associated with *H influenzae* in unimmunized children or other organisms such as nontypeable *H influenzae*, *Neisseria meningitidis*, or *Streptococcus* species in immunized populations.

► Clinical Findings

A. Symptoms and Signs

The classic presentation is a sudden onset of fever, dysphagia, drooling, muffled voice, inspiratory retractions, cyanosis, and soft stridor. Patients often sit in the so-called sniffing dog position, which gives them the best airway possible under the

circumstances. Progression to total airway obstruction may occur and result in respiratory arrest. The definitive diagnosis is made by direct inspection of the epiglottis, a procedure that should be done by an experienced airway specialist under controlled conditions (usually the operating room). The typical findings are cherry-red and swollen epiglottis and arytenoids.

B. Imaging

Diagnostically, lateral neck radiographs may be helpful in demonstrating a classic “thumbprint” sign. Obtaining radiographs, however, may delay important airway intervention.

► Treatment

Once the diagnosis of epiglottitis is made, endotracheal intubation must be performed immediately in children but not necessarily in adult populations. Most anesthesiologists prefer general anesthesia (but not muscle relaxants) to facilitate intubation. After an airway is established, cultures of the blood and epiglottis should be obtained and the patient started on appropriate intravenous antibiotics to cover *H influenzae* and *Streptococcus* species (ceftriaxone sodium or equivalent cephalosporin). Extubation can usually be accomplished in 24–48 hours, when direct inspection shows significant reduction in the size of the epiglottis. Intravenous antibiotics should be continued for 2–3 days, followed by oral antibiotics to complete a 10-day course.

► Prognosis

Prompt recognition and appropriate treatment usually results in rapid resolution of swelling and inflammation. Recurrence is unusual.

Faden H: The dramatic change in the epidemiology of pediatric epiglottitis. *Pediatr Emerg Care* 2006;22:443 [PMID: 16801849].

3. Bacterial Tracheitis

Bacterial tracheitis (pseudomembranous croup) is a severe life-threatening form of laryngotracheobronchitis. As the management of severe viral croup has been improved with the use of dexamethasone and vaccination has decreased the incidence of epiglottitis, tracheitis has now become the most common pediatric airway emergency requiring admission to the pediatric intensive care unit. This diagnosis must be high in the differential when a patient presents with severe upper airway obstruction. The organism most often isolated is *Staphylococcus aureus*, but organisms such as *H influenzae*, group A *Streptococcus pyogenes*, *Neisseria* species, *Moraxella catarrhalis*, and others have been reported. The disease probably represents localized mucosal invasion of bacteria in patients with primary viral croup, resulting in inflammatory edema, purulent secretions, and pseudomembranes. Although cultures of the tracheal secretions are frequently positive, blood cultures are almost always negative.

► Clinical Findings

A. Symptoms and Signs

The early clinical picture is similar to that of viral croup. However, instead of gradual improvement, patients develop higher fever, toxicity, and progressive or intermittent severe upper airway obstruction that is unresponsive to standard croup therapy. The incidence of sudden respiratory arrest or progressive respiratory failure is high; in such instances, airway intervention is required. Findings of toxic shock and the acute respiratory distress syndrome may also be seen. Recently, subsets of patients with tracheal membranes have been reported with a less severe clinical presentation. Aggressive medical treatment and debridement still must occur in these patients. A higher index of suspicion is required for this life-threatening condition.

B. Laboratory Findings and Imaging

The white cell count is usually elevated, with left shift. Cultures of tracheal secretions usually demonstrate one of the causative organisms. Lateral neck radiographs show a normal epiglottis but often severe subglottic and tracheal narrowing. Irregularity of the contour of the proximal tracheal mucosa can frequently be seen radiographically and should elicit concern. Bronchoscopy showing a normal epiglottis and the presence of copious purulent tracheal secretions and membranes confirm the diagnosis.

► Treatment

Suspected bacterial tracheitis should be managed in a fashion similar to that for epiglottitis, with visualization of the airway in a controlled environment but with the added capability to debride the airway. The incidence of respiratory arrest or progressive respiratory failure is high, necessitating intubation. Patients often have thick, purulent tracheal secretions requiring debridement, and humidification, frequent suctioning, and intensive care monitoring are required to prevent endotracheal tube obstruction. Intravenous antibiotics to cover *S aureus*, *H influenzae*, and the other organisms are indicated. Thick secretions persist for several days, usually resulting in longer periods of intubation for bacterial tracheitis than for epiglottitis or croup. Despite the severity of this illness, the reported mortality rate is very low if it is recognized and treated promptly.

Salamone FN et al: Bacterial tracheitis reexamined: Is there a less severe manifestation? *Otolaryngol Head Neck Surg* 2004;131:871 [PMID: 15577783].

VOCAL CORD PARALYSIS

Unilateral or bilateral vocal cord paralysis may be congenital, or more commonly may result from injury to the recurrent laryngeal nerves. Risk factors for acquired paralysis include difficult delivery (especially face presentation), neck and tho-

racic surgery (eg, ductal ligation or repair of tracheoesophageal fistula), trauma, mediastinal masses, and central nervous system disease (eg, Arnold-Chiari malformation). Patients usually present with varying degrees of hoarseness, aspiration, or high-pitched stridor. Unilateral cord paralysis is more likely to occur on the left because of the longer course of the left recurrent laryngeal nerve and its proximity to major thoracic structures. Patients with unilateral paralysis are usually hoarse but rarely have stridor. With bilateral cord paralysis, the closer to midline the cords are positioned, the greater the airway obstruction; the more lateral the cords are positioned, the greater the tendency to aspirate and experience hoarseness or aphonia. If partial function is preserved (paresis), the adductor muscles tend to operate better than the abductors, with a resultant high-pitched inspiratory stridor and normal voice.

Airway intervention (tracheostomy) is rarely indicated in unilateral paralysis but is often necessary for bilateral paralysis. Clinically, paralysis can be assessed by direct visualization of vocal cord function with laryngoscopy or more invasively by recording the electrical activity of the muscles (electromyography). Electromyogram recordings can differentiate vocal fold paralysis from arytenoid dislocation, which has prognostic value. Recovery is related to the severity of nerve injury and the potential for healing.

Ysunza A et al: The role of laryngeal electromyography in the diagnosis of vocal fold immobility in children. *Int J Pediatr Otorhinolaryngol* 2007;71:949 [PMID: 17418427].

SUBGLOTTIC STENOSIS

Subglottic stenosis may be congenital, or more commonly may result from endotracheal intubation. Neonates and infants are particularly vulnerable to subglottic injury from intubation: The subglottis is the narrowest part of an infant's airway, and the cricoid cartilage, which supports the subglottis, is the only cartilage that completely encircles the airway. The clinical presentation may vary from totally asymptomatic to the typical picture of severe upper airway obstruction. Patients with signs of stridor who repeatedly fail extubation are likely to have subglottic stenosis. Subglottic stenosis should also be suspected in children with multiple, prolonged, or severe episodes of croup. Diagnosis is made by direct visualization of the subglottic space with bronchoscopy and maneuvers to size the airway. Tracheostomy is often required when airway compromise is severe. Surgical intervention is ultimately required to correct the stenosis. Depending on the type of stenosis, a cricoid split in which the cricoid cartilage is surgically opened (better for acquired than for congenital lesions) may be tried. Laryngotracheal reconstruction in which a cartilage graft from another source (eg, rib) is used to expand the airway has become the standard procedure for symptomatic subglottic stenosis in children.

LARYNGEAL PAPILLOMATOSIS

Papillomas of the larynx are benign, warty growths that are difficult to treat and are the most common laryngeal neoplasm in children. Human papillomaviruses 6, 11, and 16 have been implicated as causative agents. A substantial percentage of mothers of patients with laryngeal papillomas have a history of genital condylomas at the time of delivery, so the virus may be acquired during passage through an infected birth canal.

The age at onset is usually 2–4 years, but juvenile-onset recurrent respiratory papillomatosis is well documented. A younger age of onset may be a worse prognostic indicator. Patients usually develop hoarseness, voice changes, croupy cough, or stridor that can lead to life-threatening airway obstruction. Diagnosis is by direct laryngoscopy. The larynx was involved at the time of diagnosis in over 95% of patients, most of whom had only one site involved.

Treatment is directed toward relieving airway obstruction, usually by surgical removal of the lesions. Tracheostomy is necessary when life-threatening obstruction or respiratory arrest occurs. Various surgical procedures (laser, cup forceps, or cryosurgery) have been used to remove papillomas, but recurrences are the rule, and frequent reoperation may be needed. The lesions occasionally spread down the trachea and bronchi, making surgical removal more difficult. The use of interferon therapy remains controversial. Fortunately, spontaneous remissions do occur, usually by puberty, so that the goal of therapy is to maintain an adequate airway until remission occurs.

CONGENITAL DISORDERS OF THE INTRATHORACIC AIRWAYS

MALACIA OF AIRWAYS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Chronic monophonic wheeze with or without a barking cough.
- ▶ Respiratory symptoms do not respond to bronchodilators.

▶ General Considerations

Tracheomalacia or bronchomalacia exists when the cartilaginous framework of the airway is inadequate to maintain airway patency. Because cartilage of the infant airway is normally soft, all infants may have some degree of dynamic collapse of a central airway when pressure outside the airway exceeds intraluminal pressure. In tracheomalacia, whether congenital or acquired, dynamic collapse leads to airway obstruction. The congenital variety may be isolated or associated with another developmental defect. Congenital tracheomalacia and bronchomalacia may also be associated with developmental abnormalities such as tracheoesophageal fistula, vascular ring, or cardiac anomalies causing extrinsic airway compression during development. Tracheomalacia is also associated with various syndromes. Congenital tracheomalacia may be localized to part of the trachea, or more commonly may involve the entire trachea as well as the remainder of the conducting airways. In severe cases, cartilage in the involved area may be missing or underdeveloped. Acquired tracheomalacia has been associated with long-term ventilation of premature newborns that results in chronic tracheal injury, severe tracheobronchitis, and airway compression due to tumors, abscess or infection, and cysts.

▶ Clinical Findings

Coarse wheezing, cough, stridor, recurrent illnesses, recurrent wheezing that does not respond to bronchodilators, or radiographic changes are common findings. Symptoms classically present insidiously over the first few months of life and can increase with agitation, excitement, or upper respiratory tract infections. Diagnosis can be made by airway fluoroscopy or bronchoscopy. Barium swallow may be indicated to rule out coexisting conditions.

▶ Treatment

Conservative treatment is usually indicated for the isolated condition, which generally improves over time with growth. Coexisting lesions such as tracheoesophageal fistulas and vascular rings need primary repair. In severe cases of tracheomalacia, intubation or tracheostomy may be necessary. However, this alone is seldom satisfactory because airway collapse continues to exist below the tip of the artificial airway. Positive pressure ventilation may be required to stent the collapsing airway. Surgical approaches to the problem (tracheopexy or aortopexy) may be considered as alternatives prior to or in an effort to wean off of ventilatory support.

VASCULAR RINGS & SLINGS

The most common vascular anomaly to compress the trachea or esophagus is a vascular ring. A vascular ring can be formed by a double aortic arch, a right aortic arch with left ligamentum arteriosum, or a patent ductus arteriosus. The pulmonary sling is created when the left pulmonary artery branches off from the right pulmonary artery. Other common vascular anomalies include an anomalous innominate, a left carotid artery, and an aberrant right subclavian artery. All but the right subclavian artery can cause tracheal compression and present in infancy with symptoms of chronic airway obstruction (stridor, coarse wheezing, and croupy cough). Symptoms are often worse in the supine position. Respiratory compromise is most severe with double aortic arch and may lead to apnea, respiratory arrest, or even death. Esophageal compression, present in all but anomalous innominate or carotid artery, may result in feeding difficulties, including dysphagia and vomiting. Barium swallow showing esophageal compression is the mainstay of diagnosis. Chest radiographs and echocardiograms may miss abnormalities. Anatomy can be further defined by angiography, chest CT with contrast, MRI or magnetic resonance angiography, or bronchoscopy.

Patients with significant symptoms require surgical correction, especially those with double aortic arch. Patients usually improve following correction but may have persistent but milder symptoms of airway obstruction due to associated tracheomalacia.

BRONCHOGENIC CYSTS

Bronchogenic cysts generally occur in the middle mediastinum (see later section on Mediastinal Masses) near the carina and adjacent to the major bronchi but can be found elsewhere in the lung. They range in size from 2–10 cm. Cyst walls are thin and may contain pus, mucus, or blood. Cysts develop from abnormal lung budding of the primitive foregut. They can be seen in involvement with other congenital pulmonary malformations such as pulmonary sequestration or lobar emphysema.

Clinically, respiratory distress can appear acutely in early childhood due to airway compression or infection of the bronchogenic cyst or they may remain asymptomatic into adulthood. Symptoms may include chronic wheezing, chronic cough, tachypnea, recurrent pneumonia, or stridor, depending on the location and size of the cysts and the degree of airway compression. However, all asymptomatic cysts will eventually become symptomatic with chest pain being the most common presenting complaint. On examination, the trachea may deviate from the midline, breath sounds over

such areas will be decreased, and percussion over involved lobes may be hyperresonant due to air trapping.

The choice of diagnostic studies for bronchogenic cysts is controversial. Chest radiographs can show air trapping and hyperinflation of the affected lobes or may show a spherical lesion with or without an air-fluid level. However, early detected or smaller lesions may not be seen on chest radiographs. CT scan is the preferred imaging study and can differentiate solid versus cystic mediastinal masses and define the cyst's relationship to the airways and the rest of the lung. A barium swallow can help determine whether the lesion communicates with the gastrointestinal tract. MRI and ultrasound are other imaging modalities used.

Treatment is surgical resection. Postoperatively, vigorous pulmonary physiotherapy is required to prevent complications (atelectasis or infection of the lung distal to the site of resection of the cyst).

ACQUIRED DISORDERS OF THE INTRATHORACIC AIRWAYS

FOREIGN BODY ASPIRATION

Aspiration of a foreign body into the respiratory tract is rarely observed. Onset is generally abrupt, with a history of the child running with food in the mouth or playing with seeds, small coins, or toys. Symptoms at the time of the ingestion are often abrupt and include cough, choking, or wheezing.

The foreign body can lodge itself anywhere along the respiratory tract. Often it is trapped in the supraglottic airway, triggering protective reflexes that result in laryngospasm. Small objects such as coins may pass through the glottis and obstruct the trachea. Finally, foreign bodies that lodge in the esophagus may compress the airway and cause dysphagia and respiratory distress.

The most commonly seen objects in foreign body aspiration include peanuts, hot dogs, popcorn, small coins, hard candy, and small toys. Children aged 6 months to 4 years are at highest risk, and many deaths are caused by foreign body aspiration and airway obstruction each year.

1. Foreign Bodies in the Upper Respiratory Tract

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Sudden onset of coughing or respiratory distress.
- ▶ Difficulty vocalizing.

► Clinical Findings

The diagnosis is established by acute onset of choking along with *inability* to vocalize or cough and cyanosis with marked distress (complete obstruction), or with drooling, stridor, and *ability* to vocalize (partial obstruction).

Foreign bodies that lodge in the esophagus may compress the airway and cause respiratory distress. More typically, the foreign body lodges in the supraglottic airway, triggering protective reflexes that result in laryngospasm. Onset is generally abrupt, with a history of the child running with food in the mouth or playing with seeds, small coins, toys, and the like. Homes and child care centers in which an older sibling or child feeds age-inappropriate foods (eg, peanuts, hard candy, or carrot slices) to the younger child are typical. Without treatment, progressive cyanosis, loss of consciousness, seizures, bradycardia, and cardiopulmonary arrest can follow.

► Treatment

The emergency treatment of upper airway obstruction due to foreign body aspiration is somewhat controversial. If *complete* obstruction is present, then one must intervene immediately. If partial obstruction is present, then the choking subject should be allowed to use his or her own cough reflex to remove the foreign body. If after a brief observation period the obstruction increases or the airway becomes completely obstructed, acute intervention is required. The American Academy of Pediatrics and the American Heart Association distinguish between children younger than and older than age 1 year. A choking infant younger than age 1 year should be placed face down over the rescuer's arm, with the head positioned below the trunk. Five measured back blows are delivered rapidly between the infant's scapulas with the heel of the rescuer's hand. If obstruction persists, the infant should be rolled over and five rapid chest compressions performed (similar to cardiopulmonary resuscitation). This sequence is repeated until the obstruction is relieved. In a choking child older than age 1 year, abdominal thrusts (Heimlich maneuver) may be performed, with special care in younger children because of concern about possible intra-abdominal organ injury.

Blind finger sweeps should *not* be performed in infants or children because the finger may actually push the foreign body further into the airway causing further obstruction. The airway may be opened by jaw thrust, and if the foreign body can be directly visualized, careful removal with the fingers or instruments (Magill forceps) can be attempted. Patients with persistent apnea and inability to achieve adequate ventilation may require emergency intubation, tracheotomy, or needle cricothyrotomy, depending on the setting and the rescuer's skills.

Ralston M et al (editors): *Pediatric Advanced Life Support Provider Manual*. American Heart Association and American Academy of Pediatrics, 2006.

2. Foreign Bodies in the Lower Respiratory Tract

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Sudden onset of coughing, wheezing, or respiratory distress.
- Asymmetrical physical findings of decreased breath sounds or localized wheezing.
- Asymmetrical radiographic findings, especially with forced expiratory view.

► Clinical Findings

A. Symptoms and Signs

Respiratory symptoms and signs vary depending on the site of obstruction and the duration following the acute episode. For example, a large or central airway obstruction may cause marked distress. The acute cough or wheezing caused by a foreign body in the lower respiratory tract may diminish over time only to recur later as chronic cough or persistent wheezing, monophonic wheezing, asymmetrical breath sounds on chest examination, or recurrent pneumonia in one location. Foreign body aspiration should be suspected in children with chronic cough, persistent wheezing, or recurrent pneumonia. Long-standing foreign bodies may lead to bronchiectasis or lung abscess. Hearing asymmetrical breath sounds or localized wheezing also suggests a foreign body.

B. Imaging

Inspiratory and forced expiratory (obtained by manually compressing the abdomen during expiration) chest radiographs should be obtained if foreign body aspiration is suspected. Chest radiographs may be normal up to 25% of the time. If abnormal, the initial inspiratory view may show localized hyperinflation due to the ball-valve effect of the foreign body, causing distal air trapping or aeration within an area of atelectasis. A positive forced expiratory study shows a mediastinal shift away from the affected side. If airway obstruction is complete, atelectasis and related volume loss will be the major radiologic findings. Lateral decubitus views may be helpful if the child is too young to cooperate. Chest fluoroscopy is an alternative approach for detecting air trapping and mediastinal shift.

► Treatment

When a foreign body is highly suspected, a normal chest radiograph should not rule out the possibility of an airway foreign body. If clinical suspicion persists based on two of three findings—history of possible aspiration, focal abnormal lung examination, or an abnormal chest radiograph—

then a bronchoscopy is indicated. Rigid bronchoscopy under general anesthesia is recommended. Flexible bronchoscopy may be helpful for follow-up evaluations (after the foreign object has been removed).

Children with suspected acute foreign body aspiration should be admitted to the hospital for evaluation and treatment. Chest postural drainage is no longer recommended because the foreign body may become dislodged and obstruct a major central airway. Bronchoscopy should not be delayed in children with respiratory distress but should be performed as soon as the diagnosis is made—even in children with more chronic symptoms. Following the removal of the foreign body, β -adrenergic nebulization treatments followed by chest physiotherapy are recommended to help clear related mucus or treat bronchospasm. Failure to identify a foreign body in the lower respiratory tract can result in bronchiectasis or lung abscess. This risk justifies an aggressive approach to suspected foreign bodies in suspicious cases.

Rovin JD, Rodgers BM: Pediatric foreign body aspiration. *Pediatr Rev* 2000;21:86 [PMID: 10702322].

BRONCHIOLITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Clinical syndrome characterized by one or more of the following findings: coughing, tachypnea, labored breathing, and hypoxia.
- ▶ Irritability, poor feeding, vomiting.
- ▶ Wheezing and crackles on chest auscultation.

Bronchiolitis is the most common serious acute respiratory illness in infants and young children. One to 3% of infants with bronchiolitis will require hospitalization, especially during the winter months. The typical presentation is acute onset of tachypnea, cough, and expiratory wheezing after 1–2 days of rhinorrhea. RSV is by far the most common viral cause of acute bronchiolitis. Parainfluenza, human metapneumovirus, influenza, adenovirus, *Mycoplasma*, *Chlamydia*, *Ureaplasma*, and *Pneumocystis* are less common causes of bronchiolitis during early infancy. Major concerns include not only the acute effects of bronchiolitis but also the possible development of chronic airway hyperreactivity (asthma). Bronchiolitis due to RSV infection contributes substantially to morbidity and mortality in children with underlying medical disorders,

including chronic lung disease of prematurity, CF, congenital heart disease, and immunodeficiency.

▶ Clinical Findings

A. Symptoms and Signs

The usual course of RSV bronchiolitis is 1–2 days of fever, rhinorrhea, and cough, followed by wheezing, tachypnea, and respiratory distress. Typically the breathing pattern is shallow, with rapid respirations. Nasal flaring, cyanosis, retractions, and rales may be present, along with prolongation of the expiratory phase and wheezing, depending on the severity of illness. Some young infants present with apnea and few findings on auscultation but may subsequently develop rales, rhonchi, and expiratory wheezing.

B. Laboratory Findings and Imaging

A viral nasal wash may be performed to identify the causative pathogen but is not necessary to make the diagnosis of bronchiolitis. The peripheral white blood cell count may be normal or may show a mild lymphocytosis. Chest radiographic findings are generally nonspecific and typically include hyperinflation, peribronchial cuffing, increased interstitial markings, and subsegmental atelectasis.

▶ Prevention & Treatment

The most effective prevention against RSV infection is to use proper handwashing techniques and to reduce exposure to potential environmental risk factors. Major challenges have impeded the development of an RSV vaccine, but a licensed product may be expected in the near future. Prophylaxis with a monoclonal antibody (palivizumab) has proven effective in reducing the rate of hospitalization and associated morbidities in high-risk premature infants and those with chronic cardiopulmonary conditions.

Although most children with RSV bronchiolitis are readily treated as outpatients, hospitalization is required in infected children with hypoxemia on room air, a history of apnea, moderate tachypnea with feeding difficulties, and marked respiratory distress with retractions. Children at high risk for hospitalization include young infants (under 6 months of age), especially with any history of prematurity, and those with underlying chronic cardiopulmonary disorders. While in the hospital, treatment should include supportive strategies such as frequent suctioning and providing adequate fluids to maintain hydration. If hypoxemia is present, supplemental oxygen should be administered. Although bronchodilators and corticosteroids may attenuate airway obstruction, their use remains controversial and empiric, and patients should be assessed individually to determine responsiveness.

In immunocompromised patients, especially bone marrow transplant recipients, a combination of RSV intravenous immune globulin and the antiviral ribavirin has been tried.

Therapy for RSV, however, remains limited, controversial, and mostly supportive.

► Prognosis

The prognosis for the majority of infants with acute bronchiolitis is very good. With improved supportive care and prophylaxis with palivizumab, the mortality rate among high-risk infants has decreased substantially.

DISORDERS OF MUCOCILIARY CLEARANCE

Mucociliary clearance is the primary defense mechanism for the lung. Inhaled particles including microbial pathogens are entrapped in mucus on the airway surface, then cleared by the coordinated action of cilia. The volume and composition of airway surface liquid influence the efficiency of ciliary function and mucus clearance. The two main genetic diseases of mucociliary clearance involve disorders of ion transport (cystic fibrosis, CF) and disorders in ciliary function (primary ciliary dyskinesia, PCD).

CYSTIC FIBROSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Greasy, bulky, malodorous stools; failure to thrive.
- Recurrent respiratory infections.
- Digital clubbing on examination.
- Bronchiectasis on chest imaging.
- Sweat chloride > 60 mmol/L.

► General Considerations

CF, an autosomal recessive disease, results in a syndrome of chronic sinopulmonary infections, malabsorption, and nutritional abnormalities. It is one of the most common lethal genetic diseases in the United States, with an incidence of approximately 1:3000 among Caucasians. Although CF is characterized by abnormalities in the hepatic, gastrointestinal, and male reproductive systems, lung disease is the major

cause of morbidity and mortality. Most individuals with CF develop obstructive lung disease associated with chronic infection that leads to progressive loss of pulmonary function.

The cause of CF is a defect in a single gene on chromosome 7 that encodes a cyclic adenosine monophosphate–regulated chloride channel called the cystic fibrosis transmembrane conductance regulator (CFTR) protein. CFTR functions primarily as an ion channel and controls the movement of salt and water into and out of epithelial cells lining the airways, biliary tree, intestines, vas deferens, sweat ducts, and pancreatic ducts. Approximately 1500 disease-causing mutations in the CF gene have been identified. The most common mutation, $\Delta F508$, is a deletion of three base pairs. This and other gene mutations lead to defects or deficiencies in CFTR, causing problems in salt and water movement across cell membranes, resulting in abnormally thick secretions in various organ systems and critically altering host defense in the lung.

► Clinical Findings

A. Symptoms and Signs

Approximately 15% of newborns with CF present at birth with meconium ileus, a severe intestinal obstruction resulting from inspissation of tenacious meconium in the terminal ileum. Meconium ileus is virtually diagnostic of CF, so the infant should be treated presumptively as having CF until a sweat test or genotyping can be obtained.

During infancy and beyond, a common presentation of CF is failure to thrive. These children fail to gain weight despite good appetite and typically have frequent, bulky, foul-smelling, oily stools. These symptoms are the result of severe exocrine pancreatic insufficiency, the failure of the pancreas to produce sufficient digestive enzymes to allow breakdown and absorption of fats and protein. Pancreatic insufficiency occurs in over 85% of persons with CF. (Chapter 21 describes gastrointestinal and hepatobiliary manifestations of CF; see also Table 21–9 there.) Infants with undiagnosed CF may also present with hypoproteinemia with or without edema, anemia, and deficiency of the fat-soluble vitamins A, D, E, and K, because of ongoing steatorrhea.

From a respiratory standpoint, clinical manifestations include productive cough, wheezing, chronic bronchitis and recurrent pneumonias, progressive obstructive airways disease, exercise intolerance, dyspnea, hemoptysis, anorexia, and weight loss. CF lung disease is characterized by a cycle of chronic, persistent infections with CF-related pathogens and an excessive inflammatory response that progressively damages the airways and lung parenchyma. This results in a characteristic airflow obstruction on lung function testing and bronchiectasis and other structural lung abnormalities on chest imaging (best demonstrated by high-resolution CT scans). Airway infection with bacteria, including *S aureus* and *H influenzae*, often begins in the first few months of life,

even in asymptomatic infants. Eventually, *Pseudomonas aeruginosa* becomes the predominant pathogen. Acquisition of the characteristic mucoid *Pseudomonas* is associated with a more rapid decline in pulmonary function.

An acute change in respiratory signs and symptoms from the subject's baseline is generically termed a pulmonary exacerbation. Clinically, an exacerbation is typically manifested by increased cough and sputum production, decreased exercise tolerance, malaise, and anorexia. These symptoms are usually associated with decreased measures of lung function, new chest radiographic findings, or both. Treatment for pulmonary exacerbations generally consists of antibiotics and augmented airway clearance.

CF should also be considered in infants and children who present with severe dehydration and hypochloremic alkalosis. Other findings that should prompt a diagnostic evaluation for CF include unexplained bronchiectasis, rectal prolapse, nasal polyps, chronic sinusitis, and unexplained pancreatitis or cirrhosis.

B. Diagnostic Studies

The diagnosis of CF is made by a sweat chloride concentration greater than 60 mmol/L in the presence of one or more typical clinical features (chronic sinopulmonary disease, pancreatic insufficiency, salt loss syndromes) or an appropriate family history (sibling or first cousin who has CF). The most acceptable type of sweat test is performed by iontophoresis of pilocarpine into the skin to stimulate sweating. Sweat then is collected and analyzed for chloride. This test should be performed at a CF Foundation–accredited laboratory. A diagnosis can also be confirmed by genotyping that reveals two alleles that have CF-causing mutations. Many states now perform newborn screening for CF by measuring immunoreactive trypsin (IRT), a pancreatic enzyme, in blood. Most infants with CF have elevated IRT in the newborn period. In newborns with elevated IRT, the diagnosis of CF must then be confirmed by sweat testing, mutation analysis, or both.

▶ Treatment

It is strongly recommended that individuals with CF be followed at a CF Foundation–accredited CF care center (<http://www.cff.org>).

The cornerstone of gastrointestinal treatment is pancreatic enzyme supplementation. Persons with CF are required to take pancreatic enzyme capsules immediately prior to each meal and with snacks. Occasionally, enzyme supplementation alone does not control the malabsorption, and antacids are added to the regimen. Individuals should also take daily multivitamins that contain vitamins A, D, E, and K. Moreover, caloric supplements are often added to the patient's diet to optimize growth.

Airway clearance therapy and aggressive antibiotic use form the mainstays of treatment for CF lung disease. Antibiotic therapy appears to be one of the primary reasons for the increased life expectancy of persons with CF. Three evi-

dence-based medications that are now routinely used in many persons with CF are an inhaled mucolytic agent, recombinant human DNase (Pulmozyme), inhaled tobramycin (TOBI), and oral azithromycin for those with chronic *Pseudomonas* infection. These therapies have been shown to maintain lung function and reduce the need for hospitalizations and intravenous antibiotics. Bronchodilators and anti-inflammatory therapies are also frequently used.

▶ Prognosis

A few decades ago, CF was fatal in early childhood. Now the median life expectancy is around 35 years of age. The rate of lung disease progression usually determines survival. Lung transplantation may be performed in those with end-stage lung disease. In addition, new treatments, including gene therapy trials and agents that modulate CFTR protein function, are being developed based on improved understanding of the disease at the cellular and molecular levels.

PRIMARY CILIARY DYSKINESIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Chronic bronchitis, sinusitis, and otitis.
- ▶ Situs inversus in approximately 50% of cases.
- ▶ Unexplained respiratory distress in the newborn period.
- ▶ Consistent ultrastructural defect of cilia demonstrated by electron microscopy.

▶ General Considerations

PCD, also known as immotile cilia syndrome or Kartagener syndrome, is a human genetic disease associated with abnormal ciliary structure and function. Occurring in approximately 1 in 15,000 births, PCD is an inherited disease that causes impaired clearance of bacteria from the lung, paranasal sinuses, and middle ear. Half of the patients with PCD have their internal organs reversed (situs abnormalities), and men are usually infertile.

▶ Clinical Findings

A. Symptoms and Signs

Children with PCD have a variety of clinical features including chronic productive cough, wheezing, nasal congestion

and rhinorrhea, chronic sinusitis, bronchitis, and pneumonias. Recurrent, chronic otitis media is a serious problem, and hearing loss is common. A history of transient neonatal respiratory distress and unexplained atelectasis in the newborn period is frequently elicited. Approximately 50% of PCD patients have situs inversus totalis or other organ rotation abnormalities, suggesting a role for embryonic cilia in the rotation of internal organs. The diagnosis of PCD should also be considered in any patients with unexplained bronchiectasis or in males with infertility issues.

B. Diagnostic Studies

The diagnosis of PCD currently requires a compatible clinical phenotype and specific ultrastructural defects of the cilia detected by transmission electron microscopy. Cilia samples may be obtained from either the upper airways (nasal passage) or lower airways (trachea). Semen collection from older male patients can also be obtained to analyze sperm tails, which have the same ultrastructure as cilia. Significant expertise is required to produce high-quality transmission electron micrographs of cilia, and to distinguish primary (genetic) defects from secondary (acquired) defects in ciliary ultrastructure. Functional assessments of cilia consist of crude measures of nasal mucociliary clearance (the saccharin test), or measures of lung mucociliary clearance, using radioisotopic techniques. The current limitations in diagnosis of PCD provide a compelling case to define disease-causing genetic mutations, which will allow great improvement in the identification and diagnosis of PCD through genetic testing. Although structural and functional assessments of cilia have been the diagnostic gold standard in PCD diagnosis, nasal nitric oxide has the potential to become a useful adjunctive diagnostic test for PCD. Recent studies have demonstrated extremely low levels of nasal nitric oxide in persons with PCD, suggesting that nasal nitric oxide could be used as a screening test for PCD.

▶ Treatment

At present, no specific therapies are available to correct the ciliary dysfunction in PCD. Management includes aggressive airway clearance therapy and frequent courses of antibiotics to treat bacterial infections in the airways, sinuses, and middle ear. No randomized clinical trials have been conducted in this disease because it is so rare and most centers follow only a few PCD patients. A national consortium has been created to improve diagnostic techniques for PCD, including genetic testing to better define the pathogenesis of PCD and study treatments in this population (<http://rare diseases network.epi.usf.edu/>).

▶ Prognosis

The progression of lung disease in PCD is quite variable and for most affected individuals is less severe than in CF. Importantly, though, persons with PCD are at risk for chronic lung

disease with bronchiectasis. With monitoring and aggressive treatment during times of illness, most individuals with PCD should experience a normal or near-normal life span.

BRONCHIECTASIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Chronic cough with sputum production.
- ▶ Rhonchi or wheezes (or both) on chest auscultation.
- ▶ Diagnosis is confirmed by high-resolution CT scan.

▶ General Considerations

Bronchiectasis is the permanent dilation of bronchi. The dilation may be regular, with the airway continuing to have a smooth outline (cylindric bronchiectasis); irregular, with areas of dilation and constriction (varicose bronchiectasis); or marked, with destruction of structural components of the airway wall (saccular or cystic bronchiectasis).

Bronchiectasis results from airway obstruction by retained mucus secretions or inflammation in response to chronic or repeated infection. It occurs either as a consequence of a preceding illness (severe pneumonia or foreign body aspiration) or as a manifestation of an underlying systemic disorder (CF, PCD, or immunodeficiency).

▶ Clinical Findings

A. Symptoms and Signs

Persons with bronchiectasis will typically have chronic cough, purulent sputum, fever, and weight loss. Recurrent respiratory infections and dyspnea on exertion are also common. Hemoptysis occurs less frequently in children than in adults with bronchiectasis. On physical examination, finger clubbing may be seen. Rales, rhonchi, and decreased air entry are often noted over the bronchiectatic areas.

B. Laboratory Findings and Imaging

Cultures from the lower respiratory tract usually reveal normal oropharyngeal flora. These include *Streptococcus pneumoniae*, *Staphylococcus aureus*, and nontypeable *H influenzae*. *Pseudomonas aeruginosa* can also be found in children with bronchiectasis, even in those without CF.

Chest radiographs may be mildly abnormal with slightly increased bronchovascular markings or areas of atelectasis, or

they may demonstrate cystic changes in one or more areas of the lung. The extent of bronchiectasis is best defined by high-resolution CT scan of the lung, which often reveals far wider involvement of lung than expected from the plain chest radiograph. Pulmonary function testing often reveals airflow obstruction. Evaluation of lung function after use of a bronchodilator is helpful in assessing the benefit a patient may have from bronchodilators. Serial assessments of lung function help define the progression or resolution of the disease.

► Differential Diagnosis

Bronchiectasis has numerous causes. It can occur following severe respiratory tract infections by bacteria (*Bordetella pertussis*), viruses (adenovirus), or other organisms (*Mycobacterium tuberculosis*). Bronchiectasis is commonly seen in persons with CF, PCD, immunodeficiency, and collagen-vascular conditions. Other diagnostic considerations include foreign body aspiration, chronic aspiration of gastric or oropharyngeal contents, and allergic bronchopulmonary aspergillosis.

► Treatment

Aggressive antibiotic therapy during pulmonary exacerbations and routine airway clearance are mainstays of treatment. Inhaled mucolytic agents and bronchodilators may also be of benefit in individual patients.

Surgical removal of an area of lung affected with severe bronchiectasis is considered when the response to medical therapy is poor. Other indications for operation include severe localized disease, repeated hemoptysis, and recurrent pneumonia in one area of lung. If bronchiectasis is widespread, surgical resection offers little advantage.

► Prognosis

The prognosis depends on the underlying cause and severity of bronchiectasis, the extent of lung involvement, and the response to medical management. Good pulmonary hygiene and avoidance of infectious complications in the involved areas of lung may reverse cylindrical bronchiectasis.

Chang AB et al: Non-CF bronchiectasis: Clinical and HRCT evaluation. *Pediatr Pulmonol* 2003;35:477 [PMID: 12746947].

BRONCHIOLITIS OBLITERANS

Bronchiolitis obliterans is characterized by partial or complete occlusion of the lumens of terminal and respiratory bronchioles by inflammatory and fibrous tissue. This condition follows damage to the lower respiratory tract from any of a number of insults, such as inhalation of toxic gases, infections (adenovirus, influenza virus, rubeola virus, *Bordetella*, or *Mycoplasma*), connective tissue diseases, transplan-

tation, and aspiration. Bronchiolitis obliterans may also develop in children who have Stevens-Johnson syndrome with pulmonary involvement. Many cases of bronchiolitis obliterans are idiopathic. Adenovirus-induced bronchiolitis obliterans occurs more frequently in the Native American population.

► Clinical Findings

A. Symptoms and Signs

Persons with bronchiolitis obliterans usually experience dyspnea, coughing, and exercise intolerance. This diagnosis should be considered in children with persistent cough, wheezing, crackles, or hypoxemia following an episode of acute pneumonia or bronchiolitis.

B. Laboratory Findings and Imaging

Chest radiograph abnormalities include evidence of localized or generalized air trapping as well as (in some cases) nodular densities and alveolar opacification. Scattered areas of matched decreases in ventilation and perfusion are seen when the lung is scanned. Pulmonary angiograms reveal decreased vasculature in involved lung, and bronchograms show marked pruning of the bronchial tree. An assessment of lung function demonstrates an obstructive process that may be combined with evidence of restriction. Inhaled bronchodilators or corticosteroids provide little improvement in lung function.

► Differential Diagnosis

Poorly treated asthma, CF, and bronchopulmonary dysplasia must be considered in children with persistent airway obstruction. A trial of medications (including bronchodilators and corticosteroids) may help to determine the reversibility of the process when the primary differential is between asthma and bronchiolitis obliterans. Although the results of imaging and pulmonary function testing are very suggestive, the most definitive way to establish a diagnosis is by lung biopsy.

► Complications

Sequelae of bronchiolitis obliterans include persistent airway obstruction, recurrent wheezing, bronchiectasis, chronic atelectasis, recurrent pneumonia, and unilateral hyperlucent lung syndrome.

► Treatment

Supplemental oxygen should be given to patients with oxygen desaturation during normal activities or sleep. In addition, early treatment should be directed at preventing ongoing airway damage due to problems such as aspiration, which may be either the primary insult or an acquired problem secondary to marked hyperinflation. The effective-

ness of other forms of treatment may be more difficult to evaluate. Oral and inhaled bronchodilators may reverse airway obstruction if the disease has a reactive component. Many children also receive at least one course of corticosteroid treatment in an attempt to reverse the obstruction or prevent ongoing damage. Antibiotics should be used as indicated for pneumonia.

► Prognosis

Prognosis may depend in part on the underlying cause as well as the age at which the insult occurred. The course varies from mild asthma-like symptoms to rapidly fatal deterioration despite therapy.

Kurland G, Michelson P: Bronchiolitis obliterans in children. *Pediatr Pulmonol* 2005;39:193 [PMID: 15635614].

BRONCHOPULMONARY DYSPLASIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Acute respiratory distress in the first week of life.
- ▶ Required oxygen therapy or mechanical ventilation, with persistent oxygen requirement at 36 weeks' gestational age.
- ▶ Persistent respiratory abnormalities, including physical signs and radiographic findings.

► General Considerations

Bronchopulmonary dysplasia (BPD) remains one of the most significant sequelae of acute respiratory distress in the neonatal intensive care unit, with an incidence of about 30% for infants with a birth weight of less than 1000 g. This disease was first characterized in 1967 when Northway and coworkers reported the clinical, radiologic, and pathologic findings in a group of premature newborns that required prolonged mechanical ventilation and oxygen therapy to treat hyaline membrane disease. The progression from acute hyaline membrane disease to chronic lung disease was divided into four stages: acute respiratory distress shortly after birth, usually hyaline membrane disease (stage I); clinical and radiographic worsening of the acute lung disease, often due to increased pulmonary blood flow secondary to a patent ductus arteriosus (stage II); and progressive signs of chronic lung disease (stages III and IV).

The pathologic findings and clinical course of BPD in recent years have changed due to a combination of new therapies (surfactants, prenatal glucocorticoids, and different ventilation strategies) and increased survival of infants born at earlier gestational ages. Although the incidence of BPD has not changed, the severity of the lung disease has

decreased. Pathologically this “new” BPD is characterized by a reduction in inflammation, decreased alveolar number, and a dysmorphic vascular structure.

► Pathogenesis

The precise mechanism that results in the development of BPD is unclear. The premature lung makes insufficient functional surfactant; furthermore, the antioxidant defense mechanisms are not sufficiently mature to protect the lung from the toxic oxygen metabolites, and lungs destined to develop BPD show early inflammation and hypercellularity followed by healing with fibrosis. Thus abnormal lung mechanics due to structural immaturity, surfactant deficiency, atelectasis, and pulmonary edema—plus lung injury secondary to hyperoxia and mechanical ventilation—lead to further abnormalities of lung function, causing increases in ventilator and oxygen requirements and resulting in a vicious cycle that compounds the progression of lung injury. Excessive fluid administration, patent ductus arteriosus, pulmonary interstitial emphysema, pneumothorax, infection, pulmonary hypertension, and inflammatory stimuli secondary to lung injury or infection also play important roles in the pathogenesis of the disease. Although the exact mechanisms are not completely understood, BPD represents the consequences of lung injury caused by oxygen toxicity, barotrauma, and inflammation superimposed on a susceptible, generally immature lung.

► Clinical Findings

A recent summary of a National Institutes of Health workshop on BPD proposes a definition of the disease that includes oxygen requirement for more than 28 days, a history of positive pressure ventilation or continuous positive airway pressure, and gestational age. The new definition accommodates several key observations regarding the disease, as follows: (1) although most of these children were premature and had hyaline membrane disease, full-term newborns with such disorders as meconium aspiration or persistent pulmonary hypertension can also develop bronchopulmonary dysplasia; (2) some extremely preterm newborns require minimal ventilator support yet subsequently develop a prolonged oxygen requirement despite the absence of severe acute manifestations of respiratory failure; (3) newborns dying within the first weeks of life can already have the aggressive, fibroproliferative pathologic lesions that resemble bronchopulmonary dysplasia; and (4) physiologic abnormalities (increased airway resistance) and biochemical markers of lung injury (altered protease-antiprotease ratios, and increased inflammatory cells and mediators), which may be predictive of BPD, are already present in the first week of life.

► Differential Diagnosis

The radiologic appearance of BPD is changing, and severe chronic lung findings of fibrosis with infiltrate are less common. The changes in severe BPD necessitate ruling out

meconium aspiration syndrome, congenital infection (eg, with cytomegalovirus or *Ureaplasma*), cystic adenomatoid malformation, recurrent aspiration, pulmonary lymphangiectasia, total anomalous pulmonary venous return, overhydration, and idiopathic pulmonary fibrosis.

► Treatment

A. Clinical Course

The clinical course of infants with BPD ranges from a mild increased oxygen requirement that gradually resolves over a few months to more severe disease requiring chronic tracheostomy and mechanical ventilation for the first 2 years of life. In general, patients show slow, steady improvements in oxygen or ventilator requirements but can have frequent respiratory exacerbations leading to frequent and prolonged hospitalizations. Clinical management generally includes careful attention to growth, nutrition (caloric requirements of infants with oxygen dependence and respiratory distress are quite high), metabolic status, developmental and neurologic status, and related problems, along with the various cardiopulmonary abnormalities described in a later discussion.

B. Corticosteroid Therapy

Short courses of postnatal glucocorticoid therapy have been helpful in increasing the success of weaning from the ventilator. Longer courses of postnatal glucocorticoids have been linked to an increased incidence of cerebral palsy. Inhaled glucocorticoids may help reduce the need for systemic steroids, but the overall incidence of BPD has not been affected. Early use of surfactant therapy with adequate lung recruitment increases the chance for survival without BPD and can decrease the overall mortality and reduce the need for ventilation. Thus early interventions are important prior to the development of BPD to decrease morbidity and mortality. Inhaled corticosteroids together with occasional use of β -adrenergic agonists are commonly part of the treatment plan. Part of the rationale for the use of corticosteroids is to decrease lung inflammation and enhance responsiveness to β -adrenergic drugs, as in the treatment of severe asthma. β -Adrenergic agonists followed by chest physiotherapy are often used for the thick secretions that may contribute to airway obstruction or recurrent atelectasis.

C. Airway Evaluation

Children with significant stridor, sleep apnea, chronic wheezing, or excessive respiratory distress need diagnostic bronchoscopy to evaluate for structural lesions (eg, subglottic stenosis, vocal cord paralysis, tracheal stenosis, tracheomalacia, bronchial stenosis, and granulomatous bronchial polyps). In addition, the contribution of gastroesophageal reflux and aspiration should be considered in the face of worsening chronic lung disease.

D. Diuretic Therapy

Salt and water retention secondary to chronic hypoxemia, hypercapnia, or other stimuli may be present. Chronic or intermittent diuretic therapy is commonly used if rales or signs of persistent pulmonary edema are present, and clinical studies show acute improvement in lung function with this therapy. Unfortunately, diuretics often have adverse effects, including severe volume contraction, hypokalemia, alkalosis, and hyponatremia. Potassium and arginine chloride supplements are commonly required.

E. Management of Pulmonary Hypertension

Infants with BPD are at risk of developing pulmonary hypertension, and in many of these children even mild hypoxemia can cause significant elevations of pulmonary arterial pressure. To minimize the harmful effects of hypoxemia, the arterial oxygen saturation should be kept above 93%, with care to avoid hyperoxia during retinal vascular development. Electrocardiographic and echocardiographic studies should be performed to monitor for the development of right ventricular hypertrophy. If hypertrophy persists or if it develops where it was not previously present, intermittent hypoxemia should be considered and further assessments of oxygenation pursued, especially while the infant sleeps. Infants with a history of intubation can develop obstructive sleep apnea secondary to a high-arched palate or subglottic narrowing. Barium swallow, esophageal pH probe studies, bronchoscopy, and cardiac catheterization will diagnose unsuspected cardiac or pulmonary lesions that contribute to the underlying pathophysiology, such as aspiration, tracheomalacia, obstructive sleep apnea, and anatomic cardiac lesions. Long-term care should include monitoring for systemic hypertension and the development of left ventricular hypertrophy.

F. Nutrition

Nutritional problems in infants may be due to increased oxygen consumption, feeding difficulties, gastroesophageal reflux, and chronic hypoxemia. Hypercaloric formulas and gastrostomies are often required to ensure adequate intake while avoiding overhydration. Influenza vaccination is recommended. With the onset of acute wheezing secondary to suspected viral infection, rapid diagnostic testing for RSV infection may facilitate early treatment. Immune prophylaxis of RSV reduces the morbidity of bronchiolitis in infants with BPD.

G. Ventilation

For children who remain ventilator-dependent, attempts should be made to maintain PaCO_2 below 60 mm Hg—even when pH is normal—because of the potential adverse effects of hypercapnia on salt and water retention, cardiac function, and perhaps pulmonary vascular tone. Changes in ventilator settings in children with severe lung disease should be slow,

because the effects of many of the changes may not be apparent for days.

► Prognosis

Surfactant replacement therapy has had a significant effect on reducing morbidity and mortality from BPD. Infants of younger gestational age are surviving in greater numbers. Surprisingly, the effect of neonatal care has not decreased the incidence of BPD significantly, as 50% of survivors go on to develop this diagnosis. The disorder typically develops in the most immature infants, but the long-term outlook for most survivors is generally favorable. Long-term follow-up studies suggest that lung function may be altered for life. Hyperinflation and damage to small airways has been reported in children 10 years out from the first signs of BPD. In addition, these infants are at a higher risk for developing such sequelae as persistent airway hyperreactivity, exercise intolerance, pulmonary hypertension, increased risk for chronic obstructive pulmonary disease, and perhaps abnormal lung growth. As smaller, more immature infants survive, abnormal neurodevelopmental outcomes become more likely. The incidence of cerebral palsy, hearing loss, vision abnormalities, spastic diplegia, and developmental delays is increased. Feeding abnormalities, behavior difficulties, and increased irritability have all been reported. Finally, children with BPD frequently develop airway obstruction, hyperreactive airways, and decreased oxygen saturation during exercise. This should be taken into account for children residing at higher altitudes. A focus on good nutrition, prophylaxis against respiratory pathogens and airway hyperreactivity, and attention to school performance continue to provide the best outcomes. Patience, continued family support, attention to developmental issues, and speech and physical therapy help to improve the long-term outlook.

CONGENITAL MALFORMATIONS OF THE LUNG

What follows is a brief description of selected congenital pulmonary malformations.

PULMONARY AGENESIS & HYPOPLASIA

With unilateral pulmonary agenesis (complete absence of one lung), the trachea continues into a main bronchus and often has complete tracheal rings. The left lung is affected more often than the right. With compensatory postnatal growth, the remaining lung often herniates into the contralateral chest. Chest radiographs show a mediastinal shift toward the affected side, and vertebral abnormalities may be present. Absent or incomplete lung development may be associated with other congenital abnormalities, such as absence of one or both kidneys or fusion of ribs, and the outcome is primarily related to the severity of associated lesions. About 50% of patients survive; the mortality rate is higher with agenesis of the right lung than of the left lung. This difference is probably not related to the higher incidence of associated anomalies but rather to a greater shift in the mediastinum that leads to tracheal compression and distortion of vascular structures.

Pulmonary hypoplasia is incomplete development of one or both lungs, characterized by a reduction in alveolar number and a reduction in airway branches. Pulmonary hypoplasia is present in up to 10–15% of perinatal autopsies. The hypoplasia can be a result of an intrathoracic mass, resulting in lack of space for the lungs to grow; decreased size of the thorax; decreased fetal breathing movements; decreased blood flow to the lungs; or possibly a primary mesodermal defect affecting multiple organ systems. Congenital diaphragmatic hernia is the most common cause, with an incidence of 1:2200 births. Other causes include extralobar sequestration, diaphragmatic eventration or hypoplasia, thoracic neuroblastoma, fetal hydrops, and fetal hydrochylothorax. Chest cage abnormalities, diaphragmatic elevation, oligohydramnios, chromosomal abnormalities, severe musculoskeletal disorders, and cardiac lesions may also result in hypoplastic lungs. Postnatal factors may play important roles. For example, infants with advanced BPD can have pulmonary hypoplasia.

► Clinical Findings

A. Symptoms and Signs

The clinical presentation is highly variable and is related to the severity of hypoplasia as well as associated abnormalities. Lung hypoplasia is often associated with pneumothorax. Some newborns present with perinatal stress, severe acute respiratory distress, and persistent pulmonary hypertension of the newborn secondary to primary pulmonary hypoplasia (without associated anomalies). Children with lesser degrees of hypoplasia may present with chronic cough, tachypnea, wheezing, and recurrent pneumonia.

B. Laboratory Findings and Imaging

Chest radiographic findings include variable degrees of volume loss in a small hemithorax with mediastinal shift. Pulmonary agenesis should be suspected if tracheal deviation is evident on the chest radiograph. The chest CT scan is the optimal diagnostic imaging procedure if the chest radiograph is not definitive. Ventilation-perfusion scans, angiography, and bronchoscopy are often helpful in the evaluation, demonstrating decreased pulmonary vascularity or premature blunting of airways associated with the maldeveloped lung tissue. The degree of respiratory impairment is defined by analysis of arterial blood gases.

► Treatment & Prognosis

Treatment is supportive. The outcome is determined by the severity of underlying medical problems, the extent of the hypoplasia, and the degree of pulmonary hypertension.

PULMONARY SEQUESTRATION

Pulmonary sequestration is nonfunctional pulmonary tissue that does not communicate with the tracheobronchial tree and receives its blood supply from one or more anomalous systemic arteries. This abnormality originates during the embryonic period of lung development. It is classified as either extralobar or intralobar. Extralobar sequestration is a mass of pulmonary parenchyma anatomically separate from the normal lung, with a distinct pleural investment. Its blood supply derives from the systemic circulation (more typical), from pulmonary vessels, or from both. Rarely, it communi-

cates with the esophagus or stomach. Pathologically, extralobar sequestration appears as a solitary thoracic lesion near the diaphragm. Abdominal sites are rare. Size varies from 0.5–12 cm. The left side is involved in over 90% of cases. In contrast to intralobar sequestrations, venous drainage is usually through the systemic or portal venous system.

Histologic findings include uniformly dilated bronchioles, alveolar ducts, and alveoli. Occasionally the bronchial structure appears normal; however, often the cartilage in the wall is deficient, or no cartilage-containing structures can be found. Lymphangiectasia is sometimes found within the lesion. Extralobar sequestration can be associated with other anomalies, including bronchogenic cysts, heart defects, and diaphragmatic hernia, the latter occurring in over half of cases.

Intralobar sequestration is an isolated segment of lung within the normal pleural investment that often receives blood from one or more arteries arising from the aorta or its branches. Intralobar sequestration is usually found within the lower lobes (98%), two thirds are found on the left side, and it is rarely associated with other congenital anomalies (< 2% versus 50% with extralobar sequestration). It rarely presents in the newborn period (unlike extralobar sequestration). Some researchers have hypothesized that intralobar sequestration is an acquired lesion secondary to chronic infection. Clinical presentation includes chronic cough, wheezing, or recurrent pneumonias. Rarely, patients with intralobar sequestration can present with hemoptysis. Diagnosis is often made by angiography, which shows large systemic arteries perfusing the lesion. Recently spiral CT scans with contrast or magnetic resonance angiography have proved useful in identifying anomalous systemic arterial supply to the lung. Treatment is usually by surgical resection.

CONGENITAL LOBAR EMPHYSEMA

Patients with congenital lobar emphysema—also known as infantile lobar emphysema, congenital localized emphysema, unilobar obstructive emphysema, congenital hypertrophic lobar emphysema, or congenital lobar overinflation—present most commonly with severe neonatal respiratory distress or

progressive respiratory impairment during the first year of life. Rarely the mild or intermittent nature of the symptoms in older children or young adults results in delayed diagnosis. Most patients are white males. Although the cause of congenital lobar emphysema is not well understood, some lesions show bronchial cartilaginous dysplasia due to abnormal orientation or distribution of the bronchial cartilage. This leads to expiratory collapse, producing obstruction and the symptoms outlined in the following discussion.

► Clinical Findings

A. Symptoms and Signs

Clinical features include respiratory distress, tachypnea, cyanosis, wheezing, retractions, and cough. Breath sounds are reduced on the affected side, perhaps with hyperresonance to percussion, mediastinal displacement, and bulging of the chest wall on the affected side.

B. Imaging

Radiologic findings include overdistention of the affected lobe (usually an upper or middle lobe; > 99%), with wide separation of bronchovascular markings, collapse of adjacent lung, shift of the mediastinum away from the affected side, and a depressed diaphragm on the affected side. The radiographic diagnosis may be confusing in the newborn because of retention of alveolar fluid in the affected lobe causing the appearance of a homogeneous density. Other diagnostic studies include chest radiograph with fluoroscopy, ventilation-perfusion study, and chest CT scan followed by bronchoscopy, angiography, and exploratory thoracotomy.

► Differential Diagnosis

The differential diagnosis of congenital lobar emphysema includes pneumothorax, pneumatocele, atelectasis with compensatory hyperinflation, diaphragmatic hernia, and congenital cystic adenomatoid malformation. The most common site of involvement is the left upper lobe (42%) or right middle lobe (35%). Evaluation must differentiate regional obstructive emphysema from lobar hyperinflation secondary to an uncomplicated ball-valve mechanism due to extrinsic compression from a mass (ie, bronchogenic cyst, tumor, lymphadenopathy, foreign body, pseudotumor or plasma cell granuloma, or vascular compression) or intrinsic obstruction from a mucus plug due to infection and inflammation from various causes.

► Treatment

When respiratory distress is marked, a segmental or complete lobectomy is usually required. Less symptomatic older children may do equally well with or without lobectomy.

CONGENITAL CYSTIC ADENOMATOID MALFORMATION

Patients with congenital cystic adenomatoid malformations, which are unilateral hamartomatous lesions, generally present with marked respiratory distress within the first days of life. This disorder accounts for 95% of cases of congenital cystic lung disease.

Right and left lungs are involved with equal frequency. These lesions originate during the first 4–6 weeks of gestation during the embryonic period of lung development. They appear as glandlike space-occupying masses or have an increase in terminal respiratory structures, forming intercommunicating cysts of various sizes, lined by cuboidal or ciliated pseudostratified columnar epithelium. The lesions may have polypoid formations of mucosa, with focally increased elastic tissue in the cyst wall beneath the bronchial type of epithelium. Air passages appear malformed and tend to lack cartilage.

There are three types of such malformations. Type 1 is most common (55%) and consists of single or multiple large cysts (> 2 cm in diameter) with features of mature lung tissue. Type 1 is amenable to surgical resection. A mediastinal shift is evident on examination or chest radiograph in 80% of patients and can mimic infantile lobar emphysema. Approximately 75% of type 1 lesions are on the right side. A survival rate of 90% is generally reported.

Type 2 lesions (40% of cases) consist of multiple small cysts (< 2 cm) resembling dilated simple bronchioles and are often (60%) associated with other anomalies, especially renal agenesis or dysgenesis, cardiac malformations, and intestinal atresia. Approximately 60% of type 2 lesions are on the left side. Mediastinal shift is evident less often (10%) than in type 1, and the survival rate is worse (40%).

Type 3 lesions consist of small cysts (< 0.5 cm). They appear as bulky, firm masses. The reported survival rate is 50%.

Recently, two additional types have been described: type 0, a malformation of the proximal tracheobronchial tree (incompatible with life), and type 4, a malformation of the distal acinus. Both types are extremely uncommon.

► Clinical Findings

A. Symptoms and Signs

Clinically, respiratory distress is noted soon after birth. Expansion of the cysts occurs with the onset of breathing and produces compression of normal lung areas with mediastinal herniation. Breath sounds are decreased. With type 3 lesions, dullness to percussion may be present. Older patients can present with a spontaneous pneumothorax or with pneumonia-like symptoms.

B. Imaging

With type 1 lesions, chest radiograph shows an intrapulmonary mass of soft tissue density with scattered radiolucent areas of varying sizes and shapes, usually with a mediastinal shift and pulmonary herniation. Placement of a radiopaque feeding tube into the stomach helps in the differentiation from diaphragmatic hernia. Type 2 lesions appear similar except that the cysts are smaller. Type 3 lesions may appear as a solid homogeneous mass filling the hemithorax and causing a marked mediastinal shift. Differentiation from sequestration is not difficult because congenital cystic adenomatoid malformations have no systemic blood supply.

▶ Treatment

Treatment of type 1 and 3 lesions involves surgical removal of the affected lobe. Resection is often indicated because of the risk of infection and air trapping, since the malformation communicates with the tracheobronchial tree but mucous clearance is compromised. Because type 2 lesions are often associated with other severe anomalies, management may be more complex. Segmental resection is not feasible because smaller cysts may expand after removal of the more obviously affected area. Cystic adenomatoid malformations have been reported to have malignant potential; therefore, expectant management with observation alone should proceed with caution. Recent development of intrauterine surgery for congenital malformations has led to promising results.

ACQUIRED DISORDERS INVOLVING ALVEOLI

BACTERIAL PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Fever, cough, dyspnea.
- ▶ Abnormal chest examination (rales or decreased breath sounds).
- ▶ Abnormal chest radiograph (infiltrates, hilar adenopathy, pleural effusion).

▶ General Considerations

Bacterial pneumonia is inflammation of the lung classified according to the infecting organism. Patients with the following problems are particularly predisposed to this disease: aspiration, immunodeficiency or immunosuppression, congenital anomalies (intrapulmonary sequestration, tracheoesophageal fistula, or cleft palate), abnormalities in clearance of mucus (CF, ciliary dysfunction, tracheomalacia, or bronchiectasis), congestive heart failure, and perinatal contamination.

▶ Clinical Findings

A. Symptoms and Signs

The bacterial pathogen, severity of the disease, and age of the patient may cause substantial variations in the presentation of acute bacterial pneumonia. Infants may have few or nonspecific findings on history and physical examination. Immunocompetent older patients may not be extremely ill. Some patients may present with fever only or only with signs of generalized toxicity. Others may have additional symptoms or signs of lower respiratory tract disease (respiratory distress, cough, and sputum production), pneumonia (rales, decreased breath sounds, dullness to percussion, and abnormal tactile or vocal fremitus), or pleural involvement (splinting, pain, friction rub, and dullness to percussion). Some patients may have additional extrapulmonary findings, such as meningismus or abdominal pain, due to pneumonia itself. Others may have evidence of infection at other sites due to the same organism causing their pneumonia: meningitis, otitis media, sinusitis, pericarditis, epiglottitis, or abscesses.

B. Laboratory Findings

Elevated white blood cell counts ($> 15,000/\mu\text{L}$) frequently accompany bacterial pneumonia. However, a low white blood count ($< 5000/\mu\text{L}$) can be an ominous finding in this disease.

C. Imaging

Chest radiographic findings (lateral and frontal views) define bacterial pneumonia. Patchy infiltrates, atelectasis, hilar adenopathy, or pleural effusion may be observed. Radiographs should be taken in the lateral decubitus position to identify pleural fluid. Complete lobar consolidation is not a common finding in infants and children. Severity of disease may not correlate with radiographic findings. Clinical resolution precedes resolution apparent on chest radiograph.

D. Special Tests

Invasive diagnostic procedures (bronchial brushing or washing, lung puncture, or open or thoracoscopic lung biopsy) should be undertaken in critically ill patients when other means do not adequately identify the cause (see earlier section on Culture of Material from the Respiratory Tract).

► Differential Diagnosis

The differential diagnosis of pneumonia varies with the age and immunocompetence of the host. The spectrum of potential pathogens to be considered includes aerobic, anaerobic, and acid-fast bacteria as well as *Chlamydia trachomatis*, *C pneumoniae*, *C psittaci*, *Coxiella burnetii* (Q fever), *Pneumocystis jiroveci*, *Bordetella pertussis*, *Mycoplasma pneumoniae*, *Legionella pneumophila*, and respiratory viruses. *Streptococcus pneumoniae* is the most prevalent bacterial pathogen. Vaccination with pneumococcal vaccine will aid in the prevention of pneumonia.

Noninfectious pulmonary disease (including gastric aspiration, foreign body aspiration, atelectasis, congenital malformations, congestive heart failure, malignancy, tumors such as plasma cell granuloma, chronic interstitial lung diseases, and pulmonary hemosiderosis) should be considered in the differential diagnosis of localized or diffuse infiltrates. When effusions are present, additional noninfectious disorders such as collagen diseases, neoplasm, and pulmonary infarction should also be considered.

► Complications

Empyema may occur frequently with staphylococcal, pneumococcal, and group A β -hemolytic streptococcal disease. Distal sites of infection—meningitis, otitis media, sinusitis (especially of the ethmoids), and septicemia—may be present, particularly with disease due to *S pneumoniae* or *H influenzae*. Certain immunocompromised patients, such as those who have undergone splenectomy or who have hemoglobin SS or SC disease or thalassemia, are especially prone to overwhelming sepsis with these organisms. Distal infection of the bones, joints, or other organs (eg, liver abscess) may occur in certain hosts with specific organisms.

► Treatment

Antimicrobial therapy should be guided by Gram stain of sputum, tracheobronchial secretions, or pleural fluid if available; radiographic findings; age and known or suspected immunocompetence of the host; and local epidemiologic information. Reasonable coverage for pneumonia in the sick, immunocompromised, or debilitated patient, pending the results of bronchoalveolar lavage or thoracoscopic biopsy, should include ceftazidime, clindamycin, vancomycin, a macrolide for *Legionella* and *Mycoplasma*, and possibly trimethoprim-sulfamethoxazole for *P jiroveci*. Depending on the circumstances and the level of illness, empiric antifungal or antiviral therapy may be considered. In specific circumstances such as aspiration due to neurologic impairment or in patients with tracheostomies, clindamycin is indicated, pending culture and sensitivity studies, owing to the likely presence of resistant anaerobes.

Less severe pneumonias can often be treated with oral antibiotics based on the patient's age and suspected organ-

ism. Lobar pneumonias presumed to be due to *S pneumoniae* can be treated initially with oral β -lactams, including cefuroxime axetil, amoxicillin, or amoxicillin-clavulanate. However, persistence or worsening of symptoms within 3–5 days suggests the presence of a resistant organism, and newer quinolones, clindamycin, or vancomycin may be required. When possible, therapy can be guided by the antibiotic sensitivity pattern of the organisms isolated. (For further discussion, see Chapter 37.)

Whether a child should be hospitalized depends on his or her age, the severity of illness, the suspected organism, and the anticipated reliability of adherence to the treatment regimen at home. Home treatment is adequate for most older children. With febrile pneumonias, infants generally—and toddlers often—require admission. Moderate to severe respiratory distress, apnea, hypoxemia, poor feeding, clinical deterioration on treatment, or associated complications (large effusions, empyema, or abscess) indicate the need for immediate hospitalization. Careful follow-up within 12 hours to 5 days is often indicated in those not admitted. Cefuroxime or a macrolide, depending on the clinical picture, may be appropriate initial therapy for patients in this category.

Additional therapeutic considerations include oxygen, humidification of inspired gases, hydration and electrolyte supplementation, and nutrition. Removal of pleural fluid for diagnostic purposes is indicated initially to guide antimicrobial therapy. Many experts feel that early chest tube drainage of empyema fluid is indicated. Repeat pleural taps should be considered in the patient who has persistent high fever and respiratory symptoms in association with significant pleural effusions. The persistence of organisms in this fluid or the persistence of toxicity, malaise, anorexia, and wasting in the patient suggests the potential need for pleural decortication, a procedure that can be made less morbid by thoracoscopy in skilled hands.

Endotracheal intubation or mechanical ventilation may be indicated in patients with respiratory failure or in those too debilitated or overwhelmed to handle their secretions.

► Prognosis

For the immunocompetent host in whom bacterial pneumonia is adequately recognized and treated, the survival rate is high. For example, the mortality rate from uncomplicated pneumococcal pneumonia is less than 1%. If the patient survives the initial illness, persistently abnormal pulmonary function following empyema is surprisingly uncommon, even when treatment has been delayed or inappropriate.

VIRAL PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Upper respiratory infection prodrome (fever, coryza, cough, hoarseness).
- ▶ Wheezing or rales.
- ▶ Myalgia, malaise, headache (older children).

▶ General Considerations

Most pneumonias in children are caused by viruses. RSV, parainfluenza (1, 2, and 3) viruses, influenza (A and B) viruses, and human metapneumovirus are responsible for the large majority of cases. Severity of disease, severity of fever, radiographic findings, and the characteristics of cough or lung sounds do not reliably differentiate viral from bacterial pneumonias. Furthermore, such infections may coexist. However, substantial pleural effusions, pneumatoceles, abscesses, lobar consolidation with lobar volume expansion, and “round” pneumonias are generally inconsistent with viral disease.

▶ Clinical Findings

A. Symptoms and Signs

An upper respiratory infection frequently precedes the onset of lower respiratory disease due to viruses. Although wheezing or stridor may be prominent in viral disease, cough, signs of respiratory difficulty (tachypnea, retractions, grunting, and nasal flaring), and physical findings (rales and decreased breath sounds) may not be distinguishable from those in bacterial pneumonia.

B. Laboratory Findings

The peripheral white blood cell count can be normal or slightly elevated and is not useful in distinguishing viral from bacterial disease.

Rapid viral diagnostic methods—such as fluorescent antibody tests or enzyme-linked immunosorbent assay—should be performed on nasopharyngeal secretions to confirm this diagnosis in high-risk patients and for epidemiology or infection control. Rapid diagnosis of RSV infection does not preclude the possibility of concomitant infection with other pathogens.

C. Imaging

Chest radiographs frequently show perihilar streaking, increased interstitial markings, peribronchial cuffing, or patchy bronchopneumonia. Lobar consolidation or atelectasis may occur, however, as in bacterial pneumonia. Patients with adenovirus disease may have severe necrotizing pneu-

monias, resulting in the development of pneumatoceles. Hyperinflation of the lungs may occur when involvement of the small airways is prominent.

▶ Differential Diagnosis

The differential diagnosis of viral pneumonia is the same as for bacterial pneumonia. Patients with prominent wheezing may have asthma, airway obstruction caused by foreign body aspiration, acute bacterial or viral tracheitis, or parasitic disease.

▶ Complications

Viral pneumonia or laryngotracheobronchitis may predispose the patient to subsequent bacterial tracheitis or pneumonia as immediate sequelae. Bronchiolitis obliterans or severe chronic respiratory failure may follow adenovirus pneumonia. Bronchiolitis or viral pneumonia may contribute to persistent asthma in some patients. Bronchiectasis, chronic interstitial lung diseases, and unilateral hyperlucent lung (Sawyer-James syndrome) may follow measles, adenovirus, and influenzal pneumonias. Plasma cell granuloma may develop as a rare sequela to viral or bacterial pneumonia.

▶ Treatment

General supportive care for viral pneumonia does not differ from that for bacterial pneumonia. Patients can be quite ill and should be hospitalized according to the level of their illness. Because bacterial disease often cannot be definitively excluded, antibiotics may be indicated.

Patients at risk for life-threatening RSV infections (eg, those with BPD or other severe pulmonary conditions, congenital heart disease, or significant immunocompromise) should be hospitalized and ribavirin should be considered. Rapid viral diagnostic tests may be a useful guide for such therapy (see Bronchiolitis section, earlier, regarding prevention). These high-risk patients and all children 6 months to 5 years of age should be immunized annually against influenza A and B viruses. Despite immunization, however, influenza infection can still occur. When available epidemiologic data indicate an active influenza A infection in the community, rimantadine, amantadine hydrochloride, or oseltamivir phosphate should be considered early for high-risk infants and children who appear to be infected. Children with suspected viral pneumonia should be placed in respiratory isolation.

▶ Prognosis

Although most children with viral pneumonia recover uneventfully, worsening asthma, abnormal pulmonary function or chest radiographs, persistent respiratory insufficiency, and even death may occur in high-risk patients such as newborns or those with underlying lung, cardiac, or immunodeficiency disease. Patients with adenovirus infection or those concomitantly infected with RSV and second

pathogens such as influenza, adenovirus, cytomegalovirus, or *P jiroveci* also have a worse prognosis.

Klig JE: Current challenges in lower respiratory infections in children. *Curr Opin Pediatr* 2004;16:107 [PMID: 14758123].

CHLAMYDIAL PNEUMONIAS

- ▶ Cough, pharyngitis, tachypnea, rales, few wheezes, fever.
- ▶ Inclusion conjunctivitis, eosinophilia, and elevated immunoglobulins in some cases.

▶ General Considerations

Pulmonary disease due to *C trachomatis* usually evolves gradually as the infection descends the respiratory tract. Infants may appear quite well despite the presence of significant pulmonary illness. Infant infections are now at epidemic proportions in urban environments worldwide. *C pneumoniae* is now recognized as a common cause of respiratory infections in adults and children.

▶ Clinical Findings

A. Symptoms and Signs

About 50% of infants with *C trachomatis* pneumonia have active inclusion conjunctivitis or a history of it. Rhinopharyngitis with nasal discharge or otitis media may have occurred or may be currently present. Female patients may have vulvovaginitis. Cough is usually present. It can have a staccato character and resemble the cough of pertussis. The infant is usually tachypneic. Scattered inspiratory rales are commonly heard, wheezes rarely. Significant fever suggests a different or additional diagnosis.

In children *C pneumoniae* is a common respiratory pathogen and may cause 5–20% of all community-acquired pneumonias. Often these lower respiratory tract illnesses are mild or asymptomatic, although this can occasionally be a serious pathogen.

B. Laboratory Findings

Although patients may frequently be hypoxemic, carbon dioxide retention is not common. Peripheral blood eosinophilia (400 cells/ μ L) has been observed. Serum immunoglobulins are usually abnormal. IgM is virtually always elevated, IgG is high in many, and IgA is less frequently abnormal.

C trachomatis can usually be identified in nasopharyngeal washings using fluorescent antibody or culture techniques. *C pneumoniae* isolation can be difficult and the diagnosis is often made by serologic testing. These tests can be performed to confirm this diagnosis in difficult to diagnose or high-risk patients and for epidemiology or infection control.

C. Imaging

Chest radiographs may reveal diffuse interstitial and patchy alveolar infiltrates, peribronchial thickening, or focal consolidation. A small pleural reaction can be present. Despite the usual absence of wheezes, hyperexpansion is commonly present.

▶ Differential Diagnosis

Bacterial, viral, and fungal (*P jiroveci*) pneumonias should be considered. Premature infants and those with BPD may also have chlamydial pneumonia. *C pneumoniae* is often accompanied by coinfection with other pathogens, particularly *S pneumoniae* and *M pneumoniae*.

▶ Treatment

Erythromycin or sulfisoxazole therapy should be administered for 14 days. Hospitalization may be required for children with significant respiratory distress, coughing paroxysms, or posttussive apnea. Oxygen therapy may be required for prolonged periods in some patients.

▶ Prognosis

An increased incidence of obstructive airway disease and abnormal pulmonary function tests may occur for at least 7–8 years following infection.

Principi N, Esposito S: Emerging role of *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* in paediatric respiratory tract infections. *Lancet Infect Dis* 2001;1:334 [PMID: 11871806].

MYCOPLASMAL PNEUMONIA

- ▶ Fever.
- ▶ Cough.
- ▶ Most common in children older than age 5 years.

▶ General Considerations

M pneumoniae is a common cause of symptomatic pneumonia in older children although it may be seen in children younger than 5 years of age. Endemic and epidemic infection can occur. The incubation period is long (2–3 weeks), and the onset of symptoms is slow. Although the lung is the primary infection site, extrapulmonary complications sometimes occur.

▶ Clinical Findings

A. Symptoms and Signs

Fever, cough, headache, and malaise are common symptoms as the illness evolves. Although cough is usually dry at the onset, sputum production may develop as the illness progresses. Sore throat, otitis media, otitis externa, and bullous myringitis may occur. Rales are frequently present on chest examination; decreased breath sounds or dullness to percussion over the involved area may be present.

B. Laboratory Findings

The total and differential white blood cell counts are usually normal. The cold hemagglutinin titer can be determined and may be elevated during the acute presentation. A titer of 1:64 or higher supports the diagnosis. Acute and convalescent titers for *M pneumoniae* demonstrating a fourfold or greater rise in specific antibodies confirm the diagnosis. Diagnosis of mycoplasmal pneumonia by polymerase chain reaction is becoming more readily available.

C. Imaging

Chest radiographs usually demonstrate interstitial or bronchopneumonic infiltrates, frequently in the middle or lower lobes. Pleural effusions are extremely uncommon.

▶ Complications

Extrapulmonary involvement of the blood, central nervous system, skin, heart, or joints can occur. Direct Coombs-positive autoimmune hemolytic anemia, occasionally a life-threatening disorder, is the most common hematologic abnormality that can accompany *M pneumoniae* infection. Coagulation defects and thrombocytopenia can also occur. Cerebral infarction, meningoencephalitis, Guillain-Barré syndrome, cranial nerve involvement, and psychosis all have been described. A wide variety of skin rashes, including erythema multiforme and Stevens-Johnson syndrome, can occur. Myocarditis, pericarditis, and a rheumatic fever–like illness can also occur.

▶ Treatment

Antibiotic therapy with a macrolide for 7–10 days usually shortens the course of illness. Ciprofloxacin is a possible alternative. Supportive measures, including hydration, antiemetics, and bed rest, are helpful.

▶ Prognosis

In the absence of the less common extrapulmonary complications, the outlook for recovery is excellent. The extent to which *M pneumoniae* can initiate or exacerbate chronic lung disease is not well understood.

TUBERCULOSIS (SEE ALSO CHAPTER 40)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Positive tuberculin skin test or anergic host.
- ▶ Positive culture for *Mycobacterium tuberculosis*.
- ▶ Symptoms of active disease (if present): chronic cough, anorexia, weight loss or poor weight gain, fever, night sweats.

▶ General Considerations

Tuberculosis is a widespread and deadly disease resulting from infection with *M tuberculosis*. The clinical spectrum of disease includes asymptomatic primary infection, calcified nodules, pleural effusions, progressive primary cavitating lesions, contiguous spread into adjacent thoracic structures, acute miliary tuberculosis, acute respiratory distress syndrome, overwhelming reactivation infection in the immunocompromised host, occult lymphohematogenous spread, and metastatic extrapulmonary involvement at almost any site. Because transmission is usually through respiratory droplets, isolated pulmonary parenchymal tuberculosis constitutes more than 85% of presenting cases. Pulmonary tuberculosis is the focus of discussion here; additional manifestations of tuberculosis are discussed in Chapter 40.

Following a resurgence in the 1980s and early 1990s, tuberculosis has declined among all age groups in the United States, including children. This trend has continued through 2006, the most recent year for which data are available. However, the disease remains a significant cause of morbidity and mortality worldwide.

▶ Clinical Findings

A. Symptoms and Signs

Most children with tuberculosis are asymptomatic and present with a positive tuberculin skin test. Symptoms of active disease, if present, might include chronic cough, anorexia, weight loss or poor weight gain, fever, and night

sweats. Children can also present with symptoms of airway obstruction, sometimes with secondary bacterial pneumonia or airway collapse resulting from hilar adenopathy.

Because most children infected with tuberculosis are asymptomatic, a clue to infection may be contact with an individual with tuberculosis—often an elderly relative, a caregiver, or a person previously residing in a region where tuberculosis is endemic—or a history of travel to or residence in such an area. Homeless and extremely impoverished children are also at high risk, as are those in contact with high-risk adults (patients with AIDS, residents or employees of correctional institutions or nursing homes, drug users, and health care workers). Once exposed, pediatric patients at risk for developing active disease include infants and those with malnutrition, AIDS, diabetes mellitus, or immunosuppression (cancer chemotherapy or corticosteroids).

The symptoms of active disease listed previously most often occur during the first year of infection. Thereafter, infection remains quiescent until adolescence, when reactivation of pulmonary tuberculosis is common. At any stage, chronic cough, anorexia, weight loss or poor weight gain, and fever are useful clinical signs of reactivation. Of note, except in patients with complications or advanced disease, physical findings are few.

B. Tuberculin Skin Testing

A positive tuberculin skin test is defined by the size of induration as measured by a medical provider 48–72 hours after intradermal injection of 5 tuberculin units of purified protein derivative (PPD). A positive test is defined as an induration greater than or equal to 5 mm in patients who are at high risk for developing active disease (ie, immunocompromised, those with a history of a positive test or radiograph, children younger than 4 years, and those known to have close contact with someone with active disease); greater than 10 mm in patients from or exposed to high-risk populations (ie, born in countries with a high prevalence, users of injected drugs, having poor access to health care, or living in facilities such as jails, homeless shelters, or nursing homes); and greater than 15 mm in those who are at low risk. Tine tests should not be used. Appropriate control skin tests, such as those for hypersensitivity to diphtheria-tetanus, mumps, or *Candida albicans*, should be applied in patients with suspected or proven immunosuppression or in those with possible severe disseminated disease. If the patient fails to respond to PPD, the possibility of tuberculosis is not excluded.

In suspected cases, the patient, immediate family, and suspected carriers should also be tuberculin-tested. Because healing—rather than progression—is the usual course in the uncompromised host, a positive tuberculin test may be the only manifestation. The primary focus (usually single) and associated nodal involvement may not be seen radiographically. For patients born outside the United States or those who have received a previous bacillus Calmette-Guérin immunization, induration greater than 5 mm should be considered positive and further evaluated.

C. Laboratory Findings and Imaging

Anteroposterior and lateral chest radiographs should be obtained in all suspected cases. Culture for *M tuberculosis* is critical for proving the diagnosis and for defining drug susceptibility. Early morning gastric lavage following an overnight fast should be performed on three occasions in infants and children with suspected active pulmonary tuberculosis before treatment is started, when the severity of illness allows. Although stains for acid-fast bacilli on this material are of little value, this is the ideal culture site. Despite the increasing importance of isolating organisms because of multiple drug resistance, only 40% of children will yield positive cultures.

Sputum cultures from older children and adolescents can also be useful. Stains and cultures of bronchial secretions can be obtained using bronchoscopy. When pleural effusions are present, pleural biopsy for cultures and histopathologic examination for granulomas or organisms provide diagnostic information. Meningeal involvement is also possible in young children, and lumbar puncture should be considered in their initial evaluation.

▶ Differential Diagnosis

Fungal diseases that affect mainly the lungs, such as histoplasmosis, coccidioidomycosis, cryptococcosis, and North American blastomycosis, may resemble tuberculosis and in cases where the diagnosis is unclear, should be excluded by biopsy or appropriate serologic studies. Atypical tuberculous organisms may involve the lungs, especially in the immunocompromised patient. Depending on the presentation, diagnoses such as lymphoreticular and other malignancies, collagen-vascular disorders, or other pulmonary infections may be considered.

▶ Complications

In addition to those complications listed in the sections on general considerations and clinical findings, lymphadenitis, meningitis, osteomyelitis, arthritis, enteritis, peritonitis, and renal, ocular, middle ear, and cutaneous disease may occur. Infants born to parents infected with *M tuberculosis* are at great risk for developing illness. The possibility of life-threatening airway compromise must always be considered in patients with large mediastinal or hilar lesions.

▶ Treatment

Because the risk of hepatitis due to isoniazid is extremely low in children, this drug is indicated in those with a positive tuberculin skin test. This greatly reduces the risk of subsequent active disease and complications with minimal morbidity. Isoniazid plus rifampin treatment for 6 months, plus pyrazinamide during the first 2 months, is indicated when the chest radiograph is abnormal or when extrapulmonary disease is present. Without pyrazinamide, isoniazid plus

rifampin must be given for 9 months. In general, the more severe tuberculous complications are treated with a larger number of drugs (see Chapter 40). Enforced, directly observed therapy (twice or three times weekly) is indicated when nonadherence is suspected. Recommendations for antituberculosis chemotherapy based on disease stage are continuously being updated. The most current edition of the American Academy of Pediatrics *Red Book* is a reliable source for these protocols.

Corticosteroids are used to control inflammation in selected patients with potentially life-threatening airway compression by lymph nodes, acute pericardial effusion, massive pleural effusion with mediastinal shift, or miliary tuberculosis with respiratory failure.

► Prognosis

In patients with an intact immune system, modern antituberculous therapy offers good potential for recovery. The outlook for patients with immunodeficiencies, organisms resistant to multiple drugs, poor drug adherence, or advanced complications is guarded. Organisms resistant to multiple drugs are increasingly common. Resistance emerges either because the physician prescribes an inadequate regimen or because the patient discontinues medications. When resistance to or intolerance of isoniazid and rifampin prevents their use, cure rates are 50% or less.

Powell DA, Hunt WG: Tuberculosis in children: An update. *Adv Pediatr* 2006;53:279 [PMID: 17089872].

ASPIRATION PNEUMONIA

Patients whose anatomic defense mechanisms are impaired are at risk of aspiration pneumonia (Table 18–3). Acute disease is commonly caused by bacteria present in the mouth (especially gram-negative anaerobes). Chronic aspiration often causes recurrent bouts of acute febrile pneumonia. It may also lead to chronic focal infiltrates, atelectasis, an illness resembling asthma or interstitial lung disease, bronchiectasis, or failure to thrive.

► Clinical Findings

A. Symptoms and Signs

Acute onset of fever, cough, respiratory distress, or hypoxemia in a patient at risk suggests aspiration pneumonia. Chest physical findings, such as rales, rhonchi, or decreased breath sounds, may initially be limited to the lung region into which aspiration occurred. Although any region may be affected, the right side—especially the right upper lobe in the supine patient—is commonly affected. In patients with

Table 18–3. Risk factors for aspiration pneumonia.

Seizures
Depressed sensorium
Recurrent gastroesophageal reflux, emesis, or gastrointestinal obstruction
Neuromuscular disorders with suck-swallow dysfunction
Anatomic abnormalities (laryngeal cleft, tracheoesophageal fistula, vocal cord paralysis)
Debilitating illnesses
Occult brainstem lesions
Near-drowning
Nasogastric, endotracheal, or tracheostomy tubes
Severe periodontal disease

chronic aspiration, diffuse wheezing may occur. Generalized rales may also be present. Such patients may not develop acute febrile pneumonias.

B. Laboratory Findings and Imaging

Chest radiographs may reveal lobar consolidation or atelectasis and focal or generalized alveolar or interstitial infiltrates. In some patients with chronic aspiration, perihilar infiltrates with or without bilateral air trapping may be seen.

In severely ill patients with acute febrile illnesses, and especially when the pneumonia is complicated by a pleural effusion, a bacteriologic diagnosis should be made. In addition to blood cultures and cultures of the pleural fluid, cultures of tracheobronchial secretions and bronchoalveolar lavage specimens may be considered (see earlier section on Culture of Material from the Respiratory Tract).

In patients with chronic aspiration pneumonitis, documentation of aspiration as the cause of illness may be elusive. Barium contrast studies using liquids of increasing consistency may provide evidence of suck-swallow dysfunction or laryngeal cleft. Bolus barium swallow studies with good distention of the esophagus may help to identify an occult tracheoesophageal fistula. Gastroesophageal reflux may be a risk factor for aspiration while the child is sleeping, and an overnight or 24-hour esophageal pH probe studies may also help establish the diagnosis of gastroesophageal reflux. Although radionuclide scans are commonly used, the yield from such studies is disappointingly low. Rigid bronchoscopy in infants or flexible bronchoscopy in older children can be used to identify anatomic abnormalities such as tracheal cleft and tracheoesophageal fistula. Flexible bronchoscopy and bronchoalveolar lavage specimens to search for lipid-laden macrophages can also suggest chronic aspiration.

► Differential Diagnosis

In the acutely ill patient, bacterial and viral pneumonias should be considered. In the chronically ill patient, the differential diagnosis may include disorders causing recur-

rent pneumonia (eg, immunodeficiencies, ciliary dysfunction, or foreign body), chronic wheezing, or interstitial lung disorders (see next section), depending on the presentation.

► Complications

Empyema or lung abscess may complicate acute aspiration pneumonia. Chronic aspiration may also result in bronchiectasis.

► Treatment

Antimicrobial therapy for acute aspiration pneumonia includes coverage for gram-negative anaerobic organisms. In general, clindamycin is appropriate initial coverage. However, in some hospital-acquired infections, additional coverage for multiple resistant *P aeruginosa*, streptococci, and other organisms may be required.

Treatment of recurrent and chronic aspiration pneumonia may include the following: surgical correction of anatomic abnormalities; improved oral hygiene; improved hydration; and inhaled bronchodilators, chest physical therapy, and suctioning. In patients with compromise of the central nervous system, exclusive feeding by gastrostomy and (in some) tracheostomy may be required to control airway secretions. Gastroesophageal reflux, if present in these patients, also often requires surgical correction.

► Prognosis

The outlook is directly related to the disorder causing aspiration.

CHILDREN'S INTERSTITIAL LUNG DISEASE SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Occurs acutely in the neonatal period or subacutely in infancy or childhood.
- Infants and young children have different diagnoses than adolescents and adults.
- Presence of three to five of the following criteria in the absence of any identified primary etiology is suggestive of an interstitial lung disease (ILD) syndrome:
 - Symptoms of impaired respiratory function (cough, tachypnea, retractions, exercise intolerance).

- Evidence of impaired gas exchange (resting hypoxemia or hypercarbia, desaturation with exercise).
 - Diffuse infiltrates on imaging.
 - Presence of adventitious sounds (crackles, wheezing).
 - Abnormal spirometry, lung volumes, or carbon monoxide diffusing capacity.
- History of exposure (eg, birds, organic dusts, drug therapy, hot tubs, molds), previous lung disease, immunosuppression, symptoms of connective tissue disease; family history of familial lung disease (especially ILD) or early infant death from lung disease.

► General Considerations

Children's Interstitial Lung Disease (chILD) syndrome is a constellation of signs and symptoms and not a specific diagnosis. Once recognized, chILD syndrome should elicit a search for a more specific rare ILD. Known disorders can present as chILD syndrome and must be excluded as the primary cause of symptoms. These disorders include CF, cardiac disease, asthma, acute infection, immunodeficiency, neuromuscular disease, scoliosis, thoracic cage abnormality, typical BPD or premature respiratory distress syndrome, and confirmed significant aspiration on a swallow study. However, if patients present with symptoms out of proportion to the diagnosis, consideration should be given to other ILD disorders.

► Clinical Findings

A. Symptoms and Signs

chILD syndrome may present acutely in the newborn period with respiratory failure or gradually over time with a chronic dry cough or a history of dyspnea on exertion. The child with more advanced disease may have increased dyspnea, tachypnea, retractions, cyanosis, clubbing, failure to thrive, or weight loss.

B. Diagnostic Studies

Once chILD syndrome is recognized, initial evaluations should be directed at ruling out known conditions. The initial evaluations should include the following diagnostic studies: radiographs, barium swallow, pulmonary function tests, and skin tests (see earlier section on Tuberculosis); complete blood count and erythrocyte sedimentation rate; sweat chloride test for CF; electrocardiogram or echocardiogram; serum immunoglobulins and other immunologic evaluations; sputum studies (see later section on Pneumonia in the Immunocompromised Host); and possibly studies for Epstein-Barr virus, cytomegalovirus, *M pneumoniae*, *Chlamydia*, *Pneumocystis*, and *Ureaplasma urealyticum*.

Chest radiographs are normal in up to 10–15% of patients. Frequently, specific chILD disorders can be sus-

pected by findings on controlled volume inspiratory and expiratory high-resolution CT, which should be considered early in the course of evaluation. Infants and children younger than age 5 years require sedation, which allows either infant pulmonary function testing or bronchoscopy evaluations to be completed at the same time.

On pulmonary function testing, multiple patterns can be seen depending on the specific ILD condition such as (1) a restrictive pattern of decreased lung volumes, compliance, and carbon monoxide diffusing capacity, (2) an obstructive pattern with hyperinflation, or (3) a mixed obstructive-restrictive pattern. Infant pulmonary function testing can provide insight into pulmonary mechanics and different chILD disorders. Exercise-induced or nocturnal hypoxemia is often the earliest detectable abnormality of lung function in children.

During the second evaluation phase, bronchoscopy is performed to exclude anatomic abnormalities, obtain multiple bronchial brushings to examine cilia if ciliary dysfunction is considered a possibility, and obtain bronchoalveolar lavage for microbiologic and cytologic testing.

In patients with static or slowly progressing disease, one can then await results of bronchoscopic studies. In patients with acute, rapidly progressive disease, this stage should be combined with video-assisted thoracoscopic biopsy. Lung biopsy is the most reliable method for definitive diagnosis when analyzed by pathologists experienced in chILD disorders. A new chILD histology classification has been proposed to improve diagnostic yields. Tissue should be processed in a standard manner for special stains and cultures, electron microscopy, and immunofluorescence for immune complexes if indicated. Although transbronchial biopsy may be useful in diagnosing a few diffuse disorders and graft rejection in transplantation (eg, sarcoidosis), its overall usefulness in chILD is limited at this time.

C. Genetic Testing

Genomic mutational analysis of tissue or blood for surfactant proteins B and C (SP-B, SP-C) and *ABCA3* is now offered in clinical laboratories and should be considered in most patients with diffuse lung disease or a strong family history of ILD.

► Differential Diagnosis

chILD syndrome is composed of a group of diverse conditions that can differ from adult ILD conditions. Common adult causes of ILD such as UIP (usual interstitial pneumonitis, also known as idiopathic pulmonary fibrosis), which is associated with a high mortality rate, and respiratory bronchiolitis, associated with smoking, have not been found in children. Conversely, newly identified conditions unique to infancy such as neuroendocrine cell hyperplasia of infancy (NEHI) or pulmonary interstitial glycogenosis (PIG), have not been described in adults. Other chILD conditions

include the genetically recognized surfactant dysfunction mutations SP-B, SP-C, and *ABCA3*; developmental abnormalities; and growth disorders, especially in younger children. Older children are more likely to have SP-C or *ABCA3* surfactant mutations, hypersensitivity pneumonitis, or collagen-vascular disease. Other known conditions must also be ruled out.

► Complications

Respiratory failure or pulmonary hypertension with cor pulmonale may occur. Mortality and morbidity can be significant in some chILD disorders.

► Treatment

Therapy for known causes of ILD such as infection, aspiration, or cardiac disorders should be directed toward the primary disorder. It must be recognized that treatment for chILD conditions is anecdotal and based on case reports and small case series. In noninflammatory chILD syndrome conditions such as neuroendocrine cell hyperplasia of infancy or developmental or growth abnormalities, treatment is supportive and may not require corticosteroids. For chILD conditions such as surfactant dysfunction mutations, pulmonary interstitial glycogenosis, hypersensitivity pneumonitis, and systemic collagen-vascular disease, patients are frequently treated initially with oral (2 mg/kg/d for 6 weeks) or monthly pulse glucocorticoids (IV doses of 10–30 mg/kg for 1–3 days). Many patients require even more protracted therapy with alternate-day prednisone. Chloroquine (5–10 mg/kg/d) may be useful in selected disorders such as desquamative interstitial pneumonitis, surfactant dysfunction mutations, or refractory disease. In refractory cases, azathioprine and cyclophosphamide may be tried. Newer antifibrotic agents such as interferon- γ , which are being investigated in adult patients with interstitial pulmonary fibrosis, have not been tried in children to date. Finally, some patients with severe disease may require long-term mechanical ventilation or lung transplantation for survival. chILD disorders should be evaluated and cared for by a multidisciplinary team experienced in chILD. The chILD Family Foundation can provide further supportive resources for families (<http://www.childfoundation.us>).

► Prognosis

The prognosis is guarded in children with ILD due to collagen-vascular disease, surfactant dysfunction mutations, and developmental disorders (eg, alveolar-capillary dysplasia). Other conditions such as neuroendocrine cell hyperplasia of infancy and pulmonary interstitial glycogenosis have not had deaths reported.

HYPERSENSITIVITY PNEUMONIA

► General Considerations

Hypersensitivity pneumonitis, or extrinsic allergic alveolitis, is a T-cell–mediated disease involving the peripheral airways, interstitium, and alveoli and presents as chILD. Both acute and chronic forms may occur. In children, the most common forms are brought on by exposure to domestic and occasionally wild birds or bird droppings (eg, pigeons, parakeets, parrots, or doves). However, inhalation of almost any organic dust (moldy hay, compost, logs or tree bark, sawdust, or aerosols from humidifiers or hot tubs) can cause disease. Methotrexate-induced hypersensitivity has also been described in a child with juvenile rheumatoid arthritis. Hot tub lung can be caused by exposure to aerosolized *Mycobacterium avium* complex. A high level of suspicion and a thorough history are required for diagnosis.

► Clinical Findings

A. Symptoms and Signs

Episodic cough and fever can occur with acute exposures. Chronic exposure results in weight loss, fatigue, dyspnea, cyanosis, and ultimately, respiratory failure.

B. Laboratory Findings

Acute exposure may be followed by polymorphonuclear leukocytosis with eosinophilia and evidence of airway obstruction on pulmonary function testing. Chronic disease results in a restrictive picture on lung function tests. Arterial blood gases may reveal hypoxemia with a decreased PaCO₂ and normal pH.

The serologic key to diagnosis is the finding of precipitins (precipitating IgG antibodies) to the organic material that contain avian proteins or fungal or bacterial antigens. Ideally, to identify avian proteins, the patient's sera should be tested with antigens from droppings of the suspected species of bird. However, exposure may invoke precipitins without causing disease.

Bronchoscopy with bronchoalveolar lavage findings of lymphocytosis or *M avium* complex may be suggestive. Normal cell counts may help rule out acute hypersensitivity pneumonitis.

► Differential Diagnosis

Patients with mainly acute symptoms must be differentiated from those with atopic asthma. Patients with chronic symp-

toms must be distinguished from those with collagen-vascular, immunologic, or primary interstitial pulmonary disorders.

► Complications

Prolonged exposure to offending antigens may result in pulmonary hypertension due to chronic hypoxemia, cor pulmonale, irreversible restrictive lung disease due to pulmonary fibrosis, or respiratory failure.

► Treatment & Prognosis

Complete elimination of exposure to the offending antigens is required. If drug-induced hypersensitivity pneumonitis is suspected, discontinuation is required. Corticosteroids may hasten recovery. With appropriate early diagnosis and identification and avoidance of offending antigens, the prognosis is excellent.

Stauffer EM: Bird breeder's disease: A rare diagnosis in young children. *Eur J Pediatr* 2006;165:55 [PMID: 16270199].

EOSINOPHILIC PNEUMONIA

► General Considerations

Eosinophilic pneumonia is another rare condition that can be considered under the heading of chILD syndrome. A spectrum of diseases should be considered under this heading: (1) allergic bronchopulmonary helminthiasis (ABPH), (2) pulmonary eosinophilia with asthma (allergic bronchopulmonary aspergillosis and related disorders), (3) hyper-eosinophilic mucoid impaction, (4) bronchocentric granulomatosis, and (5) collagen-vascular disorders. The former term, *Löffler syndrome* (transient migratory pulmonary infiltrates and eosinophilia), is no longer used because most patients had undiagnosed ABPH, medication reactions (see <http://www.pneumotox.com>), or allergic bronchopulmonary aspergillosis. Many of these disorders occur in children with personal or family histories of allergies or asthma. ABPH may be related to hypersensitivity to migratory parasitic nematodes (*Ascaris*, *Strongyloides*, *Ancylostoma*, *Toxocara*, or *Trichuris*) and larval forms of filariae (*Wuchereria bancrofti*). Allergic bronchopulmonary aspergillosis is related to hypersensitivity to the fungus *Aspergillus*. Hypersensitivity to other fungi has also been documented. Eosinophilic pneumonias are rare but can be associated with drug hypersensitivity, sarcoidosis, Hodgkin disease or other lymphomas, and bacterial infections, including brucellosis and those caused by *M tuberculosis* and atypical mycobacteria.

► Clinical Findings

A. Symptoms and Signs

Cough, wheezing, and dyspnea are common presenting complaints. In allergic bronchopulmonary helminthiasis, fever, malaise, sputum production, and rarely hemoptysis may be present. In allergic bronchopulmonary aspergillosis, patients may present with all of these findings and occasionally produce brown mucus plugs. Anorexia, weight loss, night sweats, and clubbing can also occur.

B. Laboratory Findings and Imaging

Elevated absolute peripheral blood eosinophil counts (3000/ μ L and often exceeding 50% of leukocytes) are present in ABPH and allergic bronchopulmonary aspergillosis. Serum IgE levels as high as 1000–10,000 IU/mL are common. In allergic bronchopulmonary aspergillosis, the serum IgE concentration appears to correlate with activity of the disease. Stools should be examined for ova and parasites—often several times—to clarify the diagnosis. Isohemagglutinin titers are often markedly elevated in ABPH.

In allergic bronchopulmonary aspergillosis and related disorders, patients may show central bronchiectasis on chest radiograph (so-called tramlines) or CT scan. Saccular proximal bronchiectasis of the upper lobes is pathognomonic. Although the chest radiograph may be normal, peribronchial haziness, focal or platelike atelectasis, or patchy to massive consolidation can occur. Positive immediate skin tests, serum IgG precipitating antibodies, or IgE specific for the offending fungus is present.

► Differential Diagnosis

These disorders must be differentiated from exacerbations of asthma, CF, or other underlying lung disorders that cause infiltrates to appear on chest radiographs. Allergic bronchopulmonary aspergillosis can occur in patients with CF.

► Complications

Delayed recognition and treatment of allergic bronchopulmonary aspergillosis may cause progressive lung damage and bronchiectasis. Lesions of the conducting airways in bronchocentric granulomatosis can extend into adjacent lung parenchyma and pulmonary arteries, resulting in secondary vasculitis.

► Treatment

Therapy for the specific parasite causing ABPH should be given, and corticosteroids may be required when illness is severe. Treatment of disease due to microfilariae is both diagnostic and therapeutic. Allergic bronchopulmonary aspergillosis and related disorders are treated with prolonged courses of oral corticosteroids, bronchodilators, and chest physical therapy. In patients with CF, itraconazole may

decrease corticosteroid doses for those with allergic bronchopulmonary aspergillosis. Pulmonary vasculitis associated with collagen-vascular disease is usually treated with high-dose steroids or cytotoxic agents.

PNEUMONIA IN THE IMMUNOCOMPROMISED HOST

► General Considerations

Immunocompromised children can present with focal pneumonia or ILD. Pneumonia in an immunocompromised host may be due to any common bacteria (streptococci, staphylococci, or *M pneumoniae*) or less common pathogens such as *Toxoplasma gondii*, *P jiroveci*, *Aspergillus* species, *Mucor*, *Candida* species, *Cryptococcus neoformans*, gram-negative enteric and anaerobic bacteria, *Nocardia*, *Legionella pneumophila*, mycobacteria, and viruses (cytomegalovirus, varicella-zoster, herpes simplex, influenza virus, RSV, human metapneumovirus, or adenovirus). Multiple organisms are commonly present.

► Clinical Findings

A. Symptoms and Signs

Patients often present with subtle signs such as mild cough, tachypnea, or low-grade fever that can rapidly progress to high fever, respiratory distress, and hypoxemia or cILD syndrome. An obvious portal of infection, such as an intravascular catheter, may predispose to bacterial or fungal infection.

B. Laboratory Findings and Imaging

Fungal, parasitic, or bacterial infection, especially with antibiotic-resistant bacteria, should be suspected in the neutropenic child. Cultures of peripheral blood, sputum, tracheobronchial secretions, urine, nasopharynx or sinuses, bone marrow, pleural fluid, biopsied lymph nodes, or skin lesions or cultures through intravascular catheters should be obtained as soon as infection is suspected.

Invasive methods are commonly required to make a diagnosis. Appropriate samples should be obtained soon after a patient with pneumonia fails to respond to initial treatment. The results of these procedures usually lead to important changes in empiric preoperative therapy. Sputum is often unavailable. Bronchoalveolar lavage frequently provides the diagnosis of one or more organisms and should be done early in evaluation. The combined use of a wash, brushing, and lavage has a high yield. In patients with rapidly

advancing disease, lung biopsy becomes more urgent. The morbidity and mortality of this procedure can be reduced by a surgeon skilled in video-assisted thoracoscopic surgical (VATS) techniques. Because of the multiplicity of organisms that may cause disease, a comprehensive set of studies should be done on lavage and biopsy material. These consist of rapid diagnostic studies, including fluorescent antibody studies for *Legionella*; rapid culture and antigen detection for viruses; Gram, acid-fast, and fungal stains; cytologic examination for viral inclusions; cultures for viruses, anaerobic and aerobic bacteria, fungi, mycobacteria, and *Legionella*; and rapid immunofluorescent studies for *P jiroveci*.

Chest radiographs and increasingly high-resolution CT scans may be useful in identifying the pattern and extent of disease. In *P jiroveci* pneumonia, dyspnea and hypoxemia may be marked despite minimal radiographic abnormalities.

► Differential Diagnosis

The organisms causing disease vary with the type of immunocompromise present. For example, the splenectomized patient may be overwhelmed by infection with *S pneumoniae* or *H influenzae*. The infant receiving adrenocorticotropic hormone therapy may be more likely to have *P jiroveci* infection. The febrile neutropenic child who has been receiving adequate doses of intravenous broad-spectrum antibiotics may have fungal disease. The key to diagnosis is to consider all possibilities of infection.

Depending on the form of immunocompromise, perhaps only half to two thirds of new pulmonary infiltrates in such patients represents infection. The remainder are caused by pulmonary toxicity of radiation, chemotherapy, or other drugs; pulmonary disorders, including hemorrhage, embolism, atelectasis, aspiration, idiopathic pneumonia syndrome in bone marrow transplant patients, or acute respiratory distress syndrome; recurrence or extension of primary malignant growths or immunologic disorders; transfusion reactions, leukostasis, or tumor cell lysis; or interstitial lung disease, such as lymphocytic interstitial pneumonitis with HIV infection.

► Complications

Progressive respiratory failure, shock, multiple organ damage, disseminated infection, and death commonly occur in the infected immunocompromised host if the primary etiology is not treated effectively.

► Treatment

Broad-spectrum intravenous antibiotics are indicated early in febrile, neutropenic, or immunocompromised children. Trimethoprim-sulfamethoxazole (for *Pneumocystis*) and macrolides (for *Legionella*) are also indicated early in the treatment of immunocompromised children before an organism is identified. Further therapy should be based on studies of specimens obtained from bronchoalveolar lavage

or lung biopsy. Recent data suggest that use of noninvasive ventilation strategies early in the course of pulmonary insufficiency or respiratory failure may decrease mortality.

► Prognosis

Prognosis is based on the severity of the underlying immunocompromise, appropriate early diagnosis and treatment, and the infecting organisms. Intubation and mechanical ventilation have been associated with high mortality rates, especially in bone marrow transplant patients.

Haug L et al: An Official ATS Workshop Summary: Recent advances and future directions in *Pneumocystis pneumonia* (PCP). *Proc Am Thorac Soc* 2006;3:655 [PMID: 17065370].

LUNG ABSCESS

► General Considerations

Lung abscesses are most likely to occur in immunocompromised patients; in those with severe infections elsewhere (embolic spread); or in those with recurrent aspiration, malnutrition, or blunt chest trauma. Although organisms such as *S aureus*, *H influenzae*, *S pneumoniae*, and viridans streptococci more commonly affect the previously normal host, anaerobic and gram-negative organisms as well as *Nocardia*, *Legionella* species, and fungi (*Candida* and *Aspergillus*) should also be considered in the immunocompromised host.

► Clinical Findings

A. Symptoms and Signs

High fever, malaise, and weight loss are often present. Symptoms and signs referable to the chest may or may not be present. In infants, evidence of respiratory distress can be present.

B. Laboratory Findings and Imaging

Elevated peripheral white blood cell count with a neutrophil predominance or an elevated erythrocyte sedimentation rate may be present. Blood cultures are rarely positive except in the overwhelmed host.

Chest radiographs usually reveal single or multiple thick-walled lung cavities. Air-fluid levels can be present. Local compressive atelectasis, pleural thickening, or adenopathy may also occur. Chest CT scan may provide better localization and understanding of the lesions.

In patients producing sputum, stains and cultures may provide the diagnosis. Direct percutaneous aspiration of material for stains and cultures guided by fluoroscopy or ultrasonography should be considered in the severely compromised or ill.

► Differential Diagnosis

Loculated pyopneumothorax, an *Echinococcus* cyst, neoplasms, plasma cell granuloma, and infected congenital cysts and sequestrations should be considered. Pneumatoceles, non-fluid-filled cysts, are common in children with emphysema and usually resolve over time.

► Complications

Although complications due to abscesses are now rare, mediastinal shift, tension pneumothorax, and spontaneous rupture can occur. Diagnostic maneuvers such as lung puncture may also cause complications (pneumothorax).

► Treatment

Because of the risks of lung puncture, uncomplicated abscesses are frequently conservatively treated in the uncompromised host with appropriate broad-spectrum antibiotics directed at *S aureus*, *H influenzae*, and streptococci. Additional coverage for anaerobic and gram-negative organisms should be provided for others. Prolonged therapy (3 weeks or more) may be required. Attempts to drain abscesses via bronchoscopy have caused life-threatening airway compromise. Surgical drainage or lobectomy is occasionally required, primarily in immunocompromised patients. However, such procedures may themselves cause life-threatening complications.

► Prognosis

Although radiographic resolution may be very slow, resolution occurs in most patients without risk factors for lower respiratory tract infections or loss of pulmonary function. In the immunocompromised host, the outlook depends on the underlying disorder.

Chan PC et al: Clinical management and outcome of childhood lung abscess: A 16-year experience. *J Microbiol Immunol Infect* 2005;38:183 [PMID: 15986068].

DISEASES OF THE PULMONARY CIRCULATION

PULMONARY HEMORRHAGE

► General Considerations

Pulmonary hemorrhage is caused by a spectrum of disorders affecting the large and small airways and alveoli. It can occur as an acute or chronic process. Hemorrhage involving the alveoli is termed diffuse alveolar hemorrhage. If pulmonary hemorrhage is subacute or chronic, hemosiderin-laden macrophages are found in the sputum and tracheal or gastric

aspirate. Many cases are secondary to infection (bacterial, mycobacterial, parasitic, viral, or fungal), lung abscess, bronchiectasis (CF or other causes), foreign body, coagulopathy (often with overwhelming sepsis), or elevated pulmonary venous pressure (secondary to congestive heart failure or anatomic heart lesions). Other causes include lung contusion from trauma, arteriovenous fistula, multiple telangiectasias, pulmonary sequestration, agenesis of a single pulmonary artery, and esophageal duplication or bronchogenic cyst. Rarer causes are tumors (eg, bronchial adenoma or left atrial myxoma) and pulmonary infarction secondary to pulmonary embolus.

Diffuse alveolar hemorrhage may be idiopathic or drug-related or may occur in Goodpasture syndrome, rapidly progressive glomerulonephritis, and systemic vasculitides (often associated with such collagen-vascular diseases as systemic lupus erythematosus, rheumatoid arthritis, Wegener granulomatosis, polyarteritis nodosa, Henoch-Schönlein purpura, and Behçet's disease). Idiopathic pulmonary hemosiderosis refers to the accumulation of hemosiderin in the lung, especially the alveolar macrophage, as a result of chronic or recurrent hemorrhage (usually from pulmonary capillaries) that is not associated with the previously listed causes. Children and young adults are mainly affected, with the age at onset ranging from 6 months to 20 years. This group of disorders includes milk allergy in young infants (Heiner syndrome).

Several cases of pulmonary hemorrhage and pulmonary hemosiderosis have been reported in infants exposed to a toxigenic mold, *Stachybotrys chartarum*, and other fungi. This association was initially noted in Cleveland, Ohio. The infants were primarily African American, living in older homes, and often the homes had recent water damage. Environmental tobacco smoke was also frequently present in the environment. Other forms of hypersensitivity pneumonitis have also been reported to cause pulmonary bleeding.

► Clinical Findings

A. Symptoms and Signs

Pulmonary hemorrhage has as many symptoms as it has causes. Large airway hemorrhage presents with hemoptysis and symptoms of the underlying cause, such as infection, foreign body, or bronchiectasis in CF. Hemoptysis from larger airways is often bright red or contains clots. Idiopathic pulmonary hemosiderosis usually presents with nonspecific respiratory symptoms (cough, tachypnea, and retractions) with or without hemoptysis, poor growth, and fatigue. Some children or young adults may present with massive hemoptysis, marked respiratory distress, stridor, or a pneumonia-like syndrome. Fever, abdominal pain, digital clubbing, and chest pain may be reported. Jaundice and hepatosplenomegaly may be present with chronic bleeding. Physical examination often reveals decreased breath sounds, rales, rhonchi, or wheezing.

B. Laboratory Findings and Imaging

Laboratory studies vary depending on the cause of hemorrhage. Following long-standing idiopathic pulmonary hemorrhage, iron deficiency anemia and heme-positive sputum are present. Nonspecific findings may include lymphocytosis and an elevated erythrocyte sedimentation rate. Peripheral eosinophilia is present in up to 25% of patients. Chest radiographs demonstrate a range of findings, from transient perihilar infiltrates to large, fluffy alveolar infiltrates with or without atelectasis and mediastinal adenopathy. Pulmonary function testing generally reveals restrictive impairment, with low lung volumes, poor compliance, and an increased diffusion capacity. Hemosiderin-laden macrophages are found in bronchial or gastric aspirates. The diagnostic usefulness of lung biopsy is controversial.

Diffuse alveolar hemorrhage with underlying systemic disease such as systemic lupus erythematosus, Wegener granulomatosis, and occasionally Goodpasture syndrome can occur with the histologic entity known as necrotizing pulmonary capillaritis. On lung biopsy the alveolar septa are infiltrated with neutrophils, and alveolar hemorrhage is acute or chronic. The septa can fill with edema or fibrinoid necrosis. Idiopathic pulmonary hemosiderosis may represent a mild form of capillaritis associated with alveolar hemorrhage. It might represent a process that waxes and wanes, and capillaritis may be focal or mild. Likewise, an immune-mediated process may cause idiopathic pulmonary hemosiderosis, although no serologic marker has yet been identified. Although capillaritis has been described without evidence of underlying systemic disease, the search for collagen-vascular disease, vasculitis, or pulmonary fibrosis should be exhaustive.

The investigation should include serologic studies such as circulating antineutrophilic cytoplasmic autoantibodies for Wegener granulomatosis, perinuclear antineutrophilic cytoplasmic autoantibodies for microscopic polyangiitis, antinuclear antibodies for systemic lupus erythematosus, and anti-basement membrane antibodies for Goodpasture syndrome. α_1 -Antitrypsin deficiency has been associated with vasculitides and should be considered.

Suspected cases of cow's milk-induced pulmonary hemosiderosis can be confirmed by laboratory findings that include high titers of serum precipitins to multiple constituents of cow's milk and positive intradermal skin tests to various cow's milk proteins. Improvement after an empiric trial of a diet free of cow's milk also supports the diagnosis.

► Differential Diagnosis

The search for the site of respiratory bleeding, underlying systemic illness, and cardiac or vascular abnormalities will help define the diagnosis. When gross hemoptysis is present, large airway bronchiectasis, epistaxis, foreign body, and arteriovenous or pulmonary malformations should be ruled out. MRI or CT-assisted angiography can localize abnormal or systemic arterial flow.

Alveolar bleeding with hemoptysis is often frothy and pink. The differential diagnosis includes the disorders causing diffuse alveolar hemorrhage listed earlier. In contrast to idiopathic pulmonary hemosiderosis, Goodpasture syndrome occurs in a slightly older age group (15–35 years), tends to have a more aggressive pulmonary course, and has renal involvement (crescentic proliferative glomerulonephritis and circulating antiglomerular basement membrane antibody). Wegener granulomatosis also has renal involvement (granulomatous glomerulitis with necrotizing vasculitis, but renal biopsy findings may be nonspecific) and other systemic manifestations, especially with upper and lower respiratory tract inflammation. Upper tract involvement includes sinusitis, rhinitis, recurrent epistaxis, otitis media, saddle-nose deformity, and subglottic stenosis. Wegener granulomatosis may occur without renal involvement early in the course of the disease. The diagnosis can be made based on biopsy findings or an elevated circulating antineutrophilic cytoplasmic autoantibody titer.

► Treatment

Therapy should be aimed at direct treatment of the underlying disease. Supportive measures, including iron therapy, supplemental oxygen, and blood transfusions, may be needed. A diet free of cow's milk should be tried in infants. Systemic corticosteroids have been used for various causes of diffuse alveolar hemorrhage and have been particularly successful in those secondary to collagen-vascular disorders and vasculitis. Case reports have been published describing the variable effectiveness of steroids, chloroquine, cyclophosphamide, and azathioprine for idiopathic pulmonary hemosiderosis.

► Prognosis

The outcome of idiopathic pulmonary hemosiderosis is variable, characterized by a waxing and waning course of intermittent intrapulmonary bleeds and the gradual development of pulmonary fibrosis over time. The severity of the underlying renal disease contributes to the mortality rates associated with Goodpasture syndrome and Wegener granulomatosis. Diffuse alveolar hemorrhage is considered a lethal pulmonary complication of systemic lupus erythematosus.

PULMONARY EMBOLISM

► General Considerations

Although pulmonary embolism is apparently rare in children, the incidence is probably underestimated because it is often not considered in the differential diagnosis of respiratory distress. It occurs most commonly in children with sickle cell anemia as part of the acute chest syndrome and with rheumatic fever, infective endocarditis, schistosomiasis, bone fracture, dehydration, polycythemia, nephrotic syndrome, atrial fibrillation, and other conditions. A recent report suggests that a majority of children with pulmonary emboli referred for hematology evaluation have coagulation regulatory protein abnormalities and antiphospholipid antibodies. Emboli may be single or multiple, large or small, with clinical signs and symptoms dependent on the severity of pulmonary vascular obstruction.

► Clinical Findings

A. Symptoms and Signs

Pulmonary embolism usually presents clinically as an acute onset of dyspnea and tachypnea. Heart palpitations or a sense of impending doom may be reported.

Pleuritic chest pain and hemoptysis may be present (not common), along with splinting, cyanosis, and tachycardia. Massive emboli may be present with syncope and cardiac arrhythmias. Physical examination is usually normal (except for tachycardia and tachypnea) unless the embolism is associated with an underlying disorder. Mild hypoxemia, rales, focal wheezing, or a pleural friction rub may be found.

B. Laboratory Findings and Imaging

Radiographic findings may be normal, but a peripheral infiltrate, small pleural effusion, or elevated hemidiaphragm can be present. If the emboli are massive, differential blood flow and pulmonary artery enlargement may be appreciated. The electrocardiogram is usually normal unless the pulmonary embolus is massive. Echocardiography is useful in detecting the presence of a large proximal embolus. A negative D-dimer has a more than 95% negative predictive value for an embolus. Ventilation-perfusion scans show localized areas of ventilation without perfusion.

Spiral CT with contrast may be helpful, but pulmonary angiography is the gold standard. Further evaluation may include Doppler ultrasound studies of the legs to search for

deep venous thrombosis. Coagulation studies, including assessments of antithrombin III and protein C or S deficiencies or defective fibrinolysis may be indicated. Antiphospholipid antibodies and other coagulation regulatory proteins (proteins C and S, and factor V Leiden) should be checked, as abnormalities have been demonstrated in 70% of the hematology referrals in one pediatric institution.

► Treatment

Acute treatment includes supplemental oxygen, sedation, and anticoagulation. Current recommendations include heparin administration to maintain an activated partial thromboplastin time that is 1.5 or more times the control value for the first 24 hours. Urokinase (2000–4000 units/kg for 36 hours) can be used to help dissolve the embolus. Tissue plasminogen activator is another option via central or peripheral administration. These therapies should be followed by warfarin therapy for at least 6 weeks with an international normalized ratio (INR) greater than 2. In patients with identifiable deep venous thrombosis of the lower extremities and significant pulmonary emboli (with hemodynamic compromise despite anticoagulation), inferior vena caval interruption may be necessary. However, long-term prospective data regarding this latter therapy are lacking.

PULMONARY EDEMA

► General Considerations

Pulmonary edema is excessive accumulation of extravascular fluid in the lung. This occurs when fluid is filtered into the lungs faster than it can be removed, leading to changes in lung mechanics such as decreased lung compliance, worsening hypoxemia from ventilation-perfusion mismatch, bronchial compression, and if advanced, decreased surfactant function. There are two basic types of pulmonary edema: increased pressure (cardiogenic or hydrostatic) and increased permeability (noncardiogenic or primary). Hydrostatic pulmonary edema is usually due to excessive increases in pulmonary venous pressure, which is most commonly due to congestive heart failure from multiple causes. In contrast, many lung diseases, especially acute respiratory distress syndrome, are characterized by the development of pulmonary

edema secondary to changes in permeability due to injury to the alveolocapillary barrier. In these settings, pulmonary edema occurs independently of the elevations of pulmonary venous pressure.

► Clinical Findings

A. Symptoms and Signs

Cyanosis, tachypnea, tachycardia, and respiratory distress are commonly present. Physical findings include rales, diminished breath sounds, and (in young infants) expiratory wheezing. More severe disease is characterized by progressive respiratory distress with marked retractions, dyspnea, and severe hypoxemia.

B. Imaging

Chest radiographic findings depend on the cause of the edema. Pulmonary vessels are prominent, often with diffuse interstitial or alveolar infiltrates. Heart size is usually normal in permeability edema but enlarged in hydrostatic edema.

► Treatment

Although specific therapy depends on the underlying cause, supplemental oxygen therapy is indicated and, if needed, ventilator support for respiratory failure. Diuretics, digoxin, and vasodilators may be indicated for congestive heart failure along with restriction of salt and water. Recommended interventions for permeability edema are reduction of vascular volume and maintenance of the lowest central venous or pulmonary arterial wedge pressure possible without sacrificing cardiac output or causing hypotension (see following discussion). β -Adrenergic agonists such as terbutaline have been shown to increase alveolar clearance of lung water, perhaps through the action of a sodium-potassium channel pump. Maintaining normal albumin levels and a hematocrit concentration above 30 maintains the filtration of lung liquid toward the capillaries, avoiding low oncotic pressure.

CONGENITAL PULMONARY LYMPHANGIECTASIA

► General Considerations

Structurally, congenital pulmonary lymphangiectasia appears as dilated subpleural and interlobular lymphatic channels and may present as part of a generalized lymphangiectasis (in association with obstructive cardiovascular lesions—

especially total anomalous pulmonary venous return) or as an isolated idiopathic lesion. Pathologically, the lung appears firm, bulky, and noncompressible, with prominent cystic lymphatics visible beneath the pleura. On cut section, dilated lymphatics are present near the hilum, along interlobular septa, around bronchovascular bundles, and beneath the pleura. Histologically, dilated lymphatics have a thin endothelial cell lining overlying a delicate network of elastin and collagen.

► Clinical Findings

Congenital pulmonary lymphangiectasia is a rare, usually fatal disease that generally presents as acute or persistent respiratory distress at birth. Although most patients do not survive the newborn period, some survive longer, and there are isolated case reports of its diagnosis later in childhood. It may be associated with features of Noonan syndrome, asplenia, total anomalous pulmonary venous return, septal defects, atrioventricular canal, hypoplastic left heart, aortic arch malformations, and renal malformations. Chylothorax has been reported. Chest radiographic findings include a ground-glass appearance, prominent interstitial markings suggesting lymphatic distention, diffuse hyperlucency of the pulmonary parenchyma, and hyperinflation with depression of the diaphragm.

► Prognosis

Although the onset of symptoms may be delayed for as long as the first few months of life, prolonged survival is extremely rare. Most deaths occur within weeks after birth. Rapid diagnosis is essential in order to expedite the option of pulmonary transplantation.

Huber A et al: Congenital pulmonary lymphangiectasia. *Pediatr Pulmonol* 1991;10:310 [PMID: 1896243].

DISORDERS OF THE CHEST WALL

EVENTRATION OF THE DIAPHRAGM

Eventration of the diaphragm occurs when striated muscle is replaced with connective tissue and is demonstrated on radiograph by elevation of part or all of the diaphragm. There are two types: congenital and acquired. The congenital type is thought to represent incomplete formation of the diaphragm in utero. The acquired type is related to atrophy of diaphragm muscles secondary to prenatal or postnatal phrenic nerve injury. The differential diagnosis of eventration includes phrenic nerve injury and partial diaphragmatic hernia. Small eventrations may be an incidental finding on a chest radiograph, commonly seen on the right side. Ultrasound provides useful information to further define a suspected eventration. When defects are small, there is no

paradoxical movement of the diaphragm and little symptomatology. When defects are large, paradoxical movement of the diaphragm may be present. The degree of respiratory distress depends in large part on the amount of paradoxical motion of the diaphragm. When the diaphragm moves upward during inspiration, instability of the inferior border of the chest wall increases the work of breathing and can lead to respiratory muscle fatigue and potential failure when stressed. Symptoms include persistent increased work of breathing, particularly with feeding or failure to extubate.

Treatment is based on severity of symptoms. If symptoms persist for 2–4 weeks, the diaphragm is surgically plicated, which stabilizes it. Function returns to the diaphragm in about 50% of cases of phrenic nerve injury whether or not plication was performed. Recovery periods of up to 100 days have been reported in these cases.

Eren S et al: Congenital diaphragmatic eventration as a cause of anterior mediastinal mass in children: Imaging modalities and literature review. *Eur J Radiol* 2004;51:85 [PMID: 15186890].

SCOLIOSIS

Scoliosis is defined as lateral curvature of the spine and is commonly categorized as idiopathic, congenital, or neuromuscular. No pulmonary impairment is typically seen with a Cobb angle showing thoracic curvature of less than 35 degrees. Most cases of idiopathic scoliosis occur in adolescent girls and are corrected before significant pulmonary impairment occurs. Congenital scoliosis of severe degree or with other major abnormalities carries a more guarded prognosis. Patients with progressive neuromuscular disease, such as Duchenne muscular dystrophy, can be at risk for respiratory failure due to severe scoliosis. Severe scoliosis can also lead to impaired lung function and possible death from cor pulmonale if uncorrected. (See also Chapter 24.)

Kearon C et al: Factors determining pulmonary function in adolescent idiopathic thoracic scoliosis. *Am Rev Respir Dis* 1993;148:288 [PMID: 8342890].

PECTUS EXCAVATUM

Pectus excavatum is anterior depression of the chest wall that may be symmetrical or asymmetrical with respect to the midline. Its presence can be psychologically difficult for the patient. Whether or not it is cause for cardiopulmonary limitations is controversial. While subjective exertional dyspnea can be reported and may improve with repair, objective cardiopulmonary function may not change postoperatively. Therefore, the decision to repair the deformity may be based on cosmetic or physiologic considerations.

Surgical literature is providing more information regarding long-term outcomes following repair. Timing of repair is critical in light of growth plate maturation. Pectus excavatum may be associated with congenital heart disease.

Borowitz D et al: Pulmonary function and exercise response in patients with pectus excavatum after Nuss repair. *J Pediatr Surg* 2003;38:544 [PMID: 12677562].

Lawson ML et al: Impact of pectus excavatum on pulmonary function before and after repair with the Nuss procedure. *J Pediatr Surg* 2005;40:174 [PMID: 15868581].

Malek MH et al: Ventilatory and cardiovascular responses to exercise in patients with pectus excavatum. *Chest* 2003;124:870 [PMID: 12970011].

PECTUS CARINATUM

Pectus carinatum is a protrusion of the upper or lower (more common) portion of the sternum, more commonly seen in males. Again, although the disorder may have a psychological impact, impedance of cardiopulmonary function is debated. The decision to repair this deformity is often based on cosmetic grounds, but research has shown that those with reduced endurance or dyspnea with mild exercise experienced marked improvement within 6 months following repair, suggesting possible physiologic indications. Pectus carinatum may be associated with systemic diseases such as the mucopolysaccharidoses and congenital heart disease.

Williams AM, Crabbe DC: Pectus deformities of the anterior chest wall. *Paediatr Respir Rev* 2003;4:237 [PMID: 12880759].

NEUROMUSCULAR DISORDERS

Neuromuscular disorders are discussed in detail in Chapter 23. Weakness of the respiratory and pharyngeal muscles leads to chronic or recurrent pneumonia secondary to aspiration and infection, atelectasis, hypoventilation, and respiratory failure in severe cases. Scoliosis, which frequently accompanies long-standing neuromuscular disorders, may further compromise respiratory function. Typical physical findings are a weak cough, decreased air exchange, crackles, wheezing, and dullness to percussion. Signs of cor pulmonale (loud pulmonary component to the second heart sound, hepatomegaly, and elevated neck veins) may be evident in advanced cases. Chest radiographs generally show small lung volumes. If chronic aspiration is present, increased interstitial infiltrates and areas of atelectasis or consolidation may be present. Arterial blood gases demonstrate hypoxemia in the early stages and compensated respiratory acidosis in the late stages. Typical pulmonary function abnormalities include low lung volumes and decreased inspiratory force generated against an occluded airway.

Treatment is supportive and includes vigorous pulmonary toilet, antibiotics with infection, and oxygen to correct

hypoxemia. Consideration of bilevel positive airway pressure and mechanical airway clearance support, like mechanical in-exsufflation, should be introduced before respiratory failure is present. Unfortunately, despite aggressive medical therapy, many neuromuscular conditions progress to respiratory failure and death. The decision to intubate and ventilate is a difficult one; it should be made only when there is real hope that deterioration, though acute, is potentially reversible or when chronic ventilation is wanted. Chronic mechanical ventilation using either noninvasive or invasive techniques is being used more frequently in patients with chronic respiratory insufficiency.

DISORDERS OF THE PLEURA & PLEURAL CAVITY

The *parietal* pleura covers the inner surface of the chest wall. The *visceral* pleura covers the outer surface of the lungs. Disease processes can lead to accumulation of air or fluid in the pleural space. Pleural effusions are classified as transudates or exudates. Transudates occur when there is imbalance between hydrostatic and oncotic pressure, so that fluid filtration exceeds reabsorption (eg, congestive heart failure). Exudates form as a result of inflammation of the pleural surface leading to increased capillary permeability (eg, parapneumonic effusions). Other pleural effusions include chylothorax and hemothorax.

Thoracentesis is helpful in characterizing the fluid and providing definitive diagnosis. Recovered fluid is considered an exudate (as opposed to a transudate) if any of the following are found: a pleural fluid–serum protein ratio greater than 0.5, a pleural fluid–serum lactate dehydrogenase ratio greater than 0.6, or a pleural fluid lactate dehydrogenase level greater than 200 units/L. Important additional studies on pleural fluid include cell count; pH and glucose; Gram, acid-fast, and fungal stains; cultures; counterimmunoelectrophoresis for specific organisms; and occasionally, amylase concentration. Cytologic examination of pleural fluid should be performed to rule out leukemia or other neoplasm.

Hilliard TN et al: Management of parapneumonic effusion and empyema. *Arch Dis Child* 2003;88:915 [PMID: 14500314].

PARAPNEUMONIC EFFUSION & EMPYEMA

▶ General Considerations

Bacterial pneumonia is often accompanied by pleural effusion. Some of these effusions harbor infection, and others are inflammatory reactions to pneumonia. The nomenclature in this area is somewhat confusing. Some authors use the term *empyema* for grossly purulent fluid and *parapneumonic effusion* for nonpurulent fluid. It is clear, however, that some nonpurulent effusions will also contain organisms and represent either partially treated or early empyema. It is probably best to refer to all effusions associated with pneumonia as parapneumonic effusions, some of which are infected and some not.

The most common organism associated with empyema is *S pneumoniae*. Other common organisms include *H influenzae* and *S aureus*. Less common causes are group A streptococci, gram-negative organisms, anaerobic organisms, and *M pneumoniae*. Effusions associated with tuberculosis are almost always sterile and constitute an inflammatory reaction.

▶ Clinical Findings

A. Symptoms and Signs

Patients usually present with typical signs of pneumonia, including fever, tachypnea, and cough. They may have chest pain, decreased breath sounds, and dullness to percussion on the affected side and may prefer to lie on the affected side. With large effusions, there may be tracheal deviation to the contralateral side.

B. Laboratory Findings

The white blood cell count is often elevated, with left shift. Blood cultures are sometimes positive. The tuberculin skin test is positive in most cases of tuberculosis. Thoracentesis reveals findings consistent with an exudate. Cells in the pleural fluid are usually neutrophils in bacterial disease and lymphocytes in tuberculous effusions. In bacterial disease, pleural fluid pH and glucose are often low. pH less than 7.2 suggests active bacterial infection. The pH of the specimen should be determined in a blood gas syringe sent to the laboratory on ice. Extra heparin should not be used in the syringe as it can falsely lower the pH. Although in adults the presence of low pH and glucose necessitates aggressive and thorough drainage procedures, the prognostic significance of these findings in children is unknown. Gram stain, cultures, and counterimmunoelectrophoresis are often positive for the offending organism.

C. Imaging

The presence of pleural fluid is suggested by a homogeneous density that obscures the underlying lung on chest radiograph. Large effusions may cause a shift of the mediastinum to the contralateral side. Small effusions may only blunt the costophrenic angle. Lateral decubitus radiographs may help

to detect freely movable fluid by demonstrating a layering-out effect. If the fluid is loculated, no such effect is perceived. Ultrasonography can be extremely valuable in localizing the fluid and detecting loculations, especially when thoracentesis is contemplated, but availability may be limited. Chest CT scan can help determine if loculations are present and direct further care of complicated pneumonias.

► Treatment

After initial thoracentesis and identification of the organism, appropriate intravenous antibiotics and adequate drainage of the fluid remain the mainstay of therapy, but the approach is debated. Although there is a trend toward managing smaller pneumococcal empyemas without a chest tube, most larger effusions require chest tube drainage. Often the empyema has been present for more than 7 days, increasing the chance for loculation of fluid. Evidence of early decortication using thoroscopic techniques such as video-assisted thoracoscopic surgery (VATS) may reduce morbidity and has been shown to shorten length of hospital stay when done by an experienced surgeon. While there is growing use of VATS as first-line therapy, it is not standard of care. Aggressive management with drainage of pleural cavity fluid and release of adhesions with fibrinolytics is often sought in many institutions where the chest tube is placed in the operating room under anesthesia. The decision on therapeutic choice will vary depending on the resources available to the clinician.

► Prognosis

The prognosis is related to the severity of disease but is generally excellent, with complete or nearly complete recovery expected in most instances.

Rodgers BM: The role of thoracoscopy in pediatric surgical practice. *Semin Pediatr Surg* 2003;12:62 [PMID: 12520474].

HEMOTHORAX

Accumulation of blood in the pleural space can be caused by surgical or accidental trauma, coagulation defects, and pleural or pulmonary tumors. With blunt trauma, hemopneumothorax may be present. Symptoms are related to blood loss and compression of underlying lung parenchyma. There is some risk of secondary infection, resulting in empyema.

► Treatment

Drainage of a hemothorax is required when significant compromise of pulmonary function is present, as with

hemopneumothorax. In uncomplicated cases, observation is indicated because blood is readily absorbed spontaneously from the pleural space.

VATS has been used successfully in the management of hemothorax. Chest CT scan is helpful to select patients who may require surgery, as identification of blood and the volume of blood may be more predictive by this method than by chest radiograph.

Bliss D, Silen M: Pediatric thoracic trauma. *Crit Care Med* 2002;30(Suppl):S409 [PMID: 12528782].

CHYLOTHORAX

The accumulation of chyle, fluid of intestinal origin containing fat digestion products, in the pleural space usually results from accidental or surgical trauma to the thoracic duct. In the newborn, chylothorax can be congenital or secondary to birth trauma. This condition also occurs as a result of superior vena caval obstruction secondary to central venous lines and following Fontan procedures for tricuspid atresia. Symptoms of chylothorax are related to the amount of fluid accumulation and the degree of compromise of underlying pulmonary parenchyma. Thoracentesis reveals typical milky fluid (unless the patient has been fasting) containing chiefly T lymphocytes.

► Treatment

Treatment should be conservative because many chylothoraces resolve spontaneously. Oral feedings with medium-chain triglycerides reduce lymphatic flow through the thoracic duct. Recent literature has shown somatostatin as a viable therapeutic option. Drainage of chylous effusions should be performed only for respiratory compromise because the fluid often rapidly reaccumulates. Repeated or continuous drainage may lead to protein malnutrition and T-cell depletion, rendering the patient relatively immunocompromised. If reaccumulation of fluid persists, surgical ligation of the thoracic duct or sclerosis of the pleural space can be attempted, although the results may be less than satisfactory.

Romero S: Nontraumatic chylothorax. *Curr Opin Pulm Med* 2000;6:287 [PMID: 10912634].

PNEUMOTHORAX & RELATED AIR LEAK SYNDROMES

Pneumothorax can occur spontaneously in newborns and in older children, or more commonly, as a result of birth trauma, positive pressure ventilation, underlying obstructive or restrictive lung disease, and rupture of a congenital or acquired lung cyst. Pneumothorax can also occur as an acute complication of tracheostomy. Air usually dissects from the

alveolar spaces into the interstitial spaces of the lung. Migration to the visceral pleura ultimately leads to rupture into the pleural space. Associated conditions include pneumomediastinum, pneumopericardium, pneumoperitoneum, and subcutaneous emphysema. These conditions are more commonly associated with dissection of air into the interstitial spaces of the lung with retrograde dissection along the bronchovascular bundles toward the hilum.

► Clinical Findings

A. Symptoms and Signs

The clinical spectrum can vary from asymptomatic to severe respiratory distress. Associated symptoms include cyanosis, chest pain, and dyspnea. Physical examination may reveal decreased breath sounds and hyperresonance to percussion on the affected side with tracheal deviation to the opposite side. When pneumothorax is under tension, cardiac function may be compromised, resulting in hypotension or narrowing of the pulse pressure. Pneumopericardium is a life-threatening condition that presents with muffled heart tones and shock. Pneumomediastinum rarely causes symptoms by itself.

B. Imaging

Chest radiographs usually demonstrate the presence of free air in the pleural space. If the pneumothorax is large and under tension, compressive atelectasis of the underlying lung and shift of the mediastinum to the opposite side may be demonstrated. Cross-table lateral and lateral decubitus radiographs can aid in the diagnosis of free air. Pneumopericardium is identified by the presence of air completely surrounding the heart, whereas in patients with pneumomediastinum, the heart and mediastinal structures may be outlined with air, but the air does not involve the diaphragmatic cardiac border. Chest CT scan may be helpful with recurrent spontaneous pneumothoraces to look for subtle pulmonary disease not seen on chest radiograph, but this is debated.

► Differential Diagnosis

Acute deterioration of a patient on a ventilator can be caused by tension pneumothorax, obstruction or dislodgment of the endotracheal tube, or ventilator failure. Radiographically, pneumothorax must be distinguished from diaphragmatic hernia, lung cysts, congenital lobar emphysema, and cystic adenomatoid malformation, but this task is usually not difficult.

► Treatment

Small or asymptomatic pneumothoraces usually do not require treatment and can be managed with close observation. Larger or symptomatic ones usually require drainage, although inhalation of 100% oxygen to wash out blood nitrogen can be tried.

Needle aspiration should be used to relieve tension acutely, followed by chest tube or pigtail catheter placement.

Pneumopericardium requires immediate identification, and if clinically symptomatic, needle aspiration to prevent death, followed by pericardial tube placement.

In older patients with spontaneous pneumothorax, recurrences are common; sclerosing and surgical procedures are often required.

SLEEP-DISORDERED BREATHING

► General Considerations

Sleep apnea is recognized as a major public health problem in adults, with the risk of excessive daytime sleepiness, driving accidents, poor work performance, and effects on mental health. Pediatric sleep disorders are less commonly recognized because of a lack of training in sleep problem recognition and the presentation, risks, and outcome all differ from those in adults. The spectrum of sleep-disordered breathing includes obstructive sleep apnea, upper airway resistance disorder, and primary snoring. Sleep apnea is defined as cessation of breathing and can be classified as obstructive (the attempt to breathe through an obstructed airway) or central (the lack of effort to breathe). Snoring, mouth breathing, and upper airway obstruction are further discussed in Chapter 17.

► Clinical Findings & Differential Diagnosis

A. Obstructive Sleep Apnea

Obstructive sleep apnea occurs in normal children with an incidence of about 2%, increasing in children with craniofacial abnormalities, neuropathies, or other medical problems. The incidence also increases when children are medicated with hypnotics, sedatives, or anticonvulsants. While not all children who snore have sleep apnea, there is recent literature that raises concerns that snoring without apnea has neurobehavioral consequences. (See Chapter 17.) Obstructive sleep apnea should be suspected whenever a child presents with nightly snoring, witnessed apnea, labored breathing, frequent nighttime arousals, failure to thrive, oxygen desaturations, life-threatening events, behavior abnormalities, obesity, or craniofacial abnormalities. Upper airway resistance syndrome is characterized by the presence of daytime fatigue or sleepiness in the presence of a normal polysomnogram and oxygen saturations. Symptoms are similar to obstructive sleep apnea, including change in appetite, poor performance in school, and problems with behavior.

B. Central Sleep Apnea

Central apneas are common in infants and children. They are considered significant if longer than 20 seconds or associated with bradycardia or desaturations. Clinical significance is uncertain, but may be relevant if they occur frequently or gas exchange problems exist. Healthy children have been shown to have central apneas lasting 25 seconds without clear consequences. In comparison, central hypoventilation syndrome patients have intact voluntary control of ventilation, but lack automatic control. During sleep, they will hypoventilate to the point at which they need ventilatory support that may require treatment with positive airway pressure and a rated tidal volume via tracheostomy. Central sleep apnea may be present with this syndrome, but is not usually noted.

C. Diagnostic Studies

When sleep apnea is suspected, the polysomnogram is the diagnostic test of choice. This test measures sleep state with electroencephalogram leads and electromyography, airflow at the nose, heart rate and rhythm, gas exchange (CO₂ and oxygenation), and leg movements, along with other potential data including esophageal pH, end-tidal CO₂, body position, muscle activity, and other optional additions. Polysomnography allows diagnosis of various forms of apnea, sleep fragmentation, periodic limb movement disorder, or other sleep disorders of children. Overnight oximetry is not an ideal study to diagnose obstructive sleep apnea. While it may identify subjects with severe obstructive sleep apnea, its sensitivity is low. Literature has shown normal oximetry studies in half a population of subjects with polysomnogram-confirmed obstructive sleep apnea.

► Treatment

First-line therapy for obstructive sleep apnea in children is adenotonsillectomy, which improves the clinical status for most children with normal craniofacial structure. Even children with craniofacial anomalies or neuromuscular disorders may benefit, although additional treatment with continuous positive airway pressure may be indicated. Down syndrome presents unique challenges: Up to half of these children can still have obstructive sleep apnea despite adenotonsillectomy. Treatment of young or developmentally delayed children with apnea also presents several challenges. (See Chapter 17 for additional discussion.)

Because the differential diagnosis of sleepiness is quite varied among children, pediatric sleep disorder centers are the referral of choice for testing and initiation of therapy.

APPARENT LIFE-THREATENING EVENTS IN INFANCY

► General Considerations

Apparent life-threatening events (ALTEs) are characterized as being frightening to the observer and commonly include some combination of apnea, color change (usually cyanosis or pallor), a marked change in muscle tone (usually extreme limpness), choking, or gagging. The observer sometimes fears the infant has died. The most frequent problems associated with an ALTE are gastrointestinal (~50%), neurologic (30%), respiratory (20%), cardiovascular (5%), metabolic and endocrine (< 5%), or diverse other problems, including child abuse. Up to 50% of ALTEs remain unexplained and are referred to as apnea of infancy. The relationship between ALTE and future risk of sudden infant death syndrome (SIDS) is not clear. The term *apparent life-threatening event* replaced “near-miss SIDS” in order to distance the event from a direct association with SIDS. Literature has reported an increased risk when extreme cardiopulmonary events were present at the time of the ALTE. Fewer than 10% of SIDS victims have had a prior history of ALTE.

The mechanism for ALTEs is unknown, but because they do not occur after infancy, immaturity is felt to play a major role. Indeed, classic studies on the nervous system, reflexes, and responses to apnea or hypoxia during sleep show profound cardiovascular compromise in infants during stimulation of the immature autonomic nervous system; adults would not be affected.

The following section describes an approach to the patient who has undergone an ALTE, taking note of the very broad differential diagnosis and uncertainties in both evaluation and treatment.

► Clinical Findings & Differential Diagnosis

A. History and Physical Examination

Table 18–4 classifies disorders associated with ALTEs. A careful history is often the most helpful part of the evaluation. It is useful to determine whether the infant has been chronically ill or essentially well. A history of several days of poor feeding, temperature instability, or respiratory or gastrointestinal symptoms suggests an infectious process. Reports of “struggling to breathe” or “trying to breathe” imply airway obstruction. Association of the episodes with feeding implies disorganized swallowing, gastroesophageal reflux, or airway obstruction. Episodes that typically follow crying may be related to breath-holding. Association of

Table 18-4. Potential causes of apparent life-threatening events.

Infectious	Viral: respiratory syncytial virus and other respiratory viruses Bacterial: sepsis, pertussis, chlamydia
Gastrointestinal	Gastroesophageal reflux with or without obstructive apnea
Respiratory	Airway abnormality; vascular rings, pulmonary slings, tracheomalacia Pneumonia
Neurologic	Seizure disorder Central nervous system infection: meningitis, encephalitis Vasovagal response Leigh encephalopathy Brain tumor
Cardiovascular	Congenital malformation Dysrhythmias Cardiomyopathy
Nonaccidental trauma	Battering Drug overdose Munchausen syndrome by proxy
No definable cause	Apnea of infancy

episodes with sleeping may also suggest gastroesophageal reflux, apnea of infancy, or sleep-disordered breathing. Attempts should be made to determine the duration of the episode, but this is often difficult. It is helpful to role-play the episode with the family. Details regarding the measures taken to resuscitate the infant and the infant's recovery from the episode are often useful in determining severity.

The physical examination provides further direction in pursuing the diagnosis. Fever or hypothermia suggests infection. An altered state of consciousness implies a postictal state or drug overdose. Respiratory distress implies cardiac or pulmonary lesions.

Apneic episodes have been linked to child abuse in several ways. Head injury following nonaccidental trauma may be first brought to medical attention because of apnea. Other signs of abuse are usually immediately apparent in such cases. Drug overdose, either accidental or intentional, may also present with apnea. Several series document that apneic episodes may be falsely reported by parents seeking attention (ie, Munchausen syndrome by proxy). Parents may physically interfere with a child's respiratory efforts, in which case pinch marks on the nares are sometimes found.

B. Laboratory Findings

Most patients are hospitalized for observation in order to reduce stress on the family and allow prompt completion of

the evaluation. Laboratory evaluation includes a complete blood count for evidence of infection. Serum electrolytes are usually obtained. Elevations in serum bicarbonate suggest chronic hypoventilation, whereas decreases suggest acute acidosis, perhaps due to hypoxia during the episode. Chronic acidosis suggests an inherited metabolic disorder. Arterial blood gas studies provide an initial assessment of oxygenation and acid-base status, and low PaO_2 or elevated PaCO_2 (or both) implies cardiorespiratory disease. A significant base deficit suggests that the episode was accompanied by hypoxia or circulatory impairment. Oxygen saturation measurements in the hospital assess oxygenation status during different activities and are more comprehensive than a single blood gas sample.

Because apnea has been associated with respiratory infections, diagnostic studies for RSV and other viruses, pertussis, and *Chlamydia* may help with diagnosis. Apnea occurring with infection often precedes other physical findings.

C. Imaging

The chest radiograph is examined for infiltrates suggesting acute infection or chronic aspiration and for cardiac size as a clue to intrinsic cardiac disease. If the episode might have involved airway obstruction, the airway should be examined either directly, by fiberoptic bronchoscopy, or radiographically, by CT or barium swallow. Barium swallow is a useful tool to rule out the possibility of anatomic abnormalities such as vascular ring and tracheoesophageal fistula. This study may also demonstrate reflux and aspiration. If reflux is suspected, it should be documented by esophageal pH monitoring coupled with respiratory pattern recording. Most infants with reflux and apnea can be given medical antireflux treatment. Infants with reflux and repeated episodes of apnea may benefit from a surgical antireflux procedure.

D. Polysomnography and Other Studies

ALTEs occur in the same age group as infants who die of sudden death (2–4 months is the peak age). Sleep-disordered breathing has been implicated as a possible cause of ALTEs and perhaps sudden death. Depending on the discretion of the clinician in appropriate scenarios, polysomnograms can be useful to determine abnormalities of cardiorespiratory function, sleep state, oxygen saturation, CO_2 retention, and seizure activity. They can be used in conjunction with pH monitoring to determine the contribution of reflux to apnea. Esophageal pressure manometry can be useful to detect subtle changes in respiratory effort related to partial obstructive breathing (hypopnea). Infants may be at more risk of adverse events from sleep-disordered breathing due to their immature nervous system.

There are several neurologic causes of ALTEs. Apnea as the sole manifestation of a seizure disorder is unusual but may occur. In cases of repeated episodes, 24-hour electroencephalographic monitoring may be helpful in detecting a

seizure disorder. Leigh disease, a brainstem disorder characterized pathologically by neuronal dropout, may present with apneic episodes.

► Treatment

Therapy is directed at the underlying cause if one is found. After blood cultures are taken, antibiotics should be given to infants who appear toxic. Seizure disorders are treated with anticonvulsants. Gastroesophageal reflux should be treated, but may not prevent future episodes of ALTE. Vascular rings and pulmonary slings must be corrected surgically because of severe morbidity and high mortality rates when untreated.

The approach to care of infants with ALTEs where no definable cause can be ascertained is controversial. Home monitoring has been used in the past as treatment, but the efficacy of monitoring has not been demonstrated in controlled trials. The rationale for use of monitors is that infants at risk for subsequent severe episodes can be identified. With over 20 years of home monitoring, the sudden infant death rate did not change due to this intervention. Although monitors can detect apnea or bradycardia, they do not predict which children will have future ALTEs. Parents should be taught cardiopulmonary resuscitation prior to discharge. They should also be aware of the possibility of frequent false alarms. It must be noted that many parents cannot handle the stress associated with having a monitor in the home.

The decision to monitor these infants involves the participation of the family. Infants with severe initial episodes or repeated severe episodes are now thought to be at significantly increased risk and should probably be monitored in the home. Episodes in these children are so severe that the parents want to know the infant's condition at all times. The decision to discontinue monitoring is usually based on the infant's ability to go several months without triggering the alarm.

Oxygen has been used as therapy for ALTEs for several reasons. First, it reduces periodic breathing of infancy, an immature pattern of breathing that can cause some degree of oxygen desaturation. Second, infants have small chest capacities with increased chest wall compliance that reduces lung volume. Oxygen can increase the baseline saturation, reducing the severity of desaturation with short apneas. Respiratory stimulants such as caffeine and aminophylline have been used in specific cases of central apnea or periodic breathing.

SUDDEN INFANT DEATH SYNDROME

► General Considerations

SIDS is defined as the sudden death of an infant younger than age 1 year that remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history. The postmortem examination is an important feature of the definition because approximately 20% of cases of sudden death can be explained by autopsy findings. The incidence of SIDS in the United States has declined to less than 1 in 1000 live births. The part of the decline that has occurred since 1994 is likely due to alterations of risk factors (see following discussion).

► Epidemiology & Pathogenesis

Epidemiologic and pathologic data constitute most of what is known about SIDS. The number of deaths peaks between ages 2 and 4 months, and most deaths occur in infants a few weeks to 6 months of age. Most deaths occur between midnight and 8 AM, while the infant and often the caregiver are sleeping. In fact, the only unifying features of all SIDS cases are age and sleep. Previous studies showed a peak in SIDS during the respiratory virus season, but the association becomes weaker when the data are controlled for risk factors such as tobacco exposure. SIDS is more common among ethnic and racial minorities and socioeconomically disadvantaged populations. Racial disparity in the prevalence of prone positioning may also be contributing to the continued disparity in SIDS rates between black and white infants. There is a 3:2 male predominance in most series. Other risk factors include low birth weight, teenage or drug-addicted mothers, maternal smoking, and a family history of SIDS. Most of these risk factors are associated with a two- to threefold elevation of incidence but are not specific enough to be useful in predicting which infants will die unexpectedly. Recent immunization is not a risk factor.

The most consistent pathologic findings are intrathoracic petechiae and mild inflammation and congestion of the respiratory tract. Subtler pathologic findings include brainstem gliosis, extramedullary hematopoiesis, and increases in periadrenal brown fat. These latter findings suggest that infants who succumb to SIDS have had intermittent or chronic hypoxia before death.

The mechanism or mechanisms of death in SIDS are unknown. For example, it is unknown whether the initiating event at the time of death is cessation of breathing, cardiac arrhythmia, or asystole. Hypotheses have included upper airway obstruction, catecholamine excess, and increased fetal hemoglobin. However, maldevelopment or delay in maturation of the brainstem, which is responsible for arousal, remains the predominant theory. It has been recognized that some infants who presented with apneic episodes subsequently died from SIDS; however, study of these infants and

prospective studies of large numbers of newborns have indicated that most infants with apnea do not die from SIDS and that most infants with SIDS have no identifiable episodes of apnea. The American Academy of Pediatrics has recommended that infant home monitoring not be used as a strategy to prevent SIDS, but may be useful in some infants who have had an ALTE (see section on Apparent Life-Threatening Events, earlier).

A history of mild symptoms of upper respiratory infection before death is not uncommon, and SIDS victims are sometimes seen by physicians a day or so before death. When infants are discovered blue, cold, and motionless by parents or caregivers, they are most commonly taken to the emergency department, where resuscitation usually fails. Families must then be supported following the death. The National SIDS Resource Center (<http://www.sidscenter.org>) provides information about psychosocial support groups and counseling for families of SIDS victims. The postmortem examination is essential for the diagnosis of SIDS and may help the family by excluding other possible causes of death. A death scene investigation is also important in determining the cause of sudden unexpected deaths in infancy.

► Prevention

Since 1990, SIDS rates have declined more than 60% worldwide. Population studies in New Zealand and Europe identified risk factors, which when changed had a major effect on the incidence of SIDS. Since 1994 the American Academy of Pediatrics' "Back-to-Sleep" campaign has promoted education about SIDS risk factors in the United States. Modifiable risk factors include sleeping position, bottle feeding, maternal smoking, and infant overheating; sleeping position and smoke exposure may have the largest influence. The prone sleep position could contribute to SIDS through decreased arousal during sleep or during hypoxia, rebreathing of exhaled gases, or effects on the immature autonomic nervous system. The side position, often used in hospitals and then mimicked at home, also shows increased risk of SIDS compared with the supine position. Maternal smoking, especially prenatal maternal smoking, increases the risk of SIDS. Investigations of tobacco effects on the autonomic nervous system of the developing fetus, pulmonary growth and function of the newborn, or its combination with viral infection all point to differences in SIDS compared with control subjects. Although the mechanism is not known, recent literature review has shown a reduced risk of SIDS associated with pacifier use. While beneficial for many reasons, breast feeding is debated regarding decreasing SIDS risk.

The health care provider is instrumental in parental education regarding the modifiable risk factors for SIDS (Table 18–5). Education includes promotion of the supine sleeping position, firm sleep surface, pacifier use at nap or bedtime, avoidance of overheating, and smoking cessation; and identification of child care settings, as many parents rely on others to watch their children, where the impor-

MEDIASTINUM

MEDIASTINAL MASSES

► General Considerations

Children with mediastinal masses may present because of symptoms produced by pressure on the esophagus, airways, nerves, or vessels within the mediastinum, or the masses may be discovered on a routine chest radiograph. Once the mass is identified, localization to one of four mediastinal compartments aids in the differential diagnosis. The superior mediastinum is the area above the pericardium that is bordered

inferiorly by an imaginary line from the manubrium to the fourth thoracic vertebra. The anterior mediastinum is bordered by the sternum anteriorly and the pericardium posteriorly, and the posterior mediastinum is defined by the pericardium and diaphragm anteriorly and the lower eight thoracic vertebrae posteriorly. The middle mediastinum is surrounded by these three compartments.

► Clinical Findings

A. Symptoms and Signs

Respiratory symptoms, when present, are due to pressure on an airway (cough or wheezing) or an infection (unresolving pneumonia in one area of lung). Hemoptysis can also occur but is an unusual presenting symptom. Dysphagia may occur secondary to compression of the esophagus. Pressure on the recurrent laryngeal nerve can cause hoarseness due to paralysis of the left vocal cord. Superior vena caval obstruction can lead to dilation of neck vessels and other signs and symptoms of obstruction of venous return from the upper part of the body (superior mediastinal syndrome).

B. Laboratory Findings and Imaging

The mass is initially defined by frontal and lateral chest radiographs together with thoracic CT scans and perhaps MRI. A barium swallow may also help define the extent of a mass. Other studies that may be required include angiography (to define the blood supply to large tumors), electrocardiography, echocardiography, ultrasound of the thorax, fungal and mycobacterial skin tests, and urinary catecholamine assays. MRI or myelography may be necessary in children suspected of having a neurogenic tumor in the posterior mediastinum.

► Differential Diagnosis

The differential diagnosis of mediastinal masses is determined by their location. Within the superior mediastinum, one may find cystic hygromas, vascular or neurogenic tumors, thymic masses, teratomas, intrathoracic thyroid

tissue, and esophageal lesions. A mediastinal abscess may also be found in this region. Within the anterior mediastinum, thymic tissue (thymomas, hyperplasia, and cysts) and teratomas, vascular tumors, and lymphatic tissue (lymphomas or reactive lymphadenopathy) give rise to masses. An intrathoracic thyroid and a pleuropericardial cyst may also be found in this region. Within the middle mediastinum one may again find lymphomas and hypertrophic lymph nodes, granulomas, bronchogenic or enterogenous cysts, metastases, and pericardial cysts. Abnormalities of the great vessels and aortic aneurysms may also present as masses in this compartment. Within the posterior mediastinum, neurogenic tumors, enterogenous cysts, thoracic meningoceles, or aortic aneurysms may be present.

In some series, more than 50% of mediastinal tumors occur in the posterior mediastinum and are mainly neurogenic tumors or enterogenous cysts. Most neurogenic tumors in children younger than age 4 years are malignant (neuroblastoma or neuroganglioblastoma), whereas a benign ganglioneuroma is the most common histologic type in older children. In the middle and anterior mediastinum, tumors of lymphatic origin (lymphomas) are the primary concern. Bulky anterior mediastinal tumors that compress the trachea and the great vessels can lead to a superior mediastinal syndrome, which presents a diagnostic problem because of anesthesia hazards. Definitive diagnosis in most instances relies on surgery to obtain the mass or a part of the mass for histologic examination. In cases of lymphoma, the scalene nodes may also contain tumor, and a biopsy should be performed in an attempt to establish a diagnosis.

► Treatment & Prognosis

The appropriate therapy and the response to therapy depend on the cause of the mediastinal mass.

Cardiovascular Diseases

Henry M. Sondheimer, MD
 Jeffrey R. Darst, MD
 Elizabeth M. Shaffer, MD
 Shelley D. Miyamoto, MD

19

Eight in 1000 infants are born with a congenital heart defect. Acquired heart diseases such as Kawasaki disease, myocarditis, and rheumatic heart disease also cause significant morbidity and mortality in children. Advances in medical and surgical care now allow more than 90% of children with congenital heart defects to enter adulthood. It is therefore important that current pediatric cardiac care include not only the diagnosis and treatment of congenital heart disease but also the prevention of risk factors for adult cardiovascu-

lar disease—obesity, smoking and hyperlipidemia. Specialty clinics addressing the needs of adults with repaired or palliated congenital heart disease are needed to assess and advise patients regarding such adult issues as the impact of pregnancy, the risks of anticoagulation during pregnancy, and appropriate adult career choices.

CARDIOVASCULAR DISEASE ABBREVIATIONS

ASD	Atrial septal defect
AVSD	Atrioventricular septal defect
ccTGA	Congenitally corrected transposition of the great arteries
DCM	Dilated cardiomyopathy
HCM	Hypertrophic cardiomyopathy
HF	Heart failure
HLHS	Hypoplastic left heart syndrome
LVH	Left ventricular hypertrophy
MVP	Mitral valve prolapse
PA/IVS	Pulmonary atresia with intact ventricular septum
PDA	Patent (persistent) ductus arteriosus
PPH	Primary pulmonary hypertension
RVH	Right ventricular hypertrophy
TAPVR	Total anomalous pulmonary venous return
TGA	Transposition of the great arteries
ToF	Tetralogy of Fallot
VSD	Ventricular septal defect
WPW	Wolff-Parkinson-White syndrome

DIAGNOSTIC EVALUATION

The presence of a heart murmur suggests the possibility of heart disease. Murmurs, however, may be functional or innocent, and not all serious cardiovascular disorders are accompanied by an easily detectable murmur.

HISTORY

Most congenital defects lead either to decreased pulmonary blood flow or increased pulmonary blood flow with pulmonary congestion. Symptoms vary according to the alteration in pulmonary blood flow (Table 19–1). The presence of other cardiovascular symptoms such as palpitations and chest pain should also be determined by history in the older child, paying particular attention to the timing (at rest or activity-related), onset, and termination (gradual versus sudden), and precipitating and relieving factors.

PHYSICAL EXAMINATION

General

The examination should begin with a visual assessment of skin perfusion and skin color. Heart rate, respiratory rate, blood pressure (in all four extremities), and oxygen saturation are required. Many congenital cardiac defects occur as part of a genetic syndrome (Table 19–2) and the complete assessment includes an evaluation for dysmorphic features that may be clues to the associated cardiac defect.

Table 19-1. Symptoms of increased and decreased pulmonary blood flow.

Decreased Pulmonary Blood Flow	Increased Pulmonary Blood Flow
Infant/Toddler	
Cyanosis	Tachypnea with activity/feeds
Squatting	Diaphoresis
Loss of consciousness	Poor weight gain
Older Child	
Dizziness	Exercise intolerance
Syncope	Dyspnea on exertion, diaphoresis

Cardiovascular Examination

A. Inspection and Palpation

Chest conformation should be noted in the supine position. A precordial bulge indicates cardiomegaly. Palpation may reveal increased precordial activity, right ventricular lift, or left-sided heave; a diffuse point of maximal impulse; or a precordial thrill caused by a grade IV/VI murmur. The thrill of aortic stenosis is found in the suprasternal notch. In patients with severe pulmonary hypertension, a palpable pulmonary closure (P_2) is frequently noted at the upper left sternal border.

B. Auscultation

1. Heart sounds—The first heart sound (S_1) is the sound of atrioventricular (AV) valve closure. It is best heard at the lower left sternal border and is usually medium-pitched. Although S_1 has multiple components only one of these (M_1) is usually audible.

Table 19-2. Cardiac defects in common syndromes.

Genetic Syndrome	Commonly Associated Cardiac Defect
Down syndrome	AVSD
Turner syndrome	Bicuspid aortic valve, coarctation
Noonan syndrome	Dysplastic pulmonic valve, HCM
Williams-Beuren syndrome	Supravalvular aortic stenosis, PPS
Marfan syndrome	MVP, MR, dilated aortic root
Fetal alcohol syndrome	VSD, ASD
Maternal rubella	PDA, PPS

ASD, atrial septal defect; AVSD, atrioventricular septal defect; HCM, hypertrophic cardiomyopathy; MR, mitral regurgitation; MVP, mitral valve prolapse; PDA, patent ductus arteriosus; PPS, peripheral pulmonary stenosis; VSD, ventricular septal defect.

The second heart sound (S_2) is the sound of semilunar valve closure. It is best heard at the upper left sternal border. S_2 has two component sounds, A_2 and P_2 (aortic and pulmonic valve closure). Splitting of S_2 varies with respiration, widening with inspiration and narrowing with expiration. Abnormal splitting of S_2 may be an indication of cardiac disease (Table 19-3).

The third heart sound (S_3) is the sound of rapid left ventricular filling. It occurs in early diastole, after S_2 , and is medium-to low-pitched. In healthy children, S_3 diminishes or disappears when going from supine to sitting or standing. A persistent S_3 is often heard in the presence of a dilated left ventricle (LV) caused by cardiomyopathy or a large left-to-right shunt. The fourth heart sound (S_4) is associated with atrial contraction and increased atrial pressure and has a low pitch similar to that of S_3 . It occurs just prior to S_1 and is not normally audible. It is heard in the presence of atrial contraction into a noncompliant ventricle as in hypertrophic or restrictive cardiomyopathy or hypertrophied LV from other causes.

Ejection clicks are usually related to dilated great vessels or valve abnormalities. They can be heard throughout ventricular systole and are classified as early, mid, or late. Early ejection clicks at the mid left sternal border are from the pulmonic valve. Aortic clicks are typically best heard at the apex. In contrast to aortic clicks, pulmonic clicks vary with respiration, becoming louder during inspiration. A mid to late ejection click at the apex is most typically caused by mitral valve prolapse.

2. Murmurs—A heart murmur is the most common cardiovascular finding leading to a cardiology referral. Innocent or functional heart murmurs are common, and 40–45% of children have an innocent murmur at some time during childhood.

A. CHARACTERISTICS—All murmurs should be described based on the following characteristics:

(1) **Location and radiation**—Where the murmur is best heard and where the sound extends.

(2) **Relationship to cardiac cycle and duration**—Systolic ejection (immediately following S_1 with a crescendo/decrecendo change in intensity), pansystolic (occurring through-

Table 19-3. Abnormal splitting of S_2 .

Causes of wide split S_2
RV volume overload: ASD, anomalous pulmonary venous return, PI
RV pressure overload: Pulmonary valve stenosis
Delayed RV conduction: RBBB
Causes of narrow split S_2
Pulmonary hypertension
Single semilunar valve (aortic atresia, pulmonary atresia, truncus arteriosus)

ASD, atrial septal defect; PI, pulmonic insufficiency; RBBB, right bundle branch block; RV, right ventricle.

Table 19-4. Pathologic murmurs.

Systolic Ejection	Pansystolic	Diastolic	Continuous
Semilunar valve stenosis (AS/PS/truncal stenosis)	VSD	Semilunar valve regurgitation	Runoff lesions
ASD	AVVR (MR/TR)	(AI/PI/truncal insufficiency)	(PDA/AVM/aortopulmonary collaterals)
Coarctation		AV valve stenosis (MS/TS)	

AI/PI, aortic insufficiency/pulmonic insufficiency; AS/PS, aortic stenosis/pulmonic stenosis; ASD, atrial septal defect; AV, atrioventricular; MS/TS, mitral stenosis/tricuspid stenosis; AVVR, atrioventricular valve regurgitation; MR/TR, mitral regurgitation/tricuspid regurgitation; PDA/AVM, patent ductus arteriosus/arteriovenous malformation; VSD, ventricular septal defect.

out most of systole and of constant intensity), diastolic, and continuous. The timing of the murmur provides valuable clues as to underlying pathology (Table 19-4).

(3) **Intensity**—Grade I describes a soft murmur heard with difficulty; grade II, soft but easily heard; grade III, loud but without a thrill; grade IV, loud and associated with a precordial thrill; grade V, loud, with thrill, and audible with the edge of the stethoscope; grade VI, very loud and audible with the stethoscope off the chest.

(4) **Quality**—Harsh, musical, or rough; high, medium, or low in pitch.

(5) **Variation with position**—Audible when the patient is supine, sitting, standing, or squatting.

B. INNOCENT MURMURS—The six most common innocent murmurs of childhood are:

(1) **Newborn murmur**—Heard in the first few days of life, this murmur is at the lower left sternal border, without significant radiation. It has a soft, short, vibratory grade I–II/VI quality that often subsides when mild pressure is applied to the abdomen. It usually disappears by age 2–3 weeks.

(2) **Peripheral arterial pulmonary stenosis**—This murmur, often heard in newborns, is caused by the normal branching of the pulmonary artery. It is heard with equal intensity at the upper left sternal border, at the back, and in both axillae. It is a soft, short, high-pitched, grade I–II/VI systolic ejection murmur and usually disappears by age 2. This murmur must be differentiated from true peripheral pulmonary stenosis (Williams syndrome, Alagille syndrome, or rubella syndrome), coarctation of the thoracic aorta, and valvular pulmonary stenosis.

(3) **Still murmur**—This is the most common innocent murmur of early childhood. It is typically heard between 2 and 7 years of age. It is loudest midway between the apex and the lower left sternal border. Still murmur is a musical or vibratory, short, high-pitched, grade I–III early systolic murmur. It is loudest when the patient is supine. It diminishes or disappears with inspiration or when the patient is sitting. The Still murmur is louder in patients with fever, anemia, or sinus tachycardia from any reason.

(4) **Pulmonary ejection murmur**—This is the most common innocent murmur in older children and adults. It is

heard from age 3 years onward. It is usually a soft systolic ejection murmur, grade I–II in intensity at the upper left sternal border. The murmur is louder when the patient is supine or when cardiac output is increased. The pulmonary ejection murmur must be differentiated from murmurs of pulmonary stenosis, coarctation of the aorta, atrial septal defect (ASD), and peripheral pulmonary artery stenosis.

(5) **Venous hum**—A venous hum is usually heard after age 2 years. It is located in the infraclavicular area on the right. It is a continuous musical hum of grade I–III intensity and may be accentuated in diastole and with inspiration. It is best heard in the sitting position. Turning the child’s neck, placing the child supine, and compressing the jugular vein obliterates the venous hum. Venous hum is caused by turbulence at the confluence of the subclavian and jugular veins.

(6) **Innominate or carotid bruit**—This murmur is more common in the older child and adolescent. It is heard in the right supraclavicular area. It is a long systolic ejection murmur, somewhat harsh and of grade II–III intensity. The bruit can be accentuated by light pressure on the carotid artery and must be differentiated from all types of aortic stenosis.

When functional murmurs are found in a child, the physician should assure the parents that these are normal heart sounds of the developing child and that they do not represent heart disease.

Extracardiac Examination

A. Arterial Pulse Rate and Rhythm

Cardiac rate and rhythm vary greatly during infancy and childhood, so multiple determinations should be made. This is particularly important for infants (Table 19-5) whose heart rate varies with activity. The rhythm may be regular or there may be a phasic variation with respiration (sinus arrhythmia), which is normal.

B. Arterial Pulse Quality and Amplitude

The pulses of the upper and lower extremities should be compared. A bounding pulse is characteristic of runoff lesions, including patent ductus arteriosus (PDA), aortic regurgitation, arteriovenous malformation, or any condition

Table 19–5. Resting heart rates.

Age	Low	High
< 1 mo	80	160
1–3 mo	80	200
2–24 mo	70	120
2–10 y	60	90
11–18 y	40	90

with a low diastolic pressure (fever, anemia, or septic shock). Narrow or thready pulses occur in patients with conditions reducing cardiac output such as cardiomyopathy, myocarditis, pericardial tamponade, or severe aortic stenosis. A reduction in pulse amplitude or blood pressure (> 10 mm Hg) with inspiration is referred to as pulsus paradoxus and is a telltale sign of pericardial tamponade. The femoral pulse should be palpable and equal in amplitude and simultaneous with the brachial pulse. A femoral pulse that is absent or weak, or that is delayed in comparison with the brachial pulse, suggests coarctation of the aorta.

C. Arterial Blood Pressure

Blood pressures should be obtained in the upper and lower extremities. Systolic pressure in the lower extremities should be greater than or equal to that in the upper extremities. The cuff must cover the same relative area of the arm and leg. Measurements should be repeated several times.

D. Cyanosis of the Extremities

Cyanosis results from an increased concentration ($> 4\text{--}5$ g/dL) of reduced hemoglobin in the blood. Bluish skin color is usually, but not always, a sign. Visible cyanosis accompanies low cardiac output, hypothermia, and systemic venous congestion, even in the presence of adequate oxygenation. Cyanosis should be judged only by the color of the mucous membranes (lips). Bluish discoloration around the mouth (acrocyanosis) is a feature of skin that has not been exposed to sun, and it does not correlate with cyanosis.

E. Clubbing of the Fingers and Toes

Clubbing is often associated with severe cyanotic congenital heart disease. It usually appears after age 1 year. Hypoxemia with cyanosis is the most common cause, but clubbing also occurs in patients with endocarditis, chronic liver disease, inflammatory bowel diseases, chronic pulmonary disease, and lung abscess. Digital clubbing may be a benign genetic variant.

F. Edema

Edema of dependent areas (lower extremities in the older child and the face and sacrum in the younger child) is

characteristic of elevated right heart pressure, which may be seen with tricuspid valve pathology or right ventricle (RV) dysfunction (right heart failure) from a variety of causes including LV dysfunction.

G. Abdomen

Hepatomegaly is the cardinal sign of right heart failure in the infant and child. Hepatomegaly may also be seen in the child with pulmonary edema from lesions causing left-to-right shunting or left heart failure. Splenomegaly may be present in patients with long-standing heart failure (HF), and is characteristic of infective endocarditis. Ascites is also a feature of chronic right heart failure. Examination of the abdomen may reveal shifting dullness or a fluid wave.

ELECTROCARDIOGRAPHY

The electrocardiogram (ECG) is essential in the evaluation of the cardiovascular system. The heart rate should first be determined, then the cardiac rhythm (Is the patient in a normal sinus rhythm or other rhythm as evidenced by a P wave with a consistent PR interval before every QRS complex?), and then the axis (Are the P and QRS axes normal for patient age?). Once this initial assessment of rate, rhythm, and axis is performed, attention can be directed toward assessment of chamber enlargement and finally to assessment of cardiac intervals and ST segments.

Age-Related Variations

The ECG evolves with age. The rate decreases and intervals increase with age. RV dominance in the newborn changes to LV dominance in the older infant, child, and adult. The normal ECG of the 1-week-old infant is abnormal for a 1-year-old child, and the ECG of a 5-year-old child is abnormal for an adult.

Electrocardiographic Interpretation

Figure 19–1 defines the events recorded by the ECG.

A. Rate

The heart rate varies markedly with age, activity, and state of emotional and physical well-being. In most infants and

▲ **Figure 19-1.** Complexes and intervals of the electrocardiogram.

younger children, the heart rate ranges from 70–200 beats per minute depending on the above.

B. Rhythm

Sinus rhythm should always be present in normal children. In contrast to adults, premature atrial and ventricular contractions are uncommon during childhood.

C. Axis

1. P wave axis—The P wave is generated from atrial contraction beginning in the high right atrium at the site of the sinus node. The impulse proceeds leftward and inferiorly, thus leading to a positive deflection in all left-sided and

inferior leads (II, III, and aVF). The P wave in patients in normal sinus rhythm should be negative in lead aVR.

2. QRS axis—The net voltage should be positive in leads I and aVF in children with a normal axis. In the young child, RV dominance may persist, leading to a negative deflection in lead I. Several congenital cardiac lesions are associated with alterations in the normal QRS axis (Table 19–6).

D. P Wave

In the pediatric patient, the amplitude of the P wave is normally no greater than 3 mm and the duration no more than 0.08 second. The P wave is best seen in leads II and V₁.

E. PR Interval

The PR is measured from the beginning of the P wave to the beginning of the QRS complex. It increases with age and with slower rates. The PR interval ranges from a minimum of 0.10 second in infants to a maximum of 0.18 second in older children with slow rates. The PR interval is commonly prolonged in patients who have rheumatic heart disease and by digitalis.

F. QRS Complex

This represents ventricular depolarization, and its amplitude and direction of force (axis) reveal the relative size of the

Table 19-6. QRS axis deviation.

Cardiac medications
Antiarrhythmics: IA (quinidine, procainamide, disopyramide) class III (amiodarone, sotalol)
Inotropic agents: dobutamine, dopamine, epinephrine, isoproterenol
Noncardiac medications
Antibiotics/antivirals: azithromycin, clarithromycin, levofloxacin, amantadine
Antipsychotics: risperidol, thioridazine, lithium, haloperidol
Sedatives: chloral hydrate, methadone
Other: albuterol, levalbuterol, ondansetron, phenytoin, pseudoephedrine
Electrolyte disturbances: hypokalemia, hypomagnesemia, hypocalcemia

^aPartial list only.

ventricular mass in hypertrophy, hypoplasia, and infarction. Abnormal ventricular conduction (ie, right or left bundle-branch block) is also revealed.

G. QT Interval

This interval is measured from the beginning of the QRS complex to the end of the T wave. The QT duration may be prolonged as a primary condition or secondarily due to drugs or electrolyte imbalances (Table 19-7). The normal QT duration is rate-related and must be corrected using the Bazett formula:

$$QTc = \frac{QT \text{ interval}(s)}{\sqrt{R - R \text{ interval}(s)}}$$

The normal QTc is less than or equal to 0.44 second.

H. ST Segment

This segment, lying between the end of the QRS complex and the beginning of the T wave, is affected by drugs, electrolyte imbalances, or myocardial injury.

I. T Wave

The T wave represents myocardial repolarization and is altered by electrolytes, myocardial hypertrophy, and ischemia.

J. Impression

The ultimate impression of the ECG is derived from a systematic analysis of the features described earlier as compared with expected normal values for the child's age.

Left atrium	Double shadow behind cardiac silhouette Increase in subcarinal angle
Right atrium	Prominence of right atrial border of the heart

CHEST RADIOGRAPH

Evaluation of the chest radiograph for cardiac disease should focus on (1) position of the heart, (2) position of the abdominal viscera, (3) cardiac size, (4) cardiac configuration, and (5) character of the pulmonary vasculature.

Cardiac position is either levocardia (heart predominantly in the left chest), dextrocardia (heart predominantly in the right chest), or mesocardia (midline heart). The position of the liver and stomach bubble is either in the normal position (abdominal situs solitus), inverted with the stomach bubble on the right (abdominal situs inversus), or variable with midline liver (abdominal situs ambiguous). The heart appears relatively large in normal newborns and decreases on the chest radiograph with age. The heart size should be less than 50% of the chest diameter in children older than age 1 year. The cardiac configuration on chest radiograph may provide useful diagnostic information, as certain cardiac lesions have a characteristic radiographic appearance (Tables 19-8 and 19-9). The pulmonary vasculature should be assessed. The presence of increased or decreased pulmonary blood flow provides a clue to cardiac diagnosis, particularly in the cyanotic infant (Table 19-10).

The standard posteroanterior and left lateral chest radiographs are used (Figure 19-2).

Table 19-9. Lesion-specific chest radiographic findings.

Diagnosis	Chest Radiograph Appearance
D-transposition of the great arteries	Egg on a string
Tetralogy of Fallot	Boot-shaped heart
Unobstructed total anomalous pulmonary venous drainage	Snowman
Obstructed total anomalous pulmonary venous drainage	Small heart with congested lungs
Coarctation	Figure 3 sign + rib notching

Dextrocardia

Dextrocardia is a radiographic term used when the heart is on the right side of the chest. When dextrocardia occurs with reversal of position of the other important organs of the chest and abdomen (eg, liver, lungs, and spleen), the condition is called situs inversus totalis, and the heart is usually normal. When dextrocardia occurs with the other organs normally located (situs solitus), the heart usually has severe defects.

Rarely, the abdominal organs and lungs are in situs ambiguous. The liver is central and anterior in the upper abdomen, with the stomach pushed posteriorly. Bilateral right-sidedness (asplenia syndrome) or bilateral left-sidedness (polysplenia syndrome) may occur, but in virtually all cases of situs ambiguous, congenital heart disease is present.

ECHOCARDIOGRAPHY

Echocardiography is a fundamental tool of pediatric cardiology. Using multiple ultrasound modalities (two-dimensional imaging, Doppler, and M-mode), cardiac anatomy, blood flow, intracardiac pressures, and ventricular function can be

assessed. Echocardiography is based on the physical principles of sound waves. The ultrasound frequencies utilized in cardiac imaging range from 2–10 million cycles/s.

M-mode echocardiography uses short bursts of ultrasound sent from a transducer. At acoustic interfaces, sound waves are reflected back to the transducer. The time it takes for the sound wave to return to the transducer is measured and the distance to the interface is calculated. That calculated distance is displayed against time, and a one-dimensional image is constructed that demonstrates cardiac motion. **Two-dimensional imaging** extends this technique by sending a rapid series of ultrasound bursts across a 90-degree sector, which allows construction of a two-dimensional image of the heart. **Doppler ultrasound** measures blood flow. The ultrasound transducer sends out a known frequency of sound which reflects off moving red blood cells. The transducer receives the reflected frequency and compares it with the transmitted frequency. The blood flow velocity can be calculated from the measured frequency shift. This information is used to estimate pressure gradients by the simplified Bernoulli equation, in which the pressure gradient is equal to four times the calculated velocity (Pressure gradient = $4(V^2)$).

A transthoracic echocardiogram is obtained by placing the transducer on areas of the chest where there is minimal lung interference. At each transducer position, the beam is swept through the heart and a three-dimensional image of the heart is constructed in the interpreter’s mind. Complex intracardiac anatomy and spatial relationships can be described, making possible the accurate diagnosis of simple and complex congenital heart disease. In addition to structural details, Doppler gives information about intracardiac blood flow and pressure gradients. Commonly used Doppler techniques include color flow imaging, pulsed wave, and continuous wave Doppler. Color flow imaging gives general information on the direction and velocity of flow. Pulsed and continuous wave Doppler imaging give more precise measurements of blood velocity. The role of M-mode in the ultrasound examination has decreased as other ultrasound modalities have been developed. M-mode is still used to measure LV end-diastolic and end-systolic dimensions and

▲ Figure 19–2. Position of cardiovascular structures in principal radiograph views. AO, aorta; IVC, inferior vena cava; LA, left atrium; LA APP, left atrial appendage; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

permits calculation of the LV shortening fraction, a standard estimate of LV function ($SF = \text{LV end-diastolic volume} - \text{LV systolic volume} / \text{LV end-diastolic volume}$).

A typical transthoracic echocardiogram performed by a skilled sonographer takes about 30 minutes, and patients must be still for the examination. Frequently infants and children cannot cooperate for the examination and sedation may be required.

Although echocardiography is an excellent tool for cardiac examination, there are drawbacks to the technique. Two-dimensional imaging can accurately diagnose intracardiac anatomy, but extracardiac structures such as pulmonary arteries and the aortic arch are more difficult to assess. Doppler imaging measures pressure gradients accurately but does not obtain exactly the same information obtained by cardiac catheterization. The indications for pediatric echocardiography are summarized in the American College of Cardiology/American Heart Association (ACC/AHA) practice guidelines published in 2003.

Snider AR et al: *Echocardiography in Congenital Heart Disease*. Mosby, 1997.

NUCLEAR CARDIOLOGY

Nuclear imaging is a useful adjunct to cardiopulmonary exercise testing in assessing both fixed and reversible areas of myocardial ischemia. It is valuable in evaluating myocardial perfusion in patients with Kawasaki disease, repaired anomalous left coronary artery or other coronary anomalies, myocardial bridging in the setting of hypertrophic cardiomyopathy, or chest pain in association with ECG changes with exercise.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) is valuable for evaluation and noninvasive follow-up of many congenital heart defects. It is particularly useful in imaging the thoracic vessels, which are difficult to image by transthoracic echocardiogram. Cardiac gated imaging allows dynamic evaluation of structure and blood flow of the heart and great vessels. It is invaluable to diagnose and follow aortic coarctation, to follow the progress of aortic dilation in Marfan syndrome, to quantify regurgitant lesions such as pulmonary insufficiency after repair of tetralogy of Fallot, and to measure ventricular function in patients with inadequate echocardiographic images. Because it allows computer manipulation of the images of heart and great vessels, three-dimensional MRI is an ideal noninvasive way of obtaining accurate reconstructions of the heart. If a cardiac MRI is performed in a child younger than age 8 years, general anesthesia is often required.

Boxt LM, Rozenshtein A: MR imaging of congenital heart disease. *Magn Reson Imaging Clin North Am* 2003;11:27 [PMID: 12797509].

CARDIOPULMONARY STRESS TESTING

Most children with heart disease are capable of normal activity. Data on cardiac function after exercise are essential to preventing unnecessary restriction of activities. The response to exercise is helpful in determining the need for and the timing of cardiovascular surgery as well as a useful objective outcome measure of the results of medical and surgical interventions.

Bicycle ergometers or treadmills can be used in children as young as age 5 years. The addition of a metabolic cart enables one to assess whether exercise impairment is secondary to cardiac limitation, pulmonary limitation, deconditioning, or lack of effort. Exercise variables include the ECG, blood pressure response to exercise, oxygen saturation, ventilation, maximal oxygen consumption, and peak work load attained. Cardiopulmonary stress testing is routine in children with congenital cardiac lesions to ascertain limitations, develop exercise prescriptions, assess the effect of therapies, and decide on the need for cardiac transplantation. Stress testing is also employed in children with structurally normal hearts to rule out cardiac or pulmonary pathology in children with symptoms during exertion. Significant stress ischemia or dysrhythmias warrant physical restrictions or appropriate therapy. Children with poor performance due to suboptimal conditioning benefit from a planned exercise program.

McManus A, Leung M: Maximizing the clinical use of exercise gaseous exchange testing in children with repaired cyanotic congenital heart defects: The development of an appropriate test strategy. *Sports Med* 2000;29:229 [PMID: 10783899].

ARTERIAL BLOOD GASES

Quantitating the partial oxygen pressure (P_{O_2}) or O_2 saturation (eg, by pulse oximetry) during the administration of 100% oxygen is the most useful method of distinguishing cyanosis produced primarily by heart disease or by lung disease in sick infants. In cyanotic heart disease, the partial arterial oxygen pressure (P_{aO_2}) increases very little when 100% oxygen is administered over the values obtained while breathing room air. However, P_{aO_2} usually increases very significantly when oxygen is administered to a patient who has lung disease. Table 19–11 illustrates the

Table 19–11. Examples of responses to 10 minutes of 100% oxygen in lung disease and heart disease.

	Lung Disease		Heart Disease	
	Room Air	100% O_2	Room Air	100% O_2
Color	Blue → Pink		Blue → Blue	
Oximetry	60% → 99%		60% → 62%	
P_{aO_2} (mm Hg)	35 → 120		35 → 38	

P_{aO_2} , partial arterial oxygen pressure.

responses seen in patients with heart or lung disease during the hyperoxic test. Routine pulse oximetry has been advocated as an adjunct to the current newborn screening evaluation, as it is a simple, cost-effective means of screening for major cardiac defects prior to hospital discharge.

Koppel RI et al. Effectiveness of pulse oximetry screening for congenital heart disease in asymptomatic newborns. *Pediatrics* 2003;111:451 [PMID: 12612220].

CARDIAC CATHETERIZATION & ANGIOCARDIOGRAPHY

Cardiac catheterization precisely defines the anatomic and physiologic abnormalities in simple and complex cardiac malformations. Cardiac catheterization may be performed for diagnostic purposes when further anatomic or physiologic data are needed prior to a therapeutic decision or may be performed for therapeutic purposes when the cardiac condition can be palliated or treated in the catheterization laboratory.

Therapeutic Cardiac Catheterization

Therapeutic procedures performed during cardiac catheterization include coil embolization of a PDA, balloon angioplasty with or without stent placement for aortic coarctation or branch pulmonary artery stenoses, balloon atrial septostomy, valvuloplasty of stenotic aortic or pulmonic valves, and placement of ASD and ventricular septal defect (VSD) devices. Cardiac catheterization is also performed to evaluate the effects of pharmaceutical therapy. An example of this use of catheterization is monitoring changes in pulmonary vascular resistance during the administration of nitric oxide or prostacyclin in a child with primary pulmonary hypertension. Electrophysiologic evaluation and ablation of abnormal electrical pathways in children can be performed by qualified personnel in the pediatric catheterization laboratory.

The risks of cardiac catheterization (morbidity and mortality) must be explained to the patient's family. Although the risks are very low for elective studies in older children (< 0.1%), the risk of major complications in distressed infants is about 2%. Interventional procedures such as balloon valvuloplasty increase these risks further.

Cardiac Catheterization Data

Figure 19-3 shows oxygen saturation (in percent) and pressure (in millimeters of mercury) values obtained at cardiac catheterization from the chambers and great arteries of the heart. These values are within the normal range for a child.

A. Oxygen Content and Saturation; Pulmonary (Q_p) and Systemic (Q_s) Blood Flow (Cardiac Output)

In most laboratories, left-to-right shunting is determined by changes of blood oxygen content or saturation during sam-

▲ **Figure 19-3.** Pressures (in millimeters of mercury) and oxygen saturation (in percent) obtained by cardiac catheterization in a healthy child. 3, mean pressure of 3 mm Hg in the right atrium; 5, mean pressure of 5 mm Hg in the left atrium.

pling through the right side of the heart. A significant increase in oxygen saturation between one right chamber and the other indicates the presence of a left-to-right shunt at the site of the increase. The oxygen saturation of the peripheral arterial blood should always be determined during cardiac catheterization. Normal arterial oxygen saturation is 95–97% at sea level and 92–94% at 5280 feet. Subnormal saturations suggest the presence of a right-to-left shunt, underventilation, or pulmonary disease.

The size of a left-to-right shunt is usually expressed as a ratio of pulmonary to systemic blood flow (Q_p/Q_s) or as liters per minute as determined by the Fick principle:

$$\text{Cardiac output (L/min)} = \frac{\text{Oxygen consumption (mL/min)}}{\text{Arteriovenous difference (mL/L)}}$$

B. Pressures

Pressures should be determined in all chambers and major vessels entered. It is not normal for systolic pressure in the ventricles to exceed systolic pressure in the great arteries, or mean diastolic pressure in the atria to exceed end-diastolic pressure in the ventricles. If a gradient in pressure exists, an obstruction is present, and the severity of the gradient is one criterion for the necessity of operative repair or catheter intervention. An RV systolic pressure of 100 mm Hg and a

pulmonary artery systolic pressure of 20 mm Hg yield a gradient of 80 mm Hg. In this case, the patient would be classified as having severe pulmonary stenosis requiring balloon dilation of the pulmonic valve or surgery if valvuloplasty fails to significantly reduce the gradient.

C. Pulmonary and Systemic Vascular Resistance

The vascular resistance is calculated from the following formula and reported in units or in $\text{dynes} \times \text{cm}^{-5}/\text{m}^2$:

$$\text{Resistance} = \frac{\text{Pressure}}{\text{Flow}}$$

The pressure drop used to determine pulmonary vascular resistance is calculated by subtracting the mean pulmonary artery wedge or left atrial pressure from the mean pulmonary artery pressure. This pressure drop is divided by pulmonary blood flow per square meter of body surface area. (Pulmonary blood flow is determined by thermodilution or from the Fick principle, as noted earlier.) Similarly, systemic vascular resistance is determined by subtracting the mean central venous pressure from the mean systemic arterial pressure and dividing this pressure drop by systemic blood flow.

Normally, the pulmonary vascular resistance ranges from 1–3 U/m^2 , or from 80–240 $\text{dynes} \times \text{cm}^{-5}/\text{m}^2$. Systemic vascular resistance ranges from 15–20 U/m^2 , or from 1200–1600 $\text{dynes} \times \text{cm}^{-5}/\text{m}^2$. If pulmonary resistance is greater than 10 units or the ratio of pulmonary to systemic resistance is greater than 0.5, the child may have pulmonary vascular disease and therefore be inoperable.

Freedom RM et al: *Congenital Heart Disease: Textbook of Angiography*. Futura, 1997.

Simpson JM et al: Cardiac catheterization of low birth weight infants. *Am J Cardiol* 2001;87:1372 [PMID: 11397356].

PERINATAL & NEONATAL CIRCULATION

At birth, two events occur that affect the cardiovascular and pulmonary system (1) the umbilical cord is clamped, removing the placenta from the maternal circulation; and (2) breathing commences. As a result, marked changes in the circulation occur. During fetal life, the placenta offers low resistance to blood flow. In contrast, the pulmonary arterioles are markedly constricted and offer high resistance to the flow of blood into the lungs. Pulmonary blood flow accounts for only 7–10% of the combined in utero ventricular output. At birth, pulmonary blood flow dramatically increases with the fall in pulmonary vascular resistance and pressure. The causes of prolonged high pulmonary vascular resistance include physical factors (lack of an adequate air-liquid interface or ventilation), low oxygen tension, and vasoactive mediators such as elevated endothelin peptide levels or

leukotrienes. Clamping the cord produces an immediate increase in resistance to flow in the systemic circuit. As breathing commences, the PO_2 of the small pulmonary arterioles increases, causing their constriction to decrease and producing a decrease in pulmonary vascular resistance. Increased oxygen tension, rhythmic lung distention, and production of nitric oxide as well as prostacyclin play major roles in the fall in pulmonary vascular resistance at birth. The pulmonary vascular resistance falls below that of the systemic circuit, resulting in a reversal in direction of blood flow across the ductus arteriosus.

Functional closure of the ductus arteriosus begins shortly after birth. The ductus arteriosus usually remains patent for 3–5 days. During the first hour after birth, a small right-to-left shunt is present (as in the fetus). However, after 1 hour, bidirectional shunting occurs, with the left-to-right direction predominating. In most cases, right-to-left shunting disappears completely by 8 hours. In patients with severe hypoxia (eg, in the syndrome of persistent pulmonary hypertension of the newborn), pulmonary vascular resistance remains high, resulting in a continued right-to-left shunt. Increased PO_2 of the arterial blood causes spasm of the ductus. Although flow through the ductus arteriosus usually is gone by 5 days of life, the vessel does not close anatomically for 7–14 days.

In fetal life, the foramen ovale serves as a one-way valve shunting blood from the inferior vena cava through the right atrium into the left atrium. At birth, because of the changes in the pulmonary and systemic vascular resistance and the increase in the quantity of blood returning from the pulmonary veins to the left atrium, the left atrial pressure rises above that of the right atrium. This functionally closes the flap of the foramen ovale, preventing flow of blood across the septum. The foramen ovale remains probe patent in 10–15% of adults.

Persistent pulmonary hypertension is a clinical syndrome of full-term infants. The neonate develops tachypnea, cyanosis, and pulmonary hypertension during the first 8 hours after delivery. These infants have massive right-to-left ductal or foramen shunting (or both) for 3–7 days because of high pulmonary vascular resistance. Progressive hypoxia and acidosis will cause early death unless the pulmonary resistance can be lowered. Postmortem findings include increased thickness of the pulmonary arteriolar media. Increase alveolar PO_2 with hyperventilation, alkalosis, paralysis, surfactant administration, high-frequency ventilation, and cardiac pressors can usually reverse the resistance. Inhaled nitric oxide selectively dilates pulmonary vasculature, produces a sustained improvement in oxygenation, and has reduced the need for extracorporeal membrane oxygenation.

In the normal newborn, pulmonary vascular resistance and pulmonary arterial pressure continue to fall during the first weeks of life as a result of demuscularization of the pulmonary arterioles. Adult levels of pulmonary resistance and pressure are normally achieved by 4–6 weeks of age. It is

at this time typically that signs of pulmonary overcirculation associated with left-to-right shunts (VSD or atrioventricular septal defect [AVSD]) appear.

Fineman JR, Soifer SJ: The fetal and neonatal circulations. In Rudolph AR (editor): *Congenital Diseases of the Heart: Clinical Physiologic Considerations*, 2nd ed. Futura, 2001.

HEART FAILURE

Heart failure (HF) is the clinical condition in which the heart fails to meet the circulatory and metabolic needs of the body. The term *congestive heart failure* is falling out of favor, as some patients with significant cardiac dysfunction have symptoms of exercise intolerance and fatigue without evidence of congestion. Almost all infants who develop HF from congenital heart lesions do so by 6 months of age. Common causes of HF in infants include VSD, PDA, coarctation of the aorta, AV septal defect, large arteriovenous malformations, and chronic atrial tachyarrhythmias. Metabolic, mitochondrial, and neuromuscular disorders with associated cardiomyopathy present at various ages depending on the diagnosis. HF due to acquired conditions such as myocarditis occur at any age. Children with HF may present with irritability, diaphoresis with feeds, fatigue, exercise intolerance, or evidence of pulmonary congestion (see Table 19–1).

Treatment of Heart Failure

The therapy of HF should be directed toward the underlying cause as well as the symptoms. Regardless of the cause, neurohormonal activation occurs early when ventricular systolic dysfunction is present. Plasma catecholamine levels (eg, norepinephrine) increase and cause tachycardia, diaphoresis, and, by activating the renin-angiotensin system, peripheral vasoconstriction and salt and water retention. There is no gold standard diagnostic or therapeutic approach to HF in children. Treatment must be individualized and

therapies should be aimed at improving cardiac performance by targeting the three determinants of cardiac performance: (1) preload, (2) afterload, and (3) contractility.

Inpatient Management of Heart Failure

Patients with cardiac decompensation may require hospitalization for initiation or augmentation of HF therapy. Table 19–12 demonstrates intravenous inotropic agents used to augment cardiac output and their relative effect on heart rate, systemic vascular resistance, and cardiac index. The drug used will depend in part on the cause of the HF.

A. Intravenous Inotropic Support

1. Afterload reduction

A. MILRINONE—This selective phosphodiesterase inhibitor increases cyclic adenosine monophosphate, thereby improving the inotropic state of the heart. In addition to a dose-dependent increase in cardiac contractility, milrinone is a systemic and pulmonary vasodilator and thus an effective agent in both right and left ventricular systolic dysfunction. Milrinone reduces the incidence of low cardiac output syndrome following open heart surgery. The usual dosage range is 0.25–0.75 mcg/kg/min.

B. NITROGLYCERIN—Nitroglycerin functions primarily as a dilator of venous capacitance vessels and causes a reduction of right and left atrial pressure. Systemic blood pressure may also fall, and reflex tachycardia may occur. Nitroglycerin is used to improve coronary blood flow and may be especially useful when cardiac output is reduced because of coronary underperfusion following congenital heart surgery. The usual intravenous dosage range is 1–3 mcg/kg/min.

2. Enhancement of contractility

A. DOPAMINE—This naturally occurring catecholamine increases myocardial contractility primarily via cardiac β -adrenergic activation. Dopamine also directly acts on renal dopamine receptors to improve renal perfusion. The usual dose range for HF is 3–10 mcg/kg/min.

Table 19–12. Intravenous inotropic agents.

Drug	Dose	Renal Perfusion	Heart Rate	Cardiac Index	SVR
Dopamine	2–5 mcg/kg/min	↑ via vasodilation	0	0	0
	5–10	↑ via ↑ cardiac index	↑	↑	0
	> 10	↓	↑	↑	↑
Dobutamine	2.5–10 mcg/kg/min	↑ via ↑ cardiac index	↑	↑	↑↓
Epinephrine	0.2–2.0 mcg/kg/min	↓	↑	↑	↑
Norepinephrine	0.05–0.1 mcg/kg/min	↓	0	↑	↑↑
Isoproterenol	0.05–2.0 mcg/kg/min	0	↑↑	↑	↓↓

SVR, systemic vascular resistance.

B. DOBUTAMINE—This synthetic catecholamine increases myocardial contractility secondary to cardiospecific β -adrenergic activation and produces little peripheral vasoconstriction. Dobutamine does not usually cause marked tachycardia, which is a distinct advantage. However, the drug does not selectively improve renal perfusion as does dopamine. The usual dose range is essentially the same as for dopamine.

3. Mechanical circulatory support—Mechanical support is indicated in children with severe, refractory myocardial failure secondary to cardiomyopathy, myocarditis, or following cardiac surgery. Mechanical support is used for a limited time while cardiac function improves, or as a bridge to cardiac transplantation.

A. EXTRACORPOREAL MEMBRANE OXYGENATION (ECMO)—ECMO is a temporary means of providing oxygenation, carbon dioxide removal, and hemodynamic support to patients with cardiac or pulmonary failure refractory to conventional therapy. Flow from a catheter positioned in the venous system (eg, right atrium) passes through a membrane oxygenator and then is delivered back to the patient via a catheter in the arterial system (eg, aorta or common carotid artery). Flow rates are adjusted to maintain adequate systemic perfusion, as judged by mean arterial blood pressure, acid-base status, end-organ function, and mixed venous oxygen saturation. The patient is monitored closely for improvement in cardiac contractility. Risks are significant and include severe internal and external bleeding, infection, thrombosis, and pump failure.

B. VENTRICULAR ASSIST DEVICES—Use of pulsatile assist devices is limited in children by patient size, availability, and institutional expertise. These devices allow for less invasive hemodynamic support than ECMO. A cannula positioned in the apex of the ventricle removes blood from the ventricle using a battery-operated pump. Blood is then returned to the patient through a separate cannula positioned in the aorta or pulmonary artery, depending on the ventricle being supported. Ventricular assist carries lower risk of bleeding and pump failure than ECMO, but the risk of infection and thrombosis remain.

Outpatient Management of Heart Failure

A. Medications

1. Afterload-reducing agents—Oral afterload-reducing agents improve cardiac output by decreasing systemic vascular resistance. Angiotensin-converting enzyme (ACE) inhibitors (captopril, enalapril, and lisinopril) are first-line therapy in patients with HF requiring long-term treatment. These agents block angiotensin II-mediated systemic vasoconstriction and are particularly useful in children with structurally normal hearts but reduced LV myocardial function (ie, myocarditis or dilated cardiomyopathies). They are also useful in ameliorating mitral and aortic insufficiency and

have a role in controlling refractory HF in patients with large left-to-right shunts in whom systemic vascular resistance is elevated.

2. β -Blockade— β -Blockers may be useful adjunctive therapy in children with refractory HF already taking ACE inhibitors. Excessive circulating catecholamines are present due to the activation of the sympathetic nervous system by HF. Although beneficial acutely, this compensatory response over time produces myocardial fibrosis, myocyte hypertrophy, and myocyte apoptosis that contribute to the progression of HF. β -Blockers (eg, carvedilol and metoprolol) antagonize this sympathetic activation and may offset these deleterious effects. Side effects of β -blockers are significant and include bradycardia, hypotension, and worsening HF in some patients.

3. Diuretics—Diuretic therapy may be necessary in HF to maintain the euvolemic state.

A. FUROSEMIDE—This rapid-acting loop diuretic may be given intravenously or orally. It removes large amounts of potassium and chloride from the body, producing hypochloremic metabolic alkalosis when used chronically. Electrolytes should be monitored during long-term therapy.

B. THIAZIDES—Thiazides are distal tubular diuretics used to complement furosemide in severe cases of HF.

C. SPIRONOLACTONE—Spironolactone is a potassium-sparing aldosterone inhibitor. It is used frequently in conjunction with furosemide or thiazides for its enhanced diuretic function. Because it spares potassium, supplemental potassium may be avoided. Spironolactone may also be used as a neurohormonal antagonist with potential benefit in HF regardless of its diuretic effect.

4. Digitalis—Digitalis is a cardiac glycoside with a positive inotropic effect on the heart and an associated decrease in systemic vascular resistance. The preparation of digitalis used in clinical practice is digoxin. Large studies in adult patients with HF have not demonstrated decreased mortality of HF with digoxin use, but treatment is associated with reduced hospitalization rates for HF exacerbations.

A. DOSING—The routine schedule consists of giving one half of the total digitalizing dose initially, then one quarter of the total digitalizing dose at 6 and 12 hours of therapy (Table 19–13). Twenty-four hours after the last digitalizing dose, maintenance therapy is started. Serum digoxin levels are not routinely monitored unless there are concerns regarding compliance or toxicity.

B. DIGITALIS TOXICITY—Any dysrhythmia that occurs during digoxin therapy should be attributed to the drug until proven otherwise. Ventricular bigeminy and first-, second-, or third-degree AV block are characteristic of digoxin toxicity. A trough level should be obtained if digoxin toxicity is suspected.

Table 19-13. Digoxin dosing schedule.

Age	Parenteral	Oral
Premature	0.035 mg/kg	0.04 mg/kg
1 wk-2 y	0.05 mg/kg	0.06 mg/kg
< 1 wk or > 2 y	0.04 mg/kg	0.05 mg/kg

c. DIGITALIS POISONING—This acute emergency must be treated without delay. Digoxin poisoning most commonly occurs in toddlers who have taken their parents' or grandparents' medications. The child's stomach should be emptied immediately by gastric lavage even if several hours have passed since ingestion. Patients who have ingested massive amounts of digoxin should receive large doses of activated charcoal. In advanced heart block, atropine or temporary ventricular pacing may be needed. Digoxin immune Fab can be used to reverse potentially life-threatening intoxication. Antiarrhythmic agents may be useful.

5. Fluid restriction—Fluid restriction is rarely used in pediatric cardiology due to the effectiveness of diuretics. Ensuring adequate caloric intake to promote growth is a more important goal in children with HF.

GENETIC BASIS OF CONGENITAL HEART DISEASE

Congenital heart disease often has a genetic basis. The most common genetic abnormality is a microdeletion in the long arm of chromosome 22 (22q11) associated with DiGeorge syndrome. These children often have conotruncal abnormalities such as truncus arteriosus, tetralogy of Fallot, or double-outlet RV. Intrauterine factors such as maternal diabetes, alcohol consumption, progesterone use, viral infection, and other maternal teratogen exposure are associated with an increased incidence of cardiac malformations. Genetic diagnosis may allow for more accurate prediction of recurrence risk in subsequent pregnancies.

ACYANOTIC CONGENITAL HEART DISEASE

DEFECTS IN SEPTATION

1. Atrial Septal Defect (Ostium Secundum Variant)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Fixed, widely split S_2 , RV heave.
- ▶ Grade I-III/VI ejection systolic murmur at the pulmonary area.
- ▶ Large shunts cause a diastolic flow murmur at the lower left sternal border.
- ▶ ECG shows rsR' in lead V_1 .
- ▶ Frequently asymptomatic.

▶ General Considerations

Atrial septal defect (ASD) is an opening in the atrial septum permitting the shunting of blood between the atria. There are three major types: ostium secundum, ostium primum, and sinus venosus. Ostium secundum is the most common type. Ostium primum defect is associated with atrioventricular septal defect. The sinus venosus defect is frequently associated with abnormal pulmonary venous return, as the location of the sinus venosus is intimately related to the right upper pulmonary vein.

Ostium secundum ASD occurs in 10% of patients with congenital heart disease and is two times more common in females than males. The defect is most often sporadic but may be familial. Pulmonary hypertension and growth failure are uncommon complications in infancy and childhood. After the third decade, atrial arrhythmias or pulmonary vascular disease may develop. In the setting of pulmonary vascular disease, left-to-right shunting decreases, and right-to-left shunting becomes the major clinical abnormality (Eisenmenger syndrome).

▶ Clinical Findings

A. Symptoms and Signs

Most infants and children with ASD have no cardiovascular symptoms. With age, some never develop symptoms. Others develop easy fatigability as older children or adults, or rarely, HF. The direction of flow across the ASD is determined by the compliance of the underlying ventricle. Therefore, cyanosis does not occur unless RV dysfunction occurs, usually as a result of pulmonary hypertension that causes reversal of the shunt across the defect.

Peripheral pulses are normal and equal. The heart is usually hyperactive, with an RV heave felt best at the mid to lower left sternal border. S_2 at the pulmonary area is widely split and often fixed. The pulmonary component is normal

in intensity. A grade I–III/VI ejection-type systolic murmur is heard best at the left sternal border in the second intercostal space. This murmur is caused by increased flow across the pulmonic valve, not flow across the ASD. A mid-diastolic murmur is often heard in the fourth intercostal space at the left sternal border. This murmur is caused by increased flow across the tricuspid valve during diastole. The presence of this murmur suggests high flow with a pulmonary-to-systemic blood flow ratio greater than 2:1.

B. Imaging

Radiographs may show cardiac enlargement. The main pulmonary artery may be dilated and pulmonary vascular markings increased in large defects owing to the increased pulmonary blood flow.

C. Electrocardiography

The usual ECG shows right axis deviation. In the right precordial leads, an rsR' pattern is usually present. In patients with a mutation in the cardiac homeobox gene (*NKX2-5*), AV heart block may be present.

D. Echocardiography

Echocardiography shows a dilated right atrium and RV. Direct visualization of the ASD by two-dimensional echocardiography, plus demonstration of a left-to-right shunt through the defect by color-flow Doppler, confirms the diagnosis and has eliminated the need for cardiac catheterization prior to surgical or catheter closure of the defect. Assessment of all pulmonary veins should be made to rule out associated anomalous pulmonary venous return.

E. Cardiac Catheterization

Oximetry shows significant increase in oxygen saturation at the atrial level. The pulmonary artery pressure and pulmonary vascular resistance are usually normal. The $Q_p:Q_s$ may vary from 1.5:1 to 4:1. Cardiac catheterization is rarely needed for diagnostic purposes but transcatheter closure of an ostium secundum ASD is now the preferred method of closure.

► Treatment

Surgical or catheterization closure is generally recommended for symptomatic children with a large atrial level defect and associated right heart dilation. In the asymptomatic child with a large hemodynamically significant defect, closure is performed electively at age 1–3 years. Many defects are amenable to nonoperative device closure during cardiac catheterization, but the defect must have adequate tissue rims on all sides on which to anchor the device. The mortality for surgical closure is less than 1%. When closure is performed by age 3 years, late complications of RV dysfunction and dysrhythmias are avoided.

► Course & Prognosis

Patients usually tolerate an ASD well in the first two decades of life, and the defect often goes unnoticed until middle or late adulthood. Pulmonary hypertension and reversal of the shunt are rare late complications. Infective endocarditis is uncommon. Spontaneous closure occurs, most frequently in children with a defect less than 4 mm in diameter. Exercise tolerance and oxygen consumption in surgically corrected children are generally normal, and restriction of physical activity is unnecessary.

Sigler M et al: Histological confirmation of complete endothelialisation of a surgically removed Amplatzer ASD occluder. *Heart* 2006;92:1723 [PMID: 17105877].

2. Ventricular Septal Defect

- Holosystolic murmur at lower left sternal border with RV heave.
- Presentation and course depend on size of defect and the pulmonary vascular resistance.
- Clinical features are HF, failure to thrive, and diaphoresis with feeds.
- Left-to-right shunt with normal pulmonary vascular resistance.
- Large defects may cause Eisenmenger syndrome if not repaired early.

► General Considerations

Simple ventricular septal defect (VSD) is the most common congenital heart malformation, accounting for about 30% of all congenital heart disease. Defects in the ventricular septum occur both in the membranous portion of the septum (most common) and the muscular portion. VSDs follow one of four courses:

A. Small, Hemodynamically Insignificant Ventricular Septal Defects

Between 80% and 85% of VSDs are small (< 3 mm in diameter) at birth and will close spontaneously. In general, small defects in the muscular interventricular septum will close sooner than those in the membranous septum. In most cases, a small VSD never requires surgical closure. Fifty percent of

small VSDs will close by age 2 years, and 90% by age 6 years. The remaining 10% will close during the school years. Parents should be told at the time of diagnosis and echocardiographic confirmation that all small VSDs will eventually close.

B. Moderate Ventricular Septal Defects

Asymptomatic patients with moderate VSDs (3–5 mm in diameter) account for 3–5% of children with VSDs. In general these children do not have clear indicators for surgical closure. Historically, in those who had cardiac catheterization, the ratio of pulmonary to systemic blood flow is usually less than 2:1, and serial cardiac catheterizations demonstrate that the shunts get progressively smaller. If there is neither HF nor pulmonary hypertension, these defects can be followed until spontaneous closure.

C. Large Ventricular Septal Defects with Normal Pulmonary Vascular Resistance

These defects are usually 6–10 mm in diameter. Unless they become markedly smaller within a few months after birth, they will require surgery. The timing of surgery depends on the clinical situation. Many infants with large VSDs and normal pulmonary vascular resistance develop HF and failure to thrive by age 3–6 months, and require correction at that time. In all cases, surgery before age 2 years is required to decrease the risk of pulmonary vascular disease.

D. Large Ventricular Septal Defects with Pulmonary Vascular Obstructive Disease

The direction of flow across a VSD is determined by the downstream resistance, explaining why flow is usually left-to-right. In large VSDs, ventricular pressures are equal, causing increased pulmonary artery pressure. In addition, shear stress caused by increased volume in the pulmonary circuit causes increased resistance over time. The vast majority of patients with inoperable pulmonary hypertension develop the condition progressively. The combined data of the multicenter National History Study indicate that almost all cases of irreversible pulmonary hypertension can be prevented by surgical repair of a large VSD before age 2 years.

► Clinical Findings

A. Symptoms and Signs

Patients with small or moderate left-to-right shunts usually have no cardiovascular symptoms. Patients with large left-to-right shunts are usually ill early in infancy. These infants have frequent respiratory infections and gain weight slowly. Dyspnea, diaphoresis, and fatigue are common. HF can develop as early as 1 to 6 months of age. After the first year, symptoms usually improve, although easy fatigability may persist. Older children may experience exercise intolerance. Over time, in children with persistent large left-to-right shunt, the pulmonary vascular bed undergoes structural

changes, leading to increased pulmonary vascular resistance and reversal of the shunt from left-to-right, to right-to-left (Eisenmenger syndrome). Cyanosis will then be present.

1. Small left-to-right shunt—No lifts, heaves, or thrills are present. The first sound at the apex is normal, and the second sound at the pulmonary area is split physiologically. A grade II–IV/VI, medium- to high-pitched, harsh pansystolic murmur is heard best at the left sternal border in the third and fourth intercostal spaces. The murmur radiates over the entire precordium. No diastolic murmurs are heard.

2. Moderate left-to-right shunt—Slight prominence of the precordium with moderate LV heave is evident. A systolic thrill may be palpable at the lower left sternal border between the third and fourth intercostal spaces. The second sound at the pulmonary area is most often split but may be single. A grade III–IV/VI, harsh pansystolic murmur is heard best at the lower left sternal border in the fourth intercostal space. A mitral diastolic flow murmur indicates that the pulmonary blood flow is significantly increased by the large shunt.

3. Large ventricular septal defects with pulmonary hypertension—The precordium is prominent, and the sternum bulges. Both LV and RV heaves are palpable. S_2 is palpable in the pulmonary area. A thrill may be present at the lower left sternal border. S_2 is usually single or narrowly split, with accentuation of the pulmonary component. The murmur ranges from grade I to grade IV/VI and is usually harsh and pansystolic. Occasionally, when the defect is large or ventricular pressures approach equivalency, a murmur is difficult to hear. A diastolic flow murmur may be heard, depending on the size of the shunt.

B. Imaging

In patients with small shunts, the chest radiograph may be normal. Patients with large shunts have significant cardiac enlargement involving both the left and right ventricles and the left atrium. The main pulmonary artery segment may be dilated. The pulmonary vascular markings are increased.

C. Electrocardiography

The ECG is normal in small left-to-right shunts. Left ventricular hypertrophy (LVH) usually occurs in patients with large left-to-right shunts and normal pulmonary vascular resistance. Combined ventricular enlargement occurs in patients with pulmonary hypertension caused by increased flow, increased resistance, or both. Pure RV hypertrophy occurs in patients with pulmonary hypertension secondary to pulmonary vascular obstruction induced by long-standing left-to-right shunt (Eisenmenger syndrome).

D. Echocardiography

Two-dimensional echocardiography can reveal the size of a VSD and pinpoint its anatomic location. Color-flow Dop-

pler allows detection of the smallest VSDs. Multiple defects can be detected by combining two-dimensional and color-flow imaging. Doppler can further evaluate the VSD by estimating the pressure difference between the left and right ventricles. A pressure difference greater than 50 mm Hg confirms the absence of severe pulmonary hypertension.

E. Cardiac Catheterization and Angiocardiography

The ability to describe the VSD anatomy and estimate the pulmonary artery pressures on the basis of the gradient across the VSD, allows for the vast majority of isolated defects to be repaired without cardiac catheterization and angiocardiography. Catheterization is indicated in those patients with increased pulmonary vascular resistance. The pulmonary artery pressure may vary from normal to systemic level (equal to the aortic pressure). Pulmonary artery wedge pressure (a surrogate for direct left atrial pressure) may be normal to increased. Pulmonary vascular resistance varies from normal to markedly increased. Angiocardiographic examination defines the number, size, and location of the defects.

► Treatment

A. Medical Management

Patients who develop HF should receive anticongestive measures (see section on Heart Failure, earlier), particularly diuretics and systemic afterload reduction. If the patient does not respond to anticongestive measures, or if he or she shows progressive pulmonary hypertension, surgery is indicated without delay.

B. Surgical Treatment

Patients with cardiomegaly, poor growth, poor exercise tolerance, or other clinical abnormalities who have a significant shunt (> 2:1) without significant pulmonary hypertension typically undergo surgical repair at age 3–6 months. A synthetic or pericardial patch is used for primary closure. The age of elective surgery has decreased and most defects are now closed in infancy. Patients with pulmonary artery pressures equal to systemic pressure undergo surgical repair well before age 2 years to avoid pulmonary vascular disease. In most centers these children have surgery before age 1 year. As a result, Eisenmenger syndrome has been virtually eliminated. In all cases of VSD, the surgical mortality rate is below 2%.

Transcatheter closure of muscular VSDs is now becoming common. Perimembranous VSDs have also been closed in children during catheterization, but an alarmingly high incidence of complete heart block after placement of the occluding device has slowed the acceptance of this approach.

► Course & Prognosis

Significant late dysrhythmias are uncommon. Functional exercise capacity and oxygen consumption are usually nor-

mal, and physical restrictions are unnecessary. Adults with corrected defects have normal quality of life. With complete VSD closure, antibiotic prophylaxis for bacterial endocarditis can be discontinued 6 months after surgery.

Sondheimer HM, Rahimi-Alangi K: Current management of ventricular septal defect. *Cardiol Young* 2006;16(Suppl 3):131 [PMID: 17378052].

3. Atrioventricular Septal Defect

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Murmur often inaudible in neonates.
- Loud pulmonary component of S₂.
- Common in infants with Down syndrome.
- ECG with extreme left axis deviation.

► General Considerations

Atrioventricular septal defect (AVSD) results from incomplete fusion of the embryonic endocardial cushions. The endocardial cushions help to form the “crux” of the heart, which includes the lower portion of the atrial septum, the membranous portion of the ventricular septum, and the septal leaflets of the tricuspid and mitral valves. AVSD accounts for about 4% of all congenital heart disease. Sixty percent of children with Down syndrome have congenital heart disease, and of these, 35–40% has AVSD.

AV septal defects are defined as partial or complete. The physiology of the defect is determined by the location of the AV valves. If the valves are located in the midportion of the defect (complete AVSD), both atrial and ventricular components of the septal defect are present and the left- and right-sided AV valves share a common ring or orifice. In the partial form there is a low insertion of the AV valves resulting in primum ASD without a ventricular component. In partial AVSD, there are two separate AV valve orifices and usually a cleft in the left-sided valve

Partial AVSD behaves like an isolated ASD with variable amounts of regurgitation through the cleft in the left AV valve. The complete form causes large left-to-right shunts at both the ventricular and atrial levels with AV valve regurgitation. If there is increased pulmonary vascular resistance, the shunts may be bidirectional. Bidirectional shunting is more common in Down syndrome or in older children who have not undergone repair.

► Clinical Findings

A. Symptoms and Signs

The partial form may produce symptoms similar to ostium secundum ASD. Patients with complete AVSD usually are severely affected. HF often develops in infancy, and recurrent bouts of pneumonia are common.

In the neonate with the complete form, the murmur may be inaudible due to relatively equal systemic and pulmonary vascular resistance (PVR). After 4–6 weeks, as PVR drops, a nonspecific systolic murmur develops. The murmur is usually not as harsh as that of isolated VSD. There is both right- and left-sided cardiac enlargement. S_2 is loud, and a pronounced diastolic flow murmur may be heard at the apex and the lower left sternal border.

If severe pulmonary vascular obstructive disease is present, there is usually dominant RV enlargement. S_2 is palpable at the pulmonary area and no thrill is felt. A nonspecific short systolic murmur is heard at the lower left sternal border. No diastolic flow murmurs are heard. In severe cases predominant right-to-left shunting causes cyanosis.

B. Imaging

Cardiac enlargement is always present. In the complete form, all four chambers are enlarged. Pulmonary vascular markings are increased. In patients with pulmonary vascular obstructive disease, only the main pulmonary artery segment and its branches are prominent and the peripheral pulmonary vascular markings are usually decreased.

C. Electrocardiography

In all forms of AVSD, there is extreme left axis deviation with a counterclockwise loop in the frontal plane. The ECG is an important diagnostic tool. Only 5% of isolated VSDs have this ECG abnormality. First-degree heart block occurs in over 50% of patients. Right, left, or combined ventricular hypertrophy is present depending on the particular defect and the presence or absence of pulmonary hypertension.

D. Echocardiography

Echocardiography is the diagnostic test of choice. The anatomy can be well visualized by two-dimensional echocardiography. Both AV valves are at the same level, compared with the normal heart in which the tricuspid valve is more apically positioned. The size of the atrial and ventricular components of the defect can be measured. AV valve regurgitation can be detected. The LV outflow tract is elongated (gooseneck appearance), which produces systemic outflow obstruction.

E. Cardiac Catheterization and Angiography

Cardiac catheterization is not routinely used to evaluate AVSD but may be used to assess pulmonary artery pressures

in the older infant with Down syndrome, as this patient group is predisposed to early-onset pulmonary hypertension. Increased oxygen saturation in the RV or the right atrium identifies the level of the shunt. Angiography reveals the characteristic gooseneck deformity of the LV outflow tract in the complete form.

► Treatment

Spontaneous improvement does not occur. Surgery is always required. In the partial form, surgery carries a low mortality rate (1–2%), but patients require follow-up because of late-occurring LV outflow tract obstruction and mitral valve dysfunction. The complete form carries a higher mortality rate. Complete correction in the first year of life, prior to the onset of irreversible pulmonary hypertension, is obligatory. If possible, primary correction should be performed when the child is well and weighs more than 5 kg. During surgery, transesophageal echocardiography is used to assess the adequacy of repair before discontinuing cardiopulmonary bypass.

PATENT (PERSISTENT) DUCTUS ARTERIOSUS

► General Considerations

PDA is the persistence of the normal fetal vessel joining the pulmonary artery to the aorta. It closes spontaneously in normal term infants at 3–5 days of age. PDA accounts for 10% of all congenital heart disease. The incidence of PDA is higher in infants born at altitudes over 10,000 ft. It is twice as common in females as in males. The frequency of PDA in preterm infants weighing less than 1500 g ranges from 20–60%. The defect may occur as an isolated abnormality or with associated lesions, commonly coarctation of the aorta and VSD. It is critical to recognize patients with a PDA, but without readily apparent findings of other associated lesions, who are being kept alive by the patent ductus (eg, a patient with PDA and unsuspected pulmonary atresia).

► Clinical Findings

A. Symptoms and Signs

The clinical findings and course depend on the size of the shunt and the degree of pulmonary hypertension.

1. Typical patent ductus arteriosus—Pulses are bounding, and pulse pressure is widened due to diastolic runoff through the ductus. S_1 is normal and S_2 is usually narrowly split. In large shunts, S_2 may have a paradoxical split (ie, S_2 closes on inspiration and splits on expiration). Paradoxical

splitting is caused by volume overload of the LV and prolonged ejection of blood from this chamber.

The murmur is characteristic. It is a rough machinery murmur maximal at the second left intercostal space. It begins shortly after S_1 , rises to a peak at S_2 , and passes through the S_2 into diastole, where it becomes a decrescendo murmur and fades before the S_1 . The murmur tends to radiate well to the anterior lung fields but relatively poorly to the posterior lung fields. A diastolic flow murmur is often heard at the apex.

2. Patent ductus arteriosus with increased pulmonary vascular resistance—Flow across the ductus is diminished. S_2 is single and accentuated, and no significant heart murmur is present. The pulses are normal rather than bounding.

B. Imaging

In simple PDA, the radiographic appearance depends on the size of the shunt. If the shunt is small, the heart is not enlarged. If the shunt is large, both left atrial and LV enlargement may be seen. The aorta and the main pulmonary artery segment may be prominent.

C. Electrocardiography

The ECG may be normal or may show LVH, depending on the size of the shunt. In patients with pulmonary hypertension caused by increased blood flow, biventricular hypertrophy usually occurs. In pulmonary vascular obstructive disease, pure right ventricular hypertrophy (RVH) occurs.

D. Echocardiography

Echocardiography provides direct visualization of the ductus and confirms the direction and degree of shunting. High-velocity left-to-right flow argues against abnormally elevated pulmonary vascular resistance, and as pulmonary vascular resistance drops during the neonatal period, higher velocity left-to-right shunting is usually seen. If suprasystemic pulmonary vascular resistance is present, flow across the ductus will be seen from right-to-left. Ductal-dependent pulmonary or systemic blood flow must be recognized by echocardiography, as closure of a PDA in this setting would obviously be contraindicated.

E. Cardiac Catheterization and Angiography

Children with PDA never require a cardiac catheterization for diagnostic purposes. However, children more than 5 kg with PDA routinely undergo PDA closure in the catheterization laboratory.

► Treatment

Treatment is surgical when the PDA is large and the patient is small, except in patients with pulmonary vascular obstructive disease. Patients with large left-to-right shunts require

repair by age 1 year to prevent the development of progressive pulmonary vascular obstructive disease. Symptomatic PDA with normal pulmonary artery pressure can be safely coil or device-occluded in the catheterization laboratory after the child has reached 5 kg.

Patients with nonreactive pulmonary vascular obstruction with resistance greater than 10 Wood units (normal, < 3) and a ratio of pulmonary to systemic resistance greater than 0.7 (normal, < 0.3) despite vasodilator therapy (eg, nitric oxide) should not undergo PDA closure. These patients are made worse by PDA closure because the flow through the ductus maintains cardiac output to the systemic circulation in the presence of high pulmonary vascular resistance.

Symptomatic PDA is common in preterm infants. Indomethacin, a prostaglandin synthesis inhibitor, is often used to close PDA in premature infants. Indomethacin does not close the PDA of full-term infants or children. The success of indomethacin therapy is as high as 80–90% in premature infants with a birth weight greater than 1200 g, but it is less successful in smaller infants. Indomethacin (0.1–0.3 mg/kg orally every 8–24 hours or 0.1–0.3 mg/kg parenterally every 12 hours) can be used if there is adequate renal, hematologic, and hepatic function. Because indomethacin may impair renal function, urine output, BUN, and creatinine should be monitored during therapy. If indomethacin is not effective and the ductus remains hemodynamically significant, surgical ligation should be performed. If the ductus closes substantially so that it is no longer hemodynamically significant, even with some residual flow from left to right, surgery is not needed, and a second course of indomethacin may be used. Recent studies from Europe indicate that ibuprofen may be as effective as indomethacin for medical closure of preterm PDA.

► Course & Prognosis

Patients with simple PDA and small-to-moderate shunts usually do well without surgery. However, in the third or fourth decade of life, symptoms of easy fatigability, dyspnea on exertion, and exercise intolerance appear, usually as a consequence of progressive pulmonary hypertension or HF.

Spontaneous closure of a PDA may occur up to age 1 year, especially in preterm infants. After age 1 year, spontaneous closure is rare. Because infective endocarditis is a potential complication, closure is recommended if the defect persists beyond age 1 year.

The prognosis for patients with large shunts or pulmonary hypertension is not as good. Poor growth and development, frequent pneumonias, and HF occur in these children. Patients beyond the newborn period with PDA and large shunts should have transcatheter device closure of their PDA.

RIGHT-SIDED OBSTRUCTIVE LESIONS

1. Pulmonary Valve Stenosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ No symptoms in mild or moderate stenosis.
- ▶ Cyanosis and a high incidence of right-sided HF in ductal-dependent lesions.
- ▶ RV lift with systolic ejection click heard at the third left intercostal space.
- ▶ S_2 widely split with soft to inaudible P_2 ; grade I-VI/VI systolic ejection murmur, maximal at the pulmonary area.
- ▶ Dilated pulmonary artery on chest radiograph.

▶ General Considerations

Pulmonic valve stenosis accounts for 10% of all congenital heart disease. In the usual case, the cusps of the pulmonary valve are fused to form a membrane or diaphragm with a hole in the middle from 2–10 mm in diameter. Occasionally, only two cusps are fused, producing a bicuspid pulmonary valve. In more severe cases, secondary infundibular (subvalve) stenosis occurs. The pulmonary valve annulus is usually small with moderate to marked poststenotic dilation of the main pulmonary arteries.

Obstruction to blood flow across the pulmonary valve causes an increase in RV pressure. Pressures greater than systemic are potentially life-threatening and are associated with critical obstruction. Because of the increased RV strain, severe RVH and eventual RV failure can occur.

When obstruction is severe and the ventricular septum is intact, a right-to-left shunt will often occur at the atrial level through a patent foramen ovale. In neonates with severe obstruction, pulmonary blood flow will shunt through the ductus, making prostaglandin a necessary intervention at the time of birth. Patients with this condition are cyanotic.

▶ Clinical Findings

A. Symptoms and Signs

Patients with mild or even moderate valvular pulmonary stenosis are acyanotic and asymptomatic. Patients with severe valvular obstruction may develop cyanosis early. Patients with mild to moderate obstruction are usually well developed and well nourished. They are not prone to pulmonary infections. The pulses are normal. The precordium may be prominent, often with palpable RV heave. A systolic thrill is often present in the pulmonary area. In patients with mild to moderate stenosis, a prominent ejection click of pulmonary origin is heard at the third left

intercostal space. The click varies with respiration, being more prominent during expiration than inspiration. In severe stenosis, the click tends to merge with S_1 . S_2 varies with the degree of stenosis. In mild pulmonic stenosis, S_2 is normal. In moderate pulmonic stenosis, S_2 is more widely split and the pulmonary component is softer. In severe pulmonary stenosis, S_2 is single because the pulmonary component cannot be heard. A rough systolic ejection murmur is best heard at the second left interspace. It radiates well to the back. With severe pulmonary valve obstruction, the murmur is usually short. No diastolic murmurs are audible.

B. Imaging

The heart size is normal. Post-stenotic dilation of the main pulmonary artery and the left pulmonary artery often occurs.

C. Electrocardiography

The ECG is usually normal with mild obstruction. RVH is present with moderate to severe pulmonic stenosis. In severe obstruction, RV hypertrophy with an RV strain pattern (deep inversion of the T wave) occurs in the right precordial leads (V_{3R} , V_1 , V_2). Right atrial enlargement may be present. Right axis deviation occurs in moderate to severe stenosis.

D. Echocardiography

The diagnosis often is made by physical examination, but the echocardiogram supports the diagnosis when the pulmonary valve is unusually thickened with reduced valve leaflet excursion. The transvalvular pressure gradient can be estimated accurately by Doppler, which provides evidence of the RV pressure and can assist in determining the appropriate time to intervene.

E. Cardiac Catheterization and Angiography

Pulmonic stenosis is easily diagnosed by physical examination, ECG, and echocardiography. Catheterization is reserved for therapeutic balloon pulmonic valvuloplasty. In severe cases with RV dysfunction, a right-to-left shunt at the atrial level is indicated by a lower left atrial saturation than pulmonary vein saturation. Pulmonary artery pressure is normal. The gradient across the pulmonary valve varies from 10–200 mm Hg. In severe cases, the right atrial pressure is elevated, with a predominant “a” wave. Angiocardiography in the RV shows a thick pulmonary valve with a narrow opening producing a jet of contrast into the pulmonary artery. Infundibular (RV outflow tract) hypertrophy may be present.

▶ Treatment

Relief of pulmonic stenosis is recommended for children with RV systolic pressure greater than two thirds of systemic

pressure. Immediate correction is indicated for patients with systemic or suprasystemic RV pressure. Percutaneous balloon valvuloplasty is the procedure of choice. It is as effective as surgery in relieving obstruction and causes less valve insufficiency. Surgery is needed to treat pulmonic valve stenosis when balloon pulmonic valvuloplasty is unsuccessful.

► Course & Prognosis

Patients with mild pulmonary stenosis live normal lives. Even those with moderate stenosis are rarely symptomatic. Those with severe valvular obstruction may develop cyanosis in infancy.

After balloon pulmonary valvuloplasty or surgery, most patients have good maximum exercise capacity unless they have significant pulmonary insufficiency (PI). Limitation of physical activity is unwarranted. The quality of life of adults with successfully treated pulmonary stenosis and minimal PI is normal. Patients with PI, a frequent side effect of intervention, may be significantly limited in exercise performance. Severe PI leads to progressive RV dilation and dysfunction, which may precipitate ventricular arrhythmias or right heart failure in adulthood. Patients with severe PI may benefit from replacement of the pulmonic valve.

 Davlourous PA et al. The right ventricle in congenital heart disease. *Heart* 2006;92(Suppl 1):i27 [PMID: 16543599].

2. Subvalvular Pulmonary Stenosis

Pure infundibular (subvalvular) pulmonary stenosis is rare. Infundibular hypertrophy, often associated with a small perimembranous VSD, may lead to a “double-chambered RV” characterized by obstruction between the inflow and outflow portion of the RV. One should suspect such an abnormality if there is a prominent precordial thrill, no audible pulmonary ejection click, and a murmur maximal in the third and fourth intercostal spaces rather than in the second intercostal space. The clinical picture is otherwise identical to that of pulmonic valve stenosis. Intervention, if indicated, is always surgical because this condition does not improve with balloon catheter dilation.

3. Supravalvular Pulmonary Stenosis

Supravalvular pulmonary stenosis is a relatively rare condition caused by narrowing of the main pulmonary artery. The clinical picture may be identical to valvular pulmonary stenosis, although the murmur is maximal in the first intercostal space at the left sternal border and in the suprasternal notch. No ejection click is audible, as the valve itself is not involved. The murmur radiates toward the neck and over the lung fields. This condition occurs most often in children with Noonan syndrome.

4. Peripheral (Branch) Pulmonary Artery Stenosis

In peripheral pulmonary stenosis, there are multiple narrowings of the branches of the pulmonary artery at the bifurcation of the main pulmonary artery or in the periphery of the lung. Systolic murmurs may be heard over both lung fields, anteriorly and posteriorly. Mild pulmonary branch stenosis produces a murmur in infancy that resolves by 6 months of age. Severe forms of peripheral pulmonary stenosis persist. The three most common causes of pulmonary artery branch stenosis are Williams syndrome, Alagille syndrome, and congenital rubella. Surgery is often unsuccessful, as stenoses near and in the hilum of the lung are not surgically correctable. Transcatheter balloon angioplasty is currently being used to treat this condition, with moderate success. In some instances, the stenoses improve spontaneously with age.

5. Ebstein Malformation of the Tricuspid Valve

In Ebstein malformation of the tricuspid valve, the septal leaflet of the tricuspid valve is displaced toward the apex of the heart and is attached to the endocardium of the RV rather than at the tricuspid annulus. As a result, the upper portion of the RV is physiologically within the right atrium. This “atrialized” portion of the RV is thin-walled and does not contribute to RV output. The portion of the ventricle below the displaced tricuspid valve is diminished in volume and represents the functioning RV.

► Clinical Findings

A. Symptoms and Signs

The clinical picture of Ebstein malformation varies with the degree of displacement of the tricuspid valve. In the most extreme form, the septal leaflet is markedly displaced into the RV outflow tract, causing obstruction of antegrade flow into the pulmonary artery. The degree of tricuspid insufficiency may be so severe that forward flow out the RV outflow tract is further diminished leading to cyanosis. At the opposite extreme, symptoms may not develop until adulthood when tachyarrhythmias associated with right atrial dilation or associated reentrant electrical pathway occur. These older patients typically have less displacement of the septal leaflet of the tricuspid valve.

B. Imaging

The chest radiograph usually shows cardiomegaly with prominence of the right heart border. The extent of cardiomegaly depends on the degree of tricuspid valve insufficiency and the presence and size of the atrial level shunt. Massive cardiomegaly with a “wall-to-wall heart” occurs with severe displacement and a restrictive atrial level defect.

C. Electrocardiography

ECG may be normal but usually shows right atrial enlargement and right bundle-branch block (RBBB). There is an association between Ebstein anomaly and Wolff-Parkinson-White (WPW) syndrome. In these cases a delta wave is present.

D. Echocardiography

Echocardiography is necessary to confirm the diagnosis and may aid in predicting outcome. Degree of displacement, size of the right atrium, and presence of associated atrial level shunt all affect outcome. The size of the atrialized portion of the RV is determined by echocardiography, and in severe cases, the RV can become so enlarged that it encroaches on the LV mass, impeding LV filling.

▶ Course & Prognosis

In cyanotic neonates, prostaglandin E is used to maintain pulmonary blood flow until pulmonary vascular resistance decreases, facilitating antegrade pulmonary artery flow. If the neonate remains significantly cyanotic, surgical intervention is required but the outcome is poor. Intervention in older children or adults has a better outcome.

Surgical repair consists of an annuloplasty to modify the level of the tricuspid orifice and diminish tricuspid insufficiency. The success of the procedure is highly variable. Late arrhythmias are common due to the preexisting atrial dilation. If a significant Ebstein malformation is not treated, atrial tachyarrhythmias frequently begin during adolescence. Postoperative exercise tolerance improves but remains lower than age-related norms.

6. Other Rare Right-Sided Malformations

A. Absence of a Pulmonary Artery

Absence of a pulmonary artery (left or right) may be an isolated malformation or may occur in association with other congenital heart diseases. It occurs occasionally in patients with tetralogy of Fallot.

B. Absence of the Pulmonary Valve

Absence of the pulmonary valve is rare and usually associated with VSD. In about 50% of cases, infundibular pulmonary stenosis is also present (termed tetralogy of Fallot with absent pulmonary valve).

Knott-Craig CJ et al: Repair of neonates and young infants with Ebstein's anomaly and related disorders. *Ann Thorac Surg* 2007;84:587 [PMID: 17643640].

LEFT-SIDED OBSTRUCTIVE LESIONS

1. Coarctation of the Aorta

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Absent or diminished femoral pulses.
- ▶ Upper to lower extremity systolic blood pressure gradient of > 20 mm Hg.
- ▶ Blowing systolic murmur in the back or left axilla.

▶ General Considerations

Coarctation accounts for about 6% of all congenital heart disease. Three times as many males as females are affected. Many affected females have Turner syndrome (45,XO). Coarctation usually occurs in the proximal descending aorta near the takeoff of the left subclavian artery next to the ductus arteriosus. The abdominal aorta is rarely involved. The incidence of associated bicuspid aortic valve with coarctation is 80–85%.

▶ Clinical Findings

A. Symptoms and Signs

The cardinal physical finding is decreased or absent femoral pulses. Infants with severe coarctation have equal upper and lower extremity pulses from birth until the ductus arteriosus closes. This is either because the coarctation is so severe that the ductus supplies blood flow to the descending aorta, or because the coarctation itself is the result of ductal tissue in the aorta sufficient to cause aortic obstruction. Approximately 40% of children with coarctation will present as young infants. Coarctation alone, or in combination with VSD, ASD, or other congenital cardiac anomalies, is the leading cause of HF in the first month of life.

Coarctation presents insidiously in the 60% of children with no symptoms in infancy. Coarctation is usually diagnosed by a pulse discrepancy between the arms and legs on physical examination or by right arm hypertension on blood pressure measurement. The pulses in the legs are diminished or absent. The left subclavian artery is occasionally involved in the coarctation, in which case the left brachial pulse is also weak. The pathognomonic murmur of coarctation is heard in the left axilla and the left back. The murmur is usually systolic but may spill into diastole, as forward flow continues across the narrow coarctation site throughout the cardiac cycle. A systolic ejection murmur is often heard at the aortic area and the lower left sternal border along with an apical ejection click from a bicuspid aortic valve.

B. Imaging

In the older child, radiographs may show a normal-sized heart, or more often some degree of LV enlargement. The

aorta proximal to the coarctation is prominent. The aortic outline may indent at the level of the coarctation. The post-stenotic segment is often dilated. This combination of abnormalities results in the “figure 3” sign on chest radiograph. Notching of the ribs caused by marked enlargement of the intercostal collaterals can be seen. In patients with severe coarctation and associated HF, marked cardiac enlargement and pulmonary venous congestion occur.

C. Electrocardiography

ECGs in older children may be normal or may show LVH. ECG usually shows RVH in infants with severe coarctation because the RV has been a “systemic” ventricle during fetal life.

D. Echocardiography

Two-dimensional echocardiography and color-flow Doppler are used to visualize the coarctation directly, and continuous-wave Doppler estimates the degree of obstruction. Diastolic run-off flow is detected by continuous-wave Doppler if the obstruction is severe. In neonates with a PDA, a coarctation cannot be ruled out, as one may develop as the PDA closes. Associated lesions such as a bicuspid aortic valve or mitral abnormalities may suggest the presence of a coarctation. In the face of poor LV systolic function, the gradient across the coarctation will be falsely low, as the LV is unable to generate adequate pressure proximal to the narrowing.

E. Cardiac Catheterization and Angiocardiography

Cardiac catheterization and angiocardiography are rarely performed for diagnosis in infants or children with coarctation, but are used if transcatheter intervention is planned. If completed, these studies demonstrate the anatomy and severity of the coarctation and assess the adequacy of collateral circulation.

► Treatment

Infants with coarctation of the aorta and HF may present in extremis secondary to LV dysfunction and low cardiac output. Resuscitative measures include prostaglandin infusion (0.05–0.1 mcg/kg/min) to reopen the ductus arteriosus. End-organ damage distal to the coarctation is not rare, and inotropic support is frequently needed. Once stabilized, the infant should undergo corrective repair. In patients with poor LV function, balloon angioplasty is sometimes performed as a palliative measure. Recent data suggest that balloon angioplasty of the aorta can be the definitive procedure in many patients with good LV function. Surgery also has a high success rate. The main complication of both surgery and balloon angioplasty is recurrent coarctation. Fortunately, this complication is treatable in the catheter-

ization laboratory. In older patients, particularly those of adult size, transcatheter stent placement is effective for recurrent coarctation.

► Course & Prognosis

Children who survive the neonatal period without developing HF do well through childhood and adolescence. Fatal complications (eg, hypertensive encephalopathy or intracranial bleeding) are uncommon in childhood. Infective endarteritis is rare before adolescence. Children with coarctation corrected after age 5 years are at increased risk for systemic hypertension and myocardial dysfunction even with successful surgery. Exercise testing is mandatory for these children prior to their participation in athletic activities.

Golden AB et al: Coarctation of the aorta: Stenting in children and adults. *Catheter Cardiovasc Interv* 2007;69:289 [PMID: 17191237].

2. Aortic Stenosis

- Harsh systolic ejection murmur at the upper right sternal border.
- Thrill in the carotid arteries.
- Systolic click at the apex.
- Dilation of the ascending aorta on chest radiograph.

► General Considerations

Aortic stenosis is defined as obstruction to outflow from the LV at or near the aortic valve producing a systolic pressure gradient of more than 10 mm Hg between the LV and the aorta. Aortic stenosis accounts for approximately 7% of congenital heart disease. There are three anatomic types of congenital aortic stenosis.

A. Valvular Aortic Stenosis (75%)

In critical aortic stenosis presenting in infancy, the aortic valve is usually a unicuspid diaphragm-like structure without well-defined commissures. Preschool- and school-aged children more commonly have bicuspid aortic valve. Teenagers and young adults characteristically have a tricuspid valve with partially fused leaflets. This lesion is more common in males than in females.

B. Subvalvular Aortic Stenosis (23%)

In this type, a membranous or fibrous ring occurs just below the aortic valve that causes obstruction to LV outflow. The aortic valve itself and the anterior leaflet of the mitral valve are often malformed.

C. Supravalvular Aortic Stenosis (2%)

In this type, constriction of the ascending aorta occurs just above the coronary arteries. The condition is often familial, and two different genetic patterns are found, one with abnormal facies and mental retardation (Williams syndrome) and one with normal facies and no developmental delay.

► Clinical Findings

A. Symptoms and Signs

Most patients with aortic stenosis have no cardiovascular symptoms. Except in the most severe cases, patients do well until the third to fifth decades of life. Some patients have mild exercise intolerance and fatigability. In a small percentage of patients significant symptoms (ie, dizziness and syncope) manifest in the first decade. Sudden death is uncommon but may occur in all forms of aortic stenosis with the greatest risk in patients with subvalvular obstruction (similar to hypertrophic cardiomyopathy).

Although isolated valvular aortic stenosis seldom causes symptoms in infancy, severe HF occasionally occurs when critical obstruction is present at birth. Response to medical therapy is poor; therefore, an aggressive approach using interventional catheterization or surgery is required. The physical findings vary depending on the anatomic type of lesion:

1. Valvular aortic stenosis—Patients are well developed and well nourished. Pulses are usually normal and equal throughout. If the stenosis is severe with a gradient greater than 80 mm Hg, the pulses are diminished with a slow upstroke. Cardiac examination reveals an LV thrust at the apex. A systolic thrill at the right base, the suprasternal notch, and over both carotid arteries may accompany moderate disease.

A prominent aortic ejection click is best heard at the apex. The click corresponds to the opening of the aortic valve. It is separated from S_1 by a short but appreciable interval. It does not vary with respiration. S_2 at the pulmonary area is normal. A loud, rough, medium- to high-pitched ejection-type systolic murmur is evident. It is loudest at the first and second intercostal spaces, radiating well into the suprasternal notch and along the carotids. The grade of the murmur correlates well with the severity of the stenosis.

2. Discrete membranous subvalvular aortic stenosis—

The findings are the same as those of valvular aortic stenosis except for the absence of a click. The murmur and thrill are usually somewhat more intense at the left sternal border in the third and fourth intercostal spaces. A diastolic murmur of aortic insufficiency is commonly heard after age 5 years.

3. Supravalvular aortic stenosis—The thrill and murmur are best heard in the suprasternal notch and along the carotids but are well transmitted over the aortic area and near the mid left sternal border. There may be a difference in pulses and blood pressure between the right and left arms if

the narrowing is just distal to the takeoff of the innominate artery, with more prominent pulse and pressure in the right arm (the Coanda effect).

B. Imaging

In most cases the heart is not enlarged. The LV, however, may be slightly prominent. In valvular aortic stenosis, dilation of the ascending aorta is frequently seen.

C. Electrocardiography

Patients with mild aortic stenosis have normal ECGs. Some patients with severe obstruction have LVH and LV strain but even in severe cases, 25% of ECGs are normal. Progressive LVH on serial ECGs indicates a significant obstruction. LV strain is an indication for surgery.

D. Echocardiography

This is a reliable noninvasive technique for the evaluation of all forms of aortic stenosis. Doppler accurately estimates the transvalvular gradient, and the level of obstruction can be confirmed by both two-dimensional echocardiographic images and by the level of flow disturbance revealed by color Doppler.

E. Cardiac Catheterization and Angiocardiology

Left heart catheterization demonstrates the pressure differential between the LV and the aorta and the anatomic level at which the gradient exists. Echocardiography is the standard method for following the severity of aortic valve stenosis, and catheterization is reserved for patients whose resting gradient has reached 60–80 mm Hg and in whom intervention is planned. For those with valvular aortic stenosis, balloon valvuloplasty is usually the first option. In subvalvular or supravalvular aortic stenosis, interventional catheterization is not effective and surgery is required.

► Treatment

Percutaneous balloon valvuloplasty is now standard initial treatment. Surgery should be considered in patients with symptoms, a high resting gradient (60–80 mm Hg) despite balloon angioplasty, or coexisting aortic insufficiency. In many cases, the gradient cannot be significantly diminished without producing aortic insufficiency. Patients who develop significant aortic insufficiency require surgical intervention to repair or replace the valve. In the Ross procedure, the patient's own pulmonic valve is moved to the aortic position, and an RV-to-pulmonary artery conduit is used to replace the pulmonic valve. Discrete subvalvular aortic stenosis is usually surgically repaired at a lesser gradient because continued trauma to the aortic valve by the subvalvular jet may damage the valve and produce aortic insufficiency. Unfortunately, simple resection is followed by recurrence in more than 25% of patients with subvalvular aortic stenosis.

► Course & Prognosis

All forms of LV outflow tract obstruction tend to be progressive. Pediatric patients with LV outflow tract obstruction—with the exception of those with critical aortic stenosis of infancy—are usually asymptomatic. Symptoms accompanying severe unoperated obstruction (angina, syncope, or HF) are rare but imply serious disease. Preoperative or postoperative children whose obstruction is mild to moderate have normal oxygen consumption and maximum voluntary working capacity. Children in this category with normal heart size and normal resting and exercising ECGs may safely participate in vigorous physical activity, including nonisometric competitive sports. Children with severe aortic stenosis are predisposed to ventricular dysrhythmias.

Mertens L et al: The role of imaging techniques in diagnosis and evaluation of congenital aortic stenosis. *Acta Cardiol* 2006;61:208 [PMID: 16716029].

3. Mitral Valve Prolapse

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Midsystolic click.
- Late systolic “whooping” or “honking” murmur.
- Typical symptoms include chest pain, palpitations, and dizziness.
- Often overdiagnosed on routine cardiac ultrasound.

► General Considerations

In this condition the mitral valve prolapses, moving posteriorly or superiorly into the left atrium during ventricular systole as the mitral valve closes. A midsystolic click occurs at the time of this movement and is the hallmark of this entity. Mitral insufficiency may occur late in systole, causing a short, atypical murmur with variable radiation. Mitral valve prolapse (MVP) occurs in about 2% of thin female adolescents, a minority of whom have concomitant mitral insufficiency. Although MVP is usually an isolated lesion, it can occur in association with Marfan syndrome and Ehlers-Danlos syndrome. These coexisting conditions should be ruled out by clinical examination.

► Clinical Findings

A. Symptoms and Signs

Most patients with MVP are asymptomatic. Chest pain, palpitations, and dizziness may be reported, but it is unclear whether these symptoms are more common in affected

patients than in the normal population. Chest pain on exertion is rare and should be assessed with cardiopulmonary stress testing. Significant dysrhythmias have been reported, including increased ventricular ectopy and non-sustained ventricular tachycardia. If significant mitral regurgitation is present, atrial arrhythmias may also occur. Standard auscultation technique must be modified to diagnose MVP. Clicks, with or without systolic murmur, are elicited best in the standing position due to the decrease in LV volume. Conversely, maneuvers that increase LV volume, such as squatting or handgrip exercise, will cause delay or obliteration of the click-murmur complex. The systolic click usually is heard at the apex but may be audible at the left sternal border. A systolic murmur after the click implies mitral insufficiency and is much less common than isolated prolapse. The murmur is not holosystolic, in contrast to rheumatic mitral insufficiency.

B. Imaging

Most chest radiographs are normal. They are not indicated in this condition. In the rare case of significant mitral valve insufficiency, the left atrium may be enlarged.

C. Electrocardiography

The ECG may be normal. Diffuse flattening or inversion of T waves may occur in the precordial leads. U waves are sometimes prominent.

D. Echocardiography

Significant posterior systolic movement of the mitral valve leaflets to the atrial side of the mitral annulus is diagnostic. Echocardiography assesses the degree of myxomatous change of the mitral valve and the degree of mitral insufficiency.

E. Other Testing

Invasive procedures are rarely indicated. Holter monitoring or event recorders may be useful in establishing the presence of ventricular dysrhythmias in patients with palpitations.

► Treatment & Prognosis

Propranolol may be effective in treatment of coexisting arrhythmias. Prophylaxis for infectious endocarditis is now longer indicated, based on 2007 AHA guidelines.

The natural course of this condition is not well defined. Twenty years of observation indicate that isolated MVP in childhood is usually a benign entity. Surgery for mitral insufficiency is rarely needed.

Knackstedt C et al: Ventricular fibrillation due to severe mitral valve prolapse. *Int J Cardiol* 2007;116:e101 [PMID: 17137658].

Mechleb BK et al: Mitral valve prolapse: Relationship of echocardiography characteristics to natural history. *Echocardiography* 2006;23:434 [PMID: 16686634].

4. Other Congenital Left Heart Valvular Lesions

A. Congenital Mitral Stenosis

Congenital mitral stenosis is a rare disorder in which the valve leaflets are thickened and fused, producing a diaphragm-like or funnel-like structure with a central opening. When mitral stenosis occurs with other left-sided obstructive lesions, such as subaortic stenosis and coarctation of the aorta, the complex is called Shone syndrome. Most patients develop symptoms early in life with tachypnea, dyspnea, and failure to thrive. Physical examination reveals an accentuated S₁ and a loud pulmonary closure sound. No opening snap can be heard. In most cases, a presystolic crescendo murmur is heard at the apex. Occasionally, only a mid-diastolic murmur can be heard. Rarely, no murmur is present. ECG shows right axis deviation, biatrial enlargement, and RVH. Chest radiograph reveals left atrial enlargement and frequently pulmonary venous congestion. Echocardiography shows abnormal mitral valve structures with reduced leaflet excursion and left atrial enlargement. Cardiac catheterization reveals an elevated pulmonary capillary wedge pressure and pulmonary hypertension, owing to the elevated left atrial pressure.

Mitral valve repair or mitral valve replacement with a prosthetic mitral valve may be performed, even in young infants, but is a technically difficult procedure. Mitral valve repair is the preferred surgical option, as valve replacement has a poor outcome in very young children.

B. Cor Triatriatum

Cor triatriatum is a rare abnormality in which the pulmonary veins join at their confluence but the confluence is not completely incorporated into the left atrium. The confluence communicates with the left atrium through an opening of variable size, and may be obstructed. The consequences are similar to those of mitral stenosis. Clinical findings depend on the size of the opening. If the opening is small, symptoms develop early in life. Echocardiography reveals a linear density in the left atrium with a gradient between the pulmonary venous chamber and the true left atrium. Cardiac catheterization may be needed if the diagnosis is in doubt. High pulmonary wedge pressure and low left atrial pressure (with the catheter passed through the foramen ovale into the true left atrium) support the diagnosis. Angiocardiography identifies both the proximal and distal left atria. Surgical repair is always required in the presence of an obstructive membrane, and long-term results are good. Coexisting mitral valve abnormalities may be noted, including a supravalvular mitral ring or a dysplastic mitral valve.

C. Congenital Mitral Regurgitation

Congenital mitral regurgitation is a rare abnormality usually associated with other congenital heart lesions, such as ccTGA, AV septal defect, and anomalous left coronary artery. Isolated

congenital mitral regurgitation is very rare. It is sometimes present in patients with Marfan syndrome, usually associated with a myxomatous prolapsing mitral valve.

D. Congenital Aortic Regurgitation

Congenital aortic regurgitation is rare. The most common causes are bicuspid aortic valve, with or without coarctation of the aorta; VSD with aortic cusp prolapse and aortic insufficiency; and fenestration of the aortic valve cusp (one or more holes in the cusp).

Beierlein W et al: Long-term follow-up after mitral valve replacement in childhood: Poor event-free survival in the young child. *Eur J Cardiothorac Surg* 2007;31:860 [PMID: 17383889].

DISEASES OF THE AORTA

Although more common in mid to late adulthood, aortic dilation and dissection may occur in children. Although the aorta may not be dilated at birth, the structural abnormality that predisposes to dilation is presumed to be congenital. Patients at risk for progressive aortic dilation and dissection include those with isolated bicuspid aortic valve, Marfan syndrome, Turner syndrome, and type IV Ehlers-Danlos syndrome.

1. Bicuspid Aortic Valve

Patients with bicuspid aortic valves have an increased incidence of aortic dilation and dissection, regardless of the presence of aortic stenosis. Histologic examination demonstrates cystic medial degeneration of the aortic wall, similar to that seen in patients with Marfan syndrome. Patients with isolated bicuspid aortic valve require regular follow-up even in the absence of aortic insufficiency or aortic stenosis. Significant aortic root dilation requiring surgical intervention typically does not occur until adulthood.

2. Marfan Syndrome

Marfan syndrome is an autosomal dominant disorder of connective tissue caused by a mutation in the fibrillin-1 gene. Spontaneous mutations account for 25–30% of cases, and thus family history is not always helpful. Patients are diagnosed by the Ghent criteria and must have at a minimum, major involvement of two body systems plus involvement of a third body system or a positive family history. Body systems involved include cardiovascular, ocular, musculoskeletal, pulmonary, and integumentary. Cardiac manifestations include aortic root dilation and MVP, which may be present at birth. Patients are at risk for aortic dilation and dissection and are restricted from competitive athletics, contact sports, and isometric activities. β -Blockers or ACE inhibitors are used to lower blood pressure and slow the rate of aortic dilation. More recently, studies are ongoing to evaluate the effectiveness of angiotensin receptor blockers (losartan). Elective surgical

intervention is performed in patients of adult size when the aortic root dimension reaches 50 mm. The ratio of actual to expected aortic root dimension is used to determine the need for surgery in the young child. Surgical options include replacement of the dilated aortic root with a composite valve graft (Bentall technique) or a David procedure in which the patient's own aortic valve is spared and a Dacron tube graft is used to replace the dilated ascending aorta. Young age at diagnosis was previously thought to confer a poor prognosis; however, early diagnosis with close follow-up and early medical therapy has been associated with more favorable outcome. Ventricular dysrhythmias may contribute to the mortality in Marfan syndrome.

3. Turner Syndrome

Cardiovascular abnormalities are common in Turner syndrome. Patients are at risk for aortic dissection, typically during adulthood. Risk factors include hypertension regardless of cause, aortic dilation, bicuspid aortic valve, and coarctation of the aorta. There are rare reports of aortic dissection in adult Turner syndrome patients in the absence of any risk factors. Patients with Turner syndrome require routine follow-up from adolescence onward to monitor this potentially lethal complication.

CORONARY ARTERY ABNORMALITIES

Several anomalies involve the origin, course, and distribution of the coronary arteries. The only abnormality seen with regularity, and which has disastrous consequences if unrecognized, is anomalous origin of the left coronary artery.

Anomalous Origin of the Left Coronary Artery from the Pulmonary Artery (ALCAPA)

In this condition, the left coronary artery arises from the pulmonary artery rather than the aorta. In neonates, whose pulmonary artery pressure is high, perfusion of the left coronary artery may be adequate and the infant may be asymptomatic. By age 2 months the pulmonary arterial pressure falls, causing a progressive decrease in myocardial perfusion by the left coronary artery. Ischemia and infarction of the LV occur. Immediate surgery is needed to reimplant the left coronary artery and restore myocardial perfusion. The surgery is relatively high-risk, especially if infarction of the papillary muscles supporting the mitral apparatus has occurred. Mitral valve replacement will then sometimes be needed.

► Clinical Findings

A. Symptoms and Signs

Neonates appear healthy and growth and development are relatively normal for a few months while pulmonary artery pressure is dropping. Detailed questioning may disclose a history of intermittent abdominal pain, pallor, and sweating, especially during or after feeding. Presentation may be subtle, with nonspecific complaints of "fussiness" or intermittent "colic." The colic and fussiness are probably attacks of true angina. Presentation may be fulminant at age 2–4 months with sudden, severe HF due to LV dysfunction and mitral insufficiency. On physical examination, the infants are usually well developed and well nourished. The pulses are typically weak but equal. A prominent left precordial bulge is present. A holosystolic murmur of mitral regurgitation is sometimes present, though frequently auscultation alone reveals no obvious abnormalities.

B. Imaging

Chest radiographs show cardiac enlargement and left atrial enlargement and may show pulmonary venous congestion if left ventricular function has been compromised.

C. Electrocardiography

The ECG is very helpful. There is T-wave inversion in leads I and aVL. The precordial leads also show T-wave inversion from V₄–V₇. Deep and wide Q waves are present in leads I, aVL, and sometimes in V₄–V₆. These findings of myocardial infarction are similar to those in adults.

D. Echocardiography

The diagnosis can be made with two-dimensional echo techniques by visualizing a single large right coronary artery arising from the aorta and visualization of the anomalous left coronary artery arising from the main pulmonary artery. Flow reversal in the left coronary (heading *toward* the aorta, rather than away) confirms the diagnosis. LV dysfunction, echo-bright (ischemic) papillary muscles, and mitral regurgitation may be seen.

E. Cardiac Catheterization and Angiocardiology

Angiogram of the aorta fails to show the origin of the left coronary artery. A large right coronary artery fills directly from the aorta, and contrast flows from the right coronary system via collaterals into the left coronary arteries and finally into the pulmonary artery. Angiogram of the RV or main pulmonary artery may show the origin of the anomalous vessel. Rarely, a left-to-right shunt may be detected as oxygenated blood passes through the collateral system without delivering oxygen to the myocardium, and passes into the pulmonary artery.

► Treatment & Prognosis

Anomalous left coronary artery is a high-risk diagnosis. The prognosis is guarded at best. Medical management with diuretics and afterload reduction can help stabilize the ill patient, but surgical intervention should not be delayed. Most surgeons relocate the anomalous coronary button into the aorta. The mitral valve may have to be replaced, depending on the degree of mitral insufficiency.

Lange R et al: Long-term results of repair of anomalous origin on the left coronary artery from the pulmonary artery. *Ann Thorac Surg* 2007;83:1463 [PMID: 17383358].

CYANOTIC CONGENITAL HEART DISEASE

TETRALOGY OF FALLOT

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Hypoxemic spells during infancy.
- ▶ Right-sided aortic arch in 25% of patients.
- ▶ Systolic ejection murmur at the upper left sternal border.

► General Considerations

In tetralogy of Fallot (ToF), a single embryologic abnormality causes multiple morphologic problems. Anterior deviation of the infundibular (pulmonary outflow) septum causes narrowing of the right ventricular outflow tract. This deviation also causes a VSD and the aorta overrides the crest of the ventricular septum. The RV hypertrophies, not because of pulmonary stenosis, but because it is pumping against systemic resistance across a (usually) large VSD. ToF is the most common cyanotic cardiac lesion and accounts for 10% of all congenital heart disease. A right-sided aortic arch is present in 25% of cases, and ASD occurs in 15%.

Obstruction to RV outflow with a large VSD causes a right-to-left shunt at the ventricular level with arterial desaturation. The greater the obstruction and the lower the systemic vascular resistance, the greater is the right-to-left shunt. ToF is associated with deletions in the long arm of chromosome 22 (22q11) in as many as 15% of affected children.

► Clinical Findings

A. Symptoms and Signs

Clinical findings vary with the degree of RV outflow obstruction. Patients with mild obstruction are minimally cyanotic or acyanotic. Those with maximal obstruction are deeply cyanotic from birth. Few children are asymptomatic. Most

have cyanosis by age 4 months, and the cyanosis usually is progressive, as subvalvular obstruction increases. Growth and development are not typically delayed, but easy fatigability and dyspnea on exertion are common. The fingers and toes show variable clubbing depending on age and severity of cyanosis. Historically, older children with ToF would frequently squat to increase systemic vascular resistance. This decreased the amount of right-to-left shunt, forcing blood through the pulmonary circuit, and would help ward off cyanotic spells. Squatting is rarely seen as the diagnosis is now made much earlier.

Hypoxemic spells, also called cyanotic or “Tet spells,” are one of the hallmarks of severe ToF. They are characterized by (1) sudden onset of cyanosis or deepening of cyanosis; (2) dyspnea; (3) alterations in consciousness, from irritability to syncope; and (4) decrease or disappearance of the systolic murmur (as RV outflow tract flow becomes completely obstructed). These episodes most commonly start at age 4–6 months. Cyanotic spells are treated acutely by administration of oxygen and placing the patient in the knee-chest position. Intravenous morphine should be administered cautiously. Propranolol produces β -blockade and may reduce the obstruction across the RV outflow tract. Acidosis, if present, should be corrected with intravenous sodium bicarbonate. Chronic oral prophylaxis of cyanotic spells with propranolol may be useful to delay surgery but the onset of Tet spells usually prompts expedient intervention.

An RV lift is palpable. S_2 is predominantly aortic and single. A grade II–IV/VI, rough, systolic ejection murmur is present at the left sternal border in the third intercostal space and radiates well to the back.

B. Laboratory Findings

Hemoglobin, hematocrit, and red blood cell count are usually elevated secondary to arterial desaturation.

C. Imaging

Chest radiographs show a normal size heart. The RV is hypertrophied, often shown by an upturning of the apex (boot-shaped heart). The main pulmonary artery segment is usually concave and, if there is a right aortic arch, the aortic knob is to the right of the trachea. The pulmonary vascular markings are usually decreased.

D. Electrocardiography

The QRS axis is rightward, ranging from +90 to +180 degrees. The P waves are usually normal. RVH is always present, but RV strain patterns are rare.

E. Echocardiography

Two-dimensional imaging is diagnostic, revealing thickening of the RV wall, overriding of the aorta, and a large subaortic VSD. Obstruction at the level of the infundibulum

and pulmonary valve can be identified, and the size of the proximal pulmonary arteries can be measured. The anatomy of the coronary arteries should be visualized, as abnormal branches crossing the RV outflow tract are at risk for transection during surgical enlargement of the area.

F. Cardiac Catheterization and Angiography

Cardiac catheterization reveals a right-to-left shunt at the ventricular level in most cases. Arterial desaturation of varying degrees is present. The RV pressure is at systemic levels and the pressure tracing in the RV is identical to that in the LV if the VSD is large. The pulmonary artery pressure is invariably low. Pressure gradients may be noted at the valvular level, the infundibular level, or both. RV angiography reveals RV outflow obstruction and a right-to-left shunt at the ventricular level. The major indications for cardiac catheterization are to establish coronary artery and distal pulmonary artery anatomy.

► Treatment

A. Palliative Treatment

A few centers currently advocate complete repair of ToF during the neonatal period regardless of patient size. Many centers prefer palliative treatment for small infants in whom complete correction is deemed risky. Medical palliation with long-term oral β -blocking agents may delay surgery. Some patients may be palliated by balloon dilation of the RV outflow tract during infancy. While this may improve the pulmonary blood flow and delay surgical intervention, hypercyanotic spells are frequent when the RV outflow tract is manipulated, making this procedure somewhat risky.

The most common surgical palliation is the insertion of a GoreTex shunt from the subclavian artery to the ipsilateral pulmonary artery (modified Blalock-Taussig shunt). This improves pulmonary blood flow regardless of the level of infundibular or valvular obstruction, and some believe, allows for growth of the patient's pulmonary arteries (which are usually small) prior to complete surgical correction.

B. Total Correction

Open-heart surgery for repair of ToF is performed at ages ranging from birth to 2 years, depending on the experience of each center. The current surgical trend is toward earlier repair for symptomatic infants. The major limiting anatomic feature of total correction is the size of the pulmonary arteries. During surgery, the VSD is closed and the obstruction to RV outflow removed. Surgical mortality is low.

► Course & Prognosis

Infants with severe ToF are usually deeply cyanotic at birth. These children require early surgery, either a Blalock-Taussig shunt or primary correction. All children with ToF require

open-heart surgery. Complete repair before age 2 years usually produces a good result, and patients are currently living well into adulthood. Depending on the extent of the repair required, patients frequently require additional surgery 10–15 years after their initial repair for replacement of the pulmonary valve. Transcatheter pulmonary valves are under investigation and may help these patients avoid additional open-heart surgery in the future. The greatest risk for death in ToF patients is ventricular dysrhythmias. A competent pulmonary valve without a dilated RV appears to diminish arrhythmias and enhance exercise performance.

PULMONARY ATRESIA WITH VENTRICULAR SEPTAL DEFECT

This condition, complete atresia of the pulmonary valve in association with VSD, is essentially an extreme form of ToF. Because there is no antegrade flow from the RV to the pulmonary artery, pulmonary blood flow must be derived from a PDA or from multiple aortopulmonary collateral arteries (MAPCAs). Symptoms depend on the amount of pulmonary blood flow. If flow is significant, patients may be stable. If pulmonary flow is inadequate, severe hypoxemia occurs and immediate palliation is required. Newborns are stabilized with intravenous prostaglandin E₁ (PGE₁) to maintain the PDA while being prepared for surgery. Rarely, if the ductus does not contribute significantly to pulmonary blood flow (ie, the MAPCAs alone are sufficient), PGE₁ may be discontinued. Once stabilized, palliative aortopulmonary shunt or primary correction is undertaken. In most centers, a palliative shunt is performed in the newborn to augment pulmonary blood flow, and open-heart surgical correction planned for age 9–18 months.

Echocardiography is usually diagnostic. Cardiac catheterization and angiography are required to confirm the source(s) of pulmonary blood flow. With small native pulmonary arteries and inadequate blood flow, an aortopulmonary shunt is created, either by rerouting the patient's own vessels or by creating a shunt with artificial material. When the pulmonary arteries are large enough, relocation of the MAPCAs from the aorta to the pulmonary trunk (unifocalization) is performed to complete the repair.

Pulmonary vascular disease is common in pulmonary atresia with VSD, due both to intrinsic abnormalities of the pulmonary vasculature and to abnormal amounts of pulmonary blood flow. Even patients who have undergone surgical correction as infants are at risk. Pulmonary vascular disease is a common cause of death as early as the third decade of life.

Ishibashi N et al: Clinical results of staged repair with complete unifocalization for pulmonary atresia with ventricular septal defect and major aortopulmonary collateral arteries. *Eur J Cardiothorac Surg* 2007;32:202 [PMID: 17512210].

PULMONARY ATRESIA WITH INTACT VENTRICULAR SEPTUM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Completely different from pulmonary atresia with VSD.
- ▶ Cyanosis at birth.
- ▶ Always ductal dependent with rare aortopulmonary collateral arteries.
- ▶ RV-dependent coronary arteries sometimes are present.

▶ General Considerations

Although pulmonary atresia with intact ventricular septum (PA/IVS) sounds as if it might be related to pulmonary atresia with VSD, it is a distinct cardiac condition. As the name suggests, the pulmonary valve is atretic. The pulmonic annulus usually has a small diaphragm consisting of the fused valve cusps. The ventricular septum is intact. The main pulmonary artery segment is usually present and closely approximated to the atretic valve, but is somewhat hypoplastic. Although the RV is always reduced in size, the degree of reduction is variable. The size of the RV is critical to the success of surgical repair. In some children with PA/IVS, the RV is adequate for ultimate two-ventricular repair. A normal RV has three component parts (inlet, trabecular or body, and outlet). The absence of any one of the components makes adequate RV function unlikely. Even with all three components, some RVs are inadequate.

After birth, the pulmonary circulation is maintained by the ductus arteriosus. Multiple aortopulmonary collateral arteries are usually not present in this disease, in contrast to pulmonary atresia with VSD. A continuous infusion of PGE₁ must be started as soon as possible after birth to maintain ductal patency.

▶ Clinical Findings

A. Symptoms and Signs

Neonates are usually cyanotic and become more so as the ductus arteriosus closes. A blowing systolic murmur resulting from the associated PDA may be heard at the pulmonary area. A holosystolic murmur is often heard at the lower left sternal border, as many children develop tricuspid insufficiency if the RV is of good size and egress from that ventricle is only through the tricuspid valve.

B. Imaging

The heart size varies from small to markedly enlarged depending on the degree of tricuspid insufficiency. With severe tricuspid insufficiency, right atrial enlargement may be massive and the cardiac silhouette may fill the chest on radiograph.

C. Electrocardiography

ECG reveals a left axis for age (45–90 degrees) in the frontal plane. Left ventricular forces dominate the ECG, and there is a paucity of RV forces, particularly with hypoplastic RV. Findings of right atrial enlargement are usually striking.

D. Echocardiography

Echocardiography shows atresia of the pulmonary valve with varying degrees of RV cavity and tricuspid annulus hypoplasia. The severity of tricuspid regurgitation correlates with RV size.

E. Cardiac Catheterization and Angiography

RV pressure is almost always suprasystemic. Angiogram of the RV reveals no filling of the pulmonary artery. It also demonstrates the size of the RV chamber, relative hypoplasia of the three components of the RV, and the presence or absence of tricuspid regurgitation. Some children with pulmonary atresia and an intact ventricular septum have sinusoids between the RV and the coronary arteries. The presence of sinusoids indicates that the coronary circulation may depend on high right ventricular pressure. Any attempt to decompress the RV in patients with RV-dependent coronary circulation causes myocardial infarction and death because of the precipitous decrease in coronary perfusion.

▶ Treatment & Prognosis

As in all ductal-dependent lesions, PGE₁ is used to stabilize the patient and maintain patency of the ductus until surgery can be performed. Surgery is usually undertaken in the first week of life. Unrestricted flow through the ASD is a necessity, since the only outflow from the right atrium is via the atrial defect and into the left atrium.

A Rashkind balloon atrial septostomy may be required, depending on RV size, to open a communication across the atrial septum. If the RV is tripartite and an eventual two-chamber repair is planned, the pulmonary valve plate may be perforated and dilated during cardiac catheterization in the newborn to allow antegrade flow from the RV to the pulmonary artery and thus encourage RV cavity growth. If the RV is inadequate, if significant sinusoids are present, or if the pulmonic valve cannot be opened successfully during cardiac catheterization, a Blalock-Taussig shunt is performed to establish pulmonary blood flow. Later in infancy, a communication between the RV and pulmonary artery can be created to stimulate RV cavity growth. If either RV dimen-

sion or function is inadequate for two-ventricular repair, an approach similar to that taken for a single ventricle pathway best serves these children (see section on Hypoplastic Left Heart Syndrome, later). Children with significant sinusoids are often considered for cardiac transplantation if they are at risk for coronary insufficiency and sudden death.

The prognosis in this condition is guarded. Experience strongly favors opening the atretic valve in the catheterization laboratory in the newborn period if possible. Ultimate plans for two-ventricular repair, Fontan procedure, or cardiac transplantation depend on the anatomy.

TRICUSPID ATRESIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Marked cyanosis present from birth.
- ▶ ECG with left axis deviation, right atrial enlargement, and LVH.

▶ General Considerations

In tricuspid atresia, there is complete atresia of the tricuspid valve with no direct communication between the right atrium and the RV. There are two types of tricuspid atresia based on the relationship of the great arteries. The entire systemic venous return must flow through the atrial septum (either ASD or patent foramen ovale) to reach the left atrium. The left atrium thus receives both the systemic venous return and the pulmonary venous return. Complete mixing occurs in the left atrium, resulting in variable degrees of arterial desaturation.

Because there is no flow to the RV, development of the RV depends on the presence of a ventricular left-to-right shunt. Severe hypoplasia of the RV occurs when there is no VSD or when the VSD is small.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms usually develop in early infancy with cyanosis present at birth in most infants. Growth and development are poor, and the infant usually exhibits exhaustion during feedings, tachypnea, and dyspnea. Patients with an increased pulmonary blood flow—types 1(c) and 2(b)—may develop HF with less prominent cyanosis. A murmur from the VSD is usually present and heard best at the lower left sternal

border. Digital clubbing is present in older children with long standing cyanosis.

B. Imaging

The heart is slightly to markedly enlarged. The main pulmonary artery segment is usually small or absent. The size of the right atrium is moderately to massively enlarged, depending on the size of the communication at the atrial level. The pulmonary vascular markings are usually decreased. Pulmonary vascular markings may be increased if pulmonary blood flow is not restricted by the VSD or pulmonary stenosis.

C. Electrocardiography

The ECG shows marked left axis deviation. The P waves are tall and peaked, indicative of right atrial hypertrophy. LVH or LV dominance is found in almost all cases. RV forces on the ECG are usually low or absent.

D. Echocardiography

Two-dimensional methods are diagnostic and show absence of the tricuspid valve, the relationship between the great arteries, and the size of the pulmonary arteries. Color-flow Doppler imaging can help identify levels of restriction of pulmonary blood flow, either at the VSD or in the RV outflow tract.

E. Cardiac Catheterization and Angiocardiography

Catheterization reveals a right-to-left shunt at the atrial level. Because of mixing in the left atrium, oxygen saturations in the LV, RV, pulmonary artery, and aorta are identical to that in the left atrium. Right atrial pressure is increased if the ASD is restrictive. LV and systemic pressures are normal. The catheter cannot be passed through the tricuspid valve from the right atrium to the RV. A balloon atrial septostomy is performed if a restrictive foramen ovale or ASD is present.

▶ Treatment & Prognosis

In infants with unrestricted pulmonary blood flow, conventional anticongestive therapy with diuretics and afterload reduction should be given until the infant begins to outgrow the VSD. Sometimes, a pulmonary artery band is needed to protect the pulmonary bed from excessive flow.

Staged palliation of tricuspid atresia is the usual surgical approach. In infants with diminished pulmonary blood flow, PGE₁ is given until an aortopulmonary shunt can be performed. A Glenn procedure (superior vena cava to pulmonary artery anastomosis) is done with takedown of the aortopulmonary shunt at 4–6 months when saturations begin to fall, and completion of the Fontan procedure (redirection of inferior vena cava and superior vena cava to pulmonary artery) is performed when the child reaches around 15 kg.

The prognosis for patients with tricuspid atresia depends on achieving a pulmonary blood flow that permits adequate

oxygenation of the tissues without producing HF. The long-term prognosis for children treated by the Fontan procedure is unknown, although patients now are living into their late 20s and early 30s. In the short term, the best results for the Fontan procedure occur in children with low pulmonary artery pressures prior to open-heart surgery.

Wald RM et al: Outcome after prenatal diagnosis of tricuspid atresia: A multicenter experience. *Am Heart J* 2007;153:772 [PMID: 17452152].

HYPOPLASTIC LEFT HEART SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Mild cyanosis at birth.
- ▶ Minimal auscultatory findings.
- ▶ Rapid onset of shock with ductal closure.

▶ General Considerations

Hypoplastic left heart syndrome (HLHS) includes several conditions in which lesions of the left heart result in hypoplasia of the LV. The syndrome occurs in 1.4–3.8% of infants with congenital heart disease.

Stenosis or atresia of the mitral and aortic valves is the rule. In the neonate, survival depends on a PDA because antegrade flow into the systemic circulation is inadequate or nonexistent. The PDA provides the only flow to the aorta. Children with HLHS are usually stable at birth, but they deteriorate rapidly as the ductus closes in the first week of life. Untreated, the average age at death is the first week of life. Rarely, the ductus remains patent and infants may survive for several months without PGE₁ therapy.

Currently, in settings with the expertise, the diagnosis is made prepartum by fetal echocardiography. Prepartum diagnosis aids greatly in planning for the delivery of the infant at or near a center with experience in treating HLHS.

▶ Clinical Findings

A. Symptoms and Signs

Neonates with HLHS appear stable at birth because the ductus is patent. They deteriorate rapidly as the ductus closes, with shock and acidosis secondary to inadequate systemic perfusion. Oxygen saturation may initially increase as more blood flows to the lungs with ductal closure.

B. Imaging

Chest radiograph at presentation shows cardiac enlargement with severe pulmonary venous congestion if the PDA has begun closing. Chest radiograph in the first day of life may

be relatively unremarkable, with the exception of a small cardiac silhouette.

C. Electrocardiography

The ECG shows right axis deviation, right atrial enlargement, and RVH with a relative paucity of LV forces. The small Q wave in lead V₆ may be absent, and a qR pattern is often seen in lead V₁.

D. Echocardiography

Echocardiography is diagnostic. A very small aorta and LV with atretic or severely stenotic mitral and aortic valves are diagnostic. The systemic circulation is dependent on the PDA. Color-flow Doppler imaging shows retrograde flow in the ascending aorta, as the coronary arteries must be supplied by the ductus via the small native aorta.

▶ Treatment & Prognosis

PGE₁ is essential initially, as systemic circulation depends on a patent ductus arteriosus. Later management depends on balancing pulmonary and systemic blood flow both of which depend on the RV. At a few days of age the pulmonary resistance falls, favoring pulmonary overcirculation and systemic underperfusion. Therapy is then directed at encouraging systemic blood flow. Nitrogen is used to decrease inspired oxygen to as low as 17%. This therapy must be carefully monitored but results in increased pulmonary arterial tone and better systemic perfusion. Systemic afterload reduction will also increase systemic perfusion. Adequate perfusion can usually be obtained by keeping systemic O₂ saturation between 65% and 80%, or more accurately a PO₂ of 40 mm Hg.

A choice must be made shortly after birth among several treatment options. In the Norwood procedure, the relatively normal main pulmonary artery is transected and connected to the small ascending aorta. The aortic arch must be reconstructed due to its small size. Then, either a Blalock-Taussig shunt (from the subclavian artery to the pulmonary artery) or a Sano shunt (from the RV to the pulmonary artery) must be created to restore pulmonary blood flow. Children who have a Norwood procedure will later require a Glenn anastomosis (superior vena cava to pulmonary artery with takedown of the systemic-pulmonary shunt) and then a Fontan (inferior vena cava to pulmonary artery, completing the systemic venous bypass of the heart) at ages 6 months and 2–3 years, respectively. Although this is a major improvement over nonsurgical intervention, HLHS remains one of the most challenging lesions in pediatric cardiology, as survival is still only 60% at 5 years.

Orthotopic heart transplantation is also a treatment for HLHS. Survival after transplantation is better than survival after the Norwood operation, but death while awaiting transplantation increases overall mortality to the same level as the Norwood.

Recently, many centers have moved toward a “hybrid” approach to HLHS as a result of collaboration between surgeons and interventional cardiologists. In the hybrid procedure, the chest is opened surgically and the pulmonary arteries are banded, to limit pulmonary blood flow. Then, also through the open chest, a PDA stent is placed by the interventionalist to maintain systemic output. The second stage is considered a “comprehensive Glenn,” in which the pulmonary artery bands and ductal stent are taken down, and the superior vena cava is surgically connected to the pulmonary arteries. Aortic arch reconstruction is done during the second stage, in contrast to the Norwood operation. Survival after the first-stage “hybrid” is greater than 90% at the most experienced centers. Long-term follow-up is not yet available.

Pedra CA et al: New transcatheter techniques for creation or enlargement of atrial septal defects in infants with complex congenital heart disease. *Catheter Cardiovasc Interv* 2007;70:731 [PMID: 17621660].

TRANSPOSITION OF THE GREAT ARTERIES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Cyanotic newborn without respiratory distress.
- ▶ More common in males.

▶ General Considerations

Transposition of the great arteries (TGA) is the second most common cyanotic congenital heart disease, accounting for 5% of all cases of congenital heart disease. The male-to-female ratio is 3:1. It is caused by an embryologic abnormality in the spiral division of the truncus arteriosus in which the aorta arises from the RV and the pulmonary artery from the LV. This is referred to as “ventriculoarterial discordance.” Patients may have a VSD, or the ventricular septum may be intact. Left unrepaired, transposition is associated with a high incidence of early pulmonary vascular obstructive disease. Because pulmonary and systemic circulations are in parallel, survival is impossible without mixing between the two circuits. The PDA and the patent foramen ovale are critically important. The majority of mixing occurs at the atrial and ductal levels. These communications are frequently inadequate at birth, and patients are therefore severely cyanotic.

▶ Clinical Findings

A. Symptoms and Signs

Many neonates are large (up to 4 kg) and profoundly cyanotic without respiratory distress or a significant mur-

mur. Infants with a large VSD may be less cyanotic and they usually have a prominent murmur. The findings on cardiovascular examination depend on the intracardiac defects. Obstruction to outflow from either ventricle is possible, and coarctation must be ruled out.

B. Imaging

The chest radiograph in transposition is usually nondiagnostic. Sometimes there is an “egg on a string” appearance because the aorta is directly anterior to the main pulmonary artery, giving the image of a narrow mediastinum.

C. Electrocardiography

Because the newborn ECG normally has RV predominance, the ECG in transposition is of little help, as it will frequently look normal.

D. Echocardiography

Two-dimensional imaging and Doppler evaluation demonstrate the anatomy and physiology well. The aorta arises from the RV and the pulmonary artery arises from the LV. Associated defects, such as a VSD, RV or LV outflow tract obstruction, or coarctation, must be evaluated. The atrial septum should be closely evaluated, as any restriction could prove detrimental as the child awaits repair. The coronary anatomy is variable and must be defined prior to surgery.

E. Cardiac Catheterization and Angiography

A Rashkind balloon atrial septostomy is frequently performed in complete transposition to open the atrial septum no true ASD exists. The coronary anatomy can be delineated by ascending aortography if not well seen by echocardiography.

▶ Treatment

Early corrective surgery is recommended. The arterial switch operation (ASO) has replaced the previously performed atrial switch procedures (Mustard and Senning operations). The ASO is performed at age 4–7 days. The arteries are switched in the anterior chest, and the coronaries are separately reimplemented. Small associated VSDs may be left to close on their own, but large VSDs are closed at this time. The atrial septum is also closed. The LV must be able to function against systemic vascular resistance, so the longer the LV faces only the falling pulmonary vascular resistance, the more deconditioned it becomes. For this reason, the ASO is rarely delayed beyond age 14 days in infants with an intact ventricular septum or small VSD. If a large, unrestrictive VSD is present to maintain LV pressure at systemic levels, the LV does not become deconditioned, and corrective surgery can be delayed for a few months. Surgery should still be performed by age 3–4 months because of the high risk of early pulmonary vascular disease associated with transposition.

Survival after the ASO is greater than 95% in major centers. The switch procedure greatly shortens the duration of severe cyanosis before corrective surgery. Early relief of cyanosis may improve the developmental outcome. Finally, the switch procedure leaves the LV as the systemic ventricle. The older atrial corrective procedures left the RV in this role and there was a significant late RV failure.

Warnes CA: Transposition of the great arteries. *Circulation* 2006;114:2699 [PMID: 17159076].

1. Congenitally Corrected Transposition of the Great Arteries

Congenitally corrected transposition of the great arteries (ccTGA) is a relatively uncommon congenital heart disease. Patients may present with cyanosis, depending on the associated lesions. In ccTGA, both atrioventricular and ventriculoarterial discordance occurs so that the right atrium connects to a morphologic LV, which supports the pulmonary artery. Conversely, the left atrium empties via a tricuspid valve into a morphologic RV, which supports the aorta. Common associated lesions are VSD and pulmonary stenosis. A dysplastic left-sided tricuspid valve is almost always present. In the absence of associated lesions, patients with ccTGA are often undiagnosed until adulthood when they present with left-sided AV valve insufficiency or arrhythmias.

Previously, surgical repair was directed at VSD closure and relief of pulmonary outflow tract obstruction—a technique that maintained the RV as the systemic ventricle supporting the aorta. It is now recognized that these patients have a reduced life span; thus other surgical techniques have been advocated. The double-switch procedure is one such technique. An atrial level switch (Mustard or Senning technique) is performed, in which pulmonary and systemic venous blood are baffled across the atrial mass in a way that prevents mixing and drains into the contralateral ventricle. An ASO then restores the morphologic LV to its position as systemic ventricle.

Patients with ccTGA have an increased incidence of complete heart block with an estimated risk of 1% per year and an overall frequency of 50%.

Bove EL et al: Anatomic correction of congenitally corrected transposition and its close cousins. *Cardiol Young* 2006;16(Suppl 3):85 [PMID: 17378045].

2. Double-Outlet Right Ventricle

In this uncommon malformation, both great arteries arise from the RV. There is always a VSD that allows blood to exit

the LV. Presenting symptoms depend on the relationship of the VSD to the semilunar valves. The VSD can be in variable positions, and the great arteries could be normally related or malposed. In the absence of outflow obstruction, a large left-to-right shunt exists and the clinical picture resembles that of a large VSD. Pulmonary stenosis may be present, particularly if the VSD is remote from the pulmonary artery. This physiology is similar to ToF. Alternatively, if the VSD is nearer the pulmonary artery, aortic outflow may be obstructed (called the Taussig-Bing malformation). Early primary correction is the goal. LV flow is directed to the aorta across the VSD, and frequently an RV-pulmonary artery conduit is placed to maintain an unobstructed pulmonary circuit. If the aorta is far from the VSD, an arterial switch may be necessary. Echocardiography is usually sufficient to make the diagnosis and determine the orientation of the great vessels and their relationship to the VSD.

TOTAL ANOMALOUS PULMONARY VENOUS RETURN

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Abnormal pulmonary venous connection *leading to cyanosis.*
- ▶ Occurs with or without murmur and may have accentuated P₂.
- ▶ Right atrial enlargement and RVH.

▶ General Considerations

This malformation accounts for 2% of all congenital heart lesions. The pulmonary venous blood drains into a confluence behind the left atrium, but the confluence is not connected to the left atrium. The pulmonary venous blood finds another route to rejoin the circulation via the larger systemic veins. This leads to complete mixing at the level of the right atrium. The presentation of total anomalous pulmonary venous return (TAPVR) depends on the route of return to the systemic circulation and whether or not the return is obstructed.

The malformation is classified by the site of entry of the pulmonary venous drainage into the right side of the heart. Supradiaphragmatic return is defined as a confluence that drains into the right superior vena cava, innominate vein or persistent left superior vena cava. In infradiaphragmatic return the confluence returns below the diaphragm usually

into the portal venous system which empties into the inferior vena cava. Infradiaphragmatic pulmonary venous return is essentially always obstructed. It is a surgical emergency. Supradiaphragmatic veins may also be obstructed, though less commonly. Rarely, pulmonary veins can drain directly to the right atrium, or a single confluence may drain to more than one location, called mixed TAPVR.

Because the entire venous drainage from the body comes to the right atrium, a right-to-left shunt must be present at the atrial level, either as an ASD or a patent foramen ovale. Occasionally the atrial septum is restrictive and balloon septostomy is needed at birth to allow filling of the left heart.

► Clinical Findings

A. Unobstructed Pulmonary Venous Return

Patients with a large atrial communication tend to have high pulmonary blood flow and typically present with cardiomegaly and HF rather than cyanosis. Oxygen saturations in the high 80s or low 90s are common. Most patients in this group have mild to moderate elevation of pulmonary artery pressure owing to elevated pulmonary blood flow. In most instances, PA pressure does not reach systemic levels.

1. Symptoms and signs—Patients may have mild cyanosis in the neonatal period and early infancy. Thereafter, they do relatively well except for frequent respiratory infections. They are usually small and thin, resembling patients with other large left-to-right shunts. Examination discloses dusky nail beds and mucous membranes, but overt cyanosis and digital clubbing are usually absent. The arterial pulses are normal. An RV heave is palpable, and P_2 is increased. A systolic and diastolic murmur may be heard as a result of increased flow across the pulmonary and tricuspid valves, respectively.

2. Imaging—Chest radiography reveals cardiomegaly involving the right heart and pulmonary artery. Pulmonary vascular markings are increased. The characteristic cardiac contour called a “snowman” or “figure 8” is often seen when the anomalous veins drain via a persistent left superior vena cava to the innominate vein and then the right superior vena cava, but this is not apparent until about 3 months of age when the vertical and innominate vein have dilated.

3. Electrocardiography—ECG shows right axis deviation and varying degrees of right atrial enlargement and right ventricular hypertrophy. A qR pattern is often seen over the right precordial leads.

4. Echocardiography—Demonstration by echocardiography of a discrete chamber posterior to the left atrium is strongly suggestive of the diagnosis. The availability of two-dimensional echocardiography plus color-flow Doppler has increased diagnostic accuracy such that diagnostic cardiac catheterization is rarely required.

B. With Obstructed Pulmonary Venous Return

This group includes all patients with infradiaphragmatic TAPVR and a few of the patients in whom venous drainage is into a systemic vein above the diaphragm.

1. Symptoms and signs—Infants usually present shortly after birth with severe cyanosis and require early corrective surgery. Cardiac examination discloses a striking RV impulse. S_1 is accentuated and S_2 is markedly accentuated and single. There is no murmur in many cases. Sometimes, a systolic murmur is heard over the pulmonary area with radiation over the lung fields. Diastolic murmurs are uncommon.

2. Imaging—The heart is usually small and pulmonary venous congestion severe with associated air bronchograms. The chest radiographic appearance may lead to an erroneous diagnosis of severe lung disease. In less severe cases, the heart size may be normal or slightly enlarged with mild pulmonary venous congestion.

3. Electrocardiography—The ECG shows right axis deviation, right atrial enlargement, and RVH.

4. Echocardiography—Echocardiography shows a small left atrium and LV. For infradiaphragmatic TAPVR, appearance of a vessel lying parallel and anterior to the descending aorta and to the left of the inferior vena cava may represent the vein draining the confluence caudally toward the diaphragm. Color-flow Doppler echocardiography may reveal flow disturbance, commonly near the confluence or in the liver, where flow is obstructed.

5. Cardiac catheterization and angiocardiography—If echocardiography does not confirm the anatomy, cardiac catheterization and angiography demonstrate the site of entry of the anomalous veins. Catheterization can also assist in calculating the ratio of pulmonary to systemic blood flow and the degree of pulmonary hypertension and pulmonary vascular resistance.

► Treatment

Surgery is always required for TAPVR. If pulmonary venous return is obstructed, surgery must be performed immediately. In unobstructed TAPVR, surgery may be delayed for weeks to months. The timing of surgery is determined by the child's weight gain and the risk of pulmonary infection. If early surgery is not required and the atrial septum is restrictive, a balloon atrial septostomy can be performed in newborns.

► Course & Prognosis

Most children with TAPVR do well after surgery. Some surgical survivors develop late stenosis of the pulmonary veins. Pulmonary vein stenosis is an intractable condition that is difficult to treat either with interventional catheterization or surgery and has a poor prognosis. By avoiding direct suturing at the pulmonary venous ostia, the chance of

recurrent stenosis at the anastomotic site is lessened. Unfortunately, any manipulation of the pulmonary veins increases the risk of stenosis.

Lacour-Gayet F: Surgery for pulmonary venous obstruction after repair of total anomalous pulmonary venous return. *Semin Thorac Cardiovasc Surg Pediatr Card Surg Annu* 2006;45 [PMID: 16638547].

TRUNCUS ARTERIOSUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Early HF with or without cyanosis.
- ▶ Systolic ejection click.

▶ General Considerations

Truncus arteriosus accounts for less than 1% of congenital heart malformations. A single great artery arises from the heart, giving rise to the systemic, pulmonary, and coronary circulations. Truncus develops embryologically as a result of failure of the division of the common truncus arteriosus into the aorta and the pulmonary artery. A VSD is always present. The number of truncal valve leaflets varies from two to six, and the valve may be insufficient or stenotic.

Truncus arteriosus is divided into subtypes by the anatomy of the pulmonary circulation. A single main pulmonary artery may arise from the base of the trunk and gives rise to branch pulmonary arteries (type 1). Alternatively, the pulmonary arteries may arise separately from the common trunk, either in close association with one another (type 2) or widely separated (type 3).

In patients with truncus, blood from both ventricles leaves the heart through a single exit. Thus, oxygen saturation in the pulmonary artery is equal to that in the systemic arteries. The degree of systemic arterial oxygen saturation depends on the ratio of pulmonary to systemic blood flow. If pulmonary vascular resistance is normal, the pulmonary blood flow is greater than the systemic blood flow and the saturation is relatively high. If pulmonary vascular resistance is elevated because of pulmonary vascular obstructive disease or small pulmonary arteries, pulmonary blood flow is reduced and oxygen saturation is low. The systolic pressures are systemic in both ventricles.

▶ Clinical Findings

A. Symptoms and Signs

High pulmonary blood flow characterizes most patients with truncus arteriosus. These patients are usually acyanotic and present in HF. Examination of the heart reveals a hyperactive precordium. A systolic thrill is common at the lower left

sternal border. A loud early systolic ejection click is commonly heard. S_2 is single and accentuated. A loud holosystolic murmur is audible at the left lower sternal border. A diastolic flow murmur can often be heard at the apex due to increased pulmonary venous return crossing the mitral valve. An additional diastolic murmur of truncal insufficiency may be present.

Patients with decreased pulmonary blood flow are cyanotic early. The most common manifestations are growth retardation, easy fatigability, and HF. The heart is not hyperactive. S_1 and S_2 are single and loud. A systolic murmur is heard at the lower left sternal border. No mitral flow murmur is heard, as pulmonary venous return is decreased. A loud systolic ejection click is commonly heard.

B. Imaging

The common radiographic findings are a boot-shaped heart, absence of the main pulmonary artery segment, and a large aorta that has a right arch 30% of the time. The pulmonary vascular markings vary with the degree of pulmonary blood flow.

C. Electrocardiography

The axis is usually normal. RVH or combined ventricular hypertrophy is commonly present.

D. Echocardiography

Images generally show override of a single great artery (similar to ToF, but no second great artery arises directly from the heart). The origin of the pulmonary arteries and the degree of truncal valve abnormality can be seen. Color-flow Doppler can aid in the description of pulmonary flow and the function of the truncal valve, both of which are critical to management.

E. Angiocardiology

Cardiac catheterization is not routinely performed but may be of value in older infants in whom pulmonary vascular disease must be ruled out. The single most important angiogram would be from the truncal root, as both the origin of the pulmonary arteries and the amount of truncal insufficiency would be seen from one injection.

▶ Treatment

Anticongestive measures are needed for patients with high pulmonary blood flow and congestive failure. Surgery is always required in this condition. Because of HF, surgery is usually performed in the neonatal period. The VSD is closed to allow LV egress to the truncal valve. The pulmonary artery (type 1) or arteries (types 2–3) are separated from the truncus as a block, and a valved conduit is fashioned from the RV to the pulmonary circulation.

Course & Prognosis

Children with a good surgical result generally do well. Similar to patients with ToF, they almost always outgrow the RV-to-pulmonary artery conduit placed in infancy and require revision of the conduit in later childhood. The risk of early pulmonary vascular obstructive disease is high in the unrepaired patient and a decision to delay open-heart surgery beyond age 4–6 months is not wise even in stable patients.

ACQUIRED HEART DISEASE

RHEUMATIC FEVER

Rheumatic fever remains a major cause of morbidity and mortality in developing countries that suffer from poverty, overcrowding, and poor access to health care. Even in developed countries, rheumatic fever has not been entirely eradicated. The overall incidence in the United States is less than 1 per 100,000. There have been regional resurgences, such as in Utah in the 1980s, with an incidence of nearly 12 per 100,000 children between the ages of 3 and 17 years.

Group A β -hemolytic streptococcal infection of the upper respiratory tract is the essential trigger in predisposed individuals. Only certain serotypes of group A *Streptococcus* cause rheumatic fever. The latest attempts to define host susceptibility implicate immune response genes that are present in approximately 15% of the population. The immune response triggered by colonization of the pharynx with group A streptococci consists of (1) sensitization of B lymphocytes by streptococcal antigens, (2) formation of antistreptococcal antibody, (3) formation of immune complexes that cross-react with cardiac sarcolemma antigens, and (4) myocardial and valvular inflammatory response.

The peak age of risk in the United States is 5–15 years. The disease is slightly more common in girls and in African Americans. The annual death rate from rheumatic heart disease in school-aged children (whites and nonwhites) recorded in the 1980s was less than 1 per 100,000.

Clinical Findings

Two major or one major and two minor manifestations (plus supporting evidence of streptococcal infection) based on the modified Jones criteria are needed for the diagnosis of acute rheumatic fever (Table 19–14). Except in cases of rheumatic fever manifesting solely as Sydenham chorea or long-standing carditis, there should be clear evidence of a streptococcal infection such as scarlet fever, a positive throat

Table 19–14. Jones criteria (modified) for diagnosis of rheumatic fever.

Major manifestations

Carditis
Polyarthritides
Sydenham chorea
Erythema marginatum
Subcutaneous nodules

Minor manifestations

Clinical

Previous rheumatic fever or rheumatic heart disease
Polyarthralgia
Fever

Laboratory

Acute phase reaction: elevated erythrocyte sedimentation rate,
C-reactive protein, leukocytosis
Prolonged PR interval

plus

Supporting evidence of preceding streptococcal infection, that is, increased titers of antistreptolysin O or other streptococcal antibodies, positive throat culture for group A *Streptococcus*

culture for group A β -hemolytic *Streptococcus*, and increased antistreptolysin O or other streptococcal antibody titers. The antistreptolysin O titer is significantly higher in rheumatic fever than in uncomplicated streptococcal infections.

A. Carditis

Carditis is the most serious consequence of rheumatic fever and varies from minimal to life-threatening HF. The term *carditis* implies pancardiac inflammation, but it may be limited to valves, myocardium, or pericardium. Valvulitis is frequently seen, with the mitral valve most commonly affected. Mitral insufficiency is the most common valvular residua of acute rheumatic carditis. Mitral stenosis after acute rheumatic fever is rarely encountered until 5–10 years after the first episode. Thus, mitral stenosis is much more commonly seen in adults than in children.

An early decrescendo diastolic murmur consistent with aortic insufficiency is occasionally encountered as the sole valvular manifestation of rheumatic carditis. The aortic valve is the second most common valve affected in polyvalvular as well as in single-valve disease. The aortic valve is involved more often in males and in African Americans. Dominant aortic stenosis of rheumatic origin does not occur in pediatric patients. In one large study, the shortest length of time observed for a patient to develop dominant aortic stenosis secondary to rheumatic heart disease was 20 years.

B. Polyarthritides

The large joints (knees, hips, wrists, elbows, and shoulders) are most commonly involved and the arthritis is typically migratory. Joint swelling and associated limitation of move-

ment should be present. This is one of the more common major criteria, occurring in 80% of patients. Arthralgia alone is not a major criterion.

C. Sydenham Chorea

Sydenham chorea is characterized by involuntary and purposeless movements and is often associated with emotional lability. These symptoms become progressively worse and may be accompanied by ataxia and slurring of speech. Muscular weakness becomes apparent following the onset of the involuntary movements. Chorea is self-limiting, although it may last up to 3 months. Chorea may not be apparent for months to years after the acute episode of rheumatic fever.

D. Erythema Marginatum

A macular, serpiginous, erythematous rash with a sharply demarcated border appears primarily on the trunk and the extremities. The face is usually spared.

E. Subcutaneous Nodules

These usually occur only in severe cases, and then most commonly over the joints, scalp, and spinal column. The nodules vary from a few millimeters to 2 cm in diameter and are nontender and freely movable under the skin.

► Treatment & Prophylaxis

A. Treatment of the Acute Episode

1. Anti-infective therapy—Eradication of the streptococcal infection is essential. Long-acting benzathine penicillin is the drug of choice. Depending on the age and weight of the patient, give a single intramuscular injection of 0.6–1.2 million units; alternatively, give penicillin V, 125–250 mg orally four times a day for 10 days. Erythromycin, 250 mg orally four times a day, may be substituted if the patient is allergic to penicillin.

2. Anti-inflammatory agents

A. ASPIRIN—Aspirin, 30–60 mg/kg/d, is given in four divided doses. This dose is usually sufficient to effect dramatic relief of arthritis and fever. Higher dosages carry a greater risk of side effects and there are no proven short- or long-term benefits of high doses that produce salicylate blood levels of 20–30 mg/dL. The duration of therapy is tailored to meet the needs of the patient, but 2–6 weeks of therapy with reduction in dose toward the end of the course is usually sufficient. Other nonsteroidal anti-inflammatory agents used because of concerns about Reye syndrome are less effective than aspirin.

B. CORTICOSTEROIDS—Corticosteroids are seldom indicated except in the rare patient with severe carditis and HF, in whom they may be lifesaving. Steroids are given as follows: prednisone, 2 mg/kg/d orally for 2 weeks; reduce prednisone to 1 mg/kg/d during the third week, and begin aspirin, 50

mg/kg/d; stop prednisone at the end of 3 weeks, and continue aspirin for 8 weeks or until the C-reactive protein is negative and the sedimentation rate is falling.

3. Therapy in heart failure—Treatment for HF is based on symptoms and severity of valve involvement and cardiac dysfunction (see section on Heart Failure, earlier).

4. Bed rest and ambulation—Bed rest is not required in most cases. Activity level should be commensurate with symptoms and children should be allowed to self-limit their activity level while affected. Children should not return to school while there is clear evidence of rheumatic activity. Most acute episodes of rheumatic fever are managed on an outpatient basis.

B. Treatment after the Acute Episode

1. Prevention—Prevention is critical, as patients who have had rheumatic fever are at greater risk of recurrence if future group A β -hemolytic streptococcal infections are inadequately treated. Follow-up visits are essential to reinforce the necessity for prophylaxis with regular long-acting benzathine penicillin. Intramuscular rather than oral medication is associated with better adherence and is the preferred method of prophylaxis. If myocardial or valvular disease persists, antibacterial prophylaxis is a lifelong commitment. More commonly with transient or no cardiac involvement, 3–5 years of therapy or discontinuance in early adulthood (age 21) is an effective approach.

The following preventive regimens are in current use:

A. PENICILLIN G BENZATHINE—1.2 million units intramuscularly every 21–28 days is the drug of choice.

B. SULFADIAZINE—500 mg daily as a single oral dose for patients weighing more than 27 kg is the drug of second choice. Blood dyscrasias and lesser effectiveness in reducing streptococcal infections make this drug less satisfactory than penicillin benzathine G.

C. PENICILLIN V—250,000 units orally twice daily offers approximately the same protection afforded by sulfadiazine but is much less effective than intramuscular penicillin benzathine G (5.5 versus 0.4 streptococcal infections per 100 patient-years).

D. ERYTHROMYCIN—250 mg orally twice a day may be given to patients who are allergic to both penicillin and sulfonamides.

2. Residual valvular damage—As described above, the mitral and aortic valves are most commonly affected by rheumatic fever and the severity of carditis is quite variable. In the most severe cases, cardiac failure or the need for a valve replacement can occur in the acute setting. In less severe cases, valve abnormalities can persist, requiring lifelong medical management and eventual valve replacement. Other patients fully recover without residual cardiac sequelae.

Dajani A et al: Treatment of acute streptococcal pharyngitis and prevention of rheumatic fever: A statement for health professionals. Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the Council on Cardiovascular Disease in the Young, the American Heart Association. *Pediatrics* 1996;96(4 Pt 1):758 [PMID: 7567345].

KAWASAKI DISEASE

Kawasaki disease was first described in Japan in 1967 and was initially called mucocutaneous lymph node syndrome. The cause is unclear and there is no specific diagnostic test. Kawasaki disease is the leading cause of acquired heart disease in children in the United States. Eighty percent of patients are younger than 5 years old (median age at diagnosis is 2 years), and the male-to-female ratio is 1.5:1. Diagnostic criteria are fever for more than 5 days and at least four of the following features: (1) bilateral, painless, nonexudative conjunctivitis; (2) lip or oral cavity changes (eg, lip cracking and fissuring, strawberry tongue, and inflammation of the oral mucosa); (3) cervical lymphadenopathy ≥ 1.5 cm in diameter and usually unilateral); (4) polymorphous exanthema; and (5) extremity changes (redness and swelling of the hands and feet with subsequent desquamation). Clinical features not part of the diagnostic criteria, but frequently associated with Kawasaki disease, are shown in Table 19–15.

The potential for cardiovascular complications is the most serious aspect of Kawasaki disease. Complications during the acute illness include myocarditis, pericarditis, valvular heart disease (usually mitral or aortic regurgitation), and coronary arteritis. Patients with fever for at least 5 days

Table 19–15. Noncardiac manifestations of Kawasaki disease.

System	Associated Signs and Symptoms
Gastrointestinal	Vomiting, diarrhea, gallbladder hydrops, elevated transaminases
Blood	Elevated ESR or CRP, leukocytosis, hypoalbuminemia, mild anemia in acute phase and thrombocytosis in subacute phase (usually second to third week of illness)
Renal	Sterile pyuria, proteinuria
Respiratory	Cough, rhinorrhea, infiltrate on chest radiograph
Joint	Arthralgia and arthritis
Neurologic	Mononuclear pleocytosis of cerebrospinal fluid, irritability, facial palsy

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate.

but fewer than four of the diagnostic features can be diagnosed with atypical Kawasaki disease if they have coronary artery abnormalities detected by echocardiography.

Coronary artery lesions range from mild transient dilation of a coronary artery to large aneurysms. Aneurysms rarely form before day 10 of illness. Untreated patients have a 15–25% risk of developing coronary aneurysms. Those at greatest risk of aneurysm are males, young children (< 6 months), and those not treated with intravenous immunoglobulin (IVIG). Most coronary artery aneurysms resolve within 5 years of diagnosis; however, as aneurysms resolve, associated obstruction or stenosis (19% of all aneurysms) may develop, which may result in coronary ischemia. Giant aneurysms (> 8 mm) are less likely to resolve, and nearly 50% eventually become stenotic. Of additional concern, acute thrombosis of an aneurysm can occur, resulting in myocardial infarction that is fatal in approximately 20% of cases.

▶ Treatment

Immediate management of Kawasaki disease is IVIG and high-dose aspirin. This therapy is effective in decreasing the incidence of coronary artery dilation and aneurysm formation. The currently recommended regimen is 2 g/kg of IVIG administered over 10–12 hours and 80–100 mg/kg/d of aspirin in four divided doses. The duration of high-dose aspirin is institution-dependent: many centers reduce the dose once the patient is afebrile for 48–72 hours; others continue through day 14 of the illness. Once high-dose aspirin is discontinued, low-dose aspirin (3–5 mg/kg/d) is given through the subacute phase of the illness (6–8 weeks) or until coronary artery abnormalities resolve. If fever recurs within 48–72 hours of the initial treatment course and no other source of the fever is detected, a second dose of IVIG is often recommended; however, the effectiveness of this approach has not been clearly demonstrated. A recent multicenter, randomized, double-blind, placebo-controlled study (Newburger et al) demonstrated no beneficial effect of pulsed corticosteroids on the development of coronary abnormalities in patients responsive to IVIG. However, corticosteroids should be considered for patients with persistent fever despite at least two infusions of IVIG.

Follow-up of patients with treated Kawasaki disease depends on the degree of coronary involvement. In those with no or minimal coronary disease at the time of diagnosis, an echocardiogram 2 weeks and again 6–8 weeks after diagnosis is sufficient. Repeat echocardiography more than 8 weeks after diagnosis in those with no coronary abnormalities is optional. In 2004, the AHA published updated guidelines for the long-term management of Kawasaki disease based on the risk level of the patient. The risk stratification and recommended follow-up can be reviewed in Table 19–16.

Burns JC et al: Intravenous gamma-globulin treatment and retreatment in Kawasaki disease. US/Canadian Kawasaki Syndrome Group. *Pediatr Infect Dis J* 1998;17:1144 [PMID: 9877364].

Table 19-16. Long-term management in Kawasaki disease.

Risk Level	Definition	Management Guidelines
I	No coronary artery changes at any stage of the illness	No ASA is needed beyond the sub-acute phase (6-8 wk). No follow-up beyond the first year.
II	Transient ectasia of coronary arteries during the acute phase	Same as above, or clinical follow-up \pm ECG every 3-5 y.
III	Single small to medium coronary aneurysm	ASA until abnormality resolves. Annual follow-up with ECG and echo if younger than age 10 y and every-other-year stress testing if older than 10 y.
IV	Giant aneurysm or multiple small to medium aneurysms without obstruction	Long-term ASA \pm warfarin. Annual follow-up with ECG, echo, and stress testing (in those older than 20 y).
V	Coronary artery obstruction	Long-term ASA \pm warfarin \pm calcium channel blocker to reduce myocardial oxygen consumption. Echo and ECG every 6 months. Stress testing and Holter examination annually.

ASA, acetyl salicylic acid; ECG, electrocardiogram; echo, echocardiogram.

CARDIOMYOPATHY

The three most common forms of cardiomyopathy in children are (1) dilated, (2) hypertrophic, and (3) restrictive. Two other cardiomyopathies recently classified as distinct entities include arrhythmogenic right ventricular dysplasia (ARVD) and left ventricular noncompaction.

1. Dilated Cardiomyopathy

This most frequent of the childhood cardiomyopathies occurs with an annual incidence of 4-8 cases per 100,000 population in the United States and Europe. Although usually idiopathic, identifiable causes of dilated cardiomyopathy

(DCM) include viral myocarditis, untreated tachyarrhythmias, left heart obstructive lesions, congenital abnormalities of the coronary arteries, toxicity (eg, anthracycline), and genetic (eg, dystrophin gene defects, responsible for Duchenne and Becker muscular dystrophies) and metabolic diseases (inborn errors of fatty acid oxidation and mitochondrial oxidative phosphorylation defects). Genetic causes are being discovered at an increasing rate with commercial testing now available for some of the more common genes.

► Clinical Findings

A. Signs and Symptoms

As myocardial function fails and the heart dilates, cardiac output falls, and affected children develop decreased exercise tolerance, failure to thrive, diaphoresis, and tachypnea. As the heart continues to deteriorate, congestive signs such as hepatomegaly and rales develop, and a prominent gallop can be appreciated on examination. The initial diagnosis in a previously healthy child can be difficult, as presenting symptoms can resemble a viral respiratory infection, pneumonia, or asthma.

B. Imaging

Chest radiograph shows generalized cardiomegaly with or without pulmonary venous congestion.

C. Electrocardiography

Sinus tachycardia with ST-T segment changes is commonly seen on ECG. The criteria for right and left ventricular hypertrophy may also be met. Evaluation for the presence of supraventricular arrhythmias on ECG is critical, as this is one of the few treatable and reversible causes of DCM in children.

D. Echocardiography

The echocardiogram shows LV and left atrial enlargement with decreased LV shortening fraction and ejection fraction. The calculated end-diastolic and end-systolic dimensions are increased and mitral insufficiency is commonly seen. A careful evaluation for evidence of structural abnormalities (especially coronary artery anomalies) must be performed in infant patients.

E. Other Testing

Cardiac catheterization is useful to evaluate hemodynamic status and coronary artery anatomy. Endomyocardial biopsies can aid in diagnosis. Biopsy specimens may show inflammation consistent with acute myocarditis, abnormal myocyte architecture and myocardial fibrosis. Electron micrographs may reveal evidence of mitochondrial and other metabolic disorders. Polymerase chain reaction (PCR) testing may be performed on biopsied specimens to detect viral genome products in infectious myocarditis. Skeletal muscle biopsy

may be helpful in patients with evidence of skeletal muscle involvement. Cardiopulmonary stress testing is useful for measuring response to medical therapy and as an objective assessment of the cardiac limitations on exercise.

► Treatment & Prognosis

Outpatient management of pediatric DCM usually entails combinations of afterload-reducing agents, digoxin, and diuretics (see section on Heart Failure, earlier). A recently completed multicenter, placebo-controlled, double-blind trial of carvedilol in children with HF will help determine the efficacy of β -blocker therapy as an adjunct in these patients. Aspirin or warfarin may be used to prevent thrombus formation in the dilated and poorly contractile cardiac chambers. Arrhythmias are more common in dilated hearts. Antiarrhythmic agents that do not suppress myocardial contractility, such as amiodarone, are used. Despite widespread use of internal defibrillators in the adult population, the technical difficulty of implanting internal defibrillators and the risk of adverse events (eg, inappropriate discharge) in children limit their use.

Therapy of the underlying cause of cardiomyopathy is always indicated if possible. Unfortunately despite complete evaluation, a diagnosis is discovered in less than 30% of patients with DCM. If medical management is unsuccessful, cardiac transplantation is considered.

2. Hypertrophic Cardiomyopathy

The most common cause of hypertrophic cardiomyopathy (HCM) is familial hypertrophic cardiomyopathy, which is found in 1 in 500 individuals. HCM is the leading cause of sudden cardiac death in young persons. The most common presentation is an older child, adolescent, or adult, although it may occur in neonates. Other causes of HCM in neonates and children are glycogen storage disease, Noonan syndrome, Friedreich ataxia, maternal gestational diabetes, mitochondrial disorders, and other metabolic disorders.

A. Familial Hypertrophic Cardiomyopathy

In the familial form, HCM is most commonly caused by a mutation in one of the several genes that encode proteins of the cardiac sarcomere (B-myosin heavy chain, cardiac troponin T or I, α -tropomyosin, and myosin-binding protein C).

1. Clinical findings—Patients may be asymptomatic despite having significant hypertrophy, or may present with symptoms of inadequate coronary perfusion such as angina, syncope, palpitations, or exercise intolerance. Patients may experience sudden cardiac death as their initial presentation, often precipitated by sporting activities. Although the cardiac examination may be normal on presentation, eventually patients develop a left precordial bulge with a diffuse point of maximal impulse. An LV heave or an S_4 gallop may be present. If outflow tract obstruction exists, a systolic ejection murmur will be audible. A murmur may not be audible at

rest but may be provoked with exercise or positional maneuvers that decrease left ventricular volume (standing) thereby increasing the outflow tract obstruction.

A. ECHOCARDIOGRAPHY—The diagnosis of HCM is usually made by echocardiography and in most familial cases demonstrates asymmetrical septal hypertrophy. Young patients with metabolic or other nonfamilial causes are more likely to have concentric hypertrophy. Systolic anterior motion of the mitral valve leaflet may occur and contribute to LV outflow tract obstruction. The mitral valve leaflet may become distorted and cause mitral insufficiency over time. LV outflow tract obstruction may be present at rest or provoked with either amyl nitrate or monitored exercise. Systolic function is most often hypercontractile in young children but may deteriorate over time, resulting in poor contractility and LV dilation. Diastolic function is almost always abnormal.

B. ELECTROCARDIOGRAPHY—The ECG may be normal, but more typically demonstrates deep Q waves in the inferolateral leads (II, III, aVF, V_5 , and V_6) secondary to the increased mass of the hypertrophied septum. ST segment abnormalities may be seen in the same leads. Age-dependent criteria for LVH are often present as are criteria for left atrial enlargement.

C. OTHER TESTING—Cardiopulmonary stress testing is valuable to evaluate for provokable LV outflow tract obstruction, ischemia, and arrhythmias, and to determine prognosis. A blunted blood pressure response and ventricular arrhythmias with exercise have both been associated with increased mortality in children. Nuclear stress testing allows for assessment of myocardial perfusion defects. Patients are at risk for myocardial ischemia, possibly as a result of systolic compression of the intramyocardial septal perforators, myocardial bridging of epicardial coronary arteries, or an imbalance of coronary artery supply and demand due to the presence of massive myocardial hypertrophy.

D. CARDIAC CATHETERIZATION—Cardiac catheterization should be performed in patients with HCM who have angina, syncope, resuscitated sudden death, or a worrisome stress test. Hemodynamic findings include elevated left atrial pressure secondary to impaired diastolic filling. If midcavitary LV outflow tract obstruction is present, an associated pressure gradient will be evident. Provocation of LV outflow tract obstruction with either rapid atrial pacing or isoproterenol may be sought. Angiography demonstrates a “ballerina slipper” configuration of the LV secondary to the midcavitary LV obliteration during systole. The myocardial biopsy specimen demonstrates myofiber disarray.

2. Treatment and prognosis—Treatment varies depending on symptoms and phenotype. Patients are usually restricted from competitive athletics and isometric exercise. Patients with resting or latent LV outflow tract obstruction may be treated with β -blockers, verapamil, or disopyramide with variable success in alleviating obstruction. Patients with severe symptoms despite medical therapy and an LV outflow tract gradient

may require additional intervention. Surgical myectomy with resection of part of the hypertrophied septum has been used with good results. At the time of myectomy, the mitral valve may require repair or replacement in patients with a long history of systolic anterior motion of the mitral valve. Ethanol ablation is being used increasingly in adults with HCM and LV outflow tract obstruction. This procedure involves selective infiltration of ethanol in a coronary septal artery branch to induce a small myocardial infarction. This leads to a reduction in septal size and improvement of obstruction. The long-term effects of this procedure are unknown and it is not currently employed in children. Although dual-chamber pacing has been used in children with good relief of obstruction, larger series demonstrate no significant improvement in obstruction. Risk stratification with respect to sudden death is important in HCM. Internal defibrillators are placed in patients with severe hypertrophy (> 3 cm septal thickness in adults), documented ventricular arrhythmias, resuscitated sudden death, or a strong family history of HCM with associated sudden death.

B. Glycogen Storage Disease of the Heart

There are at least 10 types of glycogen storage disease. The type that primarily involves the heart is Pompe disease (GSD IIa) in which acid maltase, necessary for hydrolysis of the outer branches of glycogen, is absent. There is marked deposition of glycogen within the myocardium. Affected infants are well at birth, but symptoms of growth and developmental delay, feeding problems, and cardiac failure occur by the sixth month of life. Physical examination reveals generalized muscular weakness, a large tongue, and cardiomegaly without significant heart murmurs. Chest radiographs reveal cardiomegaly with or without pulmonary venous congestion. The ECG shows a short PR interval and LVH with ST depression and T-wave inversion over the left precordial leads. Echocardiography shows severe concentric LVH. Children with Pompe disease usually die before age 1 year. Death may be sudden or result from progressive HF.

3. Restrictive Cardiomyopathy

Restrictive cardiomyopathy is a rare entity in the pediatric population, accounting for less than 5% of all cases of cardiomyopathy. The cause is usually idiopathic but can be familial or secondary to an infiltrative process (eg, amyloidosis).

► Clinical Findings

Patients present with signs of HF as outlined previously. Physical examination is remarkable for a prominent S_4 and jugular venous distention.

A. Electrocardiography

ECG demonstrates marked right and left atrial enlargement with normal ventricular voltages. ST-T-wave abnormalities including a prolonged QTc interval may be present.

B. Echocardiography

The diagnosis is confirmed echocardiographically by the presence of normal sized ventricles with normal systolic function and massively dilated atria. Cardiac MRI is useful in ruling out pericardial abnormalities that can result in similar echocardiographic and clinical findings consistent with restrictive or constrictive pericarditis.

► Treatment & Prognosis

Anticongestive therapy is used for symptomatic relief. The high risk of sudden death in restrictive cardiomyopathy and the propensity for rapid progression of pulmonary hypertension warrant close follow-up with early consideration of cardiac transplantation in most patients.

MYOCARDITIS

The most common causes of viral myocarditis are adenovirus, coxsackie A and B viruses, echovirus, cytomegalovirus, parvovirus, and influenza A virus. Human immunodeficiency virus can also cause myocarditis. The ability to identify the pathogen has been enhanced by PCR technology, which replicates identifiable segments of the viral genome from the myocardium of affected children.

► Clinical Findings

A. Symptoms and Signs

There are two major clinical patterns. In the first, sudden-onset HF occurs in an infant or child who was relatively healthy 12–24 hours previously. This malignant form of the disease is usually secondary to overwhelming viremia with tissue invasion in multiple organ systems including the heart. In the second pattern, the onset of cardiac symptoms is gradual and there is often a history of upper respiratory tract infection or gastroenteritis in the previous month. This more insidious form may have a late postinfectious or autoimmune component. Acute and chronic presentations occur at any age and with all types of myocarditis.

The signs of HF include pale gray skin; rapid, weak, and thready pulses; and edema of the face and extremities.

Patients are breathless and often orthopneic. The heart sounds may be muffled and distant, an S_3 or S_4 gallop (or both) are common. Murmurs are usually absent, although a murmur of tricuspid or mitral insufficiency may be heard. Moist rales are usually present at both lung bases. The liver is enlarged and frequently tender.

B. Imaging

Generalized cardiomegaly is seen on radiographs along with moderate to marked pulmonary venous congestion.

C. Electrocardiography

The ECG is variable. Classically, there is low-voltage QRS in all frontal and precordial leads with ST-segment depression and inversion of T waves in leads I, III, and aVF (and in the left precordial leads during the acute stage). Dysrhythmias are common, and AV and intraventricular conduction disturbances may be present.

D. Echocardiography

Echocardiography demonstrates four-chamber dilation with poor ventricular function and AV valve regurgitation. A pericardial effusion may be present.

E. Myocardial Biopsy

An endomyocardial biopsy may be helpful in the diagnosis of viral myocarditis. An inflammatory infiltrate with myocyte damage can be seen by hematoxylin and eosin staining. Viral PCR testing of the biopsy specimen may yield a positive result in 30–40% of patients suspected to have myocarditis.

► Treatment

The use of digitalis in a rapidly deteriorating child with myocarditis is dangerous and should be undertaken with great caution, as it may cause ventricular dysrhythmias. The inpatient cardiac support measures outlined previously in the section on heart failure are used in the treatment of these patients.

Administration of immunomodulating medications such as corticosteroids for myocarditis is controversial. If the patient's condition deteriorates despite anticongestive measures, corticosteroids are commonly used, although conclusive data supporting their effectiveness are lacking. Subsequent to the successful use of IVIG in children with Kawasaki disease, there have been several trials of IVIG in presumed viral myocarditis. The therapeutic value of IVIG remains unconfirmed.

► Prognosis

The prognosis of myocarditis is determined by the age at onset and the response to therapy. In patients younger than

6 months or older than 3 years with poor response to therapy, the prognosis is poor. Although complete recovery is possible, many patients recover clinically but have persistent LV dysfunction and a need for ongoing medical therapy for HF. It is possible that subclinical myocarditis in childhood is the pathophysiologic basis for some of the idiopathic dilated cardiomyopathies later in life. Children with myocarditis whose ventricular function fails to return to normal may be candidates for cardiac transplantation.

INFECTIVE ENDOCARDITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Positive blood culture.
- Intracardiac oscillating mass, abscess, or new valve regurgitation on echocardiogram.
- Fever.
- Elevated erythrocyte sedimentation rate or C-reactive protein.

► General Considerations

Bacterial or fungal infection of the endocardium of the heart is rare and usually occurs in the setting of a preexisting abnormality of the heart or great arteries. It may occur in a normal heart during septicemia or as a consequence of infected indwelling central catheters.

The frequency of infective endocarditis (IE) appears to be increasing for a several reasons: (1) increased survival in children with congenital heart disease, (2) greater use of central venous catheters, and (3) increased use of prosthetic material and valves. Pediatric patients without preexisting heart disease are also at increased risk for IE because of (1) increased survival rates for children with immune deficiencies, (2) long-term use of indwelling lines in ill newborns and patients with chronic diseases, and (3) increased intravenous drug abuse.

Patients at greatest risk are children with unrepaired or palliated cyanotic heart disease (especially in the presence of an aorta to pulmonary shunt), those with implanted prosthetic material, and patients who have had a prior episode of IE. Common organisms causing IE are viridans streptococci

(30–40% of cases), *Staphylococcus aureus* (25–30%), and fungal agents (about 5%).

► **Clinical Findings**

A. History

Almost all patients with IE have a history of heart disease. There may or may not be an antecedent infection or surgical procedure (cardiac surgery, tooth extraction, tonsillectomy). Transient bacteremia occurs frequently during normal daily activities such as flossing or brushing teeth, using a toothpick and even when chewing food. Although dental and nonsterile surgical procedures also can result in transient bacteremias these episodes are much less frequent for a given individual. This may be why a clear inciting event is often not identified in association with IE.

B. Symptoms, Signs, and Laboratory Findings

Although IE can present in a fulminant fashion with cardiovascular collapse, often it presents in an indolent manner with fever, malaise, and weight loss. Joint pain and vomiting are less common. On physical examination, there may be a new or changing murmur, splenomegaly and hepatomegaly. Classic findings of Osler nodes (tender nodules, usually on the pulp of the fingers), Janeway lesions (nontender hemorrhage macules on palms and soles), splinter hemorrhages, and Roth spots (retinal hemorrhage) are rarely noted. Laboratory findings include positive blood culture, elevated erythrocyte sedimentation rate or C-reactive protein, and hematuria. Transthoracic echocardiography can identify large vegetations in some patients, but transesophageal imaging has better sensitivity and may be necessary if the diagnosis remains in question.

► **Prevention**

In 2007, the AHA revised criteria for patients requiring prophylaxis for IE (Table 19–17). Only these high-risk patients require antibiotics before dental work (tooth extraction or cleaning) and procedures involving the respiratory tract or infected skin or musculoskeletal structures. IE prophylaxis is *not* recommended for gastrointestinal or genitourinary procedures, body piercing, or tattooing.

Table 19-17. Conditions requiring antibiotic prophylaxis for the prevention of infective endocarditis (IE).

Prosthetic cardiac valves
Prior episode of IE
Congenital heart disease (CHD)
Palliated cyanotic CHD
For 6 months post-procedure if CHD repair involves implanted prosthetic material
Repair of CHD with residual defect bordered by prosthetic material
Cardiac transplant with valvulopathy

The following schedule is recommended: under 40 kg, 50 mg/kg of oral amoxicillin; over 40 kg, 2000 mg. This dose is to be given 1 hour prior to the above defined procedures. If the patient is allergic to amoxicillin, an alternative prophylactic antibiotic is used.

► **Treatment**

In general appropriate antibiotic therapy should be initiated as soon as IE is suspected. Therapy can be tailored once the pathogen and sensitivities are defined. Vancomycin, with or without gentamicin, for a 6-week course is the most common regimen. If HF occurs and progresses in the face of adequate antibiotic therapy, surgical excision of the infected area and prosthetic valve replacement must be considered.

► **Course & Prognosis**

Factors associated with a poor outcome are delayed diagnosis, presence of prosthetic material, perioperative associated IE and *S aureus* infection. Mortality for bacterial endocarditis in children ranges from 10–25% with fungal infections having a much greater mortality at 50% or more.

PERICARDITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Chest pain made worse by deep inspiration and decreased by leaning forward.
- Fever and tachycardia.
- Shortness of breath.
- Pericardial friction rub.
- ECG with elevated ST segments.

► **General Considerations**

Pericarditis is an inflammation of the pericardium and is commonly related to an infectious process. The most common cause of pericarditis in children is viral infection (eg, coxsackievirus, mumps, Epstein-Barr, adenovirus, influenza, and HIV). Purulent pericarditis results from bacterial infection (eg, pneumococci, streptococci, staphylococci,

and *Haemophilus influenzae*) and is less common but potentially life-threatening.

In some cases, pericardial disease occurs in association with a generalized process. Associations include rheumatic fever, rheumatoid arthritis, uremia, systemic lupus erythematosus, malignancy, and tuberculosis. Pericarditis after cardiac surgery (postpericardiotomy syndrome) is most commonly seen after surgical closure of an ASD. Postpericardiotomy syndrome appears to be autoimmune in nature with high titers of anti-heart antibody and evidence of fresh or reactivated viral illness. The syndrome is often self-limited and responds well to short courses of aspirin or corticosteroids.

► Clinical Findings

A. Symptoms and Signs

Childhood pericarditis usually presents with sharp stabbing mid chest, shoulder, and neck pain made worse by deep inspiration or coughing, and decreased by sitting up and leaning forward. Shortness of breath and grunting respirations are common. Physical findings depend on the presence of fluid accumulation in the pericardial space (effusion). In the absence of significant accumulation, a characteristic scratchy, high-pitched friction rub may be heard. If the effusion is large, heart sounds are distant and muffled. A friction rub may not be present. In the absence of cardiac tamponade, the peripheral, venous, and arterial pulses are normal.

Cardiac tamponade occurs in association with a large effusion, or one that has rapidly accumulated. Tamponade is characterized by jugular venous distention, tachycardia, hepatomegaly, peripheral edema, and pulsus paradoxus, in which systolic blood pressure drops more than 10 mm Hg during inspiration. Decreased cardiac filling and subsequent decrease in cardiac output result in signs of right heart failure and the potential for cardiovascular collapse.

B. Imaging

In pericarditis with a significant pericardial effusion the cardiac silhouette is enlarged. The cardiac silhouette can appear normal if the effusion has developed over an extremely short period of time.

C. Electrocardiography

The ST segments are commonly elevated in acute pericarditis. Low voltages or electrical alternans (alteration in QRS amplitude between beats) can be seen with large pericardial effusions.

D. Echocardiography

Echocardiography is essential in diagnosis and management of pericarditis. Serial studies allow direct, noninvasive estimate of the volume of fluid and its change over time. Echocardiography also demonstrates cardiac tamponade if

there is compression of the atria or respiratory alteration of ventricular inflow.

► Treatment

Treatment depends on the cause of pericarditis and the size of associated effusion. Viral pericarditis is usually self-limited and symptoms can be improved with nonsteroidal anti-inflammatory therapy. Purulent pericarditis requires immediate evacuation of the fluid and appropriate antibiotic therapy. Cardiac tamponade from any cause must be treated by immediate removal of the fluid, usually via pericardiocentesis. Pericardiocentesis should also be considered if the underlying cause is unclear or identification of the pathogen is necessary for targeted therapy. In the setting of recurrent or persistent effusions, a surgical pericardiectomy or pericardial window may be necessary. Diuretics should be avoided in the patient with cardiac tamponade because they reduce ventricular preload and can exacerbate the degree of cardiac decompensation.

► Prognosis

Prognosis depends to a great extent on the cause of pericardial disease. Constrictive pericarditis can develop following infectious pericarditis (especially if bacterial) and can be a difficult problem to manage. Cardiac tamponade will result in death unless the fluid is evacuated.

HYPERTENSION

Blood pressure should be determined at every pediatric visit beginning at 3 years. Because blood pressure is being more carefully monitored, systemic hypertension has become more widely recognized as a pediatric problem. Pediatric standards for blood pressure have been published. Blood pressures in children must be obtained when the child is relaxed and an appropriate-size cuff must always be used. The widest cuff that fits between the axilla and the antecubital fossa should be used (covers 60–75% of the upper arm). Most children aged 10–11 years need a standard adult cuff (bladder width of 12 cm), and many high school students need a large adult cuff (width of 16 cm) or leg cuff (width of 18 cm). The pressure coinciding with the onset (K_1) and the loss (K_5) of the Korotkoff sounds determine the systolic and diastolic blood pressure respectively. The 95th percentile value for blood pressure (Table 19–18) is similar for both sexes and all three major ethnic groups. If a properly measured blood pressure exceeds the 95th percentile, the measurement should be repeated several times over a 2- to 4-week interval. If it is elevated persistently, a search for the

^aBlood pressures: S, systolic (Korotkoff sound 1; onset of tapping); Dm, diastolic muffling (Korotkoff sound 4); Dd, diastolic disappearance (Korotkoff sound 5).

cause should be undertaken. Although most hypertension in children is essential, the incidence of treatable causes is higher in children than in adults; these include conditions such as coarctation of the aorta, renal artery stenosis, chronic renal disease, and pheochromocytoma, as well as medication side effects (eg, steroids). If no cause is identified, and hypertension is deemed essential, antihypertensive therapy should be initiated and nutritional and exercise counseling given. β -Blockers or ACE inhibitors are the usual first-line medical therapies for essential hypertension in children.

ATHEROSCLEROSIS & DYSLIPIDEMIAS

Awareness of coronary artery risk factors in general—and atherosclerosis in particular—has risen dramatically in the general population since the mid-1970s. Although coronary artery disease is still the leading cause of death in the United States, the age-adjusted incidence of death from ischemic

heart disease has been decreasing as a result of improved diet, decreased smoking, awareness and treatment of hypertension, and an increase in physical activity. The level of serum lipids in childhood usually remains constant through adolescence. Biochemical abnormalities in the lipid profile appearing early in childhood correlate with higher risk for coronary artery disease in adulthood. Low-density lipoprotein (LDL) is atherogenic, while its counterpart, high-density lipoprotein (HDL) has been identified as an anti-atherogenic factor.

Routine lipid screening of children at age 3 years remains controversial. The National Cholesterol Education Program recommends selective screening in children with high-risk family members, defined as a parent with total cholesterol greater than 240 mg/dL or a parent or grandparent with early-onset cardiovascular disease. When children have LDL levels greater than 130 mg/dL on two successive tests, dietary lifestyle counseling is appropriate. Dietary modification may decrease cholesterol levels by 5–20%. If the patient is unresponsive to diet change and at extreme risk (ie, LDL > 160 mg/dL, HDL less than 35 mg/dL, and a history of cardiovascular disease in a first-degree relative at an age younger than 40 years), drug therapy may be indicated. Cholestyramine, a bile acid binding resin, is rarely used today due to poor adherence. The 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) are more commonly used in the pediatric population. Niacin is useful for treatment of hypertriglyceridemia.

De Jongh S et al: Efficacy and safety of statin therapy in children with familial hypercholesterolemia: A randomized double-blind placebo-controlled trial with simvastatin. *Circulation* 2002;106:2231 [PMID: 12390953].

CHEST PAIN

Overview

Chest pain is a common pediatric complaint, accounting for 6 in 1000 visits to urban emergency departments and urgent care clinics. Although children with chest pain are commonly referred for cardiac evaluation, chest pain in children is rarely cardiac in origin. Other more likely causes of chest pain in children include reactive airways disease, musculoskeletal pain, esophagitis, gastritis, and functional pain.

Detailed history and physical examination should guide the pediatrician to the appropriate workup of chest pain. Rarely is there a need for laboratory tests or evaluation by a specialist. The duration, location, intensity, frequency, and radiation of the pain should be documented, and possible triggering events preceding the pain should be explored. For instance, chest pain following exertion may lead to a more elaborate evaluation for a cardiac disorder. The timing of the pain in relation to meals may suggest a gastrointestinal cause.

The patient should also be asked about how pain relief is achieved. A social history to reveal psychosocial stressors and cigarette smoke exposure may be revealing. On physical examination, attention must be placed on the vital signs; general appearance of the child; the chest wall musculature; cardiac, pulmonary, and abdominal examination findings; and quality of peripheral pulses. If the pain can be reproduced through direct palpation of the chest wall, it is almost always musculoskeletal in origin.

Etiology

Cardiac disease is a rare cause of chest pain, but if misdiagnosed it may be life-threatening. Although myocardial infarction rarely occurs in healthy children, patients with diabetes mellitus, chronic anemia, anomalous left coronary artery, or hypertrophic cardiomyopathy may be at increased risk for ischemia. It is also important to ask the family about a history of Kawasaki disease, as these children are at risk for myocardial infarction secondary to thrombosis of coronary aneurysms. More than 50% of children and adolescents who exhibit sequelae from Kawasaki disease arrive at the emergency department with chest pain.

Young children may mistake palpitations for chest pain. Supraventricular tachycardia (SVT), atrial flutter, premature ventricular contractions (PVCs), or ventricular tachycardia may be associated with chest pain in children. Structural lesions that can cause chest pain include aortic stenosis, pulmonary stenosis, and mitral valve prolapse. Structural cardiac lesions are usually accompanied by significant findings on cardiac examination. Of children with mitral valve prolapse, 30% will complain of chest pain presumably caused by papillary muscle ischemia. Other cardiac lesions causing chest pain include dilated cardiomyopathy, myocarditis, pericarditis, rheumatic carditis, and aortic dissection.

Noncardiac chest pain may be due to a respiratory illness, reactive airway disease, pneumonia, pneumothorax, or pulmonary embolism. Gastrointestinal causes of chest pain include reflux, esophagitis, and foreign body ingestion. The most common cause of chest pain (30% of children) is inflammation of musculoskeletal structures of the chest wall. Costochondritis is caused by inflammation of the costochondral joints and is usually unilateral.

In most cases sophisticated testing is not required. However, if a cardiac origin is suspected, a pediatric cardiologist should be consulted. Evaluation in these instances may include an ECG, chest radiograph, echocardiogram, Holter monitor, or serum troponin levels.

Cava JR, Sayger PL: Chest pain in children and adolescents. *Pediatr Clin North Am* 2004;51:1553 [PMID: 15561173].

Cardiac Transplantation

Cardiac transplantation has become an effective therapeutic modality for infants and children with end-stage cardiac

disease. Indications for transplantation include (1) progressive HF despite maximal medical therapy, (2) complex congenital heart diseases that are not amenable to surgical repair or palliation or in instances in which the surgical palliative approach has an equal or higher risk of mortality compared with transplantation, and (3) malignant arrhythmias unresponsive to medical therapy, catheter ablation, or automatic implantable cardioverter-defibrillator. Approximately 300–400 pediatric cardiac transplant procedures are performed annually in the United States. Infant (< 1 year of age) transplants account for 30% of pediatric cardiac transplants. The current estimated half-life for children undergoing cardiac transplantation is approximately 13 years. This is a rapidly evolving field, and the most recent data indicate an optimistic future for the transplant recipient.

Careful evaluation of the recipient and the donor is performed prior to cardiac transplantation. Assessment of the recipient's pulmonary vascular resistance is critical, as irreversible and severe pulmonary hypertension is a risk factor for post-transplant right heart failure and early death. End-organ function of the recipient may also influence post-transplant outcome and should be evaluated closely. Donor-related factors that can have an impact on outcome include cardiac function, amount of inotropic support needed, active infection (HIV and hepatitis B and C are contraindications to donation), donor size, and ischemic time to transplantation.

Immunosuppression

The ideal post-transplant immunosuppressive regimen allows the immune system to continue to recognize and respond to foreign antigens in a productive manner while avoiding graft rejection. Although there are many different regimens, calcineurin inhibitors (eg, cyclosporine and tacrolimus) are the mainstay of maintenance immunosuppression in pediatric heart transplantation. Calcineurin inhibitors may be used in isolation. Double-drug therapy includes the addition of antimetabolite or antiproliferative medications such as azathioprine, mycophenolate mofetil, or sirolimus. Due to the significant adverse side effects of corticosteroids in children, attempts have been made in some centers to discontinue triple-drug therapy that would include steroid use. Growth retardation, susceptibility to infection, impaired wound healing, hypertension, and a cushingoid appearance are some of the consequences of long-term steroid use.

Graft Rejection

Despite advances in immunosuppression, graft rejection remains the leading cause of death in the first 3 years after transplantation. The pathophysiologic mechanisms of rejection are not entirely known. T cells are required for rejection, but multiple cell lines and mechanisms are likely involved. Because graft rejection can present in the absence of clinical

symptomatology, monitoring for and diagnosing rejection in a timely fashion can be difficult. Screening regimens include serial physical examinations, electrocardiography, echocardiography, and cardiac catheterization with endomyocardial biopsy.

Rejection Surveillance

A. Symptoms and Signs

Acute graft rejection may not cause symptoms in the early stages. With progression patients may develop tachycardia, tachypnea, rales, a gallop rhythm, or hepatosplenomegaly. Infants and young children may present with irritability, poor feeding, vomiting, or lethargy. The goal is to detect rejection prior to the development of hemodynamic compromise, as there is 50% mortality in the year following an episode of rejection resulting in cardiovascular compromise.

B. Imaging

Chest radiographs may show cardiomegaly, pulmonary edema, or pleural effusions.

C. Electrocardiography

Abnormalities in conduction can be present, although the most typical finding is reduced QRS voltages. Both atrial and ventricular arrhythmias can occur in rejection.

D. Echocardiography

Echocardiography is a noninvasive rejection surveillance tool that is especially useful in infant recipients, but helpful in all ages. Changes in ventricular compliance and function may initially be subtle, but are progressive with increasing duration of the rejection episode. A new pericardial effusion or worsening valvular insufficiency may also indicate rejection.

E. Cardiac Catheterization and Endomyocardial Biopsy

Hemodynamic assessment including ventricular filling pressures, cardiac output, and oxygen consumption can be obtained via cardiac catheterization. The endomyocardial biopsy has been considered the gold standard for diagnosing acute graft rejection. However, because not all episodes of symptomatic rejection result in a positive biopsy result, this tool is not universally reliable. The appearance of infiltrating lymphocytes with myocellular damage is the hallmark of graft rejection and is helpful if present.

▶ Treatment of Graft Rejection

The goal of graft rejection treatment is to reverse the immunologic inflammatory cascade. High-dose corticosteroids are the first line of treatment. Occasionally additional therapy

with antithymocyte biologic preparations such as antithymocyte globulin or OKT-3 (a murine monoclonal antibody to the CD3 T-lymphocyte epitope) is needed to reverse rejection. Most rejection episodes can be treated effectively if diagnosed promptly. Usually graft function returns to its baseline state, although severe rejection episodes can result in graft loss and patient death even with optimal therapy.

▶ Course & Prognosis

The course of cardiac transplantation in pediatric patients is usually quite good. The risk of infection is low after the immediate post-transplant period in spite of chronic immunosuppression. Cytomegalovirus is the most common pathogen responsible for infection-related morbidity and mortality in heart transplant recipients. Most children tolerate environmental pathogens well. Nonadherence with lifetime immunosuppression is of great concern especially in adolescent patients. Several recent studies have identified nonadherence as the leading cause of late death. Post-transplant lymphoproliferative disorder, a syndrome related to Epstein-Barr virus infection, can result in a Burkitt-like lymphoma that usually responds to a reduction in immunosuppression, but occasionally must be treated with chemotherapy. The overwhelming majority of children are not physically limited and do not require restrictions related to the cardiovascular system.

The greatest long-term concern after heart transplantation is related to cardiac allograft vasculopathy. Cardiac allograft vasculopathy results from concentric intimal proliferation of the coronary arteries that can ultimately result in complete luminal occlusion. These lesions are diffuse and often involve distal vessels and thus are usually not amenable to bypass grafting, angioplasty, or stent placement. Overall, despite the concerns of immunosuppression, the risk of late rejection, and coronary disease, the majority of pediatric patients enjoy a good quality of life with survival rates that are improving. Currently, 10-year survival is 80% for infant recipients and 70% overall for all pediatric recipients. Newer, more specific, and more effective immunosuppressive agents are currently being tried in clinical studies or are being evaluated in preclinical studies, making the future almost certainly better for children after cardiac transplantation. Donor availability remains a major limitation to the expansion of indications for cardiac transplantation.

PRIMARY PULMONARY HYPERTENSION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Often subtle with symptoms of dyspnea, fatigue, chest pain, and syncope.
- ▶ Loud pulmonary component of S_2 ; ECG with RVH.
- ▶ Implies exclusion of secondary causes of pulmonary hypertension.
- ▶ Rare, progressive, and often fatal disease without treatment.

▶ General Considerations

Unexplained or primary pulmonary hypertension (PPH) in children is a rare disease with an estimated overall incidence of 1–2 persons per million worldwide. Pulmonary hypertension is defined as a mean pulmonary pressure greater than 25 mm Hg at rest or greater than 30 mm Hg during exercise. PPH is a diagnosis made after exclusion of all other causes of pulmonary hypertension. Secondary pulmonary hypertension is most commonly associated with congenital heart disease, pulmonary parenchymal disease, causes of chronic hypoxia (upper airway obstruction), thrombosis, liver disease, hemoglobinopathies and collagen vascular disease. PPH is difficult to diagnose in the early stages because of its subtle manifestations. Most patients with PPH are young adult women, although the sex incidence is equal in children. As recently as 1991, the diagnosis of PPH in individuals younger than 16 years of age carried a median survival of only 10 months. Fortunately, survival is improving with the advent of new therapies. Familial PPH occurs in 6–12% of affected individuals. When a clear familial association is known, the disease shows evidence of genetic anticipation, presenting at younger ages in subsequent generations.

▶ Clinical Findings

A. Symptoms and Signs

The clinical picture varies with the severity of pulmonary hypertension, and usually early symptoms are subtle, delaying the diagnosis. Initial symptoms may be dyspnea, palpitations, or chest pain, often brought on by strenuous exercise or competitive sports. Syncope may be the first symptom, which usually implies severe disease. As the disease progresses, patients have signs of low cardiac output and right heart failure. Right heart failure may be manifested by increasing

hepatomegaly, peripheral edema, and an S_3 gallop on examination. Murmurs of pulmonary regurgitation and tricuspid regurgitation may be present, and the pulmonary component of S_2 is usually pronounced.

B. Imaging

The chest radiograph most often reveals a prominent main pulmonary artery, and the RV may be enlarged. The peripheral pulmonary vascular markings may be normal or diminished. However, in 6% of patients with confirmed PPH, the chest radiograph is normal.

C. Electrocardiography

The ECG usually shows right ventricular hypertrophy with an upright T wave in V_1 (from age 7 days to 7 years) or a qR complex in lead V_1 or V_3 . Also present may be evidence of right axis deviation and right atrial enlargement.

D. Echocardiography

The echocardiogram is an essential tool for excluding other congenital heart diseases. It frequently shows RVH and dilation. In the absence of other structural disease, any tricuspid and pulmonary insufficiency jets can be used to estimate pulmonary artery systolic and diastolic pressures, respectively. Other echocardiographic modalities such as myocardial performance index and input vascular impedance are in the early stages of use in evaluation of pulmonary hypertension.

E. Cardiac Catheterization and Angiography

Cardiac catheterization is the best method of diagnosing PPH. As an invasive test, it carries with it associated risks and should be performed with caution. The procedure is performed to rule out cardiac causes of pulmonary hypertension, determine the severity of disease, and define treatment strategies. The reactivity of the pulmonary vascular bed to short-acting vasodilator agents (oxygen, nitric oxide, or prostacyclin) can be assessed and used to determine treatment options. Angiography may show a decrease in the number of small pulmonary arteries with tortuous vessels.

F. Other Evaluation Modalities

Cardiac MRI is used in some patients to measure heart function and blood flow. Cardiopulmonary exercise testing using cycle ergometry correlates with disease severity. More simply, a 6-minute walk test, in which distance walked and perceived level of exertion are measured, has a strong independent association with mortality in late disease.

▶ Treatment

The goal of therapy is to reduce pulmonary artery pressure and increase cardiac output. Cardiac catheterization data are

used to determine treatment. Patients responsive to pulmonary vasodilators are given calcium channel blockers such as nifedipine or diltiazem. Patients unresponsive to vasodilators initially receive one of three classes of drugs: prostanoids (such as epoprostenol), endothelin receptor antagonists (such as bosentan), or phosphodiesterase inhibitors (such as sildenafil). All of these agents have distinct mechanisms of action that can reduce pulmonary vascular resistance. Warfarin is commonly used for anticoagulation to prevent thromboembolic events, usually with a goal to maintain the INR between 1.5 and 2.0.

Atrial septostomy is indicated in some patients with refractory pulmonary hypertension. Cardiac output falls as pulmonary vascular resistance rises, so an interatrial shunt can preserve left heart output, albeit with deoxygenated blood. Lung transplantation should be considered in patients with intractable pulmonary hypertension and in those with associated anatomic lesions that contribute to high pulmonary arterial pressure, like pulmonary vein stenosis. Heart-lung transplant procedures appear to have survival benefits over isolated lung transplantation in patients with pulmonary hypertension.

Although survival is less than 10 months in children with untreated pulmonary hypertension, recent studies have showed improved survival rates of more than 95% at 5 years with calcium channel blockade, and more than 80% at 5 years in children requiring epoprostenol.

Ivy DD: Chronic pulmonary hypertension. In Munoz R et al (editors): *Handbook of Pediatric Cardiac Intensive Care*. Springer-Verlag, 2008.

DISORDERS OF RATE & RHYTHM

As more children are surviving cardiac surgery and living with chronically altered hemodynamics there has been an increase in the incidence of arrhythmias in the pediatric population.

The introduction of invasive electrophysiology with recordings from the endocardium has greatly improved understanding of the conduction system. Cardiac ablation techniques offer some children with arrhythmias a cure rather than lifelong antiarrhythmia treatment.

Sinus Arrhythmia

Phasic variation in the heart rate (sinus arrhythmia) is normal. Typically, the sinus rate varies with the respiratory cycle, whereas P-QRS-T intervals remain stable. Marked sinus arrhythmia is defined as more than 100% variation in heart rate. It may occur in association with respiratory distress or increased intracranial pressure, or it may be present in normal children. In isolation, it never requires treatment; however, it may be associated with sinus node dysfunction or autonomic nervous system dysfunction.

Sinus Bradycardia

Depending on age, sinus bradycardia is defined as either (1) a heart rate below the normal limit for age (neonates to 6 years, 60 beats/min; 7–11 years, 45 beats/min; older than 12 years, 40 beats/min) or (2) a heart rate inappropriately slow for the functional status of the patient (chronotropic incompetence). In critically ill patients, common causes of sinus bradycardia include hypoxia, central nervous system damage, eating disorders, and medication side effects. Only symptomatic bradycardia (syncope, low cardiac output, or exercise intolerance) requires treatment (atropine, isoproterenol, or cardiac pacing).

Sinus Tachycardia

The heart rate normally accelerates in response to stress (eg, fever, hypovolemia, anemia, or HF). Although sinus tachycardia in the normal heart is well tolerated, symptomatic tachycardia with decreased cardiac output warrants evaluation for structural heart disease or true tachyarrhythmias. Treatment may be indicated for correction of the underlying cause of sinus tachycardia (eg, transfusion for anemia or correction of hypovolemia or fever).

PREMATURE ATRIAL CONTRACTIONS

Premature atrial contractions are triggered by an ectopic focus in the atrium. They are one of the most common premature beats occurring in pediatric patients, particularly during the fetal and newborn periods. They may be conducted (followed by a QRS) or nonconducted (not followed by a QRS, as the beat has occurred so early that the AV node is still refractory) (Figure 19–4). A less-than-compensatory pause usually occurs until the next normal sinus beat. Depending on the location of the ectopic focus of the premature contraction, the P-wave morphology may be normal or abnormal. As an isolated finding, premature atrial contractions are benign and require no treatment. They need to be treated with antiarrhythmic agents only when they trigger tachyarrhythmias or produce bradycardia secondary to nonconduction.

PREMATURE JUNCTIONAL CONTRACTIONS

Premature junctional contractions arise in the AV node or the bundle of His. They usually induce a normal QRS complex with no preceding P wave. When conducted aberrantly to the ventricles, they cannot be distinguished from PVCs except by invasive electrophysiologic study. Premature junctional contractions are usually benign and require no specific therapy.

PREMATURE VENTRICULAR CONTRACTIONS

PVCs may originate in either ventricle and are characterized by an abnormal QRS of more than 80 ms duration in

▲ **Figure 19-4.** Lead II rhythm strip with premature atrial contractions. Beats 1, 3, 7, and 8 are conducted to the ventricles, whereas beats 2, 4, 5, and 6 are not.

newborns and more than 120 ms in adolescents and adults (Figure 19-5). PVCs originating from a single ectopic focus all have the same configuration; those of multifocal origin show varying configurations. The consecutive occurrence of two PVCs is referred to as a ventricular couplet and of three or more as ventricular tachycardia.

Most unifocal PVCs in otherwise normal patients are benign. The significance of PVCs can be confirmed by having the patient exercise. As the heart rate increases, benign PVCs usually disappear. If exercise results in an increase or coupling of contractions, underlying disease may be present. Multifocal PVCs are always abnormal and may be more dangerous. They may be associated with drug overdose (tricyclic antidepressants or digoxin toxicity), electrolyte imbalance, myocarditis, or hypoxia. Treatment is directed at correcting the underlying disorder.

SINUS NODE DYSFUNCTION

Sinus node dysfunction, or sick sinus syndrome, is a clinical syndrome of inappropriate sinus nodal function and rate. The abnormality may be a true anatomic defect of the sinus

node or its surrounding tissue, or it may be an abnormality of autonomic input. It is defined as one or more of the following:

1. Sinus bradycardia
2. Marked sinus arrhythmia
3. Chronotropic incompetence
4. Sinus pause or arrest
5. Sinoatrial exit block
6. Combined bradyarrhythmias and tachyarrhythmias
7. Sinus node reentry
8. Atrial muscle reentry tachycardia

It is usually associated with postoperative repair of congenital heart disease (most commonly the Mustard or Senning repair for complete transposition of the great arteries or the Fontan procedure), but it is also seen in unoperated congenital heart disease, in acquired heart diseases, and in normal hearts. In some cases the disorder is inherited. Symptoms usually manifest between ages 2 and 17 years and consist of episodes of syncope, presyncope, or disorientation. Some patients may experience palpitations, pallor, or exercise intolerance.

▲ **Figure 19-5.** Lead V_5 rhythm strip with unifocal premature ventricular contractions in a bigeminy pattern. The arrow shows a ventricular couplet.

The evaluation of sinus node dysfunction involves both surface ECG and invasive electrophysiologic testing. Exercise testing and ambulatory monitoring help define any arrhythmias and correlate rhythm changes with symptoms.

Treatment for sinus node dysfunction is indicated only in symptomatic patients. Asymptomatic patients can be observed for the onset of exercise intolerance or syncope because there is little chance of sudden death prior to the onset of such symptoms. Bradycardias are treated with vagolytic (atropine) or adrenergic (aminophylline) agents or permanent cardiac pacemakers. Antiarrhythmic treatment of tachycardias often produces or enhances bradycardia, thus requiring permanent cardiac pacing. A pacemaker is inserted prophylactically prior to the initiation of antiarrhythmic medications.

The prognosis is excellent when appropriate treatment is provided, with morbidity and mortality rates nearly equal to those of the underlying heart disease. In severe untreated cases, sinus node dysfunction may become chronic and may lead to sudden death.

Miller MS et al: Neonatal bradycardia. *Prog Pediatr Cardiol* 2000;11:19 [PMID: 10822186].

SUPRAVENTRICULAR TACHYCARDIA

SVT, also known as paroxysmal SVT or paroxysmal atrial tachycardia, is defined as an abnormal arrhythmia mechanism arising above or within the bundle of His. The mode of presentation depends on the heart rate, the presence of underlying cardiac structural or functional abnormalities, coexisting illness, and patient age. Tachycardia may be poorly tolerated in a child with preexisting HF or an under-

lying systemic disease such as anemia or sepsis. It may go unnoticed in an otherwise healthy child. Incessant tachycardia in an otherwise healthy individual, even if fairly slow (120–150 beats/min), may cause myocardial dysfunction and HF if left untreated. The mechanisms of tachycardia are divided into three groups: reentry, enhanced automaticity, and triggered dysrhythmias.

Reentry is conduction through two or more pathways, creating a sustained repetitive circular loop. The circuit can be confined to the atrium (intra-atrial reentry, a form of atrial flutter) (Figure 19-6). It may be confined within the AV node (AV nodal reentrant tachycardia), or it may encompass an accessory connection between atria and ventricle (atrioventricular tachycardia). The arrhythmia circuit includes conduction through the normal pathway (the AV node) as well as the accessory AV connection. If during tachycardia the electrical impulse travels antegrade (from atria to ventricles) through the AV node and retrograde (from ventricle to atria) back up the accessory pathway, orthodromic reciprocating tachycardia is present. If instead the impulse travels antegrade through the accessory pathway and retrograde up through the AV node, antidromic reciprocating tachycardia is present.

Wolff-Parkinson-White (WPW) syndrome is a subclass of reentrant tachycardia in which, during sinus rhythm, the impulse travels antegrade down the accessory connection, bypassing the AV node and creating ventricular preexcitation (early eccentric activation of the ventricle with a short PR interval and slurred upstroke of the QRS, a delta wave) (Figure 19-7). Reentrant tachycardia represents approximately 80% of pediatric arrhythmias, has a wide range of rates, and may or may not demonstrate P waves. Reentrant tachycardia initiates and terminates abruptly. Most patients

▲ **Figure 19-6.** Leads aVF (F) and V₁, showing atrial flutter with “sawtooth” atrial flutter waves.

with WPW have otherwise structurally normal hearts. However, WPW has been noted to occur with increased frequency in association with the following congenital cardiac lesions: tricuspid atresia, Ebstein anomaly of the tricuspid valve, hypertrophic cardiomyopathy, and congenitally corrected transposition of the great arteries (ccTGA).

Enhanced automaticity (also known as automatic or ectopic tachycardia) is created when a focus of cardiac tissue develops an abnormally fast spontaneous rate of depolarization. These arrhythmias represent approximately 20% of childhood arrhythmias and are usually under autonomic influence. ECG demonstrates a normal QRS complex preceded by an abnormal P wave (Figure 19-8). Junctional ectopic tachycardia does not have a P wave preceding the QRS waves and may be associated with AV dissociation or 1:1 retrograde conduction. Ectopic tachycardias demonstrate a gradual onset and offset and may be paroxysmal or incessant. When they are incessant, they are usually associated with HF and a clinical picture of dilated cardiomyopathy.

Triggered dysrhythmia is extremely rare. It is caused by afterdepolarizations. These tachycardias are usually associated with diseased atrial myocardium, are triggered by premature atrial contractions or sinus tachycardia, initiate and terminate abruptly, and mimic intra-atrial reentry (atrial flutter). However, they can be distinguished from atrial flutter: they terminate with the administration of adenosine, whereas atrial flutter does not (see later section on Atrial Flutter and Fibrillation).

► Clinical Findings

A. Symptoms and Signs

Presentation varies with age. Infants tend to turn pale and mottled with onset of tachycardia and may become irritable. With long duration of tachycardia, symptoms of HF develop. Heart rates range from 240–300 beats/min. Older children complain of dizziness, palpitations, fatigue, and chest pain. Heart rates range from 240 beats/min in the younger child to 150–180 beats/min in the teenager. HF is less common in children than in infants. Tachycardia may be associated with either congenital heart defects or acquired conditions such as cardiomyopathies and myocarditis.

B. Imaging

Chest radiographs are normal during the early course of tachycardia. If HF is present, the heart is enlarged and pulmonary venous congestion is evident.

C. Electrocardiography

ECG is the most important tool in the diagnosis of SVT.

1. The heart rate is rapid and out of proportion to the patient’s physical status (ie, a rate of 140 beats/min with an abnormal P wave while quiet and asleep).
2. The rhythm is extremely regular. There is little variation in the rate throughout the entire tracing.

▲ **Figure 19-7.** Leads I and II with spontaneous intermittent ventricular preexcitation (Wolff-Parkinson-White syndrome).

▲ **Figure 19-8.** Lead II rhythm strip of ectopic atrial tachycardia. The tracing demonstrates a variable rate with a maximum of 260 beats/min, an abnormal P wave, and a gradual termination.

- P waves may or may not be present. If they are present, the PR interval and appearance do not vary. P waves may be difficult to find because they are superimposed on the preceding T wave. Furthermore, if the abnormal focus is located within the AV node, the P waves will not be seen.
- The QRS complex is usually the same as during normal sinus rhythm. However, the QRS complex is occasionally widened (SVT with aberrant ventricular conduction), in which case the condition may be difficult to differentiate from ventricular tachycardia.

► Treatment

A. Acute Treatment

During the initial episodes of SVT, patients require close monitoring. Correction of acidosis and electrolyte abnormalities is also indicated.

1. Vagal maneuvers—The “diving reflex” produced by placing an ice bag on the nasal bridge for 20 seconds (for infants) or by immersing the face in ice water (for children or adolescents) will increase parasympathetic tone and terminate some tachycardias. The Valsalva maneuver, which can be performed by older compliant children, may also terminate SVT.

2. Adenosine—Adenosine transiently blocks AV conduction and terminates tachycardias that incorporate the AV node.

Adenosine does not convert tachycardias whose mechanism is confined to the atria (atrial ectopic tachycardia or

intra-atrial reentry). However, it serves as a diagnostic tool in these arrhythmias by demonstrating continuation of the atrial tachycardia during AV block, implying that AV node conduction is not a crucial element of the tachycardia circuit. The dose is 50–250 mcg/kg by rapid intravenous bolus. It is antagonized by aminophylline and should be used with caution in patients with sinus node dysfunction or asthma.

3. Transesophageal atrial pacing—Atrial overdrive pacing and termination can be performed from a bipolar electrode-tipped catheter positioned in the esophagus adjacent to the left atrium. Overdrive pacing at rates approximately 30% faster than the tachycardia rate will interrupt the tachycardia circuit and restore sinus rhythm.

4. Direct current cardioversion—Direct current cardioversion (0.5–2 synchronized J/kg) should be used immediately when a patient presents in cardiovascular collapse.

B. Chronic Treatment

1. Digitalis—Digoxin is still used for long-term treatment and maintenance of sinus rhythm. The doses used are the same as those for HF. Conversion should be accomplished within 8–12 hours. In some patients, digoxin accelerates conduction over an accessory pathway. In such children, digitalis products are contraindicated. Patients with an accessory pathway (eg, those with WPW syndrome) often have primary atrial tachycardias (atrial flutter or fibrillation or atrial ectopic tachycardias), and with enhanced conduction in the accessory pathway these primary atrial tachycar-

dias can transmit to the ventricles, causing ventricular fibrillation. Therefore, an evaluation of the effect of digoxin on the accessory pathway should be performed in the electrophysiology lab before chronic digoxin use in patients with WPW syndrome.

2. β -Adrenergic blocking agents—Propranolol decreases sinus heart rate and AV nodal conduction. It is effective in the treatment of both reentrant and ectopic arrhythmias in doses ranging from 1–4 mg/kg/d. Long-acting β -blockers, such as atenolol and nadolol, are used because they have fewer central nervous system side effects than propranolol and may be given only once or twice a day.

3. Calcium channel antagonists—Verapamil and other calcium channel blockers markedly prolong conduction through the AV node and are effective in interrupting and preventing reentrant tachycardias that incorporate the AV node. They are ineffective in terminating atrial tachycardias but may be useful in controlling the ventricular response by producing AV blockade. Verapamil comes in short- and long-acting preparations; the dose is 3–5 mg/kg/d. It may cause myocardial dysfunction and is contraindicated in infants.

4. Other drugs—Recently introduced antiarrhythmic medications (eg, flecainide, propafenone, sotalol, and amiodarone) have increased pharmacologic actions and are extremely effective. However, these drugs also have serious side effects, including proarrhythmia (production of arrhythmias) and sudden death, and should be used only under the direction of a pediatric cardiologist.

5. Radiofrequency ablation—This is a nonsurgical transvascular catheter technique that desiccates an arrhythmia focus or accessory pathway and permanently cures an arrhythmia. The success rate is approximately 90%, with a recurrence risk of 10%. The risk of developing complete heart block is approximately 2–5% when applying burns in the vicinity of the AV node/His bundle. The procedure can be performed in infants or adults. In children younger than age 4 years, the risks are higher, and the procedure should be reserved for those whose arrhythmias are refractory to medical management. In well-tolerated SVTs that respond to vagal maneuvers, no further treatment is necessary. However, the high success rate, low complication and recurrence rates, and the elimination of the need for chronic antiarrhythmic medications have made radiofrequency ablation the primary treatment option in most pediatric cardiovascular centers.

► Prognosis

SVT has an excellent prognosis. When it occurs in early infancy, 90% will respond to initial treatment. Approximately 30% will recur at an average age of 8 years.

Basson CT: A molecular basis for Wolff-Parkinson-White syndrome. *N Engl J Med* 2001;344:1861 [PMID: 11407351].

Dubin AM et al: Radiofrequency catheter ablation: Indications and complications. *Pediatr Cardiol* 2000;21:551 [PMID: 11050279].
Moak JP: Supraventricular tachycardia in the neonate and infant. *Prog Pediatr Cardiol* 2000;11:25 [PMID: 10822187].

ATRIAL FLUTTER & FIBRILLATION

Atrial flutter and fibrillation are rare in children and are most often associated with organic heart disease—particularly postoperative congenital heart disease and sinus node dysfunction. Atrial flutter can occur in infancy and can mimic SVT. The atrial rate is usually more than 240 beats/min and often more than 300 beats/min. The ventricular rate depends on the rate of AV conduction and is usually slower than the atrial rate.

► Treatment & Prognosis

Transesophageal atrial pacing is the treatment of choice to terminate atrial flutter. When it is not successful, antiarrhythmic medications (eg, digoxin, sotalol, and amiodarone) may succeed; however, direct current cardioversion is frequently necessary.

The prognosis in neonates without structural heart disease is excellent, and after conversion these patients may need no further treatment.

POSTOPERATIVE INCISIONAL INTRA-ATRIAL REENTRY

Improved surgical survival for patients with congenital heart disease has created a new, increasingly prevalent, chronic arrhythmia: incisional intra-atrial reentry, or postoperative atrial flutter. In these tachycardias, electrically isolated corridors of atrial myocardium (eg, the tricuspid valve–inferior vena cava isthmus, or the region between an atrial incision and the crista terminalis) act as pathways for sustained reentrant circuits of electrical activity. These tachycardias are chronic, medically refractory, and clinically incapacitating. Electromagnetic mapping permits precise localization of these corridors. Long linear radiofrequency or surgical lesions are then used to interrupt the reentrant circuits.

Delacretaz E et al: Multiple atrial macro-reentry circuits in adults with repaired congenital heart disease: Entrainment mapping combined with three-dimensional electroanatomic mapping. *J Am Coll Cardiol* 2001;37:1665 [PMID: 11345382].
Van Hare GF: Intra-atrial reentry tachycardia in pediatric patients. *Prog Pediatr Cardiol* 2001;13:41 [PMID: 11413057].

VENTRICULAR TACHYCARDIA

Ventricular tachycardia is uncommon in childhood (Figure 19–9). It is usually associated with underlying abnormalities of the myocardium (myocarditis, cardiomyopathy, myocardial tumors, or postoperative congenital heart disease) or toxicity (hypoxia, electrolyte imbalance, or drug toxicity). Sustained tachycardia is generally an unstable

▲ **Figure 19-9.** Twelve-lead ECG from a child with imipramine toxicity and ventricular tachycardia.

situation, and if left untreated will usually degenerate into ventricular fibrillation.

Accelerated idioventricular rhythm is a sustained ventricular tachycardia occurring in neonates with normal hearts. The rate is within 10% of the preceding sinus rate, and it is a self-limiting arrhythmia that requires no treatment.

Acute termination of ventricular tachycardia involves restoration of the normal myocardium when possible (correction of electrolyte imbalance, drug toxicity, and so on) and direct current cardioversion (1–4 J/kg), cardioversion with lidocaine (1 mg/kg), or both. Chronic suppression of ventricular arrhythmias with antiarrhythmic drugs has many side effects (including proarrhythmia and death), and it must be initiated in the hospital under the direction of a pediatric cardiologist.

LONG QT SYNDROME

The congenital long QT syndromes (types 1–6) in children are arrhythmic disorders in which ventricular repolarization is irregular and prolonged (QTc > 0.44 second, or 0.46 second in postpubertal females). Some myocardial ion channelopathies predispose patients to torsade de pointes (multifocal ventricular tachycardia) and manifest as syncope, seizures, or sudden death, often in response to exercise. If untreated, they account for a very high mortality rate (5% per year). They are inherited genetically in an autosomal dominant or recessive pattern (the latter being associated with congenital deafness, the Jervell and Lange-Nielsen syndrome) or they may arise spontaneously. Treatment with β -blockade and exercise limitation is only partially successful.

In recurrent, medically refractory cases, implantable cardioverter defibrillators are necessary to prevent sudden death. Congenital long QT syndrome has now been demonstrated to be one of the causes of sudden infant death syndrome.

Acquired long QT syndrome—resulting from altered ventricular repolarization secondary to myocardial toxins, ischemia, or inflammation—also predisposes a patient to ventricular arrhythmias. Numerous medications as outlined previously can also cause QT prolongation. ECGs are recommended before therapy (for a baseline measurement) and after steady state is achieved.

SUDDEN DEATH

Hypertrophic cardiomyopathy (the most common cause of sudden death in young athletes) and other cardiomyopathies (dilated cardiomyopathies, restrictive cardiomyopathies, or arrhythmogenic RV dysplasia) may be hereditary

Lead I

▲ **Figure 19-10.** Lead I rhythm strip with Mobitz type I (Wenckebach) second-degree heart block. There is progressive lengthening of the PR interval prior to the nonconducted P wave (arrows).

and should be looked for in patients with resuscitated cardiac arrest or family members of those who have died suddenly. Congenital structural anomalies of the coronary arteries are the second most common cause of sudden death in young athletes. These anomalies are not hereditary. The coronary arteries need to be evaluated in survivors of sudden death events. Arrhythmias in patients with postoperative congenital heart disease are important causes of morbidity and mortality and may present as sudden death events. All survivors of cardiac arrest require thorough evaluation for arrhythmias, including invasive electrophysiology. Episodes of seizures, syncope, and presyncope in patients with congenital heart disease should be evaluated for the possibilities of arrhythmias, and they may also require thorough electrophysiologic evaluation and treatment.

When a child dies suddenly and unexpectedly, or is resuscitated from cardiac arrest that had no apparent cause, it is necessary to conduct a detailed family history looking for seizures, syncope, or early sudden death. Family members should be examined with an arrhythmia screen, physical examination, ECG, and echocardiography to detect arrhythmias or cardiomyopathies.

HEART BLOCK

1. First-Degree Heart Block

First-degree heart block is an ECG diagnosis of prolongation of the PR interval. The block does not in itself cause problems. It may be associated with structural congenital heart defects, namely AV septal defects and ccTGA, and with

diseases such as rheumatic carditis. The PR interval is prolonged in patients receiving digoxin therapy.

2. Second-Degree Heart Block

Mobitz type I (Wenckebach) heart block is recognized by progressive prolongation of the PR interval until there is no QRS following a P wave (Figure 19-10). Mobitz type I heart block occurs in normal hearts at rest and is usually benign. In Mobitz type II heart block, there is no progressive lengthening of the PR interval before the dropped beat (Figure 19-11). Mobitz type II heart block is frequently associated with organic heart disease, and a complete evaluation is necessary.

3. Complete Heart Block

In complete heart block, the atria and ventricles beat independently. Ventricular rates can range from 40–80 beats/min, whereas atrial rates are faster (Figure 19-12).

Congenital complete heart block, the most common form of complete heart block, has a very high association with maternal systemic lupus erythematosus antibodies. Serologic screening should be performed in the mother of an infant with complete heart block, even if she has no symptoms of collagen vascular disease. Congenital complete heart block is also associated with congenitally corrected transposition of the great vessels and AV septal defect. Acquired complete heart block may be secondary to acute myocarditis, drug toxicity, electrolyte imbalance, hypoxia, and cardiac surgery.

► Clinical Findings

Prenatal bradycardia is frequently noted in infants with congenital complete heart block, and emergent delivery is required if hydrops fetalis develops. Postnatal adaptation largely depends on the heart rate; infants with heart rates less than 55 beats/min are at significantly greater risk for low

Lead III

▲ **Figure 19-11.** Lead III rhythm strip with Mobitz type II second-degree heart block. There is a consistent PR interval with occasional loss of AV conduction (*arrow*).

cardiac output, HF, and death. Wide QRS complexes and a rapid atrial rate are also poor prognostic signs. Most patients have an innocent flow murmur from increased stroke volume. In symptomatic patients, the heart can be quite enlarged, and pulmonary edema may be present. In older patients, syncope can be the presenting symptom, or heart block may be found unexpectedly on routine physical examination. Complete cardiac evaluation, including echocardiography and Holter monitoring, is necessary to assess the patient for ventricular dysfunction and to relate any symptoms to concurrent arrhythmias.

► **Treatment**

In patients thought to be at risk for syncope, HF, or sudden death, the treatment of choice for complete heart block is insertion of a permanent pacemaker. Until permanent pacing can be instituted, patients can be assisted temporarily by infusions of isoproterenol or by temporary transcutaneous pacemakers.

Eronen M et al: Short- and long-term outcome of children with congenital complete heart block diagnosed in utero or as a newborn. *Pediatrics* 2000;106(1 Pt 1):86 [PMID: 10878154].

SYNCOPE (FAINTING)

Syncope is a sudden transient loss of consciousness that resolves spontaneously. The common form of syncope (simple fainting) occurs in 15% of children and is a disorder of control of heart rate and blood pressure by the autonomic nervous system that causes hypotension or bradycardia. It is often associated with rapid rising and postural hypotension, prolonged standing, or hypovolemia. Patients exhibit vagal symptoms such as pallor, nausea, or diaphoresis. Syncope, also known as autonomic dysfunction, can be evaluated with head-up tilt table testing. The patient is placed supine on a tilt table, and then—under constant heart rate and blood pressure monitoring—is tilted to the upright position. If symptoms develop, they can be classified as vasodepressor (hypotension), cardioinhibitory (bradycardia), or mixed.

Syncope is usually self-limited (lasting approximately 6 months to 2 years) and can be controlled with dietary salt and volume loading to prevent hypovolemia. In refractory cases, medications to manipulate the autonomic nervous system have been useful. Fludrocortisone (0.1 mg/kg/d) is a mineralocorticoid that causes renal salt resorption and thus increases intravascular volume. β -Blockade (atenolol, 0.5–2.0 mg/kg/d) can inhibit the catecholamine surge and help prevent the rebound bradycardia and hypotension. Vagolytic agents (disopyramide, 2.5 mg/kg four times daily) help control hypervagotonia, and the selective serotonin reuptake inhibitors have also been effective in alleviating symptoms. Syncope that occurs during exercise or stress or is associated with a positive family history is a warning sign that a serious underlying dysrhythmia may be present, calling for further investigation.

DISORDERS OF THE ESOPHAGUS

GASTROESOPHAGEAL REFLUX

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Recurrent post-prandial spitting and vomiting in healthy infants that resolves spontaneously.
- ▶ Heartburn and regurgitation in older children.
- ▶ Chronic complications—esophagitis, stricture, anemia, and Barrett esophagus.
- ▶ Diagnosis is clinical in infancy with upper gastrointestinal (GI) radiograph and upper endoscopy to rule out other GI disease.

Clinical Findings

A. Infants with Reflux

Gastroesophageal (GE) reflux is common in young infants. Frequent post-prandial regurgitation, ranging from effortless to forceful, is the most common infant symptom. Infant reflux is usually benign but in rare cases causes failure to thrive, food refusal, colic, rumination, and neck contortions (Sandifer syndrome). Apneic spells in young infants, especially occurring with position change after feeding, may be caused by reflux. GE reflux is common in neurologically impaired infants.

Reflux of gastric contents into the esophagus occurs during spontaneous relaxations of the lower esophageal sphincter that are unaccompanied by swallowing. Low pressures in the lower esophageal sphincter or developmental immaturity of the sphincter are not causes of GE reflux in infants. Normal factors promoting reflux in infants are their small stomach capacity, frequent large-volume feedings, short esophageal length, supine positioning, and slow swallowing response to

the flow of refluxed material up the esophagus. Infants' individual responses to the stimulus of reflux, particularly the maturity of their self-settling skills, are important factors determining the severity of reflux-related symptoms.

An important differential point in evaluating infants with GE reflux is whether the vomited material contains bile. Bile-stained emesis in an infant requires immediate evaluation as it may be a symptom of intestinal obstruction (malrotation with volvulus, intussusception).

B. Older Children with Reflux

GE reflux disease (GERD) is diagnosed clinically in older children when reflux causes persistent symptoms with or without inflammation of the esophagus. Older children with GERD have less frequent vomiting than infants, and more often complain of adult-type symptoms of regurgitation into the mouth, heartburn, and dysphagia. Esophagitis occurs in children with GERD and requires endoscopic evaluation. Children with asthma, cystic fibrosis, developmental handicaps, hiatal hernia, and repaired tracheoesophageal fistula are at increased risk of GERD.

C. Diagnostic Studies

In thriving infants, GE reflux is a clinical diagnosis. An upper GI series rules out anatomic causes of vomiting but is not an accurate test for GE reflux because of a 30% false-positive rate. In older children with heartburn, a trial of acid-suppressing medication may be both diagnostic and therapeutic. Persistent symptoms should be investigated by upper GI radiographs and endoscopy to rule out other organic causes. pH probe or esophageal impedance studies may be helpful in recognizing an association between episodic or unusual symptoms and reflux events. pH studies quantify the number and duration of acid reflux events. Esophageal intraluminal impedance monitoring is a pH-independent method of detecting fluid movements in the esophagus. These studies have shown that episodes of nonacid reflux occur as frequently as acid reflux

episodes and that treatment with acid-suppressing medications changes the proportions of acid versus nonacid events, not the total number of events. Esophagoscopy is not diagnostic of reflux, but esophagitis can be identified.

► Treatment & Prognosis

Reflux resolves spontaneously in 85% of affected infants by 12 months of age, coincident with assumption of erect posture and initiation of solid feedings. Until then, regurgitation volume may be reduced by offering small feedings at frequent intervals and by thickening feedings with rice cereal (2–3 tsp/oz of formula). Prethickened “anti-reflux” formulas are available. Histamine-2 (H₂)–receptor antagonists (ranitidine, 5 mg/kg/d in two doses) or proton pump inhibitors (omeprazole, 0.5–1.0 mg/kg/d in one dose) do not reduce the frequency of reflux but may reduce pain behavior. Prokinetic agents such as metoclopramide hasten gastric emptying and improve esophageal motor function, but studies have not shown efficacy in controlling symptoms. A short trial of protein hydrolysate formula (hypoallergenic) sometimes controls emesis and pain behavior in infants with protein sensitivity. Special formulas and acid suppression agents are costly and should be discontinued if there is no improvement of symptoms in 1 week.

Spontaneous resolution is less likely in older children with GERD. Episodic heartburn pain may be controlled with intermittent use of acid blockers. Patients with more severe heartburn or esophagitis require regular acid suppression. Untreated esophagitis may cause esophageal stricture and anemia from blood loss. Barrett esophagus, a precancerous condition, is rare in childhood but can occur in patients with very long-standing esophagitis.

Antireflux surgery (fundoplication) is indicated when GERD causes severe symptoms unresponsive to medications: (1) persistent vomiting with failure to thrive, (2) esophagitis or esophageal stricture, (3) life-threatening apneic spells, or (4) chronic pulmonary disease unresponsive to 2–3 months of medical therapy. Fundoplication also may be considered early in patients whose response to medication is likely to be poor—those with large hiatal hernia, neurologic handicap, previous tracheoesophageal (TE) fistula surgery, or severe esophagitis.

Rudolph CD et al: Guidelines for evaluation and treatment of gastroesophageal reflux in infants and children: Recommendations of the North American Society for Pediatric Gastroenterology and Nutrition. *J Pediatr Gastroenterol Nutr* 2001;23(Suppl):1 [PMID: 11525610].

EOSINOPHILIC ESOPHAGITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Dysphagia, esophageal food impaction, and heartburn.
- Most common in adolescent boys.

- Grossly, esophagoscopy shows white eosinophilic exudates, ringlike esophageal folds, and esophageal stricture. Esophageal mucosal biopsy shows dense eosinophilic infiltrate and hyperplasia of the basal layer of the epithelium.

► Clinical Findings

A. Symptoms and Signs

This recently recognized entity occurs most often in teenage boys but is reported in both sexes and all ages. A common initial presentation is an acute food impaction. The patient may have a long history of recurrent impactions and dysphagia. Heartburn is sometimes reported and suggests the diagnosis of GERD. There often is a family or personal history of atopy, asthma, and dysphagia in male relatives.

B. Laboratory Findings

The esophageal mucosa is thick and inflamed with long, shallow, linear mucosal fissures and visible circumferential mucosal rings that look a bit like the trachea (so-called trachealization). The esophagus is often sprinkled with innumerable pinpoint white exudates that superficially resemble *Candida*. On microscopic examination the white spots are composed of eosinophils. The basal cell layer of the esophageal mucosa is hypertrophied and infiltrated by eosinophils (usually more than 40 per 40 × light microscopic field). A lengthy stricture is often seen which tends to split during endoscopy. Serum IgE often is elevated but this is not a diagnostic finding. Specific allergens are rarely identified by skin testing even though the patient can sometimes identify foods that precipitate pain and dysphagia.

► Differential Diagnosis

The most common differential conditions are peptic esophagitis and candidal esophagitis. Eosinophilic esophagitis may be part of a generalized eosinophilic gastroenteropathy, a very rare, steroid-responsive entity. Patients with eosinophilic gastroenteropathy often present with intestinal obstruction or gastric outlet obstruction caused by large local infiltrates of eosinophils in the antrum, duodenum, and cecum.

► Treatment

An extremely hypoallergenic diet is effective in controlling symptoms. Such diets are useful in infants, but adherence to the diet in older children usually is poor. Beclomethasone, puffed or swallowed from a metered dose pulmonary inhaler, improves symptoms. Two puffs of beclomethasone from an inhaler twice daily using an age-appropriate metered dose is a common recommendation. Systemic corticosteroids, oral sodium cromolyn, and montelukast sodium also have been used with benefit in some patients. Esophageal dilation may be required to treat strictures. Repeat endoscopy after therapy

often shows persistent inflammation despite good control of symptoms. The relationship between eosinophilic esophagitis and later esophageal malignancy has not been determined.

Furuta GT, Straumann A: Review article: The pathogenesis and management of eosinophilic oesophagitis. *Aliment Pharmacol Ther* 2006;24:173 [PMID: 1682447].

ACHALASIA OF THE ESOPHAGUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Gradual onset of distal esophageal obstruction.
- ▶ Dysphagia, esophageal food impaction, chronic pulmonary aspiration.
- ▶ Failure of lower esophageal relaxation during swallowing with abnormalities of esophageal peristalsis.
- ▶ High or low resting pressure of the lower esophageal sphincter.

▶ Clinical Findings

A. Symptoms and Signs

Achalasia is uncommon in children younger than 5 years, but cases in those younger than 12 months have been reported. Symptoms include retrosternal pain and fullness, vomiting, and solid food impaction. Patients eat slowly and may drink large amounts of fluid with solid food. Dysphagia is relieved by repeated forceful swallowing or by vomiting. Familial cases occur in Allgrove syndrome (alacrima, adrenal insufficiency, and achalasia) and familial dysautonomia. Chronic cough, wheezing, recurrent aspiration pneumonitis, anemia, and poor weight gain are common.

B. Imaging and Manometry

Barium esophagram shows a dilated esophagus with a tapered “beak” at the GE junction. Esophageal dilation may not be present in infants because of the short duration of distal obstruction. Fluoroscopy shows disordered esophageal peristalsis. Esophageal manometry may show high resting pressure of the lower esophageal sphincter, failure of sphincter relaxation after swallowing, and abnormal esophageal peristalsis. The cause is unknown. There is a decrease in neuronal nitric oxide synthetase (nNOS) in the tissues of the lower esophageal sphincter and, possibly, local nitric oxide deficiency prevents sphincter relaxation. It is unclear whether the lack of nNOS is a secondary or primary phenomenon.

▶ Differential Diagnosis

Congenital or peptic esophageal stricture, esophageal webs, and esophageal masses may mimic achalasia. Intestinal

pseudo-obstruction, multiple endocrine neoplasia type 2b, systemic amyloidosis, and postvagotomy syndrome cause esophageal dysmotility and symptoms similar to achalasia. Teenage girls may be suspected of having an eating disorder. In Chagas disease, caused by the parasite *Trypanosoma cruzi*, nNOS and ganglion cells are diminished or absent in the muscular layers of the lower esophageal sphincter causing an acquired achalasia.

▶ Treatment & Prognosis

Pneumatic dilation of the lower esophageal sphincter produces temporary relief of obstruction that may last weeks to years. Local injection of botulinum toxin paralyzes the lower esophageal sphincter and temporarily relieves obstruction. More long-lasting relief of obstruction is achieved by surgically dividing the lower esophageal sphincter (Heller myotomy). The procedure can be performed laparoscopically or thoracoscopically. Because of the shorter duration of esophageal obstruction in children, there is less secondary dilation of the esophagus. Thus, the prognosis for return or retention of some normal esophageal motor function after surgery is better than in adults.

Hussain SZ et al: A review of achalasia in 33 children. *Dig Dis Sci* 2002;47:2538 [PMID: 12452392].

CAUSTIC BURNS OF THE ESOPHAGUS

Ingestion of caustic solids or liquids (pH > 12) produces esophageal lesions ranging from superficial inflammation to coagulative necrosis with ulceration, perforation, mediastinitis, or peritonitis. The severity of immediate oral or laryngeal injury after ingestion does not correlate with the degree of esophageal injury. Esophageal or laryngeal obstruction from edema and exudate may occur within 24 hours. Pain may be severe. Esophageal strictures develop in areas of anatomic narrowing (thoracic inlet, GE junction, or point of compression where the left bronchus crosses the esophagus), where contact with the caustic agent is more prolonged. Strictures may develop quickly or gradually over several months. Strictures occur only with full-thickness esophageal necrosis. Shortening of the esophagus is a late complication that may cause hiatal hernia.

The lips, mouth, and airway should be examined in suspected alkali ingestion. Vomiting should not be induced. Drooling is common and is not an accurate reflection of severity of esophageal burns. Oral injury is common with solid caustic agents. Intravenous corticosteroids (eg, methylprednisolone, 1–2 mg/kg/d) are given immediately to reduce oral swelling and laryngeal edema. Intravenous fluids are necessary if dysphagia prevents oral intake. Esophagoscopy, if needed, should be done within 24–48 hours after ingestion before liquefaction of tissues is complete. Treatment may be stopped if there are only first-degree burns at endoscopy. Corticosteroids may be beneficial in first- and second-degree

burns but do not prevent stricture formation from circumferential third-degree burns. Repeated esophageal dilations may be necessary as a stricture develops but are not performed acutely. When radiographs show erosion into the mediastinum or peritoneum, antibiotics are mandatory. Intraluminal esophageal stenting may be beneficial during early management. Surgical replacement of the esophagus by colonic interposition or gastric tube may be needed for long strictures resistant to dilation.

Although agents such as bleach, detergents, and acids may cause esophageal irritation, it is rare for any but the strongest acids and detergents to produce full-thickness necrosis and stricture.

Turner A, Robinson P: Respiratory and gastrointestinal complications of caustic ingestion in children. *Emerg Med J* 2005;22:359 [PMID: 1584706].

FOREIGN BODIES IN THE ALIMENTARY TRACT

The most common foreign bodies ingested by children are coins. Most foreign bodies pass through the GI tract without difficulty, although objects longer than 5 cm may be unable to pass the ligament of Treitz. Ingested foreign bodies tend to lodge in areas of natural constriction—valleculae, thoracic inlet, GE junction, pylorus, ligament of Treitz, and ileocecal junction. Foreign bodies lodged in the esophagus for more than 24 hours, or those causing pain or respiratory distress, should be removed. Disk-shaped batteries lodged in the esophagus should be removed immediately.

Smooth foreign bodies in the stomach, such as buttons or coins, may be monitored without attempting removal for up to several months if the child is free of symptoms. Disk-shaped batteries in the stomach will generally pass uneventfully. Straight pins, screws, and nails generally pass without incident. Large, open safety pins should be removed from the stomach because they may not pass the pyloric sphincter and may cause perforation. Wooden toothpicks should be removed. They have usually been chewed prior to accidental swallowing and carry mouth flora which may cause abscess formation if the toothpick becomes imbedded in the bowel wall. The use of balanced electrolyte lavage solutions containing polyethylene glycol may help the passage of small, smooth foreign bodies lodged in the stomach or intestine. Lavage is especially useful in hastening the passage of disk-shaped batteries or ingested tablets that may be toxic. Failure of a smooth foreign body to exit the stomach after several days suggests the possibility of gastric outlet obstruction.

Most foreign bodies can be removed from the esophagus or stomach by a skilled endoscopist. Under fluoroscopy, a Foley catheter with balloon inflated below the foreign body can be used to extract smooth, round esophageal foreign bodies if the foreign body has been present for less than a few days and if the child has not had previous esophageal surgery. Only an experienced radiologist should attempt this maneuver.

TRACHEOESOPHAGEAL FISTULA

See Chapter 1.

DISORDERS OF THE STOMACH & DUODENUM

HIATAL HERNIA

In *paraesophageal hiatal hernias*, the esophagus and GE junction are in their normal anatomic position, but the gastric cardia is herniated through the diaphragmatic hiatus along side the GE junction. In *sliding hiatal hernias*, the GE junction and a portion of the proximal stomach are displaced above the diaphragmatic hiatus. Paraesophageal hernias are rare in childhood; patients present with pain, esophageal obstruction, or respiratory compromise. The most common cause of paraesophageal hernia is previous fundoplication surgery. *Sliding hiatal hernias* are common. GE reflux may accompany sliding hiatal hernias, although most produce no symptoms. Surgery is indicated if paraesophageal or sliding hiatal hernias produce persistent symptoms.

PYLORIC STENOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Postnatal muscular hypertrophy of the pylorus.
- ▶ Progressive gastric outlet obstruction, nonbilious vomiting, dehydration, and alkalosis in infants younger than 12 weeks.
- ▶ Upper GI contrast radiographs or abdominal ultrasound are diagnostic.

The cause of postnatal pyloric muscular hypertrophy with gastric outlet obstruction is unknown. The incidence is 1–8 per 1000 births, with a 4:1 male predominance. A positive family history is present in 13% of patients. Recent studies suggest that erythromycin in the neonatal period is associated with a higher incidence of pyloric stenosis in infants younger than 30 days.

▶ Clinical Findings

A. Symptoms and Signs

Vomiting usually begins between 2 and 4 weeks of age but may start as late as 12 weeks. Vomiting rapidly becomes projectile after every feeding. Vomiting starts at birth in about 10% of cases. Onset of symptoms may be delayed in preterm infants. The vomitus is rarely bilious but may be blood-streaked. Infants are usually hungry and nurse avidly. Constipation, weight loss, fretfulness, dehydration, and

finally apathy occur. The upper abdomen may be distended after feeding, and prominent gastric peristaltic waves from left to right may be seen. An oval mass, 5–15 mm in longest dimension can be felt on deep palpation in the right upper abdomen, especially after vomiting.

B. Laboratory Findings

Hypochloremic alkalosis with potassium depletion occurs. Dehydration causes elevated hemoglobin and hematocrit. Mild unconjugated bilirubinemia occurs in 2–5% of cases.

C. Imaging

A barium upper GI series reveals retention of contrast in the stomach and a long narrow pyloric channel with a double track of barium. The hypertrophied muscle mass produces typical semilunar filling defects in the antrum. Isolated pylorospasm is common in young infants, and by itself is insufficient to make a diagnosis of pyloric stenosis. Ultrasonography shows a hypoechoic muscle ring greater than 4-mm thick with a hyperechoic center.

► Treatment & Prognosis

Pyloromyotomy is the treatment of choice and consists of incision down to the mucosa along the pyloric length. The procedure can be performed laparoscopically. Treatment of dehydration and electrolyte imbalance is mandatory before surgical treatment, even if it takes 24–48 hours. The outlook after surgery is excellent. Patients often vomit postoperatively as a consequence of gastritis, esophagitis, or associated GE reflux. The postoperative barium radiograph remains abnormal for many months despite relief of symptoms.

Mahon BE et al: Maternal and infant use of erythromycin and other macrolide antibiotics as risk factors for infantile hypertrophic pyloric stenosis. *J Pediatr* 2001;139:380 [PMID: 11562617].

GASTRIC & DUODENAL ULCER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Localized erosions of gastric or duodenal mucosa.
- Pain and bleeding are the most common symptoms.
- Underlying severe illness, *Helicobacter pylori* infection, and nonsteroidal anti-inflammatory drugs (NSAIDs) are the most common causes.
- Diagnosis by endoscopy.

► General Considerations

Gastric and duodenal ulcers occur at any age. Boys are affected more frequently than girls. In the United States, most childhood gastric and duodenal ulcers are associated with underlying illness, toxins, or drugs that cause breakdown in mucosal defenses.

Worldwide, the most common cause of gastric and duodenal ulcer is infection of the gastric mucosa with *H pylori*. Infection causes nodular gastritis and duodenal or gastric ulcer. Long-standing infection is associated with gastric lymphoid tumors and adenocarcinoma. Between 10% and 20% of North American children have antibodies against *H pylori*. Antibody prevalence increases with age, poor sanitation, crowded living conditions, and family exposure. In some developing countries, over 90% of schoolchildren have serologic evidence of past or present infection.

Illnesses predisposing to secondary ulcers include central nervous system disease, burns, sepsis, multi-organ system failure, chronic lung disease, Crohn disease, cirrhosis, and rheumatoid arthritis. The most common drugs causing secondary ulcers are aspirin, alcohol, and NSAIDs. NSAID use causes ulcers throughout the upper GI tract but most often in the stomach and duodenum.

► Clinical Findings

A. Symptoms and Signs

In children younger than 6 years, vomiting and upper GI bleeding are the most common symptoms of gastric and duodenal ulcer. Older children are more likely to complain of abdominal pain. The first attack of acute *H pylori* gastritis may be accompanied by vomiting and hematemesis. Ulcers in the pyloric channel may cause gastric outlet obstruction. Chronic blood loss may cause iron-deficiency anemia. Deep penetration of the ulcer may erode into a mucosal arteriole and cause acute hemorrhage. Penetrating duodenal ulcers (especially common during cancer chemotherapy, immunosuppression and in the intensive care setting) may perforate the duodenal wall causing peritonitis or abscess.

B. Diagnostic Studies

Upper GI endoscopy is the most accurate diagnostic examination. It also allows for identification of other causes of peptic symptoms such as esophagitis, eosinophilic enteropathy, and celiac disease. Upper GI barium radiographs may show an ulcer crater. Soft signs suggestive of peptic disease in adults (duodenal spasticity and thick irregular folds) are not reliable indicators in children. Urease activity is assessed on gastric biopsies, or by evaluation of breath after administration of radiolabeled urea by mouth. *H pylori* antigens can be measured in stool and may be an effective, noninvasive test for infection. Serum antibodies against *H pylori* do not prove that there is active infection or that treatment is needed.

Treatment

Acid suppression or neutralization is the mainstay of ulcer therapy. Liquid antacids in the volumes needed to neutralize gastric acid are usually unacceptable to children. H₂-receptor antagonists and proton pump inhibitors are more effective and usually produce endoscopic healing in 4–8 weeks. Bland “ulcer diets” do not speed healing, but foods causing pain should be avoided. Caffeine should be avoided because it increases gastric acid secretion. Aspirin, alcohol, NSAIDs, and other gastric irritants should be avoided.

Treatment of *H pylori* infection requires eradication of the organism. Spontaneous clearance of infection may occur. The optimal medical regimen is still undetermined. Combinations of amoxicillin, metronidazole, and bismuth subsalicylate for 10–14 days, or amoxicillin for 14 days with omeprazole for 6 weeks are both effective. Clarithromycin for 7 days with a proton pump inhibitor for 6 weeks also is also effective. Resistance to antibiotics is common. An unresolved clinical question is whether recurrent courses of antibiotics should be used to eradicate resistant *H pylori* infection. Some epidemiologic data suggest that the incidence of GERD and Barrett esophagus is increasing in white males as a consequence of aggressive eradication of *H pylori*.

Bourke B et al: Canadian Helicobacter Study Group Consensus Conference: Update on the approach to *Helicobacter pylori* infection in children and adolescents—an evidence-based evaluation. *Can J Gastroenterol* 2005;19:478 [PMID: 16010300].

Vakil N: Primary and secondary treatment of *Helicobacter pylori* in the United States. *Rev Gastroenterol Disord* 2005;5:67 [PMID: 15976737].

CONGENITAL DIAPHRAGMATIC HERNIA

Herniation of abdominal contents through the diaphragm usually occurs through a posteriolateral defect in the diaphragm (foramen of Bochdalek). In about 5% of cases, the diaphragmatic defect is retrosternal (foramen of Morgagni). Hernias result from failure of the diaphragmatic anlagen to fuse and divide the thoracic and abdominal cavities at 8–10 weeks' gestation. All degrees of protrusion of the abdominal viscera through the diaphragmatic opening may occur. Eighty percent of posteriolateral defects involve the left diaphragm. In eventration of the diaphragm, a leaf of the diaphragm with hypoplastic muscular elements balloons into the chest and leads to similar but milder symptoms. Occasionally, diaphragmatic hernia is first identified in an older infant or child during incidental radiograph or routine physical examination. These children usually have a much more favorable prognosis than neonates (see Chapter 1).

CONGENITAL DUODENAL OBSTRUCTION

General Considerations

Extrinsic duodenal obstruction is usually due to congenital peritoneal bands associated with intestinal malrotation, annular pancreas, or duodenal duplication. Intrinsic obstruction is caused by stenosis, mucosal diaphragm (so-called wind sock deformity), or duodenal atresia. The duodenal lumen may be obliterated by a membrane or completely interrupted with a fibrous cord between the two segments. Atresia is more often distal to the ampulla of Vater than proximal.

Clinical Findings

A. Duodenal Atresia

Maternal polyhydramnios is common and often leads to prenatal diagnosis by ultrasonography. Vomiting (usually bile-stained) and epigastric distention begin within a few hours of birth. Meconium may be passed normally. Duodenal atresia is often associated with other congenital anomalies (30%), including esophageal atresia, intestinal atresias, and cardiac and renal anomalies. Prematurity (25–50%) and Down syndrome (20–30%) are also associated. Abdominal plain radiographs show gaseous distention of the stomach and proximal duodenum (the “double-bubble” radiologic sign). With protracted vomiting, there is less air in the stomach and less abdominal distention. Absence of distal intestinal gas suggests atresia or severe extrinsic obstruction, whereas a pattern of intestinal air scattered over the lower abdomen may indicate partial duodenal obstruction. Barium enema may be helpful in determining the presence of malrotation or atresia in the lower GI tract.

B. Duodenal Stenosis

In this condition, duodenal obstruction is not complete. Onset of obvious obstructive symptoms may be delayed for weeks or years. Although the stenotic area is usually distal to the ampulla of Vater, the vomitus does not always contain bile. Children with Down syndrome have an increased risk of duodenal stenosis.

Treatment & Prognosis

Duodenoduodenostomy is performed to bypass the area of stenosis or atresia. Thorough surgical exploration is done to ensure that no lower GI tract anomalies are present. The mortality rate is increased in infants with prematurity, Down syndrome, and associated congenital anomalies. Duodenal dilation and hypomotility from antenatal obstruction may cause duodenal dysmotility with obstructive symptoms even after surgical treatment.

ANNULAR PANCREAS

Annular pancreas is a rotational defect in which normal fusion of the dorsal and ventral pancreatic anlagen does

Table 20-1. Localization and relative frequency of congenital gastrointestinal atresias and stenoses.

	Area Involved	Type of Lesion	Relative Frequency
Pylorus		Atresia; web or diaphragm	1%
Duodenum	80% are distal to the ampulla of Vater	Atresia, stenosis; web or diaphragm	45%
Jejunioileal	Proximal jejunum and distal ileum	Atresia (multiple in 6–29%); stenosis	50%
Colon	Left colon and rectum	Atresia (usually associated with atresias of the small bowel)	5–9%

not occur, and a ring of pancreatic tissue encircles the duodenum. The presenting symptom is duodenal obstruction. Down syndrome and congenital anomalies of the GI tract occur frequently. Polyhydramnios is common. Symptoms may develop late in childhood or even in adulthood if the obstruction is not complete in infancy. Treatment consists of duodenoduodenostomy or duodenojejunostomy without operative dissection or division of the pancreatic annulus.

DISORDERS OF THE SMALL INTESTINE

INTESTINAL ATRESIA & STENOSIS

Excluding anal anomalies, intestinal atresia or stenosis accounts for one third of all cases of neonatal intestinal obstruction (see Chapter 1). Antenatal ultrasound can identify intestinal atresia in utero; polyhydramnios occurs in most affected pregnancies. Prematurity and other congenital anomalies may be present. The localization and relative incidence of atresias and stenoses are listed in Table 20-1.

Bile-stained vomiting and abdominal distention begin in the first 48 hours of life. Multiple sites in the intestine may be affected. The overall length of the small intestine may be significantly shortened. Radiographic features include dilated loops of small bowel and absence of colonic gas. Barium enema reveals narrow-caliber microcolon because of lack of intestinal flow distal to the atresia. In over 10% of patients with intestinal atresia the mesentery is absent, and the superior mesenteric artery cannot be identified beyond the origin of the right colic and ileocolic arteries. The ileum coils around one of these two arteries, giving rise to the so-called Christmas tree deformity on contrast radiographs. The tenuous blood supply often compromises surgical anastomoses. The differential diagnosis of intestinal atresia includes Hirschsprung disease, paralytic ileus secondary to sepsis, midgut volvulus, and meconium ileus. Surgery is mandatory. Postoperative complications include short bowel syndrome and small bowel hypomotility secondary to antenatal obstruction.

INTESTINAL MALROTATION

▶ General Considerations

The midgut extends from the duodenojejunal junction to the mid transverse colon. It is supplied by the superior mesenteric artery, which runs in the root of the mesentery. During gestation, the midgut elongates into the umbilical sac, returning to an intra-abdominal position during the 10th week of gestation. The root of the mesentery rotates in a counterclockwise direction during retraction causing the colon to cross the abdominal cavity ventrally. The cecum moves from the left to the right lower quadrant, and the duodenum crosses dorsally becoming partly retroperitoneal. When rotation is incomplete, the dorsal fixation of the mesentery is defective and shortened, so that the bowel from the ligament of Treitz to the mid transverse colon may rotate around its narrow mesenteric root and occlude the superior mesenteric artery (volvulus).

▶ Clinical Findings

A. Symptoms and Signs

Malrotation with volvulus accounts for 10% of neonatal intestinal obstructions. Most infants present in the first 3 weeks of life with bile-stained vomiting or with overt small bowel obstruction. Intrauterine volvulus may cause intestinal obstruction or perforation at birth. The neonate may present with ascites or meconium peritonitis. Later presenting signs include intermittent intestinal obstruction, malabsorption, protein-losing enteropathy, or diarrhea. Associated congenital anomalies, especially cardiac, occur in over 25% of symptomatic patients.

B. Imaging

An upper GI series shows the duodenojejunal junction and the jejunum on the right side of the spine. The diagnosis of malrotation can be further confirmed by barium enema, which may demonstrate a mobile cecum located in the midline, right upper quadrant, or left abdomen.

▶ Treatment & Prognosis

Surgical treatment of malrotation is the Ladd procedure. In young infants the Ladd procedure should be performed even

if volvulus has not occurred. The duodenum is mobilized and the short mesenteric root is extended. The bowel is then fixed in a more normal distribution. Treatment of malrotation discovered in children older than age 12 months is uncertain. Because volvulus can occur at any age, surgical repair is usually recommended, even in asymptomatic children. Laparoscopic repair of malrotation is possible but is technically difficult and is never performed in the presence of volvulus.

Midgut volvulus is a surgical emergency. Bowel necrosis results from occlusion of the superior mesenteric artery. When necrosis is extensive, it is recommended that a first operation include only reduction of the volvulus with lysis of mesenteric bands. Resection of necrotic bowel should be delayed if possible until a second-look operation 24–48 hours later can be undertaken in the hope that more bowel can be salvaged. The prognosis is guarded if perforation, peritonitis, or extensive intestinal necrosis is present.

SHORT BOWEL SYNDROME

The most common cause of short bowel syndrome is neonatal intestinal resection. Necrotizing enterocolitis is the most common reason for resection (45%). Other causes include intestinal atresias (23%), gastroschisis (15%), volvulus (15%), and, less commonly, congenital short bowel, long-segment Hirschsprung disease, and bowel ischemic events. If bowel resection is extensive, the infant may be left with an intestine of insufficient length to support normal absorption and growth. Estimates of the small bowel length of a newborn range from 150–300 cm. Neonatal short bowel syndrome is defined as removal of more than 50% of the small intestinal length. In patients with 50% resection, it is almost certain that intravenous nutrition will be required for months to years to support growth.

The intestine remaining after resection does not undergo compensatory increase in length. However, if nutrition can be maintained, enterocytes will proliferate, villi will lengthen, and the intestine will elongate in proportion to the child's increasing height. These adaptations may eventually be sufficient for the patient's nutritional needs. Achieving independence from intravenous nutrition is less likely when less than 30 cm of small intestine remain after surgery. An intact colon and intact ileocecal sphincter are factors improving prognosis in short bowel syndrome. Liver failure (a consequence of intravenous nutrition, recurrent infection, and other injuries) is the most common cause of death in patients with short bowel syndrome. Mortality among all infants with short bowel syndrome is about 10–15%. Intestinal transplantation is an option for children with very short residual intestinal segments.

Goulet O, Ruemmele F: Causes and management of intestinal failure in children. *Gastroenterology* 2006;130:S16 [PMID: 16473066].

INTUSSUSCEPTION

Intussusception is the most frequent cause of intestinal obstruction in the first 2 years of life. It is three times more common in males than in females. In 85% of cases the cause is not apparent. Small bowel polyp, Meckel diverticulum, omphalomesenteric remnant, duplication, Henoch-Schönlein purpura, lymphoma, lipoma, parasites, foreign bodies, and viral enteritis with hypertrophy of Peyer patches all have been implicated as causes. Intussusception of the small intestine occurs in patients with celiac disease and cystic fibrosis related to the bulk of stool in the terminal ileum. In children older than 6 years, lymphoma is the most common cause. Intermittent small bowel intussusception is a rare cause of recurrent abdominal pain.

In its usual form, the intussusception starts just proximal to the ileocecal valve and extends for varying distances into the colon. The terminal ileum telescopes into the colon. Swelling, hemorrhage, incarceration, arterial and venous compromise, and necrosis of the intussuscepted ileum may occur, as well as intestinal perforation and peritonitis.

► Clinical Findings

Characteristically, a thriving infant 3–12 months of age develops recurring paroxysms of abdominal pain with screaming and drawing up of the knees. Vomiting and diarrhea occur soon afterward (90% of cases), and bloody bowel movements with mucus appear within the next 12 hours (50%). The child is characteristically lethargic between paroxysms and may be febrile. The abdomen is tender and often distended. A sausage-shaped mass may be palpated, usually in the upper mid abdomen. An intussusception can persist for several days if obstruction is not complete, and patients may present with intermittent attacks of enterocolitis. In older children, sudden attacks of abdominal pain may be related to chronic recurrent intussusception with spontaneous reduction.

► Treatment

Barium enema and air enema are both diagnostic and therapeutic. Reduction of the intussusception by barium enema should not be attempted if signs of strangulated bowel, perforation, or toxicity are present. Air insufflation of the colon under fluoroscopic guidance is a safe alternative to barium enema that has excellent diagnostic sensitivity and specificity without the risk of contaminating the abdominal cavity with barium. Care is required in performing either air or barium enema because ischemic damage to the colon secondary to vascular compromise increases the risk of perforation.

Surgery is required in extremely ill patients, in patients with evidence of bowel perforation, or in those in whom hydrostatic or pneumatic reduction has been unsuccessful (25%). Surgery has the advantage of identifying a lead point such as a Meckel diverticulum. Surgical reduction of intus-

susception is associated with a lower recurrence rate than pneumatic reduction.

► Prognosis

The prognosis relates directly to the duration of the intussusception before reduction. The mortality rate with treatment is 1–2%. The patient should be observed carefully after hydrostatic or pneumatic reduction because intussusception recurs within 24 hours in 3–4% of patients.

INGUINAL HERNIA

A peritoneal sac precedes the testicle as it descends from the genital ridge to the scrotum. The lower portion of this sac envelops the testis as the tunica vaginalis, and the remainder normally atrophies by the time of birth forming a cord (processus vaginalis). In some cases, peritoneal fluid may become trapped in the tunica vaginalis (noncommunicating hydrocele). If the processus vaginalis remains open, peritoneal fluid or an abdominal structure may be forced into it (indirect inguinal hernia).

Inguinal hernias are most often indirect and occur more frequently (9:1) in boys than in girls. Hernias may be present at birth or may appear at any age. The incidence in preterm male infants is close to 5%. Inguinal hernia is reported in 30% of male infants weighing 1000 g or less.

► Clinical Findings

No symptoms are associated with an empty processus vaginalis. In most cases, a hernia is a painless inguinal swelling. The mother of the infant may be the only person to see the mass, as it may retract when the infant is active, cold, frightened, or agitated during the physical examination. There may be a history of inguinal fullness associated with coughing or long periods of standing, or there may be a firm, globular, and tender swelling, sometimes associated with vomiting and abdominal distention. In some instances, a herniated loop of intestine may become partially obstructed, leading to pain and partial intestinal obstruction. Rarely, bowel becomes trapped in the hernia sac, and complete intestinal obstruction occurs. Gangrene of the hernia contents or testis may occur. In girls, the ovary may prolapse into the hernia sac presenting as a mass below the inguinal ligament. A suggestive history is often the only criterion for diagnosis, along with the “silk glove” feel of the rubbing together of the two walls of the empty hernia sac.

► Differential Diagnosis

Inguinal lymph nodes may be mistaken for a hernia. Nodes are usually multiple with more discrete borders. A hydrocele of the cord should transilluminate. An undescended testis is usually mobile in the canal and is associated with absence of the gonad in the scrotum.

► Treatment

Incarceration of an inguinal hernia is more likely to occur in boys and in children younger than 10 months of age. Manual reduction of incarcerated inguinal hernias can be attempted after the sedated infant is placed in the Trendelenburg position with an ice bag on the affected side. Manual reduction is contraindicated if incarceration has been present for more than 12 hours or if bloody stools are noted. Surgery is usually indicated if a hernia has ever incarcerated. Hydroceles frequently resolve by age 2 years. Controversy remains about whether the side opposite a unilateral hernia should be surgically explored. Exploration of the unaffected groin can document an open processus vaginalis, but patency does not always guarantee that herniation will occur, especially in patients older than age 1 year, in whom the risk of contralateral hernia is about 10%.

Nicholls E: Inguino-scrotal problems in children. *Practitioner* 2003;247:226 [PMID: 12640831].

UMBILICAL HERNIA

Umbilical hernias are more common in preterm than in full-term infants and more common in black than in white infants. Small bowel may incarcerate in small-diameter umbilical hernias. Most umbilical hernias regress spontaneously if the fascial defect has a diameter of less than 1 cm. Large defects and hernias persisting after age 4 years should be treated surgically. Reducing the hernia and strapping the skin over the abdominal wall defect does not accelerate the healing process.

PATENT OMPHALOMESENTERIC DUCT

The omphalomesenteric duct is an embryonic remnant connecting the ileum to the undersurface of the umbilicus. It may be patent, completely occluded as a fibrous cord, or may have blind cystic areas. Fecal discharge from the umbilicus suggests a patent omphalomesenteric duct. A fibrous cord may become the focal point of an intestinal volvulus. Mucoïd umbilical discharge may indicate a mucocele in the omphalomesenteric remnant with an opening at the umbilicus. A closed mucocele may protrude through the umbilicus and be mistaken for an umbilical granuloma because it is firm and bright red. Cauterization of a mucocele is not recommended. Surgical excision of omphalomesenteric remnants is indicated. Ultrasound examination or abdominal computed tomography (CT) can help confirm the diagnosis of omphalomesenteric duct remnant.

MECKEL DIVERTICULUM

Meckel diverticulum is the most common form of omphalomesenteric duct remnant. It is usually located on the antimesenteric border of the mid to distal ileum. It occurs in 1.5% of the population and in the majority of cases causes no

symptoms. Diverticula may be lined by ileal, gastric, pancreatic, jejunal, or colonic mucosa. Familial cases have been reported. If complications occur, they are three times more common in males than in females. More than 50% of complications occur in the first 2 years of life.

► Clinical Findings

A. Symptoms and Signs

Forty to 60% of symptomatic patients have painless episodes of maroon or melanotic rectal bleeding. The bleeding is due to deep ileal ulcers adjacent to the diverticulum caused by acid secreted by heterotopic gastric tissue. Bleeding may be voluminous enough to cause shock and anemia. Occult bleeding is less common. Intestinal obstruction occurs in 25% of symptomatic patients as a result of ileocolonic intussusception. Intestinal volvulus may occur around a fibrous remnant of the vitelline duct extending from the tip of the diverticulum to the abdominal wall. In some patients, entrapment of bowel under a band running between the diverticulum and the base of the mesentery occurs. Meckel diverticula may be trapped in an inguinal hernia (Littre hernia). Diverticulitis occurs in 10–20% of symptomatic patients and is clinically indistinguishable from acute appendicitis. Perforation and peritonitis may occur. Chronic recurrent abdominal pain is rarely the only symptom.

B. Imaging

Diagnosis of Meckel diverticulum is seldom made on barium radiograph. Technetium-99 (^{99m}Tc)-pertechnetate is taken up by the heterotopic gastric mucosa in the diverticulum and outlines the diverticulum on a nuclear scan. Giving pentagastrin or cimetidine before administering the radionuclide increases ^{99m}Tc -pertechnetate uptake and retention by the heterotopic gastric mucosa and can increase the sensitivity of the test. Angiography or tagged red cell scan may be useful when bleeding is brisk.

► Treatment & Prognosis

Treatment is surgical. At laparoscopy or laparotomy, the ileum proximal and distal to the diverticulum may reveal ulcerations and heterotopic gastric tissue adjacent to the neck of the diverticulum. The prognosis for Meckel diverticulum is good.

ACUTE APPENDICITIS

► General Considerations

Acute appendicitis is the most common indication for emergency abdominal surgery in childhood. The frequency increases with age and peaks between 15 and 30 years. Obstruction of the appendix by fecalith (25%) is a common predisposing factor. Parasites may rarely cause obstruction (especially ascarids) and most of the remaining cases are idiopathic.

The incidence of perforation is high in childhood (40%), especially in children younger than age 2 years, in whom pain is often poorly localized and symptoms nonspecific. To avoid delay in diagnosis, it is important to maintain close communication with parents and perform a thorough initial physical examination with sequential examinations at frequent intervals over several hours to correctly interpret the evolving symptoms and signs.

► Clinical Findings

A. Symptoms and Signs

The typical patient has fever and periumbilical abdominal pain, which then localizes to the right lower quadrant with signs of peritoneal irritation. Anorexia, vomiting, constipation, and diarrhea also occur. Contrary to the vomiting of acute gastroenteritis which usually precedes abdominal pain, vomiting in appendicitis usually follows the onset of pain and is often bilious. The clinical picture is frequently atypical, especially in young children and infants. A rectal examination may clarify the site of tenderness or reveal a localized appendiceal mass. Serial examinations are critical in differentiating appendicitis from the many other conditions that transiently mimic its symptoms.

B. Laboratory Findings

The white blood cell count is seldom higher than 15,000/ μL . Pyuria, fecal leukocytes, and guaiac-positive stool are sometimes present.

C. Imaging

A radio-opaque fecalith reportedly is present in two thirds of cases of ruptured appendix. In experienced hands, ultrasonography of the appendix shows a noncompressible, thickened appendix in 93% of cases. A localized fluid collection adjacent to or surrounding the appendix may also be seen. Abdominal CT after rectal instillation of contrast with thin cuts in the area of the appendix may be diagnostic. Indium-labeled white blood cell scan may localize to an inflamed appendix. Enlarged mesenteric lymph nodes are a nondiagnostic finding.

► Differential Diagnosis

The presence of pneumonia, pleural effusion, urinary tract infection, right-sided kidney stone, cholecystitis, perihepatitis, and pelvic inflammatory disease may mimic appendicitis. Other medical and surgical conditions causing acute abdomen should also be considered (see Table 20–8).

► Treatment & Prognosis

Exploratory laparotomy or laparoscopy is indicated when the diagnosis of appendicitis cannot be ruled out after a period of close observation. Postoperative antibiotic therapy

is reserved for patients with gangrenous or perforated appendix. A single intraoperative dose of cefoxitin or cefotetan is recommended for all patients to prevent postoperative infection. The mortality rate is less than 1% during childhood, despite the high incidence of perforation. In uncomplicated nonruptured appendicitis, a laparoscopic approach is associated with a shortened hospital stay.

Bundy DG et al: Does this child have appendicitis? JAMA 2007;298:438 [PMID: 17652298].

DUPLICATIONS OF THE GASTROINTESTINAL TRACT

Duplications are congenital spherical or tubular structures found most commonly in the ileum. The other common locations of duplication are the duodenum, rectum, and esophagus. Duplications usually contain fluid and sometimes blood if necrosis has taken place. Most duplications are attached to the mesenteric side of the gut. They generally do not communicate with the intestinal lumen but share a common muscular coat. The epithelial lining of the duplication is usually of the same type as the bowel from which it originates. Some duplications (neuroenteric cysts) are attached to the spinal cord and are associated with hemivertebrae and anterior or posterior spina bifida.

Symptoms of vomiting, abdominal distention, colicky pain, rectal bleeding, partial or total intestinal obstruction, or an abdominal mass may start in infancy. Diarrhea and malabsorption may result from bacterial overgrowth in communicating duplications. Physical examination may reveal a rounded, smooth, movable mass, and barium radiograph or CT of the abdomen may show a noncalcified cystic mass displacing other organs. ^{99m}Tc -pertechnetate scan may help identify duplications containing gastric mucosa. Duplications of the ileum can give rise to an intussusception. Prompt surgical treatment is indicated.

DISORDERS OF THE COLON

CONGENITAL AGANGLIONIC MEGACOLON (HIRSCHSPRUNG DISEASE)

► General Considerations

Hirschsprung disease results from an absence of ganglion cells in the mucosal and muscular layers of the colon. Neural crest cells fail to migrate into the mesodermal layers of the gut during gestation, possibly secondary to abnormal end-organ cell surface receptors or local deficiency of nitric oxide synthesis. The absence of ganglion cells results in failure of the colonic muscles to relax in front of an advancing bolus. The rectum (30%) or rectosigmoid (44%) is usually affected. The entire colon may be aganglionic (8%). Segmental aganglionosis is rare and is probably an acquired ischemic lesion.

The aganglionic segment has normal or slightly narrowed caliber with dilation of the normal colon proximal to the obstructing aganglionic segment. The mucosa of the dilated colonic segment may become thin and inflamed, causing diarrhea, bleeding, and protein loss (enterocolitis).

A familial pattern has been described, particularly in total colonic aganglionosis. The disease is four times more common in boys than girls, and 10–15% of patients have Down syndrome. Mutations in the *ret* proto-oncogene have been identified in about 15% of cases.

► Clinical Findings

A. Symptoms and Signs

Failure of the newborn to pass meconium, followed by vomiting, abdominal distention, and reluctance to feed, suggest the diagnosis of Hirschsprung disease. Enterocolitis manifested by fever, explosive diarrhea, and prostration, is reported in approximately 50% of affected newborns. Enterocolitis may lead to inflammatory and ischemic changes in the colon, with perforation and sepsis. In some patients, especially those with short segments involved, symptoms are not obvious at birth. In later infancy, alternating obstipation and diarrhea predominate. The older child is more likely to have constipation alone. The stools are foul-smelling and ribbon-like. The abdomen is distended with prominent veins. Peristaltic waves are visible and fecal masses palpable. Intermittent bouts of intestinal obstruction, hypochromic anemia, hypoproteinemia, and failure to thrive are common. Encopresis is rare.

On digital rectal examination, the anal canal and rectum are devoid of fecal material despite obvious retained stool on abdominal examination or radiographs. If the aganglionic segment is short, there may be a gush of flatus and stool as the finger is withdrawn.

Infants of diabetic mothers may have similar symptoms and, in this setting, small left colon syndrome should be suspected. Meglumine diatrizoate (Gastrografin) enema is both diagnostic and therapeutic in small left colon syndrome as it reveals a meconium plug in the left colon, which is often passed during the diagnostic radiograph. The left colon is narrow but usually functional. In a small proportion of patients with small left colon, Hirschsprung disease may later be found.

B. Laboratory Findings

Ganglion cells are absent in both the submucosal and muscular layers of involved bowel. Special stains may show nerve trunk hypertrophy and increased acetylcholinesterase activity. Ganglionated bowel above the aganglionic segment is sometimes found to contain more than normal numbers of ganglion cells in abnormal locations (neuronal dysplasia). This finding is sometimes associated with persistent motor dysfunction of the remnant colon.

C. Imaging

Plain abdominal radiographs may reveal dilated proximal colon and absence of gas in the pelvic colon. Barium enema using a catheter without a balloon and with the tip inserted barely beyond the anal sphincter usually demonstrates a narrow distal segment with a sharp transition to the proximal dilated (normal) colon. The transition zone may not be seen in neonates since the normal proximal bowel has not had time to become dilated. Retention of barium for 24–48 hours is not diagnostic of Hirschsprung disease in older children as it typically occurs in retentive constipation as well. Barium retention is a more reliable sign in neonates.

D. Special Examinations

Rectal manometric testing reveals failure of reflex relaxation of the internal anal sphincter after distention of the rectum in all patients with Hirschsprung disease, regardless of the length of the aganglionic segment. In occasional patients, a nonrelaxing internal anal sphincter is the only abnormality. This condition is often called “ultrashort segment Hirschsprung disease.”

► Differential Diagnosis

Hirschsprung disease accounts for 15–20% of cases of neonatal intestinal obstruction. It must be differentiated from the small left colon syndrome by biopsy. In childhood, Hirschsprung disease must be differentiated from retentive constipation. In older infants and children it can also be confused with celiac disease because of the striking abdominal distention and failure to thrive.

► Treatment & Prognosis

Treatment is surgical. Diverting colostomy (or ileostomy) is performed proximal to the aganglionic segment. In unstable infants, resection of the aganglionic segment may be postponed. At the time of definitive surgery, the transition zone between ganglionated and nonganglionated bowel is identified. Aganglionic bowel is resected, and a pull-through of ganglionated bowel to the preanal rectal remnant is made. Several surgical techniques, including laparoscopic pull-through, are in use. In children with ultrashort segment disease, an internal anal sphincter myotomy or botulinum toxin injection of the internal anal sphincter may control symptoms.

Complications after surgery include fecal retention, fecal incontinence, anastomotic breakdown, or anastomotic stricture. Postoperative obstruction may result from inadvertent retention of a distal aganglionic colon segment or postoperative destruction of ganglion cells secondary to vascular impairment. Neuronal dysplasia of the remaining bowel may produce a pseudo-obstruction syndrome. Enterocolitis occurs postoperatively in 15% of patients.

Garipey CE: Developmental disorders of the enteric nervous system: Genetic and molecular bases. *J Pediatr Gastroenterol Nutr* 2004;39:5 [PMID: 15187773].

CONSTIPATION

Chronic constipation in childhood is defined as two or more of the following characteristics for 2 months: (1) less than 3 bowel movements per week; (2) more than 1 episode of encopresis per week; (3) impaction of the rectum with stool; (4) passage of stool so large it obstructs the toilet; (5) retentive posturing and fecal withholding; and (6) pain with defecation. Retention of feces in the rectum results in encopresis (involuntary fecal leakage) in 60% of children with constipation. Most constipation in childhood is a result of voluntary or involuntary retentive behavior (chronic retentive constipation). About 2% of healthy primary school children have chronic retentive constipation. The ratio of males to females may be as high as 4:1. Constipation due to organic causes is much rarer.

► Clinical Findings

Infants younger than age 3 months often grunt, strain, and turn red in the face while passing normal stools. This pattern may be viewed erroneously as constipation. Failure to appreciate this normal developmental pattern may lead to the unwise use of laxatives or enemas. Infants and children may, however, develop the ability to ignore the sensation of rectal fullness and retain stool. Many factors reinforce this behavior, which results in impaction of the rectum and overflow incontinence or encopresis. Among these are painful defecation; skeletal muscle weakness; psychological issues, especially those relating to control and authority; modesty and distaste for school bathrooms; medications; and other factors listed in Table 20–2. The dilated rectum gradually becomes less sensitive to fullness, thus perpetuating the problem.

► Differential Diagnosis

It is important to distinguish chronic retentive constipation from Hirschsprung disease. Features distinguishing these two entities are summarized in Table 20–3.

► Treatment

Increased intake of high-residue foods such as bran, whole wheat, fruits, and vegetables may be sufficient therapy in mild constipation. Although extremes of dehydration may result in constipation, the most likely response to increased fluid intake in normal children is increased urination with little effect on defecation.

If diet change alone is ineffective, medications may be required. Barley malt extract (Maltsupex), 1–2 tsp added to feedings two or three times daily, or polyethylene glycol solution (MiraLax), 0.8–1 g/kg/d, are safe stool softeners in infants and children. Stool softeners such as dioctyl sodium sulfosuccinate, 5–10 mg/kg/d, may be less effective in children with voluntary stool retention. Stimulant laxatives such as standardized extract of senna fruit (Senokot syrup, Ex-Lax) can be used for short periods to relieve fecal impaction.

Table 20-2. Causes of constipation.

Functional or retentive causes	Abnormalities of myenteric ganglion cells
Dietary causes	Hirschsprung disease
Undernutrition, dehydration	Waardenburg syndrome
Excessive milk intake	Multiple endocrine neoplasia 2a
Lack of bulk	Hypo- and hyperganglionosis
Cathartic abuse	von Recklinghausen disease
Drugs	Multiple endocrine neoplasia 2b
Narcotics	Intestinal neuronal dysplasia
Antihistamines	Chronic intestinal pseudo-obstruction
Some antidepressants	Spinal cord defects
Vincristine	Metabolic and endocrine disorders
Structural defects of gastrointestinal tract	Hypothyroidism
Anus and rectum	Hyperparathyroidism
Fissure, hemorrhoids, abscess	Renal tubular acidosis
Anterior ectopic anus	Diabetes insipidus (dehydration)
Anal and rectal stenosis	Vitamin D intoxication (hypercalcemia)
Presacral teratoma	Idiopathic hypercalcemia
Small bowel and colon	Skeletal muscle weakness or incoordination
Tumor, stricture	Cerebral palsy
Chronic volvulus	Muscular dystrophy/myotonia
Intussusception	
Smooth muscle diseases	
Scleroderma and dermatomyositis	
Systemic lupus erythematosus	
Chronic intestinal pseudo-obstruction	

Modified and reproduced, with permission, from Silverman A, Roy CC: *Pediatric Clinical Gastroenterology*, 3rd ed. Mosby, 1983.

If encopresis is present, treatment should start with relieving fecal impaction. Disimpaction can be achieved in several ways, including medications such as hypertonic phosphate or saline enemas, mineral oil (2–3 mL/kg/d), and nonabsorbable

osmotic agents such as polyethylene glycol (MiraLax, 1 g/kg/d) and milk of magnesia (1–2 mL/kg/d). Effective stool softeners should thereafter be given regularly in doses sufficient to induce two or three loose bowel movements per day. After several weeks to months of regular loose stools, stool softeners can be tapered and stopped. Mineral oil should not be given to nonambulatory infants, physically handicapped or bed-bound children, or any child with GE reflux. Aspiration of mineral oil may cause lipid pneumonia. A multiple vitamin supplement is recommended while mineral oil is given. Recurrence of encopresis is common and should be treated promptly with a short course of stimulant laxatives or an enema. Psychiatric consultation may be indicated for patients with resistant symptoms or severe emotional disturbances.

Table 20-3. Differentiation of retentive constipation and Hirschsprung disease.

	Retentive Constipation	Hirschsprung Disease
Onset	2–3 years	At birth
Abdominal distention	Rare	Present
Nutrition and growth	Normal	Poor
Soiling and retentive behavior	Intermittent or constant	Rare
Rectal examination	Ampulla full	Ampulla may be empty
Rectal biopsy	Ganglion cells present	Ganglion cells absent
Rectal manometry	Normal rectoanal reflex	Nonrelaxation of internal anal sphincter after rectal distention
Barium enema	Distended rectum	Narrow distal segment with proximal megacolon

ANAL FISSURE

Anal fissure is a slitlike tear in the squamous epithelium of the anus, usually secondary to the passage of large, hard fecal

masses. Anal stenosis, anal crypt abscess, and trauma can be contributory factors. Sexual abuse must be considered in children with large, irregular, or multiple anal fissures. Anal fissures may be the presenting sign of Crohn disease in older children.

The infant or child with anal fissure typically cries with defecation and will try to hold back stools. Sparse, bright red bleeding is seen on the outside of the stool or on the toilet tissue following defecation. The fissure can often be seen if the patient is examined in a knee-chest position with the buttocks spread apart. When a fissure cannot be identified, it is essential to rule out other causes of rectal bleeding such as juvenile polyp, perianal inflammation due to group A β -hemolytic streptococcus, or inflammatory bowel disease. Anal fissures should be treated promptly to break the constipation \rightarrow fissure \rightarrow pain \rightarrow retention \rightarrow constipation cycle. A stool softener should be given. Anal dilation relieves sphincter spasm. Warm sitz baths after defecation may be helpful. Rarely, silver nitrate cauterization or surgery is indicated. Anal surgery should be avoided in patients with Crohn disease because of the high risk of recurrence and progression after surgery.

CONGENITAL ANORECTAL ANOMALIES

1. Anterior Displacement of the Anus

Anterior displacement of the anus is a common anomaly of infant girls. Its usual presentation in infants is constipation and straining with stool. On physical examination, the anus looks normal but is ventrally displaced, located close to the vaginal fourchette (in females) or to the base of the scrotum (in males). The diagnosis is made in girls if the distance from the vaginal fourchette to the center of the anal opening is less than 25% of the total distance from fourchette to coccyx. In boys the diagnosis is made if the distance from the base of the scrotum to the anal aperture is less than 33% of the total distance from scrotum to coccyx. In severe anterior displacement, when the anal opening is located less than 10% of the distance from the vaginal fourchette to the coccyx, the anal sphincter muscle may not completely encircle the anal opening and severe obstipation similar to that seen in imperforate anus may occur. Indeed, extreme anterior displacement of the anus may be a form of imperforate anus. Surgery is not needed in most cases. Stool softeners or occasional glycerin suppositories usually relieve straining. This problem improves significantly by age 3–4 years as normal toddler lordosis disappears. A thorough investigation for imperforate anus should be performed in children with severe persistent symptoms, and an anal cutback operation may be needed.

2. Anal Stenosis

Anal stenosis usually presents in the newborn period. The anal aperture may be very small and filled with a dot of meconium. Defecation is difficult, with ribbon-like stools,

blood and mucus per rectum, fecal impaction, and abdominal distention. This malformation accounts for about 10% of anorectal anomalies. Anal stenosis may not be apparent at birth because the anus looks normal. Rectal bleeding in a straining infant often leads to a rectal examination which reveals a tight ring in the anal canal. Dilation of the anal ring is usually curative but may have to be repeated daily for several weeks.

3. Imperforate Anus

Imperforate anus in its numerous forms accounts for 75% of all anorectal anomalies. These anomalies are often complicated by associated anomalies of the urinary and genital tract. They are more common in males than in females and require careful diagnostic evaluation immediately to assess the extent of bowel, urinary, genital, and other organ system anomalies, including spinal cord and heart.

Infants with low imperforate anus fail to pass meconium. There may be a greenish bulging membrane obstructing the anal aperture. Perforation of the anal membrane is a relatively simple surgical procedure. A skin tag shaped like a “bucket handle” is seen on the perineum of some males below which a stenotic aperture can be seen. The aperture is sometimes surrounded by normal anal musculature, but in many cases the aperture is a rectoperineal fistula and the anal musculature is displaced posteriorly or is absent. Eighty to 90% of patients with low imperforate anus are continent after surgery.

In high imperforate anus, physical examination usually shows no anal musculature. There may be a rectoperineal, rectovesicular, rectourethral, or rectovaginal fistula; hypoplastic buttocks; cloacal anomalies; and sometimes, evidence of distal neurologic deficit. It is critical in these cases to fully evaluate the complex anatomy and neurologic function before attempting corrective surgery. A diverting colostomy is usually performed to protect the urinary tract and relieve obstruction. After reparative surgery, only 30% of patients with high imperforate anus achieve fecal continence.

Levitt MA, Pena A: Outcomes from the correction of anorectal malformations. *Curr Opin Pediatr* 2005;17:394 [PMID: 15891433].

PSEUDOMEMBRANOUS ENTEROCOLITIS

Pseudomembranous enterocolitis occurs when previous antibiotic use allows overgrowth of *Clostridium difficile* in the colon and toxin production. The onset of colitis occurs from 1–14 days after initiation of antibiotic therapy and can occur up to 30 days after antibiotics have been discontinued. Clindamycin was one of the first antibiotics associated with pseudomembranous colitis. Almost all antibiotics are now recognized to be potential causes, although erythromycin seems less likely than most. In pediatric patients, amoxicillin and cephalosporins are commonly associated with pseudomembranous enterocolitis, probably because of their widespread use. Although antibiotic

use is the most common antecedent of pseudomembranous colitis, previous GI surgery and antimetabolite therapy in cancer patients are also associated with its development.

C difficile secretes enterotoxins that cause necrotizing inflammation of the colon mucosa. The patient characteristically has fever, abdominal distention, tenesmus, diarrhea, and generalized abdominal tenderness. Chronic presentations with low-grade fever, diarrhea, and abdominal pain have been described. Diarrheal stools contain sheets of neutrophils and sometimes gross blood. Plain abdominal radiographs show a thickened colon wall and ileus. On colonoscopy, the colon is covered by small, raised white plaques (pseudomembranes) with areas of apparently normal bowel in between. Biopsy specimens show “exploding crypts”—an eruption of white cells that appears to be shooting out of affected crypts. Stool cultures often show overgrowth of *Staphylococcus aureus*, which is probably an opportunistic organism growing in the necrotic tissue. *C difficile* can be cultured in specialized laboratories. Identification of stool toxins is the usual method of diagnosis. Infants up to 18–24 months of age may have toxins in the stool but do not develop disease or require therapy. Infants do not have sufficient receptors for the toxins to produce disease.

The treatment of pseudomembranous colitis consists of stopping antibiotics and instituting therapy with oral vancomycin (30–50 mg/kg/d) or metronidazole (30 mg/kg/d). Vancomycin is many times more expensive than metronidazole and no more efficacious. Metronidazole can be given intravenously in patients with vomiting or ileus. Relapse occurs after treatment in 10–50% of patients because of exsporation of residual spores in the colon. Retreatment with the same antibiotic regimen is usually effective, but multiple relapses are possible and may be a significant management problem. Ulcerative colitis may be an underlying problem in cases of apparent recurrent *C difficile*.

DISORDERS OF THE PERITONEAL CAVITY

PERITONITIS

Primary bacterial peritonitis accounts for less than 2% of childhood peritonitis. The most common causative organisms are *Escherichia coli*, other enteric organisms, hemolytic streptococci, and pneumococci. Primary peritonitis occurs in patients with splenectomy, splenic dysfunction, or ascites (nephrotic syndrome, advanced liver disease, kwashiorkor). It also occurs in infants with pyelonephritis or pneumonia.

Secondary peritonitis is much more common. It is associated with peritoneal dialysis, penetrating abdominal trauma, or ruptured viscus. The organisms associated with secondary peritonitis vary with the cause. Organisms not commonly pathogenic such as *Staphylococcus epidermidis* and *Candida* may cause secondary peritonitis in patients

receiving peritoneal dialysis. Multiple enteric organisms may be isolated after penetrating abdominal injury, bowel perforation, or ruptured appendicitis. Intra-abdominal abscesses may form in pelvic, subhepatic, or subphrenic areas, but discrete localization of infection is less common in young infants than in adults.

Symptoms of peritonitis include abdominal pain, fever, nausea, vomiting, acidosis, and shock. Respirations are shallow. The abdomen is tender, rigid, and distended, with involuntary guarding. Bowel sounds may be absent. Diarrhea is fairly common in primary peritonitis and less so in secondary peritonitis. Most peritonitis is an acute medical emergency. In patients receiving peritoneal dialysis, peritonitis can be a chronic infection causing milder symptoms.

Leukocyte count is high initially ($> 20,000/\mu\text{L}$) with a predominance of immature forms, and later may fall to neutropenic levels, especially in primary peritonitis. Plain abdominal radiographs and CT scan will confirm the presence of ascites. Bacterial peritonitis should be suspected if paracentesis fluid contains more than 500 leukocytes/ μL or more than 32 mg/dL of lactate; if it has a pH less than 7.34; or if the pH is over 0.1 pH unit less than arterial blood pH. Diagnosis is made by Gram stain and culture, preferably of 5–10 mL of fluid for optimal yield. The blood culture is often positive in primary peritonitis.

Antibiotic treatment and supportive therapy for dehydration, shock, and acidosis are indicated. Surgical treatment of the underlying cause of secondary peritonitis is critical. Removal of infected peritoneal dialysis catheters in patients with secondary peritonitis is sometimes necessary and almost always required if *Candida* infection is present.

CHYLOUS ASCITES

Neonatal chylous ascites may be due to congenital infection or developmental abnormality of the lymphatic system (intestinal lymphangiectasia). If the thoracic duct is involved, chylothorax may be present. Later in life, chylous ascites may result from congenital lymphangiectasia, retroperitoneal or lymphatic tumors, peritoneal bands, abdominal trauma, or infection, or it may occur after cardiac or abdominal surgery. It may be associated with intestinal malrotation.

► Clinical Findings

A. Symptoms and Signs

Both congenital and acquired lymphatic obstruction cause chylous ascites, diarrhea, and failure to thrive. The abdomen is distended, with a fluid wave and shifting dullness. Unilateral or generalized peripheral edema may be present.

B. Laboratory Findings

Laboratory findings include hypoalbuminemia, hypogammaglobulinemia, and lymphopenia. Ascitic fluid contains

lymphocytes and has the biochemical composition of chyle if the patient has just been fed; otherwise, it is indistinguishable from ascites secondary to cirrhosis.

► Differential Diagnosis

Chylous ascites must be differentiated from ascites due to liver disease and in the older child, from constrictive pericarditis, chronic elevated right heart pressure, malignancy, infection, or inflammatory diseases causing lymphatic obstruction. In the newborn, urinary ascites from anatomic abnormalities of the kidney or collecting system must be considered. A simple test to diagnose urinary ascites is urea nitrogen or creatinine concentration of abdominal fluid. Neither of these is present in chylous or hepatic ascites

► Complications & Sequelae

Chylous ascites caused by intestinal lymphatic obstruction is associated with fat malabsorption and protein loss. Intestinal loss of albumin and γ -globulin may lead to edema and increase the risk of infection. Rapidly accumulating chylous ascites may cause respiratory complications. The primary infections and malignancies causing chylous ascites may be life-threatening.

► Treatment & Prognosis

Little can be done to correct congenital abnormalities due to hypoplasia, aplasia, or ectasia of the lymphatics unless they are surgically resectable. Treatment is supportive, consisting mainly of a very high-protein diet and careful attention to infections. Shunting of peritoneal fluid into the venous system is sometimes effective. A fat-free diet supplemented with medium-chain triglycerides decreases the formation of chylous ascites. Total parenteral nutrition may rarely be necessary. Infusions of albumin generally provide only temporary relief and are rarely used for chronic management. In the neonate, congenital chylous ascites may spontaneously disappear following one or more paracenteses and a medium-chain triglyceride diet.

Chye JK et al: Neonatal chylous ascites: Report of 3 cases and review of the literature. *Pediatr Surg Int* 1997;12:296 [PMID: 9099650].

GASTROINTESTINAL TUMORS & MALIGNANCIES

JUVENILE POLYPS

Juvenile polyps are usually pedunculated and solitary. The head of the polyp is composed of hyperplastic glandular and vascular elements, often with cystic transformation. Juvenile polyps are benign, and 80% occur in the rectosigmoid. Their incidence is highest between ages 3 and 5 years, and they are

rare before age 1 year and usually autoamputate by age 15 years. They are more frequent in boys. The painless passage of small amounts of bright red blood on a normal or constipated stool is the most frequent manifestation. Abdominal pain is rare, but a juvenile polyp can be the lead point for an intussusception. Low-lying polyps may prolapse during defecation.

Rarely, many juvenile polyps may be present in the colon, causing anemia, diarrhea, and protein loss. A few cases of generalized juvenile polyposis involving the stomach, small bowel, and colon have been reported. These cases are associated with a slightly increased risk of cancer.

Colonoscopy is diagnostic and therapeutic when polyps are suspected. After removal of the polyp by electrocautery, nothing further should be done if histologic findings confirm the diagnosis. There is a slight risk of developing further juvenile polyps. Other polyposis syndromes are summarized in Table 20-4.

CANCERS OF THE ESOPHAGUS, SMALL BOWEL, & COLON

Esophageal cancer is rare in childhood. Cysts, leiomyomas, and hamartomas predominate. Caustic injury of the esophagus increases the very long-term risk of squamous cell carcinoma. Chronic peptic esophagitis is associated with Barrett esophagus, a precancerous lesion. Simple GE reflux in infancy without esophagitis is not a risk for cancer of the esophagus.

The most common **gastric or small bowel cancer** in children is lymphoma or lymphosarcoma. Intermittent abdominal pain, abdominal mass, intussusception, or a celiac-like picture may be present. Carcinoid tumors are usually benign and most often an incidental finding in the appendix. Metastasis is rare. The carcinoid syndrome (flushing, sweating, hypertension, diarrhea, and vomiting), associated with serotonin secretion, only occurs with metastatic carcinoid tumors.

Adenocarcinoma of the colon is rare in childhood. The transverse colon and rectosigmoid are the two most commonly affected sites. The low 5-year survival rate relates to the nonspecificity of presenting complaints and the large percentage of undifferentiated types. Children with a family history of colon cancer, chronic ulcerative colitis, or familial polyposis syndromes are at greater risk.

MESENTERIC CYSTS

These rare tumors may be small or large, single or multiloculated. They are thin-walled and contain serous, chylous, or hemorrhagic fluid. They are commonly located in the small bowel mesentery but are also found in the mesocolon. Most mesenteric cysts cause no symptoms. Traction on the mesentery may lead to colicky abdominal pain, which can be mild and recurrent but may appear acutely with vomiting. Volvu-

Table 20-4. Gastrointestinal polyposis syndromes.

	Location	Number	Histology	Extraintestinal Findings	Malignant Potential	Recommended Therapy
Juvenile polyps	Colon	Single (70%) Several (30%)	Hyperplastic, hamartomatous	None	None	Remove polyp for continuous bleeding or prolapse.
Familial juvenile polyposis coli ^a	Colon	> 10	Hyperplastic with focal adenomatous change	None	10-25%; higher if familial	Remove all polyps. Consider colectomy if very numerous or adenomatous.
Generalized juvenile polyposis ^a	Stomach, small bowel, colon	Multiple	Hyperplastic with focal adenomatous change	Hydrocephaly, cardiac lesions, mesenteric lymphangioma, malrotation	10-25%	Colectomy and close surveillance.
Familial adenomatous polyposis ^a	Colon; less commonly, stomach and small bowel	Multiple	Adenomatous	None	95-100%	Colectomy by age 18 years.
Peutz-Jeghers syndrome ^a	Small bowel, stomach, colon	Multiple	Hamartomatous	Pigmented cutaneous and oral macules; ovarian cysts and tumors; bony exostoses	2-3%	Remove accessible polyps or those causing obstruction or bleeding.
Gardner syndrome	Colon; less commonly, stomach and small bowel	Multiple	Adenomatous	Cysts, tumors, and desmoids of skin and bone; ampullary tumors; other tumors, retinal pigmentations can be a screening tool in families	95-100%	Colectomy by age 18 y. Upper tract surveillance.
Cronkhite-Canada syndrome	Stomach, colon; less commonly, esophagus and small bowel	Multiple	Hamartomatous	Alopecia; onychodystrophy; hyper-pigmentation	Rare	None.
Turcot syndrome ^b	Colon	Multiple	Adenomatous	Thyroid and brain tumors are the usual presentation	Possible	Central nervous system screening most important.

^aAutosomal dominant.^bAutosomal recessive.

lus may occur around a cyst, and hemorrhage into a cyst may be mild or hemodynamically significant. A rounded mass can occasionally be palpated or seen on radiograph displacing adjacent intestine. Abdominal ultrasonography is usually diagnostic. Surgical removal is indicated.

INTESTINAL HEMANGIOMA

Hemangiomas of the bowel may cause acute or chronic blood loss. They may also cause intussusception, local stricture, or intramural hematoma. Thrombocytopenia and consumptive coagulopathy are occasional complications. Some lesions are telangiectasias (Rendu-Osler-Weber syndrome), and others are capillary hemangiomas. The largest group is cavernous hemangiomas, which are composed of large, thin-walled vessels arising from the submucosal vascular plexus.

They may protrude into the lumen as polypoid lesions or may invade the intestine from mucosa to serosa.

MAJOR GASTROINTESTINAL SYMPTOMS & SIGNS

ACUTE DIARRHEA

Viruses are the most common cause of acute gastroenteritis in developing and developed countries. Bacterial and parasitic enteric infections are discussed in Chapters 40 and 41. Of the viral agents causing enteric infection, rotavirus, a 67-nm double-stranded RNA virus with at least eight serotypes, is the most common. As with most viral pathogens, rotavirus affects the small intestine, caus-

ing voluminous watery diarrhea without leukocytes or blood. In the United States, rotavirus mainly affects infants between 3 and 15 months. Peak incidence in the United States is in the winter with sporadic cases occurring at other times. The virus is transmitted via the fecal-oral route and survives for hours on hands and for days on environmental surfaces.

1. Rotavirus Infection

The incubation period for rotavirus is 24–48 hours. Vomiting is the first symptom in 80–90% of patients, followed within 24 hours by low-grade fever and watery diarrhea. Diarrhea usually lasts 4–8 days but may last longer in young infants or immunocompromised patients. The white blood cell count is rarely elevated. The stool sodium level is usually less than 40 mEq/L. As patients become dehydrated from unreplaced fecal water loss, they may become hypernatremic. The stool does not contain blood or white cells. Metabolic acidosis results from bicarbonate loss in the stool, ketosis from poor intake, and lactic acidemia from hypotension and hypoperfusion.

Replacement of fluid and electrolyte deficits and ongoing losses is critical, especially in small infants. (Oral and intravenous therapy are discussed in Chapter 43.) The use of oral rehydration fluid is appropriate in most cases. The use of clear liquids or hypocaloric (dilute formula) diets for more than 48 hours is not advisable in uncomplicated viral gastroenteritis because starvation depresses digestive function and prolongs diarrhea.

Intestinal lactase levels are reduced during rotavirus infection. Brief use of a lactose-free diet is associated with a shorter period of diarrhea but is not critical to successful recovery in healthy infants. Reduced fat intake during recovery may decrease nausea and vomiting.

Antidiarrheal medications are ineffective (kaolin-pectin combinations) or even dangerous (loperamide, tincture of opium, diphenoxylate with atropine). Bismuth subsalicylate preparations may reduce stool volume but are not critical to recovery. Oral immunoglobulin or specific antiviral agents have occasionally been useful in limiting duration of disease in immunocompromised patients.

Specific identification of rotavirus is not required in every case, especially in outbreaks. Rotavirus antigens can be identified in stool or virus can be seen by scanning electron microscopy. False-positive results (which may actually be nonpathogenic rotavirus) are seen in neonates. Most children are infected with rotavirus more than once, with the first infection being the most severe. Some protective immunity is imparted by the first infection. Prevention of infection occurs primarily by good hygiene and prevention of fecal-oral contamination. The American Academy of Pediatrics issued guidelines in January 2007 recommending the routine use of bovine-based pentavalent rotavirus vaccine to be given orally to infants at 2, 4, and 6 months of age.

2. Other Viral Infections Causing Acute Diarrhea

Other viral pathogens causing diarrhea in children can be identified in stool by electron microscopy, viral culture, or enzyme-linked immunoassay. Depending on the geographic location, enteric adenoviruses (serotypes 40 and 41) or caliciviruses are the next most common viral pathogens in infants. The symptoms of enteric adenovirus infection are similar to those of rotavirus, but infection is not seasonal and duration of illness may be longer. The Norwalk agent (now called norovirus) is a calicivirus, a small RNA virus that mainly causes vomiting but can also cause diarrhea in older children and adults, usually in common source outbreaks. The duration of symptoms is short, usually 24–48 hours. Other potentially pathogenic viruses include astroviruses, corona-like viruses, and other small round viruses.

Cytomegalovirus rarely causes diarrhea in immunocompetent children but may cause erosive colitis or enteritis in immunocompromised hosts. Cytomegalovirus enteritis is particularly common after bone marrow transplantation and in late stages of HIV infection.

Cairo JP et al: Etiology of outpatient pediatric nondysenteric diarrhea: A multicenter study in the United States. *Pediatr Infect Dis J* 1999;18:94 [PMID: 10048678].

CHRONIC DIARRHEA

Bowel habits are variable, making specific diagnosis of chronic diarrhea difficult. Some infants normally have 5–8 stools daily. A gradual or sudden increase in the number and volume of stools to more than 15 g/kg/d combined with an increase in fluidity should raise a suspicion that an organic cause of chronic diarrhea is present. Diarrhea may result from (1) interruption of normal cell transport processes for water, electrolytes, or nutrients; (2) decrease in the surface area available for absorption secondary to shortened bowel or mucosal disease; (3) increase in intestinal motility; (4) increase in unabsorbable osmotically active molecules in the intestinal lumen; (5) increase in intestinal permeability, leading to increased loss of water and electrolytes; and (6) stimulation of enterocyte secretion by toxins or cytokines. The most common entities causing chronic diarrhea are listed below. Malabsorption syndromes, which also cause chronic or recurrent diarrhea, are considered separately.

1. Noninfectious Causes of Chronic Diarrhea

A. Antibiotic Therapy

Diarrhea is reported in up to 60% of children receiving antibiotics. Only a tiny fraction of these patients have *C difficile*-related pseudomembranous enterocolitis. Eradication of normal gut flora and overgrowth of other organisms

may cause diarrhea. Most antibiotic-associated diarrhea is watery, is not associated with systemic symptoms, and decreases when antibiotic therapy is stopped.

B. Extraintestinal Infections

Infections of the urinary tract and upper respiratory tract (especially otitis media) are at times associated with diarrhea. The mechanism is obscure. Antibiotic treatment of the primary infection, toxins released by infecting organisms, and local irritation of the rectum (in patients with bladder infection) may play a role.

C. Malnutrition

Malnutrition is associated with an increased frequency of enteral infections. Decreased bile acid synthesis, decreased pancreatic enzyme output, decreased disaccharidase activity, altered motility, and changes in the intestinal flora all may cause diarrhea. Severely malnourished children are at higher risk of enteric infections because of depressed immune functions, both cellular and humoral.

D. Diet and Medications

Overfeeding may cause diarrhea, especially in young infants. Relative deficiency of pancreatic amylase in young infants causes osmotic diarrhea after starchy foods. Fruit juices, especially those high in fructose or sorbitol, produce diarrhea because these osmotically active sugars are poorly absorbed. Intestinal irritants (spices and foods high in fiber) and histamine-containing or histamine-releasing foods (eg, citrus fruits, tomatoes, fermented cheeses, red wines, and scombroid fish) also cause diarrhea.

Laxative abuse in association with eating disorders or Münchhausen syndrome by proxy can cause unpredictable diarrhea. A high concentration of magnesium in the stool may indicate overuse of milk of magnesia or other magnesium-containing laxatives. Detection of other laxative preparations in the stool or circulation requires sophisticated analysis not available in most laboratories. A high index of suspicion and careful observation may be required to make this diagnosis.

E. Allergic Diarrhea

Diarrhea resulting from allergy to dietary proteins is a frequently entertained but rarely proven diagnosis. Gastrointestinal symptoms from protein allergy are more common in infants younger than age 12 months, who may experience mild to severe colitis with diarrhea and rectal bleeding in response to cow's milk protein—either ingested directly or in minute quantities in maternal breast milk. A personal or family history of atopy is common in these infants. Skin testing is not reliable. Double-blind oral challenge with the suspected food under careful observation is necessary to confirm intestinal protein allergy. In the breast-fed infant, maternal avoidance of milk protein may be

effective in reducing the signs of colitis. Substituting a protein hydrolysate formula for cow's milk-based formula may reduce symptoms. Allergic colitis in young infants is self-limited, usually disappearing by 8–12 months of age. The condition does not require treatment if the infant is thriving and the colitic symptoms are mild. Colonoscopy is not required for diagnosis, but rectal biopsies, if performed, show mild lymphonodular hyperplasia, mucosal edema, and slight eosinophilia. Allergies to fish, peanuts, and eggs are more likely to be lifelong and more likely to be IgE mediated. Multiple food allergy (more than three) is rare.

Older children may develop a celiac-like syndrome secondary to milk protein with flattening of small bowel villi, steatorrhea, hypoproteinemia, occult blood loss, and chronic diarrhea. Skin testing is not reliable since it detects circulating antibodies, not the T-cell-mediated responses that are probably responsible for food sensitivity reactions. Double-blind oral challenge with the suspected food under careful observation is necessary to confirm intestinal protein allergy. Small bowel biopsy findings are obvious but nonspecific. The diagnosis is often confirmed by dietary trial followed by disappearance of occult blood in the stool and improvement in other symptoms.

Anaphylactic, IgE-mediated reactions to foods can occur. After ingestion, the patient quickly develops vomiting, then diarrhea, pallor, and hypotension. In these cases, skin testing is positive. Food challenges should be undertaken in a setting in which resuscitation can be performed as there is often a progressively more severe reaction with subsequent ingestions. The close association between ingestion and symptoms usually leaves little doubt about the diagnosis.

F. Chronic Nonspecific Diarrhea

Chronic nonspecific diarrhea is the most common cause of loose stools in thriving children. The typical patient is a healthy child aged 6–20 months who has three to six loose mucoid stools per day during the waking hours. The diarrhea worsens with a low-residue, low-fat, or high-carbohydrate diet and during periods of stress and infection. It clears spontaneously at about age 3½ years (usually coincident with toilet training). No organic disease is discoverable. Possible causes include abnormalities of bile acid absorption in the terminal ileum, incomplete carbohydrate absorption (excessive fruit juice ingestion seems to worsen the condition or in some cases is the primary cause), and abnormal motor function. Family history of functional bowel disease is common. Stool tests for blood, white cells, fat, parasites, and bacterial pathogens are negative.

The following measures are helpful: use of a slightly high-fat (about 40% of total calories), low-carbohydrate, high-fiber diet; avoidance of between-meal snacks; avoidance of chilled fluids, especially fruit juices. Loperamide (0.1–0.2 mg/kg/d in two or three divided doses) is often helpful. Cholestyramine (2–4 g in divided doses) or psyllium agents (1–2 tsp twice daily) are sometimes used.

G. Secretory Diarrhea

Certain malignancies of childhood (neuroblastoma, ganglioglioma, metastatic carcinoid, pancreatic VIPoma, or gastrinoma) may secrete substances such as gastrin and vasoactive intestinal polypeptide (VIP) that promote small intestinal secretion of water and electrolytes. Children may present with large-volume, chronic and intermittent watery diarrhea that does not cease when they discontinue oral feedings. Fat malabsorption is not characteristic. The serum potassium level is often low because of stool losses. The hallmark of the diarrhea is that, unlike osmotic and infectious viral diarrheas, the sodium content of stool water is high, usually between 90 and 140 mEq/L of stool. Other signs and symptoms are associated with specific tumors. Neuroblastoma and ganglioglioma produce elevations in urinary homovanillic acid and vanillylmandelic acid. Metastatic carcinoid produces characteristic flushing and sweating. Gastrinoma may produce multiple duodenal ulcers (Zollinger-Ellison syndrome).

In all secretory diarrheas, a careful radiologic search for a tumor is indicated. Intraendoscopic ultrasound examination may reveal small tumors in the bowel wall or pancreatic head. Bacterial overgrowth of the small bowel in patients with short bowel, cancer chemotherapy, or anatomic abnormalities may be associated with enterotoxins that promote secretory diarrhea. Cholera is the best known bacterial secretory diarrhea. Its enterotoxin stimulates cyclic adenosine monophosphate in the enterocyte, which promotes salt and water secretion.

2. Infectious Causes of Chronic Diarrhea

Most infections of the GI tract are acute and resolve spontaneously or with specific antibiotic therapy. Organisms most prone to cause chronic or recurrent diarrhea in immunocompetent children are *Giardia lamblia*, *Entamoeba histolytica*, *Salmonella* spp, and *Yersinia*.

Chronic diarrhea is common in immune deficiency states, especially IgA deficiency and T-cell abnormalities. The cause of is often common bacterial, viral, fungal, or parasitic organisms usually considered nonpathogenic (rotavirus, *Blastocystis hominis*, *Candida*), or unusual organisms (cytomegalovirus, *Cryptosporidium*, *Isospora belli*, *Mycobacterium* spp, microsporidia, and algal organisms such as cyanobacteria).

Between 50% and 60% of patients with idiopathic acquired hypogammaglobulinemia have steatorrhea and intestinal villous atrophy. Lymphonodular hyperplasia of the small intestine is prominent. Patients with congenital or Bruton-type agammaglobulinemia usually have diarrhea and abnormal intestinal morphology. Patients with isolated IgA deficiency have chronic diarrhea, a celiac-like picture, lymphoid nodular hyperplasia, and are prone to giardiasis. Patients with isolated cellular immunity defects, combined cellular and humoral immune incompetence, and HIV infec-

tion may have severe chronic diarrhea leading to malnutrition. Often the cause is not found. The incidence of disaccharidase deficiency is high. Chronic granulomatous disease may be associated with intestinal symptoms suggestive of chronic inflammatory bowel disease. A rectal biopsy may reveal the presence of typical macrophages.

Treatment must be directed toward correcting the immunologic defect. Specific treatments are available or are being developed for many of the unusual pathogens causing diarrhea in the immunocompromised host. Thus, a vigorous diagnostic search for specific pathogens is warranted in these individuals.

GASTROINTESTINAL BLEEDING

Vomiting blood and passing blood per rectum are alarming symptoms. The history is the key to identifying the bleeding source. The following questions should be answered:

1. Is it really blood, and is it coming from the GI tract? A number of substances simulate hematochezia or melena (Table 20-5). The presence of blood should be confirmed chemically. Coughing, tonsillitis, lost teeth, or epistaxis may cause what appears to be occult or overt GI bleeding. An adolescent female may be experiencing menarche.

Modified and reproduced, with permission, from Treem WR: Gastrointestinal bleeding in children. *Gastrointest Endosc Clin North Am* 1994;4:75.

- How much blood is there and what is its color and character? Table 20–6 lists the sites of GI bleeding predicted by the appearance of the blood in the stools. Table 20–7 lists causes of rectal bleeding.
- Is the child acutely or chronically ill? The physical examination should be thorough. Physical signs of portal hypertension, intestinal obstruction, or coagulopathy are particularly important. The nasal passages should be inspected for signs of recent epistaxis, the vagina for menstrual blood, and the anus for fissures and hemorrhoids. A systolic blood pressure below 100 mm Hg and a pulse rate above 100 beats/min in an older child suggest at least a 20% reduction of blood volume. A pulse rate increase of 20 beats/min or a drop in systolic blood pressure greater than 10 mm Hg when the patient sits up is also a sensitive index of volume depletion.
- Is the child still bleeding? Serial determination of vital signs and hematocrit are essential to assess ongoing bleeding. Detection of blood in the gastric aspirate confirms a bleeding site proximal to the ligament of Treitz. However, its absence does not rule out the duodenum as the source. Testing the stool for occult blood will help in monitoring ongoing loss of blood.

► Treatment

If a hemorrhagic diathesis is detected, vitamin K should be given intravenously. In severe bleeding, the need for volume replacement is monitored by measurement of central venous pressure. In less severe cases, vital signs, serial hematocrits, and gastric aspirates are sufficient.

Table 20–6. Identification of sites of gastrointestinal bleeding.

Symptom or Sign	Location of Bleeding Lesion
Effortless bright red blood from the mouth	Nasopharyngeal or oral lesions; tonsillitis; esophageal varices; lacerations of esophageal or gastric mucosa (Mallory-Weiss syndrome)
Vomiting of bright red blood or of “coffee grounds”	Lesion proximal to ligament of Treitz
Melanotic stool	Lesion proximal to ligament of Treitz, upper small bowel. Blood loss in excess of 50–100 mL/24 h
Bright red or dark red blood in stools	Lesion in the ileum or colon. (Massive upper gastrointestinal bleeding may also be associated with bright red blood in stool.)
Streak of blood on outside of a stool	Lesion in the rectal ampulla or anal canal

If blood is recovered from the gastric aspirate, gastric lavage with saline should be performed until only a blood-tinged return is obtained. Upper intestinal endoscopy is then done to identify the bleeding site. Endoscopy is superior to barium contrast study for lesions such as esophageal varices, stress ulcers, and gastritis. Colonoscopy may identify the source of bright red rectal bleeding but should be performed as an emergency procedure only if the extent of bleeding warrants immediate investigation and if plain abdominal radiographs show no signs of intestinal obstruction. Colonoscopy on an unprepped colon is often inadequate for making a diagnosis. Capsule endoscopy may help identify the site of bleeding if colonoscopy and upper endoscopy findings are negative. Small or large bowel lesions that bleed briskly (> 0.5 mL/min) may be localized by angiography or radionuclide scanning following injection of labeled red cells.

Persistent vascular bleeding (varices, vascular anomalies) may be relieved temporarily using intravenous octreotide, 25–30 µg/m²/h. Sustained infusion of octreotide may be used for up to 48 hours if needed. Bleeding from esophageal varices may be stopped by compression with a Sengstaken-Blakemore tube. Endoscopic sclerosis or banding of bleeding varices is effective treatment.

If gastric decompression, acid suppressive therapy, and transfusion are ineffective in stopping ulcer bleeding, laser therapy, local injection of epinephrine, electrocautery, or emergency surgery may be necessary.

Fox VL: Gastrointestinal bleeding in infancy and childhood. *Gastroenterol Clin North Am* 2000;29:37 [PMID: 10752017].

VOMITING

Vomiting is an extremely complex, poorly understood activity. The centers controlling and coordinating vomiting are in the paraventricular nuclei of the brain. These nuclei receive afferent input from many sources: drugs and neurotransmitters in cerebrospinal fluid, the chemoreceptor trigger zone (CTZ) near the distal fourth ventricle, the vestibular apparatus of the ear, the GI tract and other abdominal organs, and even from higher cortical areas. Vagal afferents from gut to brain are stimulated by ingested drugs and toxins, mechanical stretch, inflammation, and local neurotransmitters. Additionally, local feedback loops in the gut also appear capable of initiating vomiting.

Vomiting is the presenting symptom of many pediatric conditions. It is the pediatrician’s difficult job to find the underlying cause. The most common cause of vomiting in childhood is probably acute viral gastroenteritis. However, obstruction and acute or chronic inflammation of the GI tract and associated structures are also major causes. Central nervous system inflammation, pressure, or tumor may cause vomiting. Metabolic derangements associated with inborn errors of metabolism, sepsis, and drug intoxication can stimulate either the CTZ or the brain directly to promote vomiting.

Table 20-7. Differential diagnosis of gastrointestinal bleeding in children by symptoms and age at presentation.

	Infant	Child (2–12 y)	Adolescent (> 12 y)

Reproduced, with permission, from Treem WR: Gastrointestinal bleeding in children. *Gastrointest Endosc Clin North Am* 1994;4:75.

Regurgitation associated with GE reflux of infants should be distinguished from vomiting. In this instance, spontaneous relaxation of the lower esophageal sphincter creates a common cavity between the stomach and esophagus. Because the resting pressure of the thorax is negative, the mildly positive pressure of the abdominal cavity (~ 6 mm Hg) pushes gastric contents into the esophagus, causing an effortless flow into the mouth. Occasionally, regurgitated fluid stimulates the pharyngeal afferents and provokes gagging or even a complete vomiting complex.

Control of vomiting with medication is rarely needed in acute gastroenteritis and should not be attempted in other patients until the source is clear. Antihistamines and anticholinergics are appropriate for motion sickness because of their labyrinthine effects. 5-HT₃ receptor antagonists (ondansetron, granisetron) are useful for vomiting associated with surgery and chemotherapy. Benzodiazepines, corticosteroids, and substituted benzamides are also used in chemotherapy-induced vomiting. Butyrophenones (droperidol, haloperidone) are powerful drugs that block

the D2 receptor in the CTZ and are used for intractable vomiting in acute gastritis, chemotherapy, and after surgery. Phenothiazines are helpful in chemotherapy, cyclic vomiting, and acute GI infection but are not recommended for outpatient use because of extrapyramidal side effects.

1. Cyclic Vomiting Syndrome

► Clinical Findings

Cyclic vomiting syndrome (CVS) is characterized by recurrent episodes of stereotypical vomiting in children usually older than 1 year of age. The emesis is forceful and frequent, occurring up to six times per hour for up to 72 hours or more. Episode frequency ranges from two to three per month to less than one per year. Nausea, retching, and small-volume bilious emesis continue even after the stomach is emptied. Hematemesis secondary to forceful vomiting may occur. Patients experience abdominal pain, anorexia, and rarely, diarrhea. Autonomic symptoms, such as pallor, sweating, temperature instability, and lethargy are common and give the patient a very ill appearance. The episodes end suddenly, often after a period of sleep. In some children, dehydration, electrolyte imbalance, and shock may occur. Between episodes, the child is completely healthy.

The cause of CVS is unknown; however, a similarity to migraine has long been recognized. Family history is positive for migraine in 50–70% of cases and many patients develop migraine headaches as adults. Research suggests that abnormalities of neurotransmitters and hormones provoke CVS. About one quarter of patients have typical migraine symptoms during episodes: premonitory sensation, headache, photophobia, and phonophobia. Identifiable triggers include infection, positive or negative emotional stress, diet (chocolate, cheese, monosodium glutamate), menses, or motion sickness.

► Differential Diagnosis

Conditions that mimic CVS include drug toxicity, increased intracranial pressure, seizures, brain tumor, Chiari malformation, recurrent sinusitis, choledochal cyst, gallstones, recurrent small bowel obstruction, inflammatory bowel disease, familial pancreatitis, obstructive uropathy, recurrent urinary infection, diabetes, mitochondrial diseases, disorders of fatty and organic acid metabolism, adrenal insufficiency, and Münchausen syndrome by proxy. Although tests for GE reflux are often positive in these patients, it is unlikely that GE reflux and CVS are related.

► Treatment

Avoidance of triggers prevents spells in some patients. Sleep can also end a spell although some children awaken and resume vomiting. Diphenhydramine or lorazepam are used at the onset of spells in some children to reduce nausea and induce sleep. Early use of antimigraine medications (sumatriptan), antiemetics (ondansetron), or antihistamines can abort

spells in some patients. Once a spell is well established, intravenous fluids are often required to end it. With careful supervision, some children with predictable spells can receive intravenous fluids at home. Several approaches usually are tried before an effective therapy is found. Preventing spells with prophylactic propranolol, amitriptyline, or antihistamines is effective in some patients with frequent or disabling spells. Some patients have been successfully treated with anticonvulsants.

Sudel B, Li BU: Treatment options for cyclic vomiting syndrome. *Curr Treat Options Gastroenterol* 2005;8:387 [PMID: 16162304].

RECURRENT ABDOMINAL PAIN

About 10% of healthy schoolchildren between 5 and 15 years of age will at some time have recurrent episodes of unexplained abdominal pain severe enough to interfere with normal activities. An organic cause is found in fewer than 10% of patients.

► Clinical Findings

A. Symptoms and Signs

Attacks of pain are characteristically of variable duration and intensity. It is not rare for the parent or patient to report that the pain is constant, all day, every day. Although the pain is usually located in the periumbilical area, a location far from the umbilicus does not rule out recurrent abdominal pain. Pain occurs both day and night. Weight loss is rare. Pain may be associated with dramatic reactions—frantic crying, clutching the abdomen, doubling over. Parents may be alarmed, and children are often taken to emergency departments, where the evaluation is negative for an abdominal crisis. School attendance may suffer, and enjoyable family events may be disrupted. The pain may be associated with pallor, nausea, vomiting, and slight temperature elevation.

The pain usually bears little relationship to bowel habits and physical activity. However, some patients have a symptom constellation suggestive of irritable bowel syndrome—bloating, postprandial pain, lower abdominal discomfort, and erratic stool habits with a sensation of obstipation or incomplete evacuation of stool. A precipitating or stressful situation in the child's life at the time the pains began can sometimes be elicited. School phobia may be a precipitant. A history of functional GI complaints is often found in family members.

A thorough physical examination is essential and usually normal. Complaints of abdominal tenderness elicited during palpation sometimes seem out of proportion to visible signs of distress.

B. Laboratory Findings

Complete blood count, sedimentation rate, urinalysis, and stool test for occult blood usually suffice. In the adolescent female patient, ultrasound of the abdomen may be helpful to detect gallbladder or ovarian pathology. If the pain is atypi-

Table 20–8. Causes of acute abdomen.

Infection and Inflammation	Other Causes
Appendicitis	Midgut volvulus
Severe infectious enteritis and colitis	Intussusception
Pseudomembranous enterocolitis	Ovarian torsion
Toxic megacolon associated with Hirschsprung disease or ulcerative colitis	Incarcerated hernia
Mesenteric adenitis	Abdominal trauma
Pelvic inflammatory disease	Diabetic ketoacidosis
Pancreatitis	Peritonitis
Cholecystitis	Intussusception with obstruction
Abdominal vasculitis (Henoch-Schönlein purpura, polyarteritis nodosa)	Distal intestinal obstruction syndrome
Peritonitis	Testicular torsion
	Intestinal pseudo-obstruction
	Sickle cell abdominal crisis
	Metabolic conditions (eg, porphyria, lead poisoning)

cal, further testing suggested by symptoms and family history should be done.

► Differential Diagnosis

Abdominal pain secondary to disorders causing acute abdomen are listed in Table 20–8. Pinworms, mesenteric lymphadenitis, and chronic appendicitis are improbable causes of recurrent abdominal pain. *H pylori* infection is rarely the cause of recurrent abdominal pain. Lactose intolerance usually causes abdominal distention, gas, and diarrhea with milk ingestion. At times, however, abdominal discomfort may be the only symptom. Abdominal migraine and abdominal epilepsy are rare conditions with an episodic character often associated with vomiting. The incidence of peptic gastritis, esophagitis, duodenitis, and ulcer disease is probably underappreciated. Upper intestinal endoscopy may be useful.

► Treatment & Prognosis

Treatment consists of reassurance based on a thorough physical appraisal and a sympathetic, age-appropriate explanation of the nature of functional pain. The concept of “visceral hyperalgesia” or increased pain signaling from physiologic stimuli such as gas, acid secretion, or stool is one that parents can understand and helps them to respond appropriately to the child’s complaints. Reassurance without education is rarely helpful. Regular activity should be resumed, especially school attendance. Therapy for emotional problems is sometimes required, but drugs should be avoided. In older patients, and in those with what appears to be visceral hyperalgesia, amitriptyline in low doses may occasionally be helpful. Antispasmodic medications are rarely helpful and should be reserved for patients with more typical irritable bowel complaints.

Rasquin A et al: Childhood functional gastrointestinal disorders: Child/adolescent. *Gastroenterology* 2006;130:1527 [PMID: 16678566].

ACUTE ABDOMEN

An acute abdomen is a constellation of findings indicating an intra-abdominal process that may require surgery. A degree of urgency is implied when this diagnosis is suspected. The pain of an acute abdomen intensifies over time and is rarely relieved without definitive treatment. Pain is often accompanied by nausea, vomiting, diarrhea, fever, and anorexia. Pain may be localized or generalized. The abdomen may be distended and tense and bowel sounds reduced or obstructive. Patients appear ill and are reluctant to be examined or moved. The acute abdomen is usually a result of infection of the intra-abdominal or pelvic organs but also occurs with intestinal obstruction, intestinal perforation, inflammatory conditions, trauma, and some metabolic disorders. Some conditions causing acute abdomen are listed in Table 20–8. Reaching a speedy and accurate diagnosis is critical and requires skill in physical diagnosis, recognition of the symptoms of a large number of conditions, and a judicious selection of laboratory and radiologic tests. (Acute appendicitis is discussed earlier in the section on Disorders of the Small Intestine.)

MALABSORPTION SYNDROMES

Malabsorption of ingested food has many causes (Table 20–9). Shortening of the small bowel (usually via surgical resection) and mucosal damage (celiac disease) both reduce surface area. Impaired motility of the small intestine may interfere with normal propulsive movements and mixing of food with pancreatic and biliary secretions. Anaerobic bacteria proliferate under these conditions and impair fat absorption by deconjugation of bile acids (intestinal pseudo-obstruction, postoperative blind loop syndrome). Impaired intestinal lymphatic (congenital lymphangiectasia) or venous drainage also causes malabsorption. Diseases reducing pancreatic exocrine function (cystic fibrosis, Shwachman syndrome) or the production and flow of biliary secretions cause nutrient malabsorption. Malabsorption of specific nutrients may be genetically determined (disaccharidase deficiency, glucose-galactose malabsorption, and abetalipoproteinemia).

► Clinical Findings

Diarrhea, vomiting, anorexia, abdominal pain, failure to thrive, and abdominal distention are common. Stool may be bulky, foul, and pale with fat malabsorption or loose when diarrhea is osmotically induced. Microscopic examination of stools for neutral fat and fatty acids is a useful screen because most malabsorption syndromes involve some fat malabsorption. Pancreatic insufficiency is associated with neutral fat (triglycerides) in the stool. Fatty acids are the major fatty material found in the stool of patients with mucosal and liver disease.

Quantitation of fat malabsorption requires measuring fat excreted in the feces as a proportion of fat intake for a defined

Table 20-9. Malabsorption syndromes.**Intraluminal phase abnormalities**

- Acid hypersecretion (eg, Zollinger-Ellison syndrome)
- Exocrine pancreatic insufficiency
 - Cystic fibrosis
 - Shwachman syndrome
 - Malnutrition
 - Specific enzyme defects
- Decreased intraluminal bile acids
 - Chronic parenchymal liver disease
 - Biliary obstruction
 - Bile acid loss (short gut, ileal disease)
 - Bile acid deconjugation by bacterial overgrowth

Intestinal phase abnormalities

- Mucosal infection (*Giardia*, *Cryptosporidium*)
- Celiac disease
- Mucosal enzyme deficiency (primary or secondary)
- Allergic enteropathy
- Radiation enteritis
- Dumping syndrome
- Short bowel syndrome

Vascular phase abnormalities

- Whipple disease
- Intestinal lymphangiectasia
- Congestive heart failure

Metabolic genetic disease

- Abetalipoproteinemia
- Glucose-galactose malabsorption
- Acrodermatitis enteropathica
- Congenital chloride diarrhea

period. Excretion of 5% of ingested fat is normal for a child older than age 1 year; 10–15% is normal in a younger infant. Prothrombin time and serum carotene, vitamin E, and vitamin D levels may be depressed by long-standing fat malabsorption. Accurate assessment of protein absorption is difficult and requires isotopic labeling of amino acids. Loss of serum proteins across the intestinal mucosa can be estimated by measurement of fecal α_1 -antitrypsin. Malabsorption of complex carbohydrate is rarely measured. Disaccharide or monosaccharide malabsorption is estimated by reduction in stool pH, increased breath hydrogen after ingestion of carbohydrate, or decreased intestinal mucosal disaccharidase activity.

Other screening tests suggesting a specific diagnosis include sweat chloride concentration (cystic fibrosis), intestinal mucosal biopsy (celiac disease, intestinal lymphangiectasia, giardiasis, inflammatory bowel disease), liver and gallbladder function tests, and pancreatic secretion after stimulation with secretin and cholecystokinin. Some of the most common disorders associated with malabsorption in pediatric patients are detailed below.

1. Protein-Losing Enteropathy

Loss of plasma proteins into the GI tract occurs in association with intestinal inflammation, intestinal graft-versus-host disease, acute and chronic intestinal infections, venous and lym-

phatic obstruction or malformations, and infiltration of the intestine or its lymphatics and vasculature by malignant cells. Chronic elevation of venous pressure in children with the Fontan procedure may produce protein-losing enteropathy.

► Clinical Findings

Signs and symptoms are mainly those caused by hypoproteinemia, and in some instances by fat malabsorption: edema, ascites, poor weight gain, and specific vitamin and mineral deficiencies. Serum albumin and globulins may be decreased. Fecal α_1 -antitrypsin is elevated (> 3 mg/g dry weight stool; slightly higher in breast-fed infants). Disorders associated with protein-losing enteropathy are listed in Table 20–10. In the presence of intestinal bleeding, fecal α_1 -antitrypsin measurements are falsely high.

► Differential Diagnosis

Hypoalbuminemia may be due to increased catabolism, poor protein intake, impaired hepatic protein synthesis, or congenital malformations of lymphatics outside the GI tract. Protein losses in the urine from nephritis and nephrotic syndrome may also cause hypoalbuminemia.

Table 20-10. Disorders associated with protein-losing enteropathy.**Vascular obstruction**

- Congestive heart failure
- Constrictive pericarditis
- Atrial septal defect
- Primary myocardial disease
- Increased right atrial pressure^a

Stomach

- Giant hypertrophic gastritis (Ménétrier disease), often secondary to cytomegalovirus infection
- Polyps
- Gastritis secondary to *Helicobacter pylori* infection

Small intestine

- Celiac disease
- Intestinal lymphangiectasia
- Blind loop syndrome
- Abetalipoproteinemia
- Chronic mucosal ischemia (eg, from chronic volvulus or radiation enteritis)
- Allergic enteropathy
- Malrotation
- Inflammatory bowel disease

Colon

- Ulcerative colitis
- Hirschsprung disease
- Pseudomembranous colitis
- Polyposis syndromes
- Villous adenoma
- Solitary rectal ulcer

^aChildren who undergo Fontan procedure for tricuspid atresia are especially prone.

► Treatment

Albumin infusion, diuretics, and a high-protein, low-fat diet may control symptoms. Treatment must be directed toward identifying and treating the underlying cause.

2. Celiac Disease (Gluten Enteropathy)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Diarrhea, fatty stools, failure to thrive, irritability, hypoproteinemia, edema.
- Mean age of onset is 18 months.
- Tissue transglutaminase antibody testing is positive.
- Intestinal biopsy confirms the diagnosis.

Celiac disease results from intestinal sensitivity to the gliadin fraction of gluteins from wheat, rye, barley, and (possibly) oats. Most children present during the second year of life, but the age at onset and the severity are variable. Up-to-date estimates of disease frequency are being revised with the widespread use of sensitive screening tests such as the tissue transglutaminase. Screening with antigliadin antibodies is not recommended because of the high frequency of false-positive tests. The frequency of celiac disease in the United States is around 1:300. It is thought that intestinal damage and villous atrophy result from a cell-mediated immune response initiated by exposure to a polypeptide fragment of gliadin. Ten percent of first-degree relatives may be affected. The inheritance is probably polygenic but may result from a single gene in combination with an environmental precipitant such as intestinal viral infection. The increased incidence of celiac disease in children with type 1 diabetes mellitus, IgA deficiency, and Down syndrome is consistent with possible immunologic factors in the development of celiac disease. Individuals with HLA DR4 and perhaps DR3 tissue types are at higher risk.

► Clinical Findings

A. Symptoms and Signs

1. Diarrhea—Affected children usually have diarrhea starting 6–12 months after the introduction of grains. Initially, the diarrhea may be intermittent; subsequently it is continuous, with bulky, pale, frothy, greasy, foul-smelling stools. During celiac crises, dehydration, shock, and acidosis occur. If anorexia is severe (about 10% of cases), diarrhea may be absent.

2. Constipation, vomiting, and abdominal pain—This triad of symptoms may occasionally dominate the clinical picture and suggest a diagnosis of intestinal obstruction. Constipation generally results from a combination of anorexia, dehydration, muscle weakness, and bulky stools.

3. Failure to thrive—Active celiac disease is often accompanied by loss of appetite, failure to gain weight, and irritability. Weight loss is most marked in the limbs and buttocks. The abdomen becomes distended secondary to intestinal gas and fluid accumulation. Short stature and delayed puberty may be the only sign in some older children.

4. Anemia and vitamin deficiencies—Anemia usually responds to iron supplementation and is rarely megaloblastic. Anemia is a more common presenting problem in adults than in children. Fat-soluble vitamin deficiency is common. Rickets can be seen in growing children but osteomalacia even with pathologic fractures is more common. Hypoproteinemia secondary to vitamin K malabsorption can cause easy bleeding.

5. Silent celiac disease—Serologic screening in children with nonspecific GI complaints, growth failure, type 1 diabetes, thyroid disease, vitiligo, IgA deficiency, and Down syndrome, and in family members of celiac patients is widespread. The therapy for a symptom-free child with positive serology is unclear. Intestinal biopsy specimens from children with positive serology are usually abnormal and the prudent response is to recommend a gluten-free diet. In patients with positive serology but normal intestinal biopsies, careful follow-up without diet therapy is the most appropriate current recommendation.

B. Laboratory Findings

1. Fat content of stools—A 3-day collection of stools usually reveals excessive fecal fat excretion. A normal child excretes 5–10% of ingested fat. In untreated celiac disease fat excretion is more than 15% of daily fat intake. Anorexia may be so severe that steatorrhea may not be present in 10–25% of patients until normal intake is established.

2. Carbohydrate absorption—A low oral glucose tolerance curve is seen. Absorption of D-xylose is impaired, with blood levels lower than 20 mg/dL 60 minutes after ingestion.

3. Hypoproteinemia—Hypoalbuminemia can be severe enough to lead to edema. There is evidence of increased protein loss in the gut lumen and poor hepatic synthesis secondary to malnutrition.

4. Serologic and genetic testing—The most sensitive and specific screening test for celiac disease in IgA-sufficient patients is a tissue transglutaminase antibody test. In the presence of IgA deficiency, this test may be falsely negative. IgG tissue transglutaminase antibody testing is available. The tissue transglutaminase antibody results can be used to roughly gauge dietary compliance. Antigliadin antibodies are not reliable for screening. Genetic screening for typical tissue type may be an indication of risk but it is not diagnostic.

C. Imaging

A small bowel series shows a malabsorptive pattern characterized by segmentation, clumping of the barium column,

and hypersecretion. These changes are nonspecific and can be found in patients with other malabsorption states.

D. Biopsy Findings

Intestinal biopsy is the most reliable test for celiac disease. By light microscopy, the celiac mucosa has shortened or absent villi, lengthened crypts of Lieberkühn, intense plasma cell infiltration of the lamina propria, and numerous intraepithelial lymphocytes. Extent of change is quantitated from 0 (normal) to 4 (complete villous atrophy) using the Marsh scoring system.

► Differential Diagnosis

The differential diagnosis includes disorders causing malabsorption. Strict adherence to two diagnostic criteria is essential—the characteristic small bowel microscopic changes and clinical improvement on a gluten-free diet. Repeat mucosal biopsies to prove histologic recovery on gluten-free diet and relapse on gluten challenge are not indicated in typical patients.

► Treatment

A. Diet

Treatment is dietary gluten restriction for life. All sources of wheat, rye, and barley are eliminated. Some patients can tolerate oats, but this should be tested only after recovery has occurred. Lactose is poorly tolerated in the acute stage because mucosal atrophy causes secondary disaccharidase deficiency. Normal amounts of fat are advisable. Supplemental calories, vitamins, and minerals are indicated only in the acute phase. Clinical improvement usually starts within a week, but complete clinical recovery and histologic normality may require 3–12 months. Tissue transglutaminase titers may decrease on a gluten-free diet, but usually do not disappear.

B. Corticosteroids

Corticosteroids can hasten clinical improvement but are indicated only in very ill patients with profound anorexia, malnutrition, diarrhea, edema, abdominal distention, and hypokalemia.

► Prognosis

Clinical and histologic recovery is the rule but may be slow. Malignant lymphoma of the small bowel occurs with increased frequency in adults with long-standing disease. Dietary treatment seems to decrease the risk of this complication.

Fasano A et al: The prevalence of celiac disease in at-risk and not-at-risk groups in the United States: A multicenter study. *Arch Intern Med* 2003;163:286 [PMID: 12578508].

Hill I et al: Guidelines for the diagnosis and treatment of celiac disease in children: Recommendations of the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition. *J Pediatr Gastroenterol Nutr* 2005;40:1 [PMID: 15625418].

3. Disaccharidase Deficiency

Starches and the disaccharides sucrose and lactose are the most important dietary carbohydrates. Dietary disaccharides and oligosaccharide products of pancreatic amylase action on starch require hydrolysis by intestinal brush border disaccharidases before absorption takes place. Disaccharidase levels are higher in the jejunum and proximal ileum than in the distal ileum and duodenum. In primary disaccharidase deficiency, a single enzyme is affected; disaccharide intolerance is permanent; intestinal histologic findings are normal; and a positive family history is common. Because disaccharidases are located on the luminal surface of intestinal enterocytes, they are susceptible to mucosal damage. Many conditions cause secondary disaccharidase deficiency and lactase is usually the most severely depressed.

A. Lactase Deficiency

Congenital lactase deficiency is rare. All human ethnic groups are lactase-sufficient at birth. Genetic or familial lactase deficiency begins to appear in children as young as 3–5 years. In Asians, Alaskan natives, and Native Americans, genetic lactase deficiency develops in virtually 100%. In Africans, the incidence in most tribes is over 80%. In African Americans, the incidence is about 70%, and among Caucasian Americans, the incidence is between 30% and 60%. Acquired or secondary lactase deficiency caused by intestinal injury due to viral infection, inflammatory disease, radiation, and drugs is very common. Lactase deficiency secondary to viral gastroenteritis is usually self-limited, lasting days or, at most, weeks after recovery from infection.

Lactose ingestion in deficient individuals causes variable degrees of diarrhea, gassy distention, and abdominal pain depending on the residual enzyme activity and the dose of lactose. Stools are liquid or frothy, with a pH below 4.5 owing to the presence of organic acids. Vomiting is common. Severe malnutrition may occur in a milk-fed infant with lactase deficiency. Reducing substances are present in fresh stools. The blood glucose fails to rise more than 10 mg/dL after ingestion of 1 g/kg of lactose. A rise in breath hydrogen after oral administration of lactose (from hydrogen produced by normal colon flora during fermentation of unabsorbed carbohydrate) is also diagnostic.

Symptoms disappear when dietary lactose is restricted. Lactase extracted from *Aspergillus* and *Kluyvera* species can be added to milk products or taken with meals to enhance lactose hydrolysis.

B. Sucrase-Isomaltase Deficiency

This is a combined defect inherited as an autosomal recessive trait. Ten percent of Alaskan natives are affected. The condition is rare in other groups. Abdominal distention, failure to thrive, and chronic diarrhea may be the presenting symptoms. Intestinal mucosal damage from viral infection reduces the activity of all disaccharidases including sucrase,

but symptoms of sucrose intolerance are usually masked by the more striking symptoms of lactose intolerance. Distaste for and avoidance of sucrose occurs even in young infants with genetic sucrase-isomaltase deficiency.

Because sucrose is not a reducing sugar, the results of tests for reducing substances in the stool are negative unless the sucrose in the stool is hydrolyzed by colon bacteria. Oral sucrose tolerance testing (1 g/kg) is abnormal. Breath hydrogen will be elevated after ingestion of sucrose. Treatment of primary sucrase-isomaltase deficiency requires elimination of most sucrose. A preparation of yeast sucrase taken with meals is also effective.

Treem WR et al: Saccharosidase therapy for congenital sucrase-isomaltase deficiency. *J Pediatr Gastroenterol Nutr* 1999;28:137 [PMID: 9932843].

4. Glucose-Galactose Malabsorption

Glucose-galactose malabsorption is a rare disorder in which the sodium-glucose transport protein is defective. The gene has been localized to the long arm of chromosome 22. Transport of glucose in the intestinal epithelium and renal tubule is impaired. Diarrhea begins with the first feedings, accompanied by reducing sugar in the stool and acidosis. Small bowel histologic findings are normal. Glycosuria and aminoaciduria may occur. The glucose tolerance test is flat. Fructose is well tolerated. Diarrhea subsides promptly on withdrawal of glucose and galactose from the diet. The acquired form of glucose-galactose malabsorption occurs mainly in infants younger than age 6 months, usually following acute viral or bacterial enteritis.

In the congenital disease, exclusion of glucose and galactose from the diet is mandatory. A satisfactory formula is one with a carbohydrate-free base plus added fructose. The prognosis is good if the disease is diagnosed early, because tolerance for glucose and galactose improves with age. In secondary monosaccharide intolerance, prolonged parenteral nutrition may be required until intestinal transport mechanisms for monosaccharides return.

El-Naggar W et al: Nephrocalcinosis in glucose-galactose malabsorption: Association with renal tubular acidosis. *Pediatr Nephrol* 2005;20:1336 [PMID: 16010597].

Wright EM et al: Molecular basis for glucose-galactose malabsorption. *Cell Biochem Biophys* 2002;36:115 [PMID: 12139397].

5. Intestinal Lymphangiectasia

This form of protein-losing enteropathy results from a congenital ectasia of the bowel lymphatic system, often associated with abnormalities of the lymphatics in the extremities. Obstruction of lymphatic drainage of the intestine leads to rupture of the intestinal lacteals with leakage of lymph into the lumen of the bowel. Fat loss in the stool may be significant. Chronic loss of lymphocytes and immunoglobulins increases the susceptibility to infections.

► Clinical Findings

Peripheral edema, diarrhea, abdominal distention, chylous effusions, and repeated infections are common. Laboratory findings are reduced serum albumin, decreased immunoglobulin levels, lymphocytopenia, and anemia. Serum calcium and magnesium are frequently depressed as these cations are lost in complex with unabsorbed fatty acids. Lymphocytes may be seen on a stool smear. Fecal α_1 -antitrypsin is elevated. Radiographic studies reveal an edematous small bowel mucosal pattern, and biopsy findings reveal dilated lacteals in the villi and lamina propria. If only the lymphatics of the deeper layers of bowel or intestinal mesenteries are involved, laparotomy may be necessary to establish the diagnosis. Capsule (camera) endoscopy shows diagnostic brightness secondary to the fat-filled lacteals.

► Differential Diagnosis

Other causes of protein-losing enteropathy must be considered, although an associated lymphedematous extremity strongly favors this diagnosis.

► Treatment & Prognosis

A high-protein diet (6–7 g/kg/d may be needed) enriched with medium-chain triglycerides as a fat source usually allows for adequate nutrition and growth in patients with intestinal mucosal lymphangiectasia. The serum albumin may not normalize. Vitamin and calcium supplements should be given. Parenteral nutritional supplementation may be needed temporarily. Surgery may be curative if the lesion is localized to a small area of the bowel or in cases of constrictive pericarditis or obstructing tumors. Intravenous albumin and immune globulin may also be used to control symptoms but are usually not needed chronically. The prognosis is not favorable, although remission may occur with age. Malignant degeneration of the abnormal lymphatics may occur, and intestinal lymphoma of the B-cell type may be a long-term complication.

6. Cow's Milk Protein Intolerance

Milk protein intolerance is more common in males than females and in young infants with a family history of atopy. The estimated prevalence is 0.5–1.0%. Colic, vomiting, and diarrhea are the major symptoms in young infants whose stools often contain small flecks of blood and mucus. Children with these symptoms are generally healthy and gain weight normally. The diagnosis is usually made clinically. Elimination of whole milk from the maternal diet sometimes relieves symptoms. A switch to a protein hydrolysate formula almost always results in improvement. Because the blood loss and diarrhea are rarely severe, it is not essential that breast feeding be stopped. If symptoms are severe or prolonged, a trial of semielemental formula is recommended. Allergic colitis in infants usually clears spontane-

ously by age 6–12 months. When there is uncertainty or when symptoms are severe, sigmoidoscopic examination reveals a superficial colitis, often with edema, a mild eosinophilic infiltrate, and lymphonodular hyperplasia. Pneumatosis intestinalis rarely is found on radiographs. Viral gastroenteritis sometimes precedes the onset of symptoms. Early reports that patients with milk protein allergy have a 30% incidence of sensitivity to soy protein, with similar symptoms, have not been uniformly confirmed.

In older children, milk protein sensitivity may induce eosinophilic gastroenteritis with protein-losing enteropathy, iron deficiency, hypoalbuminemia, and hypogammaglobulinemia. A celiac-like syndrome with villous atrophy, malabsorption, hypoalbuminemia, occult blood in the stool, and anemia can occur.

IgE-mediated anaphylactic shock is a rare but potentially life-threatening manifestation of milk protein sensitivity in infancy. If the symptoms suggest an anaphylactic response to milk or other protein, food challenge should be performed only in a setting in which resuscitation can be carried out.

7. Pancreatic Insufficiency

The most common cause of pancreatic exocrine insufficiency in childhood is cystic fibrosis. Decreased secretion of pancreatic digestive enzymes is caused by obstruction of the exocrine ducts by thick secretions, which destroys pancreatic acinar cells. Destruction of acinar cells may occur antenatally. Some genotypes of cystic fibrosis have partially or completely preserved pancreatic exocrine function. Other conditions associated with exocrine pancreatic insufficiency are discussed in Chapter 21.

8. Other Genetic Disorders Causing Malabsorption

A. Abetalipoproteinemia

Abetalipoproteinemia is an autosomal recessive condition in which the secretion of triglyceride-rich lipoproteins from the small intestine (chylomicrons) and liver (very low-density lipoproteins) is abnormal. Profound steatosis of the intestinal enterocytes (and hepatocytes) and severe fat malabsorption occur. Deficiencies of fat-soluble vitamins develop with neurologic complications of vitamin E deficiency and atypical retinitis pigmentosa. Serum cholesterol level is very low, and red cell membrane lipids are abnormal, causing acanthosis of red blood cells, which may be the key to diagnosis.

B. Acrodermatitis Enteropathica

Acrodermatitis enteropathica is an autosomal recessive condition in which the intestine has a selective inability to absorb zinc. The condition usually becomes obvious at the time of weaning and is characterized by rash on the extremities, rashes around the body orifices, eczema, profound failure to thrive, steatorrhea, diarrhea, and immune

deficiency. Zinc supplementation by mouth results in rapid improvement.

INFLAMMATORY BOWEL DISEASE

▶ General Considerations

Inflammatory bowel disease is most commonly differentiated into Crohn disease (CD) and ulcerative colitis (UC). The etiology is most likely multifactorial, involving a complex interaction of immune, environmental (eg, smoking, breast feeding, diet), and genetic factors. The genetic association is clear, with frequency as high as 40% in first-degree relatives. Monozygotic twins have a 37% concordance for CD and 10% concordance for UC. Mutations in the *NOD2/CARD15* gene on chromosome 16 have been implicated in CD. This gene has an important role in activating nuclear factor- κ , which mediates the inflammatory response and the production of proinflammatory cytokines.

▶ Clinical Findings

A. Symptoms and Signs

The clinical presentation of inflammatory bowel disease depends on the site of inflammation. Most (50–70%) children with CD have terminal ileal disease, and more than half have colonic involvement, typically of the ascending colon. Ten to 20% have isolated colonic disease, and 10–15% have small bowel disease. Gastroduodenal inflammation is common, although isolated gastric disease is rare. CD patients may have nonspecific symptoms at presentation, leading to delays in diagnosis. The most common presentation is abdominal pain, sometimes with diarrhea and weight loss. Some patients may have anal skin tags or fistulas on examination. Rectal bleeding and nonspecific symptoms such as fever, anorexia, fatigue, nausea and vomiting, aphthous ulcerations, short stature, and delayed puberty may also occur.

The most common symptoms in UC are rectal bleeding, diarrhea, and abdominal pain. In contrast to CD, the colon is the major site of inflammation with 44–49% of patients having rectosigmoid disease; 36–41%, left-sided colonic disease; and 14–37%, pancolitis. The younger the child, the more likely it is that he or she will have pancolitis and the more aggressive the inflammatory process is likely to be.

Extraintestinal symptoms and signs are common in both CD and UC and may precede the onset of GI symptoms. Arthritis is the most common extraintestinal manifestation of inflammatory bowel disease. Nephrolithiasis, erythema nodosum, and pyoderma gangrenosum can also occur. Uveitis, conjunctivitis, and primary sclerosing cholangitis may also be seen.

B. Diagnostic Testing

Patients with inflammatory bowel disease often have low hemoglobin and serum albumin levels and increased platelet

count, erythrocyte sedimentation rate, and C-reactive protein. These findings are not always present. Serum antibodies to *Saccharomyces cerevisiae* (ASCA) are detected in 40–60% of patients with CD. Serum perinuclear antineutrophil cytoplasmic antibodies (pANCA) are present in approximately 70% of UC patients. Both of these antibodies, if positive, may be helpful screens, but they are neither sensitive nor specific enough to be diagnostic. In patients with diarrhea, it is important to evaluate for infectious and malabsorptive problems.

Barium upper GI study with small bowel follow-through shows small bowel disease. CT scan and magnetic resonance imaging may show mucosal and mural edema but are not specific. Intestinal wall thickening is often reported on CT scans performed as part of an urgent evaluation to rule out appendicitis. This finding is probably an acute reaction to infection and should not prompt an extensive evaluation for CD without other supporting symptoms or signs.

Upper endoscopy and colonoscopy including the terminal ileum are essential in diagnosing inflammatory bowel disease. Mucosal involvement in CD is typically patchy with disease-free skip areas. It can be found in any part of the GI tract (including esophagus and stomach) with transmural inflammation manifested by ulcers, fistulas, strictures, and granulomas. UC is usually localized to the colon, and generally the inflammation is mucosal or submucosal. Although inflammation seems to spread proximally from the rectum, rectal sparing sometimes occurs.

► Differential Diagnosis

When extraintestinal symptoms predominate, CD can be mistaken for rheumatoid arthritis, systemic lupus erythematosus, or hypopituitarism. The acute onset of ileocolitis may be mistaken for appendicitis. Symptoms sometimes suggest celiac disease, peptic ulcer, intestinal obstruction, intestinal lymphoma, anorexia nervosa, or growth failure from endocrine causes. In the acute stage, bacterial pathogens and toxins causing colitis must be ruled out. These include *Shigella*, *Salmonella*, *Yersinia*, *Campylobacter*, *Entamoeba histolytica*, enteroinvasive *Escherichia coli* (*E coli* O157), *Aeromonas hydrophila*, *Giardia*, and *Clostridium difficile*. Mild UC sometimes mimics irritable bowel syndrome. Eosinophilic gastroenteropathy and vasculitic lesions should also be considered. Finally, Behçet disease should be considered. It is characterized by oral aphthous ulcerations along with at least two of the following: genital ulcers, synovitis, posterior uveitis, meningoenitis, and pustular vasculitis. Patients with Behçet disease also may have anorexia, vomiting, diarrhea, abdominal pain, distention, and dyspepsia.

► Complications

A. Crohn Disease

Malnutrition is caused by anorexia and compounded by malabsorption, protein-losing enteropathy, iron-deficiency

anemia, disaccharidase deficiency, and bile salt malabsorption in poorly controlled disease. Growth failure, delayed bone age, and delayed puberty are common results of malnutrition and steroid use. Controlling active disease to the point of remission usually allows for improved nutrition and resumption of normal growth velocity. Most patients today achieve reasonable final adult height. Intestinal obstruction, fistulae, abdominal abscess, perianal disease, pyoderma gangrenosum, arthritis, and amyloidosis occur. The risk of colon cancer is increased in patients with CD colitis although not to the extent seen in UC.

B. Ulcerative Colitis

Arthritis, uveitis, pyoderma gangrenosum, and malnutrition all occur. Growth failure and delayed puberty are less common than in CD. Liver disease (chronic active hepatitis, sclerosing cholangitis) is more common. In patients with pancolitis, carcinoma of the colon occurs with an incidence of 1–2% per year after the first 10 years of disease. Cancer risk is a function of disease duration, not age at onset. The mortality rate from colon cancer is high because the usual signs (occult blood in stool, pain, and abnormal radiologic findings) are not specific and may be ignored in a patient with colitis. Routine cancer screening (colonoscopy with multiple biopsies and evaluation of specimens for metaplasia and aneuploidy) is recommended in pediatric patients after 10 years of pancolitis. Dysplasia that persists in the absence of inflammation is an indication for colectomy, as is aneuploidy in multiple biopsy specimens.

► Treatment

A. Medical Treatment

Medical treatment of CD and UC is similar and includes anti-inflammatory, antidiarrheal, and antibiotic medication. No medical therapy is uniformly effective in all patients.

1. Diet—The main priority in patients with inflammatory bowel disease is ensuring adequate caloric intake. Restrictive or bland diets are counterproductive because they usually result in poor intake. A high-protein, high-carbohydrate diet with normal amounts of fat is recommended. A diet with decreased fiber may prevent symptoms during active colitis or partial intestinal obstruction; however, increased fiber may benefit mucosal health via bacterial production of fatty acids when disease is inactive. Lactose is poorly tolerated when disease is active. Supplemental calories in the form of liquid diets are well tolerated and promote catch-up growth. Enteral administration of low-residue or elemental liquid diets is widely used outside of the United States to induce remission in patients with CD. It is less effective in UC. Total parenteral nutrition for periods of 4–6 weeks may induce remission and promote linear growth and sexual development.

2. Nonabsorbable 5-aminosalicylates (5-ASA)—Multiple preparations of 5-ASA derivatives are available and are used

to induce remission in mild CD and UC. 5-ASA derivatives are also used for maintenance therapy in patients in remission. Sulfasalazine, a common form of 5-ASA, is not absorbed systemically. Intact drug is hydrolyzed by colon flora into sulfapyridine and 5-aminosalicylate. The sulfonamide moiety is probably inactive but is responsible for the allergic side effects of the drug. The salicylate moiety has local anti-inflammatory activity. Side effects include skin rash, nausea, headache, and abdominal pain. Rarely, serum sickness, hemolytic anemia, aplastic anemia, and pancreatitis occur. Response to therapy may be slow. Sulfasalazine inhibits folic acid absorption, and supplemental folic acid is required. The recommended dosage is 2–3 g/d in three divided doses for children older than 10 years or 50 mg/kg/d for younger children. Half of this dosage is used as a maintenance medication for well-controlled UC. Salicylate polymers for oral and rectal use (olsalazine, mesalamine) are available. A variety of pH-sensitive tablet coatings and microencapsulation allow release of these products at specific locations in the GI tract, thereby improving efficacy. These drugs are no more effective than sulfasalazine but are used in sulfonamide-sensitive patients and have fewer side effects.

3. Corticosteroids—Patients with moderate to severe CD and UC require corticosteroids. Methylprednisolone (2 mg/kg/d, maximum 60 mg/d) may be given intravenously when disease is severe. For moderate disease, prednisone (1–2 mg/kg/d orally in one to two divided doses) is given for 6–8 weeks followed by gradual tapering. Alternate-day steroids produce fewer side effects as the dosage of drug is tapered. Chronic use of corticosteroids does not prevent relapse. Prednisone is usually given with a 5-ASA derivative. The patient's varicella immunity should be confirmed by history or antibody screen and parents counseled as to risks and therapy after varicella exposure. Hydrocortisone enemas or rectal foam can be used to treat tenesmus or ulcerative proctitis. Budesonide, which has “one pass metabolism” in the liver, is available in oral and rectal preparations. These preparations are most useful in rectal disease (enemas and suppositories) and right-sided colon disease (oral), and in appropriate doses have fewer corticoid side effects. Calcium and vitamin D supplementation should be considered while patients are being treated with corticosteroids.

4. Azathioprine and 6-mercaptopurine—Azathioprine (Imuran), 2–3 mg/kg/d orally, or 6-mercaptopurine (1–2 mg/kg) provides effective maintenance therapy for moderate to severe CD. These medications are used for frequently relapsing disease or when high-dose corticosteroids are necessary to control disease. The optimal dose depends on the patient's ability to metabolize the compound. Metabolites of azathioprine should be monitored to avoid over- and underdosing in patients with variable metabolizing capacity and to assess compliance. Testing prior to initiating therapy is indicated to identify patients at risk for serious side effects such as bone marrow failure. Maximum therapeutic efficacy

may not be seen for 12–16 weeks after beginning treatment. Side effects include pancreatitis, hepatotoxicity, and bone marrow suppression.

5. Antibiotics—Metronidazole has been used to treat perianal CD. It may also be effective in treating CD of the colon. The dosage of metronidazole is 15–30 mg/kg/d in three divided doses. Peripheral neuropathy may occur with prolonged use. Ciprofloxacin has similar therapeutic effect and is occasionally used in combination with metronidazole.

6. Biologic therapies—Infliximab, a chimeric monoclonal antibody against tumor necrosis factor- β (TNF β), is used for moderate to severe CD, especially in patients with resistant perianal and fistulizing disease unresponsive to milder therapy. Most patients require repeated intravenous infusion at 4–12-week intervals to remain in remission. Anaphylactic reactions have been reported. The concomitant use of azathioprine decreases the incidence of severe allergic reactions and may help maintain responsiveness to therapy. Side effects include flushing, rash, dyspnea, delayed hypersensitivity reactions, opportunistic infections, and lymphoproliferative disorders. Infliximab is also effective in severe colitis and in steroid-dependent colitis.

7. Other Agents—Cyclosporine can be used in severe, steroid-resistant UC. Because it has significant side effects and is followed by rapid relapse after discontinuation, cyclosporine is usually used to “buy time” and improve symptoms of severe colitis in patients prior to surgery. Oral or subcutaneous methotrexate has been used to treat severe, refractory CD. Liver toxicity is a risk with prolonged use. Thalidomide has been used, especially in patients with oral and vaginal ulcers secondary to CD. Its mechanism of action may include prevention of TNF secretion or antiangiogenic activity. This medication must be used under strict supervision in postpubescent female patients because of the risk of teratogenesis.

B. Surgical Treatment

1. Crohn disease—CD is not cured by surgery. Surgery is typically recommended for complications such as obstruction, perforation, abscess, stricture, fistula, and sometimes for intractable symptoms, growth retardation, and pubertal delay. Up to 50% of patients with CD eventually require a surgical procedure. There is a high relapse rate after surgery, typically at the site of anastomosis within 2 years. Recurrence rate may be less in patients with disease limited to the colon. Surgery to correct growth retardation must be performed before the completion of puberty.

2. Ulcerative colitis—Surgery is curative and is recommended for patients with uncontrolled hemorrhage, toxic megacolon, unrelenting pain and diarrhea, growth failure, high-grade mucosal dysplasia, or malignant tumors. Several surgical approaches (ileoanal anastomosis, Koch-type continent ileostomy) are available that allow a near-normal life-

style after colectomy. Liver disease associated with UC (sclerosing cholangitis) is not improved by colectomy.

LIVER DISORDERS

PROLONGED NEONATAL CHOLESTATIC JAUNDICE

The main clinical features of disorders causing prolonged neonatal cholestasis are (1) jaundice with elevated serum conjugated (or direct) bilirubin fraction (> 2 mg/dL or $> 20\%$ of total bilirubin), (2) variably acholic stools, (3) dark urine, and (4) hepatomegaly.

Prolonged neonatal cholestasis (conditions with decreased bile flow) has intrahepatic and extrahepatic causes. Specific clinical clues (Table 21–1) distinguish these two major categories of jaundice in 85% of cases. Histologic examination of tissue obtained by percutaneous liver biopsy increases the accuracy of differentiation to 95% (Table 21–2).

INTRAHEPATIC CHOLESTASIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Elevated total and conjugated bilirubin.
- ▶ Hepatomegaly and dark urine.
- ▶ Patency of extrahepatic biliary tree.

▶ General Considerations

Intrahepatic cholestasis is characterized by hepatocyte dysfunction and patency of the extrahepatic biliary system. A specific cause can be identified in about 50% of cases. Patency of the extrahepatic biliary tract is suggested by pigmented stools and lack of bile duct proliferation on liver biopsy. It can be confirmed least invasively by hepatobiliary scintigraphy using technetium-99m (^{99m}Tc)-diethyliminodi-

acetic acid (diethyl-IDA [DIDA]). Radioactivity in the bowel within 4–24 hours is evidence of bile duct patency. Finding bilirubin in duodenal aspirates also confirms patency. Patency can also be determined by cholangiography carried out intraoperatively, percutaneously by transhepatic cholecystography, or endoscopic retrograde cholangiopancreatography (ERCP) using a pediatric-size side-viewing endoscope. Magnetic resonance cholangiopancreatography in infants is of limited use and highly dependent on the operator and equipment.

1. Perinatal or Neonatal Hepatitis Resulting from Infection

This diagnosis is considered in infants with jaundice, hepatomegaly, vomiting, lethargy, fever, and petechiae. It is important to identify perinatally acquired viral, bacterial, or protozoal infections (Table 21–3). Infection may occur transplacentally, by ascent through the cervix into amniotic fluid, from swallowed contaminated fluids (maternal blood, urine) during delivery, from blood transfusions administered in the early neonatal period, or from breast milk or environmental exposure. Infectious agents associated with neonatal intrahepatic cholestasis include herpes simplex virus, varicella virus, enteroviruses (coxsackievirus and echovirus), cytomegalovirus (CMV), rubella virus, adenovirus, parvovirus, human herpesvirus type 6 (HHV-6), hepatitis B virus (HBV), human immunodeficiency virus (HIV), *Treponema pallidum*, and *Toxoplasma gondii*. Although hepatitis C may be transmitted vertically, it rarely causes neonatal cholestasis. The degree of liver cell injury caused by these agents is variable, ranging from massive hepatic necrosis (herpes simplex, enteroviruses) to focal necrosis and mild inflammation (CMV, HBV). Serum bilirubin, bile acids, alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase are elevated. The infant is jaundiced, may have petechiae or rash, and generally appears ill.

Table 21-1. Characteristic clinical features of intrahepatic and extrahepatic neonatal cholestasis.

Intrahepatic	Extrahepatic
Preterm infant, small for gestational age, appears ill	Full-term infant, seems well
Hepatosplenomegaly, other organ or system involvement	Hepatomegaly (firm to hard)
Incomplete cholestasis (stools with some pigment)	Complete cholestasis (acholic stools)
Associated cause identified (infections, metabolic, familial, etc)	Polysplenia syndrome, equal right and left hepatic lobes

► Clinical Findings

A. Symptoms and Signs

Clinical symptoms usually appear in the first 2 weeks of life, but may appear as late as age 2–3 months. Jaundice may be noted as early as the first 24 hours of life. Poor oral intake, poor sucking reflex, lethargy, and vomiting are frequent.

Table 21-2. Characteristic histologic features of intrahepatic and extrahepatic neonatal cholestasis.

	Intrahepatic	Extrahepatic
Giant cells	+++	+
Lobules	Disarray	Normal
Portal reaction	Inflammation, minimal fibrosis	Fibrosis, lymphocytic infiltrate
Neoductular proliferation	Rare	Marked
Other	Steatosis, extramedullary hematopoiesis	Portal bile duct plugging, bile lakes

Stools may be normal to pale in color but are seldom acholic. Dark urine stains the diaper. Hepatomegaly is present, and the liver has a uniform firm consistency. Splenomegaly is variably present. Macular, papular, vesicular, or petechial rashes may occur. In less severe cases, failure to thrive may be the major complaint. Unusual presentations include neonatal liver failure, hypoproteinemia, anasarca (nonhemolytic hydrops), and hemorrhagic disease of the newborn.

Table 21-3. Infectious causes of neonatal hepatitis.

Infectious Agent	Diagnostic Tests	Specimens	Treatment
Cytomegalovirus	Culture and PCR, liver histology, IgM/ ^a IgG	Urine, blood, liver	Ganciclovir (Foscarnet) ^b
Herpes simplex	PCR and culture, liver histology, Ag (skin)	Liver, blood, eye, throat, rectal, CSF, skin	Acyclovir
Rubella	Culture, IgM/ ^a IgG	Liver, blood, urine	Supportive
Varicella	Culture, PCR, Ag (skin)	Skin, blood, CSF, liver	Acyclovir (Foscarnet) ^b
Parvovirus	Serum IgM/ ^a IgG, PCR	Blood	Supportive, IVIG
Enteroviruses	Culture and PCR	Blood, urine, CSF, throat, rectal, liver	Pleconaril (investigative), IVIG
Adenovirus	Culture and PCR	Nasal/throat, rectal, blood, liver, urine	Cidofovir, ?IVIG
Hepatitis B virus (HBV)	HBsAg, HBcAg IgM	Serum	Supportive for acute infection
Hepatitis C virus (HCV)	HCV PCR, HCV-IgG	Serum	Supportive for acute infection
<i>Treponema pallidum</i>	Serology; darkfield exam	Serum, CSF	Penicillin
<i>Toxoplasma gondii</i>	IgM/ ^a IgG, PCR, culture	Serum, liver	Pyrimethamine and sulfadiazine with folinic acid for 6 mo; followed by this therapy alternating with spiramycin for 6 mo
<i>Mycobacterium tuberculosis</i>	PPD, chest radiograph, liver tissue histologic stains and culture, gastric aspirate stain and culture	Serum, liver, gastric aspirate	INH, pyrazinamide, rifampin (add streptomycin for severe disease ^c)

^aIgG = positive indicates maternal infection and transfer of antibody transplacentally; negative indicates unlikelihood of infection in mother and infant.

^bUse foscarnet for resistant viruses. Treat only if symptomatic.

^cDiscontinue streptomycin as soon as possible.

Ag, viral antigen testing; CSF, cerebrospinal fluid; HBcAg, hepatitis B core antigen; HBsAg, hepatitis B surface antigen; INH, isoniazid; IVIG, intravenous gamma globulin; PCR, polymerase chain reaction test for viral DNA or RNA; PPD, purified protein derivative.

B. Diagnostic Studies

Neutropenia, thrombocytopenia, and signs of mild hemolysis are common. Mixed hyperbilirubinemia, elevated aminotransferases with near-normal alkaline phosphatase, prolongation of clotting studies, mild acidosis, and elevated cord serum IgM suggest congenital infection. Nasopharyngeal washings, urine, stool, serum, and cerebrospinal fluid (CSF) should be cultured for virus and tested for pathogen-specific nucleic acid. Specific IgM antibody may be useful, as are long-bone radiographs to determine the presence of “celery stalking” in the metaphyseal regions of the humeri, femurs, and tibias. When indicated, computed tomography (CT) and magnetic resonance imaging (MRI) scans can identify intracranial calcifications (especially with CMV and toxoplasmosis). Hepatobiliary scintigraphy shows decreased hepatic clearance of the circulating isotope with excretion into the gut. Careful ophthalmologic examination may be useful for diagnosis of herpes simplex virus, CMV, toxoplasmosis, and rubella.

A percutaneous liver biopsy is useful in distinguishing intrahepatic from extrahepatic cholestasis, but may not identify a specific infectious agent (see Table 21–2). However, typical inclusions of CMV in hepatocytes or bile duct epithelial cells, the presence of intranuclear acidophilic inclusions of herpes simplex, or positive immunohistochemical stains for several viruses can be diagnostic. Variable degrees of lobular disarray characterized by focal necrosis, multinucleated giant-cell transformation, and ballooned pale hepatocytes with loss of cordlike arrangement of liver cells are usual. Intrahepatocytic and canalicular cholestasis may be prominent. Portal changes are not striking, but modest neoductular proliferation and mild fibrosis may occur. Viral cultures or polymerase chain reaction (PCR) testing of biopsy material may be helpful.

► Differential Diagnosis

Great care must be taken to distinguish infectious causes of intrahepatic cholestasis from genetic or metabolic disorders because the clinical presentations are similar. Galactosemia, congenital fructose intolerance, and tyrosinemia must be investigated promptly, because specific dietary therapy is available. These infants may also have concomitant bacteremia. α_1 -Antitrypsin deficiency, cystic fibrosis, bile acid synthesis defects, mitochondrial respiratory chain disorders, and neonatal iron storage disease must also be considered. Specific physical features may be helpful when considering Alagille or Zellweger syndrome. Idiopathic neonatal hepatitis may be indistinguishable from infectious causes.

Patients with intrahepatic cholestasis frequently appear ill, whereas infants with extrahepatic cholestasis do not appear ill, have stools that are usually completely acholic, and have an enlarged, firm liver. Histologic findings are described in Table 21–2.

► Treatment

Most forms of viral neonatal hepatitis are treated symptomatically. However, infections with herpes simplex virus, varicella, CMV, parvovirus, adenovirus, and toxoplasmosis have specific treatments. Fluids and adequate calories are encouraged. Intravenous dextrose is needed if feedings are not well tolerated. The consequences of cholestasis are treated as indicated (Table 21–4). Vitamin K orally or by injection and vitamins D and E orally should be provided. Cholagogues (ursodeoxycholic acid [UDCA] or cholestyramine) are used if cholestasis persists. Corticosteroids are contraindicated. Penicillin for suspected syphilis, specific antiviral therapy, or antibiotics for bacterial hepatitis, need to be administered promptly.

► Prognosis

Multiple organ involvement is commonly associated with neonatal infectious hepatitis and has a poor outcome. Death from hepatic or cardiac failure, intractable acidosis, or intracranial hemorrhage may occur, especially in herpesvirus or enterovirus infection, and occasionally in CMV or rubella infection. HBV rarely causes fulminant neonatal hepatitis; most infected infants become asymptomatic carriers of hepatitis B. Persistent liver disease results in mild chronic hepatitis, portal fibrosis, or cirrhosis. The liver in most infants who recover from congenital viral infection is left without fibrosis. Chronic cholestasis, although rare following infections, may lead to dental enamel hypoplasia, failure to thrive, biliary rickets, severe pruritus, and xanthoma.

2. Specific Infectious Agents

A. Neonatal Hepatitis B Virus Disease

Infection with HBV may occur at any time during perinatal life, but the risk is higher when acute maternal disease occurs during the last trimester of pregnancy. However, most cases of neonatal disease are acquired from mothers who are asymptomatic carriers of HBV. Although HBV has been found in most body fluids, including breast milk, neonatal transmission occurs occasionally transplacentally and primarily from exposure to maternal blood at delivery. In chronic hepatitis B surface antigen (HBsAg)–carrier mothers, fetal and infant acquisition risk is greatest if the mother (1) is also hepatitis B “e” antigen (HBeAg)–positive and hepatitis B “e” antibody (HBeAb)–negative, (2) has detectable levels of serum-specific hepatitis B DNA polymerase, (3) has high serum levels of hepatitis B core antibody (HBcAb), or (4) has high blood levels of HBV DNA. These findings are markers for circulating infectious virus; however, hepatitis B can be transmitted even if HBsAg is the only marker present.

Neonatal liver disease resulting from HBV is extremely variable. The infant has a 70–90% chance of acquiring HBV at birth from an HBsAg-positive mother if the infant does not receive prophylaxis. Most infected infants become prolonged asymptomatic “carriers” of HBV. Fulminant hepatic necrosis

Table 21-4. Treatment of complications of chronic cholestatic liver disease.

Indication	Treatment	Dose	Toxicity
Intrahepatic cholestasis	Phenobarbital	3–10 mg/kg/d	Drowsiness, irritability, interference with vitamin D metabolism
	Cholestyramine or colestipol hydrochloride	250–500 mg/kg/d	Constipation, acidosis, binding of drugs, increased steatorrhea
	Ursodeoxycholic acid	15–20 mg/kg/d	Transient increase in pruritus
Pruritus	Phenobarbital	3–10 mg/kg/d	Drowsiness, irritability, interference with vitamin D metabolism
	Cholestyramine or colestipol	250–500 mg/kg/d	Constipation, acidosis, binding of drugs, increased steatorrhea
	Antihistamines: diphenhydramine hydrochloride	5–10 mg/kg/d	Drowsiness
	Hydroxyzine	2–5 mg/kg/d	
	Ultraviolet light B	Exposure as needed	Skin burn
	Carbamazepine	20–40 mg/kg/d	Hepatotoxicity, marrow suppression, fluid retention
	Rifampin	10 mg/kg/d	Hepatotoxicity, marrow suppression
Steatorrhea	Formula containing medium-chain triglycerides (eg, Pregestimil or Alimentum)	120–150 kcal/kg/d for infants	Expensive
	Oil supplement containing medium-chain triglycerides	1–2 mL/kg/d	Diarrhea, aspiration
Malabsorption of fat-soluble vitamins	Vitamin A	10,000–25,000 U/d	Hepatitis, pseudotumor cerebri, bone lesions
	Vitamin D	800–5000 U/d	Hypercalcemia, hypercalciuria
	25-Hydroxycholecalciferol (25-OH vitamin D)	3–5 mcg/kg/d	Hypercalcemia, hypercalciuria
	1,25-Dihydroxycholecalciferol (1,25 OH ₂ vitamin D)	0.05–0.2 mcg/kg/d	Hypercalcemia, hypercalciuria
	Vitamin E (oral)	25–200 IU/kg/d	Potential of vitamin K deficiency
	Vitamin E (oral, TPGS ^a)	15–25 IU/kg/d	Potential of vitamin K deficiency
	Vitamin E (intramuscular)	1–2 mg/kg/d	Muscle calcifications
	Vitamin K (oral)	2.5 mg twice per week to 5 mg/d	
Malabsorption of other nutrients	Multiple vitamin	1–2 times the standard dose	
	Calcium	25–100 mg/kg/d	Hypercalcemia, hypercalciuria
	Phosphorus	25–50 mg/kg/d	Gastrointestinal intolerance
	Zinc	1 mg/kg/d	Interference with copper and iron absorption

^aD- α -Tocopheryl polyethylene glycol-1000 succinate.

has rarely been reported. In such cases, progressive jaundice, stupor, shrinking liver size, and coagulation abnormalities dominate the clinical picture. Respiratory, circulatory, and renal failure usually follow. Histologically, the liver shows

massive hepatocyte necrosis, collapse of the reticulum framework, minimal inflammation, and occasional pseudoacinar structures. Survival without liver transplantation is rare, but is associated with reasonable repair of liver architecture.

In less severe cases, focal hepatocyte necrosis occurs with a mild portal inflammatory response. Cholestasis is intracellular and canalicular. Chronic hepatitis may be present for many years, with serologic evidence of persisting antigenemia (HBsAg) and mildly elevated serum aminotransferases. Chronic hepatitis may rarely progress to cirrhosis within 1–2 years. Most infected infants have only mild evidence, if any, of liver injury.

To prevent perinatal transmission, all infants of mothers who are HBsAg-positive (regardless of HBeAg status) should receive hepatitis B immunoglobulin (HBIG) and hepatitis B vaccine within the first 24 hours after birth and vaccine again at ages 1 and 6 months. (See Chapter 9.) This prevents HBV infection in 85–95% of infants. HBIG can provide some protection when given as late as 72 hours after birth. If not given at birth it can be administered as late as 7 days postpartum as long as the infant has received the vaccine. Universal HBV immunization at birth, with two follow-up doses, is recommended for all infants.

B. Neonatal Bacterial Hepatitis

Most bacterial liver infections in newborns are acquired by transplacental invasion from amnionitis with ascending spread from maternal vaginal or cervical infection. Onset is abrupt, usually within 48–72 hours after delivery, with signs of sepsis and often shock. Jaundice appears early and is of the mixed type. The liver enlarges rapidly, and the histologic picture is that of diffuse hepatitis with or without microabscess. The most common organisms involved are *Escherichia coli*, *Listeria monocytogenes*, and group B streptococci. Isolated neonatal liver abscess caused by *E coli* or *Staphylococcus aureus* is associated with omphalitis or umbilical vein catheterization. Bacterial hepatitis and neonatal liver abscesses require specific antibiotics in large doses and, rarely, surgical or radiologic interventional drainage. Deaths are common, but survivors show no long-term consequences of liver disease.

C. Neonatal Jaundice with Urinary Tract Infection

Jaundice in affected infants—usually males—typically appears between the second and fourth weeks of life. This disorder causes lethargy, fever, poor appetite, jaundice, and hepatomegaly. Except for mixed hyperbilirubinemia, other liver function tests (LFTs) are mildly abnormal. Leukocytosis is present, and infection is confirmed by urine culture. The mechanism for the liver impairment is the inhibitory action on bile secretion produced by bacterial products (endotoxins) and inflammatory cytokines.

Treatment of the infection leads to prompt resolution of the cholestasis without hepatic sequelae. Metabolic liver diseases, such as galactosemia and tyrosinemia, may present with gram-negative bacterial urinary tract infection and should be excluded.

3. Intrahepatic Cholestasis Resulting from Inborn Errors of Metabolism, Familial, & “Toxic” Causes

These cholestatic syndromes caused by specific enzyme deficiencies, other genetic disorders, or certain precipitants associated with neonatal liver disease feature intrahepatic cholestasis (ie, jaundice, hepatomegaly, and normal to completely acholic stools). Some of the specific clinical conditions have characteristic clinical signs.

A. Enzyme Deficiencies and Other Inherited Disorders

Early specific diagnosis is important because dietary or pharmacologic treatment may be available (Table 21–5). Reversal of liver disease and clinical symptoms is prompt and permanent in several disorders as long as the diet is maintained. As with other genetic disorders, parents of the affected infant should be offered genetic counseling. For some disorders, prenatal genetic diagnosis is available.

Cholestasis caused by metabolic diseases such as galactosemia, fructose intolerance, and tyrosinemia may be accompanied by vomiting, lethargy, poor feeding, hypoglycemia, and irritability. Hepatomegaly is a constant finding. The infants often appear septic; gram-negative bacteria can be cultured from blood in 25–50% of cases, especially in patients with galactosemia. Neonatal screening programs for galactosemia usually detect the disorder before cholestasis develops. Other inherited conditions associated with neonatal intrahepatic cholestasis are outlined in Table 21–5. Treatment of these disorders is discussed in Chapter 34.

B. “Toxic” Causes of Neonatal Cholestasis

1. Neonatal ischemic-hypoxic conditions—Perinatal events that result in hypoperfusion of the gastrointestinal system are sometimes followed within 1–2 weeks by cholestasis. This occurs in premature infants with respiratory distress, severe hypoxia, hypoglycemia, shock, and acidosis. When these perinatal conditions develop in association with gastrointestinal lesions, such as ruptured omphalocele, gastroschisis, or necrotizing enterocolitis, a subsequent cholestatic picture is common (25–50% of cases). Liver function studies reveal mixed hyperbilirubinemia, elevated alkaline phosphatase and γ -glutamyl transpeptidase (GGT) values, and variable elevation of the aminotransferases. Stools are seldom persistently acholic.

Table 21-5. Metabolic and genetic causes of neonatal cholestasis.

Disease	Inborn Error	Hepatic Pathology	Diagnostic Studies
Galactosemia	Galactose-1-phosphate uridylyltransferase	Cholestasis, steatosis, necrosis, pseudoacini, fibrosis	Galactose-1-phosphate uridylyltransferase assay of red blood cells
Fructose intolerance	Fructose-1-phosphate aldolase	Steatosis, necrosis, pseudoacini, fibrosis	Liver fructose-1-phosphate aldolase assay or genotyping of leukocyte DNA
Tyrosinemia	Fumarylacetoacetase	Necrosis, steatosis, pseudoacini, portal fibrosis	Urinary succinylacetone, fumarylacetoacetase assay of red blood cells
Cystic fibrosis	Cystic fibrosis transmembrane conductance regulator gene	Cholestasis, neoductular proliferation, excess bile duct mucus, portal fibrosis	Sweat test and genotyping of leukocyte DNA
Hypopituitarism	Deficient production of pituitary hormones	Cholestasis, giant cells	Thyroxine, TSH, cortisol levels
α_1 -Antitrypsin deficiency	Abnormal α_1 -antitrypsin molecule (Pi ZZ phenotype)	Giant cells, cholestasis, steatosis, neoductular proliferation, fibrosis, PAS-diastase-resistant cytoplasmic globules	Serum α_1 -antitrypsin phenotype or genotype
Gaucher disease	β -Glucosidase	Cholestasis, cytoplasmic inclusions in Kupffer cells (foam cells)	β -Glucosidase assay in leukocytes
Niemann-Pick disease	Lysosomal sphingomyelinase	Cholestasis, cytoplasmic inclusions in Kupffer cells	Sphingomyelinase assay of leukocytes or liver or fibroblasts (type C); genotyping of leukocyte DNA
Glycogen storage disease type IV	Branching enzyme	Fibrosis, cirrhosis, PAS-diastase-resistant cytoplasmic inclusions	Branching enzyme analysis of leukocytes or liver, genotyping of leukocyte DNA
Neonatal hemochromatosis	Transplacental alloimmunization	Giant cells, portal fibrosis, hemosiderosis, cirrhosis	Histology, iron stains, lip biopsy, abdominal MRI
Peroxisomal disorders (eg, Zellweger syndrome)	Deficient peroxisomal enzymes or assembly	Cholestasis, necrosis, fibrosis, cirrhosis, hemosiderosis	Plasma very long chain fatty acids, qualitative bile acids, plasmalogen, pipercolic acid, liver electron microscopy
Abnormalities in bile acid metabolism	Several enzyme deficiencies defined	Cholestasis, necrosis, giant cells	Urine, serum, duodenal fluid analyzed for bile acids by fast atom bombardment-mass spectroscopy
Byler disease (familial progressive intrahepatic cholestasis)	<i>FIC-1</i> and <i>BSEP</i> genes	Cholestasis, necrosis, giant cells, fibrosis	Histology, family history, normal cholesterol, low or normal γ -glutamyl transpeptidase, genotyping of leukocyte DNA
MDR3 deficiency	<i>MDR3</i> gene	Cholestasis, bile duct proliferation, portal fibrosis	Bile phospholipid level, genotyping of leukocyte DNA
Alagille syndrome (syndromic paucity of interlobular bile ducts)	<i>JAGGED1</i> gene and <i>NOTCH2</i> mutations	Cholestasis, paucity of interlobular bile ducts, increased copper levels	Three or more clinical features, liver histology, genotyping of leukocyte DNA
Mitochondrial hepatopathies (respiratory chain disease)	<i>POLG</i> , <i>BCS1</i> , <i>SCO1</i> , <i>DGUOK</i> , and <i>MPV17</i> gene mutations	Cholestasis, steatosis, portal fibrosis, abnormal mitochondria on electron microscopy	mtDNA depletion studies, respiratory chain studies on liver or muscle, genotyping

MDR3, multiple drug resistance protein type 3; MRI, magnetic resonance imaging; mtDNA, mitochondrial DNA; PAS, periodic acid-Schiff; TSH, thyroid-stimulating hormone.

Choleretics (UDCA), introduction of enteral feedings as soon as possible, and nutritional support are the mainstays of treatment until the cholestasis resolves (see Table 21–4). In some cases, this resolution may take 3–6 months. As long as no severe intestinal problem is present (eg, short gut syndrome), complete resolution of the hepatic abnormalities is the rule. But portal fibrosis with periportal scarring is occasionally found on follow-up biopsy.

2. Prolonged parenteral nutrition—Cholestasis may develop after 1–2 weeks in premature newborns receiving parenteral nutrition. Even full-term infants with significant intestinal disease, resections, or dysmotility may develop parenteral nutrition–related cholestasis. Contributing factors may include toxicity of intravenous amino acids, diminished stimulation of bile flow from prolonged absence of feedings, small intestinal bacterial overgrowth with translocation of intestinal bacteria and their cell wall products, missing nutrients or antioxidants, photooxidation of amino acids, infusion of lipid hydroperoxides or lipid sterols, and the “physiologic cholestatic” propensity of the premature infant. Histology of the liver may resemble that of extrahepatic biliary obstruction. Early introduction of feedings has reduced the frequency of this disorder. The prognosis is generally good. Occasional cases of cirrhosis, liver failure, and hepatoma may develop, particularly in infants with intestinal resections or malformations that require prolonged parenteral nutrition. A recent study suggests that oral erythromycin as a prokinetic agent may reduce the incidence of cholestasis in very low birth infants.

3. Inspissated bile syndrome—This syndrome is the result of accumulation of bile in canaliculi and in the small- and medium-sized bile ducts in hemolytic disease of the newborn (Rh, ABO) and in some infants receiving parenteral nutrition. The same mechanisms may cause intrinsic obstruction of the common bile duct. An ischemia-reperfusion injury may also contribute to cholestasis in Rh incompatibility. In extreme hemolysis, the cholestasis may be seemingly complete, with acholic stools. Levels of bilirubin, primarily conjugated, may reach 40 mg/dL. If inspissation of bile occurs within the extrahepatic biliary tree, differentiation from biliary atresia may be difficult. A trial of choleretics is indicated. Once stools show a return to normal color or ^{99m}Tc-DIDA scanning shows biliary excretion into the duodenum, patency of the extrahepatic biliary tree is assured. Although most cases improve slowly over 2–6 months, persistence of complete cholestasis for more than 1–2 weeks requires further studies (ultrasonography, DIDA scanning, liver biopsy) with possible cholangiographic or MRI of the extrahepatic biliary tree. Irrigation of the common bile duct is sometimes necessary to dislodge the obstructing inspissated biliary material.

4. Idiopathic Neonatal Hepatitis (Giant-Cell Hepatitis)

This type of cholestatic jaundice of unknown cause presents with features of cholestasis and a typical liver biopsy appearance; it accounts for 25–40% of cases of neonatal intrahepatic cholestasis. The degree of cholestasis is variable, and the disorder may be indistinguishable from extrahepatic causes in 10% of cases. Viral infections, α_1 -antitrypsin deficiency, Alagille syndrome, Niemann-Pick type C disease (NPC), progressive familial intrahepatic cholestasis (PFIC), and bile acid synthesis defects may present in a similar clinical and histologic manner. In idiopathic neonatal hepatitis, PFIC types 1 and 2, and disease due to bile acid synthesis defects the GGT levels are normal or low. Electron microscopy of the liver biopsy (and genotyping) may help distinguish NPC and PFIC.

Intrauterine growth retardation, prematurity, poor feeding, emesis, poor growth, and partially or intermittently acholic stools are characteristic of intrahepatic cholestasis. Patients with neonatal lupus erythematosus may present with giant-cell hepatitis; however, thrombocytopenia, skin rash, or congenital heart block is usually also present.

In cases of suspected idiopathic neonatal hepatitis (diagnosed in the absence of infectious, metabolic, and toxic causes), patency of the biliary tree should be verified to exclude extrahepatic surgical disorders. DIDA scanning and ultrasonography may be helpful in this regard if stools are acholic. Some clinicians have used the enteral string test during DIDA scanning to confirm bile duct patency. Liver biopsy findings are usually diagnostic after age 6–8 weeks (see Table 21–2), but may be misleading before age 6 weeks. Failure to detect patency of the biliary tree, nondiagnostic liver biopsy findings, or persisting complete cholestasis (acholic stools) are indications for minilaparotomy and intraoperative cholangiography performed by an experienced surgeon, ERCP, percutaneous cholecystography, or magnetic resonance cholangiopancreatography (MRCP). Occasionally, a small but patent (hypoplastic) extrahepatic biliary tree is demonstrated (as in Alagille syndrome); it is probably the result, rather than the cause, of diminished bile flow. Surgical reconstruction of hypoplastic biliary trees should not be attempted.

Once a patent extrahepatic tree is confirmed, therapy should include choleretics, a special formula with medium-chain triglycerides (eg, Pregestimil, Alimentum), and supplemental fat-soluble vitamins in water-soluble form (see Table 21–4). This therapy is continued as long as significant cholestasis remains (conjugated bilirubin > 1 mg/dL). Fat-soluble vitamin serum levels should be monitored while supplements are given and at least once after their discontinuation.

Eighty percent of patients recover without significant hepatic fibrosis. However, in 20% of cases the patient has PFIC and is likely to progress to cirrhosis. In general, failure to resolve the cholestatic picture by age 6–12 months is associated with progressive liver disease and evolving cirrhosis. This may occur with either normal or diminished numbers of interlobular bile ducts (paucity of interlobular ducts). Liver transplantation has been successful when signs of hepatic decompensation are noted (rising bilirubin, coagulopathy, intractable ascites).

5. Paucity of Interlobular Bile Ducts

Forms of intrahepatic cholestasis caused by decreased numbers of interlobular bile ducts (< 0.5 bile ducts per portal tract) may be classified according to whether they are associated with other malformations. Alagille syndrome (syndromic paucity or arteriohepatic dysplasia) is caused by mutations in the gene *JAGGED1*, located on chromosome 20p, which codes for a ligand of the notch receptor, or more rarely in the gene *NOTCH2*. Alagille syndrome is sometimes recognized by identification of the characteristic facies, which becomes more obvious with age. The forehead is prominent, as is the nasal bridge. The eyes are set deep and sometimes widely apart (hypertelorism). The chin is small and slightly pointed and projects forward. The ears are prominent. The stool color varies with the severity of cholestasis. Pruritus begins by age 3–6 months. Firm, smooth hepatomegaly may be present. Cardiac murmurs are present in 95% of patients, and butterfly vertebrae (incomplete fusion of the vertebral body or anterior arch) are present in 50%. Xanthomas develop later in the disease as hypercholesterolemia becomes a problem. Occasionally, early cholestasis is mild and not recognized or the patient presents with complex congenital heart disease (eg, tetralogy of Fallot).

Conjugated hyperbilirubinemia may be mild to severe (2–15 mg/dL). Serum alkaline phosphatase, GGT, and cholesterol are markedly elevated, especially early in life. Serum bile acids are always elevated. Aminotransferases are mildly increased, but clotting factors and other liver proteins are usually normal.

The cardiovascular abnormalities include peripheral pulmonary artery, branch pulmonary artery, or pulmonary valvular stenoses (most common), atrial septal defect, coarctation of the aorta, and tetralogy of Fallot. Up to 10–15% of patients have intracranial vascular abnormalities and may develop intracranial hemorrhage early in childhood.

Eye abnormalities (posterior embryotoxon in 90%) and renal abnormalities (dysplastic kidneys, renal tubular ectasia, single kidney, hematuria) can also be present. Growth retardation with normal to increased levels of growth hormone (growth hormone resistance) is common. A variable proportion of patients may have pancreatic insufficiency that may contribute to the fat malabsorption. Although variable, the intelligence quotient is frequently low. Hypogonadism with micropenis may be present. A weak, high-pitched voice may develop. Neurologic disorders resulting from vitamin E deficiency (areflexia, ataxia, ophthalmoplegia) eventually develop in many unsupplemented children and may be profound.

In the nonsyndromic form, paucity of interlobular bile ducts occurs in the absence of the extrahepatic malformations. Paucity of interlobular bile ducts may also occur in α_1 -antitrypsin deficiency, Zellweger syndrome, in association with lymphedema (Aagaens syndrome), PFIC, cystic fibrosis, CMV or rubella infection, and inborn errors of bile acid metabolism.

High doses (250 mg/kg/d) of cholestyramine may control pruritus, lower cholesterol, and clear xanthomas. UDCA (15–25 mg/kg/d) appears to be more effective and causes fewer side effects than cholestyramine. Nutritional therapy to prevent wasting and deficiencies of fat-soluble vitamins is of particular importance because of the severity of cholestasis (see Table 21–4).

Prognosis is more favorable in the syndromic than in the nonsyndromic varieties. In the former, only 30–40% of patients have severe complications of disease, whereas over 70% of patients with nonsyndromic varieties progress to cirrhosis. Many of this latter group may have PFIC. In Alagille syndrome, cholestasis may improve by age 2–4 years, with minimal residual hepatic fibrosis. Survival into adulthood despite raised serum bile acids, aminotransferases, and alkaline phosphatase occurs in about 50% of cases. Several patients have developed hepatocellular carcinoma. Hypogonadism has been noted; however, fertility is not obviously affected in most cases. Cardiovascular anomalies may shorten life expectancy. Some patients have persistent, severe cholestasis, rendering their quality of life poor. Recurrent bone fractures may result from metabolic bone disease. Liver transplantation has been successfully performed under these circumstances. Intracranial hemorrhage may occur in up to 10–12% of affected children.

PROGRESSIVE FAMILIAL INTRAHEPATIC CHOLESTASIS (BYLER DISEASE)

PFIC is a group of disorders presenting as pruritus, diarrhea, jaundice, and failure to thrive in the first 6–12 months of life. PFIC type I (Byler disease), caused by mutations in the *FIC1* gene, is associated with low to normal serum levels of GGT and cholesterol and elevated levels of bilirubin, aminotransferases, and bile acids. Diarrhea and pruritus are common. Liver biopsy demonstrates cellular cholestasis, sometimes with a paucity of interlobular bile ducts and centrolobular fibrosis that progresses to cirrhosis. Electron microscopy shows diagnostic granular “Byler bile” in canaliculi.

Treatment includes administration of UDCA, partial biliary diversion if the condition is unresponsive to UDCA, and liver transplantation. With partial biliary diversion or ileal exclusion surgery, many patients show improved growth and liver histology, reduction in symptoms and, thus, avoidance of liver transplantation. PFIC type II is caused by mutations in the bile salt export pump (*BSEP*) gene, which codes for an adenosine triphosphate–dependent canalicular bile salt transport protein. These patients are clinically and biochemically similar to PFIC type I patients and have similar liver histology except for more “giant cells” and treatment options. There is an increased incidence of hepatocellular carcinoma in these patients. PFIC type III is caused by mutations in the multiple drug resistance protein type 3 (*MDR3*) gene, which encodes a canalicular protein that pumps phospholipid into bile. Serum GGT and bile acid levels are elevated, bile duct proliferation and portal tract fibrosis are seen in liver biopsies, and bile phospholipid levels are low. Treatment is similar to that for other forms of PFIC except for partial biliary diversion. Bile acid synthesis defects are clinically similar to PFIC I and PFIC II, with low serum levels of GGT and cholesterol; however, the serum level of total bile acids is inappropriately normal or low and urine bile acid analysis may identify a synthesis defect. Treatment is with oral cholic acid and UDCA.

EXTRAHEPATIC NEONATAL CHOLESTASIS

Extrahepatic neonatal cholestasis is characterized by complete and persistent cholestasis (acholic stools) in the first 3

months of life; lack of patency of the extrahepatic biliary tree proved by intraoperative, percutaneous, or endoscopic cholangiography; firm to hard hepatomegaly; and typical features on histologic examination of liver biopsy tissue (see Table 21–2). Causes include biliary atresia, choledochal cyst, spontaneous perforation of the extrahepatic ducts, and intrinsic or extrinsic obstruction of the common duct.

1. Biliary Atresia

▶ General Considerations

Biliary atresia is the progressive fibroinflammatory obliteration of the lumen of all, or part of, the extrahepatic biliary tree presenting within the first 3 months of life. In Americans of European origin, biliary atresia occurs in 1:10,000–1:18,000 births, and the incidence in both sexes is equal. In Asian Americans the incidence is higher and the disorder is more common in girls. The abnormality found most commonly is complete atresia of all extrahepatic biliary structures. There appear to be at least two types of biliary atresia: the perinatal form (80% of cases), in which a perinatal insult is believed to initiate inflammatory obstruction and fibrosis of the biliary tree, and the fetal-embryonic form (20% of cases), in which the extrahepatic biliary system did not develop normally. In the perinatal form, meconium and first-passed stools are usually normal in color, suggesting early patency of the ducts. Evidence obtained from surgically removed remnants of the extrahepatic biliary tree suggests an inflammatory or sclerosing cholangiopathy. Although an infectious cause seems reasonable, no agent has been consistently found in such cases. A role for reovirus type 3 and rotavirus group C has been suggested. In the fetal-embryonic type, the bile duct presumably developed abnormally and is associated with other nonhepatic congenital anomalies. The association of biliary atresia with the polysplenia syndrome (heterotaxia, preduodenal portal vein, interruption of the inferior vena cava, polysplenia, and midline liver) and asplenia syndrome supports an embryonic origin of biliary atresia in these cases.

▶ Clinical Findings

A. Symptoms and Signs

Jaundice may be noted in the newborn period and persists beyond age 2–3 weeks. The urine stains the diaper; and the stools are often pale yellow, buff-colored, gray, or acholic. Seepage of bilirubin products across the intestinal mucosa may give some yellow coloration to the stools. Hepatomegaly is common, and the liver may feel firm to hard; splenomegaly develops later. Pruritus, digital clubbing, xanthomas, and a rachitic rosary may be noted in older patients. By age 2–6 months, the growth curves reveal poor weight gain. Late in the course, ascites, failure to thrive, bone fractures and bleeding complications occur.

B. Laboratory Findings and Imaging

No single laboratory test will consistently differentiate biliary atresia from other causes of complete obstructive jaundice. A study of hepatic 2,6-dimethyliminodiacetic acid (HIDA) excretion performed early in the course of disease may help to distinguish intrahepatic from extrahepatic causes of cholestasis, although there is considerable overlap. A HIDA scan showing lack of intestinal excretion is always present in biliary atresia also but may be seen with intrahepatic cholestasis. MRCP may be of value as an imaging study to define biliary atresia. Although biliary atresia is suggested by persistent elevation of serum GGT or alkaline phosphatase levels, high cholesterol levels, and prolonged prothrombin times, these findings have also been reported in severe neonatal hepatitis, α_1 -antitrypsin deficiency, and bile duct paucity. Furthermore, these tests will not differentiate the location of the obstruction within the extrahepatic system. Generally, the aminotransferases are elevated only modestly in biliary atresia. Serum proteins and blood clotting factors are not affected early in the disease. Routine chest radiograph may reveal abnormalities suggestive of polysplenia syndrome. Ultrasonography of the biliary system should be performed to exclude the presence of choledochal cyst and intra-abdominal anomalies. Liver biopsy specimens can differentiate intrahepatic causes of cholestasis from biliary atresia in over 90% of cases (see Table 21–2).

► Differential Diagnosis

The major diagnostic dilemma is distinguishing between this entity and neonatal hepatitis, bile duct paucity, metabolic liver disease (particularly α_1 -antitrypsin deficiency), choledochal cyst, or intrinsic bile duct obstruction (stones, bile plugs). Although spontaneous perforation of extrahepatic bile ducts leads to jaundice and acholic stools, the infants are usually quite ill with chemical peritonitis from biliary ascites, and hepatomegaly is not found.

If the diagnosis of biliary atresia cannot be excluded by the diagnostic evaluation, surgical exploration should be performed as soon as possible. Laparotomy or laparoscopy must include liver biopsy and an operative cholangiogram if a gallbladder is present. The presence of yellow bile in the gallbladder implies patency of the proximal extrahepatic duct system. Radiographic visualization of cholangiographic contrast in the duodenum excludes obstruction to the distal extrahepatic ducts.

► Treatment

In the absence of surgical correction or transplantation, biliary cirrhosis, hepatic failure, and death occur, almost always by age 18–24 months.

Except for the occasional example of correctable biliary atresia, in which choledochojejunostomy is feasible, the standard procedure is hepatoportoenterostomy (Kasai pro-

cedure). Occasionally, portocholecystostomy (gallbladder Kasai procedure) may be performed if the gallbladder is present and the passage from it to the duodenum is patent. These procedures are best done in specialized centers where experienced surgical, pediatric, and nursing personnel are available. Surgery should be performed as early as possible (ideally before 45–60 days of life); the Kasai procedure should generally not be undertaken in infants older than age 4 months, because the likelihood of bile drainage at this age is very low. Orthotopic liver transplantation is now indicated for patients who do not undergo the Kasai procedure, who fail to drain bile after the Kasai procedure, or who progress to end-stage biliary cirrhosis despite surgical treatment. The 3–5-year survival rate following liver transplantation for biliary atresia is 80–90%.

Whether or not the Kasai procedure is performed, supportive medical treatment measures consist of vitamin and caloric support (vitamins A, D, K, and E and formulas containing medium-chain triglycerides [Pregestimil or Alimentum]) (see Table 21–4). Suspected bacterial infections (eg, ascending cholangitis) should be treated promptly with broad-spectrum antibiotics, and any bleeding tendency should be corrected with intramuscular vitamin K. Ascites can be managed initially with reduced sodium intake and spironolactone. Cholagogues and bile acid-binding products (cholestyramine, aluminum hydroxide gel) are of little use. The value of UDCA remains to be determined. The role of postoperative corticosteroids is controversial.

► Prognosis

When bile flow is sustained following portoenterostomy, the 10-year survival rate without liver transplantation is 25–35%. Death is usually caused by liver failure, sepsis, acidosis, or respiratory failure secondary to intractable ascites. Esophageal variceal hemorrhage develops in 40% of patients. Surprisingly, terminal hemorrhage is unusual. Occasional long-term survivors develop hepatopulmonary syndrome (intrapulmonary right to left shunting of blood resulting in hypoxia) or portopulmonary hypertension (pulmonary arterial hypertension in patients with portal hypertension). Liver transplantation has dramatically changed the outlook for these patients.

Sokol RJ et al: Screening and outcomes in biliary atresia: Summary of a National Institutes of Health workshop. *Hepatology* 2007;46:566 [PMID: 17661405].

2. Choledochal Cyst

Choledochal cysts cause 2–5% of cases of extrahepatic neonatal cholestasis; the incidence is fourfold higher in girls and higher in patients of Asian descent. In most cases, the clinical manifestations, basic laboratory findings, and histopathologic features on liver biopsy are indistinguishable from those associated with biliary atresia. Neonatal symptomatic cysts are usually associated with atresia of the distal common duct—accounting for the diagnostic dilemma—and may simply be part of the spectrum of biliary atresia. Ultrasonography or MRI reveals the presence of a cyst. Immediate surgery is indicated once abnormalities in clotting factors have been corrected and bacterial cholangitis, if present, has been treated with intravenous antibiotics. In older children, choledochal cyst presents as recurrent episodes of right upper quadrant abdominal pain, vomiting, obstructive jaundice, or pancreatitis, or as a right abdominal mass.

Excision of the cyst and choledocho-Roux-en-Y jejunal anastomosis are recommended. In some cases, because of technical problems, only the mucosa of the cyst can be removed with jejunal anastomosis to the proximal bile duct. Anastomosis of cyst to jejunum or duodenum is not recommended.

The prognosis depends on the presence or absence of associated evidence of atresia and the appearance of the intrahepatic ducts. If atresia is found, the prognosis is similar to that described in the preceding section. If an isolated extrahepatic cyst is encountered, the outcome is generally excellent, with resolution of the jaundice and return to normal liver architecture. However, bouts of ascending cholangitis may occur, particularly if intrahepatic cysts are present or obstruction of the anastomotic site develops. The risk of biliary carcinoma developing within the cyst is about 5–15% at adulthood; therefore, cystectomy or excision of cyst mucosa should be undertaken whenever possible.

Wong AM et al: Prenatal diagnosis of choledochal cyst using magnetic resonance imaging: A case report. *World J Gastroenterol* 2005;11:5082 [PMID: 16124073].

3. Spontaneous Perforation of the Extrahepatic Bile Ducts

The sudden appearance of obstructive jaundice, acholic stools, and abdominal enlargement with ascites in a sick newborn is suggestive of this condition. The liver is usually normal in size, and a yellow-green discoloration can often be discerned under the umbilicus or in the scrotum. In 24% of cases, stones or sludge obstructs the common bile duct. DIDA

scan or ERCP shows leakage from the biliary tree, and ultrasonography confirms ascites or fluid around the bile duct.

Treatment is surgical. Simple drainage, without attempts at oversewing the perforation, is sufficient in primary perforations. A diversion anastomosis is constructed in cases associated with choledochal cyst or stenosis. The prognosis is generally good.

OTHER NEONATAL HYPERBILIRUBINEMIC CONDITIONS (NONCHOLESTATIC NONHEMOLYTIC)

This group of disorders is associated with hyperbilirubinemia of two types: (1) unconjugated hyperbilirubinemia, present in breast milk jaundice, Lucey-Driscoll syndrome, congenital hypothyroidism, upper intestinal obstruction, Gilbert disease, Crigler-Najjar syndrome, and drug-induced hyperbilirubinemia; and (2) conjugated noncholestatic hyperbilirubinemia, present in the Dubin-Johnson syndrome and Rotor syndrome.

1. Unconjugated Hyperbilirubinemia

A. Breast Milk Jaundice

Persistent elevation of the indirect bilirubin fraction may occur in up to 36% of breast-fed infants. Enhanced β -glucuronidase activity in breast milk is one factor that increases absorption of unconjugated bilirubin. Substances (eg, L-aspartic acid) in casein hydrolysate formulas inhibit this enzyme. The increased enterohepatic shunting of unconjugated bilirubin exceeds the normal conjugating capacity in the liver of these infants. The mutation for Gilbert syndrome predisposes to breast milk jaundice and to more prolonged jaundice. Low volumes of ingested breast milk may also contribute to jaundice in the first week of life.

Hyperbilirubinemia does not usually exceed 20 mg/dL, with most cases in the range of 10–15 mg/dL. In patients whose bilirubin levels are above 4–5 mg/dL, the jaundice is noticeable by the fifth to seventh day of breast feeding. It may accentuate the underlying physiologic jaundice—especially early, when total fluid intake may be less than optimal. Except for jaundice, the physical examination is usually normal; urine does not stain the diaper, and the stools are golden yellow.

The jaundice peaks before the third week of life and clears before age 3 months in almost all infants, even when breast feeding is continued. All infants who remain jaundiced past age 2–3 weeks should have measurements of conjugated bilirubin to exclude hepatobiliary disease.

Kernicterus has rarely been reported in association with this condition. In special situations, breast feeding may be discontinued temporarily and replaced by formula feedings for 2–3 days until serum bilirubin decreases by 2–8 mg/dL. Cow's milk formulas inhibit the intestinal reabsorption of unconjugated bilirubin. When breast feeding is reinstated, the serum bilirubin may increase slightly, but not to the previous level. Phototherapy is not indicated in the healthy full-term infant with this condition unless bilirubin levels meet high-risk levels as defined by the American Academy of Pediatrics.

Moyer V et al: Guideline for the evaluation of cholestatic jaundice in infants: Recommendations of the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition. *J Pediatr Gastroenterol Nutr* 2004;39:115 [PMID: 15269615].

B. Congenital Hypothyroidism

Although the differential diagnosis of indirect hyperbilirubinemia should always include congenital hypothyroidism, the diagnosis may be obvious from other clinical and physical clues or from the newborn screening results. The jaundice clears quickly with replacement thyroid hormone therapy, although the mechanism is unclear.

Tiker F: Congenital hypothyroidism and early severe hyperbilirubinemia. *Clin Pediatr (Phila)* 2003;42:365 [PMID: 12800733].

C. Upper Intestinal Obstruction

The association of indirect hyperbilirubinemia with high intestinal obstruction (eg, duodenal atresia, annular pancreas, pyloric stenosis) in the newborn has been observed repeatedly; the mechanism is unknown. Diminished levels of hepatic glucuronyl transferase have been found on liver biopsy in pyloric stenosis, and genetic studies suggest that this indirect hyperbilirubinemia is an early sign of Gilbert syndrome.

Treatment is that of the underlying obstructive condition (usually surgical). Jaundice disappears once adequate nutrition is achieved.

Trioche P et al: Jaundice with hypertrophic pyloric stenosis is an early manifestation of Gilbert's syndrome. *Arch Dis Child* 1999;81:301 [PMID: 10490432].

D. Gilbert Syndrome

Gilbert syndrome is a common form (3–7% of the population) of familial hyperbilirubinemia associated with a partial reduc-

tion of hepatic bilirubin uridine diphosphate-glucuronyl transferase activity and perhaps an abnormality in the function or amount of one or more hepatocyte membrane protein carriers. Accelerated jaundice of the newborn, breast milk jaundice, and jaundice with intestinal obstruction may be present in affected infants. During puberty and beyond, mild fluctuating jaundice, especially with illness, and vague constitutional symptoms are common. Shortened red blood cell survival time in some patients is thought to be caused by reduced activity of enzymes involved in heme biosynthesis (protoporphyrinogen oxidase). Subsidence of hyperbilirubinemia has been achieved in patients by administration of phenobarbital (5–8 mg/kg/d), although this therapy is not justified.

The disease is inherited as an abnormality of the promoter region of uridine diphosphate-glucuronyl transferase-1; however, another factor is necessary for disease expression. The homozygous (16%) and heterozygous states (40%) are common. Males are affected more often than females (4:1). Serum unconjugated bilirubin is generally less than 3–6 mg/dL, although unusual cases may exceed 8 mg/dL. The findings on liver biopsy and most other LFTs are normal except for prolonged indocyanine green and bromosulphthalein retention. An increase of 1.4 mg/dL or more in the level of unconjugated bilirubin after a 2-day fast (300 kcal/d) is consistent with the diagnosis of Gilbert syndrome. Genetic testing is available but rarely needed. No treatment is necessary.

Ulgentalp A et al: Analyses of polymorphism for UGT1*1 exon 1 promoter in neonates with pathologic and prolonged jaundice. *Biol Neonate* 2003;83:258 [PMID: 12743455].

E. Crigler-Najjar Syndrome

Infants with type 1 Crigler-Najjar syndrome usually develop rapid severe elevation of unconjugated bilirubin (> 30–40 mg/dL) with neurologic consequences (kernicterus). Consanguinity is often present. Prompt recognition of this entity and treatment with exchange transfusions are required, followed by phototherapy. Some patients have no neurologic signs until adolescence or early adulthood, at which time deterioration may occur suddenly. For diagnosis of this condition it is useful to obtain a duodenal bile specimen, which characteristically will be colorless and contain a predominance of unconjugated bilirubin, small amounts of monoconjugates, and only traces of diconjugated bilirubin. Phenobarbital administration does not significantly alter these findings, nor does it lower serum bilirubin levels. The deficiency in uridine diphosphate-glucuronyl transferase-1 is inherited in an autosomal recessive pattern. A combination of phototherapy and cholestyramine may keep bilirubin levels below 25 mg/dL. The use of tin protoporphyrin or tin mesoporphyrin remains experimental. Orlistat therapy may decrease bilirubin in a subset of patients. Liver transplantation is curative and may prevent kernicterus if performed

early. An auxiliary orthotopic transplantation also relieves the jaundice while the patient retains native liver. Hepatocyte transplantation is experimental.

A milder form (type 2) with both autosomal dominant and recessive inheritance is rarely associated with neurologic complications. Hyperbilirubinemia is less severe, and the bile is pigmented and contains bilirubin monoglucuronide and diglucuronide. Patients with this form respond to phenobarbital with lowering of serum bilirubin levels. An increased proportion of monoconjugated and diconjugated bilirubin in the bile follows phenobarbital treatment. Liver biopsy findings and LFTs are consistently normal in both types.

F. Drug-Induced Hyperbilirubinemia

Vitamin K₃ (menadiol) may elevate indirect bilirubin levels by causing hemolysis. Vitamin K₁ (phytonadione) can be used safely in neonates. Carbamazepine can cause conjugated hyperbilirubinemia in infancy. Rifampin and antiretroviral protease inhibitors may cause unconjugated hyperbilirubinemia. Other drugs (eg, ceftriaxone, sulfonamides) may displace bilirubin from albumin, potentially increasing the risk of kernicterus—especially in the sick premature infant.

2. Conjugated Noncholestatic Hyperbilirubinemia (Dubin-Johnson Syndrome & Rotor Syndrome)

These diagnoses are suspected when persistent or recurrent conjugated hyperbilirubinemia and jaundice occur and liver function tests are normal. The basic defect in Dubin-Johnson syndrome is in the multiple organic anion transport protein (MRP2) of the bile canaliculus, causing impaired hepatocyte excretion of conjugated bilirubin into bile. A variable degree of impairment in uptake and conjugation complicates the clinical picture. Transmission is autosomal recessive, so a positive family history is occasionally obtained. In Rotor syndrome, the defect lies in hepatic uptake and storage of bilirubin. Bile acids are metabolized normally, so that cholestasis does not occur. Bilirubin values range from 2–5 mg/dL, and other LFTs are normal.

In Rotor syndrome, the liver is normal; in Dubin-Johnson syndrome, it is darkly pigmented on gross inspection and may be enlarged. Microscopic examination reveals numerous dark-brown pigment granules consisting of polymers of epinephrine metabolites, especially in the centrilobular regions. However, the amount of pigment varies within

families, and some jaundiced family members may have no demonstrable pigmentation in the liver. Otherwise, the liver is histologically normal. Oral cholecystography fails to visualize the gallbladder in Dubin-Johnson syndrome, but is normal in Rotor syndrome. Differences in the excretion patterns of bromosulfophthalein, in results of DIDA cholecintigraphy, in urinary coproporphyrin I and III levels, and in the serum pattern of monoglucuronide and diglucuronide conjugates of bilirubin can help distinguish between these two conditions. Genotyping of *MRP2* is available.

Choleretic agents (eg, UDCA) may help reduce the cholestasis in infants with Dubin-Johnson syndrome.

HEPATITIS A

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Gastrointestinal upset (anorexia, vomiting, diarrhea).
- ▶ Jaundice.
- ▶ Liver tenderness and enlargement.
- ▶ Abnormal LFTs.
- ▶ Local epidemic of hepatitis A infection.
- ▶ Positive anti-hepatitis A virus (HAV) IgM antibody.

▶ General Considerations

Hepatitis A virus (HAV) infection occurs in both epidemic and sporadic fashion (Table 21–6). Transmission by the fecal-oral route explains epidemic outbreaks from contaminated food or water supplies, including by food handlers. Viral particles are found in stools during the acute phase of hepatitis A infection and are similar in appearance to the enteroviruses. Sporadic cases usually result from contact with an infected individual. Transmission through blood products obtained during the viremic phase is a rare event, although it has occurred in a newborn nursery. The overt form of the disease is easily recognized by the clinical manifestations. However, two thirds of children are asymptomatic, and two thirds of symptomatic children are anicteric. Therefore, most symptomatic children with HAV are believed to have gastroenteritis. Lifelong immunity to HAV follows infection. In developing countries, most children are

HAV, hepatitis A virus; HBC, hepatitis B core; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HDV, hepatitis D (delta) virus; HEV, hepatitis E virus; PCR, polymerase chain reaction.

exposed to HAV by age 10 years, while only 20% are exposed by age 20 years in developed countries.

Antibody to HAV appears within 1-4 weeks of clinical symptoms. Although the great majority of children with infectious hepatitis are asymptomatic or have mild disease and recover completely, some will develop fulminant hepatitis leading to death or requiring liver transplantation.

HEPATITIS VIRUS ABBREVIATIONS

HAV	Hepatitis A virus
Anti-HAV IgM	IgM antibody to HAV
HBV	Hepatitis B virus
HBsAg	HBV surface antigen
HBcAg	HBV core antigen
HBeAg	HBVe antigen
Anti-HBs	Antibody to HBsAg
Anti-HBc	Antibody to HBcAg
Anti-HBc IgM	IgM antibody to HBcAg
Anti-HBe	Antibody to HBeAg
HCV	Hepatitis C virus
Anti-HCV	Antibody to HCV
HDV	Hepatitis D (delta) virus
Anti-HDV	Antibody to HDV
HEV	Hepatitis E virus
Anti-HEV	Antibody to HEV

► Clinical Findings

A. History

Features of the patient's history may include direct exposure to a previously jaundiced individual, consumption of seafood, contaminated water or imported fruits or vegetables, attendance in a day care center, or recent travel to an area of endemic infection. Following an incubation period of 15-40 days, the initial nonspecific symptoms usually precede the development of jaundice by 5-10 days.

B. Symptoms and Signs

Fever, anorexia, vomiting, headache, and abdominal pain are typical symptoms. Dark urine precedes jaundice, which peaks in 1-2 weeks and then begins to subside. The stools may become light or clay-colored during this time. Clinical improvement can occur as jaundice develops. Tender hepatomegaly and jaundice are typically present; splenomegaly is variable.

C. Laboratory Findings

Aminotransferases and conjugated and unconjugated bilirubin levels are elevated. The leukocyte count is normal to low; the sedimentation rate is elevated. Serum proteins are generally normal, but an elevation of the γ -globulin fraction (> 2.5 g/dL) can occur and indicates a worse prognosis. Hypoalbuminemia, hypoglycemia, and marked prolongation of prothrombin time (international normalized ratio [INR] > 2.0) are serious prognostic findings. Diagnosis is made by serology. A positive anti-HAV IgM indicates acute disease, whereas IgG anti-HAV persists after recovery.

Percutaneous liver biopsy is rarely indicated. “Balloon cells” and acidophilic bodies are characteristic histologic findings. Liver cell necrosis may be diffuse or focal, with accompanying infiltration of inflammatory cells containing polymorphonuclear leukocytes, lymphocytes, macrophages, and plasma cells, particularly in portal areas. Some bile duct proliferation may be seen in the perilobular portal areas alongside areas of bile stasis. Regenerative liver cells and proliferation of reticuloendothelial cells are present. Occasionally massive hepatocyte necrosis occurs, portending a bad prognosis.

► Differential Diagnosis

Before jaundice appears, the symptoms are those of nonspecific viral enteritis. Other diseases with somewhat similar onset include pancreatitis, infectious mononucleosis, leptospirosis, drug-induced hepatitis, Wilson disease, autoimmune hepatitis, and other hepatitis viruses. Acquired CMV disease may also mimic HAV, although lymphadenopathy is usually present in the former.

► Prevention

Isolation of the patient during initial phases of illness is indicated, although most patients with hepatitis A are non-infectious by the time the disease becomes overt. Stool, diapers, and other fecally stained clothing should be handled with care for 1 week after the appearance of jaundice.

Passive-active immunization of exposed susceptible persons can be achieved by giving standard immune globulin, 0.02–0.04 mL/kg intramuscularly. Illness is prevented in 80–90% of individuals if immune globulin is given within 1–2 weeks of exposure. Alternatively, HAV vaccine can be given following exposure, with equal efficacy at preventing symptomatic HAV infection. Individuals traveling to endemic disease areas should receive HAV vaccine or 0.02–0.06 mL/kg of immune globulin as prophylaxis if there is insufficient time (< 2 weeks) for the initial dose of vaccine. All children older than 12 months with chronic liver disease should receive two doses of HAV vaccine 6 months apart. It is currently recommended that all children 12–23 months of age receive HAV vaccination in the United States.

► Treatment

No specific treatment measures are required. Sedatives and corticosteroids should be avoided. At the start of the illness, a light diet is preferable. During the icteric phase, lower-fat foods may diminish gastrointestinal symptoms but do not affect overall outcome. Drugs and elective surgery should be avoided.

► Prognosis

Ninety-nine percent of children recover without sequelae. In rare cases of fulminant hepatitis, the patient may die in 5 days or may survive as long as 1–2 months without liver

transplantation. The prognosis is poor if hepatic coma or ascites develop; orthotopic liver transplantation is indicated under these circumstances. Incomplete resolution can cause a prolonged hepatitis; however, resolution invariably occurs without long-term hepatic sequelae. Rare cases of aplastic anemia following acute infectious hepatitis have been reported. A benign relapse of symptoms may occur in 10–15% of cases after 6–10 weeks of apparent resolution.

HEPATITIS B

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Gastrointestinal upset, anorexia, vomiting, diarrhea.
- Jaundice, tender hepatomegaly, abnormal LFTs.
- Serologic evidence of hepatitis B disease: HBsAg, HBeAg, anti-HBc IgM.
- History of parenteral, sexual, or household exposure or maternal HBsAg carriage.

► General Considerations

In contrast to hepatitis A, hepatitis B virus (HBV) infection has a longer incubation period of 45–160 days (see Table 21–6). The disease is caused by a DNA virus that is usually acquired perinatally from a carrier mother, or later in life from exposure to contaminated blood through shared needles, needle sticks, skin piercing, or tattoos. It is also sexually transmitted. Transmission via blood products has been almost eliminated by anti-HBc antibody donor-screening protocols. The complete HBV particle is composed of a core (28-nm particle) that is found in the nucleus of infected liver cells and a double outer shell (surface antigen). The surface antigen in blood is termed HBsAg. The antibody to it is anti-HBs. The core antigen is termed HBcAg and its antibody is anti-HBc. A specific anti-HBc IgM antibody occurs during primary viral replication.

Another important antigen-antibody system associated with HBV disease is the “e” antigen system. HBeAg, a truncated soluble form of HBcAg, appears in the serum of

infected patients early and correlates with active virus replication. Persistence of HBeAg is a marker of infectivity, whereas the appearance of anti-HBe generally implies termination of viral replication. However, HBV mutant viruses (precore mutant) may replicate with negative HBeAg tests and positive tests for anti-HBe antibody. Other serologic markers indicating viral replication include the presence of HBV DNA polymerase and circulating HBV DNA.

► Clinical Findings

A. Symptoms and Signs

Symptoms of acute hepatitis B infection include slight fever (which may be absent) and mild gastrointestinal upset. Visible jaundice is usually the first significant finding. It is accompanied by darkening of the urine and pale or clay-colored stools. Many patients, particularly infants, are asymptomatic. Hepatomegaly is frequently present. Occasionally a symptom complex (caused by antigen-antibody complexes) of macular rash, urticarial lesions, and arthritis antedates the appearance of icterus. Occasionally, HBV infection presents as a glomerulonephritis or nephrotic syndrome from immune complexes. When acquired vertically at birth, the disease is usually asymptomatic despite ongoing liver injury.

B. Laboratory Findings

To diagnose acute HBV infection, the HBsAg and anti-HBc IgM are the only tests needed. To document recovery, immunity, or response to the HBV vaccine, the anti-HBs is useful. To document previous HBV infection, the anti-HBc is most useful. If HBsAg persists after 8 weeks in acute infections, it may signify a chronic infection, although chronic infection is defined as lasting 6 months or more. Vertical transmission to newborns is documented by positive HBsAg. LFT results are similar to those discussed earlier for hepatitis A. Liver histology is similar for HAV and HBV disease, although specific stains may detect HBcAg or HBsAg in the liver, and ground-glass appearance to hepatocytes may be present. Renal involvement may be suspected on the basis of urinary findings suggesting glomerulonephritis or nephrotic syndrome.

► Differential Diagnosis

The differentiation between HAV and HBV disease is made easier by a history of parenteral exposure, an HBsAg-positive parent, or an unusually long period of incubation. HBV and hepatitis C virus (HCV) infection or Epstein-Barr virus (EBV) infection are differentiated serologically. The history may suggest a drug-induced hepatitis, especially if a serum sickness prodrome is reported. Autoimmune hepatitis, Wilson disease, hemochromatosis, nonalcoholic fatty liver disease, and α_1 -antitrypsin deficiency should also be considered. Drug-induced hepatitis is diagnosed if there is a history of specific drug exposure; autoimmune hepatitis is diag-

nosed if autoimmune markers are present; Wilson disease is diagnosed if ceruloplasmin levels are abnormal; hemochromatosis is diagnosed if transferrin saturation is high; α_1 -antitrypsin deficiency is diagnosed if serum α_1 -antitrypsin concentration is decreased; and steatohepatitis is diagnosed if liver biopsy findings are suggestive.

► Prevention

Control of hepatitis B in the population is based on screening of blood donors and pregnant women, use of properly sterilized needles and surgical equipment, avoidance of sexual contact with carriers, and vaccination of all infants and adolescents, as well as household contacts, sexual partners, medical personnel, and those at high risk. Universal immunization of all infants born in the United States and of adolescents is now recommended, as it is in most other countries. The vaccine is highly effective for preexposure prophylaxis. (See Chapter 9.) For postexposure prophylaxis, administration of HBIG (0.06 mL/kg intramuscularly, given as soon as possible after exposure, up to 7 days) and initiation of vaccination are recommended. The risk of vertical transmission is dramatically reduced with the combination of postpartum vaccination and immunoprophylaxis.

► Treatment

Supportive measures such as bed rest and a nutritious diet are used during the active symptomatic stage of disease. Corticosteroids are contraindicated. No other treatment is needed for acute HBV infection. For patients with progressive disease (chronic hepatitis with fibrosis), there are currently two treatment options. Treatment with α -interferon (5–6 million U/m² body surface area injected subcutaneously three times a week for 4–6 months) inhibits viral replication in 30–40% of patients, normalizes the ALT level, and leads to the disappearance of HBeAg and the appearance of anti-HBe. Side effects are common. Younger children may respond better than older children. Orally administered lamivudine therapy (3 mg/kg/d up to 100 mg/d for 12 months) leads to a successful response in 25% of treated children, with minimal side effects. However, resistant organisms can emerge. Pegylated interferon, several oral antiviral agents, and combination therapy are promising options being tested in children. Asymptomatic HBsAg carriers (normal serum ALT, no hepatomegaly) do not respond to either therapy. Liver transplantation is successful in acute fulminant hepatitis B; however, reinfection is common following liver transplantation for chronic hepatitis B. Chronic HBIG therapy or lamivudine therapy reduces recurrence after transplantation.

► Prognosis

The prognosis is good, although fulminant hepatitis or chronic hepatitis and cirrhosis may supervene in up to 10% of patients. The course of the acute disease is variable, but

jaundice seldom persists for more than 2 weeks. HBsAg disappears in 95% of cases at the time of clinical recovery. Persistent asymptomatic infection may occur, particularly in children with vertical transmission, Down syndrome, or leukemia, and in those undergoing chronic hemodialysis. Persistence of neonatally acquired HBsAg occurs in 70–90% of infants without immunoprophylaxis or vaccination, and the presence of HBeAg in the HBsAg carrier indicates ongoing viral replication. However, 1–2% of children infected at birth will show spontaneous seroconversion of HBeAg each year. If HBV infection is acquired later in childhood, HBV is cleared and recovery occurs in 90–95% of patients. Chronic hepatitis B disease predisposes the patient to development of hepatocellular carcinoma. Once chronic HBV infection is established, surveillance for development of hepatocellular carcinoma with serum α -fetoprotein is performed biannually and ultrasonography yearly. Routine HBV vaccination of newborns in endemic countries has reduced the incidence of fulminant hepatic failure, chronic hepatitis, and hepatocellular carcinoma in children.

HEPATITIS C

► General Considerations

Hepatitis C virus (HCV) virus is the most common cause of non-B chronic hepatitis (90% of post-transfusion hepatitis cases) (see Table 21–6). Risk factors in adults and older children include illicit use of intravenous drugs (40%), occupational or sexual exposure (10%), and transfusions (10%); 30% of cases have no known risk factors. In children, most cases are now associated with transmission from an infected mother or other household transmission. In the past, children with hemophilia or on chronic hemodialysis were at significant risk. The risk from transfused blood products has diminished greatly (from 1–2:100 to 1:100,000 units of blood) since the advent of blood testing for ALT and anti-HCV. HCV infection has also been caused by contaminated immune serum globulin preparations. Vertical transmission from HCV-infected mothers occurs more commonly with mothers who are HIV-positive (15–20%) compared with those who are HIV-negative (5–6%). About

0.4% of adolescents and 1.5% of adults in the United States have serologic evidence of infection. Vertically infected infants often have elevated ALT levels, but do not appear ill; long-term outcome is unknown, however 20–30% of infants recover completely. Transmission of the virus from breast milk is probably rare. HCV rarely causes fulminant hepatitis in children or adults in Western countries, but different serotypes do so in Asia.

HCV is a single-stranded RNA virus in the flavivirus family. At least seven genotypes of HCV exist. Several well-defined HCV antigens are the basis for serologic antibody tests. The third-generation enzyme-linked immunosorbent assay (ELISA) test for anti-HCV is highly accurate. Anti-HCV is generally present when symptoms occur; however, test results may be negative in the first few months of infection. The presence of HCV RNA in serum indicates active infection.

► Clinical Findings

A. Symptoms and Signs

The incubation period is 1–5 months, with insidious onset of symptoms. Many childhood cases, especially those acquired vertically, are asymptomatic despite development of chronic hepatitis. Flulike prodromal symptoms and jaundice occur in less than 25% of cases. Hepatosplenomegaly may or may not be evident in chronic hepatitis. Ascites, clubbing, palmar erythema, or spider angiomas are rare and indicate progression to cirrhosis.

B. Laboratory Findings

Fluctuating mild to moderate elevations of aminotransferases over long periods are characteristic of chronic HCV infection. Diagnosis is established by the presence of anti-HCV (third-generation ELISA) confirmed by the radioimmunoassay or HCV RNA by PCR. Anti-HCV is acquired passively at birth from infected mothers and cannot be used to confirm disease in the neonate for the first 15 months. HCV RNA testing should be performed in suspected cases. Results of this test may be negative in the first month of life, but become positive by 4 months.

Percutaneous liver biopsy should be considered in chronic cases. Histologic examination shows portal triaditis with chronic inflammatory cells, occasional lymphocyte nodules in portal tracts, mild macrovesicular steatosis, and variable bridging necrosis, fibrosis, and cirrhosis; most children have only mild to moderate fibrosis on liver biopsy. Cirrhosis in adults generally requires 20–30 years of chronic HCV infection, but it has occasionally developed sooner in children.

► Differential Diagnosis

HCV disease should be distinguished from HAV and HBV disease by serologic testing. Other causes of cirrhosis in children should be considered in cases of chronic illness,

such as Wilson disease or α_1 -antitrypsin deficiency. Chronic hepatitis may also be caused by drug reactions, autoimmune disease, or steatohepatitis.

► Treatment

Treatment of acute HCV hepatitis is supportive. Indications for treatment of chronic infection will be determined by current clinical trials. Chronic hepatitis caused by HCV responds to combined interferon- α (3 million U/m² three times a week for 6–12 months) and ribavirin (15 mg/kg/d), with sustained response rates of 30–50%. The response is poorer in those who have infections with genotype 1a or 1b and very good for genotypes 2 and 3. Long-acting (pegylated) interferon (with or without ribavirin), which has been studied in adults, is more effective, with sustained response rates up to 60–70%. This therapy is being tested in children. End-stage liver disease secondary to HCV responds well to liver transplantation, although reinfection is common and is occasionally rapidly progressive. Pre- and post-transplant antiviral therapy may reduce the risk of reinfection. There is no vaccine, and no benefit from using immune globulin in infants born to infected mothers. Elective cesarean delivery of HCV-infected pregnant women with a high titer of circulating virus may lessen the likelihood for vertical transmission.

► Prognosis

In adults, 70–80% of HCV patients develop chronic hepatitis, and cirrhosis develops in 20% of those with chronic infection for 10–30 years. Alcohol intake, and concomitant obesity and fatty liver, increase this risk. HCV is now the leading indication for liver transplantation in adults. A strong association exists between chronic HCV disease and the development of hepatocellular carcinoma after as little as 15 years. The outcome in children is less well defined, although cirrhosis may develop rapidly in rare cases or after decades. About 50% of children infected by transfusion in the first few years of life develop chronic infection. The prognosis for infants infected at birth with concomitant HIV infection is unknown, but the course appears benign for the first 10 years of life. In adults, chronic HCV infection has been associated with mixed cryoglobulinemia, polyarteritis nodosa, a sicca-like syndrome, and membranoproliferative glomerulonephritis.

Syriopoulou V et al: Mother to child transmission of hepatitis C virus: Rate of infection and risk factors. *Scand J Infect Dis* 2005;37:350 [PMID: 16051571].

HEPATITIS D (DELTA AGENT)

The hepatitis D virus (HDV) is a 35-nm defective virus that requires a coat of HBsAg to be infectious (see Table 21–6). Thus, HDV infection can occur only in the presence of HBV infection. In developing countries, transmission is by intimate contact; in western countries, by parenteral exposure. HDV is rare in North America. HDV can infect simultaneously with HBV, causing acute hepatitis, or can superinfect a patient with chronic HBV infection, predisposing the individual to chronic hepatitis or fulminant hepatitis. In children, the association between chronic HDV coinfection with HBV and chronic hepatitis and cirrhosis is strong. Vertical HDV transmission is rare. The diagnosis of HDV is made by anti-HDV IgM or detection of HDV by PCR. Treatment is directed at therapy for HBV infection or for fulminant hepatic failure.

Niro GA et al: Treatment of hepatitis D. *J Viral Hepat* 2005;12:2 [PMID: 15655042].

HEPATITIS E

Hepatitis E virus (HEV) infection is a cause of enterically transmitted, epidemic non-A, non-B hepatitis (see Table 21–6). It is rare in the United States. HEV is a calicivirus-like agent that is transmitted via the fecal-oral route. It occurs predominantly in developing countries in association with waterborne epidemics, and has only a 3% secondary attack rate in household contacts. Areas reporting epidemics include Southeast Asia, China, the Indian subcontinent, the Middle East, northern and western Africa, Mexico, and Central America. Its clinical manifestations resemble HAV infection except that symptomatic disease is rare in children, more common in adolescents and adults, and is associated with a high mortality (10–20%) in pregnant women, particularly in the third trimester. Diagnosis is established by detecting anti-HEV antibody. The outcome in nonpregnant individuals is benign, with no chronic hepatitis or chronic carrier state reported. A recombinant vaccine is being tested. There is no effective treatment.

Shrestha MP et al: Safety and efficacy of a recombinant hepatitis E vaccine. *N Engl J Med* 2007;356:895 [PMID: 17329696].

OTHER HEPATITIS VIRUSES

Other undiscovered viruses may be the cause of cases of fulminant hepatitis in children that can be associated with the development of aplastic anemia in a small proportion of patients recovering from hepatitis and in 10–20% of those

undergoing liver transplantation for indeterminate fulminant hepatitis. Parvovirus has been associated with fulminant hepatitis; the prognosis is relatively good in children. Infectious mononucleosis (EBV) is commonly associated with acute hepatitis. CMV, adenovirus, herpes simplex virus, HHV-6, HIV, brucella, and leptospirosis are other infectious causes of acute hepatitis.

Cacheux W et al: HHV-6-related acute liver failure in two immunocompetent adults: Favourable outcome after liver transplantation and/or ganciclovir therapy. *J Intern Med.* 2005;258:573 [PMID: 16313481].

ACUTE LIVER FAILURE (FULMINANT HEPATIC FAILURE)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Acute hepatitis with deepening jaundice.
- ▶ Extreme elevation of AST and ALT.
- ▶ Prolonged prothrombin time and INR.
- ▶ Encephalopathy and cerebral edema.
- ▶ Asterixis and fetor hepaticus.

▶ General Considerations

Acute liver failure (ALF) is defined as acute liver dysfunction resulting in hepatic coma and coagulopathy (INR > 2.0) within 6 weeks after onset. In young children, encephalopathy may be difficult to detect or absent. Mortality is approximately 50% in children (without liver transplantation). An unusually virulent infectious agent or aggressive host immune response is postulated in many cases. In the first few weeks of life, ALF can be caused by herpes simplex, enteroviruses, adenovirus, galactosemia, fructose intolerance, tyrosinemia, neonatal iron storage disease, respiratory chain and fatty acid oxidation defects, familial erythrophagocytic histiocytosis, bile acid synthesis defects, and peroxisomal diseases. In older infants and children, the most common identified diagnoses are idiopathic, acetaminophen toxicity, autoimmune hepatitis, and infections. HBV, parvovirus, and HEV are sometimes causative. HAV rarely is responsible in the United States. Patients with immunologic deficiency diseases and those receiving immunosuppressive drugs are vulnerable to herpesviruses. In children with HIV infection, nucleoside reverse transcriptase inhibitors have triggered lactic acidosis and liver failure. In patients with underlying respiratory chain defects, valproic acid may trigger ALF. In older children, Wilson disease, acute fatty liver of pregnancy, Reye syndrome, drugs (eg, acetaminophen, anesthetic agents, valproic acid) or tox-

ins (eg, poisonous mushrooms, herbs, “ecstasy”), leukemia, and cardiac dysfunction must also be considered. Some 30–40% of cases in children are without identifiable cause and labeled indeterminate.

▶ Clinical Findings

In some patients, the disease proceeds in a rapidly fulminant course with deepening jaundice, coagulopathy, hyperammonemia, ascites, a rapidly shrinking liver, and progressive coma. Terminally, AST and ALT, which were greatly elevated (2000–10,000 U/L), may improve at the time when the liver is getting smaller and undergoing massive necrosis and collapse. Some patients start with a course typical of benign hepatitis and then suddenly become severely ill during the second week of the disease. Fever, anorexia, vomiting, and abdominal pain may be noted, and worsening of LFTs parallels changes in sensorium or impending coma. Hyperreflexia and a positive extensor plantar response are seen. A characteristic breath odor (fetor hepaticus) is present. A severe coagulopathy precedes impairment of renal function, manifested by either oliguria or anuria, which is an ominous sign. Characteristic laboratory findings include elevated serum bilirubin levels (usually > 15–20 mg/dL), sustained very high AST and ALT (> 3000 U/L) that may decrease terminally, low serum albumin, hypoglycemia, and prolonged prothrombin time and INR. Blood ammonia levels become elevated, whereas blood urea nitrogen is often very low. Hyperpnea is frequent, and mixed respiratory alkalosis and metabolic acidosis are present.

▶ Differential Diagnosis

Infectious, autoimmune, metabolic, and drug or toxin causes are most common. Patients with Reye syndrome or urea cycle defects are typically anicteric. Wilson disease, autoimmune hepatitis, acute leukemia, cardiomyopathy, and Budd-Chiari syndrome should be considered. Acetaminophen overdose, herbal remedies, and other toxins (eg, “ecstasy”) need to be considered even if the history is negative.

▶ Complications

The development of renal failure and depth of hepatic coma determine the prognosis. Patients in grade 4 coma (unresponsiveness to verbal stimuli, decorticate or decerebrate posturing) rarely survive without transplantation and may have residual central nervous system deficits. Cerebral edema, which usually accompanies coma, is frequently the cause of death. Extreme prolongation of prothrombin time or INR greater than 4 predicts poor recovery except with acetaminophen overdose. Sepsis, hemorrhage, renal failure, or cardiorespiratory arrest is a common terminal event. The rare survivor of advanced disease without transplantation may have residual fibrosis or even cirrhosis.

▶ Treatment

The most effective therapy is excellent critical care. Several therapies have failed to affect outcome, including exchange transfusion, plasmapheresis with plasma exchange, total body washout, charcoal hemoperfusion, and hemodialysis using a special high-permeability membrane. Hyperammonemia and bleeding should be controlled. Extracorporeal hepatic support devices are being developed to help bridge patients to liver transplantation or allow for liver regeneration. Orthotopic liver transplantation is successful in 60–85% of cases; however, patients in grade 4 coma may not always recover cerebral function. Therefore, patients in ALF should be transferred prior to the development of hepatic coma to centers where liver transplantation can be performed. Criteria for deciding when to perform transplantation are not firmly established; however, serum bilirubin over 20 mg/dL, INR greater than 4, and factor V levels less than 20% indicate a poor prognosis. Living related donors may be required for transplantation in a timely fashion. The prognosis is better for acetaminophen ingestion, particularly when *N*-acetylcysteine treatment is given.

Corticosteroids may be harmful, except in autoimmune hepatitis for which steroids may reverse the ALF. Acyclovir is essential in herpes simplex infection. Sterilization of the colon with oral antibiotics such as metronidazole, neomycin, or gentamicin is recommended. An alternative is acidification of the colon with lactulose, 1–2 mL/kg three or four times daily, which reduces blood ammonia levels and traps ammonia in the colon. Some centers use *N*-acetylcysteine in all patients, although it is only of proven benefit in acetaminophen toxicity.

Close monitoring of fluid and electrolytes is mandatory and requires a central venous line. Ten percent dextrose solutions should be infused (6–8 mg/kg/min) to maintain normal blood glucose. Diuretics, sedatives, and tranquilizers should be used sparingly. Early signs of cerebral edema are treated with infusions of mannitol (0.5–1.0 g/kg). Comatose patients are intubated, given mechanical ventilatory support, and monitored for signs of infection. Coagulopathy is treated with fresh-frozen plasma, recombinant factor VIIa, other clotting factor concentrates, platelet infusions, or exchange transfusion. Plasmapheresis and hemodialysis may help stabilize a patient while awaiting liver transplantation. Epidural monitoring for increased intracranial pressure (hepatic coma stages 3 and 4) in patients awaiting liver transplantation is advocated by some. Artificial hepatic support devices are being developed. Continuous venous–venous dialysis may be helpful to maintain fluid balance. Prophylactic immune globulin, 0.02 mL/kg intramuscularly, should be given to close contacts of patients with HAV infection.

▶ Prognosis

The prognosis is primarily dependent on etiology and depth of coma. Children with acute acetaminophen toxicity have a high rate of spontaneous survival. Only 20–30% of children with

stage 3 or 4 hepatic encephalopathy will have a spontaneous recovery. In children with indeterminate ALF, 40% will have a spontaneous recovery. Data from a recent large study suggest that the spontaneous recovery rate is about 40–50% when all causes of ALF are combined; 30% of patients will receive a liver transplant; and 20% will die without a transplant. Exchange transfusions or other modes of heroic therapy do not improve survival figures. The presence of nests of liver cells amounting to more than 25% of the total cells seen on liver biopsy examination and rising levels of clotting factors V and VII, coupled with rising levels of serum α -fetoprotein, may signify a more favorable prognosis. The survival rate in patients who undergo liver transplantation is 60–85%.

AUTOIMMUNE HEPATITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Acute or chronic hepatitis.
- ▶ Hypergammaglobulinemia.
- ▶ Positive antinuclear antibodies (ANA), anti-smooth muscle antibodies (ASMA), anti-liver-kidney microsomal (LKM) antibodies, or anti-soluble liver antibodies (SLA).

▶ General Considerations

Autoimmune hepatitis (AIH) is most common in adolescent girls, although it occurs at all ages and in either sex. Rarely, AIH evolves from drug-induced hepatitis (eg, minocycline) or may develop in conjunction with such diseases as ulcerative colitis, Sjögren syndrome, or autoimmune hemolytic anemia. Wilson disease, α_1 -antitrypsin deficiency, cystic fibrosis, and bile acid synthesis defects may present similarly as chronic hepatitis. A positive HBsAg test implicates HBV, and a positive HCV PCR suggests HCV infection. Positive autoantibodies, elevated serum IgG, and systemic manifestations (eg, arthralgia, weight loss, acne, and amenorrhea) are characteristic of AIH.

A genetic susceptibility to development of this entity is suggested by the increased incidence of the histocompatibility antigens HLA-A1 and HLA-B8. Increased autoimmune

disease in families of patients and a high prevalence of seroimmunologic abnormalities have been noted in relatives. Occasionally patients have an “overlap syndrome” of AIH and primary sclerosing cholangitis.

► Clinical Findings

Fever, malaise, recurrent or persistent jaundice, skin rash, arthritis, amenorrhea, gynecomastia, acne, pleurisy, pericarditis, or ulcerative colitis may be found in the history of these patients, or asymptomatic hepatomegaly or splenomegaly may be found on examination. Occasionally patients present in acute liver failure. Cutaneous signs of chronic liver disease may be noted (eg, spider angiomas, palmar erythema, and digital clubbing). Hepatosplenomegaly is frequently present.

LFTs reveal moderate elevations of serum bilirubin, AST, ALT, and serum alkaline phosphatase. Serum albumin may be low. Serum IgG levels are strikingly elevated (in the range of 2–6 g/dL). Low levels of C3 complement have been reported. Three subtypes of disease have been described based on autoantibodies present: type 1—anti-smooth muscle (antiactin); type 2—anti-LKM (anti-cytochrome P-450); and type 3—anti-SLA.

Histologic examination of liver biopsy specimens shows loss of the lobular limiting plate, and interface hepatitis (“piecemeal” necrosis). Portal fibrosis, an inflammatory reaction of lymphocytes and plasma cells in the portal areas and perivascularly, and some bile duct and Kupffer cell proliferation and pseudolobule formation may be present. Cirrhosis may exist at diagnosis in up to 50% of patients.

► Differential Diagnosis

Laboratory and histologic findings differentiate other types of chronic hepatitis (eg, HBV, HCV, and HDV infection; steatohepatitis; Wilson disease; α_1 -antitrypsin deficiency; primary sclerosing cholangitis). Primary sclerosing cholangitis occasionally presents in a manner similar to AIH, including the presence of autoantibodies. Wilson disease and α_1 -antitrypsin deficiency must be excluded if HBV and HCV studies are negative. Anti-HCV antibodies can be falsely positive and should be confirmed by HCV PCR. Drug-induced (minocycline, isoniazid, methyldopa, pemoline) chronic hepatitis should be ruled out.

► Complications

Untreated disease that continues for months to years eventually results in postnecrotic cirrhosis, with complications of portal hypertension. Persistent malaise, fatigue, amenorrhea, and anorexia parallel disease activity. Bleeding from esophageal varices and development of ascites usually usher in hepatic failure.

► Treatment

Corticosteroids (prednisone, 2 mg/kg/d) decrease the mortality rate during the early active phase of the disease. Azathioprine or

6-mercaptopurine (6MP), 1–2 mg/kg/d, is of value in decreasing the side effects of long-term corticosteroid therapy but should not be used alone during the induction phase of treatment. Steroids are reduced over a 3- to 12-month period, and azathioprine is continued for 1–2 years if AST and ALT remain consistently normal. Liver biopsy is performed before stopping azathioprine therapy; if inflammation persists, then azathioprine is continued. Thiopurine methyltransferase activity should be assessed prior to starting azathioprine, to prevent extremely high blood levels and severe bone marrow toxicity. Relapses are treated similarly. Many patients require chronic azathioprine or 6MP therapy. UCDA, cyclosporine, tacrolimus, or methotrexate may be helpful in poorly responsive cases. Mycophenolate mofetil can be substituted for azathioprine, but it is more expensive. Liver transplantation is indicated when disease progresses to decompensated cirrhosis despite therapy or in unresponsive cases presenting in acute liver failure. Steroid therapy may be lifesaving in those presenting in acute liver failure.

► Prognosis

The overall prognosis for AIH is improved significantly with early therapy. Some studies report cures (normal histologic findings) in 15–20% of patients. Relapses (seen clinically and histologically) occur in 40–50% of patients after cessation of therapy; remissions follow repeat treatment. Survival for 10 years is common despite residual cirrhosis. Of children with AIH, 20–50% eventually require liver transplantation. Complications of portal hypertension (bleeding varices, ascites, spontaneous bacterial peritonitis, and hepatopulmonary syndrome) require specific therapy. Liver transplantation is successful 70–90% of the time. Disease recurs after transplantation 10–50% of the time and is treated similarly to pretransplant disease.

NONALCOHOLIC FATTY LIVER DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Hepatomegaly in patient with BMI > 95th percentile.
- Elevated ALT > AST.
- Detection of fatty infiltration of the liver on ultrasound.
- Histologic evidence of fat in the liver.
- Insulin resistance.

Nonalcoholic fatty liver disease (NAFLD) is increasingly diagnosed in children. Patients with NAFLD present with asymptomatic

matic soft hepatomegaly. If nonalcoholic steatohepatitis (NASH) is present, mild to moderately elevated aminotransferases (2–10 times the upper limit of normal) are also present. ALT is frequently higher than AST. Alkaline phosphatase and GGT may be mildly elevated, but bilirubin is normal. Ultrasonography or CT scanning indicates fat density in the liver. Liver biopsy shows micro- or macrovesicular steatosis in simple NAFLD, with the addition of portal tract inflammation, Mallory bodies, and variable degrees of portal fibrosis to cirrhosis in NASH. Most cases are associated with overweight state or type 2 diabetes mellitus. The prevalence of NAFLD is related to the prevalence of obesity in the population. The prevalence is estimated at 10% for children and adolescents with significant racial and ethnic variability. One to 3% of adolescents in the United States may have NASH, based on the observation that 15–25% of American adolescents are overweight or obese and that roughly 40% will have NAFLD and 10% will have NASH. Steatohepatitis is also associated with Wilson disease, hereditary fructose intolerance, tyrosinemia, HCV hepatitis, cystic fibrosis, fatty acid oxidation defects, kwashiorkor, Reye syndrome, respiratory chain defects, and toxic hepatopathy (ethanol and others). Treatment is weight reduction and exercise for obesity or treatment for the other causes. A pilot trial suggests that vitamin E may be helpful and is currently under study. In addition, improved control of insulin resistance with metformin or pioglitazone is also under study in NASH. Cirrhosis and liver failure have been described in adults with this disease.

α_1 -ANTITRYPSIN DEFICIENCY LIVER DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Serum α_1 -antitrypsin level < 50–80 mg/dL.
- ▶ Identification of a specific protease inhibitor (Pi) phenotype (PiZZ, PiSZ) or genotype.
- ▶ Detection of diastase-resistant glycoprotein deposits in periportal hepatocytes.
- ▶ Histologic evidence of liver disease.
- ▶ Family history of early-onset pulmonary disease or liver disease.

▶ General Considerations

The disease is caused by a deficiency in α_1 -antitrypsin, a protease inhibitor (Pi) system, predisposing patients to chronic liver disease and an early onset of pulmonary emphysema. It is most often associated with the Pi phenotypes ZZ and SZ. Heterozygotes may have a slightly higher incidence of liver disease. The exact relationship between low levels of serum α_1 -antitrypsin and the development of liver disease is unclear. Emphysema develops because of a lack of inhibition of neutrophil elastase, which destroys pulmonary connective tissue. The accumulation of misfolded aggregates of α_1 -antitrypsin protein in the liver causes the liver injury by unclear mechanisms. Although all patients with the ZZ genotype eventually have antitrypsin inclusions in hepatocytes, only about 15–20% develop significant liver disease. Thus another genetic or environmental modifier must be involved. An associated abnormality in the microsomal disposal of accumulated aggregates may contribute to the liver disease phenotype.

About 10–20% of affected individuals present with neonatal cholestasis. About 10% of individuals with α_1 -antitrypsin deficiency have clinically significant liver injury by age 18 years. Very few children have significant pulmonary involvement. Most affected children are completely asymptomatic, with no laboratory or clinical evidence of liver or lung disease.

▶ Clinical Findings

A. Symptoms and Signs

α_1 -Antitrypsin deficiency should be considered in all infants with neonatal cholestasis. Serum GGT is usually, but not always, elevated. Jaundice, acholic stools, and malabsorption may also be present. Infants are often small for gestational age, and hepatosplenomegaly may be present. The family history may be positive for emphysema or cirrhosis.

In older children, hepatomegaly or physical findings suggestive of cirrhosis and portal hypertension, especially in the face of a negative history of liver disease, should always lead one to consider α_1 -antitrypsin deficiency. Recurrent pulmonary disease (bronchitis, pneumonia) may be present in a few older children.

B. Laboratory Findings

Levels of the α_1 -globulin fraction may be less than 0.2 mg/dL on serum protein electrophoresis. α_1 -Antitrypsin level is low (< 50–80 mg/dL) in homozygotes (ZZ). Specific Pi phenotyping should be done to confirm the diagnosis. Genotyping is also available. LFTs often reflect underlying hepatic pathologic changes. Hyperbilirubinemia (mixed) and elevated aminotransferases, alkaline phosphatase, and GGT are present early. Hyperbilirubinemia generally resolves, while aminotransferase and GGT elevation may persist. Signs of cirrhosis and hypersplenism may develop even when LFTs are normal.

Liver biopsy findings after age 6 months show diastase-resistant, periodic acid–Schiff staining intracellular globules, particularly in periportal zones. These may be absent prior to age 6 months, but when present are characteristic of α_1 -antitrypsin deficiency.

► Differential Diagnosis

In newborns, other specific causes of neonatal cholestasis need to be considered, including biliary atresia. In older children, other causes of insidious cirrhosis (eg, HBV or HCV infection, autoimmune hepatitis, Wilson disease, cystic fibrosis, hemochromatosis, and glycogen storage disease) should be considered.

► Complications

Of all infants with PiZZ α_1 -antitrypsin deficiency, only 15–20% develop liver disease in childhood, and many have clinical recovery. The complications of portal hypertension, cirrhosis, and chronic cholestasis predominate in affected children. Occasionally, children develop paucity of interlobular bile ducts.

Early-onset pulmonary emphysema occurs in young adults (age 30–40 years), particularly in smokers. An increased susceptibility to hepatocellular carcinoma has been noted in cirrhosis associated with α_1 -antitrypsin deficiency.

► Treatment

There is no specific treatment for the liver disease of this disorder. Replacement of the protein by transfusion therapy is used to prevent or treat pulmonary disease in affected adults. The neonatal cholestatic condition is treated with cholagogues, medium-chain triglyceride-containing formula, and water-soluble preparations of fat-soluble vitamins (see Table 21–4). UCDA may reduce AST, ALT, and GGT, but its effect on outcome is unknown. Portal hypertension, esophageal bleeding, ascites, and other complications are treated as described elsewhere. Hepatitis A and B vaccines should be given to children with α_1 -antitrypsin deficiency. Genetic counseling is indicated when the diagnosis is made. Diagnosis by prenatal screening is possible. Liver transplantation, performed for development of end-stage liver disease, cures the deficiency. Passive and active cigarette smoke exposure should be eliminated to help prevent pulmonary manifestations, and obesity should be avoided.

► Prognosis

Of those patients presenting with neonatal cholestasis, approximately 10–25% will need liver transplantation in the first 5 years of life, 15–25% during childhood or adolescence, and 50–75% will survive into adulthood with variable degrees of liver fibrosis. A correlation between histologic patterns and clinical course has been documented in the infantile form of the disease. Liver failure

can be expected 5–15 years after development of cirrhosis. Recurrence or persistence of hyperbilirubinemia along with worsening coagulation studies indicates the need for evaluation for possible liver transplantation. Decompensated cirrhosis caused by this disease is an excellent indication for liver transplantation; the survival rate should reach 80–90%. Pulmonary involvement is prevented by liver transplantation.

WILSON DISEASE (HEPATOENTERIC DEGENERATION)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Acute or chronic liver disease.
- Deteriorating neurologic status.
- Kayser-Fleischer rings.
- Elevated liver copper.
- Abnormalities in levels of ceruloplasmin and serum and urine copper.

► General Considerations

Wilson disease is caused by mutations in the gene *ATP7B* on chromosome 13 coding for a specific P-type adenosine triphosphatase involved in copper transport. This results in impaired bile excretion of copper and incorporation of copper into ceruloplasmin by the liver. The accumulated hepatic copper causes oxidant (free-radical) damage to the liver. Subsequently, copper accumulates in the basal ganglia and other tissues. The disease should be considered in all children older than age 3 years with evidence of liver disease (especially with hemolysis) or with suggestive neurologic signs. A family history is often present, and 25% of patients are identified by screening asymptomatic homozygous family members. The disease is autosomal recessive and occurs in 1:30,000 live births in all populations.

► Clinical Findings

A. Symptoms and Signs

Hepatic involvement may be fulminant; may present as an acute hepatitis; may masquerade as chronic liver disease; or

may progress insidiously to postnecrotic cirrhosis. Findings include jaundice; hepatomegaly early in childhood; splenomegaly; Kayser-Fleischer rings; and later onset of neurologic manifestations, such as tremor, dysarthria, and drooling beginning after age 10 years. Deterioration in school performance is often the earliest neurologic expression of disease. Psychiatric symptoms may also occur. The Kayser-Fleischer rings can sometimes be detected by unaided visual inspection as a brown band at the junction of the iris and cornea, but slit-lamp examination is always necessary. Absence of Kayser-Fleischer rings does not exclude this diagnosis.

B. Laboratory Findings

The laboratory diagnosis is sometimes difficult. Serum ceruloplasmin levels (measured by the oxidase method) are usually less than 20 mg/dL. (Normal values are 23–43 mg/dL.) Low values, however, occur normally in infants younger than 3 months, and in at least 10% of homozygotes the levels may be within the lower end of the normal range (20–30 mg/dL), particularly if immunoassays are used to measure ceruloplasmin. Rare patients with higher ceruloplasmin levels have been reported. Serum copper levels are low, but the overlap with normal is too great for satisfactory discrimination. In acute fulminant Wilson disease serum copper levels are elevated markedly, owing to hepatic necrosis and release of copper. The presence of anemia, hemolysis, very high serum bilirubin levels (> 20–30 mg/dL), low alkaline phosphatase, and low uric acid are characteristic of acute Wilson disease. Urine copper excretion in children older than 3 years is normally less than 30 mcg/d; in Wilson disease, it is generally greater than 150 mcg/d. Finally, the tissue content of copper from a liver biopsy, normally less than 50 mcg/g dry tissue, is greater than 250 mcg/g in Wilson disease.

Glycosuria and aminoaciduria have been reported. Hemolysis and gallstones may be present; bone lesions simulating those of osteochondritis dissecans have also been found.

The coarse nodular cirrhosis, steatosis, and glycogenated nuclei seen on liver biopsy may distinguish Wilson disease from other types of cirrhosis. Early in the disease, vacuolation of liver cells, steatosis, and lipofuscin granules can be seen, as well as Mallory bodies. The presence of Mallory bodies in a child is strongly suggestive of Wilson disease. Stains for copper may sometimes be negative despite high copper content in the liver. Therefore, liver copper levels must be determined biochemically on biopsy specimens. Electron microscopy findings of abnormal mitochondria may be helpful.

► Differential Diagnosis

During the icteric phase, acute viral hepatitis, α_1 -antitrypsin deficiency, autoimmune hepatitis, Indian childhood cirrhosis, and drug-induced hepatitis are the usual diagnostic possibilities. Nonalcoholic steatohepatitis may have similar histology and be confused with Wilson disease in overweight

patients. Later, other causes of cirrhosis and portal hypertension require consideration. Laboratory testing for serum ceruloplasmin, 24-hour urine copper excretion, liver copper concentration, and a slit-lamp examination of the cornea will differentiate Wilson disease from the others. Urinary copper excretion during penicillamine challenge (500 mg twice a day in the older child or adult) may help differentiate Wilson disease from other causes. Genetic testing may be necessary in confusing cases. Other copper storage diseases that occur in early childhood include Indian childhood cirrhosis, Tyrolean childhood cirrhosis, and idiopathic copper toxicosis. However, ceruloplasmin concentrations are normal in these conditions.

► Complications

Progressive liver disease, postnecrotic cirrhosis, hepatic coma, progressive neurologic degeneration, and death are the rule in the untreated patient. The complications of portal hypertension (variceal hemorrhage, ascites) are poorly tolerated by these patients. Progressive degenerating central nervous system disease and terminal aspiration pneumonia are common in untreated older people. Acute hemolytic disease may result in acute renal failure and profound jaundice as part of the presentation of fulminant hepatitis.

► Treatment

Copper chelation with D-penicillamine or trientine hydrochloride, 1000–2000 mg/d orally, is the treatment of choice, whether or not the patient is symptomatic. The target dose for children is 20 mg/kg/d; begin with 250 mg/d and increase the dose weekly by 250 mg increments. Strict dietary restriction of copper intake is not practical. Supplementation with zinc acetate (25–50 mg orally, three times daily) may reduce copper absorption. Copper chelation is continued for life, although doses may be reduced transiently at the time of surgery or early in pregnancy. Vitamin B₆ (25 mg) is given daily during therapy with penicillamine to prevent optic neuritis. In some countries, after a clinical response to penicillamine or trientine, zinc therapy is substituted and continued for life. Tetrathiomolybdate is being tested as an alternative therapy. Noncompliance with the drug regimen can lead to sudden fulminant liver failure and death.

Liver transplantation is indicated for all cases of acute fulminant disease with hemolysis and renal failure, progressive hepatic decompensation despite several months of penicillamine, and severe progressive hepatic insufficiency in patients who unadvisedly discontinue penicillamine, trientine, or zinc therapy.

► Prognosis

The prognosis of untreated Wilson disease is poor. Without liver transplantation, all patients with the fulminant presentation succumb. Copper chelation reduces hepatic copper content, reverses many of the liver lesions, and can stabilize

the clinical course of established cirrhosis. Neurologic symptoms generally respond to therapy. All siblings should be immediately screened and homozygotes given treatment with copper chelation or zinc acetate therapy, even if asymptomatic. Genetic testing (haplotype analysis or genotyping) is available clinically if there is any doubt about the diagnosis and for family members.

CIRRHOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Underlying liver disease.
- ▶ Nodular hard liver.
- ▶ Nodular liver on abdominal imaging.
- ▶ Liver biopsy demonstrating cirrhosis.

▶ General Considerations

Cirrhosis is a histologically defined condition of the liver characterized by diffuse hepatocyte injury and regeneration, an increase in connective tissue (bridging fibrosis), and disorganization of the lobular and vascular architecture (regenerative nodules). It may be micronodular or macronodular in appearance. It is the vasculature distortion that leads to increased resistance to blood flow, producing portal hypertension and its consequences.

Many liver diseases may progress to cirrhosis. In children, the two most common forms of cirrhosis are postnecrotic and biliary, with different causes, symptomatology, and treatment requirements. Both forms can eventually lead to liver failure and death.

In the pediatric population, postnecrotic cirrhosis is often a result of acute or chronic liver disease (eg, idiopathic neonatal giant-cell hepatitis, viral hepatitis [HBV, HCV], autoimmune or drug-induced hepatitis); more recently, NAFLD; or certain inborn errors of metabolism (see Table 21–5). Cirrhosis is an exceptional outcome of HAV infection and only follows massive hepatic necrosis. The evolution to

cirrhosis may be insidious, with no recognized icteric phase, as in some cases of HBV or HCV infection, Wilson disease, hemochromatosis, or α_1 -antitrypsin deficiency. At the time of diagnosis of cirrhosis, the underlying liver disease may be active, with abnormal LFTs; or it may be quiescent, with normal LFTs. Most cases of biliary cirrhosis result from congenital abnormalities of the bile ducts (biliary atresia, choledochal cyst), tumors of the bile duct, Caroli disease, PFIC, primary sclerosing cholangitis, paucity of the intrahepatic bile ducts, and cystic fibrosis.

Occasionally, cirrhosis may follow a hypersensitivity reaction to certain drugs such as phenytoin. Parasites (*Opisthorchis sinensis*, *Fasciola*, and *Ascaris*) may be causative in children living in endemic areas.

▶ Clinical Findings

A. Symptoms and Signs

Malaise, loss of appetite, failure to thrive, and nausea are frequent complaints, especially in anicteric varieties. Easy bruising may be reported. Jaundice may or may not be present. The first indication of underlying liver disease may be ascites, gastrointestinal hemorrhage, or hepatic encephalopathy. Variable hepatosplenomegaly, spider angiomas, warm skin, palmar erythema, or digital clubbing may be present. A small, shrunken liver may present. Most often, the liver is enlarged slightly, especially in the subxiphoid region, where it has a firm to hard quality and an irregular edge. Ascites may be detected as shifting dullness or a fluid wave. Gynecomastia may be noted in males. Digital clubbing occurs in 10–15% of cases. Pretibial edema often occurs, reflecting underlying hypoproteinemia. In adolescent girls, irregularities of menstruation and amenorrhea may be early complaints.

In biliary cirrhosis, patients often have jaundice, dark urine, pruritus, hepatomegaly, and sometimes xanthomas in addition to the previously mentioned clinical findings. Malnutrition and failure to thrive due to steatorrhea may be more apparent in this form of cirrhosis.

B. Laboratory Findings

Mild abnormalities of aminotransferases (AST, ALT) are often present, with a decreased level of albumin and a variable increase in the level of γ -globulins. Prothrombin time is prolonged and may be unresponsive to vitamin K administration. Burr and target red cells may be noted on the peripheral blood smear. Anemia, thrombocytopenia, and leukopenia are present if hypersplenism exists. However, cirrhosis may be present despite normal blood tests.

In biliary cirrhosis, elevated conjugated bilirubin, bile acids, GGT, alkaline phosphatase, and cholesterol are common.

C. Imaging

Hepatic ultrasound or CT examination may demonstrate abnormal hepatic texture and nodules. In biliary cirrhosis,

abnormalities of the biliary tree may be apparent by ultrasonography, CT, hepatobiliary scintigraphy, or cholangiography.

D. Pathologic Findings

Liver biopsy findings of regenerating nodules and surrounding fibrosis are hallmarks of cirrhosis. Pathologic features of biliary cirrhosis also include canalicular and hepatocyte cholestasis, as well as plugging of bile ducts. The interlobular bile ducts may be increased or decreased, depending on the cause and the stage of the disease process.

► Complications & Treatment

Major complications of cirrhosis in childhood include progressive nutritional disturbances, hormonal disturbances, and the evolution of portal hypertension and its complications. Hepatocellular carcinoma occurs with increased frequency in the cirrhotic liver, especially in patients with the chronic form of hereditary tyrosinemia or after long-standing HBV or HCV disease. At present, there is no proven medical treatment for cirrhosis, but whenever a treatable condition is identified (eg, Wilson disease, galactosemia, congenital fructose intolerance, autoimmune hepatitis) or an offending agent eliminated (HBV, HCV, drugs, toxins), disease progression can be altered; occasionally regression of fibrosis has been noted. Children with cirrhosis should receive the hepatitis A and B vaccines, and they should be monitored for the development of hepatocellular carcinoma with serial serum α -fetoprotein determinations and abdominal ultrasound for hepatic nodules. Liver transplantation may be appropriate in patients with cirrhosis whose disease is continuing to progress, with evidence of worsening hepatic synthetic function, or in whom the complications of cirrhosis are no longer manageable.

► Prognosis

Postnecrotic cirrhosis has an unpredictable course. Without transplantation, affected patients may die from liver failure within 10–15 years. Patients with a rising bilirubin, a vitamin K-resistant coagulopathy, or diuretic refractory ascites usually survive less than 1–2 years. The terminal event in some patients may be generalized hemorrhage, sepsis, or cardiorespiratory arrest. For patients with biliary cirrhosis, the prognosis is similar, except for those with surgically corrected lesions that result in regression or stabilization of the underlying liver condition. With liver transplantation, the long-term survival rate is 70–90%.

PORTAL HYPERTENSION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Splenomegaly.
- Recurrent ascites.
- Variceal hemorrhage.
- Hypersplenism.

► General Considerations

Portal hypertension is defined as an increase in the portal venous pressure to more than 5 mm Hg greater than the inferior vena caval pressure. Portal hypertension is most commonly a result of cirrhosis. Portal hypertension without cirrhosis may be divided into prehepatic, suprahepatic, and intrahepatic causes. Although the specific lesions vary somewhat in their clinical signs and symptoms, the consequences of portal hypertension are common to all.

A. Prehepatic Portal Hypertension

Prehepatic portal hypertension from acquired abnormalities of the portal and splenic veins accounts for 30–50% of cases of variceal hemorrhage in children. A history of neonatal omphalitis, sepsis, dehydration, or umbilical vein catheterization may be present. Causes in older children include local trauma, peritonitis (pyelophlebitis), hypercoagulable states, and pancreatitis. Symptoms may occur before age 1 year, but in most cases the diagnosis is not made until age 3–5 years. Patients with a positive neonatal history tend to be symptomatic earlier.

A variety of portal or splenic vein malformations, some of which may be congenital, have been described, including defects in valves and atretic segments. Cavous transformation is probably the result of attempted collateralization around the thrombosed portal vein rather than a congenital malformation. The site of the venous obstruction may be anywhere from the hilum of the liver to the hilum of the spleen.

B. Suprahepatic Vein Occlusion or Thrombosis (Budd-Chiari Syndrome)

No cause can be demonstrated in most instances. One suggested cause is endothelial injury to hepatic veins by bacterial endotoxin, which has been demonstrated experimentally. The occasional association of hepatic vein thrombosis in inflammatory bowel disease favors the presence of endogenous toxins traversing the liver. Vasculitis leading to endophlebitis of the hepatic veins has been described. In addition, hepatic vein obstruction may be secondary to tumor, abdominal trauma, hyperthermia, or sepsis, or it may

occur following the repair of an omphalocele or gastroschisis. Congenital vena caval bands, webs, a membrane, or stricture above the hepatic veins are sometimes causative. Hepatic vein thrombosis may be a complication of oral contraceptive medications. Underlying thrombotic conditions (deficiency of antithrombin III, protein C or S, or factor V Leiden; antiphospholipid antibodies; or mutations of the prothrombin gene) should be evaluated.

C. Intrahepatic Portal Hypertension

1. Cirrhosis—See previous section.

2. Veno-occlusive disease (acute stage)—This entity now occurs most frequently in bone marrow transplant recipients. It may also develop after chemotherapy for acute leukemia, particularly with thioguanine. Additional causes include the ingestion of pyrrolizidine alkaloids (“bush tea”) or other herbal teas, and a familial form of the disease occurring in congenital immunodeficiency states. The acute form of the disease generally occurs in the first month after bone marrow transplantation and is heralded by the triad of weight gain (ascites), tender hepatomegaly, and jaundice.

3. Congenital hepatic fibrosis—This is a rare autosomal recessive cause of intrahepatic presinusoidal portal hypertension (see Table 21–8). Liver biopsy is generally diagnostic, demonstrating Meyenburg complexes. On angiography, the intrahepatic branches of the portal vein may be duplicated. Autosomal recessive polycystic kidney disease is often associated with the hepatic lesion; therefore, renal ultrasonography and urography should be routinely performed.

4. Other rare causes—Hepatoportal sclerosis (idiopathic portal hypertension, noncirrhotic portal fibrosis), noncirrhotic nodular transformation of the liver, and schistosomal hepatic fibrosis are also rare causes of intrahepatic presinusoidal portal hypertension.

► Clinical Findings

A. Symptoms and Signs

For prehepatic portal hypertension, splenomegaly in an otherwise well child is the most constant physical sign. Recurrent episodes of abdominal distention resulting from ascites may be noted. The usual presenting symptoms are hematemesis and melena.

The presence of prehepatic portal hypertension is suggested by the following: (1) an episode of severe infection in the newborn period or early infancy—especially omphalitis, sepsis, gastroenteritis, severe dehydration, or prolonged or difficult umbilical vein catheterizations; (2) no previous evidence of liver disease; (3) a history of well-being prior to onset or recognition of symptoms; and (4) normal liver size and tests with splenomegaly.

Most patients with suprahepatic portal hypertension present with abdominal pain, tender hepatomegaly of acute

onset, and abdominal enlargement caused by ascites. Jaundice is present in only 25% of patients. Vomiting, hematemesis, and diarrhea are less common. Cutaneous signs of chronic liver disease are often absent, as the obstruction is usually acute. Distended superficial veins on the back and the anterior abdomen, along with dependent edema, are seen when inferior vena cava obstruction affects hepatic vein outflow. Absence of hepatojugular reflux (jugular distention when pressure is applied to the liver) is a helpful clinical sign.

The symptoms and signs of intrahepatic portal hypertension are generally those of cirrhosis (see earlier section on Cirrhosis).

B. Laboratory Findings and Imaging

Most other common causes of splenomegaly or hepatosplenomegaly may be excluded by appropriate laboratory tests. Cultures, EBV titers, hepatitis serologies, blood smear examination, bone marrow studies, and LFTs may be necessary. In prehepatic portal hypertension, LFTs are generally normal. In Budd-Chiari syndrome and veno-occlusive disease, mild to moderate hyperbilirubinemia with modest elevations of aminotransferases and prothrombin time are often present. Significant early increases in fibrinolytic parameters (especially plasminogen activator inhibitor 1) have been reported in veno-occlusive disease. Hypersplenism with mild leucopenia and thrombocytopenia is often present. Upper endoscopy may reveal varices in symptomatic patients.

Doppler-assisted ultrasound scanning of the liver, portal vein, splenic vein, inferior vena cava, and hepatic veins may assist in defining the vascular anatomy. In prehepatic portal hypertension, abnormalities of the portal or splenic vein may be apparent, whereas the hepatic veins are normal. When noncirrhotic portal hypertension is suspected, angiography often is diagnostic. Selective arteriography of the superior mesenteric artery or MRI is recommended prior to surgical shunting to determine the patency of the superior mesenteric vein.

For suprahepatic portal hypertension, an inferior vena-cavogram using catheters from above or below the suspected obstruction may reveal an intrinsic filling defect, an infiltrating tumor, or extrinsic compression of the inferior vena cava by an adjacent lesion. A large caudate lobe of the liver suggests Budd-Chiari syndrome. Care must be taken in interpreting extrinsic pressure defects of the subdiaphragmatic inferior vena cava if ascites is significant.

Simultaneous wedged hepatic vein pressure and hepatic venography are useful to demonstrate obstruction to major hepatic vein ostia and smaller vessels. In the absence of obstruction, reflux across the sinusoids into the portal vein branches can be accomplished. Pressures should also be taken from the right heart and supradiaphragmatic portion of the inferior vena cava to eliminate constrictive pericarditis and pulmonary hypertension from the differential diagnosis.

► Differential Diagnosis

All causes of splenomegaly must be included in the differential diagnosis. The most common ones are infections, immune thrombocytopenic purpura, blood dyscrasias, lipidosis, reticuloendotheliosis, cirrhosis of the liver, and cysts or hemangiomas of the spleen. When hematemesis or melena occurs, other causes of gastrointestinal bleeding are possible, such as gastric or duodenal ulcers, tumors, duplications, and inflammatory bowel disease.

Because ascites is almost always present in suprahepatic portal hypertension, cirrhosis resulting from any cause must be excluded. Other suprahepatic (cardiac, pulmonary) causes of portal hypertension must also be ruled out. Although ascites may occur in prehepatic portal hypertension, it is uncommon.

► Complications

The major manifestation and complication of portal hypertension is bleeding from esophageal varices. Fatal exsanguination is uncommon, but hypovolemic shock or resulting anemia may require prompt treatment. Hypersplenism with leukopenia and thrombocytopenia occurs, but seldom causes major symptoms. Rupture of the enlarged spleen secondary to trauma is always a threat. Retroperitoneal edema has been reported (Clatworthy sign).

Without treatment, complete and persistent hepatic vein obstruction leads to liver failure, coma, and death. A non-portal type of cirrhosis may develop in the chronic form of hepatic veno-occlusive disease in which small- and medium-sized hepatic veins are affected. Death from renal failure may occur in rare cases of congenital hepatic fibrosis.

► Treatment

Definitive treatment of noncirrhotic portal hypertension is generally lacking. Aggressive medical treatment of the complications of prehepatic portal hypertension is generally quite effective. The early experience with surgical portosystemic shunts was unfavorable. Recently, several centers have reported excellent results with either portosystemic shunt or the mesorex (mesenteric–left portal bypass) shunt. When possible, the mesorex shunt is the preferred technique. Venocclusive disease may be prevented somewhat by the prophylactic use of UCDA or defibrotide prior to conditioning for bone marrow transplantation. Treatment with defibrotide and withdrawal of the suspected offending agent, if possible, may increase the chance of recovery. Transjugular intrahepatic portosystemic shunts have been successful bridging to recovery in venocclusive disease. For suprahepatic portal hypertension, efforts should be directed at correcting the underlying cause, if possible. Either surgical or angiographic relief of obstruction should be attempted if a defined obstruction of the vessels is apparent. Liver transplantation, if not contraindicated, should be considered early if direct correction is not possible. In most cases, management of portal hypertension is directed at management of the complications (Table 21–7).

► Prognosis

For prehepatic portal hypertension, the prognosis depends on the site of the block, the effectiveness of variceal eradication, the availability of suitable vessels for shunting procedures, and the experience of the surgeon. In patients treated by medical means, bleeding episodes seem to diminish with adolescence.

Table 21–7. Treatment of complications of portal hypertension.

Complication	Diagnosis	Treatment
Bleeding esophageal varices	Endoscopic verification of variceal bleeding.	Endosclerosis or variceal band ligation. Octreotide, 30 mcg/m ² /h intravenous. Pediatric Sengstaken-Blakemore tube. Surgical variceal ligation, selective venous embolization, surgical portosystemic shunt, TIPS, OLT. Propranolol may be useful to prevent recurrent bleeding.
Ascites	Clinical examination (fluid wave, shifting dullness), abdominal ultrasonography.	Sodium restriction (1–2 mEq/kg/d), spironolactone (3–5 mg/kg/d), furosemide (1–2 mg/kg/d), intravenous albumin (0.5–1 g/kg per dose), paracentesis, peritoneovenous (LeVeen) shunt, TIPS, surgical portosystemic shunt, OLT. ^a
Hepatic encephalopathy	Abnormal neurologic examination, elevated plasma ammonia.	Protein restriction (0.5–1 g/kg/d), intravenous glucose (6–8 mg/kg/min), neomycin (2–4 g/m ² BSA PO in 4 doses), rifaximin (200 mg 3 times a day in children > 12 y), lactulose (1 mL/kg per dose [up to 30 mL] every 4–6 h PO), plasmapheresis, hemodialysis, OLT. ^a
Hypersplenism	Low WBC count, platelets, and/or hemoglobin. Splenomegaly.	No intervention, partial splenic embolization, TIPS, surgical portosystemic shunt, OLT. Splenectomy may worsen variceal bleeding.

^aIn order of sequential management.

BSA, body surface area; OLT, orthotopic liver transplantation; TIPS, transjugular intrahepatic portosystemic shunt; WBC, white blood cell.

The prognosis in patients treated by medical and supportive therapy may be better than in the surgically treated group, especially when surgery is performed at an early age, although no comparative study has been done. Portacaval encephalopathy is unusual after shunting except when protein intake is excessive, but neurologic outcome may be better in patients who receive a mesorex shunt when compared with medical management alone.

The mortality rate of hepatic vein obstruction is very high (95%). In veno-occlusive disease, the prognosis is better, with complete recovery possible in 50% of acute forms and 5–10% of subacute forms.

BILIARY TRACT DISEASE

1. Cholelithiasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Episodic right upper quadrant abdominal pain.
- ▶ Elevated bilirubin, alkaline phosphatase, and GGT.
- ▶ Stones or sludge seen on abdominal ultrasound.

▶ General Considerations

Gallstones may develop at all ages in the pediatric population and in utero. Gallstones may be divided into cholesterol stones (which contain more than 50% cholesterol) and pig-

ment (black [sterile bile] and brown [infected bile]) stones. Pigment stones predominate in the first decade of life, while cholesterol stones account for up to 90% of gallstones in adolescence. For some patients, gallbladder dysfunction is associated with biliary sludge formation, which may evolve into “sludge balls” or tumefaction bile and then into gallstones. The process is reversible in many patients.

▶ Clinical Findings

A. History

Most symptomatic gallstones are associated with acute or recurrent episodes of moderate to severe, sharp right upper quadrant or epigastric pain. The pain may radiate substernally or to the right shoulder. On rare occasions, the presentation may include a history of jaundice, back pain, or generalized abdominal discomfort, when it is associated with pancreatitis, suggesting stone impaction in the common duct or ampulla hepatopancreatica. Nausea and vomiting may occur during attacks. Pain episodes often occur postprandially, especially after ingestion of fatty foods. The groups at risk for gallstones include patients with known or suspected hemolytic disease; females; teenagers with prior pregnancy; obese individuals; individuals with rapid weight loss; children with portal vein thrombosis; certain racial or ethnic groups, particularly Native Americans (Pima Indians) and Hispanics; infants and children with ileal disease (Crohn disease) or prior ileal resection; patients with cystic fibrosis or Wilson disease; and infants on prolonged parenteral hyperalimentation. Other, less certain risk factors include a positive family history, use of birth control pills, and diabetes mellitus.

B. Symptoms and Signs

During acute episodes of pain, tenderness is present in the right upper quadrant or epigastrium, with a positive inspiratory arrest (Murphy sign), usually without peritoneal signs. While rarely present, scleral icterus is helpful. Evidence of underlying hemolytic disease in addition to icterus may include pallor (anemia), splenomegaly, tachycardia, and high-output cardiac murmur. Fever is unusual in uncomplicated cases.

C. Laboratory Findings

Laboratory tests are usually normal unless calculi have lodged in the extrahepatic biliary system, in which case the serum bilirubin and GGT (or alkaline phosphatase) may be elevated. Amylase and lipase levels may be increased if stone obstruction occurs at the ampulla hepatopancreatica.

D. Imaging

Ultrasound evaluation is the best imaging technique, showing abnormal intraluminal contents (stones, sludge) as well as anatomic alterations of the gallbladder or dilation of the biliary ductal system. The presence of an anechoic acoustic shadow differentiates calculi from intraluminal sludge or sludge balls.

Ceftriaxone may cause similar findings. Plain abdominal radiographs will show calculi with a high calcium content in the region of the gallbladder in up to 15% of patients. Lack of visualization of the gallbladder with hepatobiliary scintigraphy suggests chronic cholecystitis. In selected cases, ERCP, MRCP, or endoscopic ultrasound may be helpful in defining subtle abnormalities of the bile ducts and locating intraductal stones.

► Differential Diagnosis

Other abnormal conditions of the biliary system with similar presentation are summarized in Table 21–8. Liver disease (hepatitis, abscess, or tumor) can cause similar symptoms or signs. Peptic disease, reflux esophagitis, paraesophageal hiatal hernia, cardiac disease, and pneumomediastinum must be considered when the pain is epigastric or substernal in location. Renal or pancreatic disease is a possible explanation if the pain is localized to the right flank or mid back. Subcapsular or supracapsular lesions of the liver (abscess, tumor, or hematoma) or right lower lobe infiltrate may also be a cause of nontraumatic right shoulder pain.

► Complications

Major problems are related to stone impaction in either the cystic or common duct and may lead to stricture formation or perforation. Acute distention and subsequent perforation of the gallbladder may occur when gallstones cause obstruction of the cystic duct. Stones impacted at the level of the ampulla hepatopancreatica often cause gallstone pancreatitis.

► Treatment

Symptomatic cholelithiasis is treated by laparoscopic cholecystectomy or open cholecystectomy in selected cases. Intraoperative cholangiography via the cystic duct is recommended so that the physician can be certain the biliary system is free of retained stones. Calculi in the extrahepatic bile ducts may be removed at ERCP.

Gallstones developing in premature infants on parenteral nutrition can be followed by ultrasound examination. Most of the infants are asymptomatic, and the stones will resolve in 3–36 months. Gallstone dissolution using cholelitholytics (UCDA) or mechanical means (lithotripsy) has not been approved for use in children. Asymptomatic gallstones do not usually require treatment, as less than 20% will eventually cause problems.

► Prognosis

The prognosis is excellent in uncomplicated cases that come to standard cholecystectomy.

2. Primary Sclerosing Cholangitis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pruritus and jaundice.
- Elevated GGT.
- Associated with inflammatory bowel disease.
- Abnormal ERCP or MRCP.

► General Considerations

Primary sclerosing cholangitis (PSC) is a progressive liver disease of unknown cause, characterized by chronic inflammation and fibrosis of the intrahepatic or extrahepatic bile ducts (or both), with eventual obliteration of peripheral bile ducts, cholangiographic evidence of strictures, and dilation of all or parts of the biliary tree. PSC is more common in males with inflammatory bowel disease, particularly ulcerative colitis. It can also be seen with histiocytosis X, sicca syndromes, congenital and acquired immunodeficiency syndromes, and cystic fibrosis.

► Clinical Findings

A. Symptoms and Signs

PSC often has an insidious onset. Clinical symptoms may include abdominal pain, fatigue, pruritus, and jaundice. Acholic stools and steatorrhea can occur. Physical findings include hepatomegaly, splenomegaly, and jaundice.

B. Laboratory Findings

The earliest finding may be asymptomatic elevation of the GGT. Subsequent laboratory abnormalities include elevated levels of alkaline phosphatase and bile acids. Later, cholestatic jaundice and elevated AST and ALT may occur. Patients with associated inflammatory bowel disease often test positive for perinuclear antineutrophil cytoplasmic antibodies. Other markers of autoimmune liver disease (ANA and anti-smooth muscle antibodies [ASMA]) are often found but are not specific for PSC. Sclerosing cholangitis due to cryptosporidia is common in immunodeficiency syndromes.

C. Imaging

Ultrasound may show dilated intrahepatic bile ducts behind strictures. MRCP is now the diagnostic study of choice, demonstrating irregularities of the biliary tree. ERCP may be more sensitive for the diagnosis of irregularities of the intrahepatic biliary tree.

Table 21-8. Biliary tract diseases of childhood.

	Acute Hydrops Transient Dilatation of Gallbladder^{a,b}	Choledochal Cyst^c (see Figure 21-1)	Acalculous Cholecystitis^d	Caroli Disease^e (Idiopathic Intrahepatic Bile Duct Dilatation)	Congenital Hepatic Fibrosis^f	Biliary Dyskinesia^g
Predisposing or associated conditions	Premature infants with prolonged fasting or systemic illness. Hepatitis. Abnormalities of cystic duct. Kawasaki disease. Bacterial sepsis, EBV.	Congenital lesion. Female sex. Asians. Rarely with Caroli disease or congenital hepatic fibrosis.	Systemic illness, sepsis (<i>Streptococcus</i> , <i>Salmonella</i> , <i>Klebsiella</i> , etc), HIV infection. Gallbladder stasis, obstruction of cystic duct (stones, nodes, tumor).	Congenital lesion. Also found in congenital hepatic fibrosis or with choledochal cyst. Female sex. Autosomal recessive polycystic kidney disease.	Familial (autosomal recessive) 25% with autosomal recessive polycystic kidney disease. Choledochal cyst. Caroli disease. Meckel-Gruber, Ivemark, or Jeune syndrome.	Adolescents.
Symptoms	Absent in premature infants. Vomiting, abdominal pain in older children.	Abdominal pain, vomiting, jaundice.	Acute severe abdominal pain, vomiting, fever.	Recurrent abdominal pain, vomiting. Fever, jaundice when cholangitis occurs.	Hematemesis, melena from bleeding esophageal varices.	Intermittent RUQ pain.
Signs	RUQ abdominal mass. Tenderness in some.	Icterus, acholic stools, dark urine in neonatal period. RUQ abdominal mass or tenderness in older children.	Tenderness in mid and right upper abdomen. Occasional palpable mass in RUQ.	Icterus, hepatomegaly.	Hepatosplenomegaly.	Usually normal exam.
Laboratory abnormalities	Most are normal. Increased WBC count in sepsis (may be decreased in premature infants). Abnormal LFTs in hepatitis.	Conjugated hyperbilirubinemia, elevated GGT, slightly increased AST. Elevated pancreatic serum amylase common.	Elevated WBC count, normal or slight abnormality of LFTs.	Abnormal LFTs. Increased WBC count with cholangitis. Urine abnormalities if associated with congenital hepatic fibrosis.	Low platelet and WBC count (hypersplenism), slight elevation of AST, GGT. Inability to concentrate urine.	Usually normal.
Diagnostic studies most useful	Gallbladder ultrasonography.	Gallbladder ultrasonography hepatobiliary scintigraphy, MRCP, or ERCP.	Scintigraphy to confirm nonfunction of gallbladder. Ultrasonography or abdominal CT scan to rule out other neighboring disease.	Transhepatic cholangiography, MRCP, ERCP, scintigraphy, ultrasonography, intravenous pyelography.	Liver biopsy. Ultrasonography of liver and kidneys. Upper endoscopy.	CCK stimulated scintigraphy demonstrating reduced ejection fraction.
Treatment	Treatment of associated condition. Needle or tube cystostomy rarely required. Cholecystectomy seldom indicated.	Surgical resection and choledocho-jejunostomy.	Broad-spectrum antibiotic coverage, then cholecystectomy.	Antibiotics and surgical or endoscopic drainage for cholangitis. Liver transplantation for some. Lobectomy for localized disease.	Treatment of portal hypertension. Liver and kidney transplantation for some.	Cholecystectomy in well selected cases.

(continued)

Table 21–8. Biliary tract diseases of childhood. (Continued)

	Acute Hydrops Transient Dilatation of Gallbladder ^{a,b}	Choledochal Cyst ^c (see Figure 21–1)	Acalculous Cholecystitis ^d	Caroli Disease ^e (Idiopathic Intrahepatic Bile Duct Dilatation)	Congenital Hepatic Fibrosis ^f	Biliary Dyskinesia ^g
Complications	Perforation with bile peritonitis rare.	Progressive biliary cirrhosis. Increased incidence of cholangiocarcinoma. Cholangitis in some.	Perforation and bile peritonitis, sepsis, abscess or fistula formation. Pancreatitis.	Sepsis with episodes of cholangitis, biliary cirrhosis, portal hypertension. Intraductal stones. Cholangiocarcinoma.	Bleeding from varices. Splenic rupture, severe thrombocytopenia. Progressive renal failure.	Continued pain after surgery.
Prognosis	Excellent with resolution of underlying condition. Consider cystic duct obstruction if disorder fails to resolve.	Depends on anatomic type of cyst, associated condition, and success of surgery. Liver transplantation required in some.	Good with early diagnosis and treatment.	Poor, with gradual deterioration of liver function. Multiple surgical drainage procedures expected. Liver transplantation should improve long-term prognosis.	Good in absence of serious renal involvement and with control of portal hypertension. Slightly increased risk of cholangiocarcinoma.	Good short-term outcome in well-selected patients.

► Differential Diagnosis

The differential diagnosis includes infectious hepatitis, secondary cholangitis, autoimmune hepatitis, metabolic liver disease, cystic fibrosis, choledochal cyst, or other anomalies of the biliary tree, including Caroli disease and congenital hepatic fibrosis (see Table 21–8).

► Complications

Complications include secondary bacterial cholangitis, pancreatitis, biliary fibrosis, and cirrhosis. Progression to liver failure is common, and the risk of cholangiocarcinoma is higher in PSC.

► Treatment

No completely effective treatment is available. Patients with early disease may benefit from high-dose UCDA (25–30 mg/kg/d). Patients with autoimmune markers may benefit from treatment with corticosteroids and azathioprine. Antibiotic treatment of cholangitis and dilation and stenting of dominant bile duct strictures can reduce symptoms.

► Prognosis

The majority of patients will eventually require liver transplantation, and PSC is the fifth leading indication for liver transplantation in the United States. The median duration from the time of diagnosis to end-stage liver disease is 12–15 years.

3. Other Biliary Tract Disorders

For a schematic representation of the various types of choledochal cysts, see Figure 21–1. For summary information on acute hydrops, choledochal cyst, acalculous cholecystitis, Caroli disease, biliary dyskinesia, and congenital hepatic fibrosis, see Table 21–8.

PYOGENIC & AMEBIC LIVER ABSCESS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever and painful enlarged liver.
- Ultrasound of liver demonstrating an abscess.
- Positive serum ameba antibody or positive bacterial culture of abscess fluid.

▲ **Figure 21–1.** Classification of cystic dilation of the bile ducts. Types I, II, and III are extrahepatic choledochal cysts. Type IVa is solely intrahepatic, and type IVb is both intrahepatic and extrahepatic. GB, gallbladder; CBD, common bile duct.

► General Considerations

Pyogenic liver abscesses are often caused by intestinal bacteria seeded via the portal vein from infected viscera and occasionally from ascending cholangitis or gangrenous cholecystitis. Blood cultures are positive in up to 60% of patients. The resulting lesion tends to be solitary and located in the right hepatic lobe. Bacterial seeding may also occur from infected burns, pyodermas, and osteomyelitis. Unusual causes include omphalitis, subacute infective endocarditis, pyelonephritis, Crohn disease, and perinephric abscess. In immunocompromised patients, *S aureus*, gram-negative organisms, and fungi may seed the liver from the arterial system. Multiple pyogenic liver abscesses are associated with severe sepsis. Children receiving anti-inflammatory and immunosuppressive agents and children with defects in white blood cell function (chronic granulomatous disease) are prone to pyogenic hepatic abscesses, especially those caused by *S aureus*.

Amoebic liver abscess is rare in children. An increased risk is associated with travel in areas of endemic infection (Mexico, Southeast Asia) within 5 months of presentation. *Entamoeba histolytica* invasion occurs via the large bowel, although a history of diarrhea (colitis-like picture) is not always obtained.

► Clinical Findings

With pyogenic liver abscess, nonspecific complaints of fever, chills, malaise, and abdominal pain are frequent. Weight loss

is very common, especially in delayed diagnosis. A few patients have shaking chills and jaundice. The dominant complaint is a constant dull pain over an enlarged liver that is tender to palpation. An elevated hemidiaphragm with reduced or absent respiratory excursion may be demonstrated on physical examination and confirmed by fluoroscopy. Laboratory studies show leukocytosis and, at times, anemia. LFTs may be normal or reveal mild elevation of transaminases and alkaline phosphatase. Fever and abdominal pain are the two most common symptoms of amebic liver abscess. Abdominal tenderness and hepatomegaly are present in over 50%. Early in the course, LFTs may suggest mild hepatitis. An occasional prodrome may include cough, dyspnea, and shoulder pain when rupture of the abscess into the right chest occurs. Consolidation of the right lower lobe is common (10–30% of patients).

Ultrasound liver scan is the most useful diagnostic aid in evaluating pyogenic and amebic abscesses, detecting lesions as small as 1–2 cm. MRI, CT, or nuclear scanning with gallium or technetium sulfur colloid may be useful in differentiating tumor or hydatid cyst.

The distinction between pyogenic and amebic abscesses is best made by indirect hemagglutination test for specific antibody (which is positive in more than 95% of patients with amebic liver disease) and the prompt clinical response of the latter to antiamebic therapy (metronidazole). Examination of material obtained by needle aspiration of the abscess using ultrasound guidance is often diagnostic.

► Differential Diagnosis

Hepatitis, hepatoma, hydatid cyst, gallbladder disease, or biliary tract infections can mimic liver abscess. Subphrenic abscesses, empyema, and pneumonia may give a similar picture. Inflammatory disease of the intestines or of the biliary system may be complicated by liver abscess.

► Complications

Spontaneous rupture of the abscess may occur with extension of infection into the subphrenic space, thorax, peritoneal cavity, and, occasionally, the pericardium. Bronchopleural fistula with large sputum production and hemoptysis can develop in severe cases. Simultaneously, the amebic liver abscess may be secondarily infected with bacteria (in 10–20% of patients). Metastatic hematogenous spread to the lungs and the brain has been reported.

► Treatment

Ultrasound- or CT-guided percutaneous needle aspiration for aerobic and anaerobic culture with simultaneous placement of a catheter for drainage, combined with appropriate antibiotic therapy, is the treatment of choice for solitary pyogenic liver abscess. Multiple liver abscesses may also be treated successfully by this method. Surgical intervention

may be indicated if rupture occurs outside the capsule of the liver or if enterohepatic fistulae are suspected.

Amebic abscesses in uncomplicated cases should be treated promptly with oral metronidazole, 35–50 mg/kg/d, in three divided doses for 10 days. Intravenous metronidazole can be used for patients unable to take oral medication. Failure to improve after 72 hours of drug therapy suggests superimposed bacterial infection or an incorrect diagnosis. At this point, needle aspiration or surgical drainage is indicated. Once oral feedings can be tolerated, a luminal amebicide such as iodoquinol should be initiated. Resolution of the abscess cavity occurs over 3–6 months.

► Prognosis

An unrecognized and untreated pyogenic liver abscess is universally fatal. With drainage and antibiotics, the cure rate is about 90%. Most amebic abscesses are cured with conservative medical management; the mortality rate is less than 3%. If extrahepatic complications occur (empyema, bronchopleural fistula, or pericardial complications), 10–15% of patients will succumb.

HEPATOMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Abdominal enlargement and pain, weight loss, anemia.
- Hepatomegaly with or without a definable mass.
- Mass lesion on imaging studies.
- Laparotomy and tissue biopsy.

► General Considerations

Primary epithelial neoplasms of the liver represent 0.2–5.8% of all malignant conditions in children. After Wilms tumor and neuroblastoma, hepatomas are the third most common intra-abdominal cancer. The incidence is higher in Southeast Asia, where childhood cirrhosis is more common. There are two basic morphologic types with certain clinical and prognostic differences. Hepatoblastoma predominates in male infants and children and accounts for 79% of liver cancer in children, with most cases appearing before age 5 years. There

is an increased risk of hepatoblastoma in Beckwith-Wiedemann syndrome, hemihypertrophy, familial adenomatous polyposis coli, and in premature or low-birth-weight infants. Most lesions are found in the right lobe of the liver. Pathologic differentiation from hepatocellular carcinoma, the other major malignant tumor of the liver, may be difficult. Hepatocellular carcinoma occurs more frequently after age 3 years, carries a worse prognosis than hepatoblastoma, and causes more abdominal discomfort.

Patients with chronic HBV or HCV infection, cirrhosis, glycogen storage disease type I, tyrosinemia, or α_1 -antitrypsin deficiency have an increased risk for hepatocellular carcinoma. The late development of hepatocellular carcinoma in patients receiving androgens for treatment of Fanconi syndrome and aplastic anemia must also be kept in mind. The use of anabolic steroids by body-conscious adolescents poses a risk of hepatic neoplasia.

An interesting aspect of primary epithelial neoplasms of the liver has been the increased incidence of associated anomalies and endocrine abnormalities. Virilization has been reported as a consequence of gonadotropin activity of the tumor. Feminization with bilateral gynecomastia may occur in association with high estradiol levels in the blood, the latter a consequence of increased aromatization of circulating androgens by the liver. Leydig cell hyperplasia without spermatogenesis is found on testicular biopsy. Hemihypertrophy, congenital absence of the kidney, macroglossia, and Meckel diverticulum have been found in association with hepatocellular carcinoma.

► Clinical Findings

A noticeable increase in abdominal girth with or without pain is the most constant feature of the history. A parent may note a bulge in the upper abdomen or report feeling a hard mass. Constitutional symptoms (eg, anorexia, fatigue, fever, and chills) may be present. Teenage boys may complain of gynecomastia.

A. Symptoms and Signs

Weight loss, pallor, and abdominal pain associated with a large abdomen are common. Physical examination reveals hepatomegaly with or without a definite tumor mass, usually to the right of the midline. In the absence of cirrhosis, signs of chronic liver disease are usually absent. However, evidence of virilization or feminization in prepubertal children may be noted.

B. Laboratory Findings

Normal LFTs are the rule. Anemia frequently occurs, especially in cases of hepatoblastoma. Cystathioninuria has been reported. α -Fetoprotein levels are often elevated, especially in hepatoblastoma. Estradiol levels are sometimes elevated. Tissue diagnosis is best obtained at laparotomy, although ultrasound- or CT-guided needle biopsy of the liver mass can be used.

C. Imaging

Ultrasonography, CT, and MRI are useful for diagnosis, staging, and to follow tumor response to therapy. A scintigraphic study of bone and lung and selective angiography are generally part of the preoperative workup to evaluate metastatic disease.

► Differential Diagnosis

In the absence of a palpable mass, the differential diagnosis is that of hepatomegaly with or without anemia or jaundice. Hematologic and nutritional conditions should be ruled out, as well as HBV and HCV infection, α_1 -antitrypsin deficiency disease, lipid storage diseases, histiocytosis X, glycogen storage disease, tyrosinemia, congenital hepatic fibrosis, cysts, adenoma, focal nodular hyperplasia, inflammatory pseudotumor, and hemangiomas. If fever is present, hepatic abscess (pyogenic or amebic) must be considered. Venous-occlusive disease and hepatic vein thrombosis are rare possibilities. Tumors in the left lobe may be mistaken for pancreatic pseudocysts.

► Complications

Progressive enlargement of the tumor, abdominal discomfort, ascites, respiratory difficulty, and widespread metastases (especially to the lungs and the abdominal lymph nodes) are the rule. Rupture of the neoplastic liver and intraperitoneal hemorrhage have been reported. Progressive anemia and emaciation predispose the patient to an early septic death.

► Treatment

An aggressive surgical approach has resulted in the only reports of long-term survival. Complete resection of the lesion offers the only chance for cure. It appears that every isolated lung metastasis should also be surgically resected. Radiotherapy and chemotherapy have been disappointing in the treatment of primary liver neoplasms, although they may be used for initial cytoreduction of tumors found to be unresectable at the time of primary surgery (see Chapter 29 for additional discussion). Second-look celiotomy has, in some cases, allowed resection of the tumor, resulting in a reduced mortality rate. Liver transplantation can be an option in hepatoblastoma with 85% 10-year survival in patients with unresectable disease limited to the liver. For hepatocellular carcinoma, the survival rate is poor due to the typically advanced stage at diagnosis. The survival rate may be better for those patients in whom the tumor is incidental to another disorder (tyrosinemia, biliary atresia, cirrhosis). In HBV-endemic areas, childhood HBV vaccination has reduced the incidence of hepatocellular carcinoma.

► Prognosis

If the tumor is completely removed the survival rate is 90% for hepatoblastoma and 33% for hepatocellular carcinoma. If metastases are present, survival is reduced to 40% for hepatoblastoma.

LIVER TRANSPLANTATION

Orthotopic liver transplantation is indicated in children with end-stage liver disease, acute fulminant hepatic failure, or complications from metabolic liver disorders. Recent advances in immunosuppression (eg, cyclosporine and tacrolimus, use of monoclonal antibodies against T cells, introduction of mycophenolate mofetil and sirolimus), better candidate selection, improvements in surgical techniques, antiviral medications, and experience in postoperative management have contributed to improved results.

The major indications for childhood transplantation are:

1. A failed Kasai operation or decompensated cirrhosis caused by biliary atresia.
2. α_1 -Antitrypsin deficiency causing end-stage liver disease.
3. Posthepatic (autoimmune chronic hepatitis, hepatitis B or C disease) cirrhosis.
4. Tyrosinemia.
5. Crigler-Najjar syndrome type 1.
6. Wilson disease.
7. Acute liver failure when recovery is unlikely.
8. Primary sclerosing cholangitis.
9. Hepatic-based malignancies.
10. Cases in which the consequences of chronic cholestasis severely impair the patient's quality of life (eg, Alagille syndrome).

Children should be referred early for evaluation because the limiting factor for success is the small donor pool. Pared-down adult livers, organs from living related donors, and split adult donor livers have expanded the donor pool, in addition to whole pediatric donor organs. Ten percent of recipients require retransplantation. In general, 80–90% of children survive at least 2–5 years after transplantation, with long-term survival expected to be comparable. Lifetime immunosuppression therapy, using combinations of tacrolimus, cyclosporine, prednisone, azathioprine, mycophenolate mofetil, or sirolimus, with its incumbent risks, is generally necessary to prevent rejection. Several studies have examined immunosuppression withdrawal, which can occasionally be performed successfully; however, criteria for which patients can survive off of immunosuppression have not been determined. The minimal amount of immunosuppression that will prevent

allograft rejection should be chosen. The overall quality of life for children with a transplanted liver appears to be excellent. There is an increased risk (up to 25%) of renal dysfunction. The lifelong risk of EBV-induced lymphoproliferative disease is approximately 5% and is related to age, EBV exposure status at time of transplantation, and intensity of immunosuppression. Various protocols are being tested for prevention and treatment of lymphoproliferative disease.

PANCREATIC DISORDERS

ACUTE PANCREATITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Epigastric abdominal pain radiating to the back.
- ▶ Nausea and vomiting.
- ▶ Elevated serum amylase and lipase.
- ▶ Evidence of pancreatic inflammation by CT or ultrasound.

▶ General Considerations

Most cases of acute pancreatitis are the result of drugs, viral infections, systemic diseases, abdominal trauma, or obstruction of pancreatic flow. More than 20% are idiopathic. Causes of pancreatic obstruction include stones, choledochal cyst, tumors of the duodenum, pancreas divisum, and ascariasis. Acute pancreatitis has been seen following treatment with sulfasalazine, thiazides, valproic acid, azathioprine, mercaptopurine, asparaginase, antiretroviral drugs (especially didanosine), high-dose corticosteroids, and other drugs. It may also occur in cystic fibrosis, systemic lupus erythematosus, α_1 -antitrypsin deficiency, diabetes mellitus, Crohn disease, glycogen storage disease type I, hyperlipidemia types I and V, hyperparathyroidism, Henoch-Schönlein purpura, Reye syndrome, organic acidopathies, Kawasaki disease, or chronic

renal failure; during rapid refeeding in cases of malnutrition; following spinal fusion surgery; and in familial cases. Alcohol-induced pancreatitis should be considered in the teenage patient.

► Clinical Findings

A. Symptoms and Signs

An acute onset of persistent (hours to days), moderate to severe upper abdominal and midabdominal pain occasionally referred to the back, and vomiting, is the common presenting picture. The abdomen is tender, but not rigid, and bowel sounds are diminished, suggesting peritoneal irritation. Abdominal distention is common in infants and younger children. Jaundice is unusual. Ascites may be noted, and a left-sided pleural effusion is present in some patients. Periumbilical and flank bruising indicate hemorrhagic pancreatitis.

B. Laboratory Findings

Leukocytosis and an elevated serum amylase (more than three times normal) should be expected early, except in infants younger than 6 months who may have hypoamylasemia. Serum lipase is elevated and persists longer than serum amylase. The immunoreactive trypsinogen may also be elevated. Pancreatic amylase isoenzyme determination can help differentiate nonpancreatic causes (eg, salivary, intestinal, or tubo-ovarian) of serum amylase elevation. Hyperglycemia (serum glucose > 300 mg/dL), hypocalcemia, falling hematocrit, rising blood urea nitrogen, hypoxemia, and acidosis may all occur in severe cases and imply a poor prognosis.

C. Imaging

Plain radiographic films of the abdomen may show a localized ileus (sentinel loop). Ultrasonography shows decreased echodensity of the gland in comparison with the left lobe of the liver. Pseudocyst formation can occasionally be seen early in the course. CT scanning is better for detecting pancreatic phlegmon, or abscess formation. ERCP or MRCP may be useful in confirming patency of the main pancreatic duct in cases of abdominal trauma; in recurrent acute pancreatitis; or in revealing stones, ductal strictures, and pancreas divisum.

► Differential Diagnosis

Other causes of acute upper abdominal pain include lesions of the stomach, duodenum, liver, and biliary system; acute gastroenteritis or atypical appendicitis; pneumonia; volvulus; intussusception; and nonaccidental trauma.

► Complications

Complications early in the disease include shock, fluid and electrolyte disturbances, ileus, acute respiratory distress syndrome, and hypocalcemia. Hypervolemia is seen between the

third and fifth day, at which time renal tubular necrosis may occur. The gastrointestinal, neurologic, musculoskeletal, hepatobiliary, dermatologic, and hematologic systems may also be involved.

Later, 5–20% of patients develop a pseudocyst heralded by recurrence of abdominal pain and rise in the serum amylase. Up to 60–70% of pseudocysts resolve spontaneously. Infection, hemorrhage, rupture, or fistulization may occur. Phlegmon formation is common and may extend from the gland into the retroperitoneum or into the lesser sac. Most regress, but some require drainage. Infection in this inflammatory mass may occur. Pancreatic abscess formation, which is rare (3–5%), develops 2–3 weeks after the initial insult. Fever, leukocytosis, and pain suggest this complication; diagnosis is made by ultrasound or CT scanning. Chronic pancreatitis, exocrine or endocrine pancreatic insufficiency, and pancreatic lithiasis are rare sequelae of acute pancreatitis.

► Treatment

Medical management includes careful attention to fluids, electrolytes, and respiratory status. Gastric decompression may be helpful if there is significant vomiting. Pain should be controlled with opioids. Acid suppression may be helpful. Nutrition is provided by the parenteral or enteral (jejunal) route. Broad-spectrum antibiotic coverage is useful only in necrotizing pancreatitis. Drugs known to produce acute pancreatitis should be discontinued. Surgical treatment is reserved for traumatic disruption of the gland, intraductal stone, other anatomic obstructive lesions, and unresolved or infected pseudocysts or abscesses. Early endoscopic decompression of the biliary system reduces the morbidity associated with pancreatitis caused by obstruction of the common bile duct.

► Prognosis

In the pediatric age group, the prognosis is surprisingly good with conservative management. The mortality rate is 5–10% in patients treated surgically and 1% in those treated only with medication. The morbidity rate is high with surgery as a result of fistula formation.

Lowe ME: Pancreatitis in childhood. *Curr Gastroenterol Rep* 2004;6:240 [PMID: 15128492].
Nydegger A et al: Childhood pancreatitis. *J Gastroenterol Hepatol* 2006;21:499 [PMID: 16638090].

CHRONIC PANCREATITIS

Chronic pancreatitis is differentiated from acute pancreatitis in that the pancreas remains structurally or functionally abnormal after an attack.

The causes are multiple and can be divided into toxic-metabolic (eg, alcohol, chronic renal failure, hypercalcemia), idiopathic, genetic, autoimmune, recurrent and severe acute pancreatitis, and obstructive pancreatitis (eg, pancreas divisum, choledochal cyst).

► Clinical Findings

The diagnosis often is delayed by the nonspecificity of symptoms and the lack of persistent laboratory abnormalities.

A. Symptoms and Signs

There is usually a prolonged history of recurrent upper abdominal pain of variable severity. Radiation of the pain into the back is a frequent complaint. Fever and vomiting are not common. Steatorrhea and symptoms of diabetes may develop later in the course, and malnutrition secondary to failure of pancreatic exocrine secretions may also occur.

B. Laboratory Findings

Serum amylase and lipase levels are usually elevated during early acute attacks but are often normal later. Pancreatic insufficiency and reduced volume and bicarbonate response may be found during pancreatic stimulation testing or by determination of fecal pancreatic elastase 1. Mutations of the cationic trypsinogen gene, the pancreatic secretory trypsin inhibitor, and the cystic fibrosis transmembrane conductance regulator gene (*CFTR*) are associated with recurrent acute and chronic pancreatitis. Elevated blood glucose and glycohemoglobin levels and glycosuria frequently occur in protracted disease. Sweat chloride should be checked for cystic fibrosis and serum calcium for hyperparathyroidism.

C. Imaging

Radiographs of the abdomen may show pancreatic calcifications in up to 30% of patients. Ultrasound or CT examination demonstrates pancreatic enlargement, ductal dilation, and calculi in up to 80%. CT is the initial imaging procedure of choice. MRCP or ERCP can show ductal dilation, stones, strictures, or stenotic segments. Endoscopic ultrasound in the diagnosis and staging of chronic pancreatitis is being evaluated.

► Differential Diagnosis

Other causes of recurrent abdominal pain must be considered. Specific causes of pancreatitis such as hyperparathyroidism; systemic lupus erythematosus; infectious disease; and ductal obstruction by tumors, stones, or helminths must be excluded by appropriate tests.

► Complications

Disabling abdominal pain, steatorrhea, malnutrition, pancreatic pseudocysts, and diabetes are the most frequent long-term complications. Pancreatic carcinoma occurs more frequently in chronic pancreatitis, and in up to 40% of patients with hereditary pancreatitis by age 70.

► Treatment

Medical management of acute attacks is indicated (see Acute Pancreatitis section). If ductal obstruction is strongly suspected, endoscopic therapy (balloon dilation, stenting, stone removal, or sphincterotomy) should be pursued. Relapses occur in most patients. Orally ingested nonenteric-coated pancreatic enzymes at mealtime may reduce pain episodes in some patients. Antioxidant therapy is being investigated. Pseudocysts may be marsupialized to the surface or drained into the stomach or into a loop of jejunum if they fail to regress spontaneously. Experience in pediatric patients indicates that lateral pancreaticojejunostomy or the Frey procedure can reduce pain in patients with a dilated pancreatic duct and may prevent or delay progression of functional pancreatic impairment. Pancreatectomy and islet cell autotransplantation have been used in selected cases of chronic pancreatitis.

► Prognosis

In the absence of a correctable lesion, the prognosis is not good. Disabling episodes of pain, pancreatic insufficiency, diabetes, and pancreatic cancer may ensue. Narcotic addiction and suicide are risks in teenagers with disabling disease.

GASTROINTESTINAL & HEPATOBILIARY MANIFESTATIONS OF CYSTIC FIBROSIS

Cystic fibrosis is a disease with protean manifestations. Although pulmonary and pancreatic involvement dominate the clinical picture for most patients (see Chapter 18), various other organs can be involved. Table 21–9 lists the important gastrointestinal, pancreatic, and hepatobiliary conditions that may affect patients with cystic fibrosis along with their clinical findings, incidence, most useful diagnostic studies, and preferred treatment.

Table 21-9. Gastrointestinal and hepatobiliary manifestations of cystic fibrosis.

Organ	Condition	Symptoms	Age at Presentation	Incidence (%)	Diagnostic Evaluation	Management
Esophagus	Gastroesophageal reflux, esophagitis	Pyrosis, dysphagia, epigastric pain, hematemesis.	All ages	10-20	Endoscopy and biopsy, overnight pH study	H ₂ blockers, antacids, sucralfate, PPIs, surgical antireflux procedure.
	Varices	Hematemesis, melena.	Childhood and adolescents	3-10	Endoscopy	Endosclerosis, band ligation, drugs (see text), TIPS, liver transplantation (see Table 21-7).
Stomach	Gastritis	Upper abdominal pain, vomiting, hematemesis.	School age and older	10-25	Endoscopy and biopsy	H ₂ blockers, antacids, sucralfate, PPIs.
	Hiatal hernia	Reflux symptoms (see above), epigastric pain.	School age and older	3-5	Endoscopy; UGI	As above. Surgery in some.
Intestine	Meconium ileus	Abdominal distention, bilious emesis.	Neonate	10-15	Radiologic studies, plain abdominal films; contrast enema shows microcolon	Dislodgement of obstruction with Gastrografin enema. Surgery if unsuccessful or if case complicated by atresia, perforation, or volvulus.
	Distal intestinal obstruction syndrome	Abdominal pain, acute and recurrent; distention; occasional vomiting.	Any age, usually school age through adolescence	10-15	Palpable mass in right lower quadrant, radiologic studies	Gastrografin enema, intestinal lavage solution, diet, bulk laxatives, adjustment of pancreatic enzyme intake.
	Fibrosing colonopathy	As above. History of high enzyme dosage.	≥ 3 y	< 1	Barium enema or UGI/SBFT, abdominal ultrasound, or CT	Reduce pancreatic enzyme dose to < 2000 U/kg of lipase per dose if indicated. Surgical resection may be necessary.
	Intussusception	Acute, intermittent abdominal pain; distention; emesis.	Infants through adolescence	1-3	Radiographic studies, barium enema	Reduction by barium or air enema or surgery if needed. Diet. Bulk laxatives. Adjustment of pancreatic enzyme intake.
	Rectal prolapse	Anal discomfort, rectal bleeding.	Infants and children to age 4-5 y	15-25	Visual mass protruding from anus	Manual reduction, adjustment of pancreatic enzyme dosage, reassurance as problem resolves by age 3-5 y.
	Carbohydrate intolerance	Abdominal pain, flatulence, continued diarrhea with adequate replacement therapy.	Any age	10-25	Intestinal mucosal biopsy and disaccharidase analysis. Breath hydrogen after lactose load.	Reduce lactose intake; lactase; reduction of gastric hyperacidity if mucosa shows partial villous atrophy. Beware concurrent celiac disease or <i>Giardia</i> infection.
Pancreas	Total exocrine insufficiency	Diarrhea, steatorrhea, malnutrition, failure to thrive. Specific fat-soluble vitamin deficiency states.	Neonate through infancy	85-90	72-h fecal fat evaluation, fecal pancreatic elastase, direct pancreatic function tests	Pancreatic enzyme replacement, may need elemental formula, fat-soluble vitamin and vitamin E supplements.

(continued)

Table 21-9. Gastrointestinal and hepatobiliary manifestations of cystic fibrosis. (Continued)

Organ	Condition	Symptoms	Age at Presentation	Incidence (%)	Diagnostic Evaluation	Management
	Pancreatic sufficiency (partial exocrine insufficiency)	Occasional diarrhea, mild growth delay.	Any age	10-15	72-h fecal fat evaluation, direct pancreatic function tests, fecal pancreatic elastase	Pancreatic enzyme replacement in selected patients. Fat-soluble vitamin supplements as indicated by biochemical evaluation.
	Pancreatitis	Recurrent abdominal pain, vomiting.	Older children through adolescence. Primarily in patients with partial pancreatic sufficiency.	0.1	Increased serum lipase and amylase, pancreatic provocative test, MRCP, ERCP	Addition of pancreatic enzymes to feeds, endoscopic removal of sludge or stones if present, endoscopic papillotomy.
	Diabetes	Weight loss, polyuria, polydipsia.	Older children through adolescence	5-7	Glucose tolerance test and insulin levels	Diet, insulin, oral hypoglycemics.
Liver	Steatosis	Hepatomegaly.	Neonates and infants, but can be seen at all ages	20-60	Liver biopsy	Improved nutrition, replacement of pancreatic enzymes, vitamins, and essential fatty acids.
	Focal biliary cirrhosis	Hepatomegaly.	Infants and older patients. Prevalence increases with age.	10-70	Liver biopsy	As above. Ursodeoxycholic acid.
	Multilobular biliary cirrhosis	Hepatosplenomegaly, hematemesis from esophageal varices; hypersplenism, jaundice, ascites late in course.	School age through adolescence	5-15	Liver biopsy, endoscopy	Improved nutrition, ursodeoxycholic acid, endosclerosis or band ligation of varices, or partial splenic embolization, liver transplantation.
	Neonatal jaundice	Cholestatic jaundice hepatomegaly; often seen with meconium ileus.	Neonates	0.1-1	Sweat chloride test, liver biopsy	Nutritional support, special formula with medium-chain triglyceride-containing oil, pancreatic enzyme replacement, vitamin supplements.
Gallbladder	Microgallbladder	None.	Congenital—present at any age	30	Ultrasound or hepatobiliary scintigraphy	None needed.
	Cholelithiasis	Recurrent abdominal pain, rarely jaundice.	School age through adolescence	1-10	Ultrasound	Surgery if symptomatic and low risk, trial of cholelitholytics in others.
Extrahepatic bile ducts	Intraluminal obstruction (sludge, stones, tumor)	Jaundice, hepatomegaly, abdominal pain.	Neonates, then older children through adolescence	Rare in neonates (< 0.1)	Ultrasound and hepatobiliary scintigraphy, MRCP	Surgery in neonates; ERCP in older patients or surgery.
	Extraluminal obstruction (intrapancreatic compression, tumor)	As above.	Older children to adults	Rare (< 1)	As above	Surgical biliary drainage procedure or ERCP.

CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; MRCP, magnetic resonance cholangiopancreatography; PPI, proton pump inhibitor; TIPS, transjugular intrahepatic portosystemic shunt; UGI/SBFT, upper gastrointestinal/small bowel follow-through radiologic series.

SYNDROMES WITH PANCREATIC EXOCRINE INSUFFICIENCY

Several syndromes are associated with exocrine pancreatic insufficiency. Clinically, patients present with a history of failure to thrive, diarrhea, fatty stools, and an absence of respiratory symptoms. Laboratory findings include a normal sweat chloride; low fecal pancreatic elastase 1; and low to absent pancreatic lipase, amylase, and trypsin levels on duodenal intubation. Each disorder has several associated clinical features that aid in the differential diagnosis. In Shwachman syndrome, pancreatic exocrine hypoplasia with widespread fatty replacement of the glandular acinar tissue is associated with neutropenia because of maturational arrest of the granulocyte series. Metaphyseal dysostosis and an elevated fetal hemoglobin level are common; immunoglobulin deficiency and hepatic dysfunction are also reported. CT examination of the pancreas demonstrates the widespread fatty replacement. Serum immunoreactive trypsinogen levels are extremely low.

Other associations of exocrine pancreatic insufficiency include (1) aplastic alae, aplasia cutis, deafness (Johanson-Blizzard syndrome); (2) sideroblastic anemia, developmental delay, seizures, and liver dysfunction (Pearson bone marrow pancreas syndrome); (3) duodenal atresia or stenosis; (4) malnutrition; and (5) pancreatic hypoplasia or agenesis.

The complications and sequelae of deficient pancreatic enzyme secretion are malnutrition, diarrhea, and growth failure. The degree of steatorrhea may lessen with age. Intra gastric lipolysis primarily caused by lingual lipase may compensate in patients with low or absent pancreatic function. In Shwachman syndrome, the major sequela is short stature. Increased numbers of infections may result from chronic neutropenia. Neutrophil mobility is also impaired in many patients. In addition, an increased incidence of leukemia has been noted in these patients.

Pancreatic enzyme and fat-soluble vitamin replacement are required therapy in most patients. The prognosis appears to be good for those able to survive the increased number of bacterial infections early in life and those patients without severe associated defects.

ISOLATED EXOCRINE PANCREATIC ENZYME DEFECT

Normal premature infants and most newborns produce little, if any, pancreatic amylase following meals or exogenous hormonal stimulation. This temporary physiologic insufficiency may persist for the first 3–6 months of life and be responsible for diarrhea when complex carbohydrates (cereals) are introduced into the diet.

Congenital pancreatic lipase deficiency and congenital colipase deficiency are extremely rare disorders, causing diarrhea and variable malnutrition with malabsorption of dietary fat and fat-soluble vitamins. The sweat chloride level is normal, and neutropenia is absent. Treatment is oral replacement of pancreatic enzymes and a low-fat diet or formula containing medium-chain triglycerides.

Exocrine pancreatic insufficiency of proteolytic enzymes (eg, trypsinogen, trypsin, chymotrypsin) is caused by enterokinase deficiency, a duodenal mucosal enzyme required for activation of the pancreatic proenzymes. These patients present with malnutrition associated with hypoproteinemia and edema but are free of respiratory symptoms and have a normal sweat test. They respond to pancreatic enzyme replacement therapy and feeding formulas that contain a casein hydrolysate (eg, Nutramigen, Pregestimil).

PANCREATIC TUMORS

Pancreatic tumors, whether benign or malignant, are rare. They most often arise from ductal or acinar epithelium (malignant adenocarcinoma) or from islet (endocrine) components within the gland, such as the benign insulinoma (adenoma) derived from β cells. Other pancreatic tumors also originate from these pluripotential endocrine cells (gastrinoma, VIPoma, glucagonoma). These malignant lesions produce diverse symptoms, because they release biologically active polypeptides from this ectopic location. The clinical features of these tumors are summarized in Table 21–10. The differential diagnosis of pancreatic tumors includes Wilms tumor, neuroblastoma, and malignant lymphoma. In older children, endoscopic ultrasonography can aid in localizing these tumors.

Table 21-10. Pancreatic tumors.

	Age	Major Findings	Diagnosis	Treatment	Associated Conditions
Insulinoma	Any age	Hypoglycemia, seizures; high serum insulin; weight gain; abdominal pain and mass infrequent	CT scan, MRI, EUS, SRS	Surgery, diazoxide, SSTA	
Adenocarcinoma	Any age	Epigastric pain, mass weight loss, anemia, biliary obstruction	Ultrasound, CT scan, MRI, EUS	Surgery	Chronic pancreatitis
Gastrinoma	Older than age 5-8 y	Male sex, gastric hypersecretion, peptic symptoms, multiple ulcers, gastrointestinal bleeding, anemia, diarrhea	Elevated fasting gastrin and postsecretin suppression test (> 300 pg/mL), CT scan, MRI, EUS, SRS, laparotomy	PPI, surgical resection, total gastrectomy, SSTA	Zollinger-Ellison syndrome, multiple endocrine neoplasia syndrome type 1, neurofibromatosis
VIPoma	Any age	Secretory diarrhea, hypokalemia, hypochlorhydria, weight loss, flushing	Elevated VIP levels; sometimes, elevated serum gastrin and pancreatic polypeptide; SRS	Surgery, SSTA, IV fluids	
Glucagonoma	Older patients	Diabetes, necrolytic rash, diarrhea, anemia, thrombotic events, depression	Elevated glucagon, gastrin, VIP, MRI, SRS	Surgery, SSTA	

CT, computed tomography; EUS, endoscopic ultrasound; MRI, magnetic resonance imaging; PPI, proton pump inhibitor; SRS, somatostatin-receptor scintigraphy; SSTA, somatostatin analogue; VIP, vasoactive intestinal polypeptide.

Kidney & Urinary Tract

Gary M. Lum, MD

22

EVALUATION OF THE KIDNEY & URINARY TRACT

HISTORY

When renal disease is suspected, the history should include:

1. Family history of cystic disease, hereditary nephritis, deafness, dialysis, or renal transplantation.
2. Preceding acute or chronic illnesses (eg, urinary tract infection, pharyngitis, impetigo, or endocarditis).
3. Rashes or joint pains.
4. Growth delay or failure to thrive.
5. Polyuria, polydipsia, enuresis, urinary frequency, or dysuria.
6. Documentation of hematuria, proteinuria, or discolored urine.
7. Pain (abdominal, costovertebral angle, or flank) or trauma.
8. Sudden weight gain or edema.
9. Drug or toxin exposure.
10. Data pertaining to the newborn with suspected urinary tract disease: prenatal ultrasonographic studies, birth asphyxia, Apgar scores, oligohydramnios, dysmorphic features, abdominal masses, voiding patterns, anomalous development, and umbilical artery catheterization.

PHYSICAL EXAMINATION

Important aspects of the physical examination include the height, weight, skin lesions (café-au-lait or ash leaf spots), pallor, edema, or skeletal deformities. Anomalies of the ears, eyes, or external genitalia may be associated with renal anomalies or disease. The blood pressure should be measured in a quiet setting. The cuff should cover two thirds of the child's upper arm, and peripheral pulses should be noted. The abdomen should be palpated, with attention to the kidneys, abdominal masses, musculature, and the presence of ascites. An ultrasonic device is useful for measurements in infants.

LABORATORY EVALUATION OF RENAL FUNCTION

Serum Analysis

The standard indicators of renal function are serum levels of urea nitrogen and creatinine; their ratio is normally about 10:1. This ratio may increase when renal perfusion or urine flow is decreased, as in urinary tract obstruction or dehydration. Because serum urea nitrogen levels are more affected by these and other factors (eg, nitrogen intake, catabolism, use of corticosteroids) than are creatinine levels, the most reliable single indicator of glomerular function is the serum level of creatinine. For example, an increase in serum creatinine from 0.5 mg/dL to 1.0 mg/dL represents a 50% decrease in glomerular filtration rate. The serum creatinine level of small children should be well under 0.8 mg/dL. Only larger adolescents should have levels exceeding 1 mg/dL. Less precise but nonetheless important indicators of possible renal disease are abnormalities of serum electrolytes, pH, calcium, phosphorus, magnesium, albumin, or complement.

Glomerular Filtration Rate

The endogenous creatinine clearance (C_{cr}) in milliliters per minute estimates the glomerular filtration rate (GFR). A 24-hour urine collection is usually obtained; however, in small children from whom collection is difficult, a 12-hour daytime specimen, collected when urine flow rate is greatest, is acceptable. The procedure for collecting a timed urine specimen should be explained carefully so that the parent or patient understands fully the rationale of (1) first emptying the bladder (discarding that urine) and noting the time; and (2) putting all urine subsequently voided into the collection receptacle, including the last void, 12 or 24 hours later. Reliability of the 24-hour collection can be checked by measuring the total 24-hour creatinine excretion in the specimen. Total daily creatinine excretion (creatinine index) should be 14–20 mg/kg. Creatinine indices on either side of

this range suggest collections that were either inadequate or excessive. Calculation by the following formula requires measurements of plasma creatinine (P_{cr}) in mg/mL, urine creatinine (U_{cr}) in mg/mL, and urine volume (V) expressed as mL/min:

$$C_{cr} = \frac{U_{cr}V}{P_{cr}}$$

Creatinine is a reflection of body muscle mass. Because accepted ranges of normal C_{cr} are based on adult parameters, correction for size is needed to determine normal ranges in children. Clearance is corrected to a standard body surface area of 1.73 m^2 in the formula:

$$\text{"Corrected" } C = \frac{\text{Patient's } C_{cr} \times 1.73 \text{ m}^2}{\text{Patient's body surface area}}$$

Although $80\text{--}125 \text{ mL/min}/1.73 \text{ m}^2$ is the normal range for C_{cr} , estimates at the lower end of this range may indicate problems.

A reliable formula for quick approximation of C_{cr} is based on plasma creatinine level and length in centimeters:

$$C_{cr}(\text{mL/min}/1.73 \text{ m}^2) = \frac{0.55 \times \text{Height in cm}}{P_{cr} \text{ in mg/dL}}$$

Note: Because this formula takes into account the body surface area, further correction is not necessary. Use $0.45 \times$ length in centimeters for newborns and for infants younger than age 1 year. This method of calculation does not replace creatinine clearance determinations, but is useful when a suspicious plasma creatinine needs to be checked.

Urine Concentrating Ability

Inability to concentrate urine causes polyuria, polydipsia, or enuresis and is often the first sign of chronic renal failure. The first morning void should be concentrated. Evaluation of other abnormalities of urinary concentration or dilution is discussed later in the sections on specific disease entities, such as diabetes insipidus.

Urinalysis

Commercially available dipsticks can be used to check the urine for red blood cells (RBCs), hemoglobin, leukocytes, nitrites, and protein and to approximate its pH. Positive results for blood should always be confirmed by microscopy, as should any suspicion of crystalluria. Significant proteinuria ($> 150 \text{ mg/dL}$) detected by dipstick should be confirmed by quantitation, either with a 24-hour collection or by the protein/creatinine ratio (see following section) of a random specimen.

In children with asymptomatic hematuria or proteinuria, the search for renal origins will yield the most results.

Isolated proteinuria may reflect urologic abnormalities, benign excretion, or glomerular alterations. RBC casts suggest glomerulonephritis (GN), but the absence of casts does not rule out this disease. Anatomic abnormalities such as cystic disease may also cause hematuria.

Benign hematuria, including benign familial hematuria, is diagnosed by exclusion. In this group are children whose hematuria is caused by asymptomatic hypercalciuria. Figure 22-1 suggests an approach to the renal workup of hematuria. GN is discussed in more detail later in this chapter.

Combined proteinuria and hematuria is characteristic of more significant glomerular disease. Quantitation of proteinuria is customarily accomplished by a timed collection (eg, over a 24-hour period). However, the degree of proteinuria may be estimated by the ratio of protein/creatinine in a random urine sample. A protein-to-creatinine ratio above 0.2 is abnormal.

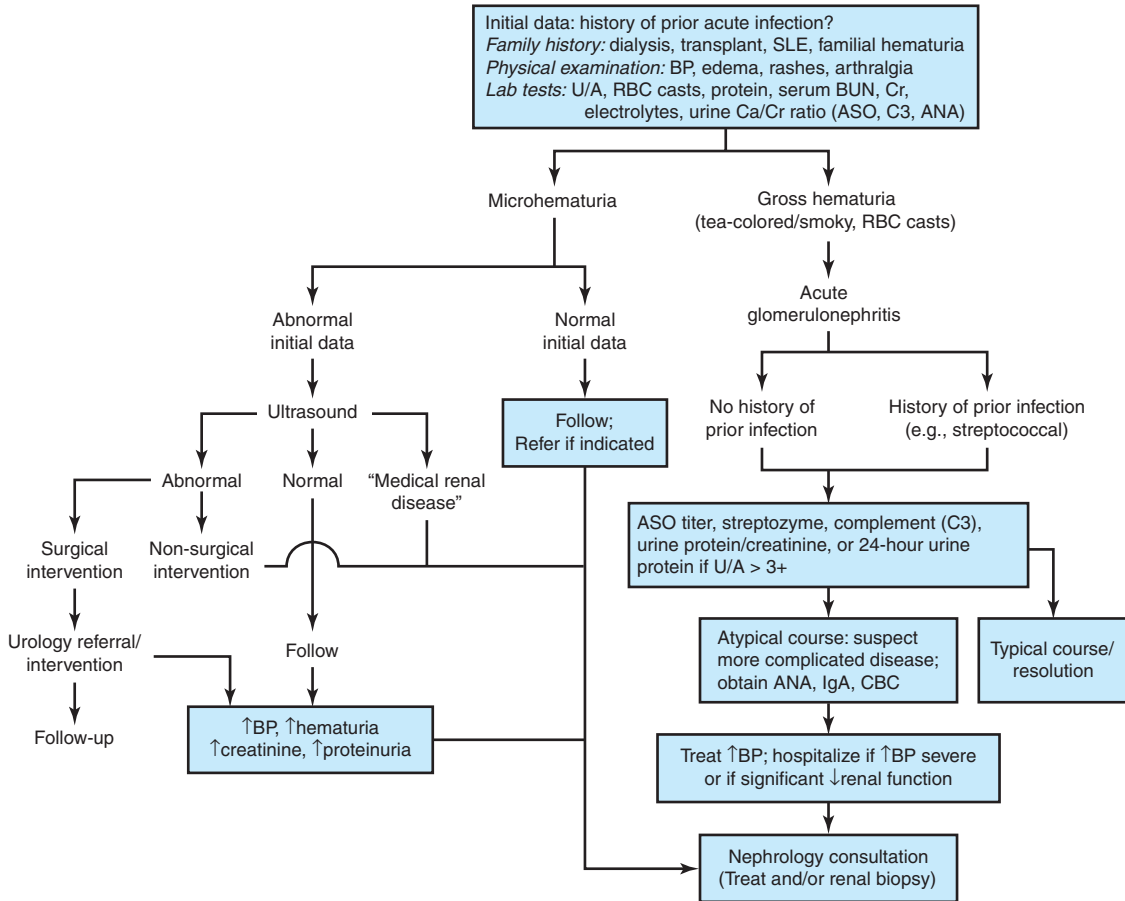

In the evaluation of asymptomatic proteinuria, orthostatic or postural proteinuria should be ruled out. The protein present in urine voided on arising in the morning is compared with that in urine formed in the upright position during the rest of the day. This can be accomplished simply by comparing the protein/creatinine ratios of the two urine samples. When quantitation is accomplished by evaluating the "upright" and "supine" portions of a 24-hour collection, a diagnosis of benign postural proteinuria is indicated if the upright collection contains $80\text{--}100\%$ of the entire 24-hour protein excretion, and if there are no other markers of renal disease.

An approach to the workup of isolated proteinuria is shown in Figure 22-2. Note that corticosteroid therapy is indicated in the algorithm because this may be initiated prior to referral. Other renal lesions with proteinuric manifestations are discussed later in this chapter.

Special Tests of Renal Function

Measurements of urinary sodium, creatinine, and osmolality are useful in differentiating prerenal from renal causes of renal insufficiency, such as acute tubular necrosis. The physiologic response to decreased renal perfusion is decreased urinary output, increased urine osmolality, increased urinary solutes (eg, creatinine), and decreased urinary sodium (usually $< 20 \text{ mEq/L}$). Prolonged underperfusion causes varying increases in serum creatinine and blood urea nitrogen (BUN) concentrations, prompting the need to differentiate between this state and acute tubular necrosis (see section on Acute Renal Failure, later).

The presence of certain substances in urine may suggest tubular dysfunction. For example, urine glucose should be less than 5 mg/dL . Hyperphosphaturia occurs with significant tubular abnormalities (eg, Fanconi syndrome). Measurement of the phosphate concentration of a 24-hour urine specimen and evaluation of tubular reabsorption of phosphorus (TRP) will help document renal tubular diseases as

▲ **Figure 22-1.** Approach to the renal workup of hematuria. (Exclude UTI, lithiasis, trauma, bleeding disorders, sickle cell disease.) Complement is depressed in acute poststreptococcal type of glomerulonephritis (about 30 days), chronic glomerulonephritis (persistent), and lupus. ANA, antinuclear antibody; ASO, antistreptolysin antibody; BP, blood pressure; BUN, blood urea nitrogen; C3, complement; Ca, calcium; CBC, complete blood count; Cr, creatinine; IgA, immunoglobulin A; RBC, red blood cell; SLE, systemic lupus erythematosus; U/A, urinalysis.

well as hyperparathyroid states. TRP (expressed as percentage of reabsorption) is calculated as follows:

$$\text{TRP} = 100 \left[1 - \frac{S_{\text{Cr}} \times \text{UPO}_4}{\text{SPO}_4 \times \text{UCr}} \right]$$

where S_{Cr} = serum creatinine; UCr = urine creatinine; SPO_4 = serum phosphate; and UPO_4 = urine phosphate. All values for creatinine and phosphate are expressed in milligrams per deciliter for purposes of calculation. A TRP value of 80% or more is considered normal, although it depends somewhat on the value of SPO_4 .

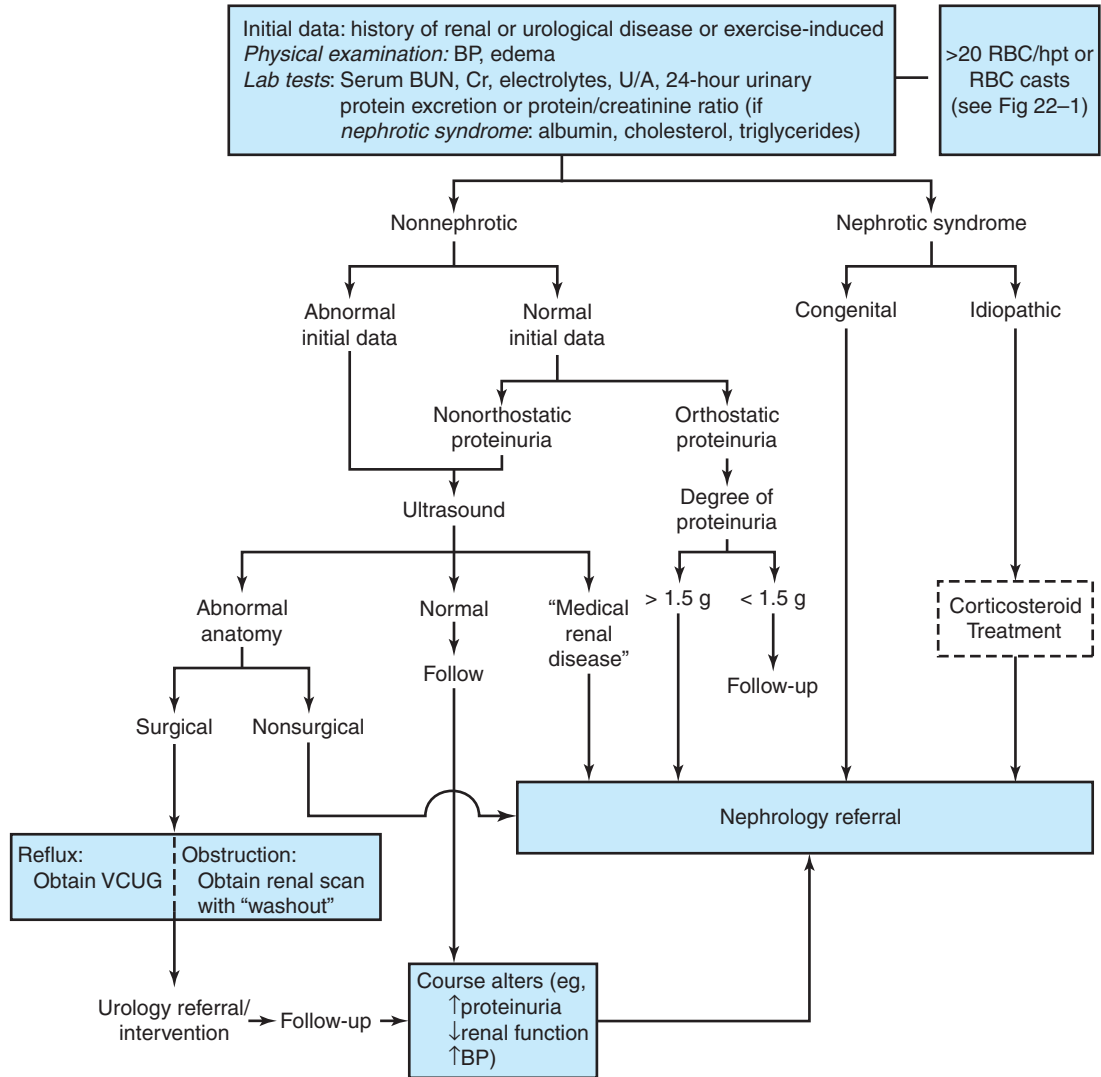

The urinary excretion of amino acids in generalized tubular disease reflects a quantitative increase rather than a qualitative change. Diseases affecting proximal tubular reabsorption of bicarbonate—including isolated renal tubular acidosis (RTA), Fanconi syndrome (which occurs in diseases

such as cystinosis), and chronic renal failure—are discussed later in the chapter.

LABORATORY EVALUATION OF IMMUNOLOGIC FUNCTION

Many parenchymal renal diseases are thought to have immune causation, although the mechanisms are largely unknown. Examples include (1) deposition of circulating antigen-antibody complexes that are directly injurious or incite injurious responses and (2) formation of antibody directed against the glomerular basement membrane (rare in children).

Total serum complement and the C3 and C4 complement components should be measured when immune-mediated renal injury or chronic GN is suspected. Where clinically indicated, antinuclear antibodies, hepatitis B surface antigen, and rheumatoid factor should be obtained. In rare cases cold-

▲ **Figure 22-2.** Approach to the workup of isolated proteinuria. BP, blood pressure; Cr, creatinine; hpf, high-power field; RBC, red blood cell; U/A, urinalysis; VCUG, voiding cystourethrogram. Rules out benign postural proteinuria with urine protein/creatinine ratio of first morning void (recumbent urine) vs day void (upright). Will normalize within a month in post-streptococcal glomerulonephritis.

precipitable proteins (cryoglobulins), C3 “nephritic” factor, or antiglomerular basement membrane (anti-GBM) antibody measurements may help confirm a specific diagnosis. At some point in the workup, the diagnosis may be supported or confirmed by histologic examination of renal tissue.

RADIOGRAPHIC EVALUATION

Renal ultrasonography is a useful noninvasive tool for evaluating renal parenchymal disease, urinary tract abnormalities,

or renal blood flow. Excretory urography is used to assess the anatomy and function of the kidney, collecting system, and bladder. Radioisotope studies provide information about renal anatomy, blood flow, and integrity and function of the glomerular, tubular, and collecting systems. Renal stones are best seen by computed tomography.

Voiding cystourethrography or cystoscopy is indicated when vesicoureteral reflux or bladder outlet obstruction is suspected. Cystoscopy is rarely useful in the evaluation of asymptomatic hematuria or proteinuria in children.

Renal arteriography or venography is indicated to define vascular abnormalities (eg, renal artery stenosis) prior to surgical intervention or transluminal angiography. Less invasive measures such as ultrasonography and Doppler studies can demonstrate renal blood flow or thromboses. More specific identification of stenoses of the renal artery is accomplished by magnetic resonance arteriography.

RENAL BIOPSY

Histologic information is valuable for diagnosis, treatment, and prognosis. Satisfactory evaluation of renal tissue requires examination by light, immunofluorescence, and electron microscopy.

When a biopsy is anticipated, a pediatric nephrologist should be consulted. In children, percutaneous renal biopsy with a biopsy needle is an acceptable low-risk procedure—avoiding the risks of general anesthesia—when performed by an experienced physician. A surgeon should perform the biopsy procedure if operative exposure of the kidney is necessary, if a risk factor (eg, bleeding disorder) is present, or if a “wedge” biopsy is preferred.

CONGENITAL ANOMALIES OF THE URINARY TRACT

RENAL PARENCHYMAL ANOMALIES

About 10% of children have congenital anomalies of the genitourinary tract, which range in severity from asymptomatic to lethal. Some asymptomatic abnormalities may have significant complications. For example, patients with “horseshoe” kidney (kidneys fused in their lower poles) have a higher incidence of renal calculi. Unilateral agenesis is usually accompanied by compensatory hypertrophy of the contralateral kidney and thus should be compatible with normal renal function. Supernumerary and ectopic kidneys are usually of no significance. Abnormal genitourinary development is associated with varying degrees of renal dysgenesis and dysfunction ranging from mild forms to complete renal agenesis. In neonates, bilateral renal agenesis is associated with severe oligohydramnios, pulmonary hypoplasia, abnormal (Potter) facies, and early death.

1. Renal Dysgenesis

Renal dysgenesis is a spectrum of anomalies. In simple hypoplasia, which may be unilateral or bilateral, the affected kidneys are smaller than normal. In some forms of dysplasia, immature, undifferentiated renal tissue persists. In some dysplasias, the number of normal nephrons is insufficient to sustain life once the child reaches a critical body size. The lack of renal tissue may not be readily discernible in the newborn period because the infant’s urine production, though poor in concentration, may be adequate in volume.

Often, the search for renal insufficiency is initiated only when growth fails or chronic renal failure develops.

Other forms of renal dysplasia include oligomeganephronia (characterized by the presence of only a few large glomeruli) and the cystic dysplasias (characterized by the presence of renal cysts). This group includes microcystic disease (congenital nephrosis). A simple cyst within a kidney may be clinically unimportant because it does not predispose to progressive polycystic development. An entire kidney lost to multicystic development with concomitant hypertrophy and normal function of the contralateral side may also be of little clinical consequence. Nonetheless, even a simple cyst could pose problems if it becomes a site for stone formation, infection, or bleeding.

2. Polycystic Kidney Disease

Autosomal recessive polycystic kidney disease is increasingly diagnosed by prenatal ultrasound. In its most severe form the cystic kidneys are nonfunctional in utero, and, therefore, newborns can have Potter facies and other complications of oligohydramnios. In infancy and childhood, kidney enlargement by cysts may initially be recognized by abdominal palpation of renal masses. Hypertension is an early problem. The rate of the progression of renal insufficiency varies, as does growth failure and other complications of chronic renal failure. Two genes (*ADPKD1* and *ADPKD2*) account for 80% and 10% of cases of autosomal dominant polycystic kidney disease, respectively. Susceptibility of family members is detected by gene linkage studies. Renal ultrasound identifies cysts in about 80% of affected children by age 5 years. Children with this diagnosis need close monitoring for the development and treatment of hypertension, and their families should be offered genetic counseling. Management of end-stage renal failure is by dialysis or renal transplantation.

3. Medullary Cystic Disease (Juvenile Nephronophthisis)

Medullary cystic disease is characterized by cysts of varying sizes in the renal medulla with tubular and interstitial nephritis. Children present with renal failure and signs of tubular dysfunction (decreased concentrating ability, Fanconi syndrome). This lesion should not be confused with medullary sponge kidney (renal tubular ectasia), a frequently asymptomatic disease occurring in adults.

DISTAL URINARY TRACT ANOMALIES

1. Obstructive Uropathy

Obstruction at the ureteropelvic junction may be the result of intrinsic muscle abnormalities, aberrant vessels, or fibrous bands. The lesion can cause hydronephrosis and usually presents as an abdominal mass in the newborn. Obstruction

can occur in other parts of the ureter, especially at its entrance into the bladder, causing proximal hydronephrosis and hydronephrosis. Renal radionuclide scan with furosemide “wash-out” will reveal or rule out obstruction as the cause of the hydronephrosis. Whether intrinsic or extrinsic, urinary tract obstruction should be relieved surgically as soon as possible to minimize damage to the kidneys.

Severe bladder malformations such as exstrophy are clinically obvious and a surgical challenge. More subtle—but urgent in terms of diagnosis—is obstruction of urine flow from vestigial posterior urethral valves. This anomaly, which occurs almost exclusively in males, usually presents in newborns with anuria or a poor voiding stream secondary to severe obstruction of urine flow. The kidneys and bladder may be easily palpable. Leakage proximal to the obstruction may produce urinary ascites. Surgical drainage of urine is urgently required to prevent irreversible damage.

Prune belly syndrome is an association of urinary tract anomalies with cryptorchidism and absent abdominal musculature. Although complex anomalies, especially renal dysplasia, usually cause early death or the need for dialysis or transplantation, some patients have lived into the third decade with varying degrees of renal insufficiency. Timely urinary diversion is essential to sustain renal function.

Other complex malformations and external genital anomalies such as hypospadias are beyond the scope of this text. The challenge presented by urologic abnormalities resulting in severe compromise and destruction of renal tissue is to preserve all remaining renal function and treat the complications of progressive chronic renal failure. Involvement of a specialist in pediatric urology in early management is essential.

2. Reflux Nephropathy

The retrograde flow of urine from the bladder into the ureter (vesicoureteral reflux), may cause renal scarring and subsequent renal insufficiency or hypertension, or both, especially in the presence of urinary tract infection. A finding of hydronephrosis on renal ultrasound is suggestive of vesicoureteral reflux. Its presence can be confirmed or eliminated by a voiding cystourethrogram, which would also be obtained to rule out reflux in the evaluation of urinary tract infection. Low-grade reflux may resolve in the absence of infection, in which case antibiotic prophylaxis is undertaken while awaiting signs of resolution. Surgery may be required for chronic severe reflux.

HEMATURIA & GLOMERULAR DISEASE

MICROHEMATURIA

Children with painful hematuria should be investigated for urinary tract infection or direct injury to the urinary tract. Dysuria is common in cystitis or urethritis; associated back pain suggests the possibility of pyelonephritis; colicky flank pain may indicate the passage of a stone. Bright red blood or clots in the urine are associated with bleeding disorders, trauma, and arteriovenous malformations. Abdominal masses suggest the presence of urinary tract obstruction, cystic disease, or tumors of the renal or perirenal structures.

Asymptomatic hematuria is a challenge because clinical and diagnostic data are required to decide whether to refer the child to a nephrologist. The diagnosis of hematuria should not rely solely on a urine “dipstick” evaluation, but should be verified by a microscopic RBC count. Ruling out hypercalciuria as a cause of hematuria by a random urine calcium/creatinine ratio is one of the initial steps in the evaluation of hematuria. A value above 0.2 requires verification with a 24-hour collection. Hypercalciuria is excretion of calcium in excess of 4 mg/kg/d. Figure 22–1 delineates the outpatient approach to renal hematuria. The concern regarding the differential diagnosis is the possible presence of glomerular disease.

GLOMERULONEPHRITIS

The various types of GN have similar manifestations. Table 22–1 lists the most commonly encountered disorders in the differential diagnosis of childhood GN, including their clinical and histopathologic abnormalities. Severe glomerular histopathologic and clinical entities, such as anti-GBM antibody disease (Goodpasture syndrome), Wegener granulomatosis, and idiopathic, rapidly progressive GN, may be considered in the differential diagnosis of acute GN, but these disorders are exceedingly rare in children.

1. Poststreptococcal Glomerulonephritis

The diagnosis of poststreptococcal disease is supported by a recent history (7–14 days previously) of group A β -hemolytic streptococcal infection. If a positive culture is not available, recent infection may be supported by an elevated antistreptolysin O titer or by high titers of other antistreptococcal antibodies. Other infections can cause similar glomerular injury; thus, “postinfection” glomerulonephritis (GN) may be a better term for this type of acute GN. In most cases, recovery is expected and usually complete within weeks. If the diagnosis is in question, or if the renal function of a patient with postinfection GN progressively deteriorates, a renal biopsy should be performed.

The clinical presentation of GN is usually gross hematuria. Urine may be coffee-colored or tea-colored. Microscopic examination of urine reveals RBCs too numerous to

Table 22-1. Glomerular diseases encountered in childhood.

Entity	Clinical Course	Prognosis
Postinfection glomerulonephritis (GN). Onset occurs 10–14 d after acute illness, commonly streptococcal. Characteristics include acute onset, tea-colored urine, mild to severe renal insufficiency, and edema.	Acute phase is usually over in 2 wk. Complete resolution occurs in 95% of cases. Severity of renal failure and hypertension varies. Microhematuria may persist to 18 mo. Hypocomplementemia resolves in 1–30 d.	Excellent. Chronic disease is rare. Severe proteinuria, atypical presentation or course, or persistent hypocomplementemia suggest another entity.
Membranoproliferative GN. Presentation ranges from mild microhematuria to acute GN syndrome. Diagnosis is made by renal biopsy. Etiology is unknown. Types I and II are most common. Lesion is chronic.	Course can be mild to severe (rapid deterioration in renal function); may mimic postinfection GN. Proteinuria can be severe. Complement depression is intermittent to persistent. Hypertension is usually significant.	Type I may respond to corticosteroids. Type II (dense deposit disease) is less treatable; function decrease varies from immediate to as long as 15 y in 30–50% of untreated cases.
IgA nephropathy. Classic presentation is asymptomatic gross hematuria during acute unrelated illness, with microhematuria between episodes. Occasional instances of acute GN syndrome occur. Etiology is unknown. Diagnosis is made by biopsy.	90% of cases resolve in 1–5 y. Gross hematuric episodes resolve with recovery from acute illness. Severity of renal insufficiency and hypertension varies. Proteinuria occurs in more severe, atypical cases.	Generally good; a small percentage develops chronic renal failure. Proteinuria in the nephrotic range is a poor sign. There is no universally accepted medication. (Corticosteroids may be useful in severe cases.)
Henoch-Schönlein purpura GN. Degree of renal involvement varies. Asymptomatic microhematuria is most common, but GN syndrome can occur. Renal biopsy is recommended in severe cases; it can provide prognostic information.	Presentation varies with severity of renal lesion. In rare cases, may progress rapidly to serious renal failure. Hypertension varies. Proteinuria in the nephrotic range and severe decline in function can occur.	Overall, prognosis is good. Patients presenting with > 50% reduction in function or proteinuria exceeding 1 g/24 h may develop chronic renal failure. Severity of renal biopsy picture can best guide approach in such cases. There is no universally accepted medication.
GN of systemic lupus erythematosus (SLE). Microhematuria and proteinuria are rarely first signs of this systemic disease. Renal involvement varies, but severe GN may ensue with remissions and exacerbations throughout the course.	Renal involvement is mild to severe. Clinical complexity depends on degree of renal insufficiency and other systems involved. Hypertension is significant. Manifestations of the severity of the renal lesion guide therapeutic intervention.	Renal involvement accounts for most significant morbidity in SLE. Control of hypertension affects renal prognosis. Medication is guided by symptoms, serology, and renal lesion. End-stage renal failure can occur.
Hereditary GN (eg, Alport syndrome). Transmission is autosomal-dominant/X-linked, with family history marked by end-stage renal failure, especially in young males. Deafness and eye abnormalities are associated.	There is no acute syndrome. Females are generally less affected but are carriers. Hypertension and increasing proteinuria occur with advancing renal failure. There is no known treatment.	Progressive proteinuria and hypertension occur early, with gradual decline in renal function in those most severely affected. Disease progresses to end-stage renal failure in most males.

count. Microscopy may reveal RBC casts. If present, these are diagnostic of GN, but their absence does not exclude the diagnosis. Edema is often seen (periorbital, facial, extremities), caused by sodium and water retention resulting from alteration in glomerular function. Symptoms are usually nonspecific. In cases accompanied by hypertension (a common finding), headache may be present. Fever is uncommon. Severe glomerular injury (which usually occurs in severe, acute presentations of the more chronic or destructive forms of GN) may be accompanied by massive proteinuria (nephrotic syndrome), anasarca, ascites, and severe compromise of renal function.

Typical poststreptococcal GN has no specific treatment. Antibiotic therapy is indicated if an infection is still present. Disturbances in renal function and resulting hypertension may require close monitoring, reduction in salt intake, diuretics or other antihypertensive drugs. In severe cases of renal failure, hemodialysis or peritoneal dialysis may be

necessary. Corticosteroids may also be administered in an attempt to influence the course of the GN.

The acute abnormalities generally resolve in 2–3 weeks. Serum complement (C3) may be normal as early as 3 days or as late as 30 days after onset. Complement-consuming glomerulonephritides also include membranoproliferative GN (chronic GN with persistent complement depression) and lupus GN. (See Chapter 27.) Although microscopic hematuria may persist for as long as a year, 85% of children recover completely. Persistent deterioration in renal function, urinary abnormalities beyond 18 months, persistent hypocomplementemia, and nephrotic syndrome are ominous signs. If any of these is present, a renal biopsy is indicated.

2. IgA Nephropathy

When asymptomatic gross hematuria appears to accompany a minor acute febrile illness or other stressful occurrence, the

diagnosis of IgA nephropathy may be entertained. In contrast to postinfection GN, IgA nephropathy is not associated with prior streptococcal infection, complement is not depressed, and in 50% of cases, serum immunoglobulin A is elevated. Often there are no associated symptoms or signs. Gross hematuria resolves within days, and there are no serious sequelae in 85% of cases. Treatment is not indicated, and the prognosis is good in most cases. Prognosis is guarded, however, if severe proteinuria, hypertension, or renal insufficiency is present or develops. In such instances, although no treatment is universally accepted, corticosteroids and other immunosuppressive drugs are used. Omega-3 fatty acids from fish oils are thought to be helpful.

3. Henoch-Schönlein Purpura

The diagnosis of Henoch-Schönlein purpura rests on the presence of a typical maculopapular rash found primarily, but not exclusively, on the dorsal surfaces of the lower extremities and buttocks. Most children have abdominal pain and bloody diarrhea. Joint pain is common, and, depending on the extent of renal involvement, hypertension may be present. Joint and abdominal pain responds to treatment with corticosteroids. Renal involvement ranges from mild GN with microhematuria to severe GN and varying degrees of renal insufficiency. GN with massive proteinuria and renal insufficiency carries a poor prognosis. Twenty percent of such cases result in end-stage renal failure. There is no universally accepted treatment, but corticosteroids are often administered (see Chapter 28).

4. Membranoproliferative Glomerulonephritis

The most common “chronic” form of GN in childhood is membranoproliferative GN. The diagnosis is established from the histologic appearance of the glomeruli on biopsy tissue. There are two major histologic types of membranoproliferative GN. Clinically, type II carries the worse prognosis, as end-stage renal failure develops in most cases. Type I more often responds to treatment with corticosteroids. C3 is depressed (in both types) and may be useful as a marker of response to treatment.

5. Lupus Glomerulonephritis

The diagnosis of systemic lupus erythematosus is based on its numerous clinical features and abnormal laboratory findings that include a positive antinuclear antibody test, depressed serum complement, and increased serum double-stranded DNA. Renal involvement is indicated by varying degrees of hematuria and proteinuria. More severe cases are accompanied by renal insufficiency and hypertension. Significant renal involvement requires treatment with immunosuppressive drugs and close monitoring. End-stage renal failure develops in 10–15% of patients with childhood SLE.

6. Hereditary Glomerulonephritis

The most commonly encountered hereditary glomerulonephritis is Alport syndrome, characterized by hearing loss and GN, occurring predominantly in males. It is a chronic form of GN and thus does not present with the clinical features typically seen in patients with acute processes. A family history is generally present, but there is a spontaneous mutation rate of about 18%. In individuals with the progressive form of GN, end-stage renal failure occurs, usually in the second to third decade of life. Although currently there is no treatment for this disorder, careful management of associated hypertension may slow the process.

ACUTE INTERSTITIAL NEPHRITIS

Acute interstitial nephritis is characterized by diffuse or focal inflammation and edema of the renal interstitium and secondary involvement of the tubules. The condition is most commonly drug related (eg, β -lactam-containing antibiotics, such as methicillin).

Fever, rigor, abdominal or flank pain, and rashes may occur in drug-associated cases. Urinalysis usually reveals leukocyturia and hematuria. Hansel staining of the urinary sediment often demonstrates eosinophils. The inflammation can cause significant deterioration of renal function. If the diagnosis is unclear because of the absence of a history of drug or toxin exposure or the absence of eosinophils in the urine, a renal biopsy may be performed to demonstrate the characteristic tubular and interstitial inflammation. Immediate identification and removal of the causative agent is imperative and may be all that is necessary. Treatment with corticosteroids is helpful in patients with progressive renal insufficiency or nephrotic syndrome. Severe renal failure requires supportive dialysis.

PROTEINURIA & RENAL DISEASE

Urine is rarely completely protein-free, but the average excretion is well below 150 mg/24 h. Small increases in urinary protein can accompany febrile illnesses or exertion and in some cases occur while in the upright posture.

An algorithm for investigation of isolated proteinuria is presented in Figure 22–2. In idiopathic nephrotic syndrome without associated features of GN, treatment with corticosteroids may be initiated. Nephrologic advice or follow-up should be sought, especially in patients with difficult or frequently relapsing unexplained proteinuria.

CONGENITAL NEPHROSIS

Congenital nephrosis is a rare autosomal recessive disorder. The kidneys are pale and large and may show microcystic dilations (microcystic disease) of the proximal tubules and glomerular abnormalities, including proliferation, crescent formation, and thickening of capillary walls. The pathogenesis is not well understood.

Infants with congenital nephrosis commonly have low birth weight, a large placenta, wide cranial sutures, and delayed ossification. Mild edema may be seen after the first few weeks of life. Anasarca follows, and the abdomen can become greatly distended by ascites. Massive proteinuria associated with typical-appearing nephrotic syndrome and hyperlipidemia is the rule. Hematuria is common. If the patient lives long enough, progressive renal failure occurs. Most affected infants succumb to infections at the age of a few months.

Treatment prior to dialysis and transplantation has little to offer other than nutritional support and management of the chronic renal failure.

IDIOPATHIC NEPHROTIC SYNDROME OF CHILDHOOD (NIL DISEASE, LIPOID NEPHROSIS, MINIMAL CHANGE DISEASE)

Nephrotic syndrome is characterized by proteinuria, hypoalbuminemia, edema, and hyperlipidemia. It may occur as a result of any form of glomerular disease and may rarely be associated with a several extrarenal conditions. In young children, the disease usually takes the form of idiopathic nephrotic syndrome of childhood (nil disease, lipoid nephrosis, minimal change disease), which has characteristic clinical and laboratory findings, but no well-understood cause.

► Clinical Findings

Affected patients are generally younger than age 6 years at onset. Typically, periorbital swelling and oliguria are noted, often following an influenza-like syndrome. Within a few days, increasing edema—even anasarca—becomes evident. Most children have few complaints other than vague malaise or abdominal pain. With significant “third spacing” of plasma volume, however, some children may present with hypotension. With marked edema, dyspnea due to pleural effusions may also occur.

Despite heavy proteinuria, the urine sediment is usually normal, although microscopic hematuria may be present. Plasma albumin concentration is low, and lipid levels increased. When azotemia occurs, it is usually secondary to intravascular volume depletion.

Glomerular morphology is unremarkable except for fusion of foot processes of the glomerular basement membrane. This nonspecific finding is associated with many proteinuric states.

► Complications

Infections (eg, peritonitis) sometimes occur, and pneumococci are frequently the cause. Hypercoagulability may be present, and thromboembolic phenomena are commonly reported. In patients with minimal change disease, hypertension can still be noted, and renal insufficiency can result from decreased renal perfusion.

► Treatment & Prognosis

As soon as the diagnosis of idiopathic nephrotic syndrome is made, corticosteroid treatment should be started. Prednisone, 2 mg/kg/d (maximum, 60 mg/d), is given for 6 weeks as a single daily dose. The same dose is then administered on an alternate-day schedule for 6 weeks; thereafter, the dose is tapered gradually and discontinued over the ensuing 2 months. The goal of this regimen is the disappearance of proteinuria. If remission is not achieved during the initial phase of corticosteroid treatment, additional nephrologic consultation should be obtained. If remission is achieved, only to be followed by relapse, the treatment course may be repeated. A renal biopsy is often considered when there is little or no response to treatment. One should take into account that the histologic findings may not alter the treatment plan, which is designed to eliminate the nephrotic syndrome regardless of underlying renal histology.

Unless the edema causes symptoms such as respiratory compromise due to ascites, diuretics should be used with extreme care. Patients may have decreased circulating volume and are also at risk for intravenous thrombosis. Careful restoration of compromised circulating volume with intravenous albumin infusion and administration of diuretics is helpful in mobilizing edema. Infections such as peritonitis should be treated promptly to reduce morbidity. Immunization with pneumococcal vaccine is advised.

A favorable response of proteinuria to corticosteroids and subsequent favorable response during relapse suggests a good prognosis. Failure to respond or early relapse usually heralds a prolonged series of relapses. This not only may indicate the presence of more serious nephropathy, but presents a challenge in choosing future therapy. Chlorambucil or cyclophosphamide drug therapy is usually effective only in children who respond to corticosteroids. Patients who do not respond to corticosteroids or who relapse frequently should be referred to a pediatric nephrologist. Intravenous Solu-Medrol may be helpful in more refractory cases. When the protracted use of corticosteroids raises concerns of toxicity, concomitant treatment with either cyclosporin A or tacrolimus appears to be helpful.

FOCAL GLOMERULAR SCLEROSIS

Focal glomerular sclerosis is one cause of corticosteroid-resistant or frequent relapsing nephrotic syndrome. The cause is unknown. The diagnosis is made by renal biopsy,

which shows normal-appearing glomeruli as well as some partially or completely sclerosed glomeruli. The lesion has serious prognostic implications because as many as 15–20% of cases can progress to end-stage renal failure. The response to corticosteroid treatment is variable. In difficult cases, cyclosporin A or tacrolimus have been used in addition to corticosteroids. There are increasing reports that poorly responsive cases may respond to rituximab, a monoclonal antibody against the B-cell surface antigen CD20. Recurrence of focal glomerular sclerosis may occur after renal transplantation. The recurrence is usually treated with plasmapheresis or rituximab (this drug is finding encouraging utility in membranous or mesangial nephropathy as well as minimal change disease).

MESANGIAL NEPHROPATHY (MESANGIAL GLOMERULONEPHRITIS)

Mesangial nephropathy is another form of corticosteroid-resistant nephrotic syndrome. The renal biopsy shows a distinct increase in the mesangial matrix of the glomeruli. Very often the expanded mesangium contains deposits of IgM demonstrable on immunofluorescent staining. The cause is unknown. Corticosteroid therapy may induce remission, but relapses are common. Choices for treating this type of nephrotic syndrome are the same as noted earlier.

MEMBRANOUS NEPHROPATHY (MEMBRANOUS GLOMERULONEPHRITIS)

Although largely idiopathic in nature, membranous nephropathy can be found in association with hepatitis B antigenemia, systemic lupus erythematosus, congenital and secondary syphilis, renal vein thrombosis; with immunologic disorders such as autoimmune thyroiditis; and with administration of drugs such as penicillamine. The pathogenesis is unknown, but the glomerular lesion is thought to be the result of prolonged deposition of circulating antigen–antibody complexes.

The onset of membranous nephropathy may be insidious or may resemble that of idiopathic nephrotic syndrome of childhood (see earlier section). It occurs more often in older children and adults. The proteinuria of membranous nephropathy responds poorly to corticosteroid therapy, although low-dose corticosteroid therapy may reduce or delay development of chronic renal insufficiency. The diagnosis is made by renal biopsy.

DISEASES OF THE RENAL VESSELS

RENAL VEIN THROMBOSIS

In newborns, renal vein thrombosis may complicate sepsis or dehydration. It may be observed in infants of diabetic mothers; may be associated with umbilical vein catheterization; or may result from any condition that produces a hypercoagulable state (eg, clotting factor deficiency, systemic lupus erythematosus, or thrombocytosis). Renal vein thrombosis is less common in older children and adolescents. It may develop following trauma or without any apparent predisposing factors. Spontaneous renal vein thrombosis has been associated with membranous glomerulonephropathy. Nephrotic syndrome may either cause or result from renal vein thrombosis.

▶ Clinical Findings

Renal vein thrombosis in newborns is generally characterized by the sudden development of an abdominal mass. If the thrombosis is bilateral, oliguria may be present; urine output may be normal with a unilateral thrombus. In older children, flank pain, sometimes with a palpable mass, is a common presentation.

No single laboratory test is diagnostic of renal vein thrombosis. Hematuria usually is present; proteinuria is less constant. In the newborn, thrombocytopenia may be found, but it is rare in older children. The diagnosis is made by ultrasonography and Doppler flow studies.

▶ Treatment

Anticoagulation with heparin is the treatment of choice in newborns and older children. In the newborn, a course of heparin combined with treatment of the underlying problem is usually all that is required. Management in other cases is less straightforward. The tendency for recurrence and embolization has led some to recommend long-term anticoagulation. If an underlying membranous GN is suspected, biopsy should be performed.

▶ Course & Prognosis

The mortality rate in newborns from renal vein thrombosis depends on the underlying cause. With unilateral thromboses, the prognosis for adequate renal function is good. Renal vein thrombosis may rarely recur in the same kidney or occur in the other kidney years after the original episode of thrombus formation. Extension into the vena cava with pulmonary emboli is possible.

RENAL ARTERIAL DISEASE

Arterial disease (eg, fibromuscular hyperplasia, congenital stenosis) is a rare cause of hypertension in children. Although few clinical clues are specific to underlying arterial lesions, they should be suspected in children with severe hypertension, with onset at or before age 10 years, or with delayed visualization on nuclear scan of the kidneys. The

diagnosis is established by renal arteriography with selective renal vein renin measurements. Some of these lesions may be approached by transluminal angioplasty or surgery (see section on Hypertension, later), but repair may be technically impossible in small children. Although thrombosis of renal arteries is rare, it should be considered in a patient with acute onset of hypertension and hematuria in an appropriate setting (eg, in association with hyperviscosity or umbilical artery catheterization). Early diagnosis and treatment provides the best chance of reestablishing renal blood flow.

HEMOLYTIC-UREMIC SYNDROME

Hemolytic-uremic syndrome is the most common glomerular vascular cause of acute renal failure in childhood. It is usually the result of infection with Shigatoxin-producing (also called verotoxin-producing) strains of *Shigella* or *Escherichia coli*. Ingestion of undercooked ground beef or unpasteurized foods is a common source. There are many serotypes, but the most common pathogen in the United States is *E coli* O157:H7. Bloody diarrhea is the usual presenting complaint, followed by hemolysis and renal failure. Circulating verotoxin causes endothelial damage, which leads to platelet deposition, microvascular occlusion with subsequent hemolysis, and thrombocytopenia. Similar microvascular endothelial activation may also be triggered by drugs (eg, cyclosporin A); by viruses (HIV); and by pneumococcal infections, in which bacterial neuraminidase exposes the Thomsen-Friedenreich antigen on RBCs, platelets, and endothelial cells, thereby causing platelet aggregation, endothelial damage, and hemolysis. Rare cases are caused by genetic factors (eg, congenitally depressed C3 complement and factor H deficiency).

► Clinical Findings

The epidemic form begins with a prodrome of abdominal pain, diarrhea, and vomiting. Oliguria, pallor, and bleeding manifestations, principally gastrointestinal, occur next. Hypertension and seizures develop in some children—especially those who develop severe renal failure and fluid overload. There may also be significant endothelial involvement in the central nervous system (CNS).

Anemia is profound, and RBC fragments are seen on blood smears. A high reticulocyte count confirms the hemolytic nature of the anemia, but may not be noted in the presence of renal failure. Thrombocytopenia is profound, but other coagulation abnormalities are less consistent. Serum fibrin split products are often present, but fulminant disseminated intravascular coagulation is rare. Hematuria and proteinuria are often present. The serum complement level is normal except in those cases related to congenital predisposition.

► Complications

These usually result from renal failure. Neurologic problems, particularly seizures, may result from hyponatremia, hyper-

tension, or CNS vascular disease. Severe bleeding, transfusion requirements, and hospital-acquired infections must be anticipated.

► Treatment

Meticulous attention to fluid and electrolyte status is crucial. The use of antimotility agents and antibiotics is believed to worsen the disease. Antibiotics may up-regulate and cause the release of large amounts of bacterial Shiga toxin. Timely dialysis improves the prognosis. Since prostacyclin-stimulating factor, a potent inhibitor of platelet aggregation, may be absent in some cases, plasma infusion or plasmapheresis has been advocated in severe cases (generally in those cases with severe CNS involvement). Platelet inhibitors have also been tried, but the results have not been impressive, especially late in the disease. Nonetheless, using a platelet inhibitor early in the disease in an attempt to halt platelet consumption and microvascular occlusion may obviate the need for platelet transfusions and reduce the progression of renal failure. RBC and platelet transfusions may be necessary. Although the risk of volume overload is significant, this can be minimized by dialysis. Erythropoietin (epoetin alfa) treatment may reduce RBC transfusion needs. Although no therapy is universally accepted, strict control of hypertension, adequate nutrition support, and the timely use of dialysis reduce morbidity and mortality. If renal failure is “nonoliguric,” and if urine output is sufficient to ensure against fluid overload and electrolyte abnormalities, management of renal failure without dialysis is possible.

► Course & Prognosis

Most commonly, children recover from the acute episode within 2–3 weeks. Some residual renal disease (including hypertension) occurs in about 30%, and end-stage renal failure occurs in about 15%. Thus follow-up of children recovering from hemolytic-uremic syndrome should include serial determinations of renal function for 1–2 years and monitoring of blood pressure for 5 years. Mortality (about 3–5%) is most likely in the early phase, primarily resulting from CNS or cardiac complications.

RENAL FAILURE

ACUTE RENAL FAILURE

Acute renal failure is the sudden inability to excrete urine of sufficient quantity or composition to maintain body fluid homeostasis. The most common cause in children is dehy-

Table 22-2. Classification of renal failure.

Prerenal
Dehydration due to gastroenteritis, malnutrition, or diarrhea
Hemorrhage, aortic or renal vessel injury, trauma, cardiac disease or surgery, renal arterial thrombosis
Diabetic acidosis
Hypovolemia associated with capillary leak or nephrotic syndrome
Shock
Heart failure
Renal
Hemolytic-uremic syndrome
Acute glomerulonephritis
Prolonged renal hypoperfusion
Nephrotoxins
Acute tubular necrosis or vascular nephropathy
Renal (cortical) necrosis
Intravascular coagulation: septic shock, hemorrhage
Diseases of renal vessels
Iatrogenic disorders
Severe infections
Drowning, especially fresh water
Crystalluria: sulfonamide or uric acid
Hypercalcemia from cancer treatment
Hepatic failure
Postrenal
Obstruction due to tumor, hematoma, posterior urethral valves, ureteropelvic junction stricture, ureterovesical junction stricture, ureterocele
Stones
Trauma to a solitary kidney or collecting system
Renal vein thrombosis

dration. However, encountering signs of acute renal insufficiency in a hospitalized patient raises many other possibilities: impaired renal perfusion or renal ischemia, acute renal disease, renal vascular compromise, acute tubular necrosis, or obstructive uropathy. Table 22-2 lists such prerenal, renal, and postrenal causes.

► Clinical Findings

The hallmark of early renal failure is oliguria. Although an exact etiologic diagnosis may be unclear at the onset, classifying oliguria as outlined in Table 22-2 is helpful in determining if an immediately reversible cause is present.

If the cause of elevation in serum BUN and creatinine or oliguria is unclear, entities that can be quickly addressed and corrected (eg, volume depletion) should be considered first. Once normal renal perfusion is ensured and no clinical evidence for de novo renal disease is present, a diagnosis of acute tubular necrosis (vasomotor nephropathy, ischemic injury) may be entertained.

A. Prerenal Causes

The most common cause of decreased renal function in children is compromised renal perfusion. It is usually sec-

Table 22-3. Urine studies.

	Prerenal Failure	Acute Tubular Necrosis
Urine osmolality	50 mOsm/kg > plasma osmolality	≤ plasma osmolality
Urine sodium	< 10 mEq/L	> 20 mEq/L
Ratio of urine creatinine to plasma creatinine	> 40:1	< 40:1
Specific gravity	> 1.020	1.012-1.018

ondary to dehydration, although abnormalities of renal vasculature and poor cardiac performance may also be considered. Table 22-3 lists the urinary indices helpful in distinguishing these “prerenal” conditions from true renal parenchymal insult, such as in acute tubular necrosis.

B. Renal Causes

Causes of renal failure intrinsic to the kidney include acute glomerulonephritides, hemolytic-uremic syndrome, acute interstitial nephritis, and nephrotoxic injury. The diagnosis of acute tubular necrosis (vasomotor nephropathy)—which is reserved for those cases in which renal ischemic insult is believed to be the likely cause—should be considered when correction of prerenal or postrenal problems does not improve renal function and there is no evidence of de novo renal disease.

C. Postrenal Causes

Postrenal failure, usually found in newborns with urologic anatomic abnormalities, is accompanied by varying degrees of renal insufficiency. The approach to the problem in the very young is addressed earlier in the chapter, but one should always keep in mind the possibility of acute urinary tract obstruction in acute renal failure, especially in the setting of anuria of acute onset.

► Complications

The clinical severity of the complications depends on the degree of renal functional impairment and oliguria. Common complications include (1) fluid overload (hypertension, congestive heart failure, pulmonary edema), (2) electrolyte disturbances (hyperkalemia), (3) metabolic acidosis, (4) hyperphosphatemia, and (5) uremia.

► Treatment

An indwelling bladder catheter is inserted to ascertain urine output. If urine volume is insignificant and renal failure is established, the catheter should be removed to minimize infection risk. Prerenal or postrenal factors should be excluded or rectified, and normal circulating volume maintained with

appropriate fluids. Strict measurement of input and output must be maintained, and input adjusted as reduction in output dictates. The patient's response is assessed by physical examination and urinary output. Measurement of central venous pressure may be indicated. Increasing urine output with diuretics, such as furosemide (1–5 mg/kg, per dose, intravenously, maximum of 200 mg), can be attempted. The effective dose will depend on the amount of functional compromise (if < 50% function, initiate attempt at diuresis with maximum dose). If a response does not occur within 1 hour and the urine output remains low (< 0.5 mL/kg/h), the furosemide dose, if not already maximized, should be increased up to 5 mg/kg. In some cases the addition of a long-acting thiazide diuretic, such as metolazone, may improve the response. If no diuresis occurs with maximum dosing, further administration of diuretics should cease.

If these maneuvers stimulate some urine flow but biochemical evidence of acute renal failure persists, the resulting non-oliguric acute renal failure should be more manageable. Fluid overload and dialysis may be averted. However, if the medications and nutrients required exceed the urinary output, dialysis is indicated. Institution of dialysis before the early complications of acute renal failure develop is likely to improve clinical management and outcome. It is important to adjust medication dosage according to the degree of renal function.

A. Acute Dialysis: Indications

Immediate indications for dialysis are (1) severe hyperkalemia; (2) unrelenting metabolic acidosis (usually in a situation where fluid overload prevents sodium bicarbonate administration); (3) fluid overload with or without severe hypertension or congestive heart failure (a situation that would seriously compromise nutrition or drug administration); and (4) symptoms of uremia, usually manifested in children by CNS depression.

B. Methods of Dialysis

Peritoneal dialysis is generally preferred in children because of the ease of performance and patient tolerance. Although peritoneal dialysis is technically less efficient than hemodialysis, hemodynamic stability and metabolic control can be better sustained because this technique can be applied on a relatively continuous basis. Hemodialysis should be considered (1) if rapid removal of toxins is desired, (2) if the size of the patient makes hemodialysis less technically cumbersome and hemodynamically well tolerated, or (3) if impediments to efficient peritoneal dialysis are present (eg, ileus, adhesions). Furthermore, if vascular access and usage of anticoagulation are not impediments, a slow, continuous hemodialytic process (continuous renal replacement treatment) may be applied.

C. Complications of Dialysis

Complications of peritoneal dialysis include peritonitis, volume depletion, and technical complications such as dialysate

leakage and respiratory compromise from intra-abdominal dialysate fluid. Peritonitis can be avoided by strict aseptic technique. Peritoneal fluid cultures are obtained as clinically indicated. Leakage is reduced by good catheter placement technique and appropriate intra-abdominal dialysate volumes. Dialysis is useful in maintaining electrolyte balance. Potassium (absent from standard dialysate solutions) can be added to the dialysate as required. Phosphate is also absent because hyperphosphatemia is an expected problem in renal failure. Nonetheless, if phosphate intake is inadequate, hypophosphatemia must be addressed. Correction of fluid overload is accomplished by using high osmolar dialysis fluids. Higher dextrose concentrations (maximum 4.25%) can correct fluid overload rapidly at the risk of causing hyperglycemia. Fluid removal may also be increased with more frequent exchanges of the dialysate, but rapid osmotic transfer of water may result in hyponatremia.

Even in small infants, hemodialysis can rapidly correct major metabolic and electrolyte disturbances, as well as volume overload. The process is highly efficient, but the speed of the changes can cause problems such as hemodynamic instability. Anticoagulation is usually required. Careful monitoring of the appropriate biochemical parameters is important. Note that during or immediately following the procedure, blood sampling will produce misleading results because equilibration between extravascular compartments and the blood will not have been achieved. Vascular access must be obtained and carefully monitored.

► Course & Prognosis

If severe oliguria occurs, it usually lasts about 10 days. Anuria or oliguria lasting longer than 3 weeks makes the diagnosis of acute tubular necrosis unlikely and favors alternative diagnoses such as vascular injury, severe ischemia (cortical necrosis), GN, or obstruction. The diuretic phase begins with an increase in urinary output to large volumes of isosthenuric urine containing sodium levels of 80–150 mEq/L. During the recovery phase, signs and symptoms subside rapidly, although polyuria may persist for several days or weeks. Urinary abnormalities usually disappear completely within a few months. If renal recovery does not ensue, arrangements are made for chronic dialysis and eventual renal transplantation.

CHRONIC RENAL FAILURE

Chronic renal failure in children most commonly results from developmental abnormalities of the kidneys or urinary tract. Infants with renal agenesis are not expected to survive. Depending on the degree of dysgenesis (including multicystic development) the resulting renal function will determine

outcome. Abnormal development of the urinary tract may not permit normal renal development. Obstructive uropathy or severe vesicoureteral reflux nephropathy, without (or despite) surgical intervention, continues to cause a significant amount of progressive renal insufficiency in children. In older children, the chronic glomerulonephritides and nephropathies, irreversible nephrotoxic injury, or hemolytic-uremic syndrome may also cause chronic renal failure.

When chronic renal failure is congenital, the inability to concentrate urine results in polyuria. Affected patients often fail to thrive. Without medical care, children with longstanding chronic renal failure may present with complications such as rickets or anemia.

Chronic renal failure may follow acute GN or develop with chronic GN in the absence of an obvious acute episode. Growth failure depends on age at presentation and the rapidity of functional decline. Some of the chronic glomerulonephritides (eg, membranoproliferative GN) can progress unnoticed if subtle abnormalities of the urinary sediment are undetected or ignored. Any child with a history of chronic GN or significant renal injury needs close follow-up and monitoring of renal function and blood pressure.

► Complications

Any remaining unaffected renal tissue can compensate for gradual loss of functioning nephrons in progressive chronic renal failure, but complications of renal insufficiency appear when compensatory ability is overwhelmed. In children who have developmentally reduced function and are unable to concentrate the urine, polyuria and dehydration are more likely to be problems than fluid overload. Output may be expected to gradually diminish as renal failure progresses to end stage; however, some children can continue to produce generous quantities of urine (but not of good quality) even though they require dialysis. A salt-wasting state can also occur. In contrast, children who develop chronic renal failure due to glomerular disease or renal injury will characteristically retain sodium and water and develop hypertension.

Metabolic acidosis and growth retardation occur early in chronic renal failure. Disturbances in calcium, phosphorus, and vitamin D metabolism leading to renal osteodystrophy require prompt attention. Although renal compensation and increased parathyroid hormone can maintain a normal serum phosphate level early in the course, this pathophysiologic response to hyperphosphatemia will be reflected by an increase in parathyroid hormone and alkaline phosphatase.

Uremic symptoms occur late in chronic renal failure, and include anorexia, nausea, and malaise. CNS features range from confusion, apathy, and lethargy to stupor and coma. Associated electrolyte abnormalities may precipitate seizures. More commonly, seizures are a result of untreated hypertension or hypocalcemia (especially with rapid correction of acidosis). Anemia (normochromic and normocytic from decreased renal erythropoietin synthesis) is common. Platelet dysfunction and other abnormalities of the coagula-

tion system may be present. Bleeding—especially gastrointestinal bleeding—may be a problem. Uremic pericarditis, congestive heart failure, pulmonary edema, and hypertension may occur.

► Treatment

A. Management of Complications

Treatment of chronic renal failure is primarily aimed at controlling the associated complications. Hypertension, hyperkalemia, hyperphosphatemia, acidosis, and anemia are among the early problems. Acidosis may be treated with sodium citrate solutions, as long as the added sodium will not aggravate hypertension. Sodium restriction is advisable when hypertension is present. Hyperphosphatemia is controlled by dietary restriction and dietary phosphate binders (eg, calcium carbonate). Vitamin D should be given to maintain normal serum calcium. When the BUN level exceeds approximately 50 mg/dL, or if the child is lethargic or anorexic, dietary protein should be restricted. Potassium restriction will be necessary as the GFR falls to a level where urinary output decreases sharply. Diet must be maintained to provide the child's daily requirements.

Renal function must be monitored regularly (creatinine and BUN), and serum electrolytes, calcium, phosphorus, alkaline phosphatase, and hemoglobin and hematocrit levels monitored to guide changes in fluid and dietary management as well as dosages of phosphate binder, citrate buffer, vitamin D, blood pressure medications, and epoetin alfa. Growth failure may be treated with human recombinant growth hormone. These treatment areas require careful monitoring to minimize symptoms while the need for chronic dialysis and transplantation continues to be assessed.

Care must be taken to avoid medications that aggravate hypertension; increase the body burden of sodium, potassium, or phosphate; or increase production of BUN. Successful management relies greatly on education of the patient and family.

Attention must also be directed toward the psychosocial needs of the patient and family as they adjust to chronic illness and the eventual need for dialysis and kidney transplantation.

B. Dialysis and Transplantation

At present the graft survival rate for living-related kidney transplants is 90% at 1 year, 85% at 2 years, and 75% at 5 years. With cadaveric transplantation, graft survivals are 76%, 71%, and 62%, respectively. Overall, the mortality rate is 4% for recipients of living-related donors and 6.8% for recipients of cadaver organs. These percentages are affected by the increased mortality, reported to be as high as 75% in infants younger than age 1 year, primarily due to technical issues and complications of immunosuppression. A body weight of at least 15 kg is associated with a significantly improved survival rate. Adequate growth and well-being are

directly related to acceptance of the graft, the degree of normal function, and the side effects of medications.

Chronic peritoneal dialysis (home-based) and hemodialysis provide life-saving treatment for children awaiting renal transplantation. The best measure of the success of chronic dialysis in children is the level of physical and psychosocial rehabilitation achieved, such as continued participation in day-to-day activities and school attendance. Although catch-up growth rarely occurs, patients can grow at an acceptable rate even though they may remain in the lower percentiles. Use of epoetin alfa, growth hormone, and better control of renal osteodystrophy contribute to improved outcome.

HYPERTENSION

Hypertension in children is commonly of renal origin. It is anticipated as a complication of known renal parenchymal disease, but it may be found on routine physical examination in an otherwise normal child. Increased understanding of the roles of water and salt retention and overactivity of the renin-angiotensin system has done much to guide therapy; nevertheless, not all forms of hypertension can be explained by these two mechanisms.

The causes of renal hypertension in the newborn period include (1) congenital anomalies of the kidneys or renal vasculature, (2) obstruction of the urinary tract, (3) thrombosis of renal vasculature or kidneys, and (4) volume overload. Some instances of apparent paradoxical elevations of blood pressure have been reported in clinical situations in which chronic diuretic therapy is used, such as in bronchopulmonary dysplasia. Hypertensive infants should be examined for renal, vascular, or aortic abnormalities (eg, thrombosis, neurofibromatosis, coarctation) as well as some endocrine disorders, including pheochromocytoma and glucocorticoid-remedial aldosteronism.

► Clinical Findings

A child is normotensive if the average recorded systolic and diastolic blood pressures are lower than the 90th percentile for age and sex. The 90th percentile in the newborn period is approximately 85–90/55–65 mm Hg for both sexes. In the first year of life, the acceptable levels are 90–100/60–67 mm Hg. Incremental increases with growth occur, gradually

approaching young adult ranges of 100–120/65–75 mm Hg in the late teens. Careful measurement of blood pressure requires correct cuff size and reliable equipment. The cuff should be wide enough to cover two thirds of the upper arm and should encircle the arm completely without an overlap in the inflatable bladder. Although an anxious child may have an elevation in blood pressure, abnormal readings must not be too hastily attributed to this cause. Repeat measurement is helpful, especially after the child has been consoled.

Routine laboratory studies include a complete blood count, urinalysis, and urine culture. Radiography and ultrasonography are used to study the anatomy of the urinary tract, the blood flow to the kidneys, and their function. A renal biopsy (which rarely reveals the cause of hypertension unless clinical evidence of renal disease is present) should always be undertaken with special care in the hypertensive patient and preferably after pressures have been controlled by therapy. Figure 22–3 presents a suggested approach to the outpatient workup of hypertension.

► Treatment

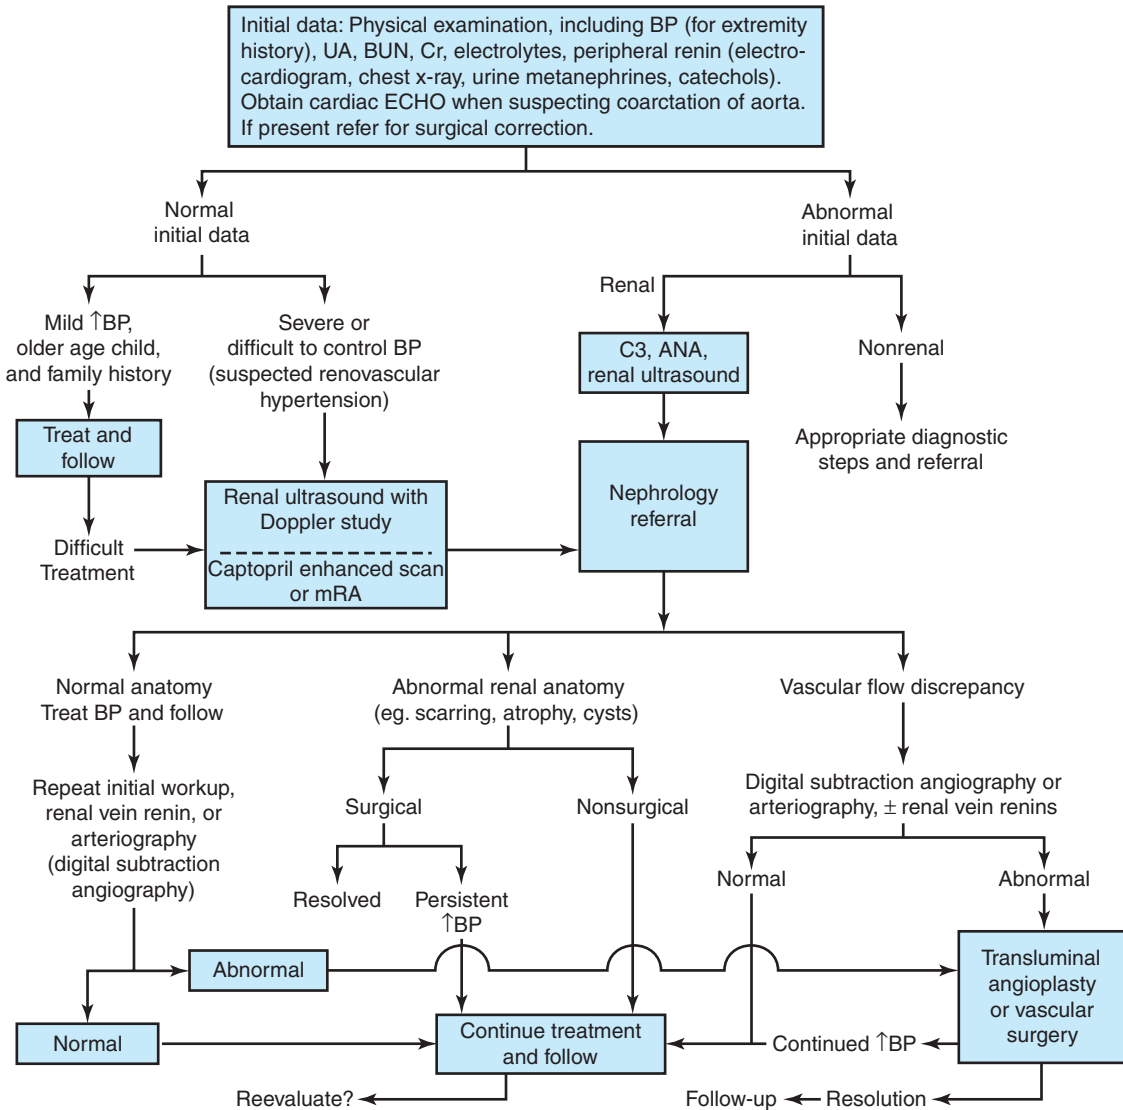

A. Acute Hypertensive Emergencies

A hypertensive emergency exists when CNS signs of hypertension appear, such as papilledema or encephalopathy. Retinal hemorrhages or exudates indicate a need for prompt and effective control. In children, end-organ abnormalities secondary to hypertension commonly are not present. Treatment varies with the clinical presentation. The primary classes of useful antihypertensive drugs are (1) diuretics, (2) α - and β -adrenergic blockers, (3) angiotensin-converting enzyme inhibitors, (4) calcium channel blockers, and (5) vasodilators.

Whatever method is used to control emergent hypertension, medications for sustained control should also be initiated so that normal blood pressure will be maintained when the emergent measures are discontinued (Table 22–4). Acute elevations of blood pressure not exceeding the 95th percentile for age may be treated with oral antihypertensives, aiming for progressive improvement and control within 48 hours.

1. Sublingual nifedipine—This calcium channel blocker is rapid acting, and, in appropriate doses, should not result in hypotensive blood pressure levels. The liquid from a 10-mg capsule can be drawn into a syringe and the dosage approximated. The exact dosage for children who weigh less than 10–30 kg is difficult to ascertain by this method, but 5 mg is a safe starting point. Because the treatment is given for rising blood pressure, it is unlikely that the effects will be greater than desired. Larger children with malignant hypertension require 10 mg. In such cases, the capsule may simply be pierced and the medication squeezed under the patient's tongue.

2. Intravenous hydralazine—This vasodilator is sometimes effective. Dosage varies according to the severity of the hypertension and should begin at about 0.15 mg/kg.

▲ **Figure 22-3.** Approach to the outpatient workup of hypertension. ANA, antinuclear antibody; BP, blood pressure; BUN, blood urea nitrogen; C3, complement; Cr, creatinine; mRA, magnetic resonance angiography; UA, urinalysis.

3. Sodium nitroprusside—In an intensive care setting, this powerful vasodilator is very effective for reducing severely elevated blood pressure. Intravenous administration of 0.5–10 mg/kg/min will reduce blood pressure in seconds; the dose must be monitored carefully. Metabolism of the drug results in thiocyanate; thus, with prolonged usage, levels of thiocyanate must be monitored, especially in renal insufficiency.

4. Furosemide—Administered at 1–5 mg/kg intravenously, this diuretic reduces blood volume and enhances the effectiveness of antihypertensive drugs.

B. Sustained Hypertension

Several choices are available (Table 22-5). A single drug such as a β -blocker (unless contraindicated, eg, in reactive airway disease) may be adequate to treat mild hypertension. Diuretics are useful to treat renal insufficiency, but the disadvantages of possible electrolyte imbalance must be considered. Single-drug therapy with an angiotensin-converting enzyme inhibitor is useful, especially because most hypertension in children is renal in origin. Calcium channel blockers are increasingly useful, and appear well tolerated in children. The use of the vasodilator type of antihypertensive drug requires concomitant

Table 22-4. Antihypertensive drugs for emergent treatment.

Drug	Oral Dose	Major Side Effects ^a
Nifedipine	0.25–0.5 mg/kg SL	Flushing, tachycardia
Labetalol	1–3 mg/kg/h IV	Secondary to β -blocking activity
Sodium nitroprusside	0.5–10 mg/kg/min IV drip	Cyanide toxicity, sodium and water retention
Furosemide	1–5 mg/kg IV	Secondary to severe volume contraction, hypokalemia
Diazoxide	2–10 mg/kg IV bolus	Hyperglycemia, hyperuricemia, sodium and water retention
Hydralazine	0.1–0.2 mg/kg IV	Sodium and water retention, tachycardia, flushing

^aMany more side effects than those listed have been reported. IV, intravenous; SL, sublingual.

administration of a diuretic to counter the effect of vasodilation on increasing renal sodium and water retention and a β -blocker to counter reflex tachycardia. Minoxidil, considered the most powerful of the orally administered vasodilators, can be extremely efficacious in the treatment of severe, sustained hypertension, but its effect is greatly offset by the other effects described. Hirsutism is a significant side effect. Hydralazine hydrochloride may still be the most common vasodilator in pediatric use—but, again, the necessity of using two additional drugs for maximum benefit relegates to severe situations calling for management with three or four drugs. The advice of a pediatric nephrologist should be sought.

INHERITED OR DEVELOPMENTAL DEFECTS OF THE KIDNEY

There are many developmental, hereditary, or metabolic defects of the kidneys and collecting system. The clinical consequences include metabolic abnormalities, failure to thrive, nephrolithiasis, renal glomerular or tubular dysfunction, and chronic renal failure. Table 22–6 lists some of the major entities; discussion of the rarer conditions is beyond the scope of this book.

DISORDERS OF THE RENAL TUBULES

Three subtypes of renal tubular acidosis (RTA) are recognized: (1) the classic form, called type I or distal RTA; (2) the

Table 22-5. Antihypertensive drugs for ambulatory treatment.

Drug	Oral Dose	Major Side Effects ^a
Hydrochlorothiazide	2–4 mg/kg/24 h as single dose or in 2 individual doses	Potassium depletion, hyperuricemia
Furosemide	1–5 mg/kg per dose, 2–3 doses per day	Potassium and volume depletion
Hydralazine	0.75 mg/kg/24 h in 4–6 divided doses	Lupus erythematosus, tachycardia, headache
Amlodipine	0.2–0.5 mg/kg/d in 2 divided doses	Fatigue, headache, facial flushing
Propranolol	0.2–5 mg/kg per dose, 2–3 doses per day	Syncope, cardiac failure, hypoglycemia
Minoxidil	0.15 mg/kg per dose, 2–3 doses per day	Tachycardia, angina, fluid retention, hirsutism
Captopril	0.3–2 mg/kg per dose, 2–3 doses per day	Rash, hyperkalemia, glomerulopathy
Enalapril	0.2–0.5 mg/kg/d in 2 divided doses	Proteinuria, cough, hyperkalemia
Nifedipine	0.5–1 mg/kg/d, 3 doses per day	Flushing, tachycardia
Verapamil	3–7 mg/kg/d in 2 or 3 divided doses	AV conduction disturbance

^aMany more side effects than those listed have been reported. AV, atrioventricular.

bicarbonate-wasting form, called type II or proximal RTA; and (3) type IV, or hyperkalemic RTA (rare in children), which is associated with hyporeninemic hypoaldosteronism. Type I and type II and their variants are encountered most frequently in children. Type III is a combination of types I and II.

Primary tubular disorders in childhood, such as glycinuria, hypouricemia, or renal glycosuria, may result from a defect in a single tubular transport pathway (see Table 22–6).

1. Distal Renal Tubular Acidosis (Type I)

The most common form of distal RTA in childhood is the hereditary form. The clinical presentation is one of failure to thrive, anorexia, vomiting, and dehydration. Hyperchloremic metabolic acidosis, hypokalemia, and a urinary pH exceeding 6.5 is found. Acidosis is more severe in the presence of a bicarbonate “leak.” This variant of distal RTA with bicarbonate wasting has been called type III but for clinical purposes need not be considered as a distinct entity. Concomitant hypercalciuria may lead to rickets, nephrocalcinosis, nephrolithiasis, and renal failure.

Other situations that may be responsible for distal RTA are found in some of the entities listed in Table 22–6.

---	---

Distal RTA results from a defect in the distal nephron, in the tubular transport of hydrogen ion, or in the maintenance of a steep enough gradient for proper excretion of hydrogen ion. This defect can be accompanied by degrees of bicarbonate wasting.

The classic test for distal RTA is an acid load from NH_4Cl . The test is cumbersome and can produce severe acidosis. A clinical trial of alkali administration should be used to rule out proximal (type II) RTA. The dose of alkali required to achieve a normal plasma bicarbonate concentration in patients with distal RTA is low (seldom exceeding 2–3 mEq/kg/24 h)—in contrast to that required in proximal RTA (> 10 mEq/kg/24 h). Higher doses are needed, however, if distal RTA is accompanied by bicarbonate wasting. Correction of acidosis can result in reduced complications and improved growth.

Distal RTA is usually permanent, although it sometimes occurs as a secondary complication. If the defect is not

caused by a significant tubular disorder and renal damage is prevented, the prognosis is good.

2. Proximal Renal Tubular Acidosis (Type II)

Proximal RTA, the most common form of RTA in childhood, is characterized by an alkaline urine pH, loss of bicarbonate in the urine, and mildly reduced serum bicarbonate concentration. This occurs as a result of a lower than normal bicarbonate threshold, above which bicarbonate appears in the urine. Thus, urinary acidification can occur when the concentration of serum bicarbonate drops below that threshold, and bicarbonate disappears from the urine; this ability to eventually acidify the urine thus reflects normal distal tubular function.

Proximal RTA is often an isolated defect, and in the newborn can be considered an aspect of renal immaturity. Onset in infants is accompanied by failure to thrive, hyper-

chloremic acidosis, hypokalemia, and, rarely, nephrocalcinosis. Secondary forms result from reflux or obstructive uropathy or occur in association with other tubular disorders (see Table 22–6). Proximal RTA requires more than 3 mEq/kg of alkali per day to correct the acidosis. Serum bicarbonate should be monitored weekly until a level of at least 20 mEq/L is attained.

Citrate solutions (eg, Bicitra, Polycitra) are somewhat more easily tolerated than sodium bicarbonate. Bicitra contains 1 mEq/mL of Na⁺ and citrate. Polycitra contains 2 mEq/mL of citrate and 1 mEq each of Na⁺ and K⁺. The required daily dosage is divided into three doses. Potassium supplementation may be required, because the added sodium load presented to the distal tubule may exaggerate potassium losses.

The prognosis is excellent in cases of isolated defects, especially when the problem is related to renal immaturity. Alkali therapy can usually be discontinued after several months to 2 years. Growth should be normal, and the gradual increase in the serum bicarbonate level to greater than 22 mEq/L heralds the presence of a raised bicarbonate threshold in the tubules. If the defect is part of a more complex tubular abnormality (Fanconi syndrome with attendant phosphaturia, glycosuria, and amino aciduria), the prognosis depends on the underlying disorder or syndrome.

OCULOCEREBRORENAL SYNDROME (LOWE SYNDROME)

Lowe syndrome results from various mutations in the *ORCL1* gene, which codes for a Golgi apparatus phosphatase. Affected males have anomalies involving the eyes, brain, and kidneys. The physical stigmata and degree of mental retardation vary with the location of the mutation. In addition to congenital cataracts and buphthalmos, the typical facies includes prominent epicanthal folds, frontal prominence, and a tendency to scaphocephaly. Muscle hypotonia is a prominent finding. The renal abnormalities are of tubule function and include hypophosphatemic rickets with low serum phosphorus levels, low to normal serum calcium levels, elevated serum alkaline phosphatase levels, RTA, and aminoaciduria. Treatment includes alkali therapy, phosphate replacement, and vitamin D. Antenatal diagnosis is possible.

CONGENITAL HYPOKALEMIC ALKALOSIS (BARTTER SYNDROME & GITELMAN SYNDROME)

Bartter syndrome is characterized by severe hypokalemic, hypochloremic metabolic alkalosis, extremely high levels of circulating renin and aldosterone, and a paradoxical absence of hypertension. On renal biopsy, a striking juxtaglomerular hyperplasia is seen.

A neonatal form of Bartter syndrome is thought to result from mutations in two genes affecting either Na⁺–K⁺ or K⁺

transport. These patients have life-threatening episodes of fever and dehydration with hypercalciuria and early-onset nephrocalcinosis. Classic Bartter syndrome presenting in infancy with polyuria and growth retardation (but not nephrocalcinosis) is thought to result from mutations in a chloride channel gene. Gitelman syndrome occurs in older children and features episodes of muscle weakness, tetany, hypokalemia, and hypomagnesemia. These children have hypocalciuria.

Treatment with prostaglandin inhibitors and potassium-conserving diuretics (eg, amiloride combined with magnesium supplements) and potassium may be beneficial. Although the prognosis is guarded, a few patients seem to have less severe forms of the disease that are compatible with long survival times.

CYSTINOSIS

There are three types of cystinosis: adult, adolescent, and infantile. The adolescent type is characterized by cystine deposition, which if not treated with phosphocysteamine (Cystagon), is accompanied by the development of the renal Fanconi syndrome and varying degrees of renal failure. Growth is usually normal. The infantile type is the most common and the most severe. Characteristically, children present in the first or second year of life with Fanconi syndrome and, without the metabolic benefit of Cystagon treatment, progress to end-stage renal failure.

Cystinosis results from mutations in the *CTNS* gene, which codes for a cystine transporter. About 50% of patients share an identical deletion. Inheritance is autosomal recessive. Cystine is stored in cellular lysosomes in virtually all tissues. Eventually, cystine accumulation results in cell damage and cell death, particularly in the renal tubules. Renal failure between ages 6 and 12 years is common.

Whenever the diagnosis of cystinosis is suspected, slit-lamp examination of the corneas should be performed. Cystine crystal deposition causes an almost pathognomonic ground-glass “dazzle” appearance. Increased white cell cystine levels are diagnostic. Hypothyroidism is common.

Cystagon therapy is helpful in the treatment of cystinosis. Depending on the progression of chronic renal failure, management is directed toward all side effects of renal failure, with particular attention paid to the control of renal osteodystrophy. Dialysis and transplantation may be needed.

NEPHROGENIC DIABETES INSIPIDUS

The congenital X-linked recessive form of nephrogenic diabetes insipidus results from mutations in the vasopressin receptor, *AVPR2*. Autosomal (recessive and dominant) forms of nephrogenic diabetes insipidus are caused by mutations of the *AQP2* gene that codes for a water channel protein, aquaporin-2. Genetic counseling and mutation testing are available.

The symptoms are polyuria, polydipsia, and failure to thrive. In some children, particularly if the solute intake is

unrestricted, adjustment to an elevated serum osmolality may develop. These children are particularly susceptible to episodes of dehydration, fever, vomiting, and convulsions.

The diagnosis can be suspected on the basis of a history of polydipsia and polyuria insensitive to the administration of vasopressin, desmopressin acetate, or lypressin. The diagnosis is confirmed by performing a vasopressin test. Carefully monitored water restriction does not increase the tubular reabsorption of water (TcH_2O) to above 3 mL/min/m². Urine osmolality remains lower than 450 mOsm/kg, whereas serum osmolality rises and total body weight falls. Before weight reduction of more than 5% occurs or before serum osmolality exceeds 320 mOsm/kg, vasopressin should be administered. Urine concentrating ability is impaired in a number of conditions—sickle cell anemia, pyelonephritis, potassium depletion, hypercalcemia, cystinosis and other renal tubular disorders, and obstructive uropathy—and as a result of nephrotoxic drugs. Children receiving lithium treatment should be monitored for the development of nephrogenic diabetes insipidus.

In infants, it is usually best to allow water as demanded and to restrict salt. Serum sodium levels should be evaluated at intervals to avoid hyperosmolality from inadvertent water restriction. In later childhood, sodium intake should continue to be restricted to 2.0–2.5 mEq/kg/24 h.

Treatment with hydrochlorothiazide is helpful, and many patients show improvement with administration of prostaglandin inhibitors such as indomethacin or tolmetin.

NEPHROLITHIASIS

Renal calculi in children may result from inborn errors of metabolism, such as cystine in cystinosis, glycine in hyperglycinuria, urates in Lesch-Nyhan syndrome, and oxalates in oxalosis. Stones may occur secondary to hypercalciuria in distal tubular acidosis, and large stones are quite often seen in children with spina bifida who have paralyzed lower limbs. Treatment is limited to that of the primary condition, if possible. Surgical removal of stones should be considered only for obstruction, intractable severe pain, and chronic infection.

1. Cystinuria

Cystinuria, like Hartnup disease and several other disorders, is primarily an abnormality of amino acid transport across both the enteric and proximal renal tubular epithelium. There are at least three biochemical types. In the first type, the bowel transport of basic amino acids and cystine is impaired, but transport of cysteine is not impaired. In the renal tubule, basic amino acids are again rejected by the tubule, but cystine absorption appears to be normal. The reason for cystinuria remains obscure. Heterozygous individuals have no aminoaciduria. The second type is similar to the first except that heterozygous individuals excrete excess cystine and lysine in the urine, and cystine transport in the bowel is normal. In the

third type, only the nephron is involved. The only clinical manifestations are related to stone formation: ureteral colic, dysuria, hematuria, proteinuria, and secondary urinary tract infection (UTI). Urinary excretion of cystine, lysine, arginine, and ornithine is increased.

The most reliable way to prevent stone formation is to maintain a constantly high free-water clearance. This involves generous fluid intake. Alkalinization of the urine is helpful. If these measures do not prevent significant renal lithiasis, the use of tiopronin (Thiola) is recommended.

2. Primary Hyperoxaluria

Oxalate in humans is derived from the oxidative deamination of glycine to glyoxylate, from the serine-glycolate pathway, and from ascorbic acid. At least two enzymatic blocks have been described. Type I is a deficiency of liver-specific peroxisomal alanine-glyoxylate aminotransferase. Type II is glyoxylate reductase deficiency.

Excess oxalate combines with calcium to form insoluble deposits in the kidneys, lungs, and other tissues, beginning during childhood. The joints are occasionally involved, but the main effect is on the kidneys, where progressive oxalate deposition leads to fibrosis and eventual renal failure.

Pyridoxine supplementation and a low-oxalate diet have been tried as therapy, but the overall prognosis is poor, and most patients succumb to uremia by early adulthood. Renal transplantation is not very successful because of destruction of the transplant kidney. However, encouraging results have been obtained with concomitant liver transplantation, correcting the metabolic defect.

Hyperoxaluria may also be a consequence of severe ileal disease or ileal resection.

URINARY TRACT INFECTIONS

It is estimated that 8% of girls and 2% of boys will acquire UTIs in childhood. Girls older than age 6 months have UTIs far more commonly than boys, whereas uncircumcised boys younger than 3 months of age have more UTIs than girls. Circumcision reduces the risk of UTI in boys. The density of distal urethral and periurethral bacterial colonization with uropathogenic bacteria correlates with the risk of UTI in children. Most UTIs are ascending infections. Specific adhesins present on the fimbria of uropathogenic bacteria allow colonization of the uroepithelium in the urethra and bladder and increase the likelihood of UTI.

▶ Pathogenesis

Dysfunctional voiding, which is uncoordinated relaxation of the urethral sphincter during voiding, leads to incomplete emptying of the bladder, increasing the risk of bacterial colonization. Similarly, any condition that interferes with complete emptying of the bladder, such as constipation or

neurogenic bladder, increases the risk of UTI. Poor perineal hygiene, structural abnormalities of the urinary tract, catheterization, instrumentation of the urinary tract, and sexual activity increase the risk as well.

The inflammatory response to pyelonephritis may produce renal parenchymal scars. Such scars in infancy and childhood may contribute to hypertension, renal disease, and renal failure later in life. The organisms most commonly responsible for UTI are fecal flora, most commonly *E coli* (> 85%), *Klebsiella*, *Proteus*, other gram-negative bacteria, and, less frequently, *Enterococcus* or coagulase-negative staphylococci.

► Clinical Findings

A. Symptoms and Signs

Newborns and infants with UTI have nonspecific signs, including fever, hypothermia, jaundice, poor feeding, irritability, vomiting, failure to thrive, and sepsis. Strong, foul-smelling or cloudy urine may be noted. Preschool children may have abdominal or flank pain, vomiting, fever, urinary frequency, dysuria, urgency, or enuresis. School-aged children commonly have classic signs of cystitis (frequency, dysuria, and urgency) or pyelonephritis (fever, vomiting, and flank pain). Costovertebral tenderness is unusual in young children, but may be demonstrated by school-aged children. Physical examination should include attention to blood pressure determination, abdominal examination, and a genitourinary examination. Urethritis, poor perineal hygiene, herpes simplex virus, or other genitourinary infections may be apparent on examination.

B. Laboratory Findings

Collection of urine for urinalysis and culture is difficult in children due to frequent contamination of the sample. In toilet-trained, cooperative, older children, a midstream, clean-catch method is satisfactory. Although cleaning of the perineum does not improve specimen quality, straddling of the toilet to separate the labia in girls, retraction of the foreskin in boys, and collecting midstream urine significantly reduce contamination. In infants and young children, bladder catheterization or suprapubic collection is necessary in most cases to avoid contaminated samples. Bagged urine specimens are helpful only if negative.

Screening urinalysis indicates pyuria (> 5 WBCs/high-power field) in most children with UTI, but many children with pyuria do not have UTI. White cells from the urethra or vagina may be present in urine or may be in the urine because of a systemic infection. The leukocyte esterase test correlates well with pyuria, but has a similar false-positive rate. The detection of urinary nitrite by dipstick is highly correlated with enteric organisms being cultured from urine. Most young children (70%) with UTI have negative nitrite tests. They empty their bladders frequently, and it requires several hours for bacteria to convert ingested nitrates to nitrite in the bladder. The sensitivity of nitrite detection is

highest on a first morning void. Gram stain of unspun urine correlates well with culture recovery of 10^5 colony-forming units (cfu)/mL or more, but this test is frequently unavailable outside the hospital.

The gold standard for diagnosis remains the culture of a properly collected urine specimen. Specimens that are not immediately cultured should be refrigerated and kept cold during transport. Any growth is considered significant from a suprapubic culture. Quantitative recovery of 10^5 cfu/mL or more is considered significant on clean-catch specimens, and 10^4 – 10^5 is considered significant on catheterized specimens. Usually the recovery of multiple organisms indicates contamination, but some contaminated specimens yield only a single species.

Asymptomatic bacteriuria is detected in 0.5–1.0% of children who are screened with urine culture. Asymptomatic bacteriuria is believed to represent colonization of the urinary tract with nonuropathogenic bacteria. Treatment may increase the risk of symptomatic UTI by eliminating nonpathogenic colonization. Screening urine cultures in non-symptomatic children are, therefore, generally discouraged. Repeated urine cultures are often helpful in differentiating asymptomatic bacteriuria from contamination of the culture versus true UTI.

Urinary function during UTI should be assessed by measurement of BUN and serum creatinine concentration.

C. Imaging

Because congenital urologic abnormalities increase the risk of UTI, radiologic evaluation of first UTI has been routinely recommended. These recommendations usually include routine ultrasound of the kidneys and voiding cystourethrogram (VCUG). Vesicoureteral reflux (VUR) is a congenital abnormality present in about 1% of the population. VUR is graded using the international scale (I—reflux into ureter; II—reflux to the kidney; III—reflux to kidney with dilation of ureter only; IV—reflux with dilation of ureter and mild blunting of renal calyces; V—reflux with dilation of ureter and blunting of renal calyces). Reflux is detected in 30–50% of children 1 year of age and younger. The natural history of reflux is to improve, and 80% of reflux of grades I, II, or III will resolve or significantly improve within 3 years following detection.

VCUG should be done selectively on children with a first UTI. Children with a suspected urologic abnormality due to weak stream, dribbling, or perineal abnormalities should be studied with VCUG. Boys with a first UTI should be studied to detect posterior urethral valves, an important congenital abnormality that requires surgery. Children older than 3 years of age who are otherwise healthy and growing well usually can be followed clinically and do not need VCUG for a first UTI. The yield in sexually active teenagers is also very low.

Ultrasonographic examination of kidneys should be done in children with acute pyelonephritis who have not improved after 3–5 days of antimicrobial treatment adjusted for the

susceptibility of the organism. The examination is done to detect renal or perirenal abscesses or obstruction of the kidney.

► Treatment

A. Antibiotic Therapy

Management of UTI is influenced by clinical assessment. Very young children (younger than 3 months) and children with dehydration, toxicity, or sepsis should be admitted to the hospital and treated with parenteral antimicrobials. Older infants and children who are not seriously ill can be treated as outpatients. Initial antimicrobial therapy is based on prior history of infection and antimicrobial use, as well as location of the infection in the urinary tract.

Uncomplicated cystitis can be treated with amoxicillin, trimethoprim–sulfamethoxazole, or a first-generation cephalosporin. These antimicrobials are concentrated in the lower urinary tract, and high cure rates are common. There are significant differences in the rates of antimicrobial resistance, so knowledge of the rates in the local community is important. More seriously ill children are initially treated parenterally with a third-generation cephalosporin or aminoglycoside. The initial antimicrobial choice is adjusted after culture and susceptibility are known. The recommended duration of antimicrobial therapy for uncomplicated cystitis is 7–10 days. For sexually mature teenagers with cystitis, fluoroquinolones such as ciprofloxacin and levofloxacin for 3 days are effective and cost-effective. Short-course therapy of cystitis is not recommended in children, because differentiating upper and lower tract disease may be difficult, and higher failure rates are reported in most studies of short-course therapy.

Acute pyelonephritis is usually treated for 10 days. The duration of parenteral therapy in uncomplicated pyelonephritis is not well defined, but most children can complete therapy orally once symptomatic improvement has occurred.

A repeat urine culture 24–48 hours after beginning therapy is not needed if the child is improving and doing well.

B. Follow-Up

Children with UTI should be followed with screening urinalysis 1 and 2 months after resolution of UTI. Dipstick nitrate determination can be used at home by parents on first morning voided urine in children with frequently recurring UTI.

C. Prophylactic Antimicrobials

Selected children with frequently recurring UTI may benefit from prophylactic antimicrobials. In children with high-grade VUR, prophylactic antimicrobials may be beneficial in reducing UTI, as an alternative to surgical correction, or in the interval prior to surgical therapy. Many experts recommend surgical correction of higher-grade reflux, particularly grade V. Trimethoprim–sulfamethoxazole and nitrofurantoin are approved for prophylaxis. The use of broader-spectrum antimicrobials leads to colonization and infection with resistant strains.

Children with dysfunctional voiding generally do not benefit from prophylactic antimicrobials; rather, addressing the underlying dysfunctional voiding is most important.

NEUROLOGIC ASSESSMENT & NEURODIAGNOSTIC PROCEDURES

HISTORY & EXAMINATION

A general physical examination (albeit sometimes truncated) and an age-appropriate developmental assessment are part of every neurologic visit. Information provided in several earlier chapters is relevant in this context. Chapter 2 delineates age-appropriate developmental landmarks (see Tables 2–1 and 2–2); the Denver II schedule (see Figure 2–12) is helpful, especially in infancy. Growth and head circumference charts (*you* should measure the head) are also included in Chapter 2. Details of the standard pediatric history and physical examination are presented in Chapter 8. Expected newborn-infant reflexes and automatisms and other examination suggestions pertinent to that age group are included in Chapter 1.

Table 23–1 outlines components of the neurologic examination. Examination of a frightened or wary infant can begin on the mother's lap. Playing games will engage a toddler or preschooler: retrieving, casting a ball, stacking blocks, hopping, jogging, counting, and drawing (circles, lines) can reduce anxiety and exhibit fine and gross motor coordination, balance, and handedness. On occasion beyond preschool age, describing a picture, drawing, writing, calculating, and spelling will aid in assessing speech and intelligence.

Emphasis (or fine tuning) of both history and physical examination strongly depends on the chief complaint. Insidious developmental delay or weakness might demand detailed exploration of pregnancy, family, and social history; developmental landmarks; and general physical, motor, and speech achievements. Headaches or seizures in an older child warrant more emphasis on precise details preceding and during these events.

LUMBAR PUNCTURE

Spinal fluid is usually obtained by inserting a small-gauge needle (eg, No. 22) through the L3–L4 intervertebral space

into the thecal sac while the patient is lying on his or her side. After an opening pressure is measured, a small amount of fluid is removed most frequently to examine for evidence of infection or inflammation (Table 23–2). Fluid is sent for red and white cell counts, for determination of the concentrations of protein and glucose, and for viral and bacterial cultures. In some cases, additional information is obtained with special staining techniques for mycobacteria and fungus. Additional fluid may be sent for polymerase chain reaction (PCR) testing for specific viral agents, antibody titer determinations, cytopathologic study, lactate and pyruvate concentrations, and amino acid and neurotransmitter analysis. Lumbar puncture is imperative when bacterial meningitis is suspected. Caution must be exercised, however, when signs of increased intracranial pressure (eg, papilledema) or focal neurologic signs are present that might indicate a substantial risk of precipitating tentorial or tonsillar herniation.

ELECTROENCEPHALOGRAPHY

Electroencephalography (EEG), a widely used noninvasive electrophysiologic method for recording cerebral activity, has its greatest clinical applicability in the study of seizure disorders. EEG is particularly helpful in showing epileptiform activity. Sometimes the findings are diagnostic, as in the hypsarrhythmia EEG of infantile spasms or the prolonged generalized 3/s spike-wave of absence seizures.

EEG is also used in the evaluation of tumors, cerebrovascular accidents, neurodegenerative diseases, and other neurologic disorders causing brain dysfunction. Recordings over a 24-hour period or all-night recordings are invaluable in the diagnosis of sleep disturbances and narcolepsy. EEG with telemetry or simultaneous monitoring of behavior on videotape has great usefulness in selected cases. The EEG can be helpful in determining a possible cause or mechanism of coma and whether subclinical seizures are contributing to the coma, and can help determine whether coma is irreversible and brain death has occurred.

Table 23-1. Neurologic examination: toddler age and up.

Category	Operation	Assesses
Station	Standing, eyes open, closed, hands out (Romberg test): truncal balance.	Cerebellum (vermis) Posterior columns
Gait	Walking (running in hall); heel-toe (tandem gait) forward, backward. Balance on each foot.	Cerebellum (vermis)
Coordination (truncal, limb)	Balance on each foot; hopping; finger-nose-finger pursuit. Stack blocks. Reach for a rattle. Rapid alternating movements.	Cerebellum: lateral lobes
Motor	Tone: trunk (infant)—hold prone, supine; manipulate relaxed limbs; hold under arms. Strength: proximal/distal—shoulder abduction/grasp; get up from floor (hips); dorsiflexion of foot. 0 = no movement; 1 = trace; 3 = against gravity; 5 = normal (0-5 grading strength)	Brain: “suprasegmental” influence Cord: lower motor neuron-“segmental” component
Reflexes	Tendon reflexes: biceps, triceps, brachioradialis, knee, ankle. Cutaneous: abdominal (cremasteric).	Pyramidal tract Spinal cord: sensory/motor nerve arc
Sensory	Light touch, sharp (pain), vibration (tuning fork-toe, finger, on bone), position (same). Cortical: 2 point, finger writing, object identification, position limb in space, barognosis (weight).	Peripheral nerve Posterior column Anterior/lateral column Parietal lobe
Cranial nerves	CN I: omit most of the time (smell). CN II: pupils (light reflex), vision (acuity), fields, fundi. CN III, IV, VI: extraocular movements, pupils, convergence, (strabismus?). CN V: facial sensation (upper, middle, lower; V ₁ , V ₂ , V ₃); motor—move jaw laterally, open, close against resistance. CN VII: upper—eye closure, brow; lower—grimace, show teeth. CN VIII: whispered voice from 10-20 ft each ear. Tuning fork tests. CN IX, X: sensation? Movement of palate to “ahh” or tongue blade (“gagging”—often omit). CN XI: turning head right, left; flexing against resistance. CN XII: protrude tongue, push it out cheek. Push left, right against resistance (examiner’s thumb).	

The limitations of EEG are considerable. In most cases, the duration of the actual tracing is about 45 minutes and reflects only surface cortical function. Many drugs, especially barbiturates and benzodiazepines, may cause artifact on the tracing and may confuse interpretation. Moreover, about 15% of nonepileptic individuals, especially children, may have an abnormal EEG. EEG findings such as those occasionally seen in migraine, learning disabilities, or behavior disorders are often nonspecific and do not reflect structural brain damage.

Computed tomography (CT) scans, evoked potentials, positron emission tomography (PET), regional cerebral blood flow studies, single-photon emission computed tomography (SPECT), and magnetic resonance imaging (MRI) supplement the EEG as a diagnostic and prognostic tool.

EVOKED POTENTIALS

Cortical visual, auditory, or somatosensory evoked potentials (evoked responses) may be recorded from the scalp surface over the temporal, occipital, or frontoparietal cortex after repetitive stimulation of the retina by light flashes, the cochlea by sounds, or a nerve by galvanic stimuli of varying frequency and intensity, respectively. Computer averaging is

used to recognize and enhance these responses while subtracting or suppressing the asynchronous background EEG activity. The presence or absence of evoked potential waves and their latencies (time from stimulus to wave peak or time between peaks) figures in the clinical interpretation.

The reproducible and quantifiable results obtained from brainstem auditory, pattern-shift visual, and short-latency somatosensory evoked potentials (see section on short-latency somatosensory evoked potentials) indicate the level of function of the relevant sensory pathway or system and identify the site of anatomic disruption. Although results of these tests alone are usually not diagnostic, the tests are noninvasive, sensitive, objective, and relatively inexpensive extensions of the clinical neurologic examination. Because the auditory and somatosensory tests and one type of visual test are completely passive, requiring only that the patient remain still, they are particularly useful in the evaluation of neonates, young children, and patients unable to cooperate. Knowledge of normal values and experience in testing are mandatory.

Brainstem Auditory Evoked Potentials

A brief auditory stimulus (click) of varying intensity and frequency is delivered to the ear to activate the auditory

Table 23-2. Characteristics of cerebrospinal fluid in the normal child and in central nervous system infections and inflammatory conditions.

Condition	Initial Pressure (mm H ₂ O)	Appearance	Cells/ μ L	Protein (mg/dL)	Glucose (mg/dL)	Other Tests	Comments
Normal	< 160	Clear	0-5 lymphocytes; first 3 months, 1-3 PMNs; neonates, up to 30 lymphocytes, rare RBCs	15-35 (lumbar), 5-15 (ventricular); up to 150 (lumbar) for short time after birth; to 6 months up to 65	50-80 (two thirds of blood glucose); may be increased after seizure	CSF-IgG index ^a < 0.7 ^a ; LDH 2-27 U/L	CSF protein in first month may be up to 170 mg/dL in small-for-date or premature infants; no increase in WBCs due to seizure
Bloody tap	Normal or low	Bloody (sometimes with clot)	One additional WBC/700 RBCs ^b ; RBCs not crenated	One additional milligram per 800 RBCs ^b	Normal	RBC number should fall between first and third tubes; wait 5 min between tubes	Spin down fluid, supernatant will be clear and colorless ^c
Bacterial meningitis, acute	200-750+	Opalescent to purulent	Up to thousands, mostly PMNs; early, few cells	Up to hundreds	Decreased; may be none	Smear and culture mandatory; LDH > 24 U/L; lactate, IL-8, TNF elevated, correlate with prognosis	Very early, glucose may be normal; PCR meningococci and pneumococci in plasma, CSF may aid diagnosis
Bacterial meningitis, partially treated	Usually increased	Clear or opalescent	Usually increased; PMNs usually predominate	Elevated	Normal or decreased	LDH usually > 24 U/L; PCR may still be positive	Smear and culture may be negative if antibiotics have been in use
Tuberculous meningitis	150-750+	Opalescent; fibrin web or pellicle	250-500, mostly lymphocytes; early, more PMNs	45-500; parallels cell count; increases over time	Decreased; may be none	Smear for acid-fast organism; CSF culture and inoculation; PCR	Consider AIDS, a common comorbidity of tuberculosis
Fungal meningitis	Increased	Variable; often clear	10-500; early, more PMNs; then mostly lymphocytes	Elevated and increasing	Decreased	India ink preparations, cryptococcal antigen, PCR, culture, inoculations, immunofluorescence tests	Often superimposed in patients who are debilitated or on immunosuppressive therapy
Aseptic meningoencephalitis (viral meningitis, or parameningeal disease); encephalitis is similar	Normal or slightly increased	Clear unless cell count > 300/ μ L	None to a few hundred, mostly lymphocytes; PMNs predominate early	20-125	Normal; may be low in mumps, herpes, or other viral infections	CSF, stool, blood, throat washings for viral cultures; LDH < 28 U/L; PCR for HSV, CMV, EBV, enterovirus, etc	Acute and convalescent antibody titers for some viruses; in mumps, up to 1000 lymphocytes; serum amylase often elevated; up to 1000 cells present in enteroviral infection

(continued)

Table 23-2. Characteristics of cerebrospinal fluid in the normal child and in central nervous system infections and inflammatory conditions. (Continued)

Condition	Initial Pressure (mm H ₂ O)	Appearance	Cells/ μ L	Protein (mg/dL)	Glucose (mg/dL)	Other Tests	Comments
Parainfectious encephalomyelitis (ADEM)	80–450, usually increased	Usually clear	0–50+, mostly lymphocytes; lower numbers, even 0, in MS	15–75	Normal	CSF-IgG index, oligoclonal bands variable; in MS, moderate increase	No organisms; fulminant cases resemble bacterial meningitis
Polyneuritis	Normal and occasionally increased	Early: normal; late: xanthochromic if protein high	Normal; occasionally slight increase	Early: normal; late: 45–1500	Normal	CSF-IgG index may be increased; oligoclonal bands variable	Try to find cause (viral infections, toxins, lupus, diabetes, etc)
Meningeal carcinomatosis	Often elevated	Clear to opalescent	Cytologic identification of tumor cells	Often mildly to moderately elevated	Often depressed	Cytology	Seen with leukemia, medulloblastoma, meningeal melanosis, histiocytosis X
Brain abscess	Normal or increased	Usually clear	5–500 in 80%; mostly PMNs	Usually slightly increased	Normal; occasionally decreased	Imaging study of brain (MRI)	Cell count related to proximity to meninges; findings as in purulent meningitis if abscess ruptures

^aCSF-IgG index = CSF IgG/serum IgG \div CSF albumin/serum albumin.

^bMany studies document pitfalls in using these ratios due to WBC lysis. Clinical judgment and repeat lumbar punctures may be necessary to rule out meningitis in this situation.

^cCSF WBC (predicted) = CSF RBC \times (blood WBC/blood RBC). O:P ratio = observed CSF WBC \div predicted CSF WBC. Also, do WBC:RBC ratio. If O:P ratio \leq 0.01, and WBC:RBC ratio \leq 1:100, meningitis is absent. ADEM, acute disseminated encephalomyelitis; AIDS, acquired immunodeficiency syndrome; CMV, cytomegalovirus; CSF, cerebrospinal fluid; EBV, Epstein-Barr virus; HSV, herpes simplex virus; IL-8, interleukin 8; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; MS, multiple sclerosis; PCR, polymerase chain reaction; PMN, polymorphonuclear neutrophil; RBC, red blood cell; TNF, tumor necrosis factor; WBC, white blood cell.

nerve (nerve VIII) and sequentially activate the cochlear nucleus, tracts and nuclei of the lateral lemniscus, and inferior colliculus. Thus this technique assesses hearing and function of the brainstem auditory tracts.

Hearing in the neonate or uncooperative patient can be assessed objectively, making the technique particularly useful in high-risk infants and in mentally retarded or autistic patients. Because high doses of anesthetic agents or barbiturates do not seriously affect results, the test is used to assess and monitor brainstem function of surgical patients (in the operating room) and those in hypoxic-ischemic coma or coma following head injury. Absence of evoked potential waves beyond the first wave from the auditory nerve usually signifies brain death. Brainstem auditory evoked potentials are also useful in the early evaluation of diseases affecting myelin such as the leukodystrophies and multiple sclerosis, although auditory evoked potentials are less valuable than visual evoked potentials in the evaluation of multiple sclerosis. Intrinsic brainstem gliomas and brainstem encephalitis (eg, enterovirus 71) can also be evaluated with auditory evoked potentials. They are sometimes useful in evaluation of hereditary ataxias, Wilson disease, and other degenerative disorders of the brainstem.

Pattern-Shift Visual Evoked Potentials

The preferred stimulus is a shift (reversal) of a checkerboard pattern, and the response is a single wave (called P-100) generated in the striate and parastriate visual cortex. The absolute latency of P-100 (time from stimulus to wave peak) and the difference in latency between the two eyes are sensitive indicators of disease. The amplitude of response is affected by any process resulting in poor fixation on the stimulus screen or affecting visual acuity. Ability to focus on a checkerboard pattern is necessary. An LED (light-emitting diode) in goggles, or bright flash stimulus can be used in younger and uncooperative children, but the norms are less standardized. This is a less sensitive whole retina (rather than only macula) stimulation that may give normal results in a child who is legally blind.

Clinical applications of the test include detection and monitoring of strabismus (eg, in amblyopia ex anopsia), optic neuritis, and lesions near the optic nerve and chiasm such as optic gliomas and craniopharyngiomas. Degenerative and immunologic diseases that affect visual transmission may be detected early and followed by serial evaluations. Examples of such diseases include adrenoleukodystrophy, Pelizaeus-Merzbacher disease, some spinocerebellar degenerations, sarcoidosis, and even multiple sclerosis. Flash visual evoked potentials are used to monitor function during surgery on the eyes or optic nerve, to assess cortical or hysterical blindness, and to evaluate patients with photosensitive epilepsy, who may have exaggerated responses.

Short-Latency Somatosensory Evoked Potentials

Responses are commonly produced by electrical stimulation of peripheral sensory nerves, because this evokes potentials

of greatest amplitude and clarity. Finger tapping and muscle stretching may also be used to stimulate somatosensory potentials. The function of this test is similar to that of the auditory test in closely correlating waveforms with function of the sensory pathways and permitting localization of conduction defects.

Short-latency somatosensory evoked potentials are used in the assessment of a wide variety of lesions of the peripheral nerve, root, spinal cord, and central nervous system (CNS) following trauma, neuropathies (eg, in diabetes mellitus or Guillain-Barré syndrome), myelodysplasias, Arnold-Chiari malformation, and achondroplasia. The procedure is often performed on an outpatient basis. One method is stimulation of the median nerve at the wrist with small (nonpainful) electrical shocks and recording of responses from the brachial plexus above the clavicle, the neck (cervical cord), and the opposite scalp area overlying the sensorimotor cortex. After stimulation from the knee (peroneal nerve) or ankle (tibial nerve), impulses are recorded from the lower lumbar spinal cord, cervical cord, and sensorimotor cortex. Such potentials are used to monitor spinal cord sensory functioning during surgery for scoliosis, myelodysplasias, tumors, and other lesions of the spinal cord or its blood vessels. The technique is also used in leukodystrophies involving peripheral nerves, in multiple sclerosis, and in the evaluation of hysteria and malingering (anesthetic limbs). In the diagnosis of coma and brain death, somatosensory evoked potentials supplement the results of auditory evoked potentials.

PEDIATRIC NEURORADIOLOGIC PROCEDURES

Sedation for Procedures

Oral chloral hydrate, 30–60 mg/kg per dose, is safest. Many radiology departments, however, use intravenously administered agents because of the risks of vomiting and aspiration. One favorite is pentobarbital, 6 mg/kg for children weighing less than 15 kg and 5 mg/kg for larger children (up to a maximum of 200 mg) given intramuscularly or rectally (at least 20 minutes before a procedure), or 2–4 mg/kg given intravenously. Equipment to support blood pressure and respiration must be available. This dosage usually achieves sedation for up to 2 hours. If, however, sedation is inadequate 30 minutes after injection, and if the child's condition permits a second dose of pentobarbital, 2 mg/kg is given. Midazolam, 0.1 mg/kg IV or 0.2 mg/kg intranasally, is gaining popularity for brief procedures (eg, Botox injection).

Computed Tomography

CT scanning consists of a series of cross-sectional (axial) roentgenograms. Radiation exposure is approximately the same as that from a skull radiographic series. CT images record variations in tissue density and can be viewed on a television screen as the scan is being done, and later examined on films. CT scanning is of high sensitivity (88–96% of

lesions larger than 1–2 cm can be seen) but low specificity (tumor, infection, or infarct may look the same). Sedation is usually not needed. CT scan is occasionally repeated after intravenous injection of iodized contrast for enhancement, which reflects the vascularity of a lesion or its surrounding tissues. Most CT scans do not require enhancement. Lastly, CT angiography (CTA; no injection is needed) is often “more available” in an acute stroke evaluation, gives excellent cross-sectional views of major arteries, and may identify the site of an acute thrombosis. Radiation dose is a disadvantage of all CT scanning.

Magnetic Resonance Imaging

MRI is a noninvasive technique that uses the magnetic properties of certain nuclei to produce diagnostically useful signals. Currently the technique is based on detecting the response (resonance) of hydrogen proton nuclei to applied radiofrequency electromagnetic radiation. These nuclei are abundant in the body and more sensitive to MRI than other nuclei. The strength of MRI signals varies with the relationship of water to protein and the amount of lipid in the tissue. The MRI image displayed provides high-resolution contrast of soft tissues. MRI can provide information about the histologic, physiologic, and biochemical status of tissues in addition to gross anatomic data. Sedation is necessary in children younger than age 6 years to avoid any movement artefact.

MRI has been used to delineate brain tumors, edema, ischemic and hemorrhagic lesions, hydrocephalus, vascular disorders, inflammatory and infectious lesions, and degenerative processes. MRI can be used to study myelination and demyelination, and through the demonstration of changes in relaxation time, metabolic disorders of the brain, muscles, and glands. Because bone causes no artifact in the images, the posterior fossa and its contents can be studied far better using MRI than with CT scans. Even blood vessels and the cranial nerves can be imaged. In contrast, the lesser ability of MRI to detect calcification limits its usefulness in the investigation of calcified lesions such as craniopharyngioma and leptomeningeal angiomatosis.

Magnetic resonance angiography (MRA) or venography (MRV) is a noninvasive (no arterial or venous puncture or dye injection) technique to show large extra- and intracranial blood vessels. It often replaces the more hazardous intra-arterial injection angiogram. An advantage over CTA (see previous section) is the lack of radiation exposure.

Perfusion imaging involving a paramagnetic contrast agent is used in stroke patients to evaluate brain ischemic penumbra. Similarly, diffusion imaging (measuring random motion of water molecules) may show reduced diffusion in areas of cytotoxic edema, and is useful in acute strokes and toxic or metabolic brain injuries. The area of involvement often exceeds the T1 hypodense or T2 hyperdense stroke area, and this penumbra possibly reflects recoverable tissue injury as compared with totally infarcted tissue, cell death, or apoptosis (programmed cell death) in the center of the stroke.

Another new MRI technique, proton MR spectroscopy, measures signals of increased cellular activity and oxidative metabolism; neuronal acetyl aspartate, phosphocreatinine, and phosphomonoester are increased. Ratios are often calculated to choline and P_i (inorganic phosphate). Increased lactate (anaerobic metabolism), choline, and creatinine, reflecting increased cell surface area—as in gliosis or scarring—can be assessed in a chosen voxel or tiny area of interest. An epileptic focus in the medial temporal lobe is an example; an active seizure site might show increased metabolism. Sclerosis and gliosis (“scar”) would show the converse.

Functional MRI can be performed at the same time as an ongoing regular MRI. Blood oxygenation changes in an area of interest (eg, an area of language acquisition) during rest and then during a verbal work paradigm can identify and lateralize the language cortex. A change in the ratio of oxyhemoglobin to deoxyhemoglobin results in a detectable MRI signal.

Positron Emission Tomography

PET is an imaging technique that measures the metabolic rate at a given site by CT scanning. For measurement of local cerebral metabolism, the radiolabeled substrate most frequently used has been intravenously administered fluorodeoxyglucose. Gray matter and white matter are clearly distinguishable; the skull and air- or fluid-filled cavities are least active metabolically.

PET has been used to study the cerebral metabolism of neonates and brain activation by visual or auditory stimuli. Pathologic states that have been studied include epilepsy, brain infarcts, brain tumors, and dementias. This functional test of brain metabolism is useful in preoperative evaluation for epilepsy surgery. The epileptogenic zone will often be hypermetabolic during seizures and hypoactive during the time between seizures. The information from PET scan complements EEG and MRI findings to aid in the decision about tissue removal. In infants with infantile spasms, PET scan has occasionally detected focal lesions, thereby leading to successful surgical removal. Clinical application is limited by the cost of the procedure and the clinician’s need for access to a nearby cyclotron for preparation of the radiopharmaceuticals.

Ultrasonography

Ultrasonography offers a pictorial display of the varying densities of tissues in a given anatomic region by recording the echoes of ultrasonic waves reflected from it. These waves, modulated by pulsations, are introduced into the tissue by means of a piezoelectric transducer. The many advantages of ultrasonography include the ability to assess a structure and its positioning quickly with easily portable equipment, without ionizing radiation, and at about one fourth the cost of CT scanning. Sedation is usually not necessary, and the procedure can be repeated as often as needed without risk to the patient. In brain imaging, B-mode and real-time sector

scanners are usually used, permitting excellent detail in the coronal and sagittal planes. Contiguous structures can be studied by a continuous sweep and reviewed on videotape.

Ultrasonography has been used for in-utero diagnosis of hydrocephalus and other anomalies. In neonates, the thin skull and the open anterior fontanelle have facilitated imaging of the brain, and ultrasonography is used to screen and follow infants of less than 32 weeks' gestation or weighing less than 1500 g for intracranial hemorrhage. Other uses in neonates include detection of hydrocephalus, major brain and spine malformations, and calcifications from intrauterine infection with cytomegalovirus (CMV) or *Toxoplasma*. In skilled hands, sonography of the neonatal spine can be used as a screening test for anomalies at the lumbosacral level.

Cerebral Angiography

Arteriography remains a useful procedure in the diagnosis of many cerebrovascular disorders, particularly in cerebrovascular accidents or in potentially operable vascular malformations. In some brain tumors, arteriography may be necessary to define the precise location or vascular bed, to differentiate among tumors, or to distinguish tumor from abscess or infarction. Noninvasive CT, MRI, and MRA scans can diagnose many cases of static or flowing blood disorders (eg, sinus thromboses). If necessary, the more risky invasive arteriography is usually done via femoral artery-aorta catheterization.

Myelography

Radiographic examination of the spine may be indicated in cases of spinal cord tumors, myelitis, or various forms of spinal dysraphism and in the rare instance of herniated disks in children. MRI has largely replaced sonography, CT, and myelography for examination of the spinal cord.

DISORDERS AFFECTING THE NERVOUS SYSTEM IN INFANTS & CHILDREN

ALTERED STATES OF CONSCIOUSNESS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Reduction or alteration in cognitive and affective mental functioning and in arousability or attentiveness.
- ▶ Acute onset.

General Considerations

Many terms are used to describe the continuum from full alertness to complete unresponsiveness and deep coma, including clouding, obtundation, somnolence or stupor, semicomma or light coma, and deep coma. Several scales have been used to grade the depth of unconsciousness (Table 23–3). The commonly used Glasgow Coma Scale is summarized in Table 11–5. Physicians should use one of these tables and provide further descriptions in case narratives. These descriptions help subsequent observers quantify unconsciousness and evaluate changes in the patient's condition.

The neurologic substrate for consciousness is the reticular activating system in the brainstem, up to and including the thalamus and paraventricular hypothalamus. Large lesions of the cortex, especially of the left hemisphere, can also cause coma. The term *locked-in syndrome* describes patients who are conscious but have no access to motor or verbal expression because of massive loss of motor function of the brainstem. *Coma vigil* refers to patients who seem comatose but have some spontaneous motor behavior, such as eye opening or eye tracking, almost always at a reflex level. *Persistent vegetative state* denotes a chronic condition in which there is preservation of the sleep-wake cycle but no awareness and no recovery of mental function.

Treatment

A. Emergency Measures

The clinician's first response is to ensure that the patient will survive. The ABCs of resuscitation are pertinent. The airway must be kept open with positioning or even endotracheal

Table 23-3. Gradation of coma.

	Deep Coma		Light Coma		
	Grade 4	Grade 3	Grade 2	Grade 1	Stupor
Response to pain	0	+	Avoidance	Avoidance	Arousal unsustained
Tone/posture	Flaccid	Decerebrate	Variable	Variable	Normal
Tendon reflexes	0	+/-	+	+	+
Pupil response	0	+	+	+	+
Response to verbal stimuli	0	0	0	0	+
Other corneal reflex	0	+	+	+	+
Gag reflex	0	+	+	+	+

intubation. Breathing and adequate air exchange can be assessed by auscultation; hand bag respiratory assistance with oxygen may be needed. Circulation must be ensured by assessing pulse and blood pressure. An intravenous line is always necessary. Fluids, plasma, blood, or even a dopamine drip (1–20 mcg/kg/min) may be required in cases of hypotension. An extremely hypothermic or febrile child may require vigorous cooling or warming to save life. The assessment of vital signs may signal the diagnosis. Slow, insufficient respirations suggest poisoning by hypnotic drugs; apnea may indicate diphenoxylate hydrochloride poisoning. Rapid, deep respirations suggest acidosis, possibly metabolic, as with diabetic coma; toxic, such as that due to aspirin; or neurogenic, as in Reye syndrome. Hyperthermia may indicate infection or heat stroke; hypothermia may indicate cold exposure, ethanol poisoning, or hypoglycemia (especially in infancy).

The signs of impending brain herniation are another priority of the initial assessment. Bradycardia, high blood pressure, irregular breathing, increased extensor tone, and third nerve palsy with the eye deviated outward and the pupil dilated are possible signs of impending temporal lobe or brainstem herniation. These signs suggest a need for slight hyperventilation, reducing cerebral edema, prompt neurosurgical consultation, and possibly, in an infant with a bulging fontanelle, subdural or ventricular tap (or both). Initial intravenous fluids should contain glucose until further assessment disproves hypoglycemia as a cause.

A history obtained from parents or witnesses is desirable. Sometimes the only history will be obtained from ambulance attendants. An important point is whether the child is known to have a chronic illness, such as diabetes, hemophilia, epilepsy, or cystic fibrosis. Recent acute illness raises the possibility of coma caused by viral or bacterial meningitis. Trauma is a common cause of coma. Lack of a history of trauma, especially in infants, does not rule it out. Nonaccidental trauma or a fall not witnessed by caregivers may have occurred. In coma of unknown cause, poisoning is always a possibility. Absence of a history of ingestion of a toxic substance or of medication in the home does not rule out poisoning as a cause.

Often the history is obtained concurrently with a brief pediatric and neurologic screening examination. After the assessment of vital signs, the general examination proceeds with a trauma assessment. Palpation of the head and fontanelle, inspection of the ears for infection or hemorrhage, and a careful examination for neck stiffness are indicated. If circumstances suggest head or neck trauma, the head and neck must be immobilized so that any fracture or dislocation will not be aggravated. The skin must be inspected for petechiae or purpura that might suggest bacteremia, infection, bleeding disorder, or traumatic bruising. Examination of the chest, abdomen, and limbs is important to exclude enclosed hemorrhage or traumatic fractures.

Neurologic examination quantifies the stimulus response and depth of coma, such as responsiveness to verbal or painful stimuli. Examination of the pupils, optic fundi, and eye movements is important. Are the eye movements spontaneous, or is it necessary to do the doll's-eye maneuver (rotating the head rapidly to see whether the eyes follow)? Motor and sensory examinations assess reflex asymmetries, Babinski sign, and evidence of spontaneous posturing or posturing induced by noxious stimuli (eg, decorticate or decerebrate posturing).

If the cause of the coma is not obvious, emergency laboratory tests must be obtained. Table 23-4 lists some of the causes of coma in children. Most comas (90%) in children have a medical (versus structural) cause. Infection is a common cause (30%). An immediate blood glucose (or Dextrostix), complete blood count, urine obtained by catheterization if necessary, pH and electrolytes (including bicarbonate), serum urea nitrogen, and aspartate aminotransferase are initial screens. Urine, blood, and even gastric contents must be saved for toxin screen if the underlying cause is not obvious. Blood culture and lumbar puncture often are necessary to rule out CNS infection. Papilledema is a relative contraindication to lumbar puncture. Occasionally, blood culture is obtained, antibiotics started, and imaging study of the brain done prior to a diagnostic lumbar puncture. If meningitis is suspected and a lumbar puncture is delayed or believed to be hazardous, antibiotics should be started and the diagnostic lumbar punc-

Table 23-4. Some causes of coma in childhood.

Mechanism of Coma	Likely Cause	
	Newborn Infant	Older Child
Anoxia Asphyxia Respiratory obstruction Severe anemia	Birth asphyxia, HIE Meconium aspiration, infection (especially respiratory syncytial virus) Hydrops fetalis	Carbon monoxide (CO) poisoning Croup, tracheitis, epiglottitis Hemolysis, blood loss
Ischemia Cardiac Shock	Shunting lesions, hypoplastic left heart Asphyxia, sepsis	Shunting lesions, aortic stenosis, myocarditis Blood loss, infection
Head trauma (structural cause)	Birth contusion, hemorrhage, nonaccidental trauma (NAT)	Falls, auto accidents, athletic injuries
Infection (most common cause in childhood)	Gram-negative meningitis, enterovirus, herpes encephalitis, sepsis	Bacterial meningitis, viral encephalitis, postinfectious encephalitis, sepsis, typhoid, malaria
Vascular (CVA or stroke, often of unknown cause)	Intraventricular hemorrhage, sinus thrombosis	Arterial or venous occlusion with congenital heart disease, head or neck trauma
Neoplasm (structural cause)	Rare this age. Choroid plexus papilloma with severe hydrocephalus.	Brainstem glioma, increased pressure with posterior fossa tumors
Drugs (toxidrome)	Maternal sedatives; injected pudendal and paracervical analgesics	Overdose, salicylates, lithium, sedatives, psychotropic agents
Epilepsy	Constant minor motor seizures; electrical seizure without motor manifestations	Nonconvulsive or, absence status, postictal state; drugs given to stop seizures
Toxins (toxidrome)	Maternal sedatives or injections	Arsenic, alcohol, CO, pesticides, mushroom, lead
Hypoglycemia	Birth injury, diabetic progeny, toxemic progeny	Diabetes, "prediabetes," hypoglycemic agents
Increased intracranial pressure (metabolic or structural cause)	Anoxic brain damage, hydrocephalus, metabolic disorders (urea cycle; amino-, organic acidurias)	Toxic encephalopathy, Reye syndrome, head trauma, tumor of posterior fossa
Hepatic causes	Hepatic failure, inborn metabolic errors in bilirubin conjugation	Hepatic failure
Renal causes, hypertensive encephalopathy	Hypoplastic kidneys	Nephritis, acute (AGN) and chronic, uremia, uremic syndrome
Hypothermia, hyperthermia	Iatrogenic (head cooling)	Cold weather exposure, drowning; heat stroke
Hypercapnia	Congenital lung anomalies, bronchopulmonary dysplasia	Cystic fibrosis (hypercapnia, anoxia)
Electrolyte changes Hyper- or hyponatremia Hyper- or hypocalcemia Severe acidosis, lactic acidosis	Iatrogenic (NaHCO ₃ use), salt poisoning (formula errors) SIADH, adrenogenital syndrome, dialysis (iatrogenic) septicemia, metabolic errors, adrenogenital syndrome	Diarrhea, dehydration Lactic acidosis Infection, diabetic coma, poisoning (eg, aspirin) hyperglycemic nonketotic coma
Purpuric	Disseminated intravascular coagulation (DIC)	DIC, leukemia, thrombotic thrombocytopenic purpura

AGN, acute glomerulonephritis; SIADH, syndrome of inappropriate antidiuretic hormone.

Modified and reproduced, with permission, from Lewis J, Moe PG: The unconscious child. In Conn H, Conn R (editors): *Current Diagnosis*, 5th ed. WB Saunders, 1977.

ture done later. Tests that are helpful in obscure cases of coma include oxygen and carbon dioxide partial pressures, ammonia levels, serum and urine osmolality, porphyrins, lead levels, and urine and serum amino acids and urine organic acids.

If head trauma or increased pressure is suspected, an emergency CT scan or MRI is necessary. Bone windows on the former study or skull radiographs can be done at the same sitting. The absence of skull fracture does not rule out

coma caused by closed head trauma. Injury that results from shaking a child is one example. In a child with an open fontanelle, a real-time ultrasound may be transiently substituted for the other, more definitive imaging studies if there is good local expertise. Treatment of head injury associated with coma is discussed in detail in Chapter 11.

Rarely, an emergency EEG aids in diagnosing the cause of coma. Nonconvulsive status epilepticus or a focal finding seen

with herpes encephalitis (periodic lateralized epileptiform discharges) and focal slowing as seen with stroke or cerebritis are cases in which the EEG might be helpful. The EEG also may correlate with the stage of coma and add prognostic information.

B. General Measures

Vital signs must be monitored and maintained. Most emergency departments and intensive care units have flow sheets that provide space for repeated monitoring of the coma; a coma scale can be a useful tool for this purpose. The patient's response to vocal or painful stimuli and orientation to time, place, and situation are monitored. Posture and movements of the limbs, either spontaneously or in response to pain, are serially noted. Pupillary size, equality, and reaction to light, and movement of the eyes to the doll's-eye maneuver or ice-water caloric tests should be recorded. Intravenous fluids can be tailored to the situation, as for treatment of acidosis, shock, or hypovolemia. Nasogastric suction is initially important. The bladder should be catheterized for monitoring urine output and for urinalysis.

C. Seizure Management

An EEG should be ordered if seizures are suspected. If obvious motor seizures have occurred, treatment for status epilepticus is given with intravenous drugs (see later section on Seizure Disorders). If brainstem herniation or increased pressure is possible, intracranial monitoring may be necessary. This procedure is described in more detail in Chapter 13. Initial treatment of impending herniation includes keeping the patient's head up (15–30 degrees) and providing slight hyperventilation. The use of mannitol, diuretics, corticosteroids, and drainage of cerebrospinal fluid (CSF) are more heroic measures covered in detail in Chapter 13.

► Prognosis

About 50% of children with nontraumatic causes of coma have a good outcome. In studies of adults assessed on admission or within the first days after the onset of coma, an analysis of multiple variables was most helpful in assessing prognosis. Abnormal neuro-ophthalmologic signs (eg, the absence of pupillary reaction or of eye movement in response to the doll's-eye maneuver or ice water caloric testing and the absence of corneal responses) were unfavorable. Delay in the return of motor responses, tone, or eye opening was also unfavorable. In children, the assessment done on admission is about as predictive as one done in the succeeding days. Approximately two thirds of outcomes can be successfully predicted at an early stage on the basis of coma severity, extraocular movements, pupillary reactions, motor patterns, blood pressure, temperature, and seizure type. Other characteristics, such as the need for assisted respiration, the presence of increased intracranial pressure, and the duration of coma, are not significantly predictive. Published reports suggest that an anoxic (in contrast to traumatic, metabolic, or toxic) coma, such as that caused by near drowning, has a much grimmer outlook.

BRAIN DEATH

Many medical and law associations have endorsed the following definition of death: An individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions or (2) irreversible cessation of all functions of the entire brain, including the brainstem, is dead. A determination of death must be made in accordance with accepted medical standards. Representatives from several pediatric and neurologic associations have endorsed the Guidelines for the Determination of Brain Death in Children. The criteria in full-term infants (ie, those born at greater than 38 weeks' gestation) were applicable 1 week after the neurologic insult. Difficulties in assessing premature infants and full-term infants shortly after birth were acknowledged.

Prerequisites

In assessment of brain death, the history is important. The physician must determine proximate causes to make sure no remediable or reversible conditions are present. Examples of such causes are metabolic conditions, toxic agents, sedative-hypnotic drugs, surgically remediable conditions, hypothermia, and paralytic agents.

Physical Examination Criteria

(See also Chapter 13.) The following criteria are those established by the Task Force on Brain Death in Children:

1. **Coexistence of coma and apnea:** The patient must exhibit complete loss of consciousness, vocalization, and volitional activity.
2. **Absence of brainstem function:** As defined by the following: (a) Midposition or fully dilated pupils that do not respond to light; drugs may influence and invalidate pupillary assessment. (b) Absence of spontaneous eye movements and those induced by side-to-side passive head movements (oculocephalic reflex) and ice water instillation in the external auditory canal (ice water caloric test; intact tympanic membranes must be documented). (c) Absence of movement of bulbar musculature, including facial and oropharyngeal muscles; the corneal, gag, cough, sucking, and rooting reflexes are absent. (d) Absence of respiratory movements when the patient is off the respirator; apnea testing using standardized methods can be performed but is done after other criteria are met.
3. **Temperature and blood pressure:** The patient must not be significantly hypothermic or hypotensive for age.
4. **Tone:** Tone is flaccid, and spontaneous or induced movements are absent, excluding spinal cord events such as reflex withdrawal or spinal myoclonus.
5. **General examination findings:** The examination should remain consistent with brain death throughout the observation and testing period.

Confirmation

Apnea testing should be carried out at a partial carbon dioxide pressure level greater than 60 mm Hg, and with normal oxygenation maintained throughout the test period. This level may be reached 3–15 minutes after taking the patient off the respirator. The recommended observation period to confirm brain death (repeated examinations) is 12–24 hours (longer in infants); reversible causes must be ruled out. If an irreversible cause is documented, laboratory testing is not essential. Helpful tests to support the clinical assertion of brain death include EEG and angiography. Electroencephalographic silence on EEG should persist for 30 minutes, and drug concentrations must be insufficient to suppress EEG activity. Absence of intracerebral arterial blood flow can be confirmed by carotid angiography and cerebral radionuclide angiography. Persistence of dural sinus flow does not invalidate the diagnosis of brain death.

Cerebral evoked potentials, intracranial blood pulsations on ultrasound, and xenon-enhanced CT have not been sufficiently studied to be considered definitive in the diagnosis of brain death. In rare cases, preserved intracranial perfusion in the presence of EEG silence has been documented, and the converse has also been reported.

SEIZURE DISORDERS (EPILEPSIES)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Recurrent unprovoked seizures.
- ▶ Often, interictal electroencephalographic changes.

▶ General Considerations

A seizure is a sudden, transient disturbance of brain function, manifested by involuntary motor, sensory, autonomic, or psychic phenomena, alone or in any combination, often accompanied by alteration or loss of consciousness. Seizures can be caused by any factor that disturbs brain function. They may occur after a metabolic, traumatic, anoxic, or infectious insult to the brain (classified as remote symptomatic seizures), or spontaneously without prior known CNS insult.

Repeated seizures without evident acute symptomatic cause (eg, fever) are defined as epilepsy. Epilepsy occurs most often in individuals at the extremes of the life span. The incidence is highest in the newborn period, and higher in childhood than in later life, with another peak in the elderly. Prevalence flattens out after age 10–15 years. The chance of having a second seizure after an initial unprovoked episode in a child is about 50%. The risk of recurrence after a second unprovoked seizure is 85%. Sixty-five to 70% of children with epilepsy will achieve seizure remission with appropriate medication. Epilepsy with childhood onset remits in about 50% of children.

▶ Classification

The International League Against Epilepsy (ILAE) has established classifications of seizures and epilepsy syndromes. Seizures are classified as either as partial (with localized onset) or generalized, involving the whole brain). Seizures and epilepsy syndromes may be partial at onset and then secondarily generalize (partial seizures with secondary generalization), or generalized from the onset.

Epilepsy syndromes are defined by the nature of the seizures (ie, localized vs generalized), age of onset, EEG findings, and other clinical factors. Epilepsy is classified as symptomatic (the cause is identified or presumed and may be due to a remote CNS injury), cryptogenic (undetermined etiology, presumably symptomatic and often due to congenital CNS abnormalities), or idiopathic (often genetic). In general, symptomatic and cryptogenic epilepsy have their onset early in life. Idiopathic (genetic) epilepsy syndromes are usually age specific, occurring at any age from early infancy to adolescence, depending on the specific syndrome. The specific epilepsy syndrome is helpful in defining prognosis, with idiopathic epilepsy more likely to be controlled and eventually remit than symptomatic epilepsy.

1. Seizures & Epilepsy in Childhood

Classifying the seizure is necessary for accurate diagnosis, which will determine the nature of further evaluation and treatment and help in prognostication (Tables 23–5 and 23–6).

Table 23-5. Seizures by age at onset, pattern, and preferred treatment.

Seizure Type	Age at Onset	Clinical Manifestations	Causative Factors	EEG Pattern	Other Diagnostic Studies	Treatment and Comments
Neonatal seizures	Birth-2 wk	Often subtle; sudden limpness or tonic posturing, brief apnea, and cyanosis; odd cry; eyes rolling up; blinking or mouthing or chewing movements; nystagmus, twitchiness or clonic movements (focal, multifocal, or generalized). Some seizures are nonepileptic: decerebrate, or other posturings, release from forebrain inhibition. Poor response to drugs.	Neurologic insults (hypoxia/ischemia; intracranial hemorrhage) present more in first 3 d or after 8th day; metabolic disturbances alone between 3rd and 8th days; hypoglycemia, hypocalcemia, hyper- and hyponatremia. Drug withdrawal. Pyridoxine dependency. CNS infections. Structural abnormalities.	May correlate poorly with clinical seizures. Focal spikes or slow rhythms; multifocal discharges. Electroclinical dissociation may occur: EEG-electrical seizure without clinical manifestations and vice versa.	Lumbar puncture; CSF PCR for herpes, enterovirus; serum Ca ²⁺ , PO ₄ ³⁻ , glucose, Mg ²⁺ ; BUN, amino acid screen, blood ammonia, organic acid screen, TORCHS IgM. Ultrasound or CT/MRI for suspected intracranial hemorrhage and structural abnormalities.	Phenobarbital, IV or IM; if seizures not controlled, add phenytoin IV (loading dose 20 mg/kg each). Diazepam, 0.3 mg/kg. Recent experience with levetiracetam and topiramate. Treat underlying disorder. Seizures due to brain damage often resistant to anticonvulsants. When cause in doubt, stop protein feedings until enzyme deficiencies of urea cycle or amino acid metabolism ruled out.
West syndrome (infantile spasms)	3-18 mo	Sudden, usually but not always symmetrical adduction or flexion of limbs with flexion of head and trunk; or abduction and extensor movements (similar to Moro reflex). Occur in clusters. Associated irritability and regression in development.	Symptomatic in approximately two thirds. Acquired CNS injury in approximately one third; biochemical, infectious, degenerative in approximately one third; cryptogenic in approximately one third. With early onset, pyridoxine dependency, inherited metabolic disorders. Tuberos sclerosis in 5-10%. TORCHS, homeobox gene mutations.	Hypsarrhythmia; chaotic high-voltage slow waves or random spikes (90%); other abnormalities in 10%. Rarely normal at onset. EEG normalization early in course usually correlates with reduction of seizures; not helpful prognostically regarding mental development.	Fundoscopic and skin examination, trial of pyridoxine. Amino and organic acid screen. Chronic inflammatory disease. TORCHS screen, CT, or MRI scan should be done to (1) establish definite diagnosis, (2) aid in genetic counseling. Occasionally, surgical resection of cortical malformation useful.	ACTH gel (40 U/d to 150 U/m ²) IM once daily. Vigabatrin, especially if tuberous sclerosis. B ₆ (pyridoxine) trial. In resistant cases, zonisamide, valproic acid, topiramate, lamotrigine, ketogenic diet. Mental retardation of varying degree in 90% of cases.
Febrile convulsions	3 mo-5 y (maximum 6-18 mo); most common childhood seizure (incidence 2%)	Usually generalized seizures, < 15 min; rarely focal in onset. May lead to status epilepticus. Recurrence risk of second febrile seizure 30% (50% if under 1 y of age); recurrence risk is same after status epilepticus.	Non-neurologic febrile illness (temperature rises to 39°C or higher); Risk factors: positive family history, day care, slow development, prolonged neonatal hospitalization.	Normal interictal EEG, especially when obtained 8-10 d after seizure.	Lumbar puncture in infants or whenever suspicion of meningitis exists.	Treat underlying illness, fever. Diazepam orally, 0.3-0.5 mg/kg, divided 3 times daily during illness may be considered. Diastat rectally for prolonged (> 5 min) seizure. Prophylaxis with phenobarbital or valproic acid rarely needed.

Cryptogenic generalized epilepsies of early childhood, including Lennox-Gastaut syndrome and myoclonic-astatic epilepsy (Doose syndrome)	Any time in childhood (usually 2–7 y)	Mixed seizures dependent on particular syndrome, including tonic, myoclonic (shocklike violent contractions of one or more muscle groups, singly or irregularly repetitive); atonic (“drop attacks”) and atypical absence with episodes of absence status epilepticus.	Multiple causes, usually resulting in diffuse neuronal damage. History of West syndrome; prenatal and perinatal brain damage; viral meningoencephalitis; CNS degenerative disorders; structural cerebral abnormalities (eg, migrational abnormalities). Doose syndrome may be genetic.	Atypical slow (1–2.5 Hz) spike-wave complexes and bursts of high-voltage generalized spikes, often with diffusely slow background frequencies. Electro-decremental and fast spikes during sleep.	As dictated by index of suspicion. Consider inherited metabolic disorders, neuronal ceroid lipofuscinosis, others. Skin or conjunctival biopsy for electron microscopy, MRI scan, WBC lysosomal enzymes, nerve conduction studies if degenerative disease suspected.	Difficult to treat. Topiramate, ethosuximide, felbamate, levetiracetam, zonisamide, valproate, clonazepam, ketogenic diet, vagus nerve stimulation. Avoid phenytoin, carbamazepine, oxcarbazepine, gabapentin.
Childhood absence epilepsy	3–12 y	Lapses of consciousness or vacant stares, lasting about 3–10 s, often in clusters. Automatisms of face and hands; clonic activity in 30–45%. Often confused with complex partial seizures but no aura or postictal confusion.	Unknown. Genetic component. Abnormal thalamocortical circuitry.	3/s bilaterally synchronous, symmetrical, high-voltage spikes and waves. EEG normalization correlates closely with control of seizures.	Hyperventilation often provokes attacks. Imaging studies rarely of value.	Valproic acid, lamotrigine, or ethosuximide. In resistant cases, zonisamide, topiramate, levetiracetam, acetazolamide, ketogenic diet.
Juvenile absence epilepsy	10–15 y	Absence seizures less frequent than in childhood absence epilepsy. May have greater risk of convulsive seizures.	Unknown (idiopathic), possibly genetic.	3-Hz spike wave and atypical generalized discharges.	Not always triggered by hyperventilation.	Same as childhood absence epilepsy but may be more difficult to treat successfully.
Simple partial or focal seizures (motor/sensory/jacksonian).	Any age	Seizure may involve any part of body; may spread in fixed pattern (jacksonian march), becoming generalized. In children, epileptogenic focus often “shifts,” and epileptic manifestations may change concomitantly.	Often unknown; birth trauma, inflammatory process, vascular accidents, meningo-encephalitis, etc. If seizures are coupled with new or progressive neurologic deficits, a structural lesion (eg, brain tumor) is likely. If epilepsy partialis continua (simple partial status epilepticus), Rasmussen syndrome is likely.	EEG may be normal; focal spikes or slow waves in appropriate cortical region; sometimes diffusely abnormal or even normal. “Rolandic spikes” (centrotemporal spikes) are typical. Possibly genetic.	If seizures are difficult to control or progressive deficits occur, neuro-radiologic studies, particularly MRI brain scan, are imperative.	Carbamazepine; oxcarbazepine, phenytoin, lamotrigine, gabapentin, topiramate, levetiracetam, and zonisamide. Valproic acid useful adjunct.

(continued)

Table 23-5. Seizures by age at onset, pattern, and preferred treatment. (Continued)

Seizure Type	Age at Onset	Clinical Manifestations	Causative Factors	EEG Pattern	Other Diagnostic Studies	Treatment and Comments
Complex partial seizures (psychomotor, temporal lobe, or limbic seizures are older terms).	Any age	Aura may be a sensation of fear, epigastric discomfort, odd smell or taste (usually unpleasant), visual or auditory hallucination. Aura and seizure stereotyped for each patient. Seizure may consist of vague stare; facial, tongue, or swallowing movements and throaty sounds; or various complex automatisms. Usually brief, 15-90 s, followed by confusion. History of aura and of automatisms involving more than face and hands establish diagnosis.	As above. Temporal lobes especially sensitive to hypoxia; seizure may be a sequela of birth trauma, febrile convulsions, viral encephalitis, especially herpes. Remediable other causes are small cryptic tumors or vascular malformations. May be genetic.	As above, but occurring in temporal lobe and its connections (eg, frontotemporal, temporoparietal, temporo-occipital regions).	MRI when structural lesions suspected. PCR of CSF in acute febrile situation for herpes or enteroviral encephalitis. SPECT, PET scan, video EEG monitoring when epilepsy surgery considered.	Carbamazepine, phenytoin. More than one drug may be necessary. Valproic acid may be useful. In cases uncontrolled by drugs and where a primary epileptogenic focus is identifiable, excision of anterior third of temporal lobe. Oxcarbazepine, topiramate, lamotrigine, levetiracetam, and zonisamide.
Benign epilepsy of childhood with centrotemporal spikes (BECTS/rolandic epilepsy)	5-16 y	Partial motor or generalized seizures. Similar seizure patterns may be observed in patients with focal cortical lesions. Usually nocturnal simple partial seizures of face, tongue, hand.	Seizure history or abnormal EEG findings in relatives of 40% of affected probands and 18-20% of parents and siblings, suggesting transmission by a single autosomal dominant gene, possibly with age-dependent penetrance.	Centrotemporal spikes or sharp waves ("rolandic discharges") appearing paroxysmally against a normal EEG background.	Seldom need CT or MRI scan.	Carbamazepine or other agent. (See complex partial seizures.) Often no medication is necessary, especially if seizure is exclusively nocturnal and infrequent. Lamotrigine, topiramate, levetiracetam, zonisamide.
Juvenile myoclonic epilepsy (of Janz)	Late childhood and adolescence, peaking at 13 y	Mild myoclonic jerks of neck and shoulder flexor muscles after awakening. Intelligence usually normal. Often absence seizures, and generalized tonic-clonic seizures as well.	40% of relatives have myoclonias, especially in females; 15% have the abnormal EEG pattern with clinical attacks.	Interictal EEG shows variety of spike-and-wave sequences or 4-6-Hz multi-spike-and-wave complexes ("fast spikes").	If course is unfavorable, differentiate from progressive myoclonic syndromes by appropriate biopsies (muscles, liver, etc).	Valproic acid, lamotrigine, topiramate, levetiracetam, zonisamide.
Generalized tonic-clonic seizures (grand mal) (GTCS)	Any age	Loss of consciousness; tonic-clonic movements, often preceded by vague aura or cry. Incontinence in 15%. Postictal confusion; sleep. Often mixed with or masking other seizure patterns.	Often unknown. Genetic component. May be seen with metabolic disturbances, trauma, infection, intoxication, degenerative disorders, brain tumors.	Bilaterally synchronous, symmetrical multiple high-voltage spikes, spikes-waves (eg, 3/s). EEG often normal in those younger than age 4 y. Focal spikes may become "secondarily generalized."	As above.	Phenobarbital in infants; carbamazepine or valproic acid; phenytoin; topiramate, lamotrigine. Combinations may be necessary.

ACTH, adrenocorticotropic hormone; BUN, blood urea nitrogen; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; IM, intramuscularly; IV, intravenously; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; PET, positron emission tomography; SPECT, single photon emission tomography; TORCHS, toxoplasmosis, other infections, rubella, cytomegalovirus, herpes simplex, and syphilis; WBC, white blood cell.

Table 23-6. Benign childhood epileptic syndromes.

Syndrome	Characteristics
Benign idiopathic neonatal convulsions (BINC)	So-called “5th day fits” (97% have onset on 3rd to 7th day of life); 6% of neonatal convulsions; clonic, multifocal, usually brief; occasional status epilepticus
Benign familial neonatal convulsions (BFNC)	Autosomal dominant; onset in 2-90 d; genes, <i>KCNQ2</i> or <i>KCNQ3</i> ; clonic; 86% recover
Generalized tonic-clonic seizures (GTCS)	Age at onset, 3-11 y; may have family or personal history of febrile convulsions; 50% have 3/s spike-wave EEG; may have concurrent absence seizures
Childhood absence seizures	Incidence higher in girls than in boys; age at onset, 3-12 y (peak 6-7 y); 10-200 seizures per day; 3/s spike-wave EEG; up to 40% have GTCS
Juvenile absence seizures	Incidence higher in boys than in girls; age at onset, 10-12 y; uncommon; less frequent seizures; 3-4/s general spike-wave EEG; most have GTCS; some remit
Juvenile myoclonic epilepsy (Janz syndrome)	Age at onset, 12-18 y (average, 15 y); myoclonic jerks upper limbs, seldom fall; 4-6/s general spike-wave EEG; untreated, 90% have GTCS, mostly on waking; 20-30% have absence seizures; 25-40% are photosensitive; 10% remission rate (90% do not remit)
Benign epilepsy with centrotemporal spikes (BECTS); “rolandic epilepsy”	Age at onset 3-13 y (most at 4-10 y); 80% have brief, 2-5 min sleep seizures only; usually simple partial seizures (face, tongue, cheek, hand) sensory or motor; occasionally have GTCS; bilateral independent spikes on EEG; may not need medication if seizures infrequent; remits at puberty
Benign epilepsy of childhood with occipital paroxysms (Panayiotopoulos syndrome)	6% of children with epilepsy; age at onset 3-6 y in 80% of patients (mean age, 5 y; range, 1-12 y); autonomic symptoms and visual aura may suggest migraine

EEG, electroencephalogram.

► Clinical Findings

A. History, Symptoms, and Signs

Seizures are clinical events; the key to diagnosis is the clinical history. Not all paroxysmal events are epileptic. A description of seizure onset is important in determining if there is localized onset (partial or focal seizure). Events prior to, during, and after the seizure need to be described (although observers often recall little except generalized convulsive activity because of its dramatic appearance). An aura (actu-

ally a simple partial seizure) may precede the clinically apparent seizure and indicates focal onset. The patient may describe a feeling of fear, numbness or tingling in the fingers, or bright lights in one visual field. The specific symptoms may help define the location of seizure onset (eg, déjà vu suggests temporal lobe onset). Often, the child does not recall or cannot define the aura though the family may note alterations in behavior at the onset.

Details of the seizure’s semiology can help determine the seizure type and, if partial, the site of onset. Did the patient become extremely pale before falling? Was the patient able to respond to queries during the episode? Was the patient unconscious or was there just impaired awareness? Did the patient fall stiffly or gradually slump to the floor? Was there an injury? How long did the tonic stiffening or clonic jerking last? Where in the body did the clonic activity take place? Postictal states can be helpful in diagnosis. After complex partial and generalized convulsive seizures, postictal sleep typically occurs, but postictal changes are not seen after generalized absence seizures. Was there loss of speech after the seizure (suggesting left temporal lobe seizure) or was the patient able to respond and speak in short order? The parent may report lateralized motor activity (eg, the child’s eyes may deviate to one side or the child may experience dystonic posturing of a limb). Motor activity without impaired awareness supports the diagnosis of simple partial seizures. Impaired awareness and automatisms define the event as a complex partial seizure.

In contrast, primary generalized seizures manifest with acute loss of consciousness, usually with generalized motor activity. Tonic posturing, tonic-clonic activity or myoclonus (spasms) may occur. In children with generalized absence seizures, behavioral arrest may be associated with automatisms such as blinking, chewing, or hand movements, making it difficult to differentiate between absence seizures and partial seizures.

Description of the semiology of the event may help determine if the child experienced an epileptic seizure or a nonepileptic event mimicking or misinterpreted as an epileptic seizure. Frequently the child presenting with a presumed first seizure has experienced unrecognized seizures before the event that brings the child to medical attention. In particular, partial and absence seizures may not be recognized except in retrospect. Thus careful questioning regarding prior events is important in the child being evaluated for new onset of seizures.

B. Diagnostic Evaluation

The extent and urgency of the diagnostic evaluation is determined, in general, by the child’s age, the severity and type of seizure, whether the child is ill or injured, and the clinician’s suspicion about the underlying cause. Seizures in early infancy are often symptomatic. Therefore, the younger the child, the more extensive must be the diagnostic assessment (Table 23-7).

Table 23-7. Diagnostic evaluation in seizures.

After a first seizure	
Well infant (not neonatal)	Emergent imaging if persistent abnormal neurologic examination (especially Todd paresis), or concern about trauma (rule out nonaccidental trauma). EEG (may be deferred unless concern about nonconvulsive status epilepticus). If clinical suspicion, calcium, BUN, or others.
Well older child	Same as above.
Ill infant	Depending on presentation consider CT, Ca ²⁺ , Mg ²⁺ , CBC, BUN, glucose, electrolytes, blood culture, lumbar puncture performed acutely. Nonemergent EEG (emergent if concern about nonconvulsive status epilepticus). Possibly MRI.
Ill older child	Depending on presentation consider CT, CBC, BUN, lumbar puncture. Nonemergent EEG. Possibly MRI.
Generalized tonic-clonic seizure	Practice parameter: EEG only. Circumstances may suggest need for toxicology screen, calcium, glucose, CBC, BUN, electrolytes, lumbar puncture, and others if concern about infection (especially HSV).
For new-onset epilepsy	
Infant (< 1 y)	Imaging (MRI is preferred study); EEG. Evaluation for inherited metabolic disorder: lumbar puncture including CSF (and serum) glucose, lactate, glycine; serum and urine amino and organic acids; high-resolution chromosome analysis; other genetic testing including Rett syndrome; FISH for Angelman syndrome.
Older child	EEG; imaging (MRI). Other evaluation dependant on epilepsy syndrome. Consider CBC and AST before initiation of treatment.
Childhood absence seizure	EEG only.
Symptomatic/cryptogenic generalized epilepsy (Lennox-Gastaut and variants; myoclonic epilepsy)	EEG. Evaluation for causes of mental retardation: MRI; serum and urine amino and organic acids; high-resolution chromosome analysis; other genetic testing including Rett syndrome; FISH for Angelman syndrome, progressive myoclonic epilepsy (neuronal ceroid lipofuscinosis [NCL]. Consider lysosomal enzymes, lumbar puncture including glucose (CSF and serum) lactate, glycine, neurotransmitters, long-chain fatty acids, skin or conjunctival biopsies.
Infantile spasms (West syndrome)	Consider tuberous sclerosis complex (including Wood's lamp, renal and cardiac scans). Evaluation as for symptomatic generalized epilepsy.
Cryptogenic focal epilepsy	EEG including video-EEG monitoring if necessary for clarification of diagnosis. MRI with attention to possible focal cortical dysplasia.
Idiopathic focal epilepsy (BECTS)	EEG.

AST, aspartate aminotransferase; BECTS, benign epilepsy with centrotemporal spikes; BUN, blood urea nitrogen; CBC, complete blood count; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; FISH, florescent in-situ hybridization; HSV, herpes simplex virus.

It is generally accepted that every child with new onset of unprovoked seizures should be evaluated with an EEG, although this need not be done emergently. An EEG is very unlikely to yield clinically useful information in the child with a febrile seizure. Other diagnostic studies should be used selectively.

Metabolic abnormalities are seldom found in the well child with seizures. Unless there is a high clinical suspicion of serious medical conditions (eg, uremia, hyponatremia, hypocalcemia, etc), “routine” laboratory tests rarely yield clinically significant information. Special studies may be necessary in circumstances that suggest an acute systemic etiology for a seizure, for example, in the presence of apparent renal failure, sepsis, or substance abuse.

Emergent imaging of the brain is usually not necessary in the absence evidence of trauma or of acute abnormalities on examination. Nonurgent MRI should be performed in any child with a significant cognitive or motor impairment, or abnormalities on neurologic examination of unknown etiology, a seizure of partial (focal) onset, or an EEG that does not

represent benign partial epilepsy of childhood or primary generalized epilepsy, and should be seriously considered in infants younger than 1 year of age.

The child with a simple febrile seizure or an unprovoked generalized seizure with normal examination and normal EEG often will not require imaging. Clinically significant abnormalities rarely are found on imaging of children with new onset of idiopathic epilepsy syndromes such as benign focal epilepsy of childhood (BECTS or rolandic epilepsy) and absence epilepsy with a normal neurologic examination and diagnostic EEG. Conversely, in children with symptomatic epileptic syndromes such as infantile spasms and Lennox-Gastaut syndrome, MRI (the preferred study) will be abnormal in as many as 60–80% of patients. Evidence of localization related epilepsy is an indication for MRI of the brain. Imaging is not necessary in children with BECTS, but the yield with other focal seizures is 15–30%, with findings supportive of the diagnosis (eg, focal cortical dysplasia) and useful in defining the prognosis. Other indications for MRI scan include difficulty in controlling seizures, progressive

neurologic findings on serial examinations, worsening focal findings on the EEG, or other evidence of progressive neurologic dysfunction, even in the instance where a prior imaging scan was normal.

C. Electroencephalography

Appropriate use of EEG requires awareness of its limitations as well as its utility. The limitations of EEG even with epilepsy, for which it is most useful, are considerable. A routine EEG captures electrical activity during a very short period of time, usually 30–40 minutes. Thus it is useful primarily for defining interictal activity (except for the fortuitous recording of a clinical seizure or in the case of childhood absence epilepsy). A seizure is a clinical phenomenon; an EEG showing epileptiform activity may confirm and even extend the clinical diagnosis, but it is only occasionally diagnostic.

1. Diagnostic value—The greatest value of the EEG in convulsive disorders is to help classify seizure types and epilepsy syndromes. This can aid in prognostication and in selecting appropriate therapy (see Table 23–5). Hypomotor seizures (absence and complex partial seizures) are sometimes difficult to distinguish. The differing EEG patterns of these seizures will then prove most helpful. The presence of a mixed seizure EEG pattern in a child with clinically generalized convulsive seizures or only focal seizures may lead to identification of specific epilepsy syndromes and help the clinician select anticonvulsants effective for the seizure types identified by the EEG. Similarly, the EEG may help in diagnosing seizures in a young infant with minimal or atypical clinical manifestations; it may show hypsarrhythmia (high-amplitude spikes and slow waves with a chaotic background) in West syndrome (infantile spasms) or the 1–4/s slow spike-wave pattern of the Lennox-Gastaut syndrome. The EEG may show focal slowing that, if constant, particularly when corresponding focal seizure manifestations and abnormal neurologic findings are present, will alert the physician to the presence of a structural lesion. In this case, brain imaging may establish the cause and help determine further investigation and treatment.

The EEG need not be abnormal in a child with epilepsy. Normal EEGs are seen following a first generalized seizure in one third of children younger than age 4 years. The initial EEG is normal in about 20% of older epileptic children and in about 10% of epileptic adults. These percentages are reduced when serial tracings are obtained. Focal spikes and generalized spike-wave discharges are seen in 30% of close nonepileptic relatives of patients with epilepsy.

2. Prognostic value—A normal EEG following a first convulsion suggests (but does not guarantee) a favorable prognosis. Hypsarrhythmia or slow spike and wave patterns support the diagnosis of West syndrome and Lennox-Gastaut syndrome respectively. Both are expressions of diffuse brain dysfunction (epileptic encephalopathy) and are generally of grave significance. Central-temporal (rolandic spikes) and

occipital spike wave activity (occipital paroxysms) are the EEG correlates of idiopathic focal epilepsies of childhood.

Following successful treatment, abnormal EEGs may become normal and may aid in the decision to discontinue medications. The normalization of the EEG in childhood absence epilepsy confirms the efficacy of treatment. Normalization can also be seen in infants with West syndrome who have been successfully treated and, less commonly, in children with epileptic encephalopathies.

Electroencephalography should be repeated when the severity and frequency of seizures increase despite adequate anticonvulsant therapy, when the clinical seizure pattern changes significantly, or when progressive neurologic deficits develop. Emergence of new focal or diffuse slowing may indicate a progressive lesion or neurodegenerative disorder.

The EEG may be helpful in determining when to discontinue anticonvulsant therapy. The presence or absence of epileptiform activity on the EEG prior to withdrawal of anticonvulsants after a seizure-free period of 2 years on medications has been shown to correlate with the degree of risk of seizure recurrence.

► Differential Diagnosis

It is extremely important to be accurate in the diagnosis of epilepsy and not to make the diagnosis without ample proof. To the layperson, epilepsy often has connotations of brain damage and limitation of activity. A person so diagnosed may be excluded from certain occupations in later life. It is often very difficult to change an inaccurate diagnosis of many years' standing.

Misinterpretation of behaviors in children is the most common reason for misdiagnosis. Psychogenic seizures are much less common in children than in adults but must be considered even in the young or cognitively impaired child. The most commonly misinterpreted behaviors are inattention in school-aged children with attention disorders, stereotypies in children with autistic spectrum disorder, sleep-related movements, habit movements such as head-banging and so-called infantile masturbation (sometimes referred to as gratification movements), and gastroesophageal reflux in very young (often impaired) infants.

Some of the common nonepileptic events that mimic seizure disorder are listed in Table 23–8.

► Complications & Sequelae

A. Psychosocial Impact

Emotional disturbances, especially depression but also including anxiety, anger, and feelings of guilt and inadequacy, often occur in the patient as well as the parents of a child with epilepsy. Actual or perceived stigma as well as issues regarding “disclosure” are common. There may be an increased risk of suicide in people with epilepsy. Schools often limit activities of children with epilepsy inappropriately and stigmatize children by these limitations.

Table 23-8. Nonepileptic paroxysmal events.**Breath-holding attacks (cyanotic and pallid)**

Cyanotic: Age 6 mo–3 y. Always precipitated by trauma and fright. Cyanosis; sometimes stiffening, tonic (or jerking-clonic) convulsion (anoxic seizure). Patient may sleep following attack. Family history positive in 30%. Electroencephalogram (EEG) normal. Treatment is interpretation and reassurance.

Pallid: No external precipitant (perhaps internal pain, cramp, or fear?). Pallor may be followed by seizure (anoxic-ischemic). Vagally (heart-slowng) mediated, like adult syncope. EEG normal; may see cardiac slowing with vagal stimulation (cold cloth on face) during EEG. May be seen in children with cyanotic spells as well.

Tics (Tourette syndrome)

Simple or complex stereotyped jerks or movements, coughs, grunts, sniffs. Worse at repose or with stress. May be suppressed during physician visit. Family history often positive for tics or for obsessive compulsive disorder. Diagnosis is clinical. MRI and EEG are negative. Medications may benefit.

Parasomnias (Night terrors, sleep talking, walking, “sit-ups”)

Ages 3–10 y. Usually occur in first sleep cycle (30–90 min after going to sleep), with crying, screaming, and autonomic discharge (pupils dilated, perspiring, etc). May last only a few minutes or be more prolonged. Child goes back to sleep and has no recall of event next day. Sleep studies (polysomnogram and EEG) are normal. Sleep talking and walking and short “sit-ups” in bed are fragmentary arousals. If a spell is recorded, EEG shows arousal from deep sleep, but behavior seems wakeful. Child needs to be protected from injury and gradually settled down and taken back to bed. Medications may be considered in rare instances.

Nightmares

Nightmares or vivid dreams occur in subsequent cycles of sleep, often in early morning hours, and generally are partially recalled the next day. The bizarre and frightening behavior may sometimes be confused with complex partial seizures but occurs during REM (rapid eye movement) sleep, whereas epilepsy usually does not. In extreme or difficult cases, an all-night sleep EEG may help differentiate seizures from nightmares.

Migraine

One migraine variant can be associated with an acute confusional state. Usual migraine prodrome of spots before the eyes, dizziness, visual field defects, and then agitated confusion may be present. History of other, more typical migraine with severe headache and vomiting but without confusion may aid in diagnosis. Severe headache with vomiting as child comes out of spell may aid in distinguishing the attack from epilepsy. Other seizure manifestations are practically never seen (eg, tonic-clonic movements, falling, complete loss of consciousness). EEG in migraine is usually normal and seldom has epileptiform abnormalities often seen in patients with epilepsy. Migraine and epilepsy are sometimes linked: migraine-caused ischemia on the surface sometimes leads to later epilepsy. Are both channelopathies?

Benign nocturnal myoclonus

Common in infants and may last even up to school age. Focal or generalized jerks (the latter also called hypnic or sleep jerks) may persist from onset of sleep on and off all night. A video record for physician review can aid in diagnosis. EEG taken during jerks is normal, proving that these jerks are not epilepsy. Treatment is reassurance.

Shuddering

Shuddering or shivering attacks can occur in infancy and be a forerunner of essential tremor in later life. Often, family history is positive for tremor. Shivering may be very frequent. EEG is normal. There is no clouding or loss of consciousness.

Gastroesophageal reflux (Sandifer syndrome)

Seen more commonly in children with cerebral palsy or brain damage; reflux of acid gastric contents may cause pain that cannot be described by child. Unusual posturing (dystonic or other) of head and neck or trunk may occur, an apparent attempt to stretch the esophagus or close the opening. There is no loss of consciousness, but eye rolling, apnea, and occasional vomiting may simulate a seizure. An upper gastrointestinal series, cine of swallowing, sometimes even an EEG (normal during episode) may be necessary to distinguish from seizures.

Infantile masturbation

Rarely in infants, repetitive rocking or rubbing motions may simulate seizures. Infant may look out of contact, be poorly responsive to environment, and have autonomic expressions (eg, perspiration, dilated pupils) that may be confused with seizures. Observation by a skilled individual, sometimes even in a hospital setting, may be necessary to distinguish from seizures. EEG is normal between or during attacks. Interpretation and reassurance are the only necessary treatment.

Conversion reaction/pseudoseizures

Up to 50% of patients with pseudoseizures have epilepsy. Episodes may involve writhing, intercourse-like movements, tonic movements, bizarre jerking and thrashing, or even apparently sudden unresponsiveness. Often, there is ongoing psychological trauma. Often, but not invariably, children are developmentally delayed. Spells must often be seen or recorded on videotape in a controlled situation to distinguish from epilepsy but are sometimes so bizarre they are easily differentiated. A normal EEG during a spell is a key diagnostic feature. Sometimes, pseudoseizures can be precipitated by suggestion with injection of normal saline in a controlled situation. Combativeness is common; self-injury and incontinence, rare.

Temper tantrums and rage attacks

Sometimes confused with epilepsy. Child is often amnesic or at least claims amnesia for events during spell. Attacks are usually precipitated by frustration or anger, often directed either verbally or physically, and subside with behavior modification and isolation. EEGs are generally normal but unfortunately seldom obtained during an attack. Anterior temporal leads may help rule out temporal or lateral frontal abnormalities, the latter sometimes seen in partial complex seizures. Improvement of attacks with psychotherapy, milieu therapy, or behavioral modification helps rule out epilepsy.

Benign paroxysmal vertigo

Brief attacks of vertigo in which child often appears frightened and pale and clutches parent. Attacks last 5–30 s. Sometimes, nystagmus is identified. There is no loss of consciousness. Usually, child is well and returns to play immediately afterward. Attacks may occur in clusters, then disappear for months. Attacks are usually seen in infants and preschoolers aged 2–5 y. EEG is normal. If caloric tests can be obtained (often very difficult in this age group), abnormalities with hypofunction of one side are sometimes seen. Medications are usually not desirable or necessary.

Staring spells

Teachers often make referral for absence or petit mal seizures in children who stare or seem preoccupied at school. Helpful in the history is the lack of these spells at home (eg, before breakfast, a common time for absence seizures). Lack of other epilepsy in child or family history often is helpful. These children sometimes have difficulties with school and cognitive or learning disabilities. Child can generally be brought out of spell by a firm command. EEG is sometimes necessary to confirm that absence seizures are not occurring. A 24-hour ambulatory EEG to record attacks during child's everyday school activities is occasionally necessary.

Epilepsy with onset in childhood has an impact on adult function. Adults with early onset of epilepsy are less likely to complete high school, have less adequate employment, and are less likely to marry. Persistent epilepsy results in significant dependence; even when epilepsy is successfully treated, patients with long-standing epilepsy often do not become independent.

Rarely, psychosis may be seen in patients with epilepsy; usually in older children and adults.

B. Cognitive Delay

There remains considerable debate about the impact of seizures and epilepsy on cognition. Clearly, epileptic encephalopathy (ie, regression in cognitive ability and development associated with uncontrolled seizures) does occur, particularly in young children with catastrophic epilepsies such as West syndrome and Lennox-Gastaut syndrome. It is less clear whether persistent partial seizures have an impact on development. It is even less likely that interictal epileptiform activity contributes to cognitive impairment. However, continuous epileptiform activity in sleep is associated with Landau-Kleffner syndrome (acquired epileptic aphasia).

Pseudodementia may occur in children with poorly controlled epilepsy because their seizures interfere with their learning. Depression is a common cause of impaired cognitive function in children with epilepsy. Anticonvulsants are less likely to cause such interference at usual therapeutic doses. However, all antiepileptic drugs carry some risk for adverse impact on cognition. Phenobarbital in particular, but also topiramate, valproate, and others, may be implicated.

Mental retardation and autistic spectrum disorders may be part of the same pathologic process that causes the seizures but may occasionally be worsened when seizures are frequent, prolonged, and accompanied by hypoxia.

C. Injury and Death

Physical injuries, especially lacerations of the forehead and chin, are frequent in atonic or akinetic seizures (so-called drop attacks), necessitating protective headgear. In all other seizure disorders in childhood, injuries as a direct result of an attack are not as common although drowning, injuries related to working in kitchens, and falls from heights remain a potential risk for all children with active epilepsy. It is therefore extremely important to stress “seizure precautions,” in particular, water safety.

Sudden unexpected death with epilepsy (SUDEP) is a very rare event. The greatest fear of a parent of a child with new-onset of epilepsy is the possibility of death or brain injury. Although children with epilepsy have an increased risk of death, SUDEP is very rare (1–2:10,000 patient-years). Nearly all of the mortality in children with epilepsy is related to the underlying neurologic disorder, not the seizures. The greatest risk for SUDEP is in children with medically uncontrolled epilepsy, especially with symptomatic epilepsy (associated with identifiable CNS etiology). Normal children with epilepsy do

not have an increased risk of death compared with the general population. There is no current proven strategy to prevent SUDEP. The mechanism for SUDEP is unclear but is probably most commonly related to postictal respiratory insufficiency. Occasionally the cause is a cardiac arrhythmia induced by a seizure. Vigorous attempts to control intractable seizure disorders remain the most important approach. Identifying life-threatening disorders (eg, identifying patients with cardiac arrhythmias, especially prolonged QT syndrome) as the cause of misdiagnosed epilepsy is clearly of utmost importance.

▶ Treatment

The ideal treatment of seizures is the correction of specific causes. However, even when a biochemical disorder, a tumor, meningitis, or another specific cause is being treated, anticonvulsant drugs are often still required.

A. First Aid

Caregivers should be instructed to protect the patient against self-injury. Turning the child to the side is useful for preventing aspiration. Thrusting a spoon handle, tongue depressor or finger into the clenched mouth of a convulsing patient or trying to restrain tonic-clonic movements may cause worse injuries than a bitten tongue or bruised limb. Parents are often concerned that cyanosis will occur during generalized convulsive seizures but it is rare for clinically significant hypoxia to occur. Mouth-to-mouth resuscitation is rarely necessary and is unlikely to be effective.

For prolonged seizures (those lasting over 5 minutes), rectal diazepam gel (Diastat) may be administered to prevent the development of status epilepticus. Diastat has proven to be safe even when administered by nonmedical professionals, including teachers and day-care providers, when appropriately instructed.

B. Antiepileptic Drug (AED) Therapy

1. Drug selection—Treat with the drug appropriate to the clinical situation, as outlined in Table 23–5.

2. Treatment strategy—The child with a single seizure has a 50% chance of recurrence. Thus, it is usually not necessary to initiate AED therapy until the diagnosis of epilepsy is established, that is, there is a second seizure. The seizure type and epilepsy syndrome as well as potential side-effects will determine which drug to initiate (see Table 23–5). Start with one drug in moderate dosage and increase the dosage until seizures are controlled. If seizures are not controlled on the maximal tolerated dosage of one major AED, gradually switch to another before using two-drug therapy. Polytherapy (ie, the use of more than two medications concurrently) is rarely sufficiently effective to warrant the considerable risk of adverse side effects from the synergistic impact of multiple medications.

Dosages and usually target serum levels of commonly prescribed AEDs are listed in Table 23–9. Individual variations

Table 23-9. Guide to pediatric antiepileptic drug (AED) therapy.^a

Drug/Target Dose	Target Serum Levels	Idiosyncratic Reactions	Dose-Related Toxicity	Other Effects
Carbamazepine Adult: 1000-2000 mg/d Pediatric: 10-30 mg/kg/d	4-12 mcg/mL	Dermatologic (rash, including Stevens-Johnson syndrome), rare hematologic, hepatic	Vertigo, visual disturbance (diplopia), leukopenia	Hyponatremia in adults; leukopenia; liver induction; myoclonus in patients with general spike-wave discharges, increased bone metabolism
Ethosuximide Adult: 1000 mg/d Pediatric: 15-40 mg/kg/d	40-100 mcg/mL	Leukopenia, SLE, nephrotic syndrome, rash	Sedation, GI upset	Behavioral changes
Felbamate Adult: 2400-3600 mg/d Pediatric: 45-60 mg/kg/d; has been used up to 200 mg/kg/d	30-100 mcg/mL	Aplastic anemia (adults only?), hepatic failure, rash (rare)	Anorexia, insomnia, headache, irritability	Aplastic anemia (postpubertal?); drug interactions
Gabapentin Adult: 1800-3600 mg/d Pediatric: 30-100 mg/kg/d	4-20 mcg/mL	Rash (rare)	Somnolence, irritability, weight gain	Renal excretion, no drug interactions
Lamotrigine Adult: 300-500 mg/d Pediatric: 1-15 mg/kg/d; dose depends on concomitant medication	3-20 mcg/mL	Rash, hypersensitivity reaction	Ataxia, diplopia, GI upset, headache	Rash (probably 5%, especially in children), Stevens-Johnson syndrome
Levetiracetam Adult: 1200-2400 mg/d Pediatric: 40-100 mg/kg/d	5-50 mcg/mL	None reported to date	Somnolence, ataxia	Agitation, aggression, depression (5-10%)
Oxcarbazepine Adult: 1200-2400 mg/d Pediatric: 15-45 mg/kg/d	MHD: 10-45 mcg/mL	Rash (25% cross-reactivity with carbamazepine)	CNS effects, diplopia	Hyponatremia (3% of adults) behavior, ?weight gain
Phenobarbital Adult: 60-120 mg/d Pediatric: 2-6 mg/kg/d	15-40 mcg/mL	Rash, Stevens-Johnson syndrome, SLE	Somnolence, irritability	Possible irreversible cognitive effects, liver induction, increased bone metabolism
Phenytoin Adult: 200-600 mg/d Pediatric: 4-8 mg/kg/d; may need higher doses in infants	10-20 mcg/mL	Rash (5-10%), hematologic, hepatic, lymphadenopathy others	Cosmetic, CNS, ataxia, nystagmus	Elevated LFTs, induction; reduced vitamin D levels; ?cerebellar degeneration; increased bone metabolism
Primidone Adult: 750-2000 mg/d Pediatric: 5-20 mg/kg/d	4-12 mcg/mL	Rash	Sedation, irritability, GI upset	Similar to phenobarbital
Tiagabine Adult: 32-56 mg/d Pediatric: 0.25-1.25 mg/kg/d	5-70 mcg/mL	Psychiatric effects	CNS, tremor, weakness, gastroesophageal reflux, gait difficulty	
Topiramate Adult: 100-400 mg/d Pediatric: 5-25 mg/kg/d; can increase if side effects are tolerated	3-25 mcg/mL	Rash (rare), acute glaucoma (rare)	Somnolence, language disturbance, renal stones, anorexia, paresthesias	Language disturbance (especially with polytherapy); avoid ketogenic diet; oligohydrosis

(continued)

Table 23-9. Guide to pediatric antiepileptic drug (AED) therapy.^a (Continued)

Drug/Target Dose	Target Serum Levels	Idiosyncratic Reactions	Dose-Related Toxicity	Other Effects
Valproic acid Adult: 750–1500 mg/d Pediatric: 20–60 mg/kg/d	50–150 mcg/mL	Hepatic failure; pancreatitis	Tremor, weight gain, alopecia, sedation and cognitive changes, thrombocytopenia, prolonged bleeding time	Hepatic failure (in 1:500 children < age 2 y receiving polytherapy), elevated LFTs; GI upset with syrup; incidence of PCOS unknown, liver enzyme inhibition
Vigabatrin Adult: maximum 3000 mg/d Pediatric: 40–150 mg/kg/d	—	Visual field constriction, sedation, CNS effects	Psychiatric symptoms (rare), visual field constriction	Especially effective for infantile spasms and tuberous sclerosis
Zonisamide Adult: 200–600 mg/d Pediatric: 4–10 mg/kg/d	10–30 mcg/mL	Rash, hematologic, hepatic	Renal stones, anorexia, somnolence	Oligohidrosis in children; cross-sensitivity with sulfa drugs

^aFor newer drugs, doses, levels, and adverse effects are based on reported clinical experience and not on adequate scientific information from clinical trials in most cases. Some medications do not have FDA approval for children. The package insert for each medication lists indications, potential adverse effects, warnings, etc. Practitioners should be familiar with current published information as regards specific dosing, as well as potential adverse effects.

CNS, central nervous system; GI, gastrointestinal; LFT, liver function test; MHD, monohydroxy derivative; PCOS, polycystic ovary syndrome; SLE, systemic lupus erythematosus.

must be expected, both in tolerance and efficacy. The therapeutic range may also vary somewhat with the method used to determine levels, and published levels are not always reflective of clinical efficacy and tolerability.

3. Counseling—Advise the parents and the patient that the prolonged use of AEDs will not produce significant or permanent mental slowing (although the underlying cause of the seizures might) and that prevention of seizures for 1–2 years substantially reduces the chances of recurrence. Advise them also that AEDs are given to prevent further seizures and that they should be taken as prescribed. Changes in medications or dosages should not be made without the physician's knowledge. Unsupervised sudden withdrawal of AEDs may precipitate severe seizures or even status epilepticus. Medications must be kept where they cannot be ingested by small children or suicidal patients.

Older children should be encouraged to manage their medications on their own, but some degree of supervision by parents is often necessary to guarantee adherence to treatment regimens. Medications are invariably missed on occasions. Making up a single dose is reasonable, but making up multiple doses should be discouraged.

4. Follow-up—Regular follow-up evaluations of the patient are appropriate at intervals that depend on the degree of control, underlying cause of the seizures, and toxic properties of the AEDs used. Blood counts and liver function tests (aspartate aminotransferase; AST) are often obtained periodically in patients taking the older AEDs, such as valproate, phenytoin, and carbamazepine. Periodic neurologic reevaluation is important. Repeat EEGs are useful for confirming

seizure-freedom in children with absence epilepsy and West syndrome but otherwise are usually not useful as measures of medication efficacy.

5. Long-term management and discontinuation of treatment—AEDs should be continued until the patient is free of seizures for at least 1–2 years. In about 75% of patients, seizures may not recur. Variables such as younger age at onset, normal EEG, idiopathic etiology and ease of controlling seizures carry a favorable prognosis, whereas symptomatic etiology, later onset, continued epileptiform EEG, difficulty in establishing initial control of the seizures, polytherapy, generalized tonic-clonic or myoclonic seizures, as well as an abnormal neurologic examination are associated with a higher risk of recurrence. Most AEDs (with the exception of barbiturates and clonazepam) can be withdrawn over 6–8 weeks. There does not appear to be an advantage to slower withdrawal.

Recurrent seizures affect up to 25% of children who attempt withdrawal from medications. Recurrence of seizures is most likely within 6–12 months of discontinuing medications. Therefore, seizure safety precautions will need to be reinstated, including driving restriction. If seizures recur during or after withdrawal, AED therapy should be reinstated and maintained for at least another 1–2 years. The vast majority of children will again achieve remission of their seizures.

6. Blood levels of AEDs

A. GENERAL COMMENTS—Most AEDs take two or three times their half-life to reach the target serum levels indicated in Table 23-9. This must be considered when blood levels are

assessed after AEDs are started or dosages are changed. Individuals vary in their metabolism and their particular pharmacokinetic characteristics. These and external factors, including, for example, food intake or illness, also affect the blood level. Thus the level reached on a milligram per kilogram basis varies among patients. Experience and clinical research in the determination of AED blood levels have shown that there is some correlation between (1) drug dose and blood level, (2) blood level and therapeutic effect, and (3) blood level and some toxic effects.

B. EFFECTIVE LEVELS—The target serum levels listed in Table 23–9 are those within which seizure control without toxicity will be achieved in most patients. The level for any given individual will vary not only with metabolic makeup (including biochemical defects) but also with the nature and severity of the seizures and their underlying cause, and with other medications being taken, among other factors. Seizure control may be achieved at lower levels in some patients, and higher levels may be reached without toxicity in others. When control is achieved at a lower level, the dosage should not be increased merely to move the level into the therapeutic range. Likewise, toxic side effects will be experienced at different levels even within the therapeutic range. Lowering the dosage may relieve the problem, but sometimes the drug must be withdrawn or another added (or both). Some serious toxic effects, including allergic reactions and bone marrow or liver toxicity, are independent of dosage.

C. INTERACTION OF AEDS—Blood levels of older AEDs may be affected by other drugs but this is less often the case with the newer medications. In addition to pharmacokinetic interaction, pharmacodynamic interactions may be observed, with increased side-effects despite “therapeutic” levels. Likewise, adverse effects noted with introduction of a second medication may be due to drug interactions and not to toxicity of the newly introduced medication per se.

D. INDICATIONS FOR DETERMINATION OF BLOOD LEVELS—There is rarely an indication for obtaining “routine” blood levels of AEDs. Thus levels should be determined for specific reasons. After a drug is introduced and seizure control is achieved, it may be useful to determine the effective level for that patient. Blood level monitoring is also useful when expected control on a usual dosage has not been achieved, when seizures recur in a patient with previously well-controlled seizures, or when there is a question of adherence to recommended treatment (“noncompliance”). A low level may indicate inadequate dosage, drug interaction, or nonadherence with the prescribed regimen. A high level may indicate slowed metabolism or excretion or drug interaction.

Blood levels are most commonly obtained when signs and symptoms of toxicity are present, especially when more than one drug is being used or when the dosage of a single drug has been changed. Blood levels may be the only means of detecting intoxication in a comatose patient, very young child, or child with severe cognitive impairment. Toxic levels also occur with

drug abuse and in the presence of liver or renal disease. Blood levels are unnecessary when the patient’s seizure control is satisfactory and he or she is free of toxic signs or symptoms.

7. Side effects of AEDs—(See also Table 23–9.)

A. IDIOSYNCRATIC REACTIONS—Serious **allergic rash** usually necessitates discontinuance of a drug. The risk of significant allergic rash is probably about 5–10% with carbamazepine, lamotrigine, oxcarbazepine, and phenobarbital, phenytoin. Stevens-Johnson syndrome is a risk in any child with a cutaneous eruption due to AEDs, although the degree of this risk is unclear. Not every rash in a child receiving an AED is drug-related. If a useful AED is discontinued and the rash disappears, restarting the drug in a smaller dosage may be warranted to see if the rash recurs.

Hepatic toxicity, pancreatitis, blood dyscrasias, renal stones, and other adverse **systemic effects** have been reported with various medications. It is not clear that routine surveillance is effective in preventing these complications of treatment. Nevertheless, routine laboratory testing is often undertaken by clinicians managing patients with epilepsy.

B. TREATMENT-EMERGENT TOXICITY—Signs of **dose-related drug toxicity** such as ataxia often disappear with relatively small decreases in medication dose. The exception is phenytoin, where protein binding and so called “zero-order kinetics” can make dose adjustments difficult.

Sedation is the most common treatment-emergent side effect of AED treatment. The sedative effect of many of these drugs may be avoided by slowly titrating medication to a moderate dose over several weeks.

Familiarity with potential side effects can allow **anticipatory counseling**. Gingival hyperplasia secondary to phenytoin is best minimized through good dental hygiene but occasionally requires gingivectomy. The hypertrichosis associated with phenytoin does not regress when the drug is discontinued. The risk of weight gain with valproate and gabapentin and weight loss with topiramate, zonisamide, and felbamate should be discussed on initiation of treatment. Adequate hydration and avoiding overheating on hot days can prevent the hypothermia associated with hypohidrosis in some patients treated with topiramate and zonisamide.

C. Alternative Treatments

1. Adrenocorticotrophic hormone (ACTH) and corticosteroids

A. INDICATIONS—ACTH is indicated for treatment of West syndrome. The utility of other immunotherapy is less clear. Duration of ACTH therapy is guided by cessation of clinical seizures and normalization of the EEG. No specific recommendations can be made regarding dosing and duration of therapy, and multiple protocols have been advocated with initial dosing ranging from 20 U/d to 150 U/m². ACTH is often continued in full doses for 2 or more weeks and then,

if seizures have ceased, tapered over a variable length of time, usually several weeks. If seizures recur, the dosage is increased to the last effective level. Alternatively, vigabatrin may be tried. Some neurologists use longer durations of treatment, keeping the patient at the effective dosage of ACTH for up to 6 months before attempting withdrawal. There is no strong evidence, however, that longer courses of treatment are more beneficial.

Oral corticosteroids and intravenous immune globulin (IVIG) are occasionally used for pharmacoresistant epilepsy. However, dosing regimens and indications are not well established. Landau-Kleffner syndrome (acquired epileptic aphasia) is reported to respond to oral steroid treatment.

B. DOSAGES—For ACTH (Acthar Gel), start with 40–80 U/d or up to 150 U/m² intramuscularly in a single morning dose. Parents can be taught to give injections. For prednisone, start with 2–4 mg/kg/d orally in two or three divided doses.

C. PRECAUTIONS—Give additional potassium, guard against infections, follow for possible hypertension, and discuss the cushingoid appearance and its disappearance. Do not withdraw oral corticosteroids suddenly. Side effects in some series occur in up to 40% of patients, especially with higher dosages than those listed here (used by some authorities). With long-term use, prophylaxis against *Pneumocystis* infection may be required. Careful and frequent follow-up is necessary. Visiting nurse services can be very helpful in surveillance such as monitoring blood pressure, weight, and potential adverse effects.

2. Ketogenic diet—A diet high in fats and low in protein and carbohydrates will result in ketosis as fatty acids replace glucose as a source of energy for cellular metabolism. Such a diet has been observed to decrease and even control seizures in some children. A ketogenic diet should be recommended in children with pharmacoresistant epilepsy, particularly those with symptomatic generalized epilepsies (astatic and myoclonic seizures and absence seizures) not responsive to drug therapy. Other seizure types may also respond. Ketosis is induced by a diet high in fats and very limited in carbohydrates with sufficient protein for body maintenance and growth. The ratio of fat-derived calories to carbohydrate and protein-derived calories is usually 4:1 in young children and somewhat lower in older children. Adding medium-chain triglycerides to the diet induces ketosis more readily than does a high level of dietary fats and thus requires less carbohydrate restriction. However, medium chain triglycerides are often not well tolerated.

Recent reports suggest efficacy with the Atkins diet or a low-glycemic index diet in older and higher functioning children who will not accept the ketogenic diet. A prepared commercially available formula is available for children receiving tube feedings. The mechanism for the anticonvulsant action of the ketogenic diet is not understood. It is, however, the ketosis, not the acidosis, that raises the seizure threshold.

The ketogenic diet requires close adherence and is often difficult for families as well as the children who cannot participate in family meals or special occasions (eg, birthday parties where cake is served). Full cooperation of all family members is required, including the patient if old enough. However, when seizure control is achieved by this method, acceptance of the diet is usually excellent.

As with all therapies, potential adverse effects can occur with the ketogenic diet. These include acidosis and hypoglycemia, particularly on initiation of the diet. Thus it is prudent to admit the child for initiation of the diet after screening laboratory studies are performed to rule out underlying metabolic disorders. Renal stones can occur, and acidosis and carnitine deficiency are often seen.

3. VAGUS NERVE STIMULATOR—The vagus nerve stimulator (VNS) is a recently developed treatment for medically intractable epilepsy. A pacemaker-like device is implanted below the clavicle on the left and attached to the left vagus nerve. A cycle of stimulation of the nerve is established (typically 30 seconds of stimulation every 5 minutes), which has an anti-epileptic effect, reducing seizures by at least 50% in over half the children so treated. In addition, turning on the stimulator by the use of a magnet may interrupt a seizure (ie, an anticonvulsant effect). With current technology, the battery in the stimulator will last 7 or more years in many patients.

D. Surgery

An evaluation for epilepsy surgery is indicated for all children with medically intractable partial epilepsy. The evaluation and surgery should be performed at a center with expertise in epilepsy surgery and which has a dedicated neurosurgeon as well as a team of physicians and other providers.

The first surgery for treatment of epilepsy took place over 100 years ago, and surgery is now established as the appropriate treatment for adults and children with epilepsy refractory to medical treatment. Evaluation for possible surgical treatment should begin as soon as it is clear that the child is not responding to standard therapy and there is evidence of focal onset of seizures. Advances in technology allow for definition and removal of the epileptogenic focus even in young infants. Many centers now have access to video-EEG monitoring, PET, and similar noninvasive techniques that can be used to identify lesions such as cortical dysplasias that are amenable to resection. Freedom from seizures is reported in 80% or more of children who have been treated surgically. Some patients such as those with Rasmussen encephalitis or extensive perinatal strokes may be candidates for hemispherectomy. Increasingly, surgery is being performed on children with tuberous sclerosis after identification of the epileptogenic tuber.

Corpus callostomy remains an option for children who are experiencing uncontrolled drop attacks. A marked reduction in injuries due seizure-related falls is usually seen.

E. General Management of the Child with Epilepsy

1. Education—The initial diagnosis is often devastating for families. Some have been told that their child has a seizure disorder but the term *epilepsy* has been avoided. The patient and parents must be helped to understand the nature of epilepsy and its management, including etiology, prognosis, safety issues, and treatment options. Many children—some even as young as age 3 years—are capable of cooperating with the physician in problems of seizure control.

Excellent educational materials are available for families of a child with epilepsy, both in print and online. Two excellent web sites are <http://www.epilepsyfoundation.org> and <http://www.epilepsy.com>. Materials on epilepsy—including pamphlets, monographs, films, and videotapes suitable for children and teenagers, parents, teachers, and medical professionals—may be purchased through the Epilepsy Foundation: 8301 Professional Place, Landover, MD 20785; (800) 332-1000. The Foundation's local chapter and other community organizations are able to provide guidance and other services. Support groups exist in many cities for older children and adolescents and for their parents and others concerned.

2. Privileges and precautions in daily life—“*No seizures and no side effects*” is a motto established by the Epilepsy Foundation. The child should be encouraged to live as normal a life as possible. Children should engage in physical activities appropriate to their age and social group. After seizure control is established, swimming is generally permissible with a buddy system or adequate lifeguard coverage. Scuba diving, gymnastic activities involving heights, and high climbing should not be permitted. There are no absolute contraindications to any other sports, although some physicians recommend against contact sports. Physical training and sports are usually to be welcomed rather than restricted. Driving is discussed in the next section.

Loss of sleep should be avoided. Emotional disturbances may need to be treated. Alcohol intake should be avoided because it may precipitate seizures. Prompt attention should be given to infections. Further neurologic disturbances should be brought to the physician's attention promptly.

Although every effort should be made to control seizures, this must not interfere with a child's ability to function. Sometimes a child is better off having an occasional mild seizure than being so heavily sedated that function at home, in school, or at play is impaired. Therapy and medication adjustment often require much art and fortitude on the physician's part. Some patients with infrequent seizures, especially if only nocturnal partial seizures (eg, rolandic seizures) may not need AEDs.

3. Driving—Driving becomes important to most young people at age 15 or 16 years. Restrictions vary from state to state. In most states, a learner's permit or driver's license will be issued to an individual with epilepsy if he or she has been

under a physician's care and free of seizures for at least 1 year (although restrictions vary from state to state in the United States and in other countries), provided that the treatment or basic neurologic problems do not interfere with the ability to drive. A guide to this and other legal matters pertaining to persons with epilepsy is published by the Epilepsy Foundation, and the Foundation's legal department may be able to provide additional information.

4. Pregnancy—Contraception (especially interaction of oral contraceptive with some AEDs) childbearing, potential teratogenicity of AEDs, and the management of pregnancy should be discussed as soon as appropriate with the adolescent young woman with epilepsy. Daily use of vitamin preparations containing folic acid is recommended. For the pregnant teenager with epilepsy, management by an obstetrician conversant with the use of AEDs in pregnancy is appropriate. The patient should be cautioned against discontinuing her medications during pregnancy. The possibility of teratogenic effects of AEDs, such as facial clefts (two to three times increased risk), must be weighed against the risks from seizures. All AEDs appear to have some risk for teratogenicity, although valproate carries a particularly high risk for spinal dysraphism.

5. School intervention and seizure response plans—Most schools will work with parents to establish a seizure action plan for their child with epilepsy. A template for such a plan is available on the Epilepsy Foundation web site at <http://www.epilepsyfoundation.org/programs/upload/snactionplan.pdf>. These plans usually require the approval of the child's physician. Schools are sometimes hesitant to administer Diastat or to activate the vagal nerve stimulator. Often, information from the physician, especially that obtained from the Epilepsy Foundation web site, will relieve anxieties. School authorities should be encouraged to avoid needless restrictions and to address the emotional and educational needs of all children with disabilities, including epilepsy. The local affiliates of the Epilepsy Foundation can often provide support for families in their interactions with the school.

2. Status Epilepticus

Status epilepticus is a clinical or electrical seizure lasting at least 30 minutes, or a series of seizures without complete recovery over the same period of time. After 30 minutes of seizure activity, hypoxia and acidosis occur, with depletion of energy stores, cerebral edema, and structural damage. Eventually, high fever, hypotension, respiratory depression, and even death may occur. Status epilepticus is a medical emergency.

Status epilepticus is classified as (1) convulsive (the common tonic-clonic, or grand mal, status epilepticus) or (2) nonconvulsive (characterized by altered mental status or behavior with subtle or absent motor components). Absence status, or spike-wave stupor, and complex partial status epilepticus are examples of the nonconvulsive type (Table 23-10). An EEG may be necessary to aid in diagnosing nonconvulsive status

Table 23–10. Status epilepticus: clinical types.

Generalized seizure (common)
Convulsive (tonic, clonic, myoclonic): 90%
Nonconvulsive (absence, atypical absence, atonic): 10%
Focal (partial) seizures (rare)
Simple partial
Complex partial
Neonatal
Many clinical varieties
May show electroclinical dissociation (on EEG with no visible clinical correlate)
Other (very rare)
Continuous epileptiform activity in sleep (Landau-Kleffner syndrome and syndrome of continuous spike-wave in slow wave sleep)

because patients sometimes appear merely stuporous and lack typical convulsive movements.

► Clinical Findings

A child with status epilepticus may have a high fever with or without intracranial infection. Studies show that 25–75% of children with status epilepticus experience it as their initial seizure. Often it is a reflection of an acute or remote insult. Tumor and stroke, which are common causes of status epilepticus in adults, are uncommon causes in childhood. Fifty percent of pediatric status epilepticus is due to acute (25%) or chronic (25%) CNS disorders. Infection and metabolic disorders are common causes of status epilepticus in children. The cause is unknown in 50% of patients, but many of these patients will be febrile. In the child with known epilepsy, medication nonadherence should be considered. Status epilepticus occurs most commonly in children aged 5 years and younger (85%). The most common age is 1 year or younger (37%); the distribution is even for each year thereafter (approximately 12% per year).

► Treatment

For treatment options, see Table 23–11.

3. Febrile Seizures

Criteria for febrile seizures are (1) age 3 months to 5 years (most occur between ages 6 and 18 months), (2) fever of greater than 38.8°C, and (3) non-CNS infection. More than 90% of febrile seizures are generalized, last less than 5 minutes, and occur early in the illness causing the fever. Febrile seizures occur in 2–3% of children. Acute respiratory illnesses are most commonly associated with febrile seizures. Gastroenteritis, especially when caused by *Shigella* or *Campylobacter*, and urinary tract infections are less common causes. Roseola infantum is a rare but classic cause. One study implicated viral causes in 86% of cases. Immunizations may be a cause.

Table 23–11. Status epilepticus treatment.

- ABCs
 - Airway: maintain oral airway; intubation may be necessary.
 - Breathing: oxygen.
 - Circulation: assess pulse, blood pressure; support with IV fluids, drugs. Monitor vital signs.
- Start glucose-containing IV; evaluate serum glucose; electrolytes, HCO₃⁻, CBC, BUN, anticonvulsant levels.
- May need arterial blood gases, pH.
- Give 50% glucose if serum glucose low (1–2 mL/kg).
- Begin IV drug therapy; goal is to control status epilepticus in 20–60 min.
 - Diazepam, 0.3–0.5 mg/kg over 1–5 min (20 mg maximum); may repeat in 5–20 min; or, lorazepam, 0.05–0.2 mg/kg (less effective with repeated doses, longer-acting than diazepam).^aMidazolam: IV, 0.1–0.2 mg/kg; intranasally, 0.2 mg/kg.
 - Phenytoin, 10–20 mg/kg IV (not IM) over 5–20 min; 1000 mg maximum; monitor with blood pressure and ECG. Fosphenytoin may be given more rapidly in the same dosage; order 10–20 mg/kg of “phenytoin equivalent.”
 - Phenobarbital, 5–20 mg/kg (sometimes higher in newborns or refractory status in intubated patients).
- Correct metabolic perturbations (eg, low-sodium, acidosis).
- Other drug approaches in refractory status:
 - Repeat phenytoin, phenobarbital (10 mg/kg). Monitor blood levels. Support respiration, blood pressure as necessary.
 - ^aMidazolam drip: 1–5 mcg/kg/min (even to 20 kg/min). Valproate sodium, available as 100 mg/mL for IV use; give 15–30 mg/kg over 5–20 min.
 - Pentobarb coma. Propofol. General anesthetic.
- Consider underlying causes:
 - Structural disorders or trauma: MRI or CT scan.
 - Infection: lumbar puncture, blood culture, antibiotics.
 - Metabolic disorders: consider lactic acidosis, toxins, uremia. May need to evaluate medication levels. Toxin screen. Judicious fluid administration.
- Give maintenance drug (if diazepam only was sufficient to halt status epilepticus): phenytoin (10 mg/kg); phenobarbital (5 mg/kg); daily dose IV (or by mouth) divided every 12 h.

^aMuch supportive data.

BUN, blood urea nitrogen; CBC, complete blood count; CT, computed tomography; ECG, electrocardiogram; IM, intramuscularly; IV, intravenously; MRI, magnetic resonance imaging.

Rarely status epilepticus may occur during a febrile seizure. Febrile seizures rarely (1–3%) lead to recurrent unprovoked seizures (epilepsy) in later childhood and adult life (risk is increased two- to fivefold compared with children who do not have febrile seizures). The chance of later epilepsy is higher if the febrile seizures have complex features, such as duration longer than 15 minutes, more than one seizure in the same day, or focal features. Other adverse factors are an abnormal neurologic status preceding the seizures (eg, cerebral palsy or mental retardation), early onset of febrile seizure (before age 1 year), and a family history of epilepsy. Even with adverse factors, the risk of epilepsy after febrile seizures is still only in the range of 15–20%, although it is increased if more than one risk factor is

present. Recurrent febrile seizures occur in 30–50% of cases but in general do not worsen the long-term outlook.

Generalized epilepsy with febrile seizures plus (GEFS+) is an autosomal dominant form of epilepsy first described in 1997. The most frequently observed GEFS+ phenotype includes childhood onset of multiple febrile seizures persisting beyond the age of 6 years, and unprovoked (afebrile) seizures, including absence, myoclonic, or atonic seizures, and rarely, myoclonic-astatic epilepsy. Originally associated with a point mutation in *SCN1B*, GEFS+ is now known to have other channelopathies.

► Clinical Findings

A. Diagnostic Evaluation

The child with a febrile seizure must be evaluated for the source of the fever, in particular to exclude CNS infection. Routine studies such as serum electrolytes, glucose, calcium, skull radiographs, or brain imaging studies are seldom helpful. A white count above 20,000/ μL or an extreme left shift may correlate with bacteremia. Complete blood count and blood cultures may be appropriate. Serum sodium is often slightly low but not low enough to require treatment or to cause the seizure. Meningitis and encephalitis must be considered. Signs of meningitis (eg, bulging fontanelle, stiff neck, stupor, and irritability) may all be absent, especially in a child younger than age 18 months.

B. Lumbar Puncture

After controlling the fever and stopping an ongoing seizure, the physician must decide whether to do a lumbar puncture. The fact that the child has had a previous febrile seizure does not rule out meningitis as the cause of the current episode. The younger the child, the more important is the procedure, because physical findings are less reliable in diagnosing meningitis. Although the yield is low, a lumbar puncture should probably be done if the child is younger than age 18 months, if recovery is slow, if no other cause for the fever is found, or if close follow-up will not be possible. Occasionally observation in the emergency department for several hours obviates the need for a lumbar puncture. A negative finding does not exclude the possibility of emergence of CNS infection during the same febrile illness. Sometimes a second procedure must be done.

► Treatment & Prognosis

Prophylactic anticonvulsants are not recommended after an uncomplicated febrile seizure.

If febrile seizures are complicated or prolonged, or if medical reassurance fails to relieve family anxiety, anticonvulsant prophylaxis may be indicated and can reduce the incidence of recurrent febrile seizures. Only phenobarbital and valproic acid have demonstrated efficacy in preventing febrile seizures; phenytoin and carbamazepine have been

show to be ineffective. Newer antiepileptic drugs have not been studied. Diazepam started at the first onset of fever for the duration of the febrile illness (0.5 mg/kg two or three times per day orally or rectally) may be effective but will sedate a child. Prophylactic diazepam is also limited by the fact that a seizure is often the first evidence of fever associated with an acute illness. Diastat (rectal diazepam gel) can be used to prevent febrile status epilepticus in the child with a prolonged febrile seizure (one lasting over 5 minutes), often the greatest concern.

Phenobarbital, 3–5 mg/kg/d as a single bedtime dose, is an inexpensive long-term prophylaxis. However, significant behavioral disturbance is seen in about one third of toddlers treated with phenobarbital. Often, increasing the dosage gradually (eg, starting with 2 mg/kg/d the first week, increasing to 3 mg/kg/d the second week, and so on) decreases side effects and nonadherence. A plasma phenobarbital level in the range of 15–40 mg/mL is desirable.

Valproate sodium is potentially more hazardous. In infants, the commonly used liquid suspension has a short half-life and causes more gastrointestinal upset than do the sprinkle capsules. The dosage is 15–60 mg/kg/d in divided doses. Precautionary laboratory studies are necessary. In the infant younger than age 2 years, there is an increased risk of hepatic toxicity. Thrombocytopenia may occur, particularly in the face of an acute illness.

Measures to control fever such as sponging or tepid baths, antipyretics, and the administration of antibiotics for proven bacterial illness are reasonable but unproven to prevent recurrent febrile seizures.

Simple febrile seizures do not have any long-term adverse consequences. An EEG may be considered if the febrile seizure is complicated, focal, or otherwise unusual. In uncomplicated febrile seizures, the EEG is usually normal. Ideally the EEG should be done at least a week after the illness to avoid transient changes due to fever or the seizure itself. In older children, 3/s spike-wave discharges, suggestive of a genetic propensity to epilepsy, may occur. In the young infant, EEG findings seldom aid in assessing the chance of recurrence of febrile seizures or in long-term prognosis.

SYNCOPE & FAINTING

Fainting is transient loss of consciousness and postural tone due to cerebral ischemia or anoxia. Up to 20–50% of children (birth–20 years) will faint at some time. There may be a prodrome of dizziness, lightheadedness, nausea, so-called gray-out, sweating, and pallor. After falling, many children stiffen or have jerking motions when unconscious, a tonic-clonic, anoxic-ischemic seizure mimicking epilepsy. Watching or undergoing a venipuncture is a common precipitant of fainting, as is prolonged standing, fatigue, illness, over-

heating and sweating, dehydration, hunger, and athleticism with slow baseline pulse. The family history is positive for similar episodes in 90% of patients.

► Classification

Ninety-five percent of cases of syncope are of the vasovagal-vasodepressive or neurocardiogenic type (Table 23–12). Vasodilation, cardiac slowing, and hypotension cause transient (1–2 minutes) cerebral ischemia and result in the patient passing out. The patient awakes in 1–2 minutes, but full recovery may take an hour or more. Besides those already listed, rare precipitants include hair grooming, cough, micturition, neck stretching, and emotional stress. More ominous is cardiac syncope, which often occurs during exercise. Angina or palpitations may occur. An obstructive lesion such as aortic stenosis, cardiomyopathy, coronary disease, or dysrhythmia may be the cause. Other spells that may mimic syncope are listed in Table 23–12.

► Clinical Findings

A. Symptoms and Signs

The workup of fainting includes a personal and a detailed family history, and a physical examination with emphasis on blood pressure and cardiac and neurologic features. In the adolescent, a blood pressure drop of more than 30 mm Hg after standing for 5–10 minutes or a baseline systolic pressure of less than 80 mm Hg suggests orthostasis.

B. Laboratory Findings and Imaging

Hemoglobin should be checked if anemia is suggested by the history. Electrocardiography should be done. Consider cardiology referral, Holter monitoring, and echocardiography if cardiac causes seem likely (eg, fainting during exercise). Tilt

Table 23–12. Classification of syncope in childhood.

Vasovagal, neurocardiogenic (neurally mediated)

- Orthostatic
- Athleticism
- Pallid breath-holding
- Situational (stress, blood drawing)

Cardiac

- Obstructive
- Arrhythmia
- Prolonged QTc
- Hypercyanotic (eg, in tetralogy of Fallot)

Nonsyncope mimicker

- Migraine with confusion or stupor
- Seizure
- Hypoglycemia
- Hysteria
- Hyperventilation
- Vertigo

testing (though norms are vague) may have a role in frequent recurrent syncope to confirm a vasodepressive cause and avoid more expensive diagnostic investigations.

► Treatment

Treatment consists mostly of giving advice about the benign nature of fainting and about avoiding precipitating situations. The patient should be cautioned to lie down if prodromal symptoms occur. Good hydration and reasonable salt intake are advisable. In some cases β -blockers and, rarely, fludrocortisone may have a role.

years. Migraine headache occurs in 5% and 15%, respectively, of children at these ages. Successful treatment requires an accurate diagnosis and proper classification of headache. Based on the patient's history, a simplified initial categorization as summarized in Table 23–13 can be made. A more exhaustive classification scheme has been developed by the International Headache Society and modified for use in children. Muscle contraction tension headaches are common in older children and adolescents. They are frequently generalized over the head with a “hat band” pressure or squeezing quality. Although appetite may be diminished, nausea and vomiting are usually not present. Symptoms specifically referable to the CNS are absent. If this type of headache becomes very frequent (three or more days per week) consideration should be given to drug (analgesic) overuse or misuse, depression, or sleep disorder. The neurologic examination is normal, neuroimaging tests are generally not needed, and treatment is judicious use of ibuprofen with or without a prophylactic (daily, at bedtime) trial of amitriptyline. If simple measures are not satisfactory, biofeedback, hypnosis, other relaxation methods, psychotherapy, or a combination of these methods may be useful.

Between 65% and 75% of children referred to neurology clinics for consultation regarding headaches have migraine. Many of these children are referred after they have seen ophthalmologists for “eye strain” or otolaryngologists to rule out sinusitis. Approximately 30% of children are referred after already undergoing one or more neuroimaging tests, the vast majority of which show normal results.

HEADACHES

Headache is one of the most common complaints in pediatric neurology clinics, accounting for 25–30% of all referrals. Epidemiologic studies indicate that headache occurs in 37% of children by age 7 years and in 69% of children by age 14

► Clinical Findings

The diagnosis and proper classification of migraine depends primarily on a thorough and detailed history (Table 23–14). Migraine headaches are paroxysmal, recurrent events separated by symptom-free intervals in a child with normal growth

Table 23–13. Differential features of headaches in children.

	Muscle Contraction (Tension/Psychogenic)	Vascular (Migraine)	Traction and Inflammatory (Increased Intracranial Pressure)
Time course	Chronic, recurrent; if headache persists > 2 h and occurs > 15 days per month, diagnose “chronic daily headache”	Acute, paroxysmal, recurrent	Chronic or intermittent but increasingly frequent; progressive severity
Prodromes	No	Yes (sometimes in children)	No
Description	Diffuse, bandlike, tight; usually mild severity, 1–5 on a 1–10 scale	Intense, pulsatile, unilateral in older child (70%); usually forehead in or behind one or both eyes; 6–10 severity	Diffuse; more occipital with infratentorial mass, more frontal with supratentorial mass
Characteristic findings	Feelings of inadequacy, depression, or anxiety	Neurologic symptoms and signs usually transient	Positive neurologic signs, especially papilledema
Predisposing factors	Problems at home or school or socially (sexually)	Positive family history (75%); trivial head trauma may precipitate	None

Table 23-14. Proposed revised IHS classification of migraine.

Pediatric Migraine without Aura (Common)	Pediatric Migraine with Aura ^a (Rare)
Diagnostic criteria A. At least five attacks fulfilling B-D B. Headache attack lasting 1-48 h C. Headache has at least two of the following: 1. Bilateral location (frontal/temporal) or unilateral location 2. Pulsating quality 3. Moderate to severe intensity 4. Aggravation by routine physical activity D. During headache, at least one of the following 1. Nausea or vomiting (or both) 2. Photophobia and/or phonophobia	Diagnostic criteria A. At least two attacks fulfilling B B. At least three of the following: 1. One or more fully reversible aura symptoms indicating focal cortical and/or brainstem dysfunction 2. At least one aura developing gradually over more than 4 min or 2 or more symptoms occurring in succession 3. No auras lasting more than 60 min 4. Headache follows in less than 60 min

^aIdiopathic recurring disorder; headache usually lasts 1-48 h.

IHS, International Headache Society.

Adapted, with permission, from: Winner P et al: Classification of pediatric migraine: Proposed revisions of the IHS criteria. *Headache* 1995;35:407.

and development and whose neurologic examination is normal. Migraine affects children of all ages but is difficult to diagnose before age 4 years. The family history is positive for vascular, migrainous headaches in 75% of patients. The headaches have a pulsatile quality and are located unilaterally or bilaterally in the frontal or temporal regions, or commonly in the retro-orbital and cheek regions. The headaches last from 2 to more than 24 hours. A nonspecific prodrome of decreased or increased appetite and change in mood and temperament may precede the headache by hours or days. Headaches may be triggered by specific foods, minor head injuries, sleep deprivation, or irregular eating patterns, but more often no precipitant can be identified. An aura such as visual scotomata is uncommon in children. The headache is frequently accompanied by nausea, vomiting, photophobia, sensitivity to sound, vertigo, lightheadedness, fatigue, and mood alterations. Occasionally children may have loss of speech, hemiparesis, ataxia, confusional states, and bizarre visual distortions (so-called Alice in Wonderland syndrome). Very young children may experience recurrent or cyclical vomiting, abdominal pain, or recurrent self-limited bouts of ataxia or vertigo as the early manifestations of migraine.

Occasionally the frequency of migraine may spontaneously increase and become an almost daily occurrence, a condition referred to as transformed migraine. When this change in frequency happens, it should at least raise suspicion of medication overuse with development of rebound headache; successful treatment requires medication withdrawal for 6-12 weeks or longer.

In contrast to tension and migraine headaches, headaches caused by intracranial disorders or increased intracranial pressure rarely occur in children who are otherwise healthy and well and who have completely normal examinations.

Laboratory studies and neuroimaging tests are rarely needed if a thorough history has been taken and the neurologic examination is normal. If the progression of headache

is atypical for migraine or tension-type headaches or if the neurologic examination is abnormal, an MRI scan should be considered. When papilledema is present but the MRI is normal, a lumbar puncture may be needed to diagnose pseudotumor cerebri.

► Treatment

Successful treatment of migraine is usually achieved with the systematic use of simple analgesics such as ibuprofen. The key to successful results is to take enough early enough to do the job. As soon as possible after the headache starts, the child is given ibuprofen, 10 mg/kg, followed in 45 minutes by 5 mg/kg if needed. Additional doses of analgesics rarely provide additional benefit. The addition of 40-65 mg of caffeine, caffeine-ergotamine combinations, or 65 mg of isometheptene (Midrin) to ibuprofen may provide more reliable relief for some patients. Nausea and vomiting can be treated with metoclopramide, taken 10-20 minutes before other medications. For frequently recurring migraine, prophylaxis (twice daily or single dose at bedtime) with propranolol, amitriptyline, cyproheptadine, valproate, or topiramate should be considered; however, none of these agents has had carefully double-blinded, controlled trials in children or teens. At this time experience with using triptan and dihydroergotamine (nasal spray) in young children is limited; in teens, studies show sumatriptan and zolmitriptan nasal sprays to be effective (although after-taste can be sometimes daunting). Oral triptans and dihydroergotamine have been shown to be effective compared with placebo and are safe and inexpensive; most studies have been done in adolescents. Biofeedback, relaxation therapy, and other nonpharmacologic approaches to managing headache may be useful in children, and they provide an alternative method of treatment that avoids medication-related side effects.

SLEEP DISORDERS

This discussion focuses on neurologic features of several sleep disorders affecting children. Chapter 2 discusses behavioral considerations in the treatment of sleep disorders. Obstructive sleep apnea and sleep-disordered breathing are described in detail in Chapters 17 and 18.

1. Sleep Apnea Syndrome in Older Children (See also Chapters 17 & 18)

Children with sleep apnea frequently have hypertrophied tonsils or adenoids, causing partial airway obstruction. Sleep apnea may also be associated with facial dysmorphism, neuromuscular disorders with poor pharyngeal muscle control, and conditions causing enlargement of soft tissue in the pharynx and neck such as obesity (pickwickian syndrome). Discovery and correction of sleep apnea may have a favorable effect on persistent parasomnias.

2. Narcolepsy

Narcolepsy, a primary disorder of sleep, is characterized by chronic, excessive daytime sleeping that occurs regardless of activity or surroundings and is not relieved by increased sleep at night. Onset occurs as early as age 3 years. Of children with narcolepsy, 18% are younger than age 10, and 60% are between puberty and their late teens. Narcolepsy

usually interferes severely with normal living. Months to years after onset, there may also be cataplexy (transient partial or total loss of muscle tone, often triggered by laughter, anger, or other emotional upsurge), hypnagogic hallucinations (visual or auditory), and sensations of paralysis on falling asleep. Studies have shown that rapid eye movement (REM) sleep, with loss of muscle tone and an EEG low-amplitude mixed frequency pattern, occurs soon after sleep onset in patients with cataplexy, whereas normal subjects experience 80–100 minutes or longer of non-REM (NREM) sleep before the initial REM period.

Recent research suggests absence of a hypothalamic neuropeptide, hypocretin, causes narcolepsy and cataplexy. Spinal fluid (but not plasma) levels of hypocretin-1 (also called orexin) are diagnostic (level will be zero). The condition persists throughout life.

Modafinil is a new effective treatment for narcolepsy or excessive daytime sleepiness. Other CNS stimulants may have a role. Amphetamine mixtures (Adderall) or long-acting methylphenidate are examples. Cataplexy responds to venlafaxine, fluoxetine, or clomipramine. Rarely, acute narcolepsy/cataplexy (autoimmune) responds to IVIG.

3. Somnambulism (Sleepwalking) (See also Chapter 2)

Somnambulism and somniloquy (sleep talking) are among a group of sleep disturbances known as disorders of arousal. The onset is abrupt, usually early in the night. It is characterized by coordinated activity (eg, walking and sometimes moving objects seemingly without purpose) in a state of veiled consciousness. The episode is relatively brief and ceases spontaneously. There is poor recall of the event on waking in the morning. Somnambulism may be related to mental activities occurring in stages 3 and 4 of NREM sleep. Incidence has been estimated at only 2–3%, but up to 15% of cases are reported in children aged 6–16 years. Boys are affected more often than girls, and many have recurrent episodes. Psychopathologic features are rarely demonstrated, but a strong association (30%) between childhood migraine and somnambulism has been noted. Episodes of somnambulism may be triggered in predisposed children by stresses, including febrile illnesses. No treatment of somnambulism is required, and it is not necessary to seek psychiatric consultation.

4. Night Terrors (See also Chapter 2)

Night terrors (pavor nocturnus) are a disorder of arousal from NREM sleep. Most cases occur in children aged 3–8 years, and the disorder rarely occurs after adolescence. It is characterized by sudden (but only partial) waking, with the severely frightened child unable to be fully roused or comforted. Concomitant autonomic symptoms include rapid breathing, tachycardia, and perspiring. The child has no recall of any nightmare. Psychopathologic mechanisms are unclear, but falling asleep after watching scenes of violence

on television or hearing frightening stories may play a role. Elimination of such causes and consideration of a sleep study (polysomnogram) to rule out obstructive apnea and partial complex seizures may have a role. Most of the time, watchful waiting and reassurance of the family are sufficient.

5. Restless Legs Syndrome (See also Chapter 2)

Restless legs syndrome refers to continuous, bothersome leg movements occurring at rest and producing unpleasant paresthesias (sensory symptoms) that often interfere with restful sleep. Occasionally, anemia (low ferritin) has been noted in adults with the disorder; in these cases improvement has occurred with ferrous sulfate treatment. Avoidance of caffeine, nicotine, alcohol, and some drugs (antidepressants, neuroleptics) has helped in adult series. No pediatric medication studies exist; anecdotally, clonazepam, possibly clonidine, and gabapentin are safe options. Dopa agonists, ropinirole, and pramipexole, used in adults, are unproven in children but also likely safe. (See also Chapter 2.)

PSEUDOTUMOR CEREBRI

Pseudotumor cerebri is characterized by increased intracranial pressure in the absence of an identifiable intracranial mass or hydrocephalus. An obese teenage girl (or adult) is the typical phenotype. Symptoms are headache, tinnitus, and visual loss; signs are those of increased intracranial pressure as outlined in Table 23–15. The cause is usually unknown, but pseudotumor cerebri has been described in association with a variety of

Table 23–15. Signs of increased intracranial pressure.

Acute, Subacute

- Headache, vomiting
- Excessive rate of head growth
- Altered behavior
- Decreased level of consciousness
- Blurred or double vision
- Optic disk swelling
- Abducens nerve paresis

Chronic

- Macrocephaly
- Growth impairment
- Developmental delay
- Optic atrophy
- Visual field loss

inflammatory, metabolic, toxic, and connective tissue disorders (Table 23–16). The diagnosis of pseudotumor cerebri is one of exclusion. MRI scan of the head is needed to exclude hydrocephalus and intracranial masses. This study demonstrates ventricles of small or normal size but no other structural abnormalities. Venous thrombosis, an underrecognized cause, must be ruled out by magnetic resonance venogram or even injected venograms of cerebral sinuses. Lumbar puncture should be performed to document elevated CSF pressure. Examination of CSF reveals normal findings except for elevated pressure. In some inflammatory and connective tissue diseases, however, the CSF protein concentration may be increased.

Treatment of pseudotumor cerebri is aimed at correcting the identifiable predisposing condition. In addition, some

- Minor head injury

patients may benefit from the use of furosemide or acetazolamide to decrease the volume and pressure of CSF within the CNS. These drugs may be used in combination with repeated lumbar punctures to remove CSF. If a program of repeated CSF removal and medical management is not successful or if central vision or visual field loss is detected despite these measures, lumboperitoneal or ventriculoperitoneal shunt or optic nerve fenestration may be necessary to prevent irreparable visual loss and damage to the optic nerves.

CEREBROVASCULAR DISEASE

Pediatric arterial ischemic stroke is subdivided into two categories: neonatal arterial ischemic stroke (neonatal stroke) and childhood arterial ischemic stroke (childhood stroke). Generally, neonatal stroke is defined as arterial ischemia occurring in a patient younger than age 28 days and older than 28 weeks' gestation. Childhood stroke is any stroke occurring in a patient between 28 days and 18 years old.

1. Childhood Stroke

Childhood stroke is emerging as a serious and increasingly recognized disorder, affecting 2–8:100,000 children. There are numerous adverse outcomes, which include death in 10%, neurologic deficits or seizures in 60–85%, and recurrent strokes in 20–35%. The initial approach to the patient should recognize that childhood stroke represents a neurologic emergency, for which promptness in diagnosis can affect treatment considerations and outcome. Unfortunately, most pediatric stroke is not recognized until 24–36 hours after onset; treatment considerations matter most in the first hours after stroke onset. When possible, all children who present with stroke should be transferred to a tertiary care center that specializes in pediatric stroke management. The evaluation should include a thorough history of prior illnesses, especially those associated with varicella (even in the prior 1–2 years) influenza, parvovirus B19, HIV, minor trauma to the head and neck, and familial clotting tendencies. A systematic search for evidence of cardiac, vascular,

- Antithrombin III deficiency
- Protein C and S deficiencies
- Leukemia

Intracranial vascular anomalies

- Arteriovenous malformation
- Arterial aneurysm
- Carotid-cavernous fistula
- Transient cerebral arteriopathy

hematologic, or intracranial disorders should be undertaken (Table 23-17). Although many strokes are not associated with a single underlying systemic disorder, previously diag-

nosed congenital heart disease is the most common predisposing illness, followed by hematologic and neoplastic disorders. In many instances the origin is multifactorial, necessitating a thorough investigation even when the cause may seem obvious. As a result, the cause of childhood stroke is increasingly determined, whereas in past studies up to 30% remained idiopathic. This is particularly important when considering that recurrence risk may be as high as 35%.

► Clinical Findings

A. Symptoms and Signs

Manifestations of stroke in childhood vary according to the vascular distribution to the brain structure that is involved. Because many conditions leading to childhood stroke result in emboli, multifocal neurologic involvement is common. Children may present with acute hemiplegia similarly to stroke in adults. Symptoms of unilateral weakness, sensory disturbance, dysarthria, and dysphagia may develop over a period of minutes, but at times progressive worsening of symptoms may evolve over several hours. Bilateral hemispheric involvement may lead to a depressed level of consciousness. The patient may also demonstrate disturbances of mood and behavior and experience focal or multifocal seizures. Physical examination of the patient is aimed not only at identifying the specific deficits related to impaired cerebral blood flow, but also at seeking evidence for any predisposing disorder. Retinal hemorrhages, splinter hemorrhages in the nail beds, cardiac murmurs, rash, neurocutaneous stigmata, and signs of trauma are especially important findings.

B. Laboratory Findings and Ancillary Testing

In the acute phase, certain investigations should be carried out emergently with consideration of treatment options. This should include complete blood count, erythrocyte sedimentation rate, basic chemistries, blood urea nitrogen, creatinine, prothrombin time/partial thromboplastin time, chest radiography, electrocardiography, urine toxicology, and imaging (see following section). Subsequent studies can be carried out systemically, with particular attention paid to disorders involving the heart, blood vessels, platelets, red cells, hemoglobin, and coagulation proteins. Twenty to 50% of all pediatric stroke patients will have a prothrombotic state. Additional laboratory tests for systemic disorders such as vasculitis, mitochondrial disorders, and metabolic disorders are sometimes indicated.

Examination of CSF is indicated in patients with fever, nuchal rigidity, or obtundation when the diagnosis of intracranial infection requires exclusion. Lumbar puncture may be deferred until a neuroimaging scan (excluding brain abscess or a space-occupying lesion that might contraindicate lumbar puncture) has been obtained. In the absence of infection and frank intracranial subarachnoid hemorrhage, CSF examination is rarely helpful in defining the cause of the cerebrovascular disorder.

When seizures are prominent, an EEG may be used as an adjunct in the patient's evaluation. An EEG and sequential EEG monitoring may help in patients with severely depressed consciousness.

Electrocardiography and echocardiography are useful both in the diagnostic approach to the patient and in ongoing monitoring and management, particularly when hypotension or cardiac arrhythmias complicate the clinical course.

C. Imaging

CT and MRI scans of the brain are helpful in defining the extent of cerebral involvement with ischemia or hemorrhage. CT scans may be normal within the first 12–24 hours of an ischemic stroke and may need to be repeated. CT scan early after the onset of neurologic deficits is valuable in excluding intracranial hemorrhage. This information may be helpful in the early stages of management and in the decision to treat with anticoagulants. State-of-the-art management of stroke in the adult population omits CT scanning but proceeds directly to urgent MRI, MRA, and diffusion-weighted imaging since these modalities are sensitive to acute stroke in the initial 3 hours, when intravenous thrombolytics might be considered. Increasingly, MRI with diffusion-weighted imaging is becoming the standard of care in diagnosing pediatric stroke.

Vascular imaging is an important part of pediatric stroke management and may include CTA, MRA, or conventional angiography. In studies in which both MRA and cerebral angiography have been used, up to 80% of patients with ischemic stroke have demonstrated a vascular abnormality. Vascular imaging is helpful in diagnosing disorders such as transient cerebral arteriopathy, arteriopathy associated with sickle cell disease, moyamoya disease, arterial dissection, aneurysm, fibromuscular dysplasia, and chronic inflammatory vasculitis. Recent studies have demonstrated that patients with vascular abnormalities on MRA or conventional angiography have a much greater recurrence risk than patients with normal vessels. When vessel imaging is performed, all major vessels should be studied from the aortic arch. If evidence of fibromuscular dysplasia is present in the intracranial or extracranial vessels, renal arteriography is indicated.

► Differential Diagnosis

Patients with an acute onset of neurologic deficits must be evaluated for other disorders that can cause focal neurologic deficits. Hypoglycemia, prolonged focal seizures, a prolonged postictal paresis (Todd paralysis), acute disseminated encephalomyelitis, meningitis, encephalitis, and brain abscess should all be considered. Migraine with focal neurologic deficits may be difficult to differentiate initially from ischemic stroke. Occasionally the onset of a neurodegenerative disorder (eg, adrenoleukodystrophy or mitochondrial disorder) may begin with the abrupt onset of seizures and focal neurologic deficits. The possibility of drug abuse (particularly

cocaine) and other toxic exposures must be investigated diligently in any patient with acute mental status changes.

► Treatment

The initial management of stroke in a child is aimed at providing support for pulmonary, cardiovascular, and renal function. Patients should be administered oxygen. Typically, maintenance fluids without added glucose are indicated to augment vascular volume. Specific treatment of stroke, including blood pressure management, fluid management, and anticoagulation measures, depends partly on the underlying pathogenesis. Meningitis or varicella infections should be treated. Sickle cell patients require specialists in hematology to perform urgent exchange transfusion and most patients will require chronic transfusions after hospital discharge. Moyamoya is usually treated with surgical revascularization. In most idiopathic cases of childhood stroke without hemorrhage, anticoagulation or aspirin therapy is indicated. The Royal College of Physicians Pediatric Stroke Working Group recommends aspirin, 5 mg/kg daily, as soon as the diagnosis is made. Aspirin use appears safe and has not been associated with Reye syndrome in pediatric stroke patients. Other groups, such as the American College of Chest Physicians, recommend initial treatment with anticoagulants, such as low-molecular-weight heparin or unfractionated heparin, for 5–7 days (while excluding cardiac sources and dissection) and then switching to aspirin (3–5 mg/d). In some situations, such as arterial dissection, stuttering stroke, emboli, and consumptive coagulopathies, emergent heparinization is usually indicated. In adults with cerebrovascular thrombosis, thrombolytic agents (tissue plasminogen activator) used systemically or delivered directly to a vascular thrombotic lesion using interventional radiologic techniques has been shown to improve outcome. Although case reports exist, studies in children have not been completed. Given the time-lag to diagnosis and the lack of evidence in children, tissue plasminogen activator is currently used in less than 2% of U.S. children with stroke.

Long-term management requires intensive rehabilitation efforts and therapy aimed at improving the child's language, educational, and psychological performance. Length of treatment with various agents, such as low-molecular-weight heparin and aspirin, is still being studied and depends on the etiology. Constraint therapy may be particularly helpful in cases of hemiparesis. Multidisciplinary stroke teams are the best resource for making these decisions.

► Prognosis

The outcome of stroke in infants and children is variable. Roughly 40% may have minimal or no deficits, 30% are moderately affected, and 30% are severely affected. Underlying predisposing conditions and the vascular territory involved all play a role in dictating the outcome for an individual patient. When the stroke involves extremely large

portions of one hemisphere or large portions of both hemispheres and cerebral edema develops, the patient's level of consciousness may deteriorate rapidly, and death may occur within the first few days. Some patients may achieve almost complete recovery of neurologic function within several days if the cerebral territory is small. Seizures, either focal or generalized, may occur in 30–50% of patients at some point in the course of their cerebrovascular disorder. Recurrence is 20–35%, and is more prominent in some conditions, such as protein C deficiency, lipoprotein (a) abnormalities and arteriopathies. Chronic problems with learning, behavior, and activity are common. Long-term follow-up with a multidisciplinary stroke team is indicated.

2. Neonatal Stroke

Neonatal stroke is more common than childhood stroke, affecting 1:4000 children. Neonatal stroke has two distinct presentations: acute and delayed. Most patients with an acute presentation develop neonatal seizures during the first week of life, usually in association with a perinatal event. The seizures in acute neonatal stroke are often focal motor seizures of the contralateral arm and leg. The presentation is stereotypical because of the predilection of the stroke to occur in the middle cerebral artery. The presence of diffusion-weighted abnormalities on an MRI scan confirms an acute perinatal stroke during the first week of life. Others patients present with delayed symptoms, typically with an evolving hemiparesis at an average of 4–8 months.

Acute treatment of a neonatal stroke is usually limited to neonates with seizures. Unless an embolic source is identified, aspirin and anticoagulation are usually deferred. Management is based on supportive care, identification of comorbid conditions, and treatment of seizures. In acute neonatal stroke, treatable causes of the stroke such as infection, cardiac embolus, metabolic derangement, and dissection must be ruled out. In appropriate cases, echocardiography, MRA, and lumbar puncture are indicated. Supportive management focuses on general measures, such as normalizing glucose levels, monitoring blood pressure, and optimizing oxygenation.

Long-term management of neonatal stroke usually starts with identifying risk factors, which might include prothrombotic states, cardiac disease, drugs, and dehydration. Although prothrombotic abnormalities with the best evidence of association are factor V Leiden, protein C deficiency, and lipoprotein (a), many neurologists perform an extensive hematologic workup. Maternal risk factors such as infertility, antiphospholipid antibodies, placental infection, premature rupture of membranes, and cocaine exposure are all independently associated with neonatal stroke.

The prognosis for children who sustain neonatal strokes is generally better than for children or adults with strokes, presumably because of the plasticity of the neonatal brain. Twenty to 40% of patients who experience neonatal strokes are neurologically normal. Motor impairment affects about

40% of patient and is predominantly hemiplegic cerebral palsy. In acute presentations, MRI can be predictive of motor impairment, as descending corticospinal tract diffusion-weighted MRI signal is associated with a higher incidence of hemiplegia. Language delays, behavioral abnormalities, and cognitive deficits are seen in 20–30% of infants who experience neonatal strokes. Patients are also at an increased risk for seizures. Stroke recurs in 3% of neonates and is usually associated with a prothrombotic abnormality or an underlying illness, such as cardiac malformation or infection. Given the low incidence of recurrence, long-term management is largely rehabilitative, including constraint therapies.

CONGENITAL MALFORMATIONS OF THE NERVOUS SYSTEM

Malformations of the nervous system occur in 1–3% of living neonates and are present in 40% of infants who die. Developmental anomalies of the CNS may result from a variety of causes, including infectious, toxic, metabolic, and vascular insults that affect the fetus. The specific type of malformation that results from such insults, however, may depend more on the gestational period during which the insult occurs than on the specific cause. The period of induction, days 0–28 of gestation, is the period during which the neural plate appears and the neural tube forms and closes. Insults during this phase can result in a major absence of neural structures, such as anencephaly, or in a defect of neural tube closure, such as spina bifida, meningomyelocele, or encephalocele. Cellular proliferation and migration characterize neural development that occurs after 28 days' gestation. Lissencephaly, pachygyria, agyria, and agenesis of the corpus callosum may be the result of disruptions (genetic, toxic, infectious, or metabolic) that can occur during the period of cellular proliferation and migration.

1. Abnormalities of Neural Tube Closure

Defects of neural tube closure constitute some of the most common congenital malformations affecting the nervous system, occurring in 1:1000 live births. Spina bifida with associated meningomyelocele or meningocele is commonly found in the lumbar region. Depending on the extent and severity of the involvement of the spinal cord and peripheral nerves, lower extremity weakness, bowel and bladder dysfunction, and hip dislocation may be present. Delivery via cesarean section followed by early surgical closure of meningoceles and meningomyeloceles is usually indicated. Additional treatment is necessary to manage chronic abnormalities of the urinary tract, orthopedic abnormalities such as kyphosis and scoliosis, and paresis of the lower extremities. Hydrocephalus associated with meningomyelocele usually requires ventriculoperitoneal shunting.

A. Arnold-Chiari Malformations

Arnold-Chiari malformation type I consists of elongation and displacement of the caudal end of the brainstem into the spinal canal with protrusion of the cerebellar tonsils through

the foramen magnum. In association with this hindbrain malformation, minor to moderate abnormalities of the base of the skull often occur, including basilar impression (platybasia) and small foramen magnum. Arnold-Chiari malformation type I may remain asymptomatic for years, but in older children and young adults it may cause progressive ataxia, paresis of the lower cranial nerves, and progressive vertigo; rarely it may present with apnea or disordered breathing. Posterior cervical laminectomy may be necessary to provide relief from cervical cord compression. Ventriculoperitoneal shunting is required for hydrocephalus.

Arnold-Chiari malformation type II consists of the malformations found in Arnold-Chiari type I plus an associated lumbar meningocele. Hydrocephalus develops in approximately 90% of children with Arnold-Chiari malformation type II. These patients may also have aqueductal stenosis, hydromyelia or syringomyelia, and cortical dysplasias. The clinical manifestations of Arnold-Chiari malformation type II are most commonly caused by the associated hydrocephalus and meningocele. In addition, dysfunction of the lower cranial nerves may be present. Up to 25% of patients may have epilepsy, likely secondary to the cortical dysplasias. Higher lesions of the thoracic or upper lumbar cord are associated with mild mental retardation in about half of patients, while over 85% of patients with lower level lesions have normal intelligence quotients (IQs). Many patients will develop a latex sensitivity or allergy.

Arnold-Chiari malformation type III is characterized by occipital encephalocele, a closure defect of the rostral end of the neural tube. Hydrocephalus is extremely common with this malformation.

B. Diagnosis and Prevention

In general, the diagnosis of neural tube defects is obvious at the time of birth. The diagnosis may be strongly suspected prenatally on the basis of ultrasonographic findings and the presence of elevated α -fetoprotein in the amniotic fluid. All women of childbearing age should take prophylactic folate, which can prevent these defects and decrease the risk of recurrence by 70%.

2. Disorders of Cortical Development

Malformations of cortical development are increasingly recognized with the advent of MRI techniques and the explosion of newly identified genetic syndromes. They are subdivided into disorders based on their etiology: neuronal migration, cortical organization, abnormal proliferation or apoptosis, and unclassified. In this section we provide some common examples of these subtypes. Lissencephaly is the most common disorder of neuronal migration. Polymicrogyria and schizencephaly are examples of organizational abnormalities. Agenesis of the corpus callosum, described below, is an example of abnormal apoptosis. Finally, some abnormalities such as Dandy-Walker syndrome remained unclassified.

A. Lissencephaly

Lissencephaly is a severe malformation of the brain characterized by an extremely smooth cortical surface with minimal sulcal and gyral development. Such a smooth surface is characteristic of fetal brain at the end of the first trimester. In addition, lissencephalic brains have a primitive cytoarchitectural construction with a four-layered cerebral mantle instead of the mature six-layered mantle. Pachygyria (thick gyri) and agyria (absence of gyri) may vary in an anterior to posterior gradient, which can be suggestive of the underlying genetic defect. Patients with lissencephaly usually have severe neurodevelopmental delay, microcephaly, and seizures (including infantile spasms); however, there is significant phenotypic heterogeneity, which can depend on the specific mutation. These disorders are autosomal recessive, except for the X-linked disorders. *LIS1* mutations on chromosome 17 are associated with dysmorphic features (Miller-Dieker syndrome). Another autosomal recessive mutation, involving the *RELN* gene, results in a lissencephaly with severe hippocampal and cerebellar hypoplasia. X-linked syndromes involving mutations in *DCX* (double cortin) and *ARX* (associated with ambiguous genitalia) affect males with lissencephaly and females with band heterotopias or agenesis of the corpus callosum. Lissencephaly in association with hydrocephalus, cerebellar malformations, and muscular dystrophy may occur in Walker-Warburg syndrome (*POMT1* mutation), Fukuyama muscular dystrophy (*fukutin* mutation), and muscle-eye-brain disease (*POMGnT1* mutation). It is particularly important to identify these syndromes not only because clinical tests are available, but also because of their genetic implications. Lissencephaly may also be a component of Zellweger syndrome, a metabolic peroxisomal abnormality associated with the presence of elevated concentrations of very-long-chain fatty acids in plasma. No specific treatment for lissencephaly is available, and seizures are often difficult to control with standard medications.

MRI scans have helped to define several presumed migrational defects that are similar to but anatomically more restricted than lissencephaly. A distinctive example is bilateral perisylvian cortical dysplasia. Patients with this disorder have pseudobulbar palsy, variable cognitive deficits, facial diplegia, dysarthria, developmental delay, and epilepsy. Seizures are often difficult to control with antiepileptic drugs; some patients have benefited from corpus callosotomy. The cause of this syndrome is as yet unknown, although intrauterine cerebral ischemic injury has been postulated. Therapy is aimed at improving speech and oromotor functions and controlling seizures.

B. Agenesis of the Corpus Callosum

Agenesis of the corpus callosum, once thought to be a rare cerebral malformation, is more frequently diagnosed with modern neuroimaging techniques; occurring in 1:4000 births. The cause of this malformation is unknown. Occa-

sionally it appears to be inherited in either an autosomal dominant or recessive pattern. X-linked recessive patterns have also been described (*ARX* as mentioned earlier). Agenesis of the corpus callosum has been found in some patients with pyruvate dehydrogenase deficiency and in others with nonketotic hyperglycinemia. Most cases are sporadic. Maldevelopment of the corpus callosum may be partial or complete. No specific syndrome is typical of agenesis of the corpus callosum, although many patients have seizures, developmental delay, microcephaly, or mental retardation. Neurologic abnormalities may be related to microscopic cytoarchitectural abnormalities of the brain that occur in association with agenesis of the corpus callosum. The malformation may be found coincidentally by neuroimaging studies in otherwise normal patients and has been described as a coincidental finding at autopsy in neurologically normal individuals. A special form of agenesis of the corpus callosum occurs in Aicardi syndrome. In this X-linked disorder, agenesis of the corpus callosum is associated with other cystic intracerebral abnormalities, infantile spasms, mental retardation, lacunar chorioretinopathy, and vertebral body abnormalities.

C. Dandy-Walker Syndrome

Despite being described nearly a century ago, the exact definition of the Dandy-Walker syndrome is still debated. Classically, it is characterized by aplasia of the vermis, cystic enlargement of the fourth ventricle, rostral displacement of the tentorium, and absence or atresia of the foramina of Magendie and Luschka. Although hydrocephalus is usually not present congenitally, it develops within the first few months of life. Ninety percent of patients who develop hydrocephalus do so by age 1 year. On physical examination, a rounded protuberance or exaggeration of the cranial occiput often exists. In the absence of hydrocephalus and increased intracranial pressure, few physical findings may be present to suggest neurologic dysfunction. An ataxic syndrome occurs in fewer than 20% of patients and is usually late in appearing. Many long-term neurologic deficits result directly from hydrocephalus. Diagnosis of Dandy-Walker syndrome is confirmed by CT or MRI scanning of the head. Treatment is directed at the management of hydrocephalus.

3. Craniosynostosis

Craniosynostosis, or premature closure of cranial sutures, is usually sporadic and idiopathic. However, some patients have hereditary disorders, such as Apert syndrome and Crouzon disease, that are associated with abnormalities of the digits, extremities, and heart. Occasionally craniosynostosis may be associated with an underlying metabolic disturbance such as hyperthyroidism and hypophosphatasia. The most common form of craniosynostosis involves the sagittal suture and results in scaphocephaly, an elongation of the head in the anterior to posterior direction. Premature clo-

sure of the coronal sutures causes brachycephaly, an increase in cranial growth from left to right. Unless many or all cranial sutures close prematurely, intracranial volume will not be compromised, and the brain's growth will not be impaired. Closure of only one or a few sutures will not cause impaired brain growth or neurologic dysfunction. Management of craniosynostosis is directed at preserving normal skull shape and consists of excising the fused suture and applying material to the edge of the craniectomy to prevent reossification of the bone edges. The best cosmetic effect on the skull is achieved when surgery is performed during the first 6 months of life.

4. Hydrocephalus

Hydrocephalus is characterized by an increased volume of CSF in association with progressive ventricular dilation. In communicating hydrocephalus, CSF circulates through the ventricular system and into the subarachnoid space without obstruction. In noncommunicating hydrocephalus, an obstruction blocks the flow of CSF within the ventricular system or blocks the egress of CSF from the ventricular system into the subarachnoid space. A wide variety of disorders, such as hemorrhage, infection, tumors, and congenital malformations, may play a causal role in the development of hydrocephalus. Attention to an X-linked inheritance pattern, the presence of radialized thumbs and aqueductal stenosis, is suggestive of X-linked hydrocephalus due to the clinically testable neural cell adhesion molecule-L1 deficiency.

Clinical features of hydrocephalus include macrocephaly, an excessive rate of head growth, irritability, vomiting, loss of appetite, impaired upgaze, impaired extraocular movements, hypertonia of the lower extremities, and generalized hyperreflexia. Without treatment, optic atrophy may occur. In infants, papilledema may not be present, whereas older children with closed cranial sutures can eventually develop swelling of the optic disk. Hydrocephalus can be diagnosed on the basis of the clinical course, findings on physical examination, and CT or MRI scan.

Treatment of hydrocephalus is directed at providing an alternative outlet for CSF from the intracranial compartment. The most common method is ventriculoperitoneal shunting. Other treatment should be directed, if possible, at the underlying cause of the hydrocephalus.

ABNORMAL HEAD SIZE

Bone plates of the skull have almost no intrinsic capacity to enlarge or grow. Unlike long bones, they depend on extrinsic forces to stimulate new bone formation at the suture lines. Although gravity and traction on bone by muscle and scalp probably stimulate some growth, the single most important stimulus for head growth during infancy and childhood is brain growth. Therefore, accurate assessment of head growth is one of the most important aspects of the neurologic examination of young children. A head circumference that is two standard deviations above or below the mean for age requires investigation and explanation.

1. Plagiocephaly

An abnormal skull shape is plagiocephaly (“oblique head”). Flatness of the head (brachycephaly) is a common complaint, and nowadays is usually secondary to supine sleep position (“back to sleep”), not from occipital lambdoid suture craniosynostosis.

Repositioning the head during naps (eg, with a rolled towel under one shoulder), and “tummy time” when awake are remedies. Rarely is a skull film or consultation necessary to rule out craniosynostosis. Most positional nonsynostotic plagiocephaly resolves by age 2 years.

2. Microcephaly

A head circumference more than two standard deviations below the mean for age and sex is by definition microcephaly. More important, however, than a single head circumference measurement is the rate or pattern of head growth over time. Head circumference measurements that progressively drop to lower percentiles with increasing age are indicative of a process or condition that has impaired the brain’s capacity to grow. The causes of microcephaly are numerous. Some examples are listed in Table 23–18.

► Clinical Findings

A. Symptoms and Signs

Microcephaly may be suspected in the full-term newborn and in infants up to age 6 months whose chest circumference exceeds the head circumference (unless the child is very obese). Microcephaly may be discovered when the child is examined because of delayed developmental milestones or neurologic problems, such as seizures or spasticity. There may be a marked backward slope of the forehead (as in familial microcephaly) with narrowing of the bitemporal

Table 23–18. Causes of microcephaly.

Causes	Examples
Chromosomal	Trisomies 13, 18, 21
Malformation	Lissencephaly, schizencephaly
Syndromes	Rubenstein-Taybi, Cornelia de Lange, Angelman
Toxins	Alcohol, anticonvulsants (?), maternal phenylketonuria (PKU)
Infections (intrauterine)	TORCHS ^a
Radiation	Maternal pelvis, first and second trimester
Placental insufficiency	Toxemia, infection, small for gestational age
Familial	Autosomal dominant, autosomal recessive
Perinatal hypoxia, trauma	Birth asphyxia, injury
Infections (perinatal)	Bacterial meningitis (especially group B streptococci) Viral encephalitis (enterovirus, herpes simplex)
Metabolic	Glut-1 deficiency, PKU, maple syrup urine disease
Degenerative disease	Tay-Sachs, Krabbe

^aTORCHS is a mnemonic for toxoplasmosis, other infections, rubella, cytomegalovirus, herpes simplex, and syphilis.

diameter. The fontanelle may close earlier than expected, and sutures may be prominent.

B. Laboratory Findings

Laboratory findings vary with the cause. Abnormal dermatoglyphics may be present when the injury occurred before 19 weeks’ gestation. In the newborn, IgM antibody titers for toxoplasmosis, rubella, cytomegalovirus (CMV), herpes simplex virus, and syphilis may be assessed. Elevated specific IgM titer is indicative of congenital infection. The urine culture for CMV will be positive at birth when this virus is the cause of microcephaly. Eye, cardiac, and bone abnormalities may also be clues to congenital infection. The child’s serum and urine amino and organic acid determinations are occasionally diagnostic. The mother may require screening for phenylketonuria. Karyotyping should be considered.

C. Imaging

CT or MRI scans may aid in diagnosis and prognosis. These studies may demonstrate calcifications, malformations, or atrophic patterns that suggest specific congenital infections or genetic syndromes. Plain skull radiographs are of limited

value. Genetic counseling should be offered to the family of any infant with significant microcephaly.

► Differential Diagnosis

Congenital craniosynostosis involving multiple sutures is easily differentiated by inspection of the head, history, identification of syndromes, hereditary pattern, and sometimes signs and symptoms of increased intracranial pressure. Common forms of craniosynostosis involving sagittal, coronal, and lambdoidal sutures are associated with abnormally shaped heads but do not cause microcephaly. Recognizing treatable causes of undergrowth of the brain such as hypopituitarism or hypothyroidism and severe protein-calorie undernutrition is critical so that therapy can be initiated as early as possible.

► Treatment & Prognosis

Except for the treatable disorders already noted, treatment is usually supportive and directed at the multiple neurologic and sensory deficits, endocrine disturbances (eg, diabetes insipidus), and seizures. Many, but not all, children with microcephaly are developmentally delayed. The notable exceptions are found in cases of hypopituitarism (rare) or familial autosomal dominant microcephaly.

Wang D et al: Glut-1 deficiency syndrome: Clinical, genetic, and therapeutic aspects. *Ann Neurol* 2005;57:111 [PMID: 15622525].

3. Macrocephaly

A head circumference more than two standard deviations above the mean for age and sex denotes macrocephaly. Rapid head growth rate suggests increased intracranial pressure, most likely caused by hydrocephalus, extra-axial fluid collections, or neoplasms. Macrocephaly with normal head growth

Table 23–19. Causes of macrocephaly.

Causes	Examples
Pseudomacrocephaly, pseudo-hydrocephalus, catch-up growth crossing percentiles	Growing premature infant; recovery from malnutrition, congenital heart disease, postsurgical correction
Increased intracranial pressure	
With dilated ventricles	Progressive hydrocephalus, subdural effusion
With other mass	Arachnoid cyst, porencephalic cyst, brain tumor
Benign familial macrocephaly (idiopathic external hydrocephalus)	External hydrocephalus, benign enlargement of the subarachnoid spaces (synonyms)
Megalencephaly (large brain)	
With neurocutaneous disorder	Neurofibromatosis, tuberous sclerosis, etc
With gigantism	Sotos syndrome
With dwarfism	Achondroplasia
Metabolic	Mucopolysaccharidoses
Lysosomal	Metachromatic leukodystrophy (late)
Other leukodystrophy	Canavan spongy degeneration
Thickened skull	Fibrous dysplasia (bone), hemolytic anemia (marrow), sickle cell anemia, thalassemia

rate suggests familial macrocephaly or true megalencephaly, as might occur in neurofibromatosis. Other causes and examples of macrocephaly are listed in Table 23–19.

► Clinical Findings

Clinical and laboratory findings vary with the underlying process. In infants, transillumination of the skull with an intensely bright light in a completely darkened room may disclose subdural effusions, hydrocephalus, hydranencephaly, and cystic defects. A surgically or medically treatable condition must be ruled out. Thus the first decision is whether and when to perform an imaging study.

A. Imaging Study Deferred

1. Catch-up growth—Catch-up growth may be evident, as it is in the thriving, neurologically intact premature infant whose rapid head enlargement is most marked in the first weeks of life, or the infant in the early phase of recovery from deprivation dwarfism. As the expected normal size is reached, head growth slows and then resumes a normal growth pattern. If the fontanelle is open, cranial ultrasonography can assess ventricular size and diagnose or exclude hydrocephalus.

2. Familial macrocephaly—This condition may exist when another family member has an unusually large head with no

signs or symptoms referable to such disorders as neurocutaneous dysplasias (especially neurofibromatosis) or cerebral gigantism (Sotos syndrome), or when there are no significant mental or neurologic abnormalities in the child.

B. Imaging Study

CT or MRI scans (or ultrasonography, if the anterior fontanelle is open) are used to define any structural cause of macrocephaly and to identify an operable disorder. Even when the condition is untreatable (or does not require treatment), the information gained may permit more accurate diagnosis and prognosis, guide management and genetic counseling, and serve as a basis for comparison should future abnormal cranial growth or neurologic changes necessitate a repeat study. An imaging study is necessary if signs or symptoms of increased intracranial pressure are present (see Table 23–15).

NEUROCUTANEOUS DYSPLASIAS

Neurocutaneous dysplasias are diseases of the neuroectoderm and sometimes involve endoderm and mesoderm. Birthmarks—and skin growths appearing later—often suggest a need to look for brain, spinal cord, and eye disease. Hamartomas (histologically normal tissue growing abnormally rapidly or in aberrant sites) are common. The most common dysplasias are dominantly inherited. Benign and even malignant tumors may develop.

1. Neurofibromatosis (von Recklinghausen Disease)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ More than six café-au-lait spots 5 mm in greatest diameter in prepubertal individuals and over 15 mm in greatest diameter in postpubertal individuals.

- ▶ Two or more neurofibromas of any type or one plexiform neurofibroma.
- ▶ Freckling in the axillary or inguinal regions.
- ▶ Optic glioma.
- ▶ Two or more Lisch nodules (iris hamartomas).
- ▶ Distinctive bony lesions, such as sphenoid dysplasia or thinning of long bone with or without pseudarthroses.
- ▶ First-degree relative (parent, sibling, offspring) with neurofibromatosis type 1 by above criteria.

▶ General Considerations

Neurofibromatosis is a multisystem disorder with a prevalence of 1:3000–4000. Fifty percent of cases are due to new mutations in the *NF1* gene. Forty percent of patients will develop medical complications of the disorder in their lifetime.

▶ Clinical Findings

A. Symptoms and Signs

The most common presenting symptoms are cognitive or psychomotor problems; 40% of patients have learning disabilities, and mental retardation occurs in 8%. The family history is important in identifying dominant gene manifestations in parents. Parents should be examined in detail. The history should focus on lumps or masses causing disfigurement, functional problems, or pain. Café-au-lait spots are seen in most affected children by age 1 year. The typical skin lesion is 10–30 mm, ovoid, and smooth-bordered. Discrete tumors are more common, are well demarcated, and can occur at any age. Plexiform neurofibromas are more diffuse and can invade normal tissue. They are congenital and are frequently detected during periods of rapid growth. If the face or a limb is involved, there may be associated hypertrophy or overgrowth.

The clinician should ask about visual problems. Strabismus or amblyopia dictates a search for optic glioma, a common tumor in neurofibromatosis. Any progressive neurologic deficit calls for studies to rule out tumor of the spinal cord or CNS. Tumors of cranial nerve VIII virtually never occur in neurofibromatosis type 1 but are the rule in neurofibromatosis type 2, a rare autosomal dominant disease.

The physician should check blood pressure and examine the spine for scoliosis and the limbs for pseudarthroses. Head measurement often shows macrocephaly. Hearing and vision need to be assessed. The eye examination should include a check for proptosis and iris Lisch nodules. The optic disk should be examined for atrophy or papilledema. Short stature and precocious puberty are occasional findings. An examination for neurologic manifestations of tumors (eg, asymmetrical reflexes or spasticity) is important.

B. Laboratory Findings

Laboratory tests are not likely to be of value in asymptomatic patients. Selected patients require brain MRI with special cuts through the optic nerves to rule out optic glioma. Hypertension necessitates evaluation of renal arteries for dysplasia and stenosis. Cognitive and school achievement testing may be indicated. Scoliosis or limb abnormalities should be studied by appropriate roentgenograms such as an MRI scan of the spinal cord and roots.

► Differential Diagnosis

Patients with McCune-Albright syndrome often have larger café-au-lait spots with precocious puberty, polyostotic fibrous dysplasia, and hyperfunctioning endocrinopathies. One or two café-au-lait spots are often seen in normal children. A large solitary café-au-lait spot is usually innocent, not neurofibromatosis type 1.

► Complications

Seizures, deafness, short stature, early puberty, and hypertension occur in less than 25% of patients with neurofibromatosis. Optic glioma occurs in about 15%. Although the tumor may be apparent at an early age, it rarely causes functional problems and is usually nonprogressive. Patients have a slightly increased risk (5% life risk) for various malignancies. Other tumors may be benign but may cause significant morbidity and mortality because of their size and location in a vital or enclosed space.

► Treatment

Genetic counseling is important. The risk to siblings is up to 50%. The disease may be progressive, with serious complications occasionally seen. Patients sometimes worsen during puberty or pregnancy. Genetic screening of family members is required. Annual or semiannual visits are important in the early detection of school problems or bony or neurologic abnormalities. The following parameters should be recorded at each annual visit:

1. Child's development and progress at school
2. Visual symptoms, visual acuity, and funduscopy until age 7 years (to detect optic pathway glioma, glaucoma)
3. Head circumference (rapid increase might indicate tumor or hydrocephalus)
4. Height (to detect abnormal pubertal development)
5. Weight (to detect abnormal pubertal development)
6. Pubertal development (to detect delayed or precocious puberty due to pituitary or hypothalamic lesion)
7. Blood pressure (to detect renal artery stenosis or pheochromocytoma)

8. Cardiovascular examination (for congenital heart disease, especially pulmonary stenosis)
9. Evaluation of spine (for scoliosis and underlying plexiform neurofibromas)
10. Evaluation of the skin (for cutaneous, subcutaneous, and plexiform neurofibromas)
11. Examination of other systems, depending on specific symptoms

Multidisciplinary clinics at medical centers around the United States are excellent resources. Prenatal diagnosis is probably on the horizon, but the variability of manifestations (trivial to severe) will make therapeutic abortion an unlikely option. Chromosomal linkage studies are under way (chromosome 17q11.2). Information for lay people and physicians is available from the National Neurofibromatosis Foundation (<http://www.nf.org>).

2. Tuberous Sclerosis (Bourneville Disease)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Facial angiofibromas or subungual fibromas.
- Often hypomelanotic macules, gingival fibromas.
- Retinal hamartomas.

- ▶ Cortical tubers or subependymal glial nodules, often calcified.
- ▶ Renal angiomyolipomas.

▶ General Considerations

Tuberous sclerosis is a dominantly inherited disease. Almost all patients have deletions on chromosome 9 (*TSC1* gene) or 16 (*TSC2* gene). The gene products hamartin and tuberlin have tumor-suppressing effects. A triad of seizures, mental retardation, and adenoma sebaceum occurs in only 33% of patients. The disease was earlier thought to have a high rate of mutation. As a result of more sophisticated techniques such as MRI, parents formerly thought not to harbor the gene are now being diagnosed as asymptomatic carriers.

Like neurofibromatosis, tuberous sclerosis is associated with a wide variety of symptoms. The patient may be asymptomatic except for skin findings or may be devastated by severe infantile spasms in early infancy, by continuing epilepsy, and by mental retardation. Seizures in early infancy correlate with later mental retardation.

▶ Clinical Findings

A. Symptoms and Signs

1. Dermatologic features—Skin findings bring most patients to the physician's attention. Ninety-six percent of patients have one or more hypomelanotic macules, facial angiofibromas, ungual fibromas, or shagreen patches. Adenoma sebaceum, the facial skin hamartomas, may first appear in early childhood, often on the cheek, chin, and dry sites of the skin where acne is not usually seen. They often have a reddish hue. The off-white hypomelanotic macules are seen more easily in tanned or dark-skinned individuals than in those with lighter skin. The macules often are oval or "ash leaf" in shape and follow dermatomes. A Wood's lamp (ultraviolet light) shows the macules more clearly, a great help in the light-skinned patient. In the scalp, poliosis (whitened hair) is the equivalent. In infancy, the presence of these macules accompanied by seizures is virtually diagnostic of the disease. Subungual or periungual fibromas are more common in the toes. Leathery, orange peel-like shagreen patches support the diagnosis. Café-au-lait spots are occasionally seen. Fibrous or raised plaques may resemble coalescent angiofibromas.

2. Neurologic features—Seizures are the most common presenting symptom. Five percent of patients with infantile spasms (a serious epileptic syndrome) have tuberous sclerosis. Thus any patient presenting with infantile spasms (and the parents as well) should be evaluated for this disorder. An imaging study of the CNS, such as a CT scan, may show calcified subependymal nodules; MRI may show

dysmyelinating white matter lesions or cortical tubers. Virtually any kind of symptomatic seizure (eg, atypical absence, partial complex, and generalized tonic-clonic seizures) may occur.

3. Mental retardation—Mental retardation occurs in up to 50% of patients referred to tertiary care centers; the incidence is probably much lower in randomly selected patients. Patients with seizures are more prone to mental retardation or learning disabilities.

4. Renal lesions—Renal cysts or angiomyolipomas may be asymptomatic. Hematuria or obstruction of urine flow sometimes occurs; the latter requires operation. Ultrasonography of the kidneys should be done in any patient suspected of tuberous sclerosis, both to aid in diagnosis if lesions are found and to rule out renal obstructive disease.

5. Cardiopulmonary involvement—Rarely cystic lung disease may occur. Rhabdomyomas of the heart may be asymptomatic but can lead to outflow obstruction, conduction difficulties, and death. Chest radiographs and echocardiograms can detect these rare manifestations. Cardiac rhabdomyoma may be detected on prenatal ultra-sound examination.

6. Eye involvement—Retinal hamartomas are often near the disk.

7. Skeletal involvement—Findings sometimes helpful in diagnosis are cystic rarefactions of the bones of the fingers or toes.

B. Diagnostic Studies

Plain radiographs may detect areas of thickening within the skull, spine, and pelvis, and cystic lesions in the hands and feet. Chest radiographs may show lung honeycombing. More helpful is CT scanning, which can show the virtually pathognomonic subependymal nodular calcifications and sometimes widened gyri or tubers and brain tumors. Contrast material may show the often classically located tumors near the interventricular foramen. Hypomyelinated lesions may be seen with MRI. Electroencephalography is helpful in delineating the presence of seizure discharges.

▶ Treatment

Therapy is as indicated by underlying disease (eg, seizures and tumors of the brain, kidney, and heart). Skin lesions on the face may need dermabrasion or laser treatment. Genetic counseling emphasizes identification of the carrier. The risk of appearance in offspring if either parent is a carrier is 50%. The patient should be seen annually for counseling and reexamination in childhood. Identification of the chromosomes (9,16; *TSC1* and *TSC2* genes) may in the future make intrauterine diagnosis possible.

3. Encephalofacial Angiomatosis (Sturge-Weber Disease)

Sturge-Weber disease consists of a facial port wine nevus involving the upper part of the face (in the first division of cranial nerve V), a venous angioma of the meninges in the occipitoparietal regions, and choroidal angioma. The syndrome has been described without the facial nevus (rare, type III, exclusive leptomeningeal angioma).

► Clinical Findings

In infancy, the eye may show congenital glaucoma, or buphthalmos, with a cloudy, enlarged cornea. In early stages, the facial nevus may be the only indication, with no findings in the brain even on radiologic studies. The characteristic cortical atrophy, calcifications of the cortex, and meningeal angiomatosis may appear with time, solidifying the diagnosis.

Physical examination may show focal seizures or hemiparesis on the side opposite the cerebral lesion. The facial nevus may be much more extensive than the first division of cranial nerve V; it can involve the lower face, mouth, lip, neck, and even torso. Hemiatrophy of the opposite limbs may occur. Mental handicap may result from poorly controlled seizures. Late-appearing glaucoma and rarely CNS hemorrhage occur.

Radiologic studies may show calcification of the cortex; CT scanning may show this much earlier than plain radiographic studies. MRI often shows underlying brain involvement.

The EEG often shows depression of voltage over the involved area in early stages; later, epileptiform abnormalities may be present focally.

► Treatment

Sturge-Weber disease is sporadic. Early control of seizures is important to avoid consequent developmental setback. If seizures do not occur, normal development can be anticipated. Careful examination of the newborn, with ophthalmologic assessment to detect early glaucoma, is indicated.

Rarely, surgical removal of the involved meninges and the involved portion of the brain may be indicated, even hemispherectomy.

4. von Hippel-Lindau Disease (Retinocerebellar Angiomatosis)

von Hippel-Lindau disease is a rare, dominantly inherited condition with retinal and cerebellar hemangioblastomas; cysts of the kidneys, pancreas, and epididymis; and sometimes renal cancers. The patient may present with ataxia, slurred speech, and nystagmus due to a hemangioblastoma of the cerebellum or with a medullary spinal cord cystic hemangioblastoma. Retinal detachment may occur from hemorrhage or exudate in the retinal vascular malformation. Rarely a pancreatic cyst or renal tumor may be the presenting symptom.

The diagnostic criteria for the disease are a retinal or cerebellar hemangioblastoma with or without a positive family history, intra-abdominal cyst, or renal cancer.

CENTRAL NERVOUS SYSTEM DEGENERATIVE DISORDERS OF INFANCY & CHILDHOOD

The CNS degenerative disorders of infancy and childhood are characterized by arrest of psychomotor development and loss, usually progressive but at variable rates, of mental and

motor functioning and often of vision as well (Tables 23–20 and 23–21). Seizures are common in some disorders. Symptoms and signs vary with age at onset and primary sites of involvement of specific types.

These disorders are fortunately rare. An early clinical pattern of decline often follows normal early development. Referral for sophisticated biochemical testing is usually necessary before a definitive diagnosis can be made. Recently, many physicians have been involved in experimental bone marrow transplantation and enzyme replacement therapy for some of these disorders, with variable results. Patients with metachromatic leukodystrophy, Krabbe disease, and adrenoleukodystrophy are candidates for experimental bone marrow transplantation, but results are uncertain. Treatment of some lysosomal storage diseases, such as Gaucher disease, with experimental enzyme replacement therapy has shown promising results.

ATAXIAS OF CHILDHOOD

1. Acute Cerebellar Ataxia

Acute cerebellar ataxia occurs most commonly in children aged 2–6 years. The onset is abrupt, and the evolution of symptoms is rapid. In about 50% of patients, a prodromal illness occurs with fever, respiratory or gastrointestinal symptoms, or an exanthem within 3 weeks of onset. Associated viral infections include varicella, rubella, mumps, rubella, echovirus infections, poliomyelitis, infectious mononucleosis, and influenza. Bacterial infections such as scarlet fever and salmonellosis have also been incriminated.

▶ Clinical Findings

A. Symptoms and Signs

Ataxia of the trunk and extremities may be so severe that the child exhibits a staggering, reeling gait and inability to sit without support or to reach for objects; or he or she may show only mild unsteadiness. Hypotonia, tremor of the extremities, and horizontal nystagmus may be present. Speech may be slurred. The child is frequently irritable, and vomiting may occur.

There are no clinical signs of increased intracranial pressure. Sensory and reflex testing usually shows no abnormalities.

B. Laboratory Findings and Imaging

CSF pressure and protein and glucose levels are normal; slight lymphocytosis (≤ 30 cells/mL) may be present. Attempts should be made to identify the etiologic viral agent. CT scans are normal; MRI may show cerebellar postinfectious demyelinating lesions. The EEG may be normal or may show nonspecific slowing.

Table 23-20. Central nervous system degenerative disorders of infancy.

Disease	Enzyme Defect and Genetics	Onset	Early Manifestations	Vision and Hearing	Somatic Findings
WHITE MATTER					
Globoid (Krabbe) leukodystrophy	Recessive galactocerebroside β -galactosidase deficiency. Chromosome 14q21-14q31.	Infantile form first 6 mo. Late-onset form 2-6 y. Adolescent and adult forms are rare.	Feeding difficulties. Shriill cry. Irritability. Arching of back.	Optic atrophy, mid-course to late. Hyperacusis occasionally.	Head often small. Often underweight.
Metachromatic leukodystrophy	Recessive. Arylsulfatase A deficiency. 22q13.	Most common is late-infantile form, presenting at 18-24 mo. Juvenile and adult forms present later.	Incoordination, especially gait disturbance; then general regression. Reverse in juveniles.	Optic atrophy, usually late. Hearing normal.	Head enlarged late. No change in juvenile form.
Pantothenate kinase-associated neurodegeneration (previously Hallervorden-Spatz syndrome)	Autosomal recessive; most common mutation is in <i>PANK2</i> gene on chromosome 20.	Early onset is by age 10 y.	Rigidity, dystonia, gait disturbance, tremor.	Abnormal ERG. Retinal degeneration.	Dystonia, gait disturbance.
Pelizaeus-Merzbacher disease	X-linked recessive; rare female. Proteolipid protein (myelin) decreased. Xq22.	Birth (connatal) to 2 y.	Eye rolling often shortly after birth. Head bobbing. Slow loss of intellect.	Slowly developing optic atrophy. Hearing normal. Nystagmus.	Head and body normal.
DIFFUSE, BUT PRIMARILY GRAY MATTER					
Poliodystrophy (Alpers disease or syndrome)	Occasionally familial, recessive. Metabolic forms.	Infancy to adolescence.	Variable: loss of intellect, seizures, incoordination. Vomiting, hepatic failure.	Cortical blindness and deafness.	Head normal initially; may fail to grow.
Tay-Sachs disease and G_{M2} gangliosidosis variants: Sandhoff disease; juvenile; chronic-adult	Recessive. Hexosaminidase deficiencies caused by <i>HEXA</i> gene on chromosome 15q23-24.62,63. Tay-Sachs (93% East European Jewish), hexosaminidase A deficiency. Sandhoff hexosaminidase A and B deficiency. Juvenile partial hexosaminidase A.	Tay-Sachs, and Sandhoff 3-6 mo; others 2-6 y or later.	Variable: shrill cry, loss of vision, infantile spasms, arrest of development. In juvenile and chronic forms: motor difficulties; later, mental difficulties.	Cherry-red macula, early blindness. Hyperacusis early. Strabismus in juvenile form, blindness late.	Head enlarged late. Liver occasionally enlarged. None in juvenile chronic forms.
Niemann-Pick disease and variants	50% Jewish. Recessive. Sphingomyelinase deficiency in types A and C involving the CNS.	First 6 mo. In variants, later onset: often non-Jewish.	Slow development. Protruding belly.	Cherry-red macula in 35-50%. Blindness late. Deafness occasionally.	Head usually normal. Spleen enlarged more than liver. Occasional xanthomas of skin. Vertical gaze palsy.
Infantile Gaucher disease (glucosylceramide lipidosi)	Recessive. Glucocerebrosidase deficiency.	First 6 mo; rarely, late infancy.	Stridor or hoarse cry; retraction; feeding difficulties.	Occasional cherry-red macula. Convergent squint. Deafness occasionally.	Head usually normal. Liver and spleen equally enlarged.

Motor System	Seizures	Laboratory and Tissue Studies	Course
Early spasticity, occasionally preceded by hypotonia. Prolonged nerve conduction.	Early. Myoclonic and generalized, decerebrate posturing.	CSF protein elevated; usually normal in late-onset forms. Sural nerve; nonspecific myelin breakdown. Enzyme deficiency in leukocytes, cultured skin fibroblasts. Demyelination, gliosis with low-signal CT scan, high-signal T ₂ -weighted MRI.	Rapid. Death usually by 1.5-2 y. Late-onset cases may live 5-10 y. Hematopoietic stem cell transplantation is an experimental treatment with variable results.
Combined upper and lower motor neuron signs. Ataxia. Prolonged nerve conduction.	Infrequent, usually late and generalized.	Metachromatic cells in urine: negative sulfatase A test. CSF protein elevated. Urine sulfatide increased. Sural nerve biopsy; metachromasia. Enzyme deficiency in leukocytes, cultured skin fibroblasts. Imaging: Same as globoid leukodystrophy.	Moderately slow. Death in infantile form by 3-8 y, in juvenile form by 10-15 y. Hematopoietic stem cell transplantation is an experimental treatment with variable results.
Extrapyramidal signs, dysarthria, increased deep tendon reflexes.	Variable, EEG may be abnormal.	Axonal degeneration (spheroids). Iron deposits in basal ganglia on MRI: eye-of-the-tiger appearance.	Progressive mental/motor deterioration.
Cerebellar signs early, hyperactive deep reflexes. Spasticity.	Usually only late.	None specific. Brain biopsy: extensive demyelination with small perivascular islands of intact myelin. Point mutations or duplications of <i>PLP</i> gene account for 65-90% of cases.	Very slow, often seemingly stationary.
Variable: incoordination, spasticity.	Often initial manifestation: myoclonic, akinetic, and generalized.	<i>POLG1</i> mutation: multiple deletions, depletions of mitochondrial DNA. Neuronal loss in cortex: may occur very late. Variably increased serum pyruvate, lactate; liver steatosis, cirrhosis late. Muscle and liver biopsy show evidence of mitochondrial dysfunction.	Usually rapid, with death within 1-3 y after onset. Variants in older children, adults.
Initially floppy. Eventual decerebrate rigidity. In juvenile and chronic forms: dysarthria, ataxia, spasticity.	Frequent, in mid-course and late. Infantile spasms and generalized.	Blood smears: vacuolated lymphocytes; basophilic hypergranulation. Enzyme deficiencies in serum, leukocytes, culture, skin fibroblasts. High-density thalami on CT scan, low-density white matter.	Moderately rapid. Death usually by 2-5 y. In juvenile form, 5-15 y.
Initially floppy. Eventually spastic. Occasionally extrapyramidal signs. Ataxia, dystonia.	Rare and late.	Blood: vacuolated lymphocytes; increased lipids. X-rays: "mottled" lungs, decalcified bones. "Foam cells" in bone marrow, spleen, lymph nodes. WBC, fibroblast enzyme studies are diagnostic.	Moderately slow. Death usually by 3-5 y.
Opisthotonos early, followed rapidly by decerebrate rigidity.	Rare and late.	Anemia. Increased acid phosphatase. X-rays: thinned cortex, trabeculation of bones. "Gaucher cells" in bone marrow, spleen. Enzyme deficiency in leukocytes or cultured skin fibroblasts.	Very rapid. Experimental enzyme replacement therapy is underway.

(continued)

Table 23–20. Central nervous system degenerative disorders of infancy. (*Continued*)

Disease	Enzyme Defect and Genetics	Onset	Early Manifestations	Vision and Hearing	Somatic Findings
Generalized gangliosidosis and juvenile type (G _{M1} gangliosidosis)	Recessive; β -galactosidase deficiency.	1–2 y in infantile form.	Arrest of development. Protruding belly. Coarse facies in infantile (generalized) form. In juvenile form, ataxia and dysarthria.	50% “cherry-red spot.” Hearing usually normal. In juvenile type. Occasionally retinitis pigmentosa.	Head enlarged early; liver enlarged more than spleen.
Subacute necrotizing encephalomyelopathy (Leigh disease)	Recessive or variable. May have deficiency of pyruvate carboxylase, pyruvate dehydrogenase, cytochrome enzymes.	Infancy to late childhood.	Difficulties in feeding; feeble or absent cry; floppiness; apnea; developmental regression; ataxia. Presentation can be highly variable.	Optic atrophy, often early. Roving eye movements. Ophthalmoplegia.	Head usually normal, occasionally small; cardiac and renal tubular dysfunction occasionally.
Menkes disease (kinky hair disease)	X-linked recessive; defect in copper absorption.	Infancy.	Peculiar facies; secondary hair white, twisted, split; hypothermia.	May show optic disk pallor and microcysts of pigment epithelium.	Growth retardation.
Carbohydrate-deficient glycoprotein syndrome	Recessive glycoprotein abnormality; glycosylation faulty.	Infancy.	Failure to thrive, retardation, protein-losing enteropathy.	Strabismus, retinopathy.	Dysmorphic facies. Prominent fat pads. Inverted nipples.
Abetalipoproteinemia (Bassen-Kornzweig disease)	Recessive; primary defect is microsomal triglyceride transfer protein (MTP) on chromosome 4q22–24.	Early childhood.	Diarrhea in infancy.	Retinitis pigmentosa; late ophthalmoplegia.	None.

► Differential Diagnosis

Acute cerebellar ataxia must be differentiated from acute cerebellar syndromes due to phenytoin, phenobarbital, primidone, or lead intoxication. For phenytoin, the toxic level in serum is usually above 25 mcg/mL; for phenobarbital, above 50 mcg/mL; for primidone, above 14 mcg/mL. (See section on Seizure Disorders, earlier.) Papilledema, anemia, basophilic stippling of erythrocytes, proteinuria, typical radiographs, and elevated CSF protein are clinical clues to lead intoxication, which is confirmed by serum, urine, or hair lead levels. Polymyoclonus-opsoclonus syndrome with an occult neuroblastoma (see following section) occasionally begins as acute cerebellar ataxia.

In rare cases, acute cerebellar ataxia may be the presenting sign of acute bacterial meningitis or may be mimicked by corticosteroid withdrawal, vasculitides such as in polyarteritis nodosa, trauma, the first attack of ataxia in a metabolic disorder such as Hartnup disease, or the onset of acute disseminated encephalomyelitis or of multiple sclerosis. The history and physical findings may differentiate these disturbances, but appropriate laboratory studies are often neces-

sary. For ataxias with more chronic onset and course, see the sections on spinocerebellar degeneration and the other degenerative disorders.

► Treatment & Prognosis

Treatment is supportive. Corticosteroids have not been shown to be of benefit; IVIG has been used. Between 80% and 90% of children with acute cerebellar ataxia not secondary to drug toxicity recover without sequelae within 6–8 weeks. In the remainder, neurologic disturbances, including disorders of behavior and of learning, ataxia, abnormal eye movements, and speech impairment, may persist for months or years, and recovery may remain incomplete.

Motor System	Seizures	Laboratory and Tissue Studies	Course
Initially floppy, eventually spastic.	Usually late.	Blood: vacuolated lymphocytes. X-rays: dorsolumbar kyphosis, "beaking" of vertebrae. "Foam cells" similar to those in Niemann-Pick disease.	Very rapid. Death within a few years. Slower in juvenile type (to 10 y).
Flaccid and immobile; may become spastic. Spinocerebellar forms; ataxia, myelopathy.	Rare and late tonic seizures.	Increased CSF and blood lactate and pyruvate. High-signal MRI T ₂ foci in thalami; globus pallidus, putamen, subthalamic nuclei. May be considered a mitochondrial disorder. DNA, enzyme tests on muscle.	Usually rapid in infants, but may be slow with death after several years. Central hypoventilation a frequent cause of death.
Variable: floppy to spastic.	Myoclonic infantile spasms, status epilepticus.	Defective absorption of copper. Cerebral angiography shows elongated arteries. Hair shows pili torti, split shafts. Copper and ceruloplasmin low.	Moderately rapid. Death usually by 3-4 y.
Variable hypotonia, neuropathy.	Rare.	Normal transferrin decreased. Carbohydrate-deficient transferrin increased. Liver steatosis. Cerebellar hypoplasia.	Cardiomyopathy, thrombosis. Hepatic fibrosis.
Ataxia, late extrapyramidal movement disorder.	None.	Abetalipoproteinemia: acanthocytosis, low serum vitamin E; cerebellar atrophy on imaging.	Progression arrested with vitamin E.

CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; EMG, electromyogram; MRI, magnetic resonance imaging; WBC, white blood cell.

2. Polymyoclonus-Opsoclonus Syndrome of Childhood (Infantile Myoclonic Encephalopathy, "Dancing Eyes-Dancing Feet" Syndrome)

The symptoms and signs of this syndrome are at first similar to those of acute cerebellar ataxia. Often of sudden onset, polymyoclonus-opsoclonus syndrome is characterized by severe incoordination of the trunk and extremities with lightning-like jerking or flinging movements of a group of muscles, causing the child to be in constant motion while awake. Extraocular muscle involvement results in sudden irregular eye movements (opsoclonus). Irritability and vomiting are often present, but

there is no depression of level of consciousness. This syndrome occurs in association with viral infections and tumors of neural crest origin among other disorders. Immunologic mechanisms have been postulated. Usually no signs of increased intracranial pressure are present. CSF may show normal or mildly increased protein levels. Special techniques show increased CSF levels of plasmacytes and abnormal immunoglobulins. The EEG may be slightly slow, but when performed together with EMG, it shows no evidence of association between cortical discharges and the muscle movements. An assiduous search must be made to rule out tumor of neural crest origin by chest radiographs and CT, MRI, or ultrasound of the adrenal area as well as by assays of urinary catecholamine metabolites (vanillylmandelic acid and others) and cystathionine.

The symptoms respond variably to ACTH or to IVIG. Plasmapheresis has been successful. Usually the underlying neural crest tumor is benign (ganglioneuroblastoma); surgical excision may be the only oncologic therapy needed. Life span is determined by the biologic behavior of the tumor. The syndrome is usually self-limited but may be characterized by exacerbations and remissions, even after the removal of the neural crest tumor and without other evidence of its

Table 23-21. Central nervous system degenerative disorders of childhood.^a

Disease	Enzyme Defect and Genetics	Onset	Early Manifestations	Vision and Hearing	Motor System	Seizures	Laboratory and Tissue Studies	Course
Adrenoleukodystrophy and variants (peroxisomal disease)	X-linked recessive. Neonatal form recessive Xq28. Acyl-CoA synthetase deficiency.	5-10 y. May also present as newborn, adolescent or adult.	Impaired intellect; behavioral problems.	Cortical blindness and deafness.	Ataxia, spasticity; motor deficits may be asymmetrical or one-sided initially; adrenomyeloneuropathy in adults.	Occasionally.	Hyperpigmentation and adrenocortical insufficiency. ACTH elevated. Accumulation of very-long-chain fatty acids in plasma. ?Stem cell, marrow transplantation early.	Variable course, many mildly involved. Severe variant with death in 2-5 y.
Neuronal ceroid lipofuscinosis (NCL; cerebromacular degeneration); infantile NCL (INCL); late infantile (LINCL); juvenile NCL (JNCL; Batten disease)	Recessive; multiple gene mutations, polymorphisms.	INCL: 6-24 mo; LINCL: 2-4 y; JNCL: 4-8 y.	Ataxia; visual difficulties; arrested intellectual development. Seizures.	Pigmentary degeneration of macula; optic atrophy; ERG, VER abnormal	Ataxia; spasticity progressing to decerebrate rigidity.	Often early: myoclonus and later generalized; refractory.	Blood: vacuolated lymphocytes. Biopsy, EM of skin, conjunctiva; WBC: "curvilinear bodies, fingerprint profiles." Molecular testing of <i>CLN1</i> , <i>CLN2</i> , <i>CLN3</i> genes. Protein gene product testing for <i>CLN1</i> and <i>CLN2</i> .	Moderately slow. Death in 3-8 y.
Subacute sclerosing panencephalitis (Dawson disease)	None. Measles "slow virus" infection. Also reported as result of rubella.	3-22 y; rarely earlier or later.	Impaired intellect; emotional lability; incoordination.	Occasionally chorioretinitis or optic atrophy; hearing normal.	Ataxia; slurred speech; occasionally involuntary movements; spasticity progressing to decerebrate rigidity.	Myoclonic and akinetic seizures relatively early; later, focal and generalized.	CSF protein normal to moderately elevated. High CSF IgG, ^b oligoclonal bands. Elevated CSF (and serum) measles (or rubella) antibody titers. Characteristic EEG. Brain biopsy; inclusion (acidophilic) body encephalitis; culturing of measles virus, perhaps rubella virus.	Variable, death in months to years. Remissions occasional. Treatment: INF- α intrathecal?
Megalencephalic leukodystrophy with subcortical cysts (MLC)	<i>MLC1</i> gene defect usually 22q.	Infancy.	Macrocephaly.		Ataxia; spasticity; ?dystonia.	Varied; epilepsy.	Characteristic MRI dysmyelination.	Slowly progressive to adulthood.
Vanishing white matter/childhood ataxia with CNS hypomyelination (VWM/CACH)	eIF2B 3q27 autosomal recessive.	Fatal infancy variant; other (slower) variants.	Episodic deterioration with fever, head trauma, fear.		Ataxia, spasticity.		MRI: dramatic disappearance of white matter.	Fatal infantile form. Slowly progressive form. Adult variant (autosomal dominant) with ovarian dysgenesis.

Alexander disease	<i>GFAP</i> gene mutation autosomal dominant.	Infancy.	Macrocephaly key finding.		As above.		Demyelination; Rosenthal fibers characteristic of biopsy.	Fatal infantile. Juvenile: bulbar signs, less retardation.
Multiple sclerosis	None. Diagnosis difficult in childhood.	Adolescent; rare in childhood.	Highly variable: may strike one or more sites of CNS; paresthesias common.	Optic neuritis; diplopia, nystagmus at some time; vestibulocochlear nerves occasionally affected.	Motor weakness; spasticity; ataxia; sphincter disturbances; slurred speech; mental difficulties.	Rare: focal or generalized.	CSF may show slight pleocytosis, elevation of protein and γ -globulin, ^b oligoclonal bands present. CT scan may show areas of demyelination. Auditory, visual, and somatosensory evoked responses often show lesions in respective pathways. Changes in T-cell subsets.	Variable: complete remission possible. Recurrent attacks and involvement of multiple sites are prerequisites for diagnosis.
Cerebrotendinous xanthomatosis	?Recessive. Abnormal accumulation of cholesterol.	Late childhood to adolescence.	Xanthomas in tendons; mental deterioration.	Cataracts; xanthelasma.	Cerebellar defects; bulbar paralysis late.	Myoclonus.	Xanthomas may appear in lungs. Xanthomas in tendons (especially Achilles).	Very slowly progressive into middle life. Replace deficient bile acid.
Huntington disease	Dominant. Chromosome 4p CAG repeat.	10% childhood onset.	Rigidity; dementia.	Ophthalmoplegia late.	Rigidity; chorea frequently absent in children.	50% with major motor seizures.	CT scan may show “butterfly” atrophy of caudate and putamen.	Moderately rapid with death in 15 y.
Refsum disease (peroxisomal disease)	Recessive. Phytanic acid oxidase deficiency.	5–10 y.	Ataxia; ichthyosis; cardiomyopathy.	Retinitis pigmentosa; nystagmus.	Ataxia; neuropathy; tendon reflexes absent.	None.	Serum phytanic acid elevated. Slow nerve conduction velocity. Elevated CSF protein. Peroxisomal disease.	Treat with low phytanic acid diet.

^aFor late infantile metachromatic leukodystrophy, Pelizaeus-Merzbacher disease, poliodystrophy, Gaucher disease of later onset, and subacute necrotizing encephalomyelopathy, see Table 23–20.

^bCSF γ -globulin (IgG) is considered elevated in children when IgG is > 9% of total protein (possibly even > 8.3%); definitively elevated when > 14%.

ACTH, adrenocorticotropic hormone; CLN, ceroid lipofuscinosis; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; EM, electron microscopy; ERG, electroretinogram; IFN- α , interferon- α ; MRI, magnetic resonance imaging; VER, visual evoked response; WBC, white blood cell.

recurrence, symptoms may reappear. Mild mental retardation may be a sequela.

3. Spinocerebellar Degeneration Disorders

Spinocerebellar degeneration disorders may be hereditary or may occur in sporadic fashion. Hereditary disorders include Friedreich ataxia, dominant hereditary ataxia, and a group of miscellaneous diseases.

A. Friedreich Ataxia

This is a recessive disorder characterized by onset of gait ataxia or scoliosis before puberty that becomes progressively worse. Reflexes, light touch, and position sensation are reduced. Dysarthria becomes progressively more severe. Cardiomyopathy usually develops, and diabetes mellitus occurs in 40% of patients, half of whom require insulin. Pes cavus typically is found. The GAA trinucleotide repeats on chromosome 9 can be used for laboratory diagnosis.

Treatment includes surgery for scoliosis and intervention as needed for cardiac disease and diabetes. Antioxidants may slow cardiac deterioration. Patients are usually confined to a wheelchair after age 20 years. Death occurs, usually from heart failure or dysrhythmias, in the third or fourth decade; some patients survive longer.

B. Dominant Ataxia

These diseases (in the past known as olivopontocerebellar atrophy, Holmes ataxia, Marie ataxia, and the like) occur with

varying manifestations, even among members of the same family. Ataxia occurs at onset, and progression continues with ophthalmoplegias (in some patients), extrapyramidal syndromes, polyneuropathy, and dementia. Several types have been found to be caused by CAG trinucleotide repeats. Levodopa may ameliorate rigidity and bradykinesia, but no other therapy is available. Only 10% of patients experience onset in childhood, and the course in these patients is often more rapid.

C. Miscellaneous Hereditary Ataxias

Associated findings permit identification of these recessive disorders. These include ataxia-telangiectasia (telangiectasia and immune defects; see below); Wilson disease (Kayser-Fleischer rings); Refsum disease (ichthyosis, cardiomyopathy, retinitis pigmentosa, and large nerves); Rett syndrome (regression to autism at age 7–18 months in girls, loss of use of hands, and progressive failure of brain growth); and abetalipoproteinemia (infantile diarrhea, acanthocytosis, and retinitis pigmentosa). Gluten sensitivity may cause ataxia. Patients with juvenile and chronic gangliosidosis and some hemolytic anemias and long-term survivors of Chédiak-Higashi disease may develop spinocerebellar degeneration. Idiopathic familial ataxia is called Behr syndrome. Neuropathies such as Charcot-Marie-Tooth disease produce ataxia.

ATAXIA-TELANGIECTASIA (LOUIS-BAR SYNDROME)

Ataxia-telangiectasia is a multisystem disorder inherited as an autosomal recessive trait. It is characterized by progres-

sive ataxia; telangiectasia of the bulbar conjunctivae, external ears, nares, and (later) other body surfaces, appearing in the third to sixth year; and recurrent respiratory, sinus, and ear infections. Ocular dyspraxia, slurred speech, choreoathetosis, hypotonia and areflexia, and psychomotor and growth retardation may be present. Endocrinopathies are common. Nerve conduction velocities may be reduced. The entire nervous system may be affected in late stages of the disease. A spectrum of involvement may be seen in the same family. Immunodeficiencies of IgA and IgE are common (see Chapter 31), and the incidence of certain cancers is high. Elevated serum α -fetoprotein is a screen for this disease.

EXTRAPYRAMIDAL DISORDERS

Extrapyramidal disorders are characterized by the presence in the waking state of one or more of the following features: dyskinesias, athetosis, ballismus, tremors, rigidity, and dystonias.

For the most part, the precise pathologic and anatomic localization of these disorders is not understood. Motor pathways synapsing in the striatum (putamen and caudate nucleus), globus pallidus, red nucleus, substantia nigra, and the body of Luys are involved; this system is modulated by pathways originating in the thalamus, cerebellum, and reticular formation.

1. Sydenham Post-Rheumatic Chorea

Sydenham chorea is characterized by an acute onset of choreiform movements and variable degrees of psychological disturbance. It is frequently associated with rheumatic endocarditis and arthritis. Although the disorder follows infections with group A β -hemolytic streptococci, the interval between infection and chorea may be greatly prolonged; throat cultures and antistreptolysin O titers may therefore be negative. Chorea has also been associated with hypocalcemia; with vascular lupus erythematosus; and with toxic, viral, infectious, parainfectious, and degenerative encephalopathies. Paraneoplastic chorea is not seen in children.

► Clinical Findings

A. Symptoms and Signs

Chorea, or rapid involuntary movements of the limbs and face, is the hallmark physical finding. In addition to the jerky incoordinate movements, the following are noted: emotional lability, waxing and waning (“milkmaid’s”) grip, darting tongue, “spooning” of the extended hands and their tendency to pronate, and knee jerks slow to return from the extended to their prestimulus position (“hung up”). Seizures, while uncommon, may be masked by choreic jerks.

B. Laboratory Findings

Anemia, leukocytosis, and an increased erythrocyte sedimentation rate and C-reactive protein may be present. The antistreptolysin O or anti-DNase titer (or both) may be elevated, and C-reactive protein present. Throat culture is sometimes positive for group A β -hemolytic streptococci.

ECG and echocardiography are often essential to detect cardiac involvement. Antineuronal antibodies are present in most patients but are not specific for this disease. Specialized radiologic procedures (MRI and SPECT) may show basal ganglia abnormalities.

► Differential Diagnosis

The diagnosis of Sydenham chorea is usually not difficult. Tics, drug-induced extrapyramidal syndromes, Huntington chorea, and hepatolenticular degeneration (Wilson disease), as well as other rare movement disorders, can usually be ruled out on historical and clinical grounds. Immunologic linkages among chorea, tics, and obsessive-compulsive disorder are being studied in pediatric patients. Stroke is a rare cause for unilateral chorea. Other causes of chorea can be ruled out by laboratory tests, such as antinuclear antibody for lupus, thyroid screening tests, serum calcium for hypocalcemia, and immunologic and virologic tests for (rare) HIV, parvovirus B19, and Epstein-Barr virus infection.

► Treatment

There is no specific treatment. Dopaminergic blockers such as haloperidol (0.5 mg to 3–6 mg/d) and pimozide (2–10 mg/d) have been used. Parkinsonian side effects such as rigidity and masked facies, and with high doses tardive dyskinesia, rarely occur in childhood. Other drugs have been used with success in individual cases; these include the anticonvulsant sodium valproate (50–60 mg/kg/d in divided doses) and prednisone (0.5–2 mg/kg/d in divided doses). IVIG has been successful in severe cases. Emotional lability and depression sometimes warrant administration of antidepressants. All patients should be given antistreptococcal rheumatic fever prophylaxis, possibly through childbearing age.

► Prognosis

Sydenham chorea is a self-limited disease that may last from a few weeks to months. Relapse of chorea may occur with nonspecific stress or illness—or with breakthrough streptococcal infections (if penicillin prophylaxis is not done). Two thirds of patients relapse one or more times, but the ultimate outcome does not appear to be worse in those with recurrences. In older studies, eventual valvular heart disease occurs in about one third of patients, particularly if other rheumatic manifestations appear. Psychoneurotic disturbances occur in a significant percentage of patients.

2. Tics (Habit Spasms)

► Clinical Findings

Tics, or habit spasms, are quick repetitive but irregular movements, often stereotyped, and briefly suppressible. Coordination and muscle tone are not affected. A psychogenic basis is seldom discernible. Transient tics of childhood (12–24% incidence in school-aged children) last from 1 month to 1 year and seldom need treatment. Many children with tics have a history of encephalopathic past events, neurologic soft signs, and school problems. Facial tics such as grimaces, twitches, and blinking predominate, but the trunk and extremities are often involved and twisting or flinging movements may be present. Vocal tics are less common.

Tourette syndrome is characterized by multiple fluctuating motor and vocal tics with no obvious cause lasting more than 1 year. Tics evolve slowly, new ones being added to or replacing old ones. Coprolalia and echolalia are relatively infrequent. Partial forms are common. The usual age at onset is 2–15 years, and the familial incidence is 35–50%.

The disorder occurs in all ethnic groups. Tourette syndrome may be triggered by stimulants such as methylphenidate and dextroamphetamine. An imbalance of or hypersensitivity to neurotransmitters, especially dopaminergic and adrenergic, has been hypothesized.

In mild cases, tics are self-limited, and when disregarded disappear. When attention is paid to one tic, it may disappear only to be replaced by another that is often worse. If the tic and its underlying anxiety or compulsive neuroses are severe, psychiatric evaluation and treatment are needed.

Important comorbidities are attention-deficit/hyperactivity disorder and obsessive-compulsive disorder. Learning disabilities, sleep difficulties, anxiety states, and mood swings are also common. Medications such as methylphenidate and dextroamphetamine should be carefully titrated to treat attention-deficit/hyperactivity disorder and avoid worsening tics. Fluoxetine and clomipramine may be useful for obsessive-compulsive disorder and rage episodes in patients with tics.

► Treatment

The most effective medications for treating Tourette syndrome are dopamine blockers; however, many pediatric patients can manage without drug treatment. Medications are generally reserved for patients with disabling symptoms; treatment may be relaxed or discontinued when the symptoms abate (Table 23–22). Nonpharmacologic treatment of Tourette syndrome includes education of patients, family members, and school personnel. In some cases, restructuring the school environment to prevent tension and teasing may be necessary. Supportive counseling, either at or outside school, should be provided. Medications usually do not eradicate the tics. The goal of treatment should be to reduce

the tics to tolerable levels without inducing undesirable side effects. Medication dosage should be increased at weekly intervals until a satisfactory response is obtained. Often a single dose at bedtime is sufficient. The two neuroleptic agents used most often are pimozide and risperidone. Sleepiness and weight gain are the most common side effects; rare are prolonged QT interval (ECG), akathisia, and tardive dyskinesia. Clonidine, guanfacine, and dopamine modulators have been used in individual patients with some success. Sometimes these agents are used in combination (eg, clonidine with pimozide). IVIG has been unsuccessful.

Sydenham chorea is a well-documented pediatric autoimmune disorder associated with streptococcal infections (pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection; PANDAS). Patients with tic disorders occasionally have obsessive-compulsive disorder precipitated or exacerbated by streptococcal infections. Less definite (much less frequent) are tic flare-ups with streptococcal infection. Active prospective antibody (antineuronal and antistreptococcal) and clinical studies are in progress. Research centers have used experimental treatments (IVIG, plasmapheresis, and corticosteroids) in severe cases. At present, most patients with a tic do not worsen with group A streptococcal infections; with rare exceptions, penicillin prophylaxis is not generally necessary for the majority of patients with tic disorders.

3. Paroxysmal Dyskinesias/Chronic Dystonia

Sudden-onset, short-duration choreoathetosis or dystonia episodes occur in childhood. Most often these episodes are of familial or genetic origin. Episodes may occur spontaneously or be set off by actions (“kinesigenic,” or movement-induced) such as rising from a chair, reaching for a glass, or walking. Sometimes only hard sustained exercise will induce the dyskinesia. (Nocturnal dyskinesia/dystonic episodes are currently thought to be frontal lobe seizures.)

The diagnosis is clinical. Onset is usually in childhood (1.5–14 years). The patient is alert and often disconcerted during an episode.

Episodes may last seconds to 5–20 minutes and occur several times daily or monthly. Laboratory work is normal. EEG is normal between or during an attack; brain imaging is normal. Inheritance is usually autosomal dominant. Anticonvulsants (eg, carbamazepine) usually prevent further attacks. Patients often grow out of this disease in one or two decades.

Nonkinesigenic dyskinesia is often secondary to an identifiable brain lesion, less or not responsive to medications, and nongenetic.

Disorders of ion channels underlie many of the genetic cases; some cases are linked to epilepsy and hemiplegic migraine. Chromosome loci are known.

The diagnosis of chronic persistent dystonia (sometimes L-dopa-responsive; DYT5) may be aided by spinal fluid neurotransmitter (DYT5) and genetic chromosome studies: DYT1 is the most common. Rarely, dyskinesia (eg, dystonia) may be precipitated by fever. Persistent chorea (rarely) may be a benign lifelong genetic disease.

Tarsy D, Simon DK: Dystonia. *N Engl J Med* 2006;355:818 [PMID: 16928997].

4. Tremor

The most common cause of persisting tremors in childhood is essential tremor. Of those with this lifelong malady, 4.6% have onset in childhood (2–16 years). A genetic dominant inheritance is probable; 20–80% afflicted report a relative with tremors. Tremor, a mild fine motor and cosmetic handicap, is worsened by anxiety, fatigue, stress, physical activity, and caffeine, and transiently improved by alcohol. Comorbidities include attention-deficit/hyperactivity disorder, dystonia, and possibly Tourette syndrome. Hand/arm tremor is the major manifestation; voice and head tremors are rare. Sometimes, “shuddering attacks” in infancy are a forerunner.

Laboratory studies are normal. Progression is usually minimal. Some patients develop other movement disorders

over a lifetime. Helpful medications (rarely needed long-term) include propranolol or primidone.

Differential diagnosis includes birth asphyxia, Wilson disease, hyperthyroidism, and hypocalcemia; history and laboratory tests rule out these rare possibilities.

Recent research studies in adults utilizing proton MRS (magnetic resonance spectroscopy) suggest decreased nerve cells in the cerebellar cortex and increased harmaline, a neurotoxin, at the same site. The latter suggests a possible environmental contribution to essential tremor.

INFECTIONS & INFLAMMATORY DISORDERS OF THE CENTRAL NERVOUS SYSTEM

Infections of the CNS are among the most common neurologic disorders encountered by pediatricians. Although infections are among the CNS disorders most amenable to treatment, they also have a very high potential for causing catastrophic destruction of the nervous system. It is imperative for the clinician to recognize infections early in order to treat and prevent massive tissue destruction.

► Clinical Findings

A. Symptoms and Signs

Patients with CNS infections, whether caused by bacteria, viruses, or other microorganisms, present with similar manifestations. Systemic signs of infection include fever; malaise; and impaired heart, lung, liver, or kidney function. General features suggesting CNS infection include headache, stiff neck, fever or hypothermia, changes in mental status (including hyperirritability evolving into lethargy and coma), seizures, and focal sensory and motor deficits. Meningeal irritation is manifested by the presence of Kernig and Brudzinski signs. In very young infants, signs of meningeal irritation may be absent, and temperature instability and hypothermia are often more prominent than fever. In young infants, a bulging fontanelle and an increased head circumference are common. Papilledema may eventually develop, particularly in older children and adolescents. Cranial nerve palsies may develop acutely or gradually during the course of neurologic infections. No specific clinical sign or symptom is reliable in distinguishing bacterial infections from infections caused by other microbes.

During the initial clinical assessment, conditions that predispose the patient to infection of the CNS should be sought. Infections involving the sinuses or other structures in the head and neck region can result in direct extension of infection into the intracranial compartment. Open head injuries, recent neurosurgical procedures, immunodeficiency, and the presence of a mechanical shunt may predispose to intracranial infection.

B. Laboratory Findings

When CNS infections are suspected, blood should be obtained for a complete blood count, general chemistry panel, and culture. Most important, however, is obtaining CSF. In the absence of focal neurologic deficits or signs of brainstem herniation, CSF should be obtained immediately from any patient in whom serious CNS infection is suspected. When papilledema or focal motor signs are present, a lumbar puncture may be delayed until a neuroimaging procedure has been done to exclude space-occupying lesions. Treatment must be started even if lumbar puncture is delayed. It is generally safe to obtain spinal fluid from infants with nonfocal neurologic examination even if the fontanelle is bulging. Spinal fluid should be examined for the presence of red and white blood cells, protein concentration, glucose concentration, bacteria, and other microorganisms; a sample should be cultured. In addition, serologic, immunologic, and nucleic acid detection (PCR) tests may be performed on the spinal fluid in an attempt to identify the specific organism. Spinal fluid that contains a high proportion of polymorphonuclear leukocytes, a high protein concentration, and a low glucose concentration strongly suggests bacterial infection (see Chapter 40). CSF containing predominantly lymphocytes, a high protein concentration, and a low glucose concentration suggests infection with mycobacteria, fungi, uncommon bacteria, and some viruses such as lymphocytic choriomeningitis virus, herpes simplex virus, mumps virus, and arboviruses (see Chapters 38 and 41). CSF that contains a high proportion of lymphocytes, normal or only slightly elevated protein concentration, and a normal glucose concentration is most suggestive of viral infections, although partially treated bacterial meningitis and parameningeal infections may also result in this type of CSF formula. Typical CSF findings in a variety of infectious and inflammatory disorders are shown in Table 23–2.

In some cases, brain biopsy may be needed to identify the presence of specific organisms and clarify the diagnosis. Herpes simplex virus infections can be confirmed using the PCR test to assay for herpes DNA in spinal fluid. This test has 95% sensitivity and 99% specificity. Brain biopsy may be needed to detect the rare PCR-negative case of herpes simplex and various parasitic infections, or in a suspected noninfectious cause with ambiguous spinal fluid findings (eg, vasculitis).

C. Imaging

Neuroimaging with CT and MRI scans may be helpful in demonstrating the presence of brain abscess, meningial

inflammation, or secondary problems such as venous and arterial infarctions, hemorrhages, and subdural effusions when these are suspected. In addition, these procedures may identify sinus or other focal infections in the head or neck region that are related to the CNS infection. CT bone windows may demonstrate bony abnormalities such as basilar fractures.

EEGs may be helpful in the assessment of patients who have had seizures at the time of presentation. The changes are often nonspecific and characterized by generalized slowing. In some instances, such as herpes simplex virus or focal enterovirus infection, lateralized epileptiform discharges may be seen early in the course and may be one of the earliest laboratory abnormalities to suggest the diagnosis. EEGs may also show focal slowing over regions of infarcts or (rare) abscesses.

BACTERIAL MENINGITIS

Bacterial infections of the CNS may present acutely (symptoms evolving rapidly over 1–24 hours), subacutely (symptoms evolving over 1–7 days), or chronically (symptoms evolving over more than 1 week). Diffuse bacterial infections involve the leptomeninges, superficial cortical structures, and blood vessels. Although the term *meningitis* is used to describe these infections, it should not be forgotten that the brain parenchyma is also inflamed and that blood vessel walls may be infiltrated by inflammatory cells that result in endothelial cell injury, vessel stenosis, and secondary ischemia and infarction. Overall clinical characteristics of bacterial meningitis (and viral meningoencephalitis) are outlined in Table 23–23.

Pathologically, the inflammatory process involves all intracranial structures to some degree. Acutely, this inflam-

matory process may result in cerebral edema or impaired CSF flow through and out of the ventricular system, resulting in hydrocephalus.

► Treatment

A. Specific Measures

(See also Chapters 37, 38, and the section on bacterial infections in Chapter 40.)

While awaiting the results of diagnostic tests, the physician should start broad-spectrum antibiotic coverage as noted in the following discussion. After specific organisms are identified, antibiotic therapy can be tailored based on antibiotic sensitivity patterns. Bacterial meningitis in children younger than age 3 months is treated initially with cefotaxime (or ceftriaxone if the child is older than age 1 month) and ampicillin; the latter agent is used to treat *Listeria* and enterococci infections, which rarely affect older children. Children older than age 3 months are given ceftriaxone, cefotaxime, or ampicillin plus gentamicin. If *Streptococcus pneumoniae* cannot be ruled out by the initial Gram stain, vancomycin or rifampin is added until cultures are reported, because penicillin-resistant pneumococci are common in the United States. Therapy may be narrowed when organism sensitivity allows. Duration of therapy is 7 days for meningococcal infections, 10 days for *Haemophilus influenzae* or pneumococcal infection, and 14–21 days for other organisms. Slow clinical response or the occurrence of complications may prolong the need for therapy.

B. General and Supportive Measures

Children with bacterial meningitis are often systemically ill. The following complications should be looked for and treated aggressively: hypovolemia, hypoglycemia, hyponatremia, acidosis, septic shock, increased intracranial pressure, seizures, disseminated intravascular coagulation, and metastatic infection (eg, pericarditis, arthritis, or pneumonia). Children should initially be monitored closely (cardiorespiratory monitor, strict fluid balance and frequent urine specific gravity assessment, daily weights, and neurologic assessment every few hours), not fed until neurologically very stable, isolated until the organism is known, rehydrated with isotonic solutions until euvolemic, and then given intravenous fluids containing dextrose and sodium at no more than maintenance rate (assuming no unusual losses occur).

► Complications

Abnormalities of water and electrolyte balance result from either excessive or insufficient production of antidiuretic hormone and require careful monitoring and appropriate adjustments in fluid administration. Monitoring serum sodium every 8–12 hours during the first 1–2 days, and urine sodium if the inappropriate secretion of antidiuretic hormone is suspected, usually uncovers significant problems.

Table 23–23. Encephalitis.

Definition: brain inflammation (usually acute)
Clinical: (fever, headache) seizures, motor paralysis, impaired consciousness
Laboratory: CSF cells, protein increased; culture/PCR; serology CSF/blood
Radiographic: swelling (?focal), dysmyelination, ?infarcts
Pathologic: perivascular cells, gray matter, even neuronophagia; edema, dysmyelination, gliosis
Infectious: (95%) enteroviruses, <i>Mycoplasma</i> , herpes, EBV, other viral
Unusual: bacteria, fungi, protozoa
Some causes are mosquito- or tick-borne; seasonal.
Para-/Postinfectious (ADEM): (25%) during or after banal respiratory infection, exanthem; most often no etiologic agent is identified
Treatment: supportive
Herpes: acyclovir
ADEM: steroids, ?IVIG

ADEM, acute disseminated encephalomyelitis; EBV, Epstein-Barr virus; IVIG, intravenous immune globulin; PCR, polymerase chain reaction.

Data from Lewis P, Glaser CA: Encephalitis. *Pediatr Rev* 2005;26:347.

Seizures occur in up to 30% of children with bacterial meningitis. Seizures tend to be most common in neonates and less common in older children. Persistent focal seizures or focal seizures associated with focal neurologic deficits strongly suggest subdural effusion, abscess, or vascular lesions such as arterial infarct, cortical venous infarcts, or dural sinus thrombosis. Because generalized seizures in a metabolically compromised child may have severe sequelae, early recognition and therapy are critical; some practitioners prefer phenytoin for acute management because it is less sedating than phenobarbital.

Subdural effusions occur in as many as 50% of young children with *S pneumoniae* meningitis. Subdural effusions are often seen on CT scans of the head during the course of meningitis. They do not require treatment unless they are producing increased intracranial pressure or progressive mass effect. Although subdural effusions may be detected in children who have persistent fever, such effusions do not usually have to be sampled or drained if the infecting organism is *H influenzae*, meningococcus, or pneumococcus. These are usually sterilized with the standard treatment duration, and slowly waning fever during an otherwise uncomplicated recovery may be followed clinically. Under any other circumstance, however, aspiration of the fluid for documentation of sterilization or for relief of pressure should be considered. Interestingly, prognosis is not worsened by subdural effusions.

Cerebral edema can participate in the production of increased intracranial pressure, requiring treatment with dexamethasone, osmotic agents, diuretics, or hyperventilation; continuous pressure monitoring may be needed.

Long-term sequelae of meningitis result from direct inflammatory destruction of brain cells, vascular injuries, or secondary gliosis. Focal motor and sensory deficits, visual impairment, hearing loss, seizures, hydrocephalus, and a variety of cranial nerve deficits can result from meningitis. Sensorineural hearing loss in *H influenzae* meningitis occurs in approximately 5–10% of patients during long-term follow-up. Recent studies have suggested that early addition of dexamethasone to the antibiotic regimen may modestly decrease the risk of hearing loss in some children with bacterial meningitis (see Chapter 40).

In addition to the variety of disorders mentioned earlier in this section, some patients with meningitis have mental retardation and severe behavioral disorders that limit their function at school and later performance in life.

BRAIN ABSCESS

Clinical Findings

Patients with brain abscess often appear to have systemic illness similar to patients with bacterial meningitis, but in addition they show signs of focal neurologic deficits, papilledema, and other evidence of increased intracranial

pressure or a mass lesion. Symptoms may be present for a week or more; children with bacterial meningitis usually present within a few days. Conditions predisposing to development of brain abscess include penetrating head trauma; chronic infection of the middle ear, mastoid, or sinuses (especially the frontal sinus); chronic dental or pulmonary infection; cardiovascular lesions allowing right-to-left shunting of blood (including arteriovenous malformations); and endocarditis. Sinus infections more characteristically cause subdural-epidural, orbital and forehead abscesses or empyemas, or cellulitis rather than intracranial abscesses. Recent reports have identified a predisposition to brain abscess in patients with congenital heart disease and acute immunosuppression, with a fungal cause in the latter, and *Citrobacter* infection in infants.

When brain abscess is strongly suspected, a neuroimaging procedure such as CT or MRI scans with contrast enhancement should be done prior to lumbar puncture. (CT scan can miss an epidural collection.) If a brain abscess is identified, lumbar puncture may be dangerous and rarely alters the choice of antibiotic or clinical management since the CSF abnormalities usually reflect only parameningeal inflammation or are often normal. With spread from contiguous septic foci, streptococci and anaerobic bacteria are most common. Staphylococci most often enter from trauma or spread from distant or occult infections. Enteric organisms may form an abscess from chronic otitis. Unfortunately, cultures from a large number of brain abscesses remain negative.

The diagnosis of brain abscess is based primarily on a strong clinical suspicion and confirmed by a neuroimaging procedure. Strongly positive inflammatory markers (erythrocyte sedimentation rate, C-reactive protein) are useful in screening. Normal results would be unlikely in patients with brain abscess. EEG changes are nonspecific but frequently demonstrate focal slowing in the region of brain abscess.

Differential Diagnosis

Differential diagnosis of brain abscess includes any condition that produces focal neurologic deficits and increased intracranial pressure, such as neoplasms, subdural effusions, cerebral infarctions, and certain infections (herpes simplex, cysticercosis, and toxocariasis).

Treatment

Initial therapy for infection from presumed contiguous foci uses penicillin and metronidazole. Cefotaxime is a good alternative to penicillin, especially if enteric organisms are suspected. Enteric organisms are also often susceptible to trimethoprim-sulfamethoxazole. Suspicion of infection by staphylococci, or their recovery from an aspirate, should be treated with nafcillin or vancomycin (for discussion of methicillin-resistant *Staphylococcus aureus* [MRSA], see Chapter 37). Treatment may include neurologic consulta-

tion and anticonvulsant and edema therapy if necessary. In their early stages, brain abscesses are areas of focal cerebritis and can be “cured” with antibiotic treatment alone. Encapsulated abscesses require surgical drainage.

► Prognosis

The surgical mortality rate in the treatment of brain abscess is lower than 5%. Untreated cerebral abscesses lead to irreversible tissue destruction and may rupture into the ventricle, producing catastrophic deterioration in neurologic function and death. Because brain abscesses are often associated with systemic illness and systemic infections, the death rate is frequently high in these patients.

VIRAL INFECTIONS

Viral infections of the CNS can involve primarily meninges (meningitis) (see Chapter 38) or cerebral parenchyma (encephalitis) (see Table 23–23). All patients, however, have some degree of involvement of both the meninges and cerebral parenchyma (meningoencephalitis). Many viral infections are generalized and diffuse, but some viruses, notably herpes simplex and some enteroviruses, characteristically cause prominent focal disease. Focal cerebral involvement is clearly evident on neuroimaging procedures. Some viruses have an affinity for specific CNS cell populations. Poliovirus and other enteroviruses can selectively infect anterior horn cells (poliomyelitis) and some intracranial motor neurons.

Although most viral infections of the nervous system have an acute or subacute course in childhood, chronic infections can occur. Subacute sclerosing panencephalitis, for example, represents a chronic indolent infection caused by altered measles virus and is characterized clinically by progressive neurodegeneration and seizures.

Inflammatory reactions within the nervous system may occur during the convalescent stage of systemic viral infections. Parainfectious or postinfectious inflammation of the CNS results in several well-recognized disorders: acute disseminated encephalomyelitis (ADEM; 25% of encephalitis), transverse myelitis, optic neuritis, polyneuritis, and Guillain-Barré syndrome. MRI findings in ADEM are distinctive: demyelinating lesions, seen on T₂ and FLAIR images, are key to the diagnosis. Small and large white matter lesions can mimic findings in multiple sclerosis (MS) but, unusually for MS, may involve gray matter such as cortex, basal ganglia, especially thalamus. Radiologic changes are usually florid when the patient is first seen but occasionally emerge only days to weeks later. Thus serial or repeat scans may be necessary.

Corticosteroids are beneficial. Current practice is to administer massive doses over 5 days, followed by tapering of the dosage over 2–4 weeks. (Older studies used 2–4 mg/kg/d; no comparative dose studies are available.) In refractory patients, IVIG or plasmapheresis (or both) may be effective.

Rarely, ADEM relapses (biphasic acute disseminated encephalomyelitis; biDEM or BDEM). Recurrence more than 3 months after treatment should raise strong suspicion of MS. Congenital viral infections can also affect the CNS. CMV, herpes simplex virus, varicella and (rare now, because of immunization) rubella virus are the most notable causes of viral brain injury in utero.

Treatment of CNS viral infections is usually limited to symptomatic and supportive measures, except for herpes simplex virus: Acyclovir is utilized in some patients with varicella-zoster virus infections of the CNS. West Nile virus, new in the United States, is an arthropod-borne flavivirus. It is found in mosquitoes, birds, and horses, and in 1991 accounted for 27% of hospitalized patients with encephalitis and muscle weakness in New York. Fourteen percent had encephalitis alone, and 6% had aseptic meningitis. CSF antibody studies and PCR (57% positive for viral RNA) were diagnostic aids. The infection is now endemic as far as the western United States, particularly in California.

This disease is often asymptomatic or mild in pediatric patients; paralysis and death occur mostly in the elderly.

ENCEPHALOPATHY OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Neurologic syndromes associated directly with HIV infection include subacute encephalitis, meningitis, myelopathy, polyneuropathy, and myositis. In addition, secondary opportunistic infections of the CNS occur in patients with HIV-induced immunosuppression. *Pneumocystis*, *Toxoplasma*, and CMV infections are particularly common. Progressive multifocal leukoencephalopathy, a secondary papillomavirus infection, and herpes simplex and varicella-zoster infections also occur frequently in patients with HIV infection. Various fungal (especially cryptococcal), mycobacterial, and bacterial infections have been described.

Neurologic abnormalities in these patients can also be the result of noninfectious neoplastic disorders. Primary CNS lymphoma and metastatic lymphoma to the nervous system are the most frequent neoplasms of the nervous system in these patients. See Chapters 31, 37, and 39 for diagnosis and management of HIV infection.

OTHER INFECTIONS

A wide variety of other microorganisms, including *Toxoplasma*, mycobacteria, spirochetes, rickettsiae, amoebae, and mycoplasmas, can cause CNS infections. CNS involvement in these infections is usually secondary to systemic infection or other predisposing factors. Appropriate cultures and serologic testing are required to confirm infections by these organisms. Parenteral antimicrobial treatment for these infections is discussed in Chapter 37.

NONINFECTIOUS INFLAMMATORY DISORDERS OF THE CENTRAL NERVOUS SYSTEM

The differential diagnosis of bacterial, viral, and other microbial infections of the CNS includes disorders that cause inflammation but for which no specific causal organism has been identified. Sarcoidosis, Behçet disease, systemic lupus erythematosus, other collagen-vascular disorders, and Kawasaki disease are examples. In these disorders, CNS inflammation usually occurs in association with characteristic systemic manifestations that allow proper diagnosis. Management of CNS involvement in these disorders is the same as the treatment of the systemic illness.

OTHER PARAINFECTIOUS ENCEPHALOPATHIES

In association with systemic infections or other illnesses, CNS dysfunction may occur in the absence of direct CNS inflammation or infection. Reye syndrome is a prominent example of this type of encephalopathy that often occurs in association with varicella virus or other respiratory or systemic viral infections. In Reye syndrome, cerebral edema and cerebral dysfunction occur, but there is no evidence of any direct involvement of the nervous system by the associated microorganism or inflammation. Cerebral edema in Reye syndrome is accompanied by liver dysfunction and fatty infiltration of the liver. As a result of efforts to discourage use of aspirin in childhood febrile illnesses, the number of patients with Reye syndrome has markedly decreased. The precise relationship, however, between aspirin and Reye syndrome is unclear.

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) can begin in childhood; 2–5% of individuals with MS have symptom onset before age 16 years. Formation of a Pediatric MS Study Group led to a supplementary issue of *Neurology*, summarizing pediatric MS and related disorders. (See Krupp and Hertz citation, included in the references below.) Essential points follow:

- Multiple sclerosis starts with clinical isolated symptoms (CSI) of CNS demyelination. Examples include optic neuritis; transverse myelitis; or brainstem, cerebellar, or hemispheric dysfunction, without fever or encephalopathy (whereas ADEM usually has both).
- Atypical clinical features (think of *other* diagnoses) include fever and involvement of the peripheral nervous system or other organ systems. Aberrant (for MS) laboratory results might include elevated erythrocyte sedimentation rate or marked CSF pleocytosis.
- A diagnosis of MS demands multiple episodes of CNS demyelination, separated in time and space. MRI (many fine-tuned criteria) and spinal fluid changes (oligoclonal bands, IgG index) are key laboratory tests.
- Differential diagnosis includes especially ADEM. Excellent tables, examples, and criteria abound in the supplementary

issue of *Neurology*. Many other infections, metabolic disorders, and degenerative diseases can mimic MS.

- Acute treatment (mainly corticosteroids) and prevention or modulation of relapses is extrapolated from adult studies; pediatric trials are in their infancy.

SYNDROMES PRESENTING AS ACUTE FLACCID PARALYSIS

Flaccid paralysis evolving over hours or a few days suggests involvement of the lower motor neuron complex (see section on Floppy Infant Syndrome, later). Anterior horn cells (spinal cord) may be involved by viral infection (paralytic poliomyelitis) or by paraviral or postviral immunologically mediated disease (acute transverse myelitis). The nerve trunks (polyneuritis) may be diseased as in Guillain-Barré syndrome or affected by toxins (diphtheria or porphyria). The neuromuscular junction may be blocked by tick toxin or botulinum toxin. The paralysis rarely will be due to metabolic (periodic paralysis) or inflammatory muscle disease (myositis). A lesion compressing the spinal cord must be ruled out. The back often is tender to percussion at that site. Plain films may show disk or bone erosion; MRI, a displaced or compressed spinal cord. Several examples with pertinent discussions are included in a recent issue of *Pediatrics in Review* (2007, volume 28; see references at the end of this section).

► Clinical Findings

A. Symptoms and Signs

Features assisting diagnosis are age, a history of preceding or waning illness, the presence (at time of paralysis) of fever, rapidity of progression, cranial nerve findings, and sensory findings (Table 23–24). The examination may show long tract findings (pyramidal tract), causing increased reflexes and a positive Babinski sign. The spinothalamic tract may be interrupted, causing loss of pain and temperature. Back pain, even tenderness to percussion, may occur, as well as bowel and bladder incontinence. Often the paralysis is ascending, symmetrical, and painful (muscle tenderness or myalgia). Laboratory findings occasionally are diagnostic.

B. Laboratory Findings (See Table 23–24)

Examination of CSF is helpful. Imaging studies of the spinal column (plain radiographs) and spinal cord (MRI) are occasionally essential. Viral cultures (CSF, throat, and stool) and titers aid in diagnosing poliomyelitis. A high sedimentation rate may suggest tumor or abscess; the presence of antinuclear antibody may suggest lupus arteritis.

EMG and nerve conduction velocity can be helpful in diagnosing polyneuropathy. Nerve conduction is usually slowed after 7–10 days. Findings in botulism and tick-bite paralysis can be specific and diagnostic. Rarely, elevation of muscle enzymes or even myoglobinuria may aid in diagnosis of myopathic paralysis. Porphyrin urine studies and heavy-metal assays (arsenic, thallium, and lead) can reveal those rare toxic causes of polyneuropathic paralysis.

► Differential Diagnosis

The child who has been well and becomes paralyzed often has polyneuritis. Acute transverse myelitis sometimes occurs in an afebrile child. The child who is ill and febrile at the time of paralysis often has acute transverse myelitis or poliomyelitis. Acute epidural spinal cord abscess (or other compressive lesion) must be ruled out. Poliomyelitis is very rare among the immunized population in the United States. Enterovirus 71 and West Nile disease are two new causes. Paralysis due to tick bites occurs seasonally (spring and summer). The tick is usually found in the occipital hair. Removal is curative.

Paralysis due to botulinum toxin occurs most commonly in those younger than age 6 months (see Chapter 40). Intravenous drug abuse can lead to myelitis and paralysis. Furthermore, chronic myelopathy occurs with two human immunodeficiency virus infections: HTLV-I and HTLV-III (now called HIV-1).

► Complications

A. Respiratory Paralysis

Early and careful attention to oxygenation is essential. Administration of oxygen, intubation, mechanical respiratory assistance, and careful suctioning of secretions may be required. Increasing anxiety and a rise in diastolic and systolic blood pressures are early signs of hypoxia. Cyanosis is a late sign. Deteriorating spirometric findings (forced expiratory volume in 1 second and total vital capacity) may indicate the need for controlled intubation and respiratory support. Blood gases (usually late changes with increased CO₂ and decreased O₂) can aid decisions.

B. Infections

Pneumonia is common, especially in patients with respiratory paralysis. Antibiotic therapy is best guided by results of cultures. Bladder infections occur when an indwelling catheter is required because of bladder paralysis. Recovery from myelitis may be delayed by urinary tract infection.

C. Autonomic Crisis

This may be a cause of death in Guillain-Barré syndrome. Strict attention to vital signs to detect and treat hypotension or hypertension and cardiac arrhythmias in an intensive care setting is advisable, at least early in the course and in severely ill patients.

► Treatment

Most of these syndromes have no specific treatment. Ticks causing paralysis must be removed. Other therapies include the use of erythromycin in *Mycoplasma* infections and botulinum immune globulin in infant botulism. Recognized associated disorders (eg, endocrine, neoplastic, or toxic) should

Table 23–24. Acute flaccid paralysis in children.

	Poliomyelitis (Paralytic, Spinal, and Bulbar), with or without Encephalitis	Guillain-Barré Syndrome (AIDP)	Botulism	Tick-Bite Paralysis	Transverse Myelitis and Neuromyelitis Optica
Etiology	Poliovirus types I, II, and III; other enteroviruses, eg, EV-71; vaccine strain poliovirus (rare); West Nile virus: epidemic in birds; mosquitoes infect horses, humans. EV-71 is hand-foot-mouth disease, rarely paralytic.	Likely delayed hypersensitivity—with T-cell-mediated antiganglioside antibodies. Mycoplasmal and viral infections (EBV, CMV), <i>Campylobacter jejuni</i> , hepatitis B.	<i>Clostridium botulinum</i> toxin. Block at neuromuscular junction. Under age 1, toxin synthesized in bowel by organisms in ingested dust or honey. At older ages toxin ingested in food. Rarely from wound infection.	Probable interference with transmission of nerve impulse caused by toxin in tick saliva.	Usually unknown; multiple viruses (herpes, EBV, varicella, hepatitis A) often postviral (see Guillain-Barré syndrome).
History	None, or inadequate polio immunization. Upper respiratory or GI symptoms followed by brief respite. Bulbar paralysis more frequent after tonsillectomy. Often in epidemics, in summer and early fall.	Nonspecific respiratory or GI symptoms in preceding 5–14 d common. Any season, though slightly lower incidence in summer.	Infancy: dusty environment (eg, construction area), honey. Older: food poisoning. Multiple cases hours to days after ingesting contaminated food.	Exposure to ticks (dog tick in eastern United States; wood ticks). Irritability 12–24 h before onset of a rapidly progressive ascending paralysis.	Rarely symptoms compatible with multiple sclerosis or optic neuritis. Progression from onset to paraplegia often rapid, usually without a history of bacterial infection.
Presenting complaints	Febrile at time of paralysis. Meningeal signs, muscle tenderness, and spasm. Asymmetrical weakness widespread or segmental (cervical, thoracic, lumbar). Bulbar symptoms early or before extremity weakness; anxiety; delirium.	Symmetrical weakness of lower extremities, which may ascend rapidly to arms, trunk, and face. Verbal child may complain of paresthesias. Fever uncommon. Facial weakness early. Miller-Fisher variant presents as ataxia and ophthalmoplegia (rare).	Infancy: constipation, poor suck and cry. “Floppy.” Apnea. Lethargy. Choking (cause of SIDS?). Bulbar palsy. Older: blurred vision, diplopia, ptosis, choking, weakness.	Rapid onset and progression of ascending flaccid paralysis; often accompanied by pain and paresthesias. Paralysis of upper extremities 2nd day after onset. Sometimes acute ataxia presentation.	Root and back pain in about 30–50% of cases. Sensory loss below level of lesion accompanying rapidly developing paralysis. Sphincter difficulties common. Fever (58%).
Findings	Flaccid weakness, usually asymmetrical. Cord level: Lumbar: legs, lower abdomen. Cervical: shoulder, arm, neck, diaphragm. Bulbar: respiratory, lower cranial nerves. Encephalopathy accompanies paralysis in West Nile.	Flaccid weakness, symmetrical, usually greater proximally, but may be more distal or equal in distribution. Rarely cranial nerves IX–XI, III–VI. Miller-Fisher variant: ophthalmoplegia, ataxia. Bulbar involvement may occur. Slight distal impairment of position, vibration, touch; difficult to assess in young children.	Infants: Flaccid weakness. Alert. Eye, pupil, facial weakness. Deep tendon reflexes decreased. Absent suck, gag. Constipation. Older: paralysis accommodation, eye movements. Weak swallow. Respiratory paralysis.	Flaccid, symmetrical paralysis. Cranial nerve and bulbar (respiratory) paralysis, ataxia, sphincter disturbances, and sensory deficits may occur. Some fever. Diagnosis rests on finding tick, which is especially likely to be on occipital scalp.	Paraplegia with areflexia below level of lesion early; later, may have hyperreflexia. Sensory loss below and hyperesthesia or normal sensation above level of lesion. Paralysis of bladder and rectum. Optic neuritis rarely may be present.
CSF	Pleocytosis (20–500+ cells) with PMN predominance in first few days, later monocytic preponderance. Protein frequently elevated (50–150 mg/dL). CSF IgM-positive in West Nile.	Cytoalbuminologic dissociation; ten or fewer mononuclear cells with high protein after first week. Normal glucose. IgG may be elevated. West Nile will have cells; nerves can be involved in a myeloradiculitis.	Normal.	Normal.	Usually no manometric block; CSF may show increased protein, pleocytosis with predominantly mononuclear cells, increased IgG.

(continued)

Table 23–24. Acute flaccid paralysis in children. (Continued)

	Poliomyelitis (Paralytic, Spinal, and Bulbar), with or without Encephalitis	Guillain-Barré Syndrome (AIDP)	Botulism	Tick-Bite Paralysis	Transverse Myelitis and Neuromyelitis Optica
EMG	Denervation after 10–21 d. Nerve conduction normal. Amplitude reduced in West Nile.	Nerve conduction velocities markedly decreased; may be normal early, or if axon only damage (AMAN ^a).	EMG distinctive: BSAP (brief small abundant potentials). Helpful if present; not diagnostic.	Nerve conduction slowed; returns rapidly to normal after removal of tick.	Normal early. Denervation at level of lesion after 10–21 d.
Other studies	Virus in stool and throat. Serial serologic titers IgG, IgM in West Nile. Hyponatremia 30% in West Nile.	Search for specific cause such as infection, intoxication, autoimmune disease. Antiganglioside antibodies to GM ₁ (GQ1b in Miller-Fisher).	Infancy: stool culture, toxin. Rare serum toxin positive. Older: serum (or wound) toxin.	Leukocytosis, often with moderate eosinophilia.	Normal spine x-rays do not exclude spinal epidural abscess. MRI to rule out cord-compressive lesions. Cord may be swollen in myelitis.
Course and prognosis	Paralysis usually maximal 3–5 d after onset. Transient bladder paralysis may occur. Outlook varies with extent and severity of involvement. Note: Mortality greatest from respiratory failure and superinfection. West Nile paralysis may be permanent.	Course progressive over a few days to about 2 wk. Note: Threat greatest from respiratory failure (10%), autonomic crises (eg, widely variable blood pressure, arrhythmia), and superinfection. Majority recover completely. Plasmapheresis may have a role. IVIG. Relapses occasionally occur.	Infancy: supportive. Penicillin. Botulism immune globulin intravenous (BIG-IV). Respiratory support, gavage feeding. Avoid aminoglycosides. Older: penicillin, antitoxin, prolonged respiratory support. Prognosis: excellent. Fatality 3%.	Total removal of tick is followed by rapid improvement and recovery. Otherwise, mortality rate due to respiratory paralysis is very high.	Large degree of functional recovery possible. Corticosteroids are of controversial benefit in shortening duration of acute attack or altering the overall course. Plasmapheresis, IVIG: anecdotal benefit.

^aAMAN is acute motor axonal neuropathy (uncommon variant in the United States).

AIDP, acute inflammatory demyelinating neuropathy; CMV, cytomegalovirus; CSF, cerebrospinal fluid; EBV, Epstein-Barr virus; EMG, electromyogram; EV-71, enterovirus 71; GI, gastrointestinal; IVIG, intravenous immune globulin; MRI, magnetic resonance imaging; PMN, polymorphonuclear neutrophil; SIDS, sudden infant death syndrome.

be treated by appropriate means. Supportive care also involves pulmonary toilet, adequate fluids and nutrition, bladder and bowel care, prevention of decubitus ulcers, and in many cases, psychiatric support.

A. Corticosteroids

These agents are believed by most to be of no benefit in Guillain-Barré syndrome. Autonomic symptoms (eg, hypertension) in polyneuritis may require treatment.

B. Plasmapheresis, Intravenous Immunoglobulin

Plasma exchange or IVIG has been beneficial in moderate or severe cases of Guillain-Barré syndrome. Some clinicians use inability to ambulate as a criterion to use IVIG.

C. Physical Therapy

Rehabilitative measures are best instituted when acute symptoms have subsided and the patient is stable.

D. Antibiotics

Appropriate antibiotics and drainage are required for epidural abscess.

DISORDERS OF CHILDHOOD AFFECTING MUSCLES (TABLE 23–25)

DIAGNOSTIC STUDIES

Serum Enzymes

Creatine kinase reflects muscle damage or “leaks” from muscle into plasma. Blood should be drawn before EMG or muscle biopsy, which may lead to release of the enzyme. Corticosteroids may suppress levels despite very active muscle disease, for example, as in polymyositis.

Electromyography

Electromyography is often helpful in grossly differentiating myopathic from neurogenic processes. Fibrillations occur in both. In the myopathies, very low spikes are more typical, and the motor unit action potentials seen during contraction characteristically are of short duration, are polyphasic, and are increased in number for the strength of the contraction (increased interference pattern). Neurogenic findings include decreased numbers of motor units, which may be polyphasic, larger than normal, or both. The interference pattern is decreased. In myotonic dystrophy, the EMG is characterized by prolonged discharge of electrical activity on movement of the probing needle (so-called “dive-bomber” sound).

Muscle Biopsy

Properly executed (by open biopsy or by using the Bergstrom muscle biopsy needle), this procedure is usually helpful. Histochemical techniques, histogram analysis of muscle fiber types and sizes, and electron microscopy are offering new classifications of the myopathies. Findings common to the muscular dystrophies include variation in the size and shape of muscle fibers, increase in connective tissue, interstitial infiltration of fatty tissue, degenerative changes in muscle fibers, and central location of nuclei.

Dystrophin is a normal intracellular plasma membrane protein in muscle, the gene product missing in Duchenne and Becker muscular dystrophies. Staining the muscle for dystrophin aids in differentiating Duchenne and Becker muscular dystrophies; dystrophin is absent in Duchenne muscular dystrophy and reduced in Becker muscular dystrophy. Electrophoresis can confirm whether the dystrophin is absent or present in small amounts and whether there is a qualitative difference from normal dystrophin, the latter two patterns being characteristic of Becker muscular dystrophy.

Genetic Testing & Carrier Detection

Previously, detection of carriers for Duchenne muscular dystrophy (mothers and sisters of affected boys) rested on creatine kinase elevations (two thirds of patients will have this finding); physical findings of mild dystrophy (large calves and muscle weakness); abnormal muscle EMGs; or biopsy results. All are unreliable for diagnostic purposes.

DNA probes are now available for carrier detection and prenatal diagnosis of Duchenne and Becker muscular dystrophies. Deletions are often (60%) found on the short arm of the X chromosome; it is postulated that all patients and most mothers will show deletions when sufficient probes are developed to search the whole Duchenne genome (perhaps 4000 kb in length).

Amplification of DNA by the PCR test can detect the deletion. Moreover, this technique plus Southern blot analysis can detect abnormal DNA base repeats. For example, in myotonic dystrophy, a GCT triplet excess is currently the most sensitive test for that disease. The tests can be used for intrauterine diagnosis and prediction of whether the triplet is within the normal or mutant range. Thus, in many cases, the greater the number of repeats, the more severely involved the fetus or patient.

Mutations (especially deletions) of survivor motor neuron and neuronal apoptosis inhibitory protein genes on chromosome 5q13 are present in 95% of patients with spinal muscular atrophy (SMA). SMA is the most common cause of inherited neonatal death, occurring in 1 in 10,000 live births.

Finally, Kearns-Sayre progressive external ophthalmoplegia with retinopathy is inherited via maternal cytoplasmic mitochondria. Assay of mutations and deletions from blood or muscle samples are now commercially available.

Genetic testing is increasingly available for common disorders, such as Duchenne and spinal muscle atrophy, as well as less common disorders found in Table 23–25.

Therapy for Duchenne muscular dystrophy continues to be frustrating. Prednisone in low doses has increased muscle strength and prolonged ambulation. Research emphasis is on gene therapy, but there is great difficulty in finding viral vectors able to carry the very large dystrophin gene into muscle cells.

BENIGN ACUTE CHILDHOOD MYOSITIS

Benign acute childhood myositis (myalgia cruris epidemica) is characterized by transient severe muscle pain and weakness affecting mainly the calves and occurring 1–2 days following an upper respiratory tract infection. Although symptoms involve mainly the gastrocnemius muscles, all skeletal muscles appear to be invaded directly by virus; recurrent episodes are due to different viral types. By seroconversion or isolation of the virus, acute myositis has been shown to be largely due to influenza types B and A and occasionally due to parainfluenza and adenovirus.

Agyeman P et al: Influenza-associated myositis in children. *Infection* 2004;32:199 [PMID: 15293074].

MYASTHENIA GRAVIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Weakness, chiefly of muscles innervated by the brainstem, usually coming on or increasing with use (fatigue).
- ▶ Positive response to neostigmine and edrophonium.
- ▶ Acetylcholine receptor antibodies in serum (except in congenital form).

General Considerations

Myasthenia gravis is characterized by easy fatigability of muscles, particularly the extraocular muscles and those of mastication, swallowing, and respiration. In the neonatal period, however, or in early infancy, the weakness may be so constant and general that an affected infant may present nonspecifically as a “floppy infant.” Girls are affected more frequently than boys. The age at onset is older than 10 years in 75% of patients, often shortly after menarche. If diagnosed before age 10 years, congenital myasthenia should be considered in retrospect. Thyrotoxicosis is found in almost 10% of affected female patients. The essential abnormality is a circulating antibody that binds to the acetylcholine receptor protein and thus reduces the number of motor end plates for binding by acetylcholine.

Clinical Findings

A. Symptoms and Signs

1. Neonatal (transient) myasthenia gravis—This disorder occurs in 12–19% of infants born to myasthenic mothers. The condition is due to maternal acetylcholine receptor antibody transferred across the placenta; a thymic factor in the infant may also be involved. Maternal thymectomy may reduce the transference rate.

Table 23-25. Muscular dystrophies, myopathies, myotonias and anterior horn diseases of childhood.

Disease	Genetic Pattern	Age at Onset	Early Manifestation	Involved Muscles	Reflexes
Muscular dystrophies					
Duchenne muscular dystrophy (pseudohypertrophic infantile)	X-linked recessive; autosomal-recessive unusual. 30–50% have no family history.	2–6 y; rarely in infancy.	Clumsiness, easy fatigability on walking, running, and climbing stairs. Walking on toes; waddling gait. Lordosis. (Climbing up on legs rising from supine position—Gower maneuver.)	Axial and proximal before distal. Pelvic girdle; pseudohypertrophy of gastrocnemius (90%), triceps brachii, and vastus lateralis. Shoulder girdle usually later, also articulation difficulties. Eventually cardiomyopathy (50%).	Knee jerks +/- or 0; ankle jerks + to ++.
Becker muscular dystrophy (late onset)	X-linked recessive. (Allele at Xp21).	Childhood (usually later than in Duchenne).	Similar to Duchenne.	Similar to Duchenne.	Similar to Duchenne.
Limb-girdle muscular dystrophy	Autosomal-recessive in 60%; high sporadic incidence. Autosomal dominant forms also identified. 17 known genetic mutations.	Variable; early childhood to adulthood.	Weakness, with distribution according to type. Waddling gait, difficulty climbing stairs. Lordosis.	Characteristic pattern involves the shoulder and pelvic girdle muscles. Truncal and distal muscles affected later.	Usually present.
Facioscapulohumeral muscular dystrophy (Landouzy-Déjérine) Scapuloperoneal variant (rare)	Autosomal dominant; sporadic cases not uncommon. Linkage to 4q35; variable number of (decreased) D4Z4 repeats.	Usually late in childhood and adolescence; rare in infancy, not uncommon in 20s.	Diminished facial movements with inability to close eyes, smile, or whistle. Face may be flat; unlined. Difficulty in raising arms over head. Lordosis. Tripping in scapuloperoneal type.	Facial muscles followed by shoulder girdle, with occasional spread to hips or distal legs (scapuloperoneal variant). (Face may be <i>uninvolved</i> .)	Present
Spinal muscular atrophy (SMA)					
Infantile SMA (Werdnig-Hoffman disease)	Autosomal-recessive. Survival motor neuron on chromosome 5q.	0–2 y.	Floppy infant.	Pelvic and shoulder girdle. Tongue. Intercostal. Fingers and toes spared.	0 or nearly so.
Juvenile SMA (Kugelburg-Welander disease)	Autosomal-recessive. Survival motor neuron on chromosome 5q.	Onset usually after age 2 y (ages 5–15 typical).	Weakness. “Fasciculations” 50%. Rarely a cause of floppy infant.	Same.	Same.
Metabolic myopathies					
Carnitine deficiency (lipid storage myopathy) Primary (rare) Secondary: multiple forms	Genetics variable, often autosomal recessive. Most common variant <i>OCTN2</i> on chromosome 5q.	Infancy to adolescence.	Fasting hypoglycemia and coma; less ketosis than expected. Myopathy. Cardiomyopathy. Fatty liver. Do not confuse with Reye, SIDS.	Weakness variable; may be precipitated by exercise (with resultant myoglobinuria) or fasting.	Normal to decreased.
Kearns-Sayre syndrome					
“Oculocranosomatic syndrome” (ophthalmoplegia and ragged red fibers; progressive external ophthalmoplegia)	Mitochondrial DNA deletion; other hereditary neurologic disorders may be found in patient or family.	Variable; from infancy to second decade; most at about age 10 y.	Ptosis and limitation of eye movements; hearing and visual loss (retinitis pigmentosa); intellectual loss; cerebellar disturbance (ataxia).	Extraocular muscles, often asymmetrical. Variable involvement of axial muscles; cardiac muscles, with conduction defect.	Depressed to +/- or 0.

Muscle Biopsy Findings	Other Diagnostic Tests	Treatment	Prognosis
Degeneration and variation in fiber size; proliferation of connective tissue. Basophilia, phagocytosis. Poor differentiation of fiber types on ATPase reaction; deficiency of type IIB fibers. Dystrophin absent.	EMG myopathic. CK (4000-5000 IU) very high with decrease towards normal over the years. 60% have C-terminal Xp21 deletion on blood, amniotic fluid or chorionic villi. Positive test obviates need for muscle biopsy.	Physical therapy, braces, wheelchair eventually, weight control. Prednisone, deflazacort improve motor function temporarily. Creatine shows some benefit. Stem cell therapies and gene therapies benefit mouse models and may eventually provide new therapeutic options for patients.	10% show nonprogressive mental retardation. Osteoporosis, scoliosis common. Death from cardiac or respiratory failure 10-15 y after diagnosis with 75% of patients dead by age 20.
Similar to above, except type IIB fibers present. Reduced or abnormal size dystrophin.	Similar to above, although muscle enzymes may not be as elevated.	As above. Wheelchair in late childhood or early adult life.	Slower progression than Duchenne, with death usually in adulthood.
Dystrophic muscle changes (see Duchenne). Dystrophin normal. Special stains for sarcoglycan (dystrophin associated glycoprotein [DAG] deficiency).	EMG myopathic. CK variable; many severe cases have sarcoglycan deficiency (severe autosomal recessive type). Must exclude dystrophinopathy and SMA.	Physical therapy, weight control and regular echocardiograms.	Mildly progressive: spread from lower to upper limbs may take 15-20 y. Life expectancy mid to late adulthood.
Predominantly large fibers with scattered tiny atrophic fibers, "moth-eaten" and whorled fibers. Inflammatory response. Little or no fiber splitting, fibrosis, or type 1 fiber predominance.	EMG myopathic. Muscle enzymes usually normal to mildly elevated. 4q35ter deletion. If blood test positive, biopsy unnecessary.	Physical therapy where indicated. Wheelchair in 20%. Inflammation seen in 40% of biopsies; however, corticosteroids are ineffective.	Very slowly progressive, often with plateaus, except in infantile form where there may be difficulties in walking by adolescences. Usually normal life span. Hearing loss in 60%.
Small, group atrophy. Twin peak fiber size. Fiber type grouping. Minimal fibrosis. Group atrophy and fiber type grouping. Small angular fibers.	EMG neuropathic. Nerve conduction, CSF, muscle enzymes normal. 90-95% have deletions or abnormalities in <i>SMN</i> (survival motor neuron) or other genes at band 5q13. Carrier detection available.	Supportive respiratory care, positioning, secretion management. Genetic and ethical counseling. Physical therapy, wheelchair positioning to avoid scoliosis. May walk, usually later lose this ability.	80-95% of patients 4 y or younger die of pneumonia and respiratory failure. Fairly normal life expectancy. 4-40+ y.
Lipid droplets [+/-] ragged red fibers may be present.	Muscle biochemistry (carnitine, CPT enzyme). Urine organic acids (at time of illness). Plasma carnitine: deficiency may be in blood alone or blood and muscle.	Avoid fasting and mitochondrial toxins, eg, ASA, valproic acid. Carbohydrate. Treat acidosis. Carnitine orally.	Variable: occasionally fatal in infants. Progressive weakness, developmental delay, cardiomyopathy may occur.
Mitochondrial abnormalities. Ragged red fibers. Changes in fiber size, usually due to type 2 fiber atrophy.	CK usually normal. ECG with conduction block. CSF protein elevated. Nerve conduction slowed. MRI of brain and brainstem auditory evoked response may be abnormal. Mitochondrial deletions.	Plastic retraction of eyelids. Cardiac support and surveillance. Anticipate diabetes mellitus. Many clinicians treat with mitochondrial cocktail.	Dysphagia may develop (50%) as well as generalized muscle weakness, cardiac conduction block, endocrinopathies and hearing loss. Prognosis poor. In severe cases, spongy vacuolization of brain and brainstem causing dementia.

(continued)

Table 23–25. Muscular dystrophies, myopathies, myotonias and anterior horn diseases of childhood. (Continued)

Disease	Genetic Pattern	Age at Onset	Early Manifestation	Involved Muscles	Reflexes
Congenital myopathies					
Myotonic dystrophy (neonatal onset)	Autosomal dominant triple repeat. Most common form is DM1 on chromosome 19.	At birth.	Decreased fetal movement, respiratory insufficiency, facial weakness, and difficulties in feeding, sucking, and swallowing.	Diffuse hypotonia. Facial and pharyngeal involvement prominent.	Decreased to 0.
“Other” myopathies Central core Nemaline (rod body) Nuclear (including myotubular and Emery-Dreifuss)	Dominant or rarely autosomal recessive. Myotubular and Emery-Dreifuss are both X-linked.	Severe variants present at birth; milder variants (more common) infancy, childhood.	Severe variant, newborns with severe hypotonia and respiratory failure is rare. Later presentation: facial weakness, mild to moderate weakness, even “toe walking” only.	Similar to myotonic dystrophy.	Decreased to 0.
Congenital muscular dystrophy: dystroglycanopathies Fukayama (FCMD) Walker-Warburg (WW) Muscle-eye-brain (MEB)	Recessive; 6 genes identified (including <i>POMT</i>). Associated with abnormalities of glycosylation of dystroglycan.	Birth to 9 mo.	Hypotonia, joint contractures, moderate to severe mental retardation and eye abnormalities (cataracts, microphthalmia, optic nerve hypoplasia).	Heterogenous. Facial (cranial) and somatic. Contracture common.	Variable.
Congenital muscular dystrophy: nondystroglycanopathies	Most common is MDC1A autosomal recessive form. Some forms demonstrate merosin deficiency.	Birth (or early infancy).	Normal IQ in most patients. Hypotonia, hypoventilation and occasional spine stiffness.	Same (merosin negative may involve heart, nerves, and brain).	Same.
Benign congenital hypotonia (Oppenheim)	Variable	Variable	Hypotonia only. Deep tendon reflexes positive. Laboratory tests, biopsy normal.	Somatic muscles (respiratory muscles spared).	Normal to decreased.
Myotonias					
Myotonia congenita (Thomsen)	Autosomal dominant on chromosome 7q. (autosomal recessive cases reported).	Early infancy to late childhood.	Difficulty in relaxing muscles after contracting them, especially after sleep; aggravated by cold, excitement.	Hands especially; muscles may be diffusely enlarged, giving patient herculean appearance.	Normal
Myotonic dystrophy I (Steinert) (childhood and adult form) Myotonic dystrophy II [Proximal myotonic myopathy (PROMM)]	Autosomal dominant triple repeat. Most common form is DM1 on chromosome 19. DM2 is a CCTG repeat in zinc finger protein gene.	Late childhood to adolescence; neonatal and infantile forms increasingly recognized (see above).	Myotonia of grasp, tongue; worsened by cold, emotions. “Hatchet-face.” Nasal voice. Weakness and easy fatigability. Mild to moderate mental retardation noted.	Wasting, weakness of facial muscles, (mastication); sternocleidomastoids, hands. Myotonic phenomena: “bunching up” of muscles of tongue, thenar eminence, finger extensors after tapping with percussion hammer.	In infantile form, marked hyporeflexia.

2. Congenital (persistent) myasthenia gravis—In this form of the disease, the mothers of the affected infants rarely have myasthenia gravis, but other relatives may. Sex distribution is equal. Symptoms are often subtle and not recognized

initially. Differential diagnosis includes many other causes of the “floppy infant” syndrome, such as infant botulism, ocular myopathy, congenital ptosis, and Möbius syndrome (facial nuclear aplasia and other anomalies). Congenital myasthenia

Muscle Biopsy Findings	Other Diagnostic Tests	Treatment	Prognosis
Generalized fiber hypertrophy, delay in maturation. Type I atrophy. Internal nuclei.	EMG myotonic in some (waning amplitude and pitch). Test mother. CK often normal. DNA testing (chromosome 19) for CTG repeat.	Supportive, even respiratory support. Genetic counseling. Cardiac referral for all affected family members to evaluate for heart block.	Severely involved infant may improve dramatically over months; expect mental retardation in this same variant. Life expectancy is shortened.
Distinctive diagnostic histochemistry, eg, "central cores," "nemaline rods," myotubes type II-I fibers of unequal size. Type I fiber predominance and atrophy.	Myopathic EMG.	Supportive. Genetic counseling.	Variable. May shorten life. Death in infancy or severe handicap in severe neonatal form. Scoliosis prominent.
"Dystrophic" changes. Fibrosis. Necrotic fibers. Internal nuclei. ?Regenerative fibers.	Myopathic EMG. CK increased. MRI scans often demonstrate neuronal migration abnormalities in WW and MEB.	Supportive.	Physical and mental handicap lifelong. Virtually all FCMD are of Japanese ancestry. WW has life expectancy of < 3 y. Mental retardation is common in FCMD and MEB, but clinical outcome is variable.
Same. Evaluate for merosin (alamenin-2 deficiency).	Brain imaging normal in pure form. Merosin-deficient form may have white matter abnormalities.	Supportive.	May improve, walk. Scoliosis.
Normal with sophisticated studies (histochemistry, electron microscopy, even metabolic studies).	Use of this diagnosis is shrinking with increasingly sophisticated biochemical (eg, cytochrome oxidase) studies.	Supportive.	Good (by definition). Few documented long-term studies.
Nonspecific and minor changes; type IIB fibers may be absent.	EMG myotonic.	Usually none. Phenytoin, especially in cold weather, may improve muscle functioning.	Normal life expectancy, with only mild disability.
Type I fiber atrophy, type II hypertrophy, sarcoplasmic masses, internal nuclei, phagocytosis, fibrosis, and cellular reaction.	EMG markedly myotonic. Glucose tolerance test, thyroid tests. ECG. Chest x-ray and pulmonary function tests. Immunoglobulins. PCR amplification of CTG repeat on chromosome 19q13 to distinguish DM1 from DM2 form.	Monitor developmental progress. May be candidate for speech and occupational therapy. Ongoing cardiac monitoring.	Frontal baldness, cataracts (85%), gonadal atrophy (85% of males), thyroid dysfunction, diabetes mellitus (20%). Cardiac conduction defects; impaired pulmonary function. Low IgG. Life expectancy decreased. Type II: slowly progressive weakening; good outlook.

ASA, acetylsalicylic acid; CK, creatine kinase; CPT, carnitine palmityl transferase; CSF, cerebrospinal fluid; CT, computed tomography; ECG, electrocardiogram; EMG, electromyogram; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; SIDS, sudden infant death syndrome.

gravis is not caused by receptor antibodies and often responds poorly to therapy. It may result from a genetic abnormality of the acetylcholine receptor protein, postsynaptic membrane structure, or other myoneural transmission defects.

3. Juvenile myasthenia gravis—In this autoimmune form, the symptoms and signs are similar to those in adults. Receptor antibodies are usually present. The patient may be first seen by an ophthalmologist or psychiatrist. The

more prominent signs are difficulty in chewing, dysphagia, a nasal voice, ptosis, and ophthalmoplegia. Pathologic fatigability of limbs, chiefly involving the proximal limb and neck muscles, may be more prominent than the bulbar signs and may lead to an initial diagnosis of conversion hysteria, muscular dystrophy, or polymyositis. Weakness may be limited to ocular muscles only. Associated disorders include autoimmune conditions, especially thyroid disease.

An acute fulminant form of myasthenia gravis has been reported in children aged 2–10 years, who present with rapidly progressive respiratory difficulties. Bulbar paralysis may evolve within 24 hours. The differential diagnosis includes Guillain-Barré syndrome and bulbar poliomyelitis. Administration of anticholinesterase agents establishes the diagnosis and is lifesaving. Rarely, myasthenia can be postinfectious, and slowly resolve to normal.

B. Laboratory Findings

1. Neostigmine test—In newborns and very young infants, the neostigmine test may be preferable to the edrophonium (Tensilon) test because the longer duration of its response permits better observation, especially of sucking and swallowing movements. There is a delay of about 10 minutes before the effect may be manifest. The physician should be prepared to suction secretions, and administer atropine if necessary.

2. Edrophonium test—Testing with edrophonium is used in older children who are capable of cooperating in certain tasks, such as raising and lowering their eyelids and squeezing a sphygmomanometer bulb or the examiner's hands. Ophthalmologic tests of ocular motility with edrophonium are often positive in patients able to cooperate. Maximum improvement occurs within 2 minutes.

3. Other laboratory tests—Serum acetylcholine receptor antibodies or muscle-specific receptor tyrosine kinase (MuSK) are often found in the neonatal and juvenile forms. In juveniles, thyroid studies are appropriate.

C. Electrical Studies of Muscle

Repetitive stimulation of a motor nerve at slow rates (3/s) with recording over the appropriate muscle reveals a progressive fall in amplitude of the muscle potential in myasthenic patients. A maximal stimulus must be given. At higher rates of stimulation (50/s), there may be a transient repair of this defect before the progressive decline is seen. If this study is negative, single-fiber EMG may be helpful diagnostically.

D. Imaging

Chest radiograph and CT scanning in older children may disclose benign thymus enlargement. Thymus tumors are rare in children.

► Treatment

A. General and Supportive Measures

In the newborn or in a child in myasthenic or cholinergic crisis (see item 5 in the following section), suctioning of secretions is essential. Respiratory assistance may be required. Treatment should be conducted by physicians with experience in this disorder.

B. Anticholinesterase Drug Therapy

1. Pyridostigmine bromide—The dosage must be adjusted for each patient. A frequent starting oral dosage is 15–30 mg orally every 6 hours, or 1 mg/kg per dose every 6 hours in pediatric patients.

2. Neostigmine—Fifteen milligrams of neostigmine are roughly equivalent to 60 mg of pyridostigmine bromide. Neostigmine often causes gastric hypermotility with diarrhea, but it is the drug of choice in newborns, in whom prompt treatment may be lifesaving. It may be given parenterally.

3. Atropine—Atropine may be added on a maintenance basis to control mild cholinergic side effects such as hypersecretion, abdominal cramps, and nausea and vomiting.

4. Immunologic intervention—Such intervention is achieved primarily with prednisone and recently with mycophenolate mofetil. Plasmapheresis is effective in removing acetylcholine receptor antibody in severely affected patients. More potent immunomodulators, such as azathioprine, are occasionally necessary.

5. Myasthenic crisis—Relatively sudden difficulties in swallowing and respiration may be observed in myasthenic patients. Edrophonium results in dramatic but brief improvement; this may make evaluation of the condition of the small child difficult. Suctioning, tracheostomy, respiratory assistance, and fluid and electrolyte maintenance may be required.

6. Cholinergic crisis—Cholinergic crisis may result from overdosage of anticholinesterase drugs. The resulting weakness may be similar to that of myasthenia, and the muscarinic effects (diarrhea, sweating, lacrimation, miosis, bradycardia, and hypotension) are often absent or difficult to evaluate. The edrophonium test may help to determine whether the patient is receiving too little of the drug or is manifesting toxic symptoms due to overdosage. Improvement after the drugs are withdrawn suggests cholinergic crisis. A respirator should be available. The patient may require atropine and tracheostomy.

C. Surgical Measures

Early video thoracoscopic thymectomy is beneficial in many patients whose disease is not confined to ocular symptoms; the effects may be delayed. Experienced surgical and postsurgical

care are prerequisites. Thymectomy demonstrates a cure rate of 10–75% and improves symptoms in over half of patients.

► Prognosis

Neonatal (transient) myasthenia presents a great threat to life, primarily because of secretion aspiration. With proper treatment, the symptoms usually begin to disappear within a few days to 2–3 weeks, after which the child usually requires no further treatment. In the congenital (persistent) form, the symptoms may initially be as acute as in the transient variety. More commonly, however, they are relatively benign and constant, with gradual worsening as the child grows older. Fatal cases occur. In the juvenile form, patients may become resistant or unresponsive to anticholinesterase compounds and require corticosteroids or treatment in a hospital where respiratory assistance can be given. The overall prognosis for survival, for remission, and for improvement after therapy with prednisone and thymectomy is favorable. Death in myasthenic or cholinergic crisis may occur unless prompt treatment is given.

PERIPHERAL NERVE PALSIES

1. Facial Weakness

Facial asymmetry may be present at birth or may develop later, either suddenly or gradually, unilaterally or bilaterally. Nuclear or peripheral involvement of the facial nerves results in sagging or drooping of the mouth and inability to close one or both eyes, particularly when newborns and infants cry. Inability to wrinkle the forehead may be demonstrated in infants and young children by getting them to follow a light moved vertically above the forehead. Loss of taste of the anterior two thirds of the tongue on the involved side may be demonstrated in cooperative children by age 4 or 5 years. Playing with a younger child and the judicious use of a tongue blade may enable the physician to note whether the child's face puckers up when something sour (eg, lemon juice) is applied with a swab to the anterior tongue. Ability to wrinkle the forehead is preserved, owing to bilateral innervation, in supranuclear facial paralysis.

Injuries to the facial nerve at birth occur in 0.25–6.5% of consecutive live births. Forceps delivery is the cause in some cases; in others, the side of the face affected may have abutted

in utero against the sacral prominence. Often, no cause can be established.

Acquired peripheral facial weakness (Bell palsy) of sudden onset and unknown cause is common in children. It often follows a viral illness (postinfectious) or physical trauma (eg, cold). It may be a presenting sign of Lyme disease, infectious mononucleosis, herpes simplex, or Guillain-Barré syndrome and is usually diagnosable by the history, physical examination, and appropriate laboratory tests. Chronic cranial nerve VII palsy may be a sign of brainstem tumor.

Bilateral facial weakness in early life may be due to agenesis of the facial nerve nuclei or muscles (part of Möbius syndrome) or may even be familial. Myasthenia gravis, polyneuritis (Miller-Fisher syndrome), and myotonic dystrophy or other congenital myopathies must be considered.

Asymmetrical crying facies, in which one side of the lower lip depresses with crying (this is the normal side) and the other does not, is usually an innocent form of autosomal dominant inherited congenital malformation. The defect in the parent (the asymmetry often improves with age) may be almost inapparent. EMG suggests congenital absence of the depressor angularis muscle of the lower lip. Forceps pressure is often erroneously incriminated as a cause of this innocent congenital anomaly. Occasionally other major (eg, cardiac septal defects) congenital defects accompany the palsy. Authorities vary in the incidence of major anomalies (10%) and extent of investigations; testing for chromosome 22q11 deletion, careful cardiac evaluation, and assessment of serum calcium level may be pertinent.

In the vast majority of cases of isolated peripheral facial palsy—both those due to birth trauma and those acquired later—improvement begins within 1–2 weeks, and near or total recovery of function is observed within 2 months. In severe palsy with inefficient blinking, methylcellulose drops, 1%, should be instilled into the eyes to protect the cornea during the day; at night the lid should be taped down with cellophane tape. Upward massage of the face for 5–10 minutes three or four times a day may help maintain muscle tone. Prednisone therapy (2–4 mg/kg orally for 5–7 days) likely does not aid recovery. In the older child, acyclovir or valacyclovir (herpes antiviral agent) therapy or antibiotics (Lyme disease) may have a role in Bell palsy.

In the few children with permanent and cosmetically disfiguring facial weakness, plastic surgical intervention at age 6 years or older may be of benefit. New procedures, such as attachment of facial muscles to the temporal muscle and transplantation of cranial nerve XI, are being developed.

CHRONIC POLYNEUROPATHY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Insidious onset of weakness and fatigability of the limbs, sometimes with pain or numbness; decreased strength and reflexes.

▶ General Considerations

Polynuropathy is usually insidious in onset and slowly progressive. Children present with disturbances of gait and easy fatigability in walking or running, and slightly less often, weakness or clumsiness of the hands. Pain, tenderness, or paresthesias are mentioned less frequently. Neurologic examination discloses muscular weakness, greatest in the distal portions of the extremities, with steppage gait and depressed or absent deep tendon reflexes. Cranial nerves are sometimes affected. Sensory deficits occur in a stocking-and-glove distribution. The muscles may be tender, and trophic changes such as glassy or parchment skin and absent sweating may occur. Rarely, thickening of the ulnar and peroneal nerves may be felt. In sensory neuropathy the patient may not feel minor trauma or burns, and thus allows trauma to occur.

Known causes include (1) toxins (lead, arsenic, mercurials, vincristine, and benzene); (2) systemic disorders (diabetes mellitus, chronic uremia, recurrent hypoglycemia, porphyria, polyarteritis nodosa, and lupus erythematosus); (3) inflammatory states (chronic or recurrent Guillain-Barré syndrome and neuritis associated with mumps or diphtheria); (4) hereditary, often degenerative conditions, which in some classifications include certain storage diseases, leukodystrophies, spinocerebellar degenerations with neurogenic components, and Bassen-Kornzweig syndrome; and (5) hereditary sensory or combined motor and sensory neuropathies. Polynuropathy

associated with malignancies, vitamin deficiencies, or excessive vitamin B₆ intake are not reported or are exceedingly rare in children.

The most common chronic motor neuropathy of insidious onset often has no identifiable cause. This chronic inflammatory demyelinating neuropathy (CIDP) is assumed to be immunologically mediated and may have a relapsing course. Sometimes facial weakness occurs. CSF protein levels are elevated. Nerve conduction is slowed, and findings on nerve biopsy are abnormal. Immunologic abnormalities are seldom demonstrated, although nerve biopsy findings may show round cell infiltration. Corticosteroids, repeated IVIG, and, occasionally, immunosuppressants may give long-term benefit.

▶ Clinical Findings

Hereditary neuropathy is the most common documented cause of chronic neuropathy in childhood. A careful genetic history (pedigree) and examination and electrical testing (motor and sensory nerve conduction and EMG) of patient and relatives are keys to diagnosis. Genetic tests are available for many of the variants. Nerve biopsy is rarely necessary.

Other hereditary neuropathies may have ataxia as a prominent finding, often overshadowing the neuropathy. Examples are Friedreich ataxia, dominant cerebellar ataxia, and Marinesco-Sjögren syndrome. Finally, some hereditary neuropathies are associated with identifiable and occasionally treatable metabolic errors (see Tables 23–20 and 23–21). These disorders are described in more detail in Chapter 34.

Laboratory diagnosis of chronic polynuropathy is made by measurement of motor and sensory nerve conduction velocities. EMG may show a neurogenic polyphasic pattern. CSF protein levels are often elevated, sometimes with an increased IgG index. Nerve biopsy, with teasing of the fibers and staining for metachromasia, may demonstrate loss of myelin, and to a lesser degree, loss of axons and increased connective tissue or concentric lamellas (so-called onion-skin appearance) around the nerve fiber. Muscle biopsy may show the pattern associated with denervation. Other laboratory studies directed toward specific causes mentioned above include screening for heavy metals and for metabolic, renal, or vascular disorders.

▶ Treatment & Prognosis

Therapy is directed at specific disorders whenever possible. Corticosteroid therapy is used first when the cause is unknown or neuropathy is considered to be due to chronic inflammation (this is not the case in acute Guillain-Barré syndrome (AIDP; acute inflammatory demyelinating neuropathy). Prednisone is initiated at 2–4 mg/kg/d orally, with tapering to the lowest effective dose; it may need to be reinstated when symptoms recur. (Prednisone should probably not be used for treatment of hereditary neuropathy.) Immunomodulating therapy may be safer or “steroid-sparing”;

IVIg, plasmapheresis, mycophenolate mofetil, and rituximab are choices.

The long-term prognosis varies with the cause and the ability to offer specific therapy. In the corticosteroid-dependent group, residual deficits are more frequent.

MISCELLANEOUS NEUROMUSCULAR DISORDERS

FLOPPY INFANT SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ In early infancy, decreased muscular activity, both spontaneous and in response to postural reflex testing and to passive motion.
- ▶ In young infants, “frog posture” or other unusual positions at rest.
- ▶ In older infants, delay in motor milestones.

▶ General Considerations

In the young infant, ventral suspension (ie, supporting the infant with a hand under the chest) normally results in the infant’s holding its head slightly up (45 degrees or less), the back straight or nearly so, the arms flexed at the elbows and slightly abducted, and the knees partly flexed. The “floppy”

infant droops over the hand like an inverted U. The normal newborn attempts to keep the head in the same plane as the body when pulled up from supine to sitting by the hands (traction response). Marked head lag is characteristic of the floppy infant. Hyperextensibility of the joints is not a dependable criterion.

The usual reasons for seeking medical evaluation in older infants are delays in walking, running, or climbing stairs or motor difficulties and lack of endurance. Hypotonia or decreased motor activity is a frequent presenting complaint in neuromuscular disorders but may also accompany a variety of systemic (non-neuromuscular) conditions or, rarely, may be due to certain disorders of connective tissue.

1. Paralytic Group

The hypotonic infant who is weak (appearing paralyzed) usually has a lesion of the lower motor neuron complex (Table 23–26). The child has significant lack of movement against gravity (eg, fails to kick the legs, hold up the arms, or attempt to stand when held) or in response to stimuli such as tickling or slight pain. Infantile progressive spinal muscular atrophy (Werdnig-Hoffman disease) is the most common cause. Neuropathy is rare. Botulism and myasthenia gravis (rare) are neuromuscular junction causes. Myotonic dystrophy and rare myopathies (eg, central core myopathy) are muscle disease entities.

In anterior horn cell or muscle disease, weakness is proximal (ie, in shoulders and hips); finger movement is preserved. Tendon reflexes are absent or depressed; strength (to noxious stimuli) is decreased (paralytic). Intelligence is preserved. Fine motor, language, and personal and social milestones are normal, as measured, for example, on a Denver Developmental Screening Test (DDST, or Denver II) (see Chapter 2).

A. Myopathies

The congenital, relatively nonprogressive myopathies, muscular dystrophy, myotonic dystrophy, polymyositis, and periodic paralysis were discussed earlier in this chapter. Most cases of congenital or early infantile muscular dystrophy reported in the past probably represented congenital myopathies (see Table 23–25). Congenital muscular dystrophy, diagnosed by muscle biopsy, occurs in two forms: (1) a benign form, with gradual improvement in strength; and (2) a severe form, in which either weakness progresses rapidly and death occurs in the first months or year of life or severe disability is present with little or no progression but lifelong marked limitation of activity.

B. Glycogenosis with Muscle Involvement

Glycogen storage diseases are described in Chapter 34. Patients with type II disease (Pompe disease, due to a deficiency of acid maltase) are most likely to present as floppy infants. Muscle cramps on exertion or easy fatigabil-

Table 23–26. Floppy infant: paralytic causes.

Disease	Genetic	Early Manifestations
Infantile progressive spinal muscular atrophy (IP SMA) “Malignant” form (often fatal in infancy-respiratory failure) “Intermediate” form	Autosomal recessive; diagnose by SMN deletion exon 7,8 (98% of cases). Rarely, X-linked SMA, a new (also fatal) variant. Autosomal recessive; same as above. EMG helpful.	In-utero movements decreased in one third. Gradual weakness, delay in gross motor milestones. Weak cry. Abdominal breathing. Poor limb motion (“no kicking”). No deep tendon reflexes. Fasciculations of tongue. Normal personal-social behavior. Onset before age 1 y usual. <i>Progression slower:</i> may be impossible to predict early course of IP SMA. Hand tremors common.
Infantile botulism	Acquired younger than age 1 y (mostly before age 6 mo); botulism spore in stool makes toxin.	Poor feeding. Constipation. Weak cry. Failure to thrive. Lethargy. Facial weakness, ptosis, ocular muscle palsy. Inability to suck, swallow. Apnea. Source: soil dust (outdoor construction workers or family gardeners may bring it home on clothes), honey. EMG helpful, RMNS.
Myasthenia gravis Neonatal transient Congenital persistent	12% of infants born from a myasthenic mother. Mother normal. Rare autosomal recessive (autosomal dominant).	Floppiness. Poor sucking and feeding; choking. Respiratory distress. Weak cry. Autoimmune antibodies from mother. As above; may improve and later exacerbate. Multiple syndromes (rare).
Myotonic dystrophy	Autosomal dominant: in 99% mother transmits gene. DNA testing 98% accurate.	Polyhydramnios; failure of suck, respirations. Facial diplegia. Ptosis. Arthrogryposis. Thin ribs. Later, developmental delay. Examine mother for myotonia, physiognomy. EMG variable in infant.
Neonatal “rare myopathy,” severe variant Nemaline, central core, “minimal change,” etc	Autosomal recessive or dominant.	Virtually all of the rare myopathies may have a severe (even fatal) neonatal or early infant form. Clinical features similar in infancy to infantile myotonic dystrophy. Muscle biopsy for definitive diagnosis.
Congenital muscular dystrophy Fukayama (FCMD) Other	Genetic.	Early onset. Facial weakness. Joint contractures. Severe mental retardation. Seizures. Brain structural abnormalities; MRI helpful. Severe or benign. No mental retardation (see text).
Infantile neuropathy Hypomyelinating (rare)	HSMN most common cause.	Demyelinating or axonal; a rare cause. Rule out mimicking IP SMA (deletion study). EMG, NCV are key studies. Nerve biopsy.
Benign congenital hypotonia	Unknown cause.	Diagnosis of exclusion. Family history variable. Mild to moderate hypotonia with weakness. (This term being used less with increasing genetic, microscopy advances.) Improves with time.

AD, autosomal dominant; AR, autosomal recessive; EMG, electromyogram; HSMN, hereditary sensory motor neuropathy; MRI, magnetic resonance imaging; NCV, nerve conduction velocity; RMNS, repetitive motor nerve stimulation; SMN, survival motor neuron.

ity, rather than floppiness in infancy, is the presenting complaint in type V disease (McArdle phosphorylase deficiency) or in the glycogenosis due to phosphofructokinase deficiency or phosphohexose isomerase inhibition.

C. Myasthenia Gravis

Neonatal transient and congenital persistent myasthenia gravis, with patients presenting as paralytic floppy infants, is described earlier in this chapter.

D. Arthrogryposis Multiplex (Congenital Deformities About Multiple Joints)

This symptom complex, sometimes associated with hypotonia, may be of neurogenic or myopathic origin (or both) and may be associated with a variety of other anomalies. Orthopedic aspects are discussed in Chapter 24.

E. Spinal Cord Lesions

Severe limpness in newborns following breech extraction with stretching or actual tearing of the lower cervical to upper thoracic spinal cord is rarely seen today, owing to improved obstetric delivery. Klumpke lower brachial plexus paralysis may be present; the abdomen is usually exceedingly soft, and the lower extremities are flaccid. Urinary retention is present initially; later, the bladder may function autonomously. MRI of the cervical cord should define the lesion. After a few weeks, spasticity of the lower limbs becomes obvious. Treatment is symptomatic and consists of bladder and skin care and eventual mobilization on crutches or in a wheelchair.

2. Nonparalytic Group

The nonparalytic hypotonic infant often has a damaged brain (Table 23–27). Rarely, tendon reflexes may be depressed or

Table 23–27. Floppy infant: nonparalytic causes.

	Causes	Manifestations
Central nervous system disorders		
Atonic diplegia (prespastic diplegia)	Intrauterine, perinatal asphyxia, cord injury.	Limpness, stupor; poor suck, cry, Moro reflex, and grasp; later, irritability, increased tone and reflexes.
Choreoathetosis	As above; kernicterus.	Hypotonic early; movement disorder emerges later (6–18 mo).
Ataxic cerebral palsy	Same as choreoathetosis.	Same as choreoathetosis.
Syndromes with hypotonia (CNS origin)		
Trisomy 21	Genetic.	All have hypotonia early.
Prader-Willi syndrome	Genetic deletion 15q11.	Hypotonia, hypopentia, hypogonadism, obesity (“H ₃ O”).
Marfan syndrome	Autosomal dominant.	Arachnodactyly.
Dysautonomia	Autosomal recessive.	Respiratory infections, corneal anesthesia.
Turner syndrome	45X, or mosaic.	Somatic stigmata (see Chapter 34).
Degenerative disorders		
Tay-Sachs disease	Autosomal recessive.	Cherry-red spot on macula.
Metachromatic leukodystrophy	Autosomal recessive.	Deep tendon reflexes increased early, polyneuropathy late; mental retardation.
Systemic diseases^a		
Malnutrition	Deprivation, cystic fibrosis, celiac disease.	
Chronic illness	Congenital heart disease; chronic pulmonary disease (eg, bronchopulmonary dysplasia); uremia, renal acidosis.	
Metabolic disease	Mitochondrial; Lowe, Pompe, Leigh disease; hypercalcemia.	
Endocrinopathy	Hypothyroid.	

^aSee elsewhere in text for manifestations.
CNS, central nervous system.

absent; usually, brisk reflexes (with hypotonia) point to “suprasegmental” or cerebral dysfunction. Intrauterine or perinatal insults to brain or upper cord, while sometimes difficult to document, are major causes. (Occasionally, severe congenital myopathies presenting in the newborn period simulate nonparalytic hypotonia.) Persisting severe hypotonia is ominous. Tone will often vary. Spasticity and other forms of cerebral palsy may emerge; hypertonia and hypotonia may occur at varying times or sites in the same infant. Associated choreoathetoid or ataxic movements and developmental delay can clarify the diagnosis. Tendon reflexes are usually increased; pathologic infant reflexes (Babinski and tonic neck) may persist or worsen.

The creatine kinase level and the EMG are usually normal. Prolonged nerve conduction velocities (rare in this situation) point to polyneuritis or leukodystrophy. Muscle biopsy evaluation, using special stains and histographic analysis, often shows a reduction in size of type II fibers associated with decreased voluntary motor activity.

Limpness in the neonatal period and early infancy and subsequent delay in achieving motor milestones are the presenting features in a large number of children with a variety of CNS disorders, including mental retardation, as in

trisomy 21. In many such cases, no specific diagnosis can be made. Close observation and scoring of motor patterns and adaptive behavior, as by the DDST, are helpful.

CEREBRAL PALSY

The term *cerebral palsy* is a nonspecific term used to describe a chronic, static impairment of muscle tone, strength, coordination, or movements. The term implies that the condition is nonprogressive and originated from some type of cerebral insult or injury before birth, during delivery, or in the perinatal period. Other neurologic deficits or disorders (eg, blindness, deafness, or epilepsy) often coexist. Some form of cerebral palsy occurs in about 0.2% of neonatal survivors. The fundamental course, severity, precise manifestations, and prognosis vary widely.

The most common forms of cerebral palsy (75% of cases) involve spasticity of the limbs. A variety of terms denote the specific limb or combination of limbs affected: monoplegia (one limb); hemiplegia (arm and leg on same side of body, but arm more affected than leg); paraplegia (both legs affected with arms unaffected); quadriplegia (all four limbs affected equally).

Ataxia is the second most common form of cerebral palsy, accounting for about 15% of cases. The ataxia frequently affects fine coordinated movements of the upper extremities, but may also involve lower extremities and trunk. An involuntary movement disorder usually in the form of choreoathetosis accounts for 5% of cases and persistent hypotonia without spasticity for 1%.

Depending on the type and severity of the motor deficits, associated neurologic deficits or disorders may occur: seizures in up to 50%, mild mental retardation in 26%, and severe retardation in up to 27%. Disorders of language, speech, vision, hearing, and sensory perception are found in varying degrees and combinations.

The findings on physical examination are variable and are predominantly those of spasticity, hyperreflexia, ataxia, and involuntary movements. Microcephaly is frequently present. In patients with hemiplegia, the affected arm and leg may be smaller and shorter than the unaffected limbs. Cataracts, retinopathy, and congenital heart defects may be indicative of congenital infections such as CMV and rubella.

Appropriate laboratory studies depend on the history and physical findings. MRI scans may be helpful in understanding the full extent of cerebral injury, and occasionally neuroimaging results suggest specific etiologies (eg, periventric-

ular calcifications in congenital CMV infections). Other diagnostic tests that may be considered include genetic studies based on history or MRI findings; urine amino acids and organic acids; and blood amino acids, lactate, pyruvate, and ammonia concentrations.

The determination that a child has cerebral palsy is based in part on excluding other neurologic disorders and following the child for a sufficient amount of time to ascertain the usually static, nonprogressive nature of the disorder.

Treatment and management are directed at assisting the child to attain maximal physical functioning and potential physical, occupational, and speech therapy; orthopedic monitoring and intervention and special educational assistance may all contribute to an improved outcome. Medications and injections (eg, botulinum toxin) for spasticity and seizures are needed in many children. A new treatment, constraint-induced (CI) movement therapy is being studied in controlled trials. Also important is the general support of the parents and family with counseling, educational programs, and support groups.

The prognosis for patients with cerebral palsy depends greatly on the child's IQ, severity of the motor deficits, and degree of incapacity. Aspiration, pneumonia, or other intercurrent infections are the most common causes of death.

In contrast, patients with mild cerebral palsy may improve with age. Some patients experience resolution of their motor deficits by age 7 years. Many children with normal intellect have normal life spans and are able to lead productive, satisfying lives.

The cause is often obscure or multifactorial. No definite etiologic diagnosis is possible in 25% of cases. The incidence is high among infants small for gestational age. Intrauterine hypoxia is a frequent cause. Other known causes are intrauterine bleeding, infections, toxins, congenital malformations, obstetric complications (including birth hypoxia), neonatal infections, kernicterus, neonatal hypoglycemia, metabolic disorders, and a small number of genetic syndromes.

Orthopedics

John D. Polousky, MD
Robert E. Eilert, MD

Orthopedics is the medical discipline that deals with disorders of the neuromuscular and skeletal systems. The most common complaints in orthopedics are pain, loss of function, and deformity. Although the medical history reveals the patient's expectations, the physical examination and radiographic imaging are the most important tools of orthopedic diagnosis.

DISTURBANCES OF PRENATAL ORIGIN

CONGENITAL AMPUTATIONS & LIMB DEFICIENCIES

▶ General Considerations

Congenital amputations are caused by teratogens (eg, drugs or viruses), amniotic bands, or metabolic diseases (eg, diabetes in the mother). Children with congenital limb deficiencies, such as absence of the femur, tibia, or fibula, also have a high incidence of associated congenital anomalies, including genitourinary and cardiac defects and cleft palate. A limb deficiency usually consists of partial absence of structures in the extremity along one side or the other. The effect on structures distal to the amputation varies. For example, in radial club hand, the entire radius is absent, while the thumb may be hypoplastic or absent. Longitudinal bone deficiency is almost always associated with complex tissue defects in the extremity because of abnormalities of the associated nerves and muscles.

▶ Treatment

Mild limb deficiencies can be treated with limb lengthening or contralateral limb shortening, or both. More severe deficiencies are treated with prostheses to compensate for the length discrepancy. For some severe anomalies, surgery to remove a portion of the malformed extremity (eg, foot) is indicated so that a prosthesis can be fitted early.

Lower extremity prostheses are best fitted between ages 12 and 15 months, when walking starts. They are consistently well accepted, because they are necessary for balance and walking. In unilateral upper extremity amputation, fitting the child with a dummy-type prosthesis as early as age 6 months is advantageous because the child becomes accustomed to an extremity of the proper length and to the habit of bimanual manipulation. Children quickly learn how to function with a prosthesis and can lead active lives, even participating in sports. Although myoelectric prostheses have a technologic appeal, most patients find that simpler constructs are more useful in the long run.

DEFORMITIES OF THE EXTREMITIES

1. Metatarsus Varus

Metatarsus varus is a common congenital foot deformity characterized by inward deviation of the forefoot. A vertical crease in the arch is present in rigid deformities. The angulation is located at the base of the fifth metatarsal, and this bone is prominent. Most flexible deformities are secondary to intrauterine positioning pressure and usually resolve spontaneously. Ten to 15% of children with metatarsus varus also have hip dysplasia. A careful hip examination is mandatory. If the deformity is rigid and cannot be manipulated past the midline, it is worthwhile to use a cast changed at intervals of 2 weeks to correct the deformity. So-called corrective shoes do not live up to their name, although they can be used to maintain correction obtained by casting.

Lincoln TL, Suen PW: Common rotational variations in children. *J Am Acad Orthop Surg* 2003;11:312 [PMID: 14565753].

2. Clubfoot (Talipes Equinovarus)

The diagnosis of classic talipes equinovarus, or clubfoot, requires three features: (1) plantarflexion of the foot at the ankle joint (equinus), (2) inversion deformity of the heel (varus), and (3) medial deviation of the forefoot (varus). The incidence of clubfoot is approximately 1:1000 live births. There are three major categories of clubfoot: (1) idiopathic, (2) neurogenic, and (3) those associated with syndromes such as arthrogryposis and Larsen syndrome. Any infant with a clubfoot should be examined carefully for associated anomalies, especially of the spine. Idiopathic clubfeet may be hereditary.

► Treatment

Treatment consists of manipulation of the foot to stretch the contracted tissues on the medial and posterior aspects, followed by splinting to hold the correction. When treatment is instituted shortly after birth, correction is rapid. When treatment is delayed, the foot tends to become more rigid within a matter of days. After full correction is obtained, a night brace is necessary for long-term maintenance of correction. Treatment by casting requires patience and experience, but fewer patients require surgery when attention is paid to details of the Ponsetti technique. If the foot is rigid and resistant to casting, surgical correction by tendon release is appropriate. Fifteen to 50% of patients require surgical correction.

Clubfoot: http://www.marchofdimes.com/professionals/681_1211.asp.

3. Developmental Dysplasia of the Hip Joint

The definition of dysplasia is abnormal growth or development. Dysplasia of the hip encompasses a spectrum of conditions in which there is an abnormal relationship between the proximal femur and the acetabulum. In the most severe condition, the femoral head is not in contact with the acetabulum and is classified as a *dislocated hip*. A *dislocatable hip* is one in which the femoral head lies within the acetabulum at rest but can be dislocated with a provocative maneuver. A *subluxatable hip* is one in which the femoral head comes partially out of the joint with a provocative maneuver. *Acetabular dysplasia* is a term describing insufficient acetabular development on radiograph.

Congenital dislocation of the hip occurs in approximately 1 in 1000 live births. At birth, both the acetabulum and femur are underdeveloped. Dysplasia becomes worse with growth unless the dislocation is corrected. If the dislocation is corrected in the first few days or weeks of life, the dysplasia is completely reversible and a normal hip will develop. In older children with persistent dislocation or subluxation, especially those who have begun walking, dysplasia will

worsen to the point that it is irreversible. For this reason, it is important to recognize the deformity early.

► Clinical Findings

A. Newborn Infant

The diagnosis of hip dislocation in the newborn depends on demonstrating instability of the joint. The infant is placed supine and complete relaxation is obtained by feeding with a bottle if necessary. The examiner's long finger is then placed over the greater trochanter and the thumb over the inner side of the thigh. Both hips are flexed 90 degrees and then slowly abducted from the midline, one hip at a time. With gentle pressure, an attempt is made to lift the greater trochanter forward. A feeling of slipping as the head relocates is a sign of instability (Ortolani sign). When the joint is more stable, the deformity must be provoked by applying slight pressure with the thumb on the medial side of the thigh as the thigh is adducted, thus slipping the hip posteriorly and eliciting a jerk as the hip dislocates (Barlow sign). The signs of instability are more reliable than a radiograph for diagnosing developmental dislocation of the hip in the newborn. Ultrasonography can be used but tends to result in overdiagnosis in the newborn. Asymmetrical skinfolds are present in about 40% of newborns and therefore are not particularly helpful.

B. Infants Aged 1–12 Months

After the first month of life, the signs of instability become less evident. Contractures begin to develop about the hip joint, limiting abduction to less than 90 degrees. It is important to hold the pelvis level to detect asymmetry of abduction. If the knees are at unequal heights when the hips and knees are flexed, the dislocated hip is on the side with the lower knee. If abduction is incomplete on examination, radiographs of the hips are indicated. After 6 weeks of age, radiologic examination is more accurate. Lateral displacement of the femoral head is the most reliable sign. In mild cases, the only radiologic abnormality may be an increased steepness of acetabular alignment and an acetabular angle greater than 35 degrees.

C. Children Older Than 1 Year

If dysplasia of the hip has not been diagnosed during the first year of life and the child begins to walk, there will be a painless limp and a lurch to the affected side. When the child stands on the affected leg, a dip of the pelvis will be evident on the opposite side, owing to weakness of the gluteus medius muscle. This is the Trendelenburg sign and accounts for the unusual swaying gait of children with unilateral hip dislocation. In children with bilateral dislocation, the loss of abduction is almost symmetrical and the findings may not be obvious. As a child with bilateral dislocation of the hips begins to walk, the gait is waddling. The perineum is widened as a

result of lateral displacement of the hips, and there is flexion contracture as a result of posterior displacement of the femoral head. Flexion contracture contributes to a marked lumbar lordosis, and the greater trochanters are easily palpable in their elevated position. Treatment is still possible in the first 2 years of life, but the results are not nearly as good as in children receiving treatment early.

► Treatment

Dislocation or dysplasia diagnosed in the first few weeks or months of life can be treated by Pavlik harness, which maintains reduction by placing the hip in a flexed and abducted position. Forced abduction is contraindicated, because this can lead to avascular necrosis of the femoral head. The use of double or triple diapers is ineffective. An experienced pediatric orthopedic surgeon should supervise treatment of children requiring splints.

In the first 4 months of life, reduction can be obtained by flexing and abducting the hip; no other manipulation is usually necessary. In late cases, preoperative traction for 2–3 weeks relaxes the soft tissues about the hip and draws the femoral head down so it is opposite the acetabulum. Reduction can then be achieved without force under general anesthesia. After reduction, a hip spica cast is used for 6 months. After closed reduction, if the hip is not stable with a reasonable range of motion, open reduction is indicated. If reduction is done at an older age, operations to correct the deformities of the acetabulum and femur may be necessary in addition to the open reduction.

Weinstein SL et al: Developmental hip dysplasia and dislocation: Part I. *Instr Course Lect* 2004;53:523 [PMID: 15116641].

Weinstein SL et al: Developmental hip dysplasia and dislocation: Part II. *Instr Course Lect* 2004;53:531 [PMID: 15116642].

4. Torticollis

Wryneck deformities in infants may be due either to injury to the sternocleidomastoid muscle during delivery or to disease affecting the cervical spine. When contracture of the sternocleidomastoid muscle causes torticollis, the chin is rotated to the side opposite the affected muscle, and the head is tilted toward the side of the contracture. A mass palpable in the midportion of the sternocleidomastoid muscle is not a true tumor but rather fibrous transformation within the muscle. Torticollis is occasionally associated with congenital deformities of the cervical spine, and radiographs of the spine are indicated in all cases. In addition, there is a 20% incidence of hip dysplasia.

In most cases, passive stretching is effective. If the deformity has not been corrected by passive stretching within the first year of life, surgical release of the muscle origin and insertion will correct it. Excising the “tumor” of the sternocleidomastoid muscle creates an unsightly scar and is unnecessary. If the deformity is left untreated, a striking facial asymmetry will persist.

Acute torticollis may follow upper respiratory infection or mild trauma. Rotatory subluxation of the upper cervical spine requires computed tomography for accurate imaging. Traction or a cervical collar usually results in resolution of the symptoms within 1–2 days. Other causes of torticollis include spinal cord or cerebellar tumors, syringomyelia, and rheumatoid arthritis.

Fernandez Cornejo VJ et al: Inflammatory atlantoaxial subluxation (Grisel's syndrome) in children: Clinical diagnosis and management. *Childs Nerv Syst* 2003;19:342 [PMID: 12783261].

GENERALIZED DISORDERS OF SKELETAL OR MESODERMAL TISSUES

1. Arthrogryposis Multiplex Congenita (Amyoplasia Congenita)

► Clinical Findings

Arthrogryposis multiplex congenita is characterized by incomplete fibrous ankylosis (usually bilateral) of many or all joints of the body. Upper extremity contractures usually produce adduction of the shoulders; extension of the elbows; flexion of the wrists; and stiff, straight fingers with poor muscle control of the thumbs. In the lower extremities, common deformities are dislocation of the hips, extension contractures of the knees, and severe clubfeet. The joints are fusiform and the joint capsules decreased in volume due to lack of movement during fetal development. Various investigations have attributed the basic defect to an abnormality of muscle or the lower motor neurons. Muscle development is poor, and muscles may be represented only by fibrous bands.

► Treatment

Passive mobilization of joints is the early treatment. Prolonged casting to correct deformities is contraindicated because it causes further stiffness. Removable splints combined with vigorous physical therapy are the most effective conservative treatments. Surgical release of the affected joints is often necessary. The clubfoot associated with arthrogryposis is very stiff and nearly always requires surgery. Surgery, including capsulotomy, osteotomy, and tendon lengthening, is used to correct deformities of the knees. In the young child, a dislocated hip may be reduced operatively by the medial approach. Multiple operative procedures on the hip joint are contraindicated because worsening stiffness and impaired range of motion may be produced. Affected children are often able to walk if the dislocations and contractures are reduced surgically. The long-term prognosis for physical and vocational independence is guarded. These patients have normal intelligence.

Bernstein RM: Arthrogryposis and amyoplasia. *J Am Acad Orthop Surg* 2002;10:417 [PMID: 12470044].

2. Marfan Syndrome

Marfan syndrome is a connective tissue disorder characterized by unusually long fingers and toes (arachnodactyly); hypermobility of the joints; flatfeet; subluxation of the ocular lenses; other eye abnormalities, including cataract, coloboma, megalocornea, strabismus, and nystagmus; a high-arched palate; a strong tendency to scoliosis; pectus carinatum; and thoracic aortic aneurysms due to weakness of the media of the vessels (see Chapter 35). Serum mucoproteins may be decreased, and urinary excretion of hydroxyproline increased. The condition is easily confused with homocystinuria, because the phenotypic presentation is identical. The two diseases are differentiated by detecting homocystine in the urine of patients with homocystinuria.

Treatment of flatfeet is usually supportive. Scoliosis may require more vigorous treatment by bracing or spine fusion. The long-term prognosis has improved for patients because better treatment for their aortic aneurysms has been devised.

ter Heide H et al: Neonatal Marfan syndrome: Clinical report and review of the literature. *Clin Dysmorphol* 2005;14:81 [PMID: 15770129].

3. Klippel-Feil Syndrome

In Klippel-Feil syndrome some or all of the cervical vertebrae fail to separate. Multiple congenital spinal anomalies may be present, with hemivertebrae and scoliosis. The neck is short and stiff, the hairline is low, and the ears are low-set. Common associated defects include congenital scoliosis, cervical rib, spina bifida, torticollis, web neck, high scapula, renal anomalies, and deafness. If there is evidence of abnormal renal function, renal ultrasound is indicated as well as a hearing test. Scoliotic deformities, if progressive, are an indication for spinal arthrodesis.

Tracy MR et al: Klippel-Feil syndrome: Clinical features and current understanding of etiology. *Clin Orthop Relat Res* 2004;424:183 [PMID: 15241163].

4. Sprengel Deformity

Sprengel deformity is a congenital condition in which one or both scapulas are elevated and small. The child cannot raise the arm completely on the affected side, and torticollis may be present. The deformity occurs alone or in association with Klippel-Feil syndrome. If the deformity is functionally limiting, the scapula may be surgically relocated lower in the thorax. Excision of the upper portion of the scapula improves cosmetic appearance but has little effect on function.

Williams MS: Developmental anomalies of the scapula—the “omo”st forgotten bone. *Am J Med Genet* 2003;120A:583 [PMID: 12884444].

5. Osteogenesis Imperfecta

Osteogenesis imperfecta is a rare genetic connective tissue disease characterized by multiple and recurrent fractures.

The severe fetal type (osteogenesis imperfecta congenita) is characterized by multiple intrauterine or perinatal fractures. Moderately affected children have numerous fractures and are dwarfed as a result of bony deformities and growth retardation. Intelligence is not affected. The shafts of the long bones are reduced in cortical thickness, and wormian bones are present in the skull. Other features include blue sclerae, thin skin, hyperextensibility of ligaments, otosclerosis with hearing loss, and hypoplastic and deformed teeth. In the tarda type, fractures begin to occur at variable times after the perinatal period. There are relatively fewer fractures and deformities in these children. Affected patients are sometimes suspected of having suffered abuse. Osteogenesis imperfecta tarda should be ruled out in any case of nonaccidental trauma with multiple fractures.

Molecular genetic studies have identified more than 150 mutations of the *COL1A1* and *COL1A2* genes, which encode for type I procollagen. Parents without this mutation can be counseled that the likelihood of a second affected child is negligible.

Bisphosphonates show promise for decreasing the incidence of fractures. Surgical treatment involves correction of deformity of the long bones. Multiple intramedullary rods have been used to prevent deformity from fracture malunion. Patients are often confined to wheelchairs during adulthood.

Millington-Ward S et al: Emerging therapeutic approaches for osteogenesis imperfecta. *Trends Mol Med* 2005;11:299 [PMID: 15949772].

6. Osteopetrosis (Osteitis Condensans Generalisata, Marble Bone Disease, Albers-Schönberg Disease)

Osteopetrosis is a rare disorder of osteoclastic resorption of bone, resulting in abnormally dense bones. The marrow spaces are reduced, resulting in anemia. There are two types: a milder autosomal dominant type and a more malignant autosomal recessive type. The findings may appear at any age. On radiologic examination, the bones show increased density, transverse bands in the shafts, clubbing of ends, and vertical striations of long bones. Thickening about the cranial foramina is present, and heterotopic calcification of soft tissues is possible.

The autosomal recessive form of osteopetrosis can be treated successfully by allogeneic bone marrow transplantation.

Tolar J et al: Osteopetrosis. *N Engl J Med* 2004;351:2839 [PMID: 15625335].

7. Achondroplasia (Classic Chondrodystrophy)

Achondroplasia is the most common form of short-limbed dwarfism. The upper arms and thighs are proportionately shorter than the forearms and legs. Findings include bowing

of the extremities, a waddling gait, limitation of motion of major joints, relaxation of the ligaments, short stubby fingers of almost equal length, frontal bossing, moderate hydrocephalus, depressed nasal bridge, and lumbar lordosis. Intelligence and sexual function are normal. The disorder is transmitted in an autosomal dominant manner, but 80% of cases result from new mutations of the fibroblast growth factor receptor-3 (*FGFR3*) gene. Radiographs demonstrate short, thick tubular bones and irregular epiphysal plates. The ends of the bones are thick, with broadening and cupping. Epiphysal ossification may be delayed. Because the spinal canal is narrowed, a herniated disk in adulthood may lead to acute paraplegia. Growth hormone is given to some children with bone dysplasia. Limb lengthening surgery remains controversial.

Carter EM et al: Advances in understanding etiology of achondroplasia and review of management. *Curr Opin Pediatr* 2007;19:32 [PMID: 17224659].

Achondroplasia: <http://www.achondroplasia.co.uk/>.

8. Osteochondrodystrophy (Morquio Disease)

Morquio disease is an autosomal recessive disorder of mucopolysaccharide storage. Skeletal abnormalities include shortening of the spine, kyphosis, scoliosis, shortened extremities, pectus carinatum, genu valgum, and a hypoplastic odontoid with atlantoaxial instability. The child generally appears normal at birth and begins to develop deformities between ages 1 and 4 years as a result of abnormal deposition of mucopolysaccharides.

Radiographs demonstrate wedge-shaped flattened vertebrae and irregular, malformed epiphyses. The ribs are broad and have been likened to canoe paddles. The lower extremities are more severely involved than the upper ones.

The major treatment issue revolves around the prevention of cervical myelopathy. Bone marrow transplantation has been successful in alleviating some of the symptoms.

Krivit W: Allogeneic stem cell transplantation for the treatment of lysosomal and peroxisomal metabolic diseases. *Springer Semin Immunopathol* 2004;26:119 [PMID: 15452666].

GROWTH DISTURBANCES OF THE MUSCULOSKELETAL SYSTEM

SCOLIOSIS

► General Considerations

Scoliosis is characterized by lateral curvature of the spine associated with rotation of the involved vertebrae. Scoliosis is classified by its anatomic location—thoracic, lumbar, and rarely, cervical. The convexity of the curve is designated right or left. Thus a right thoracic scoliosis would denote a thoracic

curve in which the convexity is to the right, which is the most common type of idiopathic curve. A mild degree of posterior curvature of the spine (kyphosis) is normal in the thoracic area. Excessive curvature is pathologic. Mild anterior curvature of the spine (lordosis) is normal in the lumbar and cervical spines. Idiopathic scoliosis generally begins at age 8 or 10 years and usually progresses during growth. In rare instances, infantile scoliosis may be seen in children aged 2 years or younger.

Idiopathic scoliosis is four to five times more common in girls than boys. Eighty percent of cases of scoliosis are idiopathic. Because 30% of family members are also affected, siblings of an affected child should be examined. The disorder is usually asymptomatic in adolescence, but severe curvature can cause pain or loss of pulmonary function in later years. The screening examination for scoliosis is performed by having the patient bend forward 90 degrees with the hands joined in the midline. Asymmetry of the height of the ribs or paravertebral muscles on one side indicates the rotation of the trunk associated with lateral curvature.

Diseases associated with scoliosis include neurofibromatosis, Marfan syndrome, cerebral palsy, muscular dystrophy, poliomyelitis, and myelodysplasia. Between 5% and 7% of cases of scoliosis are due to congenital vertebral anomalies such as a hemivertebra or unilateral vertebral bridge. These curves are more rigid than the common idiopathic curve (see later discussion) and often increase with growth, especially during adolescence.

Idiopathic infantile scoliosis, occurring in children age 2–4 years, is uncommon in the United States but more common in Great Britain. If the rib-vertebral angle of Mehta is less than 20 degrees, the curve will resolve spontaneously. If the angle is greater, the curve will progress. Sciatic scoliosis may result from pressure on the spinal cord or roots by infectious processes or herniation of the nucleus pulposus; the underlying cause must be sought. Secondary curvature will resolve as the primary problem is treated.

► Clinical Findings

A. Symptoms and Signs

Scoliosis in adolescents does not cause significant pain. If a patient has significant pain, seek the underlying cause because the scoliosis is usually secondary to another disorder such as bone or spinal cord tumor. Deformity of the rib cage and asymmetry of the waistline are evident with curvatures of 30 degrees or more. Less severe curvature may be detected by the forward bending test described earlier. This test is designed to detect early abnormalities of rotation that may not be apparent when the patient is standing erect.

B. Imaging

The most valuable radiographs are those taken of the entire spine in the standing position in both the anteroposterior and lateral planes. Usually one primary curvature is evident with a compensatory curvature that develops to balance the

body. At times two primary curvatures may be seen, usually in the right thoracic and left lumbar regions. Any left thoracic curvature should be suspected of being secondary to neurologic disease and should prompt a more meticulous neurologic examination. If the curvatures of the spine are balanced (compensated), the head is centered over the center of the pelvis and the patient is “in balance.” If the spinal alignment is uncompensated, the head will be displaced to one side, which produces an unsightly deformity. Rotation of the spine may be measured by scoliometer. Rotation is associated with a marked rib hump as the lateral curvature increases in severity. Deformity of the rib cage causes long-term problems when lung volumes are reduced.

► Treatment

Treatment of scoliosis depends on curve magnitude, skeletal maturity, and risk of progression. Curvatures less than 20 degrees usually do not require treatment unless they show progression. Bracing is controversial but often used for curvatures of 20–40 degrees in a skeletally immature child. Treatment is indicated for any curvature that demonstrates progression on serial radiologic examination. Curvatures greater than 40 degrees are resistant to treatment by bracing. Thoracic curvatures greater than 60 degrees have been correlated with poor pulmonary function in adult life. Curvatures of such severity are an indication for surgical correction and posterior spinal fusion to maintain the correction. Curvatures of 40–60 degrees may also require spinal fusion if they are progressive, are causing decompensation of the spine, or cause unacceptable deformity.

Surgical fusion involves decortication of the bone over the laminae and spinous processes, with the addition of bone graft. Rods, hooks, or pedicle screws maintain postoperative correction, with activity restriction for several months until the bone fusion is solid. Treatment requires a team approach and is best done in centers with full support facilities.

► Prognosis

Compensated small curves that do not progress may be well tolerated throughout life, with minor deformity. Counsel the parents regarding the genetic transmission of scoliosis and caution that their children's backs should be examined as part of routine physical examinations. Early detection allows for simple brace treatment. Severe scoliosis may require correction by spinal arthrodesis, although fusionless techniques are being developed.

Braun JT et al: The use of animal models in fusionless scoliosis investigations. *Spine* 2005;30(Suppl):S35 [PMID: 16138065].
Lonstien JE: Scoliosis: Surgical versus nonsurgical treatment. *Clin Orthop* 2006;443:248 [PMID: 16462448].

SLIPPED CAPITAL FEMORAL EPIPHYSIS

Slipped capital femoral epiphysis (SCFE) is caused by displacement of the proximal femoral epiphysis due to disruption

of the growth plate. The head of the femur is usually displaced medially and posteriorly relative to the femoral neck. The condition occurs in adolescence and is most common in obese males. The cause is unclear, although some authorities have shown experimentally that the strength of the perichondrial ring stabilizing the epiphysal area is sufficiently weakened by hormonal changes during adolescence that excessive body weight can cause a fracture through the growth plate. Hormonal studies in these children are usually normal, although SCFE is associated with hypothyroidism.

Clinically, SCFE is classified as stable or unstable. The condition is stable if the child is able to bear weight on the affected extremity. In unstable SCFE, the child is unable to bear weight. Inability to bear weight in SCFE correlates with increasing rate of avascular necrosis.

The condition occasionally occurs acutely following a fall or direct trauma to the hip. More commonly, vague symptoms occur over a protracted period in an otherwise healthy child who presents with pain and limp. The pain can be referred into the thigh or the medial side of the knee. The hip joint should be examined in any obese child complaining of knee pain. The consistent finding on physical examination is limitation of internal rotation of the hip. The diagnosis may be clearly apparent only in the lateral radiographic view.

Treatment is based on the same principles that govern treatment of any fracture of the femoral neck. The head of the femur is internally fixed to the neck of the femur and the fracture line allowed to heal. The long-term prognosis is guarded because most of these patients continue to be overweight, placing chronic stress on the hip joints. Follow-up studies have shown a high incidence of premature degenerative arthritis in this disease, even in those who do not develop avascular necrosis. The development of avascular necrosis almost guarantees a poor prognosis, because new bone does not readily replace the dead bone at this late stage of skeletal development. About 30% of patients have bilateral involvement, which may occur as late as 1–2 years after the primary episode.

GENU VARUM & GENU VALGUM

Genu varum (bowleg) is normal from infancy through age 2 years. The alignment then changes to genu valgum (knock-knee) until about age 8 years, at which time adult alignment is attained. Criteria for referral to an orthopedist include persistent bowing beyond age 2 years, bowing that is increasing rather than decreasing, bowing of one leg only, and knock-knee associated with short stature.

Bracing may be appropriate. Rarely, an osteotomy is necessary for a severe problem such as Blount disease (proximal tibial epiphysal dysplasia).

Sass P, Hassan G: Lower extremity abnormalities in children. *Am Fam Physician* 2003;68:461 [PMID: 12924829].

TIBIAL TORSION

“Toeing in” in small children is a common parental concern. Tibial torsion is rotation of the leg between the knee and the ankle. Internal rotation amounts to about 20 degrees at birth but decreases to neutral rotation by age 16 months. The deformity is sometimes accentuated by laxity of the knee ligaments, allowing excessive internal rotation of the leg in small children. In children who have a persistent internal rotation of the tibia beyond age 16–18 months, the condition is often due to sleeping with feet turned in and can be reversed with an external rotation splint worn only at night.

FEMORAL ANTEVERSION

Toeing in beyond age 2 or 3 years is usually secondary to femoral anteversion, which is characterized by more internal rotation of the hip compared with external rotation. This femoral alignment follows a natural history of progressive decrease toward neutral during growth. Studies comparing the results of treatment with shoes or braces to the natural history have shown that little is gained by active treatment. Active external rotation exercises, such as skating or bicycle riding, can be encouraged. Osteotomy for rotational correction is rarely required. Children who have no external rotation of hip in extension are candidates for orthopedic consultation.

Lincoln TL, Suen PW: Common rotational variations in children. *J Am Acad Orthop Surg* 2003;11:312 [PMID: 14565753].

COMMON FOOT PROBLEMS

When a child begins to stand and walk, the long arch of the foot is flat with a medial bulge over the inner border of the foot. The forefoot is mildly pronated or rotated inward, with a slight valgus alignment of the knees. As the child grows and joint laxity decreases, the long arch is better supported and more normal relationships occur in the lower extremities. (See also sections on Metatarsus Varus and Clubfoot, earlier.)

1. Flatfoot

Flatfoot is a normal condition in infants. If the heel cord is of normal length, full dorsiflexion is possible with the heel in the neutral position. As long as the heel cord is of normal length and a longitudinal arch is noted when the child is sitting in a non-weight-bearing position, the parents can be assured that a normal arch will probably develop. There is usually a familial incidence of relaxed flatfeet in children who have no apparent arch. In any child with a shortened heel cord or stiffness of the foot, other causes of flatfoot such as tarsal coalition or vertical talus should be ruled out by a complete orthopedic examination and radiograph.

In the child with an ordinary relaxed flatfoot, no active treatment is indicated unless calf or leg pain is present. In

children who have leg pains attributable to flatfoot, a supportive shoe with scaphoid pad, such as a good-quality sports shoe, is useful. An orthotic that holds the heel in neutral and supports the arch may relieve discomfort if more support is needed. An arch insert should not be prescribed unless passive correction of the arch is easily accomplished; otherwise, the skin over the medial side of the foot will be irritated.

2. Talipes Calcaneovalgus

Talipes calcaneovalgus is characterized by excessive dorsiflexion at the ankle and eversion of the foot. It is often present at birth and is due to intrauterine position. Treatment consists of passive exercises, stretching the foot into plantarflexion. In rare instances, it may be necessary to use plaster casts to help with manipulation and positioning. Complete correction is the rule.

Gore AI, Spencer JP: The newborn foot. *Am Fam Physician* 2004;69:865 [PMID: 14989573].

3. Cavus Foot

This deformity consists of an unusually high longitudinal arch of the foot. It may be hereditary or associated with neurologic conditions such as poliomyelitis, Charcot-Marie-Tooth disease, Friedreich ataxia, and diastematomyelia. There is usually an associated contracture of the toe extensor, producing a claw toe deformity in which the metatarsophalangeal joints are hyperextended and the interphalangeal joints acutely flexed. Any child presenting with cavus feet should receive a careful neurologic examination and radiographs of the spine.

Conservative therapy is ineffective. In symptomatic cases, surgery may be necessary to lengthen the contracted extensor and flexor tendons and to release the plantar fascia and other tight plantar structures. The associated varus heel deformity causes more problems than the high arch.

Statler TK, Tullis BL: Pes cavus. *J Am Podiatr Med Assoc* 2005; 95:42 [PMID: 15659413].

4. Bunions (Hallux Valgus)

Adolescents may present with lateral deviation of the great toe associated with a prominence over the head of the first metatarsal. This deformity is painful only with shoe wear and almost always can be relieved by fitting shoes that are wide enough in the toe. Surgery should be avoided in the adolescent, because further growth tends to cause recurrence of the deformity.

Talab YA: Hallux valgus in children: A 5–14-year follow-up study of 30 feet treated with a modified Mitchell osteotomy. *Acta Orthop Scand* 2002;73:195 [PMID: 12079019].

DEGENERATIVE PROBLEMS (ARTHRITIS, BURSITIS, & TENOSYNOVITIS)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Chronic condition.
- ▶ May result from overuse in adolescent athletes.
- ▶ Rule out more serious conditions first.

Degenerative arthritis may follow childhood skeletal problems, such as infection, slipped capital femoral epiphysis, avascular necrosis, or trauma, or it may occur in association with hemophilia. Early effective treatment of these disorders can prevent arthritis. Degenerative changes in the soft tissues around joints may occur as a result of overuse syndrome in adolescent athletes. Young boys throwing excessive numbers of pitches, especially curve balls, may develop “Little League” elbow, consisting of degenerative changes around the humeral condyles associated with pain, swelling, and limitation of motion (see Chapter 25). Limitation of the number of pitches thrown by Little League pitchers is the key to prevention.

Acute bursitis is uncommon in childhood, and other causes should be ruled out before this diagnosis is accepted.

Tenosynovitis is most common in the region of the knees and feet. Children taking dancing lessons, particularly toe dancing, may have pain around the flexor tendon sheaths in the toes or ankles. Rest is effective treatment. At the knee level, the patellar ligament may be irritated, with associated swelling in the infrapatellar fat pad. Synovitis in this area is usually due to overuse and is treated by rest and nonsteroidal anti-inflammatory drugs. Corticosteroid injections are contraindicated.

TRAUMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Directed physical examination shows swelling, tenderness, deformity, or instability.
- ▶ Radiographic findings are consistent with forceful injury.
- ▶ Rule out physeal fracture.

SOFT TISSUE TRAUMA (SPRAINS, STRAINS, & CONTUSIONS)

A *sprain* is the stretching of a ligament. A *strain* is a stretch of a muscle or tendon. *Contusions* are generally due to tissue

compression, with damage to blood vessels within the tissue and the formation of hematoma. A severe sprain is one in which the ligament is completely disrupted, resulting in instability of the joint. In a mild or moderate sprain, tearing of the ligament is incomplete, but local pain and swelling results. Mild or moderate sprain is not associated with instability of the joint.

The initial treatment of mild or moderate sprain consists of ice, compression, and elevation. Brief splinting followed by early range of motion of the affected joint protects against further injury and relieves swelling and pain. Ibuprofen and other nonsteroidal anti-inflammatory drugs are useful for pain.

In more severe trauma with tearing of a ligament, instability of the joint may be demonstrated by gross examination or by stress testing with radiographic documentation. Such deformity of the joint may cause persistent instability resulting from inaccurate apposition of the ligament ends during healing. If instability is evident, surgical repair of the torn ligament may be indicated. If a muscle is torn at its tendinous insertion, it should be repaired.

1. Ankle Sprains

The history will indicate that the injury was by either forceful inversion or eversion. The more common inversion injury results in tearing or injury to the lateral ligaments, whereas an eversion injury will injure the medial ligaments of the ankle. The injured ligaments may be identified by means of careful palpation for point tenderness around the ankle. The joint should be supported or immobilized at a right angle, which is the functional position. Use of an air splint produces joint rest, and the extremity can be protected by using crutches. Functional rehabilitation, including edema control, range-of-motion exercises, strengthening, and restitution of proprioceptive sensation, can prevent long-term disability.

Ivins D: Acute ankle sprain: An update. *Am Fam Physician* 2006;74:1714 [PMID: 17137000].

2. Knee Sprains

Sprains of the collateral and cruciate ligaments are uncommon in children. These ligaments are so strong that it is more common to injure the growth plates, which are the weakest structures in the knees of children. In adolescence, however, the physes have started to close, and the knee joint is more like that of an adult. Rupture of the anterior cruciate ligament can result from a rotational injury (see Chapter 25). If the injury produces avulsion of the tibial spine, anatomic reduction and fixation is often required.

Effusion of the knee after trauma should be referred to an orthopedic specialist. The differential diagnosis includes torn ligament, torn meniscus, and osteochondral fracture. Non-traumatic effusion should be evaluated for inflammatory conditions (eg, juvenile rheumatoid arthritis) or patellar malalignment.

Vaquero J et al: Intra-articular traumatic disorders of the knee in children and adolescents. *Clin Orthop Relat Res* 2005;432:97 [PMID: 15738809].

3. Internal Derangements of the Knee

Meniscal injuries are uncommon in children younger than age 12 years. Clicking or locking of the knee may occur in young children as a result of a discoid lateral meniscus, a rare congenital anomaly. As the child approaches adolescence, internal damage to the knee from a torsion weight-bearing injury may cause tearing and displacement of a meniscus and result in locking of the knee. Osteochondral fractures secondary to osteochondritis dissecans may also present as internal derangements of the knee in adolescence. Post-traumatic synovitis may mimic a meniscal lesion. In any severe injury to the knee, epiphyseal injury should be suspected. Stress films will sometimes demonstrate separation of the distal femoral epiphysis in such cases. Epiphyseal injury should be suspected whenever tenderness is present on both sides of the metaphysis of the femur after injury.

Smith AD: The skeletally immature knee: What's new in overuse injuries. *Instr Course Lect* 2003;52:691 [PMID: 12690894].

4. Back Sprains

Sprains of the ligaments and muscles of the back are unusual in children but may occur as a result of violent trauma from automobile accidents or athletic injuries. Back pain in a child may be the only symptom of significant disease and warrants clinical investigation. Inflammation, infection, renal disease, or tumors can cause back pain in children, and sprain should not be accepted as a routine diagnosis.

Balagué F et al: Low-back pain in children. *Lancet* 2003;361:1403 [PMID: 12727390].

Wall EJ et al: Backpacks and back pain: Where's the epidemic? *J Pediatr Orthop* 2003;23:437 [PMID: 12826938].

5. Contusions

Contusion of muscle with hematoma formation produces the familiar "charley horse" injury. Treatment of such injuries is by application of ice, compression, and rest. Exercise should be avoided for 5–7 days. Local heat may hasten healing once the acute phase of tenderness and swelling is past.

6. Myositis Ossificans

Ossification within muscle occurs when there is sufficient trauma to cause a hematoma that later heals in the manner of a fracture. The injury is usually a contusion and occurs most commonly in the quadriceps of the thigh or the triceps of the arm. When a severe injury with hematoma is recognized, it is important to splint the extremity and avoid activity. If further trauma causes recurrent injury, ossification may reach spectacular proportions and resemble an osteosarcoma.

Disability is great, with local swelling and heat and extreme pain on the slightest motion of the adjacent joint. The limb should be rested until the local reaction has subsided (5–7 days). After local heat and tenderness have decreased, gentle active exercises may be initiated. Passive stretching exercises are not indicated, because they may stimulate the ossification reaction. If surgery is necessary, it should not be attempted before 9 months to 1 year after injury, because it may restart the process and lead to an even more severe reaction.

TRAUMATIC SUBLUXATIONS & DISLOCATIONS

Dislocation of a joint is always associated with severe damage to the ligaments and joint capsule. In contrast to fracture reduction, which may be safely postponed, dislocations must be reduced immediately. Dislocations can usually be reduced by gentle sustained traction. It often happens that no anesthetic is necessary for several hours after the injury, because of the protective anesthesia produced by the injury. Following reduction, the joint should be splinted for transportation of the patient. A thorough neurovascular examination should be performed and documented before and after reduction.

The dislocated joint should be treated initially by immobilization followed by graduated active exercises through a full range of motion. Vigorous passive manipulation of the joint by a therapist may be harmful.

1. Subluxation of the Radial Head (Nursemaid Elbow)

Infants may sustain subluxation of the radial head as a result of being lifted or pulled by the hand. The child presents with a painful, fully pronated elbow. The usual complaint is that the child's elbow will not bend. Radiographic findings are normal, but there is point tenderness over the radial head. When the elbow is placed in full supination and slowly moved from full extension to full flexion, a click may be palpated at the level of the radial head. The relief of pain is remarkable, as the child usually stops crying immediately. The elbow may be immobilized briefly in a sling for comfort. Occasionally, symptoms last for several days, requiring more prolonged immobilization.

Pulled elbow may be a clue to child abuse. This should be considered during examination, especially if the problem is recurrent.

2. Recurrent Dislocation of the Patella

Recurrent dislocation of the patella is more common in loose-jointed individuals, especially adolescent girls. If the patella completely dislocates, it nearly always goes laterally. Pain is severe, and the patient is brought to the physician with the knee slightly flexed and an obvious bony mass lateral to the knee joint associated with a flat area over the anterior

knee. Radiologic examination confirms the diagnosis. The patella may be reduced by extending the knee and placing slight pressure on the patella while gentle traction is exerted on the leg. In subluxation of the patella, the symptoms may be more subtle, and the patient will complain that the knee “gives out” or “jumps out of place.”

In patients with first-time dislocation, the initial treatment should be nonoperative, consisting of physical therapy to strengthen the quadriceps, hips, and core stabilizers. Surgery is reserved for individuals with reparable osteochondral injuries, loose bodies, and recurrent dislocation following appropriate nonoperative therapy.

Stefancin JJ, Parker RD: First-time traumatic patellar dislocation: A systematic review. *Clin Orthop* 2007;455:93 [PMID: 17279039].

FRACTURES

1. Epiphyseal Separations

In children, epiphyseal separations and fractures are more common than ligamentous injuries. This finding is based on the fact that the ligaments of the joints are generally stronger than the associated growth plates. In instances in which dislocation is suspected, a radiograph should be taken to rule out epiphyseal fracture. Radiographs of the opposite extremity, especially for injuries around the elbow, may be valuable for comparison. Reduction of a fractured epiphysis should be done under anesthesia to align the growth plate with the least amount of force. Fractures across the growth plate may produce bony bridges that will cause premature cessation of growth or angular deformities of the extremity. Epiphyseal fractures around the shoulder, wrist, and fingers can usually be treated by closed reduction, but fractures of the epiphyses around the elbow often require open reduction. In the lower extremity, accurate reduction of the epiphyseal plate is necessary to prevent joint deformity if a joint surface is involved. If angular deformities result, corrective osteotomy may be necessary.

Mehlman CT: Growth plate fractures. Available at: <http://www.emedicine.com/orthoped/topic627.htm>.

2. Torus Fractures

Torus fractures consist of “buckling” of the cortex due to compression of the bone. They usually occur in the distal radius or ulna. Alignment is usually satisfactory, and simple immobilization for 3 weeks is sufficient.

3. Greenstick Fractures

Greenstick fractures involve frank disruption of the cortex on one side of the bone but no discernible cleavage plane on the opposite side. These fractures are angulated but not displaced, because the bone ends are not separated. Reduction is achieved by straightening the arm into normal alignment, and reduction is maintained by a snugly fitting plaster

cast. Follow-up radiographs should be obtained after 7–10 days to ensure that the reduction has been maintained in the cast. A slight angular deformity can be corrected by remodeling of the bone. The farther the fracture is from the growing end of the bone, the longer the time required for remodeling. The fracture can be considered healed when no tenderness or local heat is present and when adequate bony callus is seen on radiograph.

4. Fracture of the Clavicle

Clavicular fractures are very common injuries in infants and children. The arm can be immobilized in a sling for comfort. The healing callus will be apparent when the fracture has consolidated, but this unsightly lump will generally resolve over a period of months to a year. (See also Chapter 25.)

5. Supracondylar Fractures of the Humerus

Supracondylar fractures tend to occur in children aged 3–6 years and are potentially dangerous because of the proximity to the brachial artery in the distal arm. As they are usually associated with significant trauma, swelling may be severe. Most often, these fractures are treated by closed reduction and percutaneous pinning. Complications associated with supracondylar fractures include Volkmann ischemic contracture of the forearm due to vascular compromise and cubitus varus (decreased carrying angle) secondary to poor reduction. The so-called gunstock deformity of the elbow may be somewhat unsightly but does not usually interfere with joint function.

Gosens T, Bongers KJ: Neurovascular complications and functional outcome in displaced supracondylar fractures of the humerus in children. *Injury* 2003;34:267 [PMID: 12667778].

6. General Comments on Other Fractures in Children

Reduction of fractures in children is usually accomplished by simple traction and manipulation; open reduction is indicated if a satisfactory alignment is not obtained. Remodeling of the fracture callus usually produces an almost normal appearance of the bone over a matter of months. The younger the child, the more remodeling is possible. Angular deformities remodel reliably. Rotatory malalignment does not remodel.

The physician should be suspicious of child abuse whenever the age of a fracture does not match the history given or when the severity of the injury is more than the alleged accident would have produced. In suspected cases of battering in which no fracture is present on the initial radiograph, a repeat radiograph 10 days later is in order. Bleeding beneath the periosteum will be calcified by 7–10 days, and the radiographic appearance is almost diagnostic of severe closed trauma characteristic of a battered child.

INFECTIONS OF THE BONES & JOINTS

OSTEOMYELITIS

Osteomyelitis is an infectious process that usually starts in the spongy or medullary bone and then extends to involve compact or cortical bone. The lower extremities are most often affected, and there is commonly a history of trauma. Osteomyelitis may occur as a result of direct bacterial invasion through a penetrating wound or open fracture, but hematogenous spread of infection (eg, pyoderma or upper respiratory tract infection) from other infected areas is much more common. The most common infecting organism is *Staphylococcus aureus*, which has a tendency to infect the metaphyses of growing bones. Anatomically, circulation in the long bones is such that the blood supply to the metaphysis just below the growth plate is provided by end arteries, which turn sharply to end in venous sinusoids, causing a relative stasis. In the infant younger than age 1 year, there is direct vascular communication with the epiphysis across the growth plate, so that direct spread may occur from the metaphysis to the epiphysis and subsequently into the joint. In the older child, the growth plate provides an effective barrier, the epiphysis is usually not involved. In the older child, infection spreads retrograde from the metaphysis into the diaphysis, and by rupture through the cortical bone and along the diaphysis beneath the periosteum.

1. Exogenous Osteomyelitis

To avoid osteomyelitis by direct extension, all wounds must be carefully cleansed. Osteomyelitis is a common occurrence from pressure sores in anesthetic areas, as in patients with spina bifida. Cultures of the wound at the time of exploration and debridement may be useful if signs of infection develop subsequently. Copious irrigation is necessary, and all nonviable skin, subcutaneous tissue, fascia, and muscle must be excised. In extensive or contaminated wounds, antibiotic coverage is indicated. Contaminated lacerations should be left open and secondary closure performed 3–5 days later. At the time of delayed closure, any remaining necrotic tissue should be excised. Leaving the wound open allows the infection to stay at the surface rather than extend inward to the bone. Puncture wounds are especially liable to cause osteomyelitis and should be carefully debrided.

Initially, broad-spectrum antibiotics should be administered, but the final choice of antibiotics is directed by culture results. A tetanus toxoid booster may be indicated. Gas gangrene is best prevented by adequate debridement. After exogenous osteomyelitis has become established, treatment becomes more complicated, requiring extensive surgical debridement and intravenous antibiotics.

2. Hematogenous Osteomyelitis

Hematogenous osteomyelitis is usually caused by pyogenic bacteria; 85% of cases are due to staphylococci. Streptococci

are a less common cause of osteomyelitis. *Pseudomonas* organisms are common in cases of nail puncture wounds. Children with sickle cell anemia are especially prone to osteomyelitis caused by *Salmonella* spp.

▶ Clinical Findings

A. Symptoms and Signs

In infants, the manifestations of osteomyelitis may be subtle, presenting as irritability, diarrhea, or failure to feed properly; the temperature may be normal or slightly low; and the white blood cell count may be normal or only slightly elevated. There may be pseudoparalysis of the involved limb. In older children, the manifestations are more striking, with local tenderness and pain, high fever, rapid pulse, and elevated white blood cell count, erythrocyte sedimentation rate (ESR), and C-reactive protein. Osteomyelitis of a lower extremity often occurs around the knee joint in children aged 7–10 years. Tenderness is most marked over the metaphysis of the bone where the process originates. Lower extremity osteomyelitis should be ruled out in any child who refuses to bear weight.

B. Laboratory Findings

Blood cultures are often positive early. The most significant test in infancy is the aspiration of pus. It is useful to needle the bone in the area of suspected infection and aspirate any fluid present. This fluid should be stained for organisms and cultured. Even edema fluid may be useful for determining the causative organism. Elevation of the ESR above 50 mm/h is typical for osteomyelitis. C-reactive protein is elevated earlier than the ESR.

C. Imaging

Nonspecific local swelling is the first radiographic finding, followed by elevation of the periosteum. Formation of new bone from the cambium layer of the periosteum occurs after 3–6 days. As the infection becomes chronic, areas of cortical bone are isolated by pus spreading down the medullary canal, causing rarefaction and demineralization of the bone. Such isolated pieces of cortex become ischemic and form sequestra (dead bone fragments). These radiographic findings are late but specific. Osteomyelitis should be diagnosed clinically before significant radiographic findings are present. Bone scan is sensitive but nonspecific and should be interpreted in the clinical context before radiographic findings become positive. Magnetic resonance imaging can demonstrate edema early or soft-tissue thickening later.

▶ Treatment

A. Specific Measures

Antibiotics should be started intravenously as soon as the diagnosis of osteomyelitis is made. Oral antibiotics are begun

when tenderness, fever, the white cell count, and the C-reactive protein are all decreasing and the culture is positive. Agents that cover *S aureus* and *Streptococcus pyogenes* (eg, oxacillin, nafcillin, cefazolin, and clindamycin) are appropriate for most cases. For specific recommendations and for possible *Pseudomonas* infection, see Chapter 40. Chronic infections are treated for months. Following surgical debridement, *Pseudomonas* foot infections usually respond to 1–2 weeks of antibiotic treatment.

B. General Measures

Splinting of the limb minimizes pain and decreases spread of the infection by lymphatic channels through the soft tissue. The splint should be removed periodically to allow active use of adjacent joints and prevent stiffening and muscle atrophy. In chronic osteomyelitis, splinting may be necessary to guard against fracture of the weakened bone.

C. Surgical Measures

Aspiration of the metaphysis for culture and Gram stain is the most useful diagnostic measure in any case of suspected osteomyelitis. In the first 24–72 hours, it may be possible to treat osteomyelitis with antibiotics alone. If frank pus is aspirated from the bone, however, surgical drainage is indicated. If the infection has not shown a dramatic response within 24 hours, surgical drainage is also indicated. It is important that all devitalized soft tissue be removed and adequate exposure of the bone obtained to permit free drainage. Excessive amounts of bone should not be removed when draining acute osteomyelitis, because it will not be completely replaced by the normal healing process. Bone damage is limited by surgical drainage, whereas failure to evacuate pus in acute cases may lead to widespread damage.

► Prognosis

When osteomyelitis is diagnosed in the early clinical stages and prompt antibiotic therapy is begun, the prognosis is excellent. If the process has been unattended for 7–10 days, there is almost always some permanent loss of bone structure, as well as the possibility of growth abnormality.

Moumille K et al: Bacterial aetiology of acute osteoarticular infections in children. *Acta Paediatr* 2005;94:419 [PMID: 16092454].

PYOGENIC ARTHRITIS

The source of pyogenic arthritis varies with age. In the infant, pyogenic arthritis often develops by spread from adjacent osteomyelitis. In the older child, it presents as an isolated infection, usually without bony involvement. In teenagers with pyogenic arthritis, an underlying systemic disease or infection with an organism (eg, gonococcus) that has an affinity for joints is usually the cause.

The infecting organism also varies with age: group B streptococcus and *S aureus* in those younger than age 4 months; *Haemophilus influenzae* and *S aureus* in those aged 4 months to 4 years; and *S aureus* and *S pyogenes* in older children and adolescents. *H influenzae* is now uncommon because of effective immunization. *Kingella kingae* is a gram-negative bacterium that occasionally causes pyarthrosis.

► Clinical Findings

A. Symptoms and Signs

In older children, the signs may be striking, with fever, malaise, vomiting, and restriction of motion. In infants, paralysis of the limb due to inflammatory neuritis may be evident. Infection of the hip joint in infants should be suspected if decreased abduction of the hip is present in an infant who is irritable or feeding poorly. A history of umbilical catheter treatment in the newborn nursery should alert the physician to the possibility of pyogenic arthritis of the hip.

B. Laboratory Findings

The initial effusion of the joint rapidly becomes purulent. An effusion of the joint may accompany osteomyelitis in the adjacent bone. A white cell count exceeding 50,000/μL in the joint fluid indicates a definite purulent infection. Generally, spread of infection is from the bone into the joint, but unattended pyogenic arthritis may also affect adjacent bone. The ESR is often above 50 mm/h.

C. Imaging

Early distention of the joint capsule is nonspecific and difficult to measure on radiograph. In the infant with unrecognized pyogenic arthritis, dislocation of the joint may follow within a few days as a result of distention of the capsule by pus. Later changes include destruction of the joint space, resorption of epiphysal cartilage, and erosion of the adjacent bone of the metaphysis. The bone scan shows increased flow and increased uptake about the joint.

► Treatment

Aspiration of the joint is the key to diagnosis. In the hip joint, pyogenic arthritis is most easily treated by surgical drainage because the joint is deep, difficult to aspirate, and inaccessible to thorough cleaning by needle aspiration. Arthroscopic irrigation and debridement have been successful in treating pyogenic arthritis of the knee. If fever and clinical symptoms do not subside within 24 hours after initial treatment, open surgical drainage is indicated. Antibiotics can be selected based on the child's age, results of the Gram stain, and culture of the aspirated pus. Reasonable empiric therapy for infants is nafcillin or oxacillin plus a third-generation cephalosporin. An antistaphylococcal agent alone is usually adequate for children older than age 5 years.

For staphylococcal infections, 3 weeks of therapy is recommended; for other organisms, 2 weeks is usually sufficient. Oral therapy may be begun when clinical signs have improved markedly. It is not necessary to give intra-articular antibiotics, because good levels are achieved in the synovial fluid with parenteral administration.

► Prognosis

The prognosis for the patient with pyogenic arthritis is excellent if the joint is drained early, before damage to the articular cartilage has occurred. If infection is present for more than 24 hours, dissolution of the proteoglycans in the articular cartilage takes place, with subsequent arthrosis and fibrosis of the joint. Damage to the growth plate may also occur, especially within the hip joint, where the epiphyseal plate is intracapsular.

Frank G et al: Musculoskeletal infections in children. *Pediatr Clin North Am* 2005;52:1083 [PMID: 16009258].

TUBERCULOUS ARTHRITIS

Tuberculous arthritis is now a rare disease in the United States, but children in poor social circumstances are at risk for the infection. Generally tuberculous arthritis may be ruled out by negative skin testing. The joints most commonly affected in children are the intervertebral disks, resulting in gibbus or dorsal angular deformity at the site of involvement. Treatment is by local drainage of the abscess, followed by antituberculous therapy. Prolonged immobilization in a plaster cast or prolonged bed rest is necessary to promote healing. Spinal fusion may be required to preserve stability of the vertebral column.

Mkandawire NC, Kaunda E: Bone and joint TB at Queen Elizabeth Central Hospital 1986 to 2002. *Trop Doct* 2005;35:14 [PMID: 15712533].

DISKITIS

Diskitis is pyogenic infectious spondylitis in children; supportive treatment and intravenous antibiotics are likely to lead to rapid relief of symptoms and signs without recurrence.

McCarthy JJ et al: Musculoskeletal infections in children: Basic treatment principles and recent advancements. *Instr Course Lect* 2005;54:515 [PMID: 15948476].

TRANSIENT SYNOVITIS OF THE HIP

The most common cause of limping and pain in the hip in children in the United States is transitory synovitis, an acute inflammatory reaction that often follows an upper respiratory infection. It is generally self-limited. In questionable cases, aspiration of the hip joint yields only yellowish fluid with low protein and few if any neutrophils. Toxic synovitis of the hip

is rarely associated with elevation of the ESR, white blood cell count, or temperature above 38.3°C. It usually affects children aged 3–10 years and is more common in boys than girls. Motion of the hip joint is limited, particularly internal rotation, and radiographic changes are nonspecific, with some swelling apparent in the soft tissues around the joint.

Treatment consists of bed rest and mild traction with slight flexion of the hip. Nonsteroidal anti-inflammatory drugs shorten the course of the disease, although even with no treatment, the disease usually runs its course in days. Follow-up radiographs of the hip are important because toxic synovitis may be the precursor of avascular necrosis of the femoral head in a small percentage of patients. Radiographs can be obtained at 6 weeks, or earlier if either a persistent limp or pain is present.

Yagupsky P: Differentiation between septic arthritis and transient synovitis of the hip in children. *J Bone Joint Surg Am* 2005;87:459; author reply 459 [PMID: 15687174].

VASCULAR LESIONS & AVASCULAR NECROSIS (OSTEOCHONDROSES)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Diagnosis is made by characteristic radiographic findings.
- Radiographic resolution lags behind symptomatic resolution.

Osteochondrosis due to vascular lesions may affect several growth centers. Table 24–1 indicates the common sites and the typical ages at presentation. Although the pathologic and radiographic features of avascular necrosis of the epiphyses are well known, the cause is not generally agreed upon. Necrosis may follow trauma or infection, but idiopathic lesions are common and often occur during periods of rapid growth of the epiphyses.

In contrast to other body tissues that undergo infarction, infarcted bone heals by removal of necrotic tissue replacement with living bone in a process called creeping substitution. Replacement of necrotic bone may be so perfect that a completely normal bone results. Adequacy of replacement depends on the patient's age, the presence or absence of associated infection, the congruity of the involved joint, and other physiologic and mechanical factors.

Because of their rapid growth in relation to their blood supply, the secondary ossification centers in the epiphyses are very susceptible to avascular necrosis. Despite the number of different names referring to avascular necrosis of the epiphyses, the process is identical: necrosis of bone followed by replacement (see Table 24–1).

Table 24-1. The osteochondroses.

Ossification Center	Eponym	Typical Age (y)
Capital femoral	Legg-Calvé-Perthes disease	4-8
Tarsal navicular	Köhler bone disease	6
Second metatarsal head	Freiberg disease	12-14
Vertebral ring	Scheuermann disease	13-16
Capitellum	Panner disease	9-11
Tibial tubercle	Osgood-Schlatter disease	11-13
Calcaneus	Sever disease	8-9

AVASCULAR NECROSIS OF THE PROXIMAL FEMUR (LEGG-CALVÉ-PERTHES DISEASE)

The vascular supply of the proximal femur is precarious, and when it is interrupted, necrosis results.

▶ Clinical Findings

A. Symptoms and Signs

The highest incidence of Legg-Calvé-Perthes disease is between ages 4 and 8 years. Persistent pain is the most common symptom, and the patient may present with limp or limitation of motion.

B. Laboratory Findings

Laboratory findings, including studies of joint aspirates, are normal.

C. Imaging

Radiographic findings correlate with the progression of the process and the extent of necrosis. The early finding is effusion of the joint associated with slight widening of the joint space and periarticular swelling. Decreased bone density in and around the joint is apparent after a few weeks. The necrotic ossification center appears denser than the surrounding viable structures, and the femoral head is collapsed or narrowed.

As replacement of the necrotic ossification center occurs, rarefaction of the bone occurs in a patchwork fashion, producing alternating areas of rarefaction and relative density, referred to as “fragmentation” of the epiphysis.

In the hip, widening of the femoral head may occur associated with flattening, or coxa plana. If infarction has extended across the growth plate, a radiolucent lesion will be evident within the metaphysis. If the growth center of the femoral head has been damaged so that normal growth is arrested, shortening of the femoral neck results.

Eventually, complete replacement of the epiphysis develops as living bone replaces necrotic bone by creeping substitution. The final shape of the head depends on the extent of the necrosis and collapse of weakened bone.

▶ Differential Diagnosis

Differential diagnosis includes inflammation, infection, and dysplasia. Transient synovitis of the hip may be distinguished from Legg-Calvé-Perthes disease by serial radiographs.

▶ Treatment

The principle of treatment is protection of the joint. If the joint is deeply seated within the acetabulum and normal joint motion is maintained, a reasonably functional hip can result. Little benefit has been shown from bracing.

▶ Prognosis

The prognosis for complete replacement of the necrotic femoral head in a child is excellent, but the functional result depends on the amount of deformity that develops during the time the softened structure exists. In Legg-Calvé-Perthes disease, the prognosis depends on the extent of involvement of the epiphysal center. In general, patients with metaphysal defects, those in whom the disease develops late in childhood, and those who have more complete involvement of the femoral head have a worse prognosis.

Hesse B, Kohler G: Does it always have to be Perthes' disease? What is epiphyseal dysplasia? *Clin Orthop* 2003;414:219 [PMID: 12966296].

Joseph B et al: Natural evolution of Perthes disease: A study of 610 children under 12 years of age at disease onset. *J Pediatr Orthop* 2003;23:590 [PMID: 12960621].

OSTEOCHONDRITIS DISSECANS

In osteochondritis dissecans, a wedge-shaped necrotic area of bone and cartilage develops adjacent to the articular surface. The fragment of bone may be broken off from the host bone and displaced into the joint as a loose body. If it remains attached, the necrotic fragment may be completely replaced by creeping substitution.

The pathologic process is the same as that described previously for avascular necrosing lesions of ossification centers. Because these lesions are adjacent to articular cartilage, however, joint damage may occur. The most common sites of these lesions are the knee (medial femoral condyle), the elbow joint (capitellum), and the talus (superior lateral dome). Joint pain is the usual presenting complaint. However, local swelling or locking may be present, particularly if a fragment is free in the joint. Laboratory studies are normal.

Treatment consists of protecting the involved area from mechanical damage. If a fragment is free-floating within the joint, it must be removed. For some marginal lesions, it may

be worthwhile to drill the necrotic fragment to encourage more rapid vascular ingrowth and replacement. If large areas of a weight-bearing joint are involved, secondary degenerative arthritis may result. Adolescents have less favorable outcomes with nonoperative therapy.

Wall E, Von Stein D: Juvenile osteochondritis dissecans. *Orthop Clin North Am* 2003;34:341 [PMID: 12974484].

NEUROLOGIC DISORDERS INVOLVING THE MUSCULOSKELETAL SYSTEM

ORTHOPEDIC ASPECTS OF CEREBRAL PALSY

Early physical therapy to encourage completion of the normal developmental patterns may benefit patients with cerebral palsy. The greatest gains from this therapy are obtained during the first few years of life, and therapy should not be continued when no improvement is apparent.

Bracing and splinting are of questionable benefit, although night splints may be useful in preventing equinus deformity of the feet or adduction contractures of the hips. Orthopedic surgery is useful for treating joint contractures that interfere with function. In general, muscle transfers are unpredictable in cerebral palsy, and most orthopedic procedures are directed at tendon lengthening or bony stabilization by osteotomy or arthrodesis.

Flexion and adduction of the hip due to hyperactivity of the adductors and flexors may produce a progressive paralytic dislocation of the hip, which can lead to pain and dysfunction. Treatment of this dislocation is difficult and unsatisfactory. The principal preventive measure is abduction bracing, but this must often be supplemented by release of the adductors and hip flexors in order to prevent dislocation. In severe cases, osteotomy of the femur may also be necessary to correct the bony deformities of femoral anteversion and coxa valga that are invariably present. Patients with a predominantly athetotic pattern are poor candidates for any surgical procedure or bracing.

Because it is difficult to predict the outcome of surgical procedures in cerebral palsy, the surgeon must examine patients on several occasions before any operative procedure is undertaken. Follow-up care by a physical therapist to maximize the anticipated long-term gains should be arranged before the operation.

Aiona MD, Sussman MD: Treatment of spastic diplegia in patients with cerebral palsy: Part II. *J Pediatr Orthop B* 2004;13:S13 [PMID: 15083127].

Sussman MD, Aiona MD: Treatment of spastic diplegia in patients with cerebral palsy. *J Pediatr Orthop B* 2004;13:S1 [PMID: 15076595].

ORTHOPEDIC ASPECTS OF MYELODYSPLASIA

Patients born with spina bifida cystica (aperta) should be examined early by an orthopedic surgeon. The level of

neurologic involvement determines the muscle imbalance that will be present and apt to produce deformity with growth. The involvement is often asymmetrical and tends to change during the first 12–18 months of life. Early closure of the sac is the rule, although there has been some hesitancy to provide treatment to all of these patients because of the extremely poor prognosis associated with congenital hydrocephalus, high levels of paralysis, and associated congenital anomalies. A high percentage of these children have hydrocephalus, which may be evident at birth or shortly thereafter, requiring shunting. Associated musculoskeletal problems may include clubfoot, congenital dislocation of the hip, arthrogryposis-type changes of the lower extremities, and congenital scoliosis. The most common lesions are at the level of L3–4 and tend to affect the hip joint, with progressive dislocation occurring during growth. Foot deformities may be in any direction and are complicated by the fact that sensation is generally absent. Spinal deformities develop in a high percentage of these children, with scoliosis present in approximately 40%. Ambulation may require long leg braces. Careful urologic follow-up must be obtained to prevent complications from bladder dysfunction.

In children who have a reasonable likelihood of walking, operative treatment consists of reduction of the hip and alignment of the feet in the weight-bearing position as well as stabilization of the scoliosis. In children who lack active quadriceps function and extensor power of the knee, the likelihood of ambulation is greatly decreased. In such patients, aggressive surgery in the hip region may result in stiffening of the joints, thus preventing sitting. Multiple foot operations are also contraindicated in these children.

The overall treatment of the child with spina bifida should be coordinated in a multidisciplinary clinic where various medical specialists work with therapists, social workers, and teachers to provide the best possible care.

Mazur JM, Kyle S: Efficacy of bracing the lower limbs and ambulation training in children with myelomeningocele. *Dev Med Child Neurol* 2004;46:352 [PMID: 15132267].

NEOPLASIA OF THE MUSCULOSKELETAL SYSTEM

Neoplastic diseases of the musculoskeletal system are a serious problem because of the poor prognosis of malignant tumors arising in bone or other tissues derived from mesoderm. Fortunately, few of the benign lesions undergo malignant transformation. Accurate diagnosis depends on correlation of the clinical, radiographic, and microscopic findings. Complaints about the knee should be investigated for tumor, although the usual causes of knee pain are traumatic, infectious, or developmental in origin.

Lewis VO: Limb salvage in the skeletally immature patient. *Curr Oncol Rep* 2005;7:285 [PMID: 15946588].

OSTEOCHONDROMA

Osteochondroma is the most common bone tumor in children. It usually presents as a pain-free mass. When present, pain is caused by adventitious bursitis or tendinitis due to irritation by the tumor. The lesion may be single or multiple. Pathologically, the lesion is a bone mass capped with cartilage. These masses tend to grow during childhood and adolescence in proportion to the child's growth.

On radiograph, the tumors tend to be in the metaphyseal region of long bones and may be pedunculated or sessile. The cortex of the underlying bone "flows" into the base of the tumor.

An osteochondroma should be excised if it interferes with function, is frequently traumatized, or is large enough to be deforming. The prognosis is excellent. Malignant transformation is very rare.

Bottner F et al: Surgical treatment of symptomatic osteochondroma: A three- to eight-year follow-up study. *J Bone Joint Surg Br* 2003;85:1161 [PMID: 14653600].

OSTEOID OSTEOMA

Osteoid osteoma classically produces night pain that can be relieved by nonsteroidal anti-inflammatory drugs. On physical examination there usually is tenderness over the lesion. An osteoid osteoma in the upper femur may cause pain referred to the knee.

On radiograph, the lesion is a radiolucent nidus surrounded by dense osteosclerosis that may obscure the nidus. Bone scan shows intense uptake in the lesion.

Surgical incision or radiofrequency ablation of the nidus is curative and may be done using computed tomography imaging and minimally invasive technique. The prognosis is excellent, with no known cases of malignant transformation, although the lesion has a tendency to recur.

ENCHONDROMA

Enchondroma is usually a silent lesion unless it produces a pathologic fracture. On radiograph it is radiolucent, usually in a long bone. A speckled calcification may be present. The classic lesion looks as though someone dragged his or her fingernails through clay, making streaks in the bones. Enchondroma is treated by surgical curettage and bone grafting. The prognosis is excellent. Malignant transformation may occur but is very rare in childhood.

CHONDROBLASTOMA

In chondroblastoma, the presenting complaint is pain around a joint. This neoplasm may produce a pathologic fracture. On radiograph, the lesion is radiolucent and usually located in the epiphysis. Calcification is unusual, with little or no reactive bone. The lesion is treated by surgical curettage and bone grafting. The prognosis is excellent if complete curettage is performed. There is no known malignant transformation.

Masui F et al: Chondroblastoma: A study of 11 cases. *Eur J Surg Oncol* 2002;28:869 [PMID: 12477480].

NONOSSIFYING FIBROMA

Nonossifying fibroma is also called benign cortical defect and is nearly always an incidental finding on radiograph. The most frequent sites are the distal femur and proximal tibia. Nonossifying fibroma is a radiolucent lesion eccentrically located in the bone. Usually a thin sclerotic border is evident. Multiple lesions may be present. No treatment is needed because these lesions heal as they ossify with maturation of the bone and growth.

OSTEOSARCOMA

In osteosarcoma, the presenting complaint is usually pain in a long bone, although functional loss, the mass of the tumor, or limp may be the complaint. Pathologic fracture is common. The malignant osseous tumor produces a destructive expanding and invasive lesion. A triangle may be adjacent to the tumor produced by elevated periosteum and subsequent tumor ossification. The lesion may contain calcification and violates the cortex of the bone. Femur, tibia, humerus, and other long bones are the sites usually affected.

Surgical excision (limb salvage) or amputation is indicated based on the extent of the tumor. The lesion is radioreistant and does not respond to radiation therapy. Adjuvant chemotherapy is routinely used prior to surgical excision. The prognosis is improving, with 60–70% long-term survival rates being reported in modern series. Death usually occurs as a result of lung metastasis.

DiCaprio MR, Friedlaender GE: Malignant bone tumors: Limb sparing versus amputation. *J Am Acad Orthop Surg* 2003;11:25 [PMID: 12699369].

EWING SARCOMA

In Ewing sarcoma, the presenting complaint is usually pain and tenderness. Fever and leukocytosis may also be present, which makes osteomyelitis the main differential diagnosis. The lesion may be multicentric. Ewing sarcoma is radiolucent and destroys the cortex, frequently in the diaphyseal region. Reactive bone formation may occur about the lesion, seen as successive layers of so-called onion skin layering.

Treatment is with multiagent chemotherapy, radiation, and surgical resection. The prognosis is poor in patients with large tumor size, pelvic lesions, and poor response to chemotherapy.

MISCELLANEOUS DISEASES OF BONE

FIBROUS DYSPLASIA

Dysplastic fibrous tissue replacement of the medullary canal is accompanied by the formation of metaplastic bone in fibrous dysplasia. Three forms of the disease are recognized:

monostotic, polyostotic, and polyostotic with endocrine disturbances (precocious puberty in females, hyperthyroidism, and hyperadrenalism [Albright syndrome]).

► Clinical Findings

A. Symptoms and Signs

The lesion or lesions may be asymptomatic. Pain, if present, is probably due to pathologic fractures. In females, endocrine disturbances may be present in the polyostotic variety and associated with café-au-lait spots.

B. Laboratory Findings

Laboratory findings are normal unless endocrine disturbances are present, in which case secretion of gonadotropic, thyroid, or adrenal hormones may be increased.

C. Imaging

The lesion begins centrally within the medullary canal, usually of a long bone, and expands slowly. Pathologic fracture may occur. If metaplastic bone predominates, the contents of the lesion will be of the density of bone. The disease is often asymmetrical, and limb length disturbances may occur as a result of stimulation of epiphyseal cartilage growth. Marked deformity of the bone may result, and a shepherd's crook deformity of the upper femur is a classic feature of the disease.

► Differential Diagnosis

The differential diagnosis includes other fibrous lesions of bone as well as destructive lesions such as unicameral bone cyst, eosinophilic granuloma, aneurysmal bone cyst, nonossifying fibroma, enchondroma, and chondromyxoid fibroma.

► Treatment & Prognosis

If the lesion is small and asymptomatic, no treatment is needed. If the lesion is large and produces or threatens pathologic fracture, curettage and bone grafting are indicated. Unless the lesions impair epiphyseal growth, the prognosis for patients with fibrous dysplasia is good. Lesions tend to enlarge during the growth period but are stable during adult life. Malignant transformation is rare.

UNICAMERAL BONE CYST

Unicameral bone cyst occurs in the metaphysis of a long bone, usually in the femur or humerus. It begins within the medullary canal adjacent to the epiphyseal cartilage. It probably results from some fault in enchondral ossification. The cyst is considered active as long as it abuts onto the metaphyseal side of the epiphyseal cartilage, and there is a risk of growth arrest with or without treatment.

When a border of normal bone exists between the cyst and the epiphyseal cartilage, the cyst is inactive. The lesion is

usually identified when a pathologic fracture occurs, producing pain. Laboratory findings are normal. On radiograph, the cyst is identified centrally within the medullary canal, producing expansion of the cortex and thinning over the widest portion of the cyst.

Treatment consists of curettage and bone grafting. The cyst may heal after a fracture.

Dormans JP, Pill SG: Fractures through bone cysts: Unicameral bone cysts, aneurysmal bone cysts, fibrous cortical defects, and nonossifying fibromas. *Instr Course Lect* 2002;51:457 [PMID: 12064135].

ANEURYSMAL BONE CYST

Aneurysmal bone cyst is similar to unicameral bone cyst, but it contains blood rather than clear fluid. It usually occurs in a slightly eccentric position in the long bone, expanding the cortex of the bone but not breaking the cortex. Involvement of the flat bones of the pelvis is less common. On radiographs, the lesion appears somewhat larger than the width of the epiphyseal cartilage. This feature distinguishes it from unicameral bone cyst.

Chromosomal abnormalities have been associated with aneurysmal bone cyst. The lesion may appear aggressive histologically, and it is important to differentiate it from osteosarcoma or hemangioma. Treatment is by curettage and bone grafting. The prognosis is good.

INFANTILE CORTICAL HYPEROSTOSIS (CAFFEY SYNDROME)

Infantile cortical hyperostosis is a benign disease of unknown cause that has its onset before age 6 months and is characterized by irritability, fever, and nonsuppurating, tender, painful swellings. Swellings may involve almost any bone of the body and are frequently widespread. Classically, swellings of the mandible and clavicle occur in 50% of patients; swellings of the ulna, humerus, and ribs also occur. The disease is limited to the shafts of bones and does not involve subcutaneous tissues or joints. It is self-limited but may persist for weeks or months. Anemia, leukocytosis, an increased ESR, and elevation of the serum alkaline phosphatase concentration are usually present. Cortical hyperostosis is demonstrable by a typical radiographic appearance and may be diagnosed on physical examination by an experienced pediatrician.

Fortunately the disease appears to be decreasing in frequency. Indomethacin may be useful for treatment. The prognosis is good, and the disease usually terminates without deformity.

GANGLION

A ganglion is a smooth, small cystic mass connected by a pedicle to the joint capsule, usually on the dorsum of the

wrist. It may also occur in the tendon sheath over the flexor surfaces of the fingers. These ganglia can be excised if they interfere with function or cause persistent pain.

BAKER CYST

A Baker cyst is a herniation of the synovium in the knee joint into the popliteal region. In children, the diagnosis may be

made by aspiration of mucinous fluid, but the cyst nearly always disappears with time. Whereas Baker cysts may be indicative of intra-articular disease in the adult, they occur without internal derangement in children and rarely require excision.

Sports Medicine

Pamela E. Wilson, MD
K. Brooke Pengel, MD

Sports medicine as a separate discipline has grown since the 1980s in response to an expanding body of knowledge in the areas of exercise physiology, biomechanics, and musculoskeletal medicine. As more and more children participate in recreational and competitive activities, an understanding of sports medicine and developmental issues will be of major importance to pediatric health care providers.

BASIC PRINCIPLES

The basic unit of the musculoskeletal system is the muscle fiber, which can be classified as slow twitch, fast twitch, or intermediate type. Slow twitch (type 1) fibers are usually smaller, are recruited in muscle contractions first, and are innervated by smaller motor neurons. Fast twitch (type 2) fibers make up white muscle and are usually larger. They are recruited when the body needs to produce rapid muscle tension. They produce more lactic acid than type 1 fibers. An intermediate (type 2a) fiber is called fast oxidative glycolytic, or FOG. Untrained individuals have a 50:50 proportion of type 1 to type 2 fibers. Elite long distance runners can have up to 90% type 1 fibers. This apparent adaptation raises a question as to whether an athlete is genetically programmed or can develop adaptations that allow success in sports.

Exercise generates cardiorespiratory system responses, including increased VO_2 max (maximum amount of oxygen that can be consumed), increased cardiac output, reduced resting heart rate, and improved blood pressure responses.

Biomechanics is the study of movement and how the forces generated by the neuromuscular system translate into movement. It integrates principles of both biology and physics. Through biomechanics we can understand the intricacies of movement and how these movements affect athletic performance and result in injuries.

Types of Muscle Contraction Associated with Exercise

Muscle contractions are divided into three types: isometric, isotonic, and isokinetic. An **isometric exercise** is exercise against a fixed load in which no movement is achieved. Isometric exercise improves strength at a given angle, but does not affect endurance. Isometric exercise is beneficial for therapy during the acute phase of an injury in which certain muscles or groups of muscles need strengthening. Isometric exercise can cause an increase in blood pressure and heart rate and should be used cautiously if a cardiac condition is present. **Isokinetic exercise** uses the concept of constant velocity and can provide maximal muscle contractions through full range of motion. This type of exercise generally requires special equipment. Lastly, **isotonic exercise** uses the principle of constant load and muscle length changes to strengthen muscles. It is the most common type of exercise and can be sport-specific. Isotonic exercises can be further classified as below:

A. Concentric Exercise

In concentric exercises, the force of muscle contraction overcomes an external resistance, which results in shortening of the muscle. These muscles accelerate a distal segment in the kinetic chain and are therefore referred to as open kinetic chain movements. An example of such an exercise is a biceps curl, during which the biceps is actively contracting or shortening to lift the weight.

B. Eccentric Exercise

In eccentric exercises, contractions increase muscle tension associated with lengthening of the muscle and are used to decelerate a distal segment in the kinetic chain. This type of exercise is exemplified by the squatting motion, in which the quadriceps lengthens under tension to control downward motion. If the terminal segment in the chain is fixed, this type of movement is called closed kinetic chain movement.

De Ste Croix M et al: Assessment and interpretation of isokinetic muscle strength during growth and maturation. *Sports Med* 2003;33:727 [PMID: 12895130].

Strength Training

Strength is defined as the peak force that can be generated during a single maximal contraction. Strength training uses progressive resistance to improve an athlete's ability to resist or exert force. This can be achieved by a variety of techniques, including body weight, free weight, or machine resistance. The benefits of weight training are improved performance, endurance, and muscular strength. Weight training can be started in prepubescent athletes and if designed appropriately can be done safely with minimal risk of injury. Tanner staging (see Chapter 32) helps to define readiness for progression to more strenuous programs. Power lifting and weight lifting should be restricted to athletes who have reached or passed Tanner stage V. Individuals at Tanner stage IV or less can safely participate in a strength training program that is specifically and carefully designed for younger athletes. These programs incorporate submaximal resistance with multiple repetitions. They can be generalized or sport-specific. Care should be taken to prevent injuries while using weight-training equipment at home. Children and adults with disabilities can benefit from weight-training programs modified to meet their specific needs.

PREPARTICIPATION HISTORY & PHYSICAL EXAMINATION

The preparticipation medical examination evaluates and screens for potential medical problems that could occur during athletic participation. The objectives of this evaluation are to establish baseline medical information, detect any medical condition that might limit athletic participation, evaluate the athlete for preventable injuries, meet the legal or insurance requirements of most states, assess the athlete's maturity, and make recommendations for protective equipment. The ideal timing of the examination is at least 4–6 weeks before training starts. This allows time for any needed interventions by the physician.

Preparticipation History

The history is the most important part of the encounter. Many key elements need to be explored with the athlete. Standardized history forms are available both on the Internet and in monographs. Figure 25–1A is one example of the

essential questions contained in a preparticipation history. The history must include the following areas:

A. Cardiovascular History

The physician should note any history of cardiac murmurs, chest pain at rest or with exertion, syncopal episodes or sudden fatigue, shortness of breath, or recent illnesses with chest pain. The family history should specifically ask about underlying cardiac diseases, including hypertrophic cardiomyopathy, prolonged QT syndrome, Marfan syndrome, arrhythmias, and sudden death in family members. These questions may help identify potentially life-threatening cardiac lesions. The most common causes of sudden death in young athletes on the playing field are hypertrophic cardiomyopathy and congenital heart lesions.

B. History of Hypertension

Any history of hypertension requires investigation. The current guidelines for the diagnosis of hypertension are blood pressure above 130/75 mm Hg in a child younger than age 10 years or blood pressure above 140/85 mm Hg in a child 10 years of age or older.

C. History of Chronic Diseases

Diseases such as reactive airway disease or exercise-induced asthma, diabetes, renal disease, liver disease, chronic infections, neurologic disorders, or hematologic diseases should be noted.

D. Musculoskeletal Limitations and Prior Injuries

The physician should explore limited range of motion and muscle weakness along with prior injuries that may affect future performance. Chronic pain or soreness long after activity may reflect overuse syndromes that should be evaluated.

E. Menstrual History in Females

The physician should pay particular attention to the so-called female athletic triad: amenorrhea, eating disorders, and osteoporosis.

F. Nutritional Issues

The physician should record methods the athlete uses to maintain, gain, or lose weight.

G. Medication History

This information will provide data on current medications whose side effects may suggest activity modifications. Also, documenting drug use may provide the opportunity to explore with the patient drawbacks of using performance-enhancing compounds such as anabolic steroids, creatine, stimulants, and narcotics.

PREPARTICIPATION PHYSICAL EXAM

Name _____
 Date of birth/age _____
 Height _____ Weight _____ BP _____
 Pulse R wrist _____ L wrist _____ other _____
 Vision K 20/ _____ L 20/ _____ (was it corrected Y or N)

GENERAL EXAM *(circle normal or abnormal and record results or the form)*

APPEARANCE	normal abnormal

Kutscher EC et al: Anabolic steroids: A review for the clinician. *Sports Med* 2002;32:285 [PMID: 11929356].

Physical Examination

The physical examination should be focused on the needs of the athlete. It may be the only time that an athlete has contact with medical personnel and can be used to promote wellness along with screening for physical activity. Figure 25–1B is an example of a preparticipation physical exam form. The examination should include routine vital signs, including blood pressure measurements obtained in the upper extremity. The cardiovascular examination should include palpation of pulses, auscultation for murmurs in both sitting and standing, and evaluation of the effects of exercise on the individual. The musculoskeletal examination is used to determine strength, range of motion, flexibility, and previous injuries. Included is a quick guide that can be used to screen for abnormalities in this area (Table 25–1). The remainder of the examination should emphasize the following areas:

A. Skin

Are there any contagious lesions such as herpes or impetigo?

B. Vision

Are there any visual problems? Is there any evidence of retinal problems? Are both eyes intact?

C. Abdomen

Is there any evidence of hepatosplenomegaly?

D. Genitourinary System

Are any testicular abnormalities or hernias present?

E. Neurologic System

Are there any problems with coordination, gait, or mental processing?

F. Sexual Maturity

What is the individual's Tanner stage?

Recommendations for Participation

After completing the medical evaluation the physician can make recommendations about sports clearance. The options are unrestricted participation, limited participation, or no

Table 25–1. The screening sports examination.^a

General evaluation	<p>Have patient stand in front of examiner; evaluate both front and back along with posture.</p> <p>Look at general body habitus.</p> <p>Look for asymmetry in muscle bulk, scars, or unusual postures.</p> <p>Watch how patient moves when instructed.</p>
Neck evaluation	<p>Evaluate range of motion (ROM) by having patient bend head forward (chin to chest), rotate from side to side, and laterally bend (ear to shoulder).</p> <p>Observe for asymmetry, lack of motion, or pain with movement.</p>
Shoulder and upper extremity evaluation	<p>Observe clavicles, shoulder position, scapular position, elbow position, and fingers.</p> <p>ROM screening:</p> <ul style="list-style-type: none"> Fully abduct arms with palms in jumping jack position. Internally and externally rotate shoulder. Flex and extend wrist, pronate and supinate wrist, flex and extend fingers. <p>Do the following manual muscle testing:</p> <ul style="list-style-type: none"> Have patient shrug shoulders (testing trapezius). Abduct to 90 degrees (testing deltoid). Flex elbow (testing biceps). Extend elbow over head (testing triceps). Test wrist flexion and extension. Have patient grasp fingers.
Back evaluation	<p>General inspection to look for scoliosis or kyphosis.</p> <p>ROM screening:</p> <ul style="list-style-type: none"> Bend forward touching toes with knees straight (spine flexion and hamstring range). Rotation, side bending, and spine extension.
Gait and lower extremity evaluation	<p>General observation while walking.</p> <p>Have patient walk short distance normally (look at symmetry, heel-toe gait pattern, look at all joints involved in gait and leg lengths, any evidence of joint effusions or pain).</p> <p>Have patient toe-walk and heel-walk for short distance and check tandem walking (balance beam walking).</p>

^aIf any abnormalities are found, a more focused evaluation is required.

participation. Table 25–2 is a composite of recommendations for sports participation organized by body system. In addition, recommendations for sports participation based on medical conditions can be found on the web site and in the journal of the American Academy of Pediatrics (AAP).

REHABILITATION OF SPORTS INJURIES

Participation in sports can have great benefits. It provides physical activity, acquisition of motor skills, and social

opportunities. All sports participation, however, carries an inherent risk of injuries. These injuries are classified as either acute or chronic. Chronic injuries occur over time and are related to repetitive stress. These injuries develop in response to overuse, repeated microtrauma, and inadequate repair of injured tissue. Acute injuries or macrotrauma are one-time events that can cause alterations in biomechanics and physiology.

Response to an acute injury occurs in two predictable phases. The first week is characterized by an acute inflammatory response. During this time initial vasoconstriction is followed by vasodilation. Chemical mediators of inflammation are released, resulting in the classical physical findings of local swelling, warmth, pain, and loss of function. This phase is essential in healing of the injury. The proliferative phase occurs over the next 2–4 weeks and involves repair and clean-up. Fibroblasts infiltrate and lay down new collagen. Lastly, the maturation phase allows for repair and regeneration of the damaged tissues.

The management of acute sports injuries is geared toward optimizing healing and restoring function. The goals of immediate care are to minimize the effects of the injury by reducing pain and swelling, to educate the athlete about the nature of the injury and how to take care of it, and to maintain the health of the rest of the body. The treatment for an acute injury is captured in the acronym **PRICE**:

- **P**rotect the injury from further damage (taping, splints, braces)
- **R**est the area
- **I**ce
- **C**ompression of the injury
- **E**levation immediately

Nonsteroidal anti-inflammatory drugs (NSAIDs) reduce the inflammatory response and reduce discomfort. These medications may be used immediately after the injury. Glucocorticoids should be administered judiciously. If administered inappropriately they may prolong the acute phase of recovery. Therapeutic use of physical modalities, including early cold and later heat, hydrotherapy, massage, electrical stimulation, iontophoresis, and ultrasound, can enhance recovery in the acute phase.

The recovery phase can be lengthy and requires athlete participation. Initial treatment is focused on joint range of motion and flexibility. Range-of-motion exercises should follow a logical progression of starting with passive motion, then moving to active assistive, and finally to active movement. Active range of motion is initiated once normal joint range has been reestablished. Flexibility exercises are sport-specific and aimed at reducing tight musculature. Strength training can begin early in this phase of rehabilitation. Initially only isometric exercises are encouraged. As recovery progresses and flexibility increases, isotonic and isokinetic exercises can be added to the program. These should be done at least three times per week.

Table 25-2. Recommendations and considerations for participation in sports.

Disorders	Considerations and Recommendations	References
Cardiac		
Anticoagulation treatment	Need to avoid all contact sports	
Aortic stenosis	Individualize treatment based on disease and systolic gradient: Mild: < 20 mm Hg, all sports if asymptomatic. Moderate: limited sports. Severe: no competitive sports.	
Arrhythmias	Consult with cardiologist as WPW and long QT syndrome can have serious consequences.	
Heart failure	Screen patient with LVEF < 30% for ischemia. Use AHA risk stratification criteria to define exercise capacity.	Braith 2002
Heart implants	No jumping, swimming, or contact sports.	
Hypertrophic cardiomyopathy	Single most common cause of cardiac death in young athletes. Athletes should not participate in sports except possibly low-intensity forms (eg, golf, bowling). Consult with cardiologist.	Maron 2002a, b
Marfan syndrome	Aortic root dilation is associated with mitral valve prolapse and regurgitation. Participate in sports with minimal physical demands.	Salim et al 2001
Mitral valve prolapse	Fairly common condition. No restrictions unless there is a history of syncope, positive family history of sudden death, arrhythmias with exercise, or moderate regurgitation.	
Syncope	Unexplained syncopal episodes during exercise must be evaluated by ECG, echocardiograph, Holter, and tilt test prior to resumption of any activities.	Firoozi 2002
Endocrine		
Diabetes mellitus type 1	No restrictions to activity, however: Short-term exercise = no insulin changes. Vigorous exercise = 25% reduction in insulin with 15-30 g of carbohydrates before and every 30 min during exercise. Strenuous exercise = may require up to an 80% reduction in insulin with extra carbohydrates. Generally monitor blood glucose closely.	Birrer et al 2003, Draznin 2000
Eye		
Detached retina	Do not participate in strenuous sports regardless of contact risk.	Moeller 1996
One eye	Consider avoiding contact sports, although if patient does participate use of eye protection is mandatory.	Vinger 2000
Gentitourinary		
One testicle	Need to wear protective cups in collision and contact sports.	
Solitary kidney	Advise not to participate in collision and contact sports.	Terrell 1997
Hematologic		
Hemophilia	Avoid contact and collision sports.	
Sickle cell trait	No restrictions if disorder is well controlled. Athletes should avoid dehydration and acclimate to altitude. There is, however, a known association between exercise and sudden death.	
Infectious disease		
General considerations	Fevers: should not participate in activities with moderate fevers; exercise affects fluid balance, immune system function, and temperature regulation. Intense exercise may worsen or prolong some viral illnesses.	Howe 2003, Primos 1996

(continued)

Table 25-2. Recommendations and considerations for participation in sports. (Continued)

Disorders	Considerations and Recommendations	References
Enterovirus	Coxsackievirus causes respiratory and GI symptoms but more importantly can cause myocarditis. Anyone with systemic symptoms such as fever or myalgias should avoid strenuous exercise.	Primos 1996
Herpes simplex, impetigo, tinea corpora	Close contact is required for transmission; use common-sense guidelines. For contact sports participation should not be allowed until lesions are crusted over or healed.	Moeller 1996
Infectious mononucleosis	Splenic rupture is most important consideration. Risk of spleen rupture highest during second and third weeks of illness. No athletic participation for a minimum of 21 days! Splenic ultrasounds should be considered in decision making. Too early a return to sports could cause EBV reactivation and relapse. First week of return to activity should be noncontact. Graded increases in intensity if fatigue tolerance is improved. Return to full activity if: no abdominal pain, normal spleen, and normal laboratory results.	MacKnight 2002
Sinusitis	Similar considerations as cold (see below) except diving should be restricted until symptoms resolve.	
<i>Streptococcus A</i>	Restrict from activity until afebrile and on antibiotics for > 24 h	O'Kane 2002
Upper respiratory infections (including common cold)	"Neck check," with symptoms (fevers, myalgias, arthralgias, etc) above the neck participation can be allowed; however, if they migrate below that level activity should be limited.	Primos 1996
Neurologic		
Epilepsy	Majority of sports are safe for those with good seizure control; contact sports are allowed with proper protection. Definitely wear a helmet. Fitness may reduce number of seizures. Swimming and water sports should be supervised. Sports such as free climbing, hang gliding, and scuba are not recommended.	Howard 2004
Herniated disk (with cord compression)	Avoid contact and collision sports.	
Muscle disease or myopathy	Exercise within physical limits. Low- to moderate-intensity activity is appropriate for patients with slow progressive disorders. Patients with disorders that are rapidly progressing should avoid high-resistance and eccentric muscle activity. Modification of exercise with intercurrent illness.	Tarnopolsky 2002, Ansved 2003
Spinal stenosis	Avoid contact and collision sports.	
Orthopedic		
Scoliosis	No restrictions unless severe.	
Spondylolisthesis	Grade 2 and above should avoid high-risk sports.	
Spondylolysis	Pars intra-articularis stress fracture. No restrictions if pain-free.	
Respiratory		
Asthma	No activity restrictions. Use common sense about when to use medications.	Disabella et al 1998
Pneumothorax	Can occur in sports, especially in males. Increased risk for recurrence; should consider not participating in strenuous and contact sports.	
Tuberculosis	Not allowed to participate because of exposure to other athletes.	

(continued)

Table 25-2. Recommendations and considerations for participation in sports. (Continued)

Disorders	Considerations and Recommendations	References
Other		
Cerebral palsy	Full participation with modifications.	
Developmental disabilities	Athletes with developmental disabilities often have associated medical problems including diabetes, obesity, and hypokinesia.	Platt 2001
Down syndrome	10–20% have atlantoaxial instability. All athletes need to be cleared with a lateral view radiograph including flexion and extension. If abnormal no contact sports should be allowed. Evaluation of underlying congenital heart disorders should be considered in this population.	Platt 2001, Winell 2003
Spinal cord injury or spina bifida	Full participation. Consider modification of equipment to accommodate activity or modification of activity to accommodate disability. Consider how modification affects performance. Be aware of thermoregulatory dysfunction, medications, and pressure areas.	

AHA, American Heart Association; EBV, Epstein-Barr virus; ECG, electrocardiogram; GI, gastrointestinal; LVEF, left ventricular ejection fraction; WPW, Wolff-Parkinson-White syndrome.

As the athlete approaches near-normal strength and is pain-free, the final maintenance phase can be introduced. During this phase the athlete continues to build strength and work on endurance. The biomechanics of sport-specific activity need to be analyzed and retraining incorporated into the exercise program. Generalized cardiovascular conditioning should continue during the entire rehabilitation treatment.

COMMON SPORTS MEDICINE ISSUES & INJURIES

INFECTIOUS DISEASES

Infectious diseases are common in both recreational and competitive athletes. These illnesses have an effect on basic physiologic function and athletic performance. Given this knowledge, physicians, parents, and coaches can adopt the common-sense guidelines listed in Table 25-3.

Rihn JA et al: Community-acquired methicillin-resistant *Staphylococcus aureus*: An emerging problem in the athletic population. *Am J Sports Med* 2005;33:1924 [PMID: 16314668].

HEAD & NECK INJURIES

Head and neck injuries occur most commonly in contact and individual sports. The sports with the highest incidences of brain injury are football, bicycling, baseball, horseback riding, and golf. The treatment of these injuries is controversial, and multiple guidelines have been developed. As a general rule, however, treatment of injuries in young chil-

dren should be as conservative as possible because of their developing central nervous systems.

1. Concussion

Concussion is a temporary and immediate impairment of neurologic function and may or may not have an associated period of unconscious. It is usually defined by the duration of the loss of consciousness (LOC), post-traumatic

Table 25-3. Sports participation guidelines: infectious diseases.

Athletes with temperatures > 100°F should not participate in sporting activities.
Athletes who have had recent infectious mononucleosis can return to noncontact training at 3 wk as long as there is no splenic enlargement. They may return to contact sports after 4 wk and a normal abdominal examination.
Athletes with a streptococcal pharyngitis can resume activity once treatment has been initiated and they are afebrile.
If a localized herpes gladiatorum or impetigo lesion is present, no contact sports are allowed until the lesions have resolved. Athletes with herpes zoster have the same restrictions. There are no restrictions for athletes with common warts. Athletes with molluscum contagiosum can compete if the affected areas are covered.
Athletes with furuncles cannot be involved in contact sports or swimming until the lesions are healed.
Athletes with HIV infection may compete in all types of sports. Universal precautions should be used with all athletes who have sustained injuries.

amnesia (PTA), and confusion. The pathophysiology is related to alterations in brain metabolism and the release of neurotransmitters.

Concussions have been categorized by many different grading systems, but recent consensus recommends all athletes should be removed from play until symptoms have resolved. Once symptoms have resolved a six-step progression is outlined for return to play: (1) assess at rest; once asymptomatic progress to (2) light aerobic exercise, followed by (3) sport-specific exercise, then begin (4) noncontact drills followed by (5) contact drills, and finally (6) release to game play. If any symptoms are present, the athlete should not move to the next step.

Preseason testing may help practitioners in assessing acute concussive status. Among commonly used assessment tools are the Standardized Assessment of Concussion (SAC), Balance Error Scoring System (BESS), computerized testing, and symptoms checklist (Table 25–4). Neuropsychology testing is advocated for athletes with persistent symptoms. Recent findings related to multiple concussions in athletes indicate that one concussion episode places an athlete at a higher risk for a repeat concussion, and that children with repeat concussions may have more severe injuries with protracted recovery times. In general, conservative return to play guidelines should be used in children.

2. Second Impact Syndrome

Second impact syndrome is a rare but potentially deadly complication of head injuries. Athletes who have had a prior brain injury that has not healed and have a second injury are at risk for a loss of vascular autoregulation and subsequent malignant cerebral edema.

3. Atlantoaxial Instability

Atlantoaxial instability is common in children with Down syndrome because of underlying ligamentous laxity, including the annular ligament of C1, and hypotonia. Cervical neck films including flexion, extension, and neutral position eval-

uate the atlanto-dens interval (ADI). ADI is normally less than 2.5 mm, but up to 4.5 mm is acceptable in this population. Children with an ADI greater than 4.5 mm should be limited from contact and collision activities.

Winell J: Sports participation of children with Down syndrome. *Orthop Clin North Am* 2003;34:439 [PMID: 12974493].

4. Burners & Stingers

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Symptoms appear on the same side as an injury to the neck and shoulder.
- ▶ Burning pain or numbness in the shoulder and arm.
- ▶ Weakness may be present.

Burners and stingers are common injuries in contact sports, especially football. These types of cervical radiculopathies or brachial plexopathies occur when the head is laterally bent and the shoulder depressed. Symptoms include immediate burning pain and paresthesias down one arm generally lasting only minutes. Weakness in the muscles of the upper trunk—supraspinatus, deltoid, and biceps—can persist for weeks. The most important part of the workup is a thorough neurologic assessment to differentiate this injury from a serious cervical spine injury. The key distinguishing feature of the stinger is its unilateral nature. If symptoms persist, then a diagnostic evaluation should include cervical spine radiographs, magnetic resonance imaging (MRI) scans, and electromyography.

Treatment consists of removal from play and observation. The athlete can return to play once symptoms have resolved, neck and shoulder range of motion is pain-free, reflexes and strength are normal, and the Spurling test is negative. Preventative strategies include always wearing protective gear, proper blocking and tackling techniques, and maintaining neck and shoulder strength.

Weinberg, J et al: Etiology, treatment and prevention of athletic stingers. *Clin Sports Med* 2003;22:3 [PMID: 12852682].

SPINE INJURIES

Injuries to the spine are fairly common even in the pediatric population. As children have become more competitive in sports, the number of reported injuries has increased. Sports with a fairly high incidence of back injuries include golf, gymnastics, football, dance, wrestling, and weightlifting. Pain lasting more than 2 weeks indicates a possible structural problem and needs to be investigated.

Table 25–4. Concussion: symptom checklist.

Headache
Dizziness
Balance problems
Nausea
Vomiting
Light sensitivity
Noise sensitivity
Ringing in the ears
Fatigue or excessive sleepiness
Sleep abnormalities
Memory problems
Concentration difficulties
Irritability
Behavioral changes

Acute injury to the spine often results from an axial load injury. Patients present with focal tenderness of the thoracic or thoracolumbar spine. Evaluation includes plain radiography that may demonstrate mild wedging of the thoracic vertebra. When significant spinal tenderness or any neurological abnormalities are present, radiographs are often followed by computed tomography (CT) or MRI. Treatment of minor compression fractures includes pain control, bracing, rest from high-risk sports, and physical therapy. With appropriate rehabilitation, athletes can usually return to contact activity within 8 weeks.

1. Spondylolysis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Injury to the pars interarticularis.
- ▶ Usually presents as back pain with extension.

Spondylolysis is an injury to the pars interarticularis. Pars defects are present in 4–6% of the population. The percentage of pars defects in athletes such as gymnasts, dancers, divers, and wrestlers is significantly increased. Repetitive overload results in stress fractures. Spondylolysis occurs at L5 in 85% of cases. The athlete presents with back pain that is aggravated by extension, such as arching the back in gymnastics. There may be palpable tenderness over the lower lumbar vertebrae, along with pain on the single leg hyperextension test. Tight hamstrings are another common physical examination finding. Evaluation includes anteroposterior (AP) and lateral radiographs of the lumbar spine. Although oblique radiographic views of the lumbar spine are helpful to look for the so-called Scottie dog sign, they are falling out of favor because they often fail to show the lesion. Single photon emission computed tomography scan, CT scan, and MRI can be useful to determine the presence of an active spondylolytic lesion.

Treatment includes refraining from hyperextension and high-impact sporting activities, stretching of the hamstrings, stabilization exercises, and lumbosacral bracing. Athletes can cross-train with low-impact activity and neutral or flexion-based physical therapy. Return to play is often delayed 6 weeks or longer based on clinical signs of healing. Surgery is reserved for refractory cases.

2. Spondylolisthesis

When a bilateral pars injury occurs, slippage of one vertebra over another causes a spondylolisthesis. These injuries are graded from 1 to 4 based on the percentage of slippage: grade 1 (0–25%), grade 2 (25–49%), grade 3 (50–74%), and grade 4 (75–100%). Patients present with hyperlordosis, kyphosis, pain with hyperextension, and in severe cases, a palpable step-off. Diagnosis is based on lateral radiographs.

Treatment is often symptom based. Asymptomatic athletes with less than 30% slippage have no restrictions and are followed on a routine basis. Slippage of 50% or more requires interventions of stretching hip flexors and hamstrings, working on core stability, along with bracing or surgery. If surgery is required, the athlete must understand that he or she cannot return to activities for at least a year and may not be able to return to previous sporting activities.

3. Disk Herniation

Discogenic back pain accounts for a small percentage of back injuries in children. These injuries are almost unheard of in preadolescence. Back pain can originate from disk herniation, apophyseal injury, and disk degeneration. Most injuries occur at L4–L5 and L5–S1 vertebrae. Symptoms include back and leg pain. Pain may be increased with activities such as bending, sitting, and coughing. Pain often radiates down the lower extremity in a radicular pattern. Evaluation includes physical and neurologic examinations, including straight leg testing, sensory testing, and checking reflexes. If symptoms persist, evaluation includes electromyography, CT, and MRI scans.

Treatment usually is conservative as most back injuries improve spontaneously. The athlete can rest the back for a short period and then begin a structured exercise program of extension and isometrics followed by flexion exercises. If symptoms persist, a short course of steroids may be indicated. Surgery is recommended only if neurologic compromise persists.

Herman MJ: Spondylolysis and spondylolisthesis in the child and adolescent athlete. *Orthop Clin North Am* 2003;34:461 [PMID: 12974495].

SHOULDER INJURIES

Shoulder injury is usually a result of acute trauma or chronic overuse. Acute injuries around the shoulder include contusions, fractures, sprains (or separations), and dislocations. The age of the patient affects the injury pattern, as younger patients are more likely to sustain fractures instead of sprains.

1. Fracture of the Clavicle

Clavicular fractures occur from a fall or direct trauma to the shoulder. Focal swelling and tenderness are present over the clavicle. Diagnosis is made by radiographs of the clavicle; the fractures are most common in the middle third of the bone.

Initial treatment is focused on pain control and protection with a sling and swathe. Early range of motion is permitted, based on pain level. Progressive rehabilitation is important. Athletes cannot return to contact sports for 8–10 weeks. Surgical indications for acute clavicular fractures include open fractures or neurovascular compromise. Frac-

ture nonunion is unusual in young patients, but older adolescents with recurrent fractures or nonunion occasionally undergo surgical fixation.

2. Acromioclavicular Separation

A fall on the point of the shoulder is the most common cause of acromioclavicular separation. Tearing of the acromioclavicular joint capsule and possibly the coracoclavicular ligaments occurs. The injury is classified by the extent of the injuries to these ligaments. Athletes present with focal soft tissue swelling and tenderness over the acromioclavicular joint. More severe injuries are associated with deformity. Patients have a positive cross-arm test, in which pain is localized to the acromioclavicular joint. Radiographs are helpful to assess the degree of injury and to evaluate for a coexisting fracture.

Treatment is supportive, with rest and immobilization in a sling followed by progressive rehabilitation. Return to activity can be accomplished in 1–6 weeks depending on the severity of the injury. Full range of motion and full strength must be achieved.

3. Fracture of the Humerus

Fractures of the humerus occur from a severe blow or fall on the shoulder. Pain and swelling are localized to the proximal humeral region. The fractures can include the physes or may be extraphyseal. Some amount of displacement and angulation can be tolerated in this location because of the young athlete's potential for remodeling. Careful assessment of the brachial plexus and radial nerves are needed to rule out associated nerve damage.

Treatment consists of a sling for 4–6 weeks followed by progressive rehabilitation.

4. Acute Traumatic Anterior Shoulder Instability (Anterior Shoulder Dislocation/Subluxation)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Injury with an abducted and externally rotated arm.
- ▶ Severe pain in the shoulder.
- ▶ Squared-off shoulder on examination.
- ▶ Reduced range of motion of the shoulder

Acute traumatic anterior shoulder instability occurs from a significant force applied to the abducted and externally rotated shoulder. Most often, the humeral head is dislocated in an anterior and inferior direction. The patient has severe pain and a mechanical block to motion. Patients require immediate closed reduction. Radiographs are

helpful to confirm the position of the humeral head as well as to evaluate for coexisting fracture. MRI may be required for accurate visualization of fractures and cartilaginous injury.

Follow-up treatment for a glenohumeral dislocation in young athletes is controversial. Initially, the shoulder is immobilized for comfort. Range-of-motion exercises and progressive rehabilitation are initiated. Because of the high risk of recurrence, options for treatment should be individualized, with consideration given to both nonoperative and surgical management.

5. Rotator Cuff Injury

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Injury can be acute or chronic.
- ▶ Pain is described as diffuse or anterior and lateral.
- ▶ Overhead activities exacerbate the pain.

Numerous shoulder injuries are related to repetitive overuse and tissue failure. Rotator cuff injuries are common in sports requiring repetitive overhead motions. Muscle imbalances and injury can cause the position of the humeral head to be abnormal, which may cause impingement of the supraspinatus tendon under the acromial arch. Patients with nontraumatic shoulder instability due to ligamentous and capsular laxity (also known as multidirectional instability) are prone to overuse rotator cuff injury. The athlete presents with a chronic history of pain in the anterior and lateral shoulder, which is increased with overhead activities. Diagnostic workup includes plain radiographs and an outlet view to look for anatomic variability.

The rehabilitation of this injury is geared toward reduction of inflammation, improved flexibility, core stabilization, and strengthening of the scapular stabilizers and rotator cuff muscles. A biomechanics evaluation can assist athletes in the recovery process by building sport-specific skills and eliminating substitution patterns.

6. Little League Shoulder

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Participation in a throwing sport.
- ▶ Pain with throwing.
- ▶ Pain in the lateral aspect of the humerus.
- ▶ Swelling around the shoulder.
- ▶ Widening of the proximal humeral physis on radiographs.

Proximal humeral epiphysitis, or “Little League shoulder,” is an overuse injury that occurs in children aged 11–14 years who play overhead sports such as baseball. The patient presents with activity-related pain in the lateral aspect of the proximal humerus. Examination often shows tenderness over the proximal humerus. However, benign findings on office examination do not preclude this diagnosis. The hallmark feature is pain with throwing. Radiographs show widening, sclerosis, and irregularity of the proximal humeral physis. Comparison views are often helpful when considering this diagnosis.

Treatment consists of rest from throwing or other aggravating activity. Physical therapy is initiated during the rest period. Return to play can only be accomplished after a period of rest has significantly decreased the pain and the athlete has proceeded through a progressive throwing program. Healing can take several months. Signs of radiographic healing may lag behind the athlete’s clinical progress, and normal radiographs are not necessarily required to return an athlete to play.

Sciascia A et al: The pediatric overhead athlete: What is the problem? *Clin J Sports Med* 2006;16:6 [PMID: 17119360].
Wasserlauf BF: Shoulder disorders in the skeletally immature throwing athlete. *Orthop Clin North Am* 2003;34:427 [PMID: 12974492].

ELBOW & FOREARM INJURIES

Injuries in the forearm are quite common with both chronic and acute etiologies (eg, the chronic overuse “Little League elbow” and the frequent childhood fracture typical of falls on an outstretched arm). When evaluating the elbow, consider dividing the examination into specific anatomic areas as discussed below.

1. Medial Epicondylitis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Participation in a throwing sport.
- ▶ Pain over the medial condyles, especially with pitching.
- ▶ Swelling medial elbow.
- ▶ Elbow flexion contracture.

Medial epicondylitis, often called Little League elbow, encompasses a group of abnormalities that develop in young baseball pitchers secondary to the biomechanical forces generated around the elbow during throwing. These forces can result in shearing, inflammation, traction, and abnormal bone development. The symptoms are primarily swelling, pain, performance difficulties, and weakness. The pain localizes to the medial epicondyle, which may be tender to

palpation. Wrist flexion and pronation increase symptoms. Workup includes a series of elbow radiographs, including comparison films, to look for widening of the epiphyseal lines and possibly MRI studies.

Treatment of the acute injury includes rest from throwing. It is not uncommon for a player to be benched for up to 6 weeks. Competition can be resumed once the player is asymptomatic. The key to treating this injury is prevention. Children should be properly conditioned and coached in correct throwing biomechanics. Guidelines for pitching limits in youth baseball have been developed. Little League limits 10- to 12-year-old children to 6 innings per week and 13- to 15-year-old children to 9 innings per week. Guidelines for limiting pitches per game are outlined in Table 25–5.

2. Panner Disease

Panner disease refers to variations in the normal ossification of the capitellum. This condition occurs in children aged 5–12 years who play sports that involve overhead throwing. The child may have dull aching in the lateral elbow that generally worsens when throwing. Swelling and reduced elbow extension usually are present. Radiographs show an abnormal capitellum, with fragmentation and areas of sclerosis.

Treatment is conservative, using rest, ice, and splinting. The child can return to play after radiographs normalize. The natural history of this condition is one of complete resolution of symptoms and ultimately normal ossification of the capitellum.

3. Osteochondritis Dissecans

Lateral elbow pain in a slightly older throwing athlete, usually aged 13–15 years, can be secondary to osteochondritis dissecans. Valgus compressive forces can lead to avascular necrosis of the capitellum, which can result in the formation of loose bodies. The athlete presents with lateral pain, swelling, lack of full extension, and occasionally locking. Radiographs and MRI can more fully delineate the lesion.

Table 25–5. Guidelines for pitching limits in youth baseball.

Age (years)	Pitches per Game ^a
8–10	52 ± 15
11–12	68 ± 18
13–14	76 ± 16
15–16	91 ± 16
16–17	106 ± 16

^aBased on 2 games per week.

Treatment is based on classification and can be either conservative or surgical. The child should be seen by an orthopedic specialist with expertise in upper extremity injuries.

4. Lateral Epicondylitis

Lateral epicondylitis is common in skeletally mature athletes participating in racquet sports, particularly tennis. It is an overuse of the extensor muscle in the forearm and causes pain in the lateral elbow. Pain is increased by wrist extension.

Initial treatment is aimed at inflammation control. Stretching and strengthening of forearm muscles are the primary interventions during the subsequent phases. Stroke mechanics may need to be altered and a forearm brace used to decrease the forces in the extensor muscles.

5. Posterior Elbow Pain

Posterior elbow pain is uncommon. Etiologies include dislocations, fractures, triceps avulsions, olecranon apophysitis, and olecranon bursitis.

Benjamin HJ et al: Little League elbow. *Clin Sports Med* 2005;15:1 [PMID: 15654190].

Hang DW et al: A clinical and roentgenographic study of Little League elbow. *Am J Sports Med* 2004;32:79 [PMID: 14754727].

HAND & WRIST INJURIES

All hand and wrist injuries have the potential for long-term, serious disability and deserve a thorough evaluation.

1. Distal Phalanx Injury

Tuft injury requires splinting for 6 weeks or until the patient is pain-free. If there is significant displacement, then a K-wire can be used for reduction. **Nail bed injury** often requires splinting and drainage of subungual hematomas.

2. Distal Interphalangeal Injury

Mallet finger or **extensor tendon avulsion** occurs in ball-handling sports. The mechanism of injury is a force applied to an extended finger. Treatment is splinting in extension for 6 weeks for fractures and 8 weeks for tendon rupture.

3. Thumb Injury

Gamekeeper's thumb is an injury to the ulnar collateral ligament from forced abduction of the metacarpophalangeal joint. It is a common skiing injury. If a radiograph shows an avulsed fragment is displaced less than 2 mm, a thumb spica cast can be used. If there is no fragment and less than 35 degrees of lateral joint space opening, a spica cast for 6 weeks is indicated. Surgery is required for more serious injuries.

4. Fractures

Boxer's fracture is a neck fracture of the fifth digit. These fractures can be treated by closed reduction and casting for 3 weeks. A displaced fracture requires open reduction and internal fixation.

5. Wrist Injury

Most swollen wrists without evidence of instability can be splinted for several weeks. Radial and ulnar fractures, which are fairly common in children, must be ruled out. **Scaphoid fractures** are caused by a force applied to a hyperextended wrist. If evidence of snuffbox tenderness and swelling is present, the wrist must be immobilized for 10 days and then reassessed, even if radiographs are normal. A nondisplaced fracture requires at least 6 weeks of immobilization in a thumb spica cast. Nonunion can occur, particularly in fractures of the proximal pole of the scaphoid, and is related to the poor blood supply to this carpal bone. Displacement requires operative management.

Geissler WB: Carpal fractures in athletes. *Clin Sports Med* 2001;20:167 [PMID: 11227704].

Wang QC, Johnson BA: Fingertip injuries. *Am Fam Physician* 2001;63:1961 [PMID: 11388710].

HIP INJURIES

Because the pelvis and hip articulate with both the lower extremities and the spine, this area is rich in ligaments, muscle attachments, and nerves. Injuries in young children are rare, but sprains, strains, and avulsion fractures are common. Additionally, athletes can be susceptible to overuse injury involving the hip.

1. Hip Avulsion Fractures

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Fractures at apophyseal areas.
- ▶ Pain with weight bearing.
- ▶ Focal pain over the site of injury.

Avulsion fractures around the hip in adolescents occur at apophyseal regions such as the ischial tuberosity, anterior superior iliac spine, anterior inferior iliac spine, and iliac crest. The mechanism of injury is a forceful, unbalanced muscle contraction that causes avulsion of the muscle tendon insertion. The athlete presents with a history of an acute traumatic incident; often a “pop” is felt and the athlete is immediately unable to bear weight. Range of motion of the

hip is limited secondary to pain, and focal tenderness is present over the apophysis.

Treatment is conservative. It is rare for surgery to be required even in displaced fractures. The athlete can progress to weight bearing as tolerated. The rehabilitation phase focuses on regaining motion, flexibility training, and pelvic and core strengthening. Progressive return to activity can often be accomplished in 4–6 weeks if full range of motion, full strength, and sport-specific skills have been achieved.

2. Slipped Capital Femoral Epiphysis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Pain in the hip or knee, or both.
- ▶ Loss of internal rotation of the hip.
- ▶ Radiographs in the frog-leg position show widening of the physis and epiphyseal slippage.

Slipped capital femoral epiphysis can occur in children aged 11–16 years. The physis is weakened during times of rapid growing and is susceptible to shearing failure. Patients complain of groin, thigh, or knee pain and often have a limp. Examination shows painful range of motion of the hip, limited internal rotation, and obligatory external rotation when the hip is flexed. Radiographs include AP and frog-leg lateral films, which demonstrate widening of the physis and the epiphyseal slippage.

Treatment consists of immediate non-weight bearing and urgent referral to an orthopedic specialist for open reduction and internal fixation. Rehabilitation is a component of the postsurgical treatment, and return to activity is progressive over months. (See also Chapter 24.)

3. Acetabular Labral Tears

Acetabular labral tears cause anterior hip pain. The injury often occurs from a twisting injury of the hip that tears the fibrocartilaginous ring around the acetabulum. Athletes present with deep anterior hip or groin pain that worsens with activity and is resistant to treatment. Radiographic findings can be normal. An MRI arthrogram is used to demonstrate the tear. Treatment starts conservatively and requires rest. Arthroscopy is reserved for recalcitrant cases.

4. Adductor Strain

An adductor strain or a groin pull is generally caused by forced abduction as in running, falling, twisting, or tackling. Sports that require quick directional changes place the athlete at risk for these types of injuries. The associated pain is in the adductor muscle. There is often pain with adduction or hip flexion and tenderness over the adductor tubercle.

Treatment includes rest, ice, protection, and strengthening of the muscle when it heals. In severe cases the leg can be immobilized in a spica cast until the muscle has a chance to heal.

5. Hamstring Strain

Hamstring strain is a common injury in athletes. The mechanism of injury is forced extension of the knee or directional changes. The classic scenario is an athlete who suddenly stops play, grabbing the back of the knee. There are three grades of injury. Examination reveals pain on palpation of the muscle. Pain also occurs with knee flexion against resistance.

Initial treatment is focused on minimizing swelling, bruising, and pain. The thigh should be iced and compression applied. In moderate and severe injuries crutches may be needed for a short duration. The athlete can walk as soon as he or she can tolerate the activity. It is particularly important to stretch the hamstring because, as a two-joint muscle, it is more susceptible to injury than other types of muscle. Eccentric strengthening is an important component of rehabilitation.

6. Quadriceps Contusion

Quadriceps contusion is caused by a direct injury to the muscle, resulting in bruising, swelling, and pain. The amount of damage is directly related to the amount of force. The anterior and lateral thigh regions are most commonly injured often in contact sports such as football and lacrosse.

Treatment is rest, ice, and protection for the first 24 hours. The knee should be kept in a fully flexed position. Two to three days after the injury, range-of-motion exercises may begin in both flexion and extension. Once 120 degrees of motion has been established and movement does not cause pain, the athlete may return to competitive activity. If the muscle remains firm on examination after 2 weeks, then radiographs of the thigh should be obtained to rule out myositis ossificans. **Myositis ossificans** is an abnormal deposition of calcium in the muscle that may be induced by aggressive stretching of the muscle too early in the clinical course.

7. Hip Dislocation

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Usually produces posterior dislocation.
- ▶ Leg is flexed, adducted, and externally rotated.
- ▶ Hip pain is severe.
- ▶ This is an on-site emergency and must be treated quickly.

The hip joint can be dislocated in forceful injuries. Most hip dislocations occur in the posterior direction. Athletes with this injury classically present with hip flexion, adduction, and internal rotation. Hip dislocations in skeletally mature athletes are almost always associated with acetabular and femoral neck fracture. The preadolescent, skeletally immature competitor may have an isolated injury. Hip radiographs and CT scan may be needed to completely evaluate the injury.

This is a true on-field emergency, and the athlete should be transported to the nearest facility that has an orthopedic surgeon available. Severe bleeding, avascular necrosis, and nerve damage can result. Once reduction has been established in an uncomplicated case, protected weight bearing on crutches for 6 weeks is recommended followed by another 6 weeks of range-of-motion and strengthening exercises. An athlete may return gradually to competition after 3 months, when strength and motion are normal.

8. Pelvic Apophysitis

Pelvic apophysitis occurs in adolescent athletes who are typically competitive and are participating consistently, often year round, in their sport. Common locations are the ischial tuberosity and iliac crest. The athlete presents with pain over the apophysis and pain with resisted hip motion specific to the muscle insertion. Radiographs can show irregularity over the apophysis, or be normal. Treatment consists of relative rest, progressive rehabilitation focusing on flexibility, and pelvis and core stabilization.

9. Iliotibial Band Syndrome

Iliotibial band syndrome and associated trochanteric bursitis can cause pain when the hip is flexed, often as a result of reduced flexibility of the iliotibial band and gluteus medius tendons. The bursa is a structure that allows for improved motion by reducing friction. When a bursa becomes inflamed, movement is painful and may be limited. Other areas susceptible to inflammation, besides the hip, are the shoulder, elbow, and patella. Iliotibial band syndrome is best evaluated in a side-lying position, and pain is reproduced when the hip is actively flexed from a fully extended hip (Ober test).

Initial treatment is to alter the offending activity and then start a stretching program geared at the iliotibial band and hip abductors. Ultrasound is beneficial and corticosteroid injections may be used after conservative treatment has failed.

10. Femoral Neck Fractures

Femoral neck fractures (stress fractures) are generally the result of repetitive microtrauma. They commonly occur in running athletes who have increased their mileage. Athletes with this type of injury present with persistent pain in the groin and pain with internal and external rotation. Range of motion may be limited in hip flexion and internal rotation. If plain radiographs are negative, an MRI or a bone scan is indicated.

Treatment is based on the type of fracture. A transverse fracture generally requires internal fixation to prevent femoral displacement and the risk of avascular necrosis. A compression fracture is less likely to be displaced; treatment is conservative and involves resting the hip until it heals. Cardiovascular conditioning can be maintained easily through nonimpact exercises and activity.

KNEE INJURIES

Knee injuries are one of the most common sports-related problems. The knee is stabilized through a variety of ligaments, tendons, and the menisci. Knee injuries can be divided into two groups: those resulting from acute or chronic causes. Acute injuries occur from a well-defined traumatic incident. The mechanism of injury is an important historical feature, although many young patients have difficulty describing the details of the inciting event. The onset of rapid swelling after a traumatic event indicates the presence of a hemarthrosis and likely internal derangement such as fracture, rupture of the anterior cruciate ligament (ACL), meniscal tear, or patellar dislocation.

1. Anterior Knee Pain

The most common knee complaint is anterior knee pain. This complaint can have multiple etiologies but should always include hip pathology as a possible source. Patellofemoral dysfunction is a common cause of anterior knee pain. The differential diagnosis is quite extensive and requires a thorough examination.

A. Patellofemoral Overuse Syndrome

Patellofemoral overuse syndrome occurs in runners and in athletes participating in sports that involve repetitive stress in the lower extremity. The athlete presents with activity-related pain in the anterior knee. Classically, pain is located over the medial surface and undersurface of the patella. In young athletes, it is infrequently associated with swelling and crepitus of the knee joint. The Q-angle often is increased. The Q-angle is measured by drawing a line from the antero-superior iliac spine down to the center of the patella and then through the tibial tubercle. The intersecting angle is the Q-angle. Normal is 14 degrees for males and 17 degrees for females. Q-angles greater than 20 degrees tend to cause the patella to track laterally, changing the knee biomechanics.

Treatment should be geared toward identifying the cause. Often athletes are overtraining and need to modify their current activities. Cross-training may help. Stretching and strengthening of the hamstrings and quadriceps are recommended. Use of braces providing proprioceptive feedback during competition is controversial.

B. Patellar Tendonitis (“Jumper’s Knee”)

This overuse injury is caused by repetitive loading of the quadriceps during running or jumping. This diagnosis is common in basketball and volleyball athletes. Tenderness is located directly over the patellar tendon.

C. Osgood-Schlatter Disease (Tibial Tubercle Apophysitis)

This condition is caused by the recurrent traction on the muscle-tendon unit that occurs in jumping and running sports. Fragmentation and microfractures of the tibial tubercle occur during its time of rapid growth. The condition occurs in the preteen and adolescent years and is most common in boys aged 12–15 years and girls aged 11–13 years. Pain usually is present at the tibial tubercle, and is aggravated by activities using eccentric quadriceps muscle movement. The pain can become so extensive that routine activity must be curtailed. Radiographs typically demonstrate fragmentation or irregular ossification of the tibial tubercle.

Typically the condition resolves on its own. In the interim, pain control using NSAIDs is indicated. Stretching the hamstrings and application of ice after workouts is helpful.

D. Sinding-Larsen-Johansson Disease (Apophysitis of the Inferior Pole of the Patella)

This condition involves a process similar to that in Osgood-Schlatter disease, but occurring in younger athletes, usually between ages 9 and 12 years. Traction from the patellar tendon results in fragmentation of the inferior patella that is often obvious on a lateral knee radiograph.

► Treatment

As with many injuries, control of pain and inflammation is essential. This begins with relative rest from offending activity and ice. Alignment problems and mechanics across the anterior knee can be improved with an effective rehabilitation program that includes flexibility and strengthening. Quadriceps, pelvic, and core strengthening are all important components of this program. Orthotics, in theory, can have an impact on mechanics across the knee joint if they correct excessive pronation or supination.

Knee bracing is controversial, and the major benefits are proprioceptive feedback and patellar tracking. Return to activity is often based on symptoms.

2. Posterior Knee Pain

Posterior knee pain usually results from an injury to the gastrocnemius-soleus complex caused by overuse. It can also include a Baker cyst, tibial stress fracture, or tendonitis of the hamstring. Treatment is rest, ice, and strengthening exercises after symptoms have improved.

3. Meniscal Injuries

- Posterior knee pain.
- Effusion and joint line tenderness.
- Feeling of locking or of the knee giving way.
- Positive McMurray test.

The meniscus of the knee cushions forces in the knee joint, increases nutrient supply to the cartilage, and stabilizes the knee. Most injuries are related to directional changes on a weight-bearing extremity. **Medial meniscus injuries** have a history of tibial rotation in a weight-bearing position. This happens frequently in ball-handling sports. **Lateral meniscus injuries** occur with tibial rotation with a flexed knee, as in exercises such as squatting or certain wrestling maneuvers. These injuries are uncommon in children younger than age 10 years.

► Clinical Findings

The athlete with such an injury has a history of knee pain, swelling, snapping, or locking or may report a feeling of the knee giving way. Physical examination often reveals swelling, joint line tenderness, and a positive McMurray hyperflexion-rotation test. The diagnostic test of choice is MRI of the knee, although standard knee radiographs should be included.

► Treatment

Treatment may be symptomatic for minor, isolated injuries of the meniscus that do not involve a mechanical block. Persistent loss of motion and other signs of meniscal damage suggest meniscal impingement and require more urgent referral for surgical management. Surgery is also indicated in failure of conservative care within 4–6 weeks of the injury. If surgery is needed, weight bearing may not be allowed, depending on the amount of meniscal damage and the type of repair required. Typically, however, range-of-motion and strengthening exercises can be resumed quickly, and return to play can be achieved within 4–6 weeks.

4. Medial & Lateral Collateral Ligament Injuries

- Pain on the medial or lateral portion of the knee.
- Tenderness along the ligament.
- Positive valgus stress test at 0 and 30 degrees.

The medial and lateral collateral ligaments are positioned along either side of the knee and act to stabilize the knee during varus and valgus stress. Medial injuries occur either with a blow to the lateral aspect of the knee, as seen in a football tackle, or with a noncontact rotational stress.

► Clinical Findings

The athlete may feel a “pop” or lose sensation along the medial aspect of the knee. The examination reveals an effusion and tenderness medially. A valgus stress test performed in 20–30 degrees of flexion reproduces pain.

Medial collateral ligament injuries are graded on a scale of 1 to 3. Grade 1 injuries represent a stretching injury. Grade 2 injury involves partial disruption of the ligament. Grade 3 injury is a complete disruption of the ligament. Radiographs are useful, especially in the skeletally immature athlete, to evaluate for distal femoral or proximal tibial bone injury. MRI scans are used if grade 3 injury or concomitant intra-articular derangement is suspected.

► Treatment

Treatment is almost always conservative. Initial injuries should be iced and elevated. A protective brace needs to be worn, and full knee motion in the brace can be permitted within a few days. Weight bearing is allowed, and a strengthening program can be started. The athlete should use the brace until the pain and range of motion have improved. The use of a functional brace is often required when a player returns to competition. Bracing is temporary, until the ligament heals properly and the athlete has no subjective feelings of instability.

5. Anterior Cruciate Ligament Injuries

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pain and effusion of the knee.
- Pain along the anterior joint line.
- Positive Lachman test.

The ACL consists of three bands that prevent anterior subluxation of the tibia. It is injured by deceleration, twisting, and cutting motions. The mechanism of injury involves force applied to the knee during hyperextension, with excessive valgus stress and forced external rotation of the femur on a fixed tibia.

► Clinical Findings

The athlete often reports hearing or feeling a “pop,” followed by swelling that occurs within hours of the injury. Evaluation of the knee begins with examination of the uninjured knee.

The Lachman test provides the most accurate information about knee stability in relation to the ACL. All other structures of the knee need to be examined to rule out concomitant injuries. Imaging of the knee includes plain radiographs along with an MRI scan. In skeletally immature athletes, a tibial spine avulsion is often seen on radiographs rather than a midsubstance ACL tear.

► Treatment

Initial treatment focuses on controlling swelling and pain management. Structured physical therapy can be instituted early to assist in regaining range of motion and strength. Treatment options include both conservative and surgical management. Conservative treatment includes bracing, strengthening, and restricting physical activity. Knee braces enhance proprioception and control terminal extension. Conservative management can be complicated by continued instability and damage to meniscal cartilage. Recent advances in surgical treatment of the skeletally immature athlete have been helpful in dealing with the complicated management of young athletes with ACL tears.

Surgical repair is typically indicated for young athletes in cutting sports and is also required for persistent instability. Surgery can be performed 2–6 weeks following the injury if the swelling and motion in the knee have improved. Rehabilitation of the knee starts immediately after surgery. A continuous passive range-of-motion machine is used postoperatively. Partial weight bearing is allowed in a brace that is set in full extension as the quadriceps strengthen. After 2 weeks, partial weight bearing and walking are started. The goals of the subsequent program are continued strength, muscle reeducation, endurance, agility, and coordination. Return to cutting and pivoting sports can be achieved by 6 months after surgery.

6. Posterior Cruciate Ligament Injuries

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pain and swelling of the posterior knee.
- Increased pain with knee flexion.
- Positive posterior Drawer test.

The posterior cruciate ligament (PCL) runs from the medial femoral condyle to the posterior tibial plateau and has two parts. Its main function is to prevent posterior tibial subluxation. Injury to the PCL is uncommon; it occurs when the individual falls on a flexed knee with the ankle in plantarflexion or with forced hyperflexion of the knee. The most common sports in which PCL injuries are sustained are football and hockey.

► Clinical Findings

The athlete presents with swelling and pain in the posterior and lateral knee. The examination begins with the uninjured knee and proceeds to the injured side. Confirmatory testing includes the posterior drawer test, performed with the patient supine, the knee flexed to 90 degrees, and the foot stabilized. Grading is based on the amount of translation. Grade 1 (mild) is up to 5 mm, grade 2 (moderate) is 5–10 mm, and grade 3 (severe) is more than 10 mm. Diagnostic imaging includes plain radiographs and MRI scan.

► Treatment

Treatment can be determined as soon as the exact injury has been isolated. Treatment is controversial with respect to surgical versus nonsurgical management, although nonsurgical management is gaining popularity as outcomes tend to be similar for both groups.

Braces and a progressive rehabilitation program have been used successfully in athletes with grade 1 and 2 injuries. Athletes with grade 3 injuries and chronic instability may require surgery.

FOOT & ANKLE INJURIES

Injuries in the lower leg, ankle, and foot are quite common in pediatric athletes. The types of injuries sustained tend to depend on the age group. Young children tend to have diaphyseal injuries, in contrast to older children in rapid growth, who tend to have epiphyseal and apophyseal injuries. Skeletally mature adolescents are prone to adult-pattern ligamentous injury.

Although fractures of the ankle are possible with inversion and eversion mechanisms, the most common acute injury involving the ankle is the ankle sprain.

1. Ankle Sprain

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Mechanism is usually inversion and plantarflexion.
- Swelling and pain in the ankle over the ligament.
- Bruising over the ankle.

When a ligament is overloaded tearing occurs. These injuries are graded on a scale of 1 to 3. Grade 1 injury is a stretch without instability, grade 2 is a partial tear with some instability, and grade 3 is a total disruption of the ligament with instability of the joint. The ankle has three lateral ligaments (anterior talofibular, calcaneofibular, and posterior talofibular) and a medial deltoid ligament. Inversion of the foot generally damages the anterior talofibular ligament, whereas eversion injures the deltoid ligament. Lateral ankle sprains are far more common than medial ankle sprains because the deltoid ligament is stronger, mechanically, than the lateral ligaments.

► Clinical Findings

Physical examination often reveals swelling, bruising, and pain. Diagnostic testing should be done when a bony injury is suspected. Obtaining radiographs is especially important when evaluating skeletally immature athletes who are more prone to growth plate injury.

The adult Ottawa criteria do not pertain to patients younger than age 18 years. Tenderness over the malleoli, tenderness beyond ligament attachments, and excessive swelling are reasons to obtain radiographs.

► Differential Diagnosis

Other injuries to consider include injuries to the fifth metatarsal, which can occur with an inversion mechanism. In this injury, the athlete presents with localized swelling and tenderness over the base of the fifth metatarsal. Fractures at the base of the fifth metatarsal can be divided into avulsion, Jones, and diaphyseal fractures. Tibiofibular syndesmosis tear occurs with dorsiflexion and external rotation. Radiographs are required, and the squeeze test is positive. Fractures of the malleoli, fibula, talar dome or calcaneus may also mimic ankle sprain.

► Treatment

Appropriate treatment of ligamentous ankle injuries is imperative to ensure full recovery and should begin immediately after the injury. Phase 1 care involves immediate compressive wrapping and icing to control swelling and inflammation. Protected weight bearing is allowed in the early phase of rehabilitation. Phase 2 begins when the athlete can ambulate without pain. During this time ankle range of motion is emphasized, along with isometric contractions of the ankle dorsiflexors. Once 90% of strength has returned, active isotonic (eccentric and concentric exercises) and isokinetic exercises can be added. Phase 3 is designed to increase strength, improve proprioception, and add ballistic activity. The “foot alphabet” and “tilt board” are excellent methods to improve ankle proprioception. This program can be effective in returning athletes to activity within a few weeks, although up to 6 weeks may be required for return to full activity. The athlete should wear a protective brace for 3–4 months and continue to ice after exercising.

2. Sever Disease

Sever disease, or calcaneal apophysitis, occurs in athletes aged 9–12 years who are involved in high-impact activities such as gymnastics and soccer. Pain occurs at the point of muscle tendon insertion onto the growth center of the calcaneus. The athlete presents with activity-related heel pain, and examination reveals focal tenderness over the apophysis. Treatment consists of relative rest, heel cord stretching, ice massage and NSAIDs for pain control, and progression to activity as tolerated based on pain level.

3. Plantar Fasciitis

Plantar fasciitis is a common problem that manifests as heel pain in the adolescent or older athlete. It typically occurs in runners who log more than 30 miles per week and in athletes who have tight Achilles tendons or wear poorly fitting shoes. It is also common in people with cavus feet and in those who are overweight. The pain is worse upon first standing up in the morning and taking a few steps. A bone spur is often found on examination.

Treatment involves local massage, stretching of the gastrosoleus, NSAIDs, arch supports, and local steroid injections. Runners may need to cut back on their weekly mileage until these measures eliminate pain.

PREVENTION

As in all activities, most sports-related injuries can be prevented by the use of protective equipment, common sense, and proper training. Protective equipment should be properly fitted and maintained by an individual with training and instruction. Helmets should be used in football, baseball, hockey, bicycling, skiing, in-line skating, skateboarding, or any sport with risk of head injury. Eye protection should be used in sports that have a high incidence of eye injuries. Proper protective padding should be identified and used, including chest pads for catchers; shin guards in soccer; shoulder, arm, chest, and leg padding in hockey; and wrist and elbow protectors in skating. A few common-sense concepts should be addressed by coaches, parents, and physicians in order to ensure the safety of children participating in sports. These include inspecting playing fields for potential hazards, adapting rules to the developmental level of the participants, and matching opponents equally.

The use of the preparticipation history and physical examination, described earlier, can identify potential problems and allow for prevention and early intervention. Proper training techniques reduce injuries by encouraging flexibility, promoting endurance, and teaching correct biomechanics. Sports education reinforces the concepts of fitness and a healthy lifestyle along with sport-specific training. Early identification of an injury allows the athlete to modify techniques and avoid micro- and macrotrauma. Once an injury has occurred, it needs to be identified properly and appropriate measures used to minimize inflammation. Rehabilitation of the injury starts as soon as it has been identified. Early and appropriate care offers the athlete an optimal chance for full recovery and return to full participation.

Rehabilitation Medicine

Pamela E. Wilson, MD
Gerald H. Clayton, PhD

Rehabilitation medicine is the multispecialty discipline involved in the diagnosis and therapy of individuals with congenital and acquired disabilities. The overarching goals are to maximize the patient's functional capabilities and improve quality of life. Disabilities are described using the World Health Organization's International Classification of Function, Health, and Disability. Three aspects require evaluation in every patient: (1) the impact of the disability on body structure and function, (2) the impact of the disability on activity and participation, and (3) the environmental factors with an impact on patient function. Evaluation of these three areas provides a common framework for discussing a disabling condition and the impact it has on the body and on the individual's ability to participate in society.

PEDIATRIC BRAIN INJURY

► General Considerations

Every year there are an estimated 400,000 emergency department visits for brain injuries among children from birth through 14 years of age, with 3000 deaths and 29,000 hospitalizations. Children with brain injuries may have long-term deficits and disabilities that require identification and treatment. Brain injury is divided into primary and secondary injury.

Primary injury refers to the immediate injury causing focal or diffuse damage. *Focal damage* includes skull fracture, parenchymal bruising or contusion, extraparenchymal or intraparenchymal hemorrhage, blood clots, tearing of blood vessels, or penetrating injury. *Diffuse damage* includes diffuse axonal injury and edema. Consequences of primary injury, either focal or diffuse, include cellular disruption with release of excitatory amino acids, opiate peptides, and inflammatory cytokines.

Secondary injury refers to the loss of cellular function accompanying primary injury that results in loss of cerebrovascular regulation, altered cellular homeostasis, or cell death and functional dysregulation. A primary injury can

initiate the processes of secondary programmed cell death (apoptosis), which further exacerbates the primary injury. Secondary injury may develop hours or days after the initial insult. It appears to be precipitated by elevated intracranial pressure, cerebral edema, and release of neurochemical mediators.

Clinical Classification & Severity Scores for Head Injury

Traumatic brain injury is usually categorized as open or closed. *Open* injuries are the result of penetration of the skull by missile or sharp object, or deformation of the skull with exposure of the underlying intracranial tissues. *Closed* injuries occur secondary to blunt trauma to the head, which causes movement (intracranial acceleration or deceleration and rotational forces) and compression of brain tissue. Brain contusions are referred to as *coup* (occurring at the site of injury) or *contra-coup* (occurring on the side of the brain opposite the injury). Measures for rating severity of injury and eventual outcomes are important in medical management. Included below are several common scales:

A. Glasgow Coma Scale

The Glasgow Coma Scale (GCS) is the most commonly used system to assess the depth and duration of impaired consciousness in the acute setting. The score is derived from three different areas of evaluation: motor responsiveness (maximum score 6), verbal performance (maximum score 5), and eye opening to stimuli (maximum score 6). The scale has been modified for use in infants and children younger than 5 years of age, allowing for their lack of verbal responsiveness and understanding (see Table 11-5). Cumulative scores on the GCS define injury as mild (13-15), moderate (9-12), and severe (≤ 8). The concept of post-traumatic amnesia is used to gauge severity of injury and is an adjunct to the GCS, termed the GCS-E (extended). Post-traumatic amnesia is defined as the period of time after an injury

during which new memory cannot be incorporated and the person appears confused or disoriented. Amnesia can be retrograde, anterograde, or both.

B. Rancho Los Amigos Levels of Cognitive Function

The Rancho Los Amigos Levels of Cognitive Function (LCFS or “Rancho”) is commonly used to gauge the overall severity of cognitive deficit and can be used serially during recovery as a rough gauge of improvement. The scale has 10 levels of functioning ranging from “no response” to “purposeful, appropriate.”

C. Coma/Near Coma Score

The coma/near coma (CNC) score is a gauge of depth of coma for those with severe brain injury. It serves as a sensitive measure of clinical changes in sensory, perceptual, and primitive responses. Serial assessment of the patient’s coma status with the CNC can provide a means to track recovery and assess the potential for active participation in therapy.

Common Sequelae of Brain Injury

Depending on the severity of brain injury, there may be deficits in cognition and behavior, and a variety of physical impairments. Injuries can also produce changes in sensory and motor function, emotional stability, social behavior, mental processing speed, memory, speech, and language. The consequences of mild brain injuries may be difficult to discern. Small intraparenchymal injuries, easily identified by computed tomography (CT) or magnetic resonance imaging (MRI) scans, may not cause obvious signs or symptoms. The following are common problems associated with brain injury.

A. Seizures

Seizures occurring in the first 24 hours after injury are referred to as *immediate seizures*. Those occurring during the first week are *delayed seizures*, and those starting more than 1 week after injury are referred to as *late seizures*. Seizure prophylaxis with medications is recommended in the first week after brain injury in children at high risk for seizures and in very young children, who are at higher risk for early seizures than are older children and adults. Seizure prophylaxis is also recommended for 1 week after any penetrating brain trauma. Seizure prophylaxis is probably not effective for prevention of late-onset seizures. Late-developing seizures may require long-term treatment.

B. Motor Function Deficits

Motor function deficits after brain injury include movement disorders, spasticity, paralysis, and weakness. These deficits can result in impaired ambulation, coordination, impaired ability to use upper extremities, and speech prob-

lems. Physical therapy is the primary modality of treatment for these problems.

C. Sensory or Perceptual Deficits

Sensory deficits after traumatic brain injury are most commonly the result of cranial nerve injuries or parenchymal brain damage. Abnormal sensation may result in swallowing problems, reduced self-protective mechanisms, neglect, visual processing dysfunction, and pain.

D. Paroxysmal Autonomic Instability Associated with Dystonia

Severe brain injuries can be associated with autonomic dysfunction of the thalamus and hypothalamus, which results in a constellation of symptoms known as paroxysmal autonomic instability associated with dystonia (PAID). PAID is manifested by tachycardia, tachypnea, sweating, hyperthermia, agitation, and posturing. Common medications used in the treatment of PAID include dopamine agonists such as bromocriptine, β -blockers such as propranolol, and α -agonists such as clonidine.

E. Cognitive and Behavioral Deficits

After brain injury, cognitive and behavioral deficits may be obvious immediately or develop gradually. They include decreased arousal, decreased attention, impaired executive function, and problems with memory and concentration. Emotional lability, depression, agitation, impulsivity, and aggression can emerge. Many of these behaviors improve spontaneously, but some require behavioral or pharmacologic intervention.

F. Hypothalamic-Pituitary-Adrenal Axis Dysfunction

Dysfunction of the hypothalamic-pituitary-adrenal axis is common after head injury. The syndrome of inappropriate antidiuretic hormone secretion (SIADH) and diabetes insipidus from a posterior pituitary injury can result in significant electrolyte and osmolality imbalance and must be monitored closely. Amenorrhea is common in females and typically resolves spontaneously. Injury near the onset of puberty can complicate normal development, and endocrine status should be monitored closely.

G. Cranial Nerve Injuries

The sensory and motor components of the cranial nerves are often damaged, resulting in a wide variety of deficits not centrally mediated. Sight, hearing, taste, and smell, as well as swallowing, are among the most commonly affected functions. The vestibulocochlear nerve (cranial nerve VIII) is most often affected followed by the oculomotor nerve (cranial nerve III). Hyposmia or anosmia (cranial nerve I) can occur if the shearing forces at the cribriform plate

disrupt the olfactory afferent nerves running centrally from the nose. Injury to cranial nerves III, IV, and VI can affect vision, causing diplopia and other deficits. Optic nerve (cranial nerve II) injury is relatively rare. If injury to the optic nerve occurs, it is usually apparent within 1 month of the initial traumatic event.

Developmental Considerations

Much of what we know of traumatic brain injury is based on experience in adults. The confounding effects of age and the etiologies unique to the pediatric population (eg, child abuse) make care of the pediatric head-injured patient very complex.

The assumption that younger children will fare better than older children or adults after a brain injury is a myth. The fact that, in a child, a significant amount of development and synaptic reorganization has yet to occur does not guarantee an improved chance for functional recovery. Indeed, disruption of developmental processes, especially in very young infants or neonates, may be catastrophic as these processes often cannot be resumed once disrupted.

The mechanism of injury plays an important role in determining the severity of brain injury in very young children. Mechanisms associated with nonaccidental injury such as shaking often result in global diffuse injury. The weak neck musculature, large head-to-body mass ratio, immature blood-brain barrier, and high intracranial fluid-to-brain mass ratio all contribute to widespread damage.

During puberty, major hormonal changes have an impact on the outcome of brain injury. Behavioral problems may be pronounced in brain-injured adolescents. Precocious puberty and precocious development of sexual activity may occur in preadolescents and should be carefully monitored.

Careful consideration should be given to the developmental progress of the brain-injured child and adolescent. Delays can be anticipated after moderate and severe brain injuries related to abnormalities of cognition and behavior. It is critical to identify developmental disabilities as early as possible so that appropriate therapy can be started in order to maximize the child's residual capabilities. Educational programs should include an individualized educational program (IEP) to support the child with significant remediation and assistance needs during their school years. Programs should also include a 504 plan (named for Section 504 of the Rehabilitation Act and the Americans with Disabilities Act). The 504 plan identifies the accommodations necessary in regular school settings for students with lesser disabilities so that they may be educated in a setting with their peers.

► Treatment

The primary goal of rehabilitation after childhood brain injury is to maximize functional independence. Rehabilitative care can be divided into three phases: acute, subacute, and long term. The acute and subacute phases typically occur

in the inpatient setting while the long-term phase is an outpatient endeavor.

A. Acute Care

Therapy in the acute phase consists mainly of medical, surgical, and pharmacological measures to decrease brain edema, treat increased intracranial pressure, and normalize serum laboratory values. Nutrition is essential in the healing process and either parenteral nutrition or supplemental enteral feedings are employed. Current research suggests that transitioning to enteral nutrition (eg, nasogastric tube feeding) as soon as possible after brain injury is associated with improved outcomes. Placement of a gastrostomy tube for supplemental enteral feeding is often performed in patients with severe brain injuries when recovery will be protracted and swallowing function is inadequate for safe oral feeding.

B. Subacute Care

Therapy in the subacute phase is characterized by early, intensive participation in rehabilitative therapies promoting functional recovery. Treatment should be planned after consultation with physical therapy, occupational therapy, speech-language specialists, and neuropsychologists. Nursing staff members are a primary interface with the patient and often serve as educators for family-directed care. Most children and adolescents with brain injuries can be discharged home to continue with treatment on an outpatient basis.

C. Long-Term Care

Long-term follow-up starts immediately after discharge. Medical issues must be thoroughly and regularly reviewed to ensure that changing needs are met. Annual multidisciplinary evaluation is important, especially as the child approaches school age. Neuropsychological testing may be required to define cognitive and behavioral deficits and plan strategies to deal with them in the educational environment. Therapies should be flexible, providing strategies to maximize independence and facilitate the child's involvement in changing environments.

Medication is often required for cognitive and behavioral issues. Attention deficit, irritability, and fatigue associated with brain injury may be amenable to treatment with stimulants such as methylphenidate and modafinil. Dopaminergic agents such as amantadine, levodopa, and bromocriptine can be useful in improving cognition, processing speed, and agitation. Antidepressants such as selective serotonin reuptake inhibitors can be helpful in treating depression and mood lability. Anticonvulsants can be useful as mood stabilizers and in treating agitation and aggression. Tegretol and valproic acid are typical agents for this purpose.

Attention and arousal can also be successfully addressed by utilizing behavioral techniques to reinforce desired

behaviors as well as identifying environmental situations that optimize those behaviors. Gains made in the behavioral realm often have a positive impact on therapies designed to address physical issues.

► Prognosis & Outcomes

Directly after brain injury, poor pupillary reactivity, low blood pH, absence of deep tendon reflexes, and low GCS all correlate with poor outcome. An increased number of intracranial lesions and increased depth and duration of coma are also associated with poor functional recovery. Children younger than 1 year of age tend to have worse outcomes.

Functional outcome assessment is important for judging the efficacy of rehabilitation therapy. Global multidomain measures are used to provide a functional “snapshot in time” of select functions—motor function and mobility, self-care, cognition, socialization, and communication. Several of these measures are available; the WeeFIM is the one most commonly used in pediatrics.

Outcome associated with mild brain injury is often quite favorable. Most patients recover normal function within a short time frame. A small percentage will develop persistent problems such as chronic headache, poor focusing ability, altered memory, and vestibular abnormalities.

In children, recovery may not be fully achieved for many months or years after the initial injury. The impact of the injury on developmental processes, and its future consequences, are difficult to predict. Long-term follow-up is required, particularly as the child approaches school age.

SPINAL CORD INJURY

► General Considerations

Epidemiologic studies of spinal cord injuries (SCI) suggest that there will be about 10,000 new injuries per year and that 20% will be in children younger than age 20 years. Motor vehicle accidents are the leading cause of SCI in all ages. Falls

are common causes in young children. The phenomenon of SCI without obvious radiologic abnormality (SCIWORA) can be present in 20–40% of young children. Children from birth to 2 years tend to have high-level injuries to the cervical spine because of the anatomical features of the spine in this age group. The facets tend to be shallower and oriented horizontally, and the bony spine is more flexible than the spinal cord. In addition the head is disproportionately large and the neck muscles are weak.

SCI are classified using the American Spinal Injury Association classification (ASIA class). This classification evaluates motor and sensory function, defines the neurologic level of the injury, and assesses the completeness of the deficit. The 72-hour ASIA examination is used in predicting recovery. A complete lesion identified on ASIA examination at 72 hours predicts a very poor recovery potential.

1. ASIA class A is a complete spinal cord injury, with no motor or sensory function in the lowest sacral segments.
2. ASIA class B is an incomplete injury, with preserved sensory function but no motor function in the sacral segments.
3. ASIA class C is an incomplete lesion in which the strength of more than 50% of key muscles below the injury level is graded less than 3/5 on manual muscle testing.
4. ASIA class D is an incomplete lesion in which the strength of more than 50% of key muscles below the injury level is graded greater than 3/5 on manual muscle testing.
5. ASIA class E is an injury in which full motor and sensory function is preserved.

► Clinical Findings

A. Clinical Patterns of Spinal Cord Injury

1. Brown-Séquard injury—In this injury, the cord is hemisectioned, causing motor paralysis, loss of proprioception and vibration on the ipsilateral side and loss of pain and temperature on the contralateral side.

2. Central cord syndrome—Injury is to the central part of the cord and results in greater weakness in the arms than the legs.

3. Anterior cord syndrome—Disruption of the anterior spinal artery causes motor deficits and loss of pain and temperature sensation.

4. Conus medullaris syndrome—Injury or tumor of the conus causes minimal motor impairment but significant sensory and bowel and bladder abnormalities.

5. Cauda equina syndrome—Injury to the nerve roots produces flaccid bilateral weakness in the legs, sensory abnormalities in the perineum, and lower motor neuron bowel and bladder dysfunction.

B. Imaging

The diagnosis and anatomic description of SCI is made mainly through imaging techniques. Initial studies should include radiographs of the entire spine (including cervical spine) and special studies for bony structures. MRI imaging is required to evaluate soft tissues. CT scans, including three-dimensional reconstructions, may be used to further define the injured elements.

► Treatment

A. Initial Management

The two primary precepts of SCI treatment are early identification and immediate stabilization of the spine. The approach used to stabilize the spine is determined by the type of injury, location of injury, and underlying condition of the spinal cord. Stabilizing the spine may prevent further damage to the spinal cord. External traction devices such as halo traction and orthotics are often used. Some injuries require internal stabilization. The benefit of corticosteroid administration in pediatric SCI has not been established but treatment is usually initiated based on adult data from the National Acute Spinal Cord Injury Study. The initial loading dose is 30 mg/kg over 15 minutes, followed by 5.4 mg/kg for the next 23 hours if started within 3 hours of injury. If started within 3–8 hours of injury, corticosteroids should be continued for 48 hours.

B. Functional Expectations after Spinal Cord Injury

The lesions associated with SCI have a predictable impact on motor and sensory function. It is helpful to understand these concepts when discussing functional expectations with patients and parents (Table 26–1).

C. Special Clinical Problems Associated with Spinal Cord Injury

1. Autonomic hyperreflexia or dysreflexia—This condition occurs in spinal injuries above the level of T6. Noxious stimuli in the injured patient cause sympathetic vasoconstriction below the level of injury. Vasoconstriction produces hypertension and then a compensatory, vagally mediated bradycardia. Symptoms therefore include hypertension, bradycardia, headaches, and diaphoresis. This response may be severe enough to be life threatening. Treatment requires identification and relief of the underlying noxious stimulus. Bowel, bladder, and skin problems are the most common noxious stimuli causing this syndrome. The patient should be placed in an upright position and antihypertensive medication used if conservative measures fail. Nifedipine (oral or sublingual) has been used in treatment of this condition.

Table 26–1. Functional expectations related to spinal cord injury.

Level of Injury and Key Muscle Function	Functional Skills
C1–C4 (no upper extremity function)	Dependent for all skills, can use voice-activated computer, mouth stick; can drive power wheelchair with technology devices such as sip and puff, chin drive, or head array
C5 (biceps function)	Can assist with ADLs, power wheelchair with joy stick, push manual wheelchair short distances, use modified push rims
C6 (wrist extension)	More ADL skills; can push manual wheelchair indoors, perform level transfers; hand function augmented with adapted equipment
C7 (elbow extension)	ADLs independent; hand function augmented with adapted equipment; can push manual wheelchair indoor and outdoor
C8 (finger flexors) T1 (little finger abduction)	ADLs independent; independent manual wheelchair skills; increased transfer skills
T2–T12 (chest, abdominal and spinal extensors) ^a L1 and L2 (hip flexors)	ADLs independent; independent manual wheelchair skills; improved transfer; standing with braces Standing and walking with long leg braces, KAFO, and RGO; swing-through gait; manual wheelchair main form of mobility
L3 (knee extension)	Home and limited community ambulation; long leg or short leg braces
L4 (ankle dorsiflexion)	Community ambulation with short leg braces, AFO
L5 (long toe extensors) S1 (ankle plantar flexors)	Community ambulation; may be slower than peers and have some endurance issues

^aLevel defined by sensory dermatome.

ADLs, activities of daily living; AFO, ankle-foot orthosis; KAFO, braces named for the joints being supported (ie, knee-ankle-foot orthosis); RGO, reciprocal gait orthosis.

2. Hypercalcemia—Hypercalcemia often occurs in male adolescents within the first 2 months of becoming paraplegic or tetraplegic. The serum calcium level rises significantly in response to immobilization. Patients complain of abdominal pain and malaise. Behavioral problems may occur. Initial treatment is focused on hydration and forced diuresis using fluids and furosemide to increase urinary excretion of calcium. In severe cases, especially in older children, calcitonin and etidronate may be required.

3. Thermoregulation problems—These problems are most common and most severe in higher level injuries and usually result in a poikilothermic state. The ability to vasoconstrict and vasodilate below the injury level is impaired. The person with an SCI above T6 is particularly susceptible to environmental temperature and is at risk for hypothermia and hyperthermia.

4. Deep vein thrombosis—Thrombosis is a common complication of SCI, especially in postpubescent children. Deep vein thrombosis should be suspected in children with any unilateral extremity swelling, palpable cords in the calf muscles, fevers, erythema, or leg pain. Diagnosis is confirmed by Doppler ultrasound, and full evaluation may require spiral CT scan or ventilation-perfusion scan if pulmonary embolus is suspected. Preventative measures include elastic stockings and compression devices. Anticoagulation medications include heparin and low-molecular-weight heparin (0.5 mg/kg every 12 hours).

5. Heterotopic ossification—This complication occurs in both spinal cord and traumatic brain injuries. Ectopic calcium deposits usually appear around joints in the first 6 months after injury. They may cause swelling, decreased range of motion, pain with motion, palpable firm masses, fever, elevated sedimentation rate, and abnormal triple phase bone scan. Etidronate therapy should be started at the time of diagnosis. Surgical removal of ectopic deposits is controversial and usually performed only in cases of extreme loss of motion, pressure sores, or severe pain.

BRACHIAL PLEXUS LESIONS

▶ General Considerations

The brachial plexus is the complex nervous connection between the spinal cord and the muscles of the upper extremity and scapular area. The nerve roots forming the plexus derive from the fifth cervical through the first thoracic nerves. These

nerve roots form trunks that further divide into divisions and then into cords. The upper trunk (C5 and C6) is the most commonly injured, resulting in a symptom complex called **Erb palsy**. Injury to the lower trunk (C7–T1) produces **Klumpke palsy**. It is quite common for the entire brachial plexus to be involved. Mild brachial plexus injuries may produce only a nerve stretch or neurapraxia. Severe injury may cause complete avulsion of the nerve from the spinal cord.

▶ Clinical Findings

Erb palsy is characterized by shoulder weakness with internal rotation and adduction of the upper arm. The elbow is extended and the wrist flexed. There is good preservation of hand function. Klumpke palsy is characterized by good shoulder function but decreased or absent hand function. Brachial plexus injury may also cause Horner syndrome (unilateral miosis, ptosis and facial anhidrosis) due to disruption of cervical sympathetic nerves. Associated bony and nerve injuries are common in brachial plexus injury. The physical examination should include inspection of the humerus and clavicle for fractures. There may be injuries of the phrenic and facial nerves.

The diagnosis of a brachial plexus lesion should be based on the history and clinical examination. Diagnostic testing helps confirm, localize, and classify the lesion. Electromyography is helpful 3–4 weeks after the injury. This test not only is used diagnostically but can track recovery. MRI, myelography, and CT scan can help to locate the lesion and determine its extent.

▶ Treatment & Prognosis

Primary surgery to the nerves of the plexus is indicated for children who have no spontaneous recovery of biceps function by 6–9 months. Secondary procedures to maximize function include muscle transfers and orthopedic interventions. Physical therapy is the major treatment for brachial plexus injury and includes stretching, bracing, and functional training.

The currently accepted method of predicting recovery is based on the spontaneous recovery of the biceps. Children in whom antigravity function returns within 2 months of injury will probably have near-full recovery of function. If antigravity function is delayed until 6 months after injury, recovery will probably be limited. If antigravity function is absent at 6–9 months after injury, there will be no recovery of function and surgical options to transplant muscles and improve motor function should be considered.

COMMON REHABILITATION PROBLEMS

1. Neurogenic Bladder

The function of the bladder is to hold and eventually expel urine. The muscles of the bladder include the detrusor and urethral sphincters. During the first year of life the bladder is a reflex-driven system that empties spontaneously. After the first year control begins to develop, and most children achieve continence by age 5 years. Children with damage to the central or peripheral nervous system may develop neurogenic bladder. Neurogenic bladder is usually classified as noted below.

1. *Uninhibited* neurogenic bladder occurs after upper motor neuron injuries at the level of the brain or SCI that result in failure to inhibit detrusor contractions. This results in a hyperreflexive voiding pattern.
2. *Reflex* neurogenic bladder results from damage to the sensory and motor nerves above the S3 and S4 level. The bladder empties reflexively but coordination may not be present and dyssynergia (contraction of the bladder musculature against a closed sphincter) can occur. Increased intravesicular pressure and vesicourethral reflux may be consequences of dyssynergia.
3. *Autonomous* neurogenic bladder is a flaccid bladder and is associated with lower motor neuron damage. Bladder volumes are usually increased and overflow incontinence can occur.
4. *Motor paralytic* neurogenic bladder results from injury to the motor nerves of the S2-4 roots. Sensation is intact but there is motor dysfunction. The child has the sensation to void but has difficulty with the voluntary contractions.
5. *Sensory paralytic* neurogenic bladder results when sensory roots are disrupted. Affected patients do not have sensation of the full bladder but are able to initiate voiding.

The diagnosis of neurogenic bladder requires a complete history and physical examination. The type of neurologic damage should be identified as this will help to predict anticipated voiding issues. The upper tracts should be assessed by several techniques, including ultrasound, intravenous pyelogram, and renogram (isotope) studies. Lower tract testing includes urinalysis, postvoid residuals, urodynamics, cystography, and cystoscopy.

▶ Treatment

Treatment is geared to the type of bladder dysfunction. The simplest methods are those employing behavioral strategies. Timed voiding can be effective for children with uninhibited bladders. In this technique, children are reminded verbally or use a cueing device (watch with a timer) to void every 2–3 hours before bladder capacity is reached. The Credé and Valsalva maneuvers are used in patients with an autonomous bladder to

assist in draining a flaccid bladder. There is a risk of increasing intravesicular pressure during these maneuvers, which can provoke vesicoureteral reflux. These maneuvers should never be used in a patient with a reflex neurogenic bladder.

Medications are often employed to treat neurogenic bladder. Anticholinergics are commonly used to reduce detrusor contractions, decrease the sense of urgency, and increase bladder capacity. Medications include oxybutynin, tolterodine, and hyoscyamine. The side effects of these medications include sleepiness, nausea, and constipation. Families often find these effects unacceptable and frequently abandon treatment.

External methods are also used to improve continence and function. Absorbent pads and diapers, external catheters, internal catheters, and clean intermittent catheterization are some typical methods. Surgical procedures to protect the upper tracts from urinary reflux are often used. A young child with a high-pressure bladder is at particular risk for reflux and may need medication, clean intermittent catheterization, or vesicostomy to prevent hydrostatic renal damage and infection. An older child may require bladder augmentation or an intestinal conduit from bladder to skin surface to relieve bladder distention (Mitrofanoff procedure). If there is an incompetent urethral sphincter with urinary leakage, injections, slings, or implants may be used to increase the urethral barrier. Recently, electrical stimulation of sacral roots has been used to initiate voiding. Biofeedback training is also used to improve voiding.

2. Neurogenic Bowel

Control of bowel function depends on an intact autonomic (sympathetic and parasympathetic) and somatic nervous system. Interruption of any of these pathways can result in bowel control problems. Goals of treatment for patients with neurogenic bowel are to establish a predictable and reliable bowel habit, prevent incontinence, and prevent complications. There are two types of neurogenic bowel dysfunction: upper motor and lower motor dysfunction. The upper motor neuron bowel results from damage above the conus. Affected patients usually have reflex bowel contractions of high amplitude, absence of sensation, and no voluntary sphincter control. Patients with the lower motor neuron bowel have no sphincter control and no anocutaneous reflex. It has been described as a flaccid bowel. In general establishing a bowel program is much easier in patients with the upper motor neuron–type lesion.

▶ Treatment

Diet is extremely important in either type of bowel program. Fiber and fluids are critical elements. Stool consistency should be on the soft side, although some patients try to keep themselves constipated to prevent accidents. A predictable and scheduled bowel program is essential. Bowel movements should be scheduled to occur with meals, as the gastrocolic reflex can trigger defecation.

Laxative and stool softening medications are usually included in a comprehensive bowel program. Stool softeners such as docusate retain stool water. Mineral oil is another acceptable stool softener in patients not at risk for pulmonary aspiration. Bulking agents such as Metamucil increase fiber and water content of stool and reduce transit time. Stimulants such as senna fruit extract or bisacodyl increase peristalsis. Osmotic agents such as polyethylene glycol keep stools soft by retaining stool water.

Suppositories and enemas are often used when other methods have not been successful. Upper motor neuron bowel management may require digital rectal stimulation as part of the program. Newer surgical options include sacral nerve stimulators and techniques to provide flushing of the colon. Cecostomy button or antegrade continence enema is employed when other conservative methods have not been able to achieve desired goals.

3. Spasticity

Spasticity is a velocity-dependent increase in muscle tone and a loss of isolated muscle function. Whereas tone is the resistance felt in a muscle as it is moved in space, spasticity occurs when there is damage to the central nervous system from trauma or injury. It is included in the upper motor neuron syndrome (hyperactive and exaggerated reflexes, increased tone, clonus, positive Babinski sign). Spasticity is evaluated using the Ashworth Scale, with zero indicating no increase in muscle tone and 4 indicating complete rigidity of the extremity.

► Treatment

Treatment is goal directed and influenced by the functional status of the client. Spasticity has both positive and negative effects on quality of life. The positive aspects include the ability to use spasticity for functional tasks along with maintaining muscle strength. Negatively spasticity can interfere with positioning and hygiene, affect function, and can cause pain.

Options for therapy range from conservative to aggressive. A pyramidal approach starts from a base of prevention of nociceptive input and aggressive physical therapy. Children should be positioned properly and have appropriate equipment to support this strategy. Physical therapy is designed to reduce the long-term effects of spasticity by stretching and range-of-motion exercises. Heat and cold are useful in improving tone, but their effects are not long lived. Casting of both upper and lower extremities can decrease tone and increase range of motion. Constraint therapy can be used to try to improve upper extremity function.

The next step on the pyramid is the use of medications, mainly baclofen, diazepam, dantrolene, and tizanidine. Baclofen is a first-line medication, which produces effects at the spinal cord level. Side effects are mainly sleepiness and weakness. Seizure threshold may be reduced by baclofen. Baclofen can be delivered directly to the central nervous

system through an intrathecal pump. It has been used successfully in children with brain injury, cerebral palsy, and SCI. Diazepam affects presynaptic GABA receptors in both the brain and the spinal cord. It can cause drowsiness and dependence. Dantrolene decreases the release of calcium in muscle. Side effects include weakness and, rarely, hepatotoxicity. Tizanidine is a newer agent and works at the α_2 -adrenergic receptors presynaptically. It can cause dry mouth and sedation, and liver function tests can be elevated.

Relief of focal spasticity can be achieved by using chemodenervation techniques. Botulinum toxin A and B can be injected in selected muscles to improve range of motion, thus improving function and hygiene as well as reducing pain and deformity. More recently, botulinum toxins have been used to treat drooling, hyperhidrosis, and chronic pain. These toxins block the release of acetylcholine at the neuromuscular junction. The effects are temporary, lasting only 3–6 months, and repeat injections are often needed. Phenol injections are another option for treatment of local spasticity and are technically more challenging. Phenol denatures proteins in both myelinated and unmyelinated fibers and produces neurolysis or myolysis, depending on the site of injection. The effects may last longer than botulinum toxins. Injections carry a risk of sensory dysesthesia if mixed nerves are injected.

Surgical options include orthopedic procedures geared toward improving function and ambulation and alleviating deformities produced over time by spasticity. Contractures are common in the Achilles tendon, hamstrings, and adductors. Upper extremity contractures occur in the elbow, wrist, and finger flexors. Scoliosis is fairly common and bracing or surgery may be needed. Gait analysis may be helpful in evaluating the child with functional spasticity as a guide for the use of orthotics, therapy, and surgery. Neurosurgical techniques such as selective dorsal rhizotomy are used in a very select group of children to permanently alter spasticity patterns and improve ambulation.

JUVENILE IDIOPATHIC ARTHRITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Arthritis, involving pain, swelling, warmth, tenderness, morning stiffness, and decreased range of motion of one or more joints, lasting 6–12 weeks.
- ▶ May have associated systemic manifestations, including fever, rash, uveitis, serositis, anemia, fatigue, and growth failure.

▶ General Considerations

There are three classifications of juvenile chronic arthritis. These different systems of categorizing patients attempt to standardize the diagnosis and approach to patient care as well as assist in designing research protocols. Each classification contains three main subtypes: pauciarticular or oligoarticular, polyarticular, and systemic (Table 27–1). The exact cause of juvenile idiopathic arthritis (JIA) is not known, but there is substantial evidence that it is an autoimmune process with genetic susceptibility factors.

▶ Clinical Findings

A. Symptoms and Signs

The most common type of JIA is the pauciarticular/oligoarticular form, which affects 50% of patients and is characterized by arthritis of four or fewer joints. This type of JIA often affects medium to large joints. Because the arthritis is often asymmetrical, children may develop a leg-length discrepancy in which the involved leg grows longer due to increased blood flow and growth factors. The synovitis is usually mild and may be painless. Systemic features are uncommon except for inflammation in the eye. Up to 30% of children with this type of JIA develop insidious, asymptomatic uveitis, which may cause

blindness if untreated. The activity of the eye disease does not correlate with that of the arthritis. Therefore, routine ophthalmologic screening with slit-lamp examination must be performed at 3-month intervals if the antinuclear antibody (ANA) test is positive, and at 6-month intervals if the ANA test is negative, for 4 years after the onset of arthritis.

Polyarticular disease is defined as arthritis involving five or more joints. This type of JIA affects 35% of patients. Both large and small joints are involved, typically in a symmetrical pattern. Systemic features are not prominent, although low-grade fever, fatigue, rheumatoid nodules, and anemia may be present. This group is further divided into rheumatoid factor-positive (10%) and rheumatoid factor-negative (25%) disease. The former resembles adult rheumatoid arthritis with more chronic, destructive arthritis.

The systemic form, also known as Still disease, is the least common form, comprising 10–15% of patients with JIA. The arthritis can involve any number of joints and affects both large and small joints, but may be absent at disease onset. One of the classic features is a high fever, often as high as 39–40°C, typically occurring one to two times per day. In between fever spikes the temperature usually returns to normal or subnormal. Ninety percent of patients have a characteristic evanescent, salmon-pink macular rash that is most prominent on pressure areas and when fever is present. Other systemic features that may be present, but are not specific for JIA, include hepatosplenomegaly, lymphadenopathy, leukocytosis, and serositis.

B. Laboratory Findings

There is no diagnostic test for JIA. A normal erythrocyte sedimentation rate (ESR) does not exclude the diagnosis of JIA. However, patients with systemic JIA typically have significantly elevated markers of inflammation including ESR, C-reactive protein (CRP), white blood cell count, and platelets. Rheumatoid factor is positive in about 10–15% of patients, usually when onset of polyarticular disease occurs after age 8 years. A newer test, anti-cyclic citrullinated

RF, rheumatoid factor.

peptide (CCP) antibody, may be detectable prior to the rheumatoid factor and has a very high specificity for rheumatoid arthritis. ANA are associated with an increased risk of iridocyclitis in patients with oligoarticular disease. A positive ANA test is also fairly common in patients with the late-onset rheumatoid factor-positive form of the disease.

Table 27-2 lists the general characteristics of joint fluid in various conditions. The main indication for joint aspiration and synovial fluid analysis is to rule out infection. A positive Gram stain or culture is the only definitive test for infection. A leukocyte count over 2000/ μ L suggests inflammation; this may be due to infection, any of the collagen-vascular diseases, leukemia, or reactive arthritis. A very low glucose concentration (< 40 mg/dL) or very high polymorphonuclear leukocyte count (> 60,000/ μ L) is highly suggestive of bacterial arthritis.

C. Imaging

In the early stages of the disease, only soft-tissue swelling and periarticular osteoporosis are seen. Magnetic resonance imaging (MRI) of involved joints may show early joint damage and if

Table 27-2. Joint fluid analysis.

Disorder	Cells/ μ L	Glucose ^a
Trauma	More red cells than white cells; usually < 2000 white cells	Normal
Reactive arthritis	3000-10,000 white cells, mostly mononuclear cells	Normal
Juvenile idiopathic arthritis and other inflammatory arthritides	5000-60,000 white cells, mostly neutrophils	Usually normal or slightly low
Septic arthritis	> 60,000 white cells, > 90% neutrophils	Low to normal

^aNormal value is \geq 75% of the serum glucose value.

obtained with gadolinium, can confirm the presence of synovitis. Later in the course of the disease, particularly in patients with rheumatoid factor-positive disease, plain films may demonstrate joint space narrowing due to cartilage thinning and erosive changes of the bone related to chronic inflammation.

► Differential Diagnosis

Table 27-3 lists the most common causes of limb pain in childhood. JIA is a diagnosis of exclusion; therefore, it is important to rule out other causes of the clinical signs and symptoms prior to settling on this diagnosis. The differential diagnosis is often quite broad, including orthopedic conditions, infectious diseases, and malignancies. A few key features can help distinguish these different entities, including the timing of the pain and associated signs and symptoms. In inflammatory conditions, patients frequently have increased symptoms in the morning with associated stiffness. In contrast, patients with an orthopedic abnormality typically have increased symptoms throughout the day and with activity. Growing pains, a common cause of leg pain in childhood, are characterized by poorly localized pain at night, which frequently wakes the child from sleep; no objective signs of inflammation; and no daytime symptoms. Patients with growing pains often ask to be massaged, which is not typical of those with arthritis.

It is particularly important to establish the diagnosis in the case of monoarticular arthritis. Bacterial arthritis is usually acute and monoarticular except for arthritis associated with gonorrhea, which may be associated with a migratory pattern. Fever, leukocytosis, and increased ESR with an acute process in a single joint demand synovial fluid examination and culture to identify the pathogen. Pain in the hip or lower extremity is a frequent symptom of childhood cancer, especially leukemia, neuroblastoma, and rhabdomyosarcoma. Infiltration of bone by tumor and a joint effusion may be seen. Radiographs of the affected site and examination of the blood smear for unusual cells and thrombocytopenia are necessary. An elevated lactate dehydrogenase value should

also raise concern about an underlying neoplastic process. In doubtful cases, bone marrow examination is indicated.

In cases of reactive arthritis, a preceding illness is identified in approximately half of cases. Patients often have acute onset of arthritis, and there may be a migratory pattern. The duration of symptoms is a very important distinction between reactive arthritides and JIA. Symptoms associated with reactive arthritis typically resolve within 4–6 weeks. In contrast, to meet criteria for chronic arthritis, symptoms must be present for at least 6–12 weeks.

The arthritis of rheumatic fever is migratory, transient, and often more painful than that of JIA. Rheumatic fever is very rare in children younger than 5 years of age. In suspected cases, evidence of rheumatic carditis should be sought based on examination and electrocardiographic findings. Evidence of recent streptococcal infection is essential to the

diagnosis. The fever pattern in rheumatic fever is low grade and persistent compared with the spiking fever that characterizes the systemic form of JIA. Lyme arthritis resembles oligoarticular JIA, but the former occurs as discrete, recurrent episodes of arthritis lasting 2–6 weeks. For patients suspected of having Lyme disease, testing for antibodies against *Borrelia burgdorferi* should be performed, with confirmatory testing by Western blot.

► Treatment

The objectives of therapy are to restore function, relieve pain, maintain joint motion, and prevent damage to cartilage and bone.

A. Nonsteroidal Anti-Inflammatory Medications

First-line therapy is nonsteroidal anti-inflammatory drugs (NSAIDs). A wide range of agents is available but only a few are approved for use in children, including naproxen (10 mg/kg per dose twice daily), ibuprofen (10 mg/kg per dose three to four times daily), and meloxicam (0.125 mg/kg once daily). NSAIDs are generally well tolerated in children, as long as they are taken with food. The average time to symptomatic improvement is 1 month, but in some patients a response is not seen for 8–12 weeks.

B. Disease-Modifying and Biologic Agents

For patients with JIA who fail to respond to NSAIDs, weekly methotrexate is the second-line medication of choice. Symptomatic response usually begins within 3–4 weeks. The low dosages used (5–10 mg/m²/wk or 1 mg/kg/wk as a single dose) are generally well-tolerated. Potential side effects include nausea, vomiting, hair thinning, stomatitis, bone marrow suppression, and hepatotoxicity. A complete blood count and liver function tests should be obtained every 2–3 months. Several additional disease-modifying agents are available for use in patients with persistently active disease or those intolerant to methotrexate. Leflunomide is an antipyrimidine medication that has been shown to be as effective as methotrexate. Side effects may include diarrhea and alopecia. Medications that inhibit tumor necrosis factor, a cytokine known to play an important role in the pathogenesis of JIA, include etanercept, infliximab, and adalimumab. These drugs are generally quite effective in controlling disease and preventing cartilage and bone damage, and have been associated with healing based on radiologic changes. However, their potential long-term effects are unknown, and they are very expensive and require parenteral administration. Newer biologic agents, including anakinra, rituximab, and abatacept, have demonstrated some preliminary efficacy in patients who have not responded to other treatments.

C. Corticosteroids

Steroids are reserved for children with severe involvement, primarily patients with systemic disease. Local steroid joint

injections may be helpful in patients who have arthritis in one or a few joints. Triamcinolone hexacetonide is a long-acting steroid that can be used for injections and is often associated with at least several months of disease control.

D. Uveitis

Iridocyclitis should be closely monitored by an ophthalmologist. Typically treatment is initiated with corticosteroid eye drops and dilating agents to prevent scarring between the iris and the lens. In patients who fail topical treatments, methotrexate, cyclosporine, and infliximab may be used.

E. Rehabilitation

Physical and occupational therapy are important to focus on range of motion, stretching, and strengthening. These exercises, as well as other modalities such as heat, water therapy, and ultrasound, can help control pain, maintain and restore function, and prevent deformity and disability. Young children with oligoarticular disease affecting asymmetrical lower extremity joints can develop a leg-length discrepancy, which may require treatment with a shoe lift on the unaffected side.

► Prognosis

The course and prognosis for JIA is variable, depending on the subtype of disease. Overall, the prognosis is good; 75–80% of patients remit without serious disability. In children with extended oligoarticular and polyarticular disease, more joints are involved; these patients may have more persistent and severe disease. Patients who are rheumatoid factor-positive are at highest risk for chronic, erosive arthritis that may continue into adulthood. The systemic features associated with systemic arthritis tend to remit within months to years. The prognosis in systemic disease is worse in patients with persistent systemic disease after six months, thrombocytosis and more extensive arthritis.

ENTHESITIS-RELATED ARTHRITIS & SPONDYLOARTHROPATHY

Lower extremity arthritis, particularly in males older than 10 years of age, suggests a form of spondyloarthropathy. Inflammation of tendinous insertions (enthesopathy), such as the tibial tubercle or the heel, occurs in these diseases and not in JIA. Low back pain and sacroiliitis are commonly seen in this form of arthritis. Carriage of HLA-B27 antigen occurs in approximately 80% of patients with this disorder. No

autoantibodies are found, but inflammatory indicators such as an elevated ESR or CRP may be present. Acute, not chronic, uveitis may occur.

NSAIDs, particularly indomethacin (2–4 mg/kg/d) and naproxen (15–20 mg/kg/d), are the first-line treatments for spondyloarthropathies. Refractory cases may respond to methotrexate, etanercept, or infliximab. Local corticosteroid injections are contraindicated in Achilles tendinitis. Unlike in adults, the disorder does not frequently progress to joint destruction or ankylosis in children.

Hofer M: Spondyloarthropathies in children—are they different from those in adults? *Best Pract Res Clin Rheumatol* 2006;20:315 [PMID: 16546059].

ENTEROPATHIC ARTHRITIS

Enteropathic arthritis includes several syndromes, such as Reiter syndrome, reactive arthritis, and the arthritis of inflammatory bowel disease and celiac disease. Their unifying feature is the association of arthritis with preceding or concurrent gastrointestinal symptoms. Reactive arthritis that follows diarrhea caused by *Salmonella*, *Shigella*, or *Yersinia* infection occurs with increased frequency in individuals who are HLA-B27–positive. The arthritis associated with Crohn disease and ulcerative colitis usually begins after or concurrent with active bowel disease. Other extraintestinal manifestations such as uveitis, stomatitis, hepatitis, and erythema nodosum may occur in these individuals.

Treatment for the musculoskeletal manifestations of inflammatory bowel disease, in addition to controlling the bowel disease, is primarily NSAIDs. Patients who have persistent disease may require treatment with second-line agents such as methotrexate or infliximab (or both).

SYSTEMIC LUPUS ERYTHEMATOSUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Multisystem inflammatory disease of the joints, serosal linings, skin, kidneys, blood, and central nervous system.
- Autoantibodies such as ANA, double-stranded DNA, and anti-Smith antibodies are present and related to the pathogenesis of disease.

► General Considerations

Systemic lupus erythematosus (SLE) is the prototype of immune complex diseases; its pathogenesis is related to the formation of antibody-antigen complexes that exist in the circulation and deposit in the involved tissues. The spectrum of symptoms is due to tissue-specific autoantibodies, as well

as damage to the tissue by lymphocytes, neutrophils, and complement evoked by the deposition of immune complexes. Laboratory tests for these antibodies and complement components give an objective assessment of disease activity and response to therapy. Autoreactive T lymphocytes that have escaped clonal deletion and unregulated B-lymphocyte production of autoantibodies may initiate the disease.

► Clinical Findings

A. Symptoms and Signs

The onset of pediatric SLE is most common in girls between the ages of 9 and 15 years. Signs and symptoms depend on the organs affected by immune complex deposition. The American College of Rheumatology has established criteria to aid in the diagnosis of SLE; four of the following 11 criteria are necessary to establish the diagnosis:

1. Malar rash—photosensitive, so-called butterfly rash on the cheeks and nasal bridge.
2. Discoid rash—annular, scaly rash on the scalp, face, and extremities that can lead to scarring.
3. Photosensitivity—increased rash or other disease symptoms in response to sunlight exposure.
4. Mucous membrane ulcers—painless ulcers on the hard palate or nasal septum (or both).
5. Arthritis—nonerosive arthritis of large and small joints, typically in a symmetrical distribution.
6. Serositis—pericarditis or pleuritis (or both), often associated with chest pain and difficulty breathing.
7. Renal abnormalities—proteinuria (> 0.5 g/d) or cellular casts (or both).
8. Neurologic abnormalities—seizures or psychosis (or both).
9. Blood count abnormalities—low white blood cell count ($< 4000/\text{mm}^3$), Coombs test–positive anemia and/or thrombocytopenia ($< 100,000/\text{mm}^3$).
10. Positive ANA—seen in almost 100% of patients with SLE.
11. Autoantibodies—positive double-stranded DNA antibody, anti-Smith antibody, anticardiolipin antibodies, lupus anticoagulant, or false-positive blood test for syphilis.

Other common signs and symptoms include fever, fatigue, weight loss, anorexia, Raynaud phenomenon, myositis, vasculitis, chorea, neuropathies, depression, and cognitive changes.

B. Laboratory Findings

Complete blood count abnormalities are common, including leukopenia, anemia, and thrombocytopenia. Approximately 15% of patients are Coombs test–positive, but many patients develop anemia due to other causes, including chronic disease and blood loss. Patients with significant renal involvement may have electrolyte disturbances, elevated kidney function tests, and hypoalbuminemia. The ESR is frequently elevated

during active disease. In contrast, many patients with active SLE have a normal CRP. When the CRP is elevated, it is important to investigate possible infectious causes, particularly bacterial infections. It is critical to monitor the urinalysis in patients with SLE for proteinuria and hematuria, as the renal disease may be otherwise clinically silent. In immune complex diseases, complement is consumed; therefore, levels of C3 and C4 are depressed with active disease.

The ANA test is positive in almost 100% of patients, usually at titers of 1:320 or above. In patients with suspected SLE, it is important to obtain a full ANA profile—including antibodies directed against double-stranded DNA, Smith, ribonucleic protein, and SSA and SSB antibodies—to better characterize their serologic markers of disease. Because approximately 50–60% of pediatric SLE patients have antiphospholipid antibodies and are therefore at increased risk of thrombosis, it is important to screen all patients with SLE for anticardiolipin antibodies and lupus anticoagulant.

► Differential Diagnosis

Because there is such a wide spectrum of disease with SLE, the differential diagnosis is quite broad, including systemic JIA, mixed connective tissue disease (MCTD), rheumatic fever, vasculitis, malignancies, and bacterial and viral infections. A negative ANA test essentially excludes the diagnosis of SLE. Anti-double-stranded DNA and Smith antibodies are very specific for SLE. The preceding diagnostic criteria, which are very helpful in establishing the diagnosis of SLE, have a specificity and sensitivity of 96%.

MCTD, an overlap syndrome with features of several collagen-vascular diseases, shares many features with SLE. The symptom complex is diverse and often includes arthritis, fever, skin tightening, Raynaud phenomenon, muscle weakness, and rash. The ANA test is typically positive in very high titers. The ANA profile is negative except for antibodies directed against ribonucleic protein.

► Treatment

The treatment of SLE should be tailored to the organ system involved so that toxicities may be minimized. Prednisone is the mainstay of treatment and has significantly lowered the mortality rate in SLE. Patients with severe, life-threatening, or organ-threatening disease are typically treated with intravenous pulse methylprednisolone, 30 mg/kg per dose (maximum of 1000 mg) daily for 3 days, and then switched to 2 mg/kg/d of prednisone. The dosage should be adjusted using clinical and laboratory parameters of disease activity, and the minimum amount of corticosteroid to control the disease should be used. Skin manifestations, arthritis, and fatigue may be treated with antimalarials such as hydroxychloroquine, 5–7 mg/kg/d orally. Pleuritic pain or arthritis can often be managed with NSAIDs.

If disease control is inadequate with prednisone or if the dose required produces intolerable side effects, a steroid-sparing

agent, such as mycophenolate mofetil, azathioprine, or cyclophosphamide, should be added. More recently, rituximab, a monoclonal antibody directed against CD20, has been used for persistent active disease, particularly in patients with hematologic manifestations. Patients who have evidence of antiphospholipid antibodies should be treated with a baby aspirin every day to help prevent thrombosis. Thrombotic events due to these clotting antibodies require long-term anticoagulation.

The toxicities of the regimens must be carefully considered. Growth failure, osteoporosis, Cushing syndrome, adrenal suppression, and aseptic necrosis are serious side effects of chronic use of prednisone. When high doses of corticosteroids are used (> 2 mg/kg/d), there is a high risk of infection. Cyclophosphamide can cause bladder epithelial dysplasia, hemorrhagic cystitis, and sterility. Azathioprine has been associated with liver damage and bone marrow suppression. Immunosuppressant treatment should be withheld if the total white count falls below 3000/ μ L or the neutrophil count falls below 1000/ μ L. Retinal damage from hydroxychloroquine has not been observed with recommended dosages.

► Course & Prognosis

The prognosis in SLE relates to the presence of renal involvement or infectious complications of treatment. Nonetheless, the survival rate has improved from 51% at 5 years in 1954 to 90% today. The disease has a natural waxing and waning cycle; the disease may flare at any time and spontaneous remission may occur.

DERMATOMYOSITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pathognomonic skin rashes.
- Weakness of proximal muscles and occasionally of pharyngeal and laryngeal groups.
- Pathogenesis related to vasculitis.

► General Considerations

Dermatomyositis is a rare autoimmune disease of muscle and skin. The cause is unknown, but there are likely genetic and environmental factors predisposing to the condition.

Small arteries and veins are involved, with infiltrates of neutrophils, lymphocytes, plasma cells, and histiocytes. The lesion progresses to intimal proliferation and thrombus formation. These vascular changes are found in the skin, muscle, kidney, retina, and gastrointestinal tract. Postinflammatory calcinosis may occur.

► Clinical Findings

A. Symptoms and Signs

The predominant symptom is proximal muscular weakness, particularly affecting pelvic and shoulder girdle muscles. Tenderness, stiffness, and swelling may be found. Pharyngeal involvement, manifested as voice changes and difficulty swallowing, is associated with an increased risk of aspiration. Intestinal vasculitis can be associated with ulceration and perforation of involved areas. Flexion contractures and muscle atrophy may produce significant residual deformities. Calcinosis may follow the inflammation in muscle and skin.

Several characteristic rashes are seen in dermatomyositis. Patients often have a heliotrope rash with a reddish-purple hue on the upper eyelids, along with a malar rash that may be accompanied by edema of the eyelids and face. Gottron papules are shiny, erythematous, scaly plaques on the extensor surfaces of the knuckles, elbows, and knees. Nail-fold abnormalities, including dilation, thrombosis, and dropout of periungual capillaries, may identify patients with a worse prognosis.

B. Laboratory Findings

Determination of muscle enzyme levels, including aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, creatine phosphokinase, and aldolase, is helpful in confirming the diagnosis, assessing disease activity, and monitoring the response to treatment. Even in the face of extensive muscle inflammation, the ESR and CRP are frequently normal. An MRI scan of the quadriceps muscle can be used in equivocal cases to confirm the presence of inflammatory myositis. Electromyography is useful to distinguish myopathic from neuropathic causes of muscle weakness. Muscle biopsy is indicated in doubtful cases of myositis without the pathognomonic rash.

► Treatment

Treatment is aimed at suppression of the inflammatory response and prevention of the loss of muscle function and joint range of motion. Acutely, it is very important to assess the adequacy of the ventilatory effort and swallowing and to rule out intestinal vasculitis. Corticosteroids are the initial therapy of choice. Treatment is usually initiated with prednisone, 2 mg/kg/d, and continued until signs and symptoms of active disease are controlled; the dosage is then gradually tapered. In severe cases, intravenous pulse methylprednisolone for 3 days is indicated. Therapy is guided by the physical examination findings and muscle enzyme values. Steroid therapy is generally maintained at the lowest dose possible for at

least 2 years to minimize the risk of exacerbations and calcinosis. If patients continue to have active disease, additional steroid-sparing agents such as methotrexate, cyclosporine, and in severe cases, cyclophosphamide, should be started.

Hydroxychloroquine and intravenous immunoglobulin are particularly helpful in managing the skin manifestations. As the rashes are photosensitive, sun protection is very important.

Physical and occupational therapy should be initiated early in the course of disease. Initially, passive range-of-motion exercises are performed to prevent loss motion. Later, once the muscle enzymes have normalized, a graduated program of stretching and strengthening exercises is introduced to restore normal strength and function.

► Course & Prognosis

Most patients have a monocyclic course; 10–20% of patients have more chronic or recurrent symptoms. Factors that influence the outcome include the rapidity of symptom onset, extent of weakness, presence of cutaneous or gastrointestinal vasculitis, timeliness of diagnosis, initiation of therapy, and response to treatment. Dermatomyositis in children is not associated with an increased risk of cancer as it is in adults.

POLYARTERITIS NODOSA

Polyarteritis nodosa (PAN) is a rare disease, but a significant number of cases have been reported in childhood and infancy. No single cause has been found, but some series have reported an association with infectious triggers, including *Streptococcus*, hepatitis B, and parvovirus.

PAN is a multisystem disease that may manifest with fever, purpura, painful nodules, weight loss, myalgias, arthralgias, tingling, numbness, proteinuria or hematuria, hypertension, anorexia, and abdominal pain. Patients may also have central nervous system and cardiac involvement. Patients with isolated cutaneous disease present with painful nodules that have a predilection for the lower legs and feet. Diagnosis is confirmed by biopsies of involved tissues or arteriography demonstrating microaneurysms, stenosis, and dilation. Pathologically, the disease is a vasculitis of medium-sized arteries. Fibrosis of vessels and surrounding tissues accompanies the healing stages.

Treatment consists of prednisone and often requires other immunosuppressants, such as methotrexate, azathioprine, or cyclophosphamide. Isolated cutaneous disease can usually be managed with NSAIDs alone or with a short course of corticosteroids.

Kim S, Dedeoglu F: Update on pediatric vasculitis. *Curr Opin Pediatr* 2005;17:695 [PMID: 16282773].

Ozen S et al: Juvenile polyarteritis: Results of a multicenter survey of 110 children. *J Pediatr* 2004;145:517 [PMID: 15480378].

SCLERODERMA

Fortunately, the most common forms of scleroderma in childhood are localized morphea lesions and linear scleroderma, not the systemic disease. The skin disease begins as indurated, hyperpigmented or hypopigmented plaques (morphea) or linear bands (linear scleroderma) and ultimately leads to thickening and scarring of the involved areas. Patients may develop subcutaneous and muscular atrophy and joint contractures in underlying joints. Localized treatment with topical vitamin D analogues and ultraviolet light may be beneficial. Treatment with corticosteroids and methotrexate helps to limit extension of the disease and prevent the development of new lesions. Typically without treatment, the skin lesions progress over a 1–2-year period and then remit. No treatment is available to reverse the residual scarred areas; however, the skin tends to soften and develop more normal pigmentation over time.

In systemic sclerosis, the dermal process is generalized. Raynaud phenomenon is almost invariably present. Arthralgias, esophageal dysfunction, and renal disease are associated with systemic sclerosis. Involvement of the lungs, heart, and kidneys may lead to rapid deterioration. Supportive treatments should be initiated for the skin manifestations, Raynaud phenomenon, and gastrointestinal symptoms. Systemic immunosuppressant medications such as corticosteroids, methotrexate, and cyclophosphamide are used with variable response. Angiotensin-converting enzyme inhibitors are effective in preventing hypertensive renal crisis.

Zulian F et al; Juvenile Scleroderma Working Group of the Pediatric Rheumatology European Society (PRES): Juvenile localized scleroderma: Clinical and epidemiological features in 750 children. An international study. *Rheumatology (Oxford)* 2006;45:614 [PMID: 16368732].

RAYNAUD PHENOMENON

Raynaud phenomenon is an intermittent vasospastic disorder of the extremities. As much as 10% of the adult population has this disorder, and onset in childhood is not uncommon. The classic triphasic presentation is cold-induced pallor, then cyanosis, followed by hyperemia, but incomplete forms are frequent. In adults older than 35 years who are ANA-positive, Raynaud phenomenon may be a harbinger of rheumatic disease. This progression is rarely seen in childhood. Evalua-

tion should include a detailed history with review of systems relevant to rheumatic disease and examination for nail-fold capillary abnormalities. In the absence of positive findings, Raynaud phenomenon is likely to be idiopathic.

Treatment involves education about keeping the extremities and core body warm and the role of stress, which may be a precipitant. In very symptomatic patients, treatment with calcium channel blockers such as nifedipine can be effective.

Nigrovic PA et al: Raynaud's phenomenon in children: A retrospective review of 123 patients. *Pediatrics* 2003;111:715 [PMID: 12671102].

Pavlov-Dolijanović S et al: The prognostic value of nailfold capillary changes for the development of connective tissue disease in children and adolescents with primary Raynaud phenomenon: A follow-up study of 250 patients. *Pediatr Dermatol* 2006;23:437 [PMID: 17014637].

NONINFLAMMATORY PAIN SYNDROMES

1. Complex Regional Pain Syndrome

Complex regional pain syndrome, previously known as reflex sympathetic dystrophy, is a painful condition that is frequently confused with arthritis. Prevalence and recognition of the condition appear to be increasing. Severe extremity pain leading to nearly complete loss of function is the hallmark of the condition. Evidence of autonomic dysfunction is demonstrated by pallor or cyanosis, temperature differences (with the affected extremity cooler than surrounding areas), and generalized swelling. On examination, marked cutaneous hyperesthesia to even the slightest touch is evident. Results of laboratory tests are normal, without evidence of systemic inflammation. Radiographic findings are normal except for late development of osteoporosis. Bone scans may be helpful and may demonstrate either increased or decreased blood flow to the painful extremity.

The cause of this condition remains elusive. Unlike adults with this disorder, children infrequently have a preceding history of trauma. Treatment includes physical therapy to focus on restoration of function, maintenance of range of motion, and pain relief. NSAIDs can be helpful for pain control, and in patients with more chronic disease, gabapentin is frequently effective. Persistent disease may respond to local nerve blocks. Counseling is helpful to identify potential psychosocial stressors and to assist with pain management. Long-term prognosis is good if recovery is rapid; recurrent episodes imply a less favorable prognosis.

Wilder RT: Management of pediatric patients with complex regional pain syndrome. *Clin J Pain* 2006;22:443 [PMID: 16772799].

2. Fibromyalgia

Fibromyalgia is a chronic pain syndrome characterized by diffuse musculoskeletal pain, fatigue, sleep disturbance, and chronic headaches. Weather changes, fatigue, and stress exacerbate symptoms. Patients have normal examination

findings except for characteristic trigger points at the insertion of muscles, especially along the neck, spine, and pelvis.

Treatment centers on physical therapy, non-narcotic pain medications, improving sleep, and counseling. Low-dose amitriptyline or trazodone can help with sleep and may produce remarkable reduction in pain. Physical therapy should emphasize a graded rehabilitative approach to stretching and exercise and promote regular aerobic exercise. Pregabalin recently became the first medication to be approved by the Food and Drug Administration for the treatment of fibromyalgia. Use of the drug is associated with decreased pain in adults with fibromyalgia, and future studies are planned to test the safety and efficacy of its use in children with the condition. The prognosis for children with fibromyalgia is not clear, and long-term strategies may be necessary to enable them to cope with the condition.

Crofford LJ et al: Pregabalin for the treatment of fibromyalgia syndrome: Results of a randomized, double-blind, placebo-controlled trial. *Arthritis Rheum* 2005;52:1264 [PMID: 15818684].

Degotardi PJ et al: Development and evaluation of a cognitive-behavioral intervention for juvenile fibromyalgia. *J Pediatr Psychol* 2006;31:714 [PMID: 16120766].

3. Hypermobility Syndrome

Ligamentous laxity, which previously was thought to occur only in Ehlers-Danlos syndrome or Down syndrome, is now recognized as a common cause of joint pain. Patients with hypermobility present with episodic joint pain and occasionally with swelling that lasts a few days after increased physical activity. Depending on the activity, almost any joint may be affected. Five criteria have been established: (1) passive opposition of the thumb to the flexor surface of the forearm, (2) passive hyperextension of the fingers so that they are parallel to the extensor surface of the forearm, (3) hyperextension of the elbow, (4) hyperextension of the knee, and (5) palms on floor with knees extended. Results of laboratory tests are normal. The pain associated with the syndrome is produced by improper joint alignment caused by the laxity during exercise. Treatment consists of a graded conditioning program designed to provide muscular support of the joints to compensate for the loose ligaments and to train patients on how to protect their joints from hyperextension.

Adib N et al: Joint hypermobility syndrome in childhood. A not so benign multisystem disorder? *Rheumatology (Oxford)* 2005;44:744 [PMID: 15728418].

Hematologic Disorders

Daniel R. Ambruso, MD
Taru Hays, MD
Neil A. Goldenberg, MD

NORMAL HEMATOLOGIC VALUES

The normal ranges for peripheral blood counts vary significantly with age. Normal neonates show a relative polycythemia with a hematocrit concentration of 45–65%. The reticulocyte count at birth is relatively high at 2–8%. Within the first few days of life, erythrocyte production decreases, and the values for hemoglobin and hematocrit fall to a nadir at about 6–8 weeks. During this period, known as physiologic anemia of infancy, normal infants have hemoglobin values as low as 10 g/dL and hematocrits as low as 30%. Thereafter, the normal values for hemoglobin and hematocrit gradually increase until adult values are reached after puberty. Premature infants can reach a nadir hemoglobin level of 7–8 g/dL at 8–10 weeks.

Newborns have larger red cells than children and adults, with a mean corpuscular volume (MCV) at birth of more than 94 fL. The MCV subsequently falls to a nadir of 70–84 fL at about age 6 months. Thereafter, the normal MCV increases gradually until it reaches adult values after puberty.

The normal number of white blood cells is higher in infancy and early childhood than later in life. Neutrophils predominate in the differential white count at birth and in the older child. Lymphocytes predominate (up to 80%) between about ages 1 month and 6 years.

Normal values for the platelet count are 150,000–400,000/ μ L and vary little with age.

BONE MARROW FAILURE

Failure of the marrow to produce adequate numbers of circulating blood cells may be congenital or acquired and may cause pancytopenia (aplastic anemia) or involve only one cell line (single cytopenia). Constitutional and acquired aplastic anemias are discussed in this section and the more common single cytopenias in later sections. Bone marrow failure caused by malignancy or other infiltrative disease is discussed in Chapter 29. It is important to remember that

many drugs and toxins may affect the marrow and cause single or multiple cytopenias.

Suspicion of bone marrow failure is warranted in children with pancytopenia and in children with single cytopenias who lack evidence of peripheral red cell, white cell, or platelet destruction. Macrocytosis often accompanies bone marrow failure. Many of the constitutional bone marrow disorders are associated with a variety of congenital anomalies.

CONSTITUTIONAL APLASTIC ANEMIA (FANCONI ANEMIA)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Progressive pancytopenia.
- ▶ Macrocytosis.
- ▶ Multiple congenital anomalies.
- ▶ Increased chromosome breakage in peripheral blood lymphocytes.

▶ General Considerations

Fanconi anemia is a syndrome characterized by defective DNA repair that is caused by a variety of genetic mutations. Inheritance is autosomal recessive, and the disease occurs in all ethnic groups. Hematologic manifestations usually begin with thrombocytopenia or neutropenia and subsequently progress over the course of months or years to pancytopenia. Typically the diagnosis is made between ages 2 and 10 years.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms are determined principally by the degree of hematologic abnormality. Thrombocytopenia may cause purpura,

petechiae, and bleeding; neutropenia may cause severe or recurrent infections; and anemia may cause weakness, fatigue, and pallor. Congenital anomalies are present in at least 50% of patients. The most common include abnormal pigmentation of the skin (generalized hyperpigmentation, café-au-lait or hypopigmented spots), short stature with delicate features, and skeletal malformations (hypoplasia, anomalies, or absence of the thumb and radius). More subtle anomalies are hypoplasia of the thenar eminence or a weak or absent radial pulse. Associated renal anomalies include aplasia, so-called horse-shoe kidney, and duplication of the collecting system. Other anomalies are microcephaly, microphthalmia, strabismus, ear anomalies, and hypogenitalism.

B. Laboratory Findings

Thrombocytopenia or leukopenia typically occurs first, followed over the course of months to years by anemia and progression to severe aplastic anemia. Macrocytosis is virtually always present, is usually associated with anisocytosis and an elevation in fetal hemoglobin levels, and is an important diagnostic clue. The bone marrow reveals hypoplasia or aplasia. The diagnosis is confirmed by the demonstration of an increased number of chromosome breaks and rearrangements in peripheral blood lymphocytes. The use of diepoxybutane to stimulate these breaks and rearrangements provides a sensitive assay that is virtually always positive in children with Fanconi anemia, even before the onset of hematologic abnormalities.

Specific molecular markers or genes (Fanc-A, B, C, and others) found in different ethnic populations are identified in research laboratories and are not available as routine clinical tests.

► Differential Diagnosis

Because patients with Fanconi anemia frequently present with thrombocytopenia, the disorder must be differentiated from idiopathic thrombocytopenic purpura (ITP) and other more common causes of decreased platelets. In contrast to patients with ITP, those with Fanconi anemia usually exhibit a gradual fall in the platelet count. Counts less than 20,000/ μL are often accompanied by neutropenia or anemia, along with phenotypical features. Fanconi anemia may also be manifested initially by pancytopenia, and must be differentiated from acquired aplastic anemia and other disorders, such as acute leukemia. Examination of the bone marrow and chromosome studies of peripheral blood lymphocytes (chromosomal breakage) will usually distinguish between these disorders.

► Complications

The most important complications of Fanconi anemia are those related to thrombocytopenia and neutropenia. Endocrine dysfunction may include growth hormone deficiency, hypothyroidism, or impaired glucose metabolism. In addition, persons with Fanconi anemia have a significantly increased risk of developing malignancies, especially acute

nonlymphocytic leukemia, head and neck cancers, genital cancers, and myelodysplastic syndromes. Death is usually the result of thrombocytopenic hemorrhage, overwhelming infection, or malignancy.

► Treatment

Attentive supportive care is a critical feature of management. Patients with neutropenia who develop fever require prompt evaluation and parenteral broad-spectrum antibiotics. Transfusions are important, but should be used judiciously, especially in the management of thrombocytopenia, which frequently becomes refractory to platelet transfusions as a consequence of alloimmunization. Transfusions from family members should be discouraged because of the negative effect on the outcome of bone marrow transplantation. At least 50% of patients with Fanconi anemia respond, albeit incompletely, to oxymetholone, and many recommend institution of androgen therapy before transfusions are needed. However, oxymetholone is associated with hepatotoxicity, hepatic adenomas, and masculinization, and is particularly troublesome for female patients.

Successful bone marrow transplantation cures the aplastic anemia and is an important treatment option for children with Fanconi anemia who have a human leukocyte antigen (HLA)-identical sibling donor. Before transplantation the prospective donor must be screened for Fanconi anemia by chromosome breakage testing.

► Prognosis

Many patients succumb to bleeding, infection, or malignancy in adolescence or early adulthood. The long-term outlook after successful bone marrow transplantation is uncertain, particularly with regard to the risk of subsequently developing malignancies.

ACQUIRED APLASTIC ANEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Weakness and pallor.
- Petechiae, purpura, and bleeding.
- Frequent or severe infections.
- Pancytopenia with hypocellular bone marrow.

▶ General Considerations

Acquired aplastic anemia is characterized by peripheral pancytopenia with a hypocellular bone marrow. Approximately 50% of cases in childhood are idiopathic. Other cases are secondary to idiosyncratic reactions to drugs such as phenylbutazone, sulfonamides, nonsteroidal anti-inflammatory drugs, and anticonvulsants. Toxic causes include exposure to benzene, insecticides, and heavy metals. Infectious causes include viral hepatitis (usually non-A, non-B, non-C), infectious mononucleosis, and human immunodeficiency virus (HIV). In immunocompromised children, aplastic anemia has been associated with human parvovirus B19. Immune mechanisms of marrow suppression are suspected in most cases.

▶ Clinical Findings

A. Symptoms and Signs

Weakness, fatigue, and pallor result from anemia; petechiae, purpura, and bleeding occur because of thrombocytopenia; and fevers due to generalized or localized infections are associated with neutropenia. Hepatosplenomegaly and significant lymphadenopathy are unusual.

B. Laboratory Findings

Anemia is usually normocytic, with a low reticulocyte count. The white blood cell count is low, with a marked neutropenia. The platelet count is typically below 50,000/ μL , and is frequently below 20,000/ μL . Bone marrow aspiration and biopsy show hypocellularity, often marked.

▶ Differential Diagnosis

Examination of the bone marrow usually excludes pancytopenia caused by peripheral destruction of blood cells or by infiltrative processes such as acute leukemia, storage diseases, and myelofibrosis. Many of these other conditions are associated with hepatosplenomegaly. Preleukemic conditions also may present with pancytopenia and hypocellular bone marrows. Cytogenetic analysis of the marrow is helpful, because a clonal abnormality may predict the subsequent development of leukemia. Since congenital anomalies may not be apparent in some children with Fanconi anemia, patients with newly diagnosed aplastic anemia should be studied for chromosome breaks and rearrangements in peripheral blood lymphocytes.

▶ Complications

Acquired aplastic anemia is characteristically complicated by infection and hemorrhage, which are the leading causes of death. Other complications are those associated with therapy.

▶ Treatment

Comprehensive supportive care is most important in the management of acute acquired aplastic anemia. Febrile ill-

nesses require prompt evaluation and usually parenteral antibiotics. Red blood cell transfusions alleviate symptoms of anemia. Platelet transfusions may be lifesaving, but they should be used sparingly because many patients eventually develop platelet alloantibodies and become refractory to platelet transfusions.

Bone marrow transplantation is generally considered the treatment of choice for severe aplastic anemia when an HLA-compatible sibling donor is available. Because the likelihood of success with transplantation is influenced adversely by multiple transfusions, HLA typing of family members should be undertaken as soon as the diagnosis of aplastic anemia is made. Increasingly patients who lack HLA-matched siblings are able to find matched donors through cord blood banks or the National Marrow Donor Program.

An alternative to bone marrow transplantation from an HLA-matched sibling donor is immunomodulation, usually with antithymocyte globulin and cyclosporine. Responses are very good. Most patients show hematologic improvement and become transfusion-independent.

▶ Prognosis

Children receiving early bone marrow transplantation from an HLA-identical sibling have a long-term survival rate of greater than 80%. Sustained, complete remissions may be seen in 65–80% of patients receiving immunosuppressive therapy. However, both therapies are associated with an increased risk of myelodysplastic syndromes, acute leukemia, and other malignancies in long-term survivors.

ANEMIAS

APPROACH TO THE CHILD WITH ANEMIA

Anemia is a relatively common finding, and identifying the cause is important. Even though anemia in childhood has many causes, the correct diagnosis can usually be established with relatively little laboratory cost. Frequently the cause is identified with a careful history. The possibility of nutritional causes should be addressed by inquiry about dietary intake; growth and development; and symptoms of chronic disease, malabsorption, or blood loss. Hemolytic disease may

▲ **Figure 28-1.** Investigation of anemia.

be associated with a history of jaundice (including neonatal jaundice) or by a family history of anemia, jaundice, gallbladder disease, splenomegaly, or splenectomy. The child's ethnic background may suggest the possibility of certain hemoglobinopathies or of deficiencies of red cell enzymes, such as glucose-6-phosphate dehydrogenase (G6PD). The review of systems may reveal clues to a previously unsuspected systemic disease associated with anemia. The patient's age is important because some causes of anemia are age-related. For example, patients with iron-deficiency anemia and β -globin disorders present more commonly at ages 6–36 months than at other times in life.

The physical examination may also reveal clues to the cause of anemia. Poor growth may suggest chronic disease or hypothyroidism. Congenital anomalies may be associated with constitutional aplastic anemia (Fanconi anemia) or with congenital hypoplastic anemia (Diamond-Blackfan anemia). Other disorders may be suggested by the findings of petechiae or purpura (leukemia, aplastic anemia, hemolytic-uremic syndrome), jaundice (hemolysis or liver disease), generalized lymphadenopathy (leukemia, juvenile rheumatoid arthritis, HIV infection), splenomegaly (leukemia, sickle hemoglobinopathy syndromes, hereditary spherocyto-

sis, liver disease, hypersplenism), or evidence of chronic or recurrent infections.

The initial laboratory evaluation of the anemic child consists of a complete blood count (CBC) with differential and platelet count, review of the peripheral blood smear, and a reticulocyte count. The algorithm in Figure 28-1 uses limited laboratory information, together with the history and physical examination, to reach a specific diagnosis or to focus additional laboratory investigations on a limited diagnostic category (eg, microcytic anemia, bone marrow failure, pure red cell aplasia, or hemolytic disease). This diagnostic scheme depends principally on the MCV to determine whether the anemia is microcytic, normocytic, or macrocytic, according to the percentile curves of Dallman and Siimes (Figure 28-2).

Although the incidence of iron deficiency in the United States has decreased significantly with improvements in infant nutrition, it remains an important cause of microcytic anemia, especially at ages 6–24 months. A trial of therapeutic iron is appropriate in such children, provided the dietary history is compatible with iron deficiency and the physical examination or CBC count does not suggest an alternative cause for the anemia. If

▲ **Figure 28-2.** Hemoglobin and red cell volume in infancy and childhood. (Reproduced, with permission, from Dallman PR, Siimes MA: Percentile curves for hemoglobin and red cell volume in infancy and childhood. *J Pediatr* 1979;94:26.)

this is not the case, or if a trial of therapeutic iron fails to correct the anemia and microcytosis, further laboratory evaluation is warranted.

Another key element of Figure 28-1 is the use of both the reticulocyte count and the peripheral blood smear to determine whether a normocytic or macrocytic anemia is due to hemolysis. Typically hemolytic disease is associated with an elevated reticulocyte count, but some children with chronic hemolysis initially present during a period of virus-induced aplasia when the reticulocyte count is not elevated. Thus, review of the peripheral blood smear for evidence of hemolysis (eg, spherocytes, red cell fragmentation, sickle forms) is important in the evaluation of children with normocytic anemias and low reticulocyte counts. When hemolysis is suggested, the correct diagnosis may be suspected by specific abnormalities of red cell morphology or by clues from the history or physical examination. Autoimmune hemolysis is usually excluded by direct antiglobulin testing. Review of blood counts and the peripheral blood smears of the mother and father may suggest genetic disorders such as hereditary spherocytosis. Children with normocytic or macrocytic anemias, with relatively low reticulocyte counts and no evidence of hemolysis on the blood smear, usually have anemias caused by inadequate erythropoiesis in the bone marrow. The presence of neutropenia or thrombocytopenia in such children suggests

the possibility of aplastic anemia, malignancy, or severe folate or vitamin B₁₂ deficiency, and usually dictates examination of the bone marrow.

Pure red cell aplasia may be congenital (Diamond-Blackfan anemia), acquired and transient (transient erythroblastopenia of childhood), a manifestation of a systemic disease such as renal disease or hypothyroidism, or due to malnutrition or mild deficiencies of folate or vitamin B₁₂.

Hermiston ML: A practical approach to the evaluation of the anemic child. *Pediatr Clin North Am* 2002;49:877 [PMID: 12430617].

PURE RED CELL APLASIA

Infants and children with normocytic or macrocytic anemia, a low reticulocyte count, and normal or elevated numbers of neutrophils and platelets should be suspected of having pure red cell aplasia. Examination of the peripheral blood smear in such cases is important because signs of hemolytic disease suggest chronic hemolysis complicated by an aplastic crisis due to parvovirus infection. Appreciation of this phenomenon is important because chronic hemolytic disease may not be diagnosed until the anemia is exacerbated by an episode of red cell aplasia and subsequent rapidly falling hemoglobin level. In such cases, cardiovascular compromise and congestive heart failure may develop quickly.

1. Congenital Hypoplastic Anemia (Diamond-Blackfan Anemia)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Age: birth to 1 year.
- ▶ Macrocytic anemia with reticulocytopenia.
- ▶ Bone marrow with erythroid hypoplasia.
- ▶ Short stature or congenital anomalies in one third of patients.

▶ General Considerations

Diamond-Blackfan anemia is a relatively rare cause of anemia that usually presents in infancy or early childhood. Early diagnosis is important because treatment with corticosteroids results in increased erythropoiesis in about two thirds of patients, thus avoiding the difficulties and complications of long-term chronic transfusion therapy. The cause is unclear; both autosomal dominant and autosomal recessive modes of inheritance occur.

▶ Clinical Findings

A. Symptoms and Signs

Signs and symptoms are generally those of chronic anemia, such as pallor; congestive heart failure sometimes follows. Jaundice, splenomegaly, or other evidence of hemolysis is usually absent. Short stature or other congenital anomalies are present in one third of patients. A wide variety of anomalies have been described; those affecting the head, face, and thumbs are the most common.

B. Laboratory Findings

Diamond-Blackfan anemia is characterized by severe macrocytic anemia and marked reticulocytopenia. The neutrophil count is usually normal or slightly decreased, and the platelet count is normal or elevated. The bone marrow usually shows a marked decrease in erythroid precursors but is otherwise normal. In older children, fetal hemoglobin levels are usually increased and there is evidence of persistent fetal erythropoiesis, such as the presence of the i antigen on erythrocytes. In addition, the level of adenosine deaminase in erythrocytes is elevated.

▶ Differential Diagnosis

The principal differential diagnosis is transient erythroblastopenia of childhood. Children with Diamond-Blackfan anemia generally present at an earlier age, often have macrocytosis, and have evidence of fetal erythropoiesis and an elevated level of red cell adenosine deaminase. In addition,

short stature and congenital anomalies, are not associated with transient erythroblastopenia. Lastly, transient erythroblastopenia of childhood usually resolves within 6–8 weeks of diagnosis, whereas Diamond-Blackfan anemia is a lifelong affliction. Other disorders associated with decreased red cell production such as renal failure, hypothyroidism, and the anemia of chronic disease need to be considered.

▶ Treatment

Oral corticosteroids should be initiated as soon as the diagnosis of Diamond-Blackfan anemia is made. Two thirds of patients will respond to prednisone, 2 mg/kg/d, and many of those who respond subsequently tolerate significant tapering of the dose. Patients who are unresponsive to prednisone require chronic transfusion therapy, which inevitably causes transfusion-induced hemosiderosis and the need for chelation with parenteral deferoxamine. Bone marrow transplantation is an alternative therapy that should be considered for transfusion-dependent patients who have HLA-matched siblings. Hematopoietic growth factors have been used in some cases with limited success. Unpredictable, spontaneous remissions occur in up to 20% of patients.

▶ Prognosis

The prognosis for patients responsive to corticosteroids is generally good, particularly if remission is maintained with low doses of alternate-day prednisone. Patients dependent on transfusion are at risk for the complications of hemosiderosis, including death from congestive heart failure, cardiac arrhythmias, or hepatic failure. This remains a significant threat, particularly during adolescence, when compliance with nightly subcutaneous infusions of deferoxamine is often difficult to ensure.

Berndt A: Successful transplantation of CD34+ selected peripheral blood stem cells from an unrelated donor in an adult patient with Diamond-Blackfan anemia and secondary hemochromatosis. *Bone Marrow Transplant* 2005;35:99 [PMID: 15516941].
 Vlachos A: Hematopoietic stem cell transplantation for Diamond-Blackfan anemia: A report from the Diamond-Blackfan Anemia Registry. *Bone Marrow Transplant* 2001;27:381 [PMID: 11313667].

2. Transient Erythroblastopenia of Childhood

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Age: 6 months to 4 years.
- ▶ Normocytic anemia with reticulocytopenia.
- ▶ Absence of hepatosplenomegaly or lymphadenopathy.
- ▶ Erythroid precursors initially absent from bone marrow.

▶ General Considerations

Transient erythroblastopenia of childhood is a relatively common cause of acquired anemia in early childhood. The disorder is suspected when a normocytic anemia is discovered during evaluation of pallor or when a CBC is obtained for another reason. Because the anemia is due to decreased red cell production, and thus develops slowly, the cardiovascular system has time to compensate. Therefore, children with hemoglobin levels as low as 4–5 g/dL may look remarkably well. The disorder is thought to be autoimmune in most cases, because IgG from some patients has been shown to suppress erythropoiesis *in vitro*.

▶ Clinical Findings

Pallor is the most common sign, and hepatosplenomegaly and lymphadenopathy are absent. The anemia is normocytic, and the peripheral blood smear shows no evidence of hemolysis. The platelet count is normal or elevated, and the neutrophil count is normal or, in some cases, decreased. Early in the course, no reticulocytes are identified. The Coombs test is negative, and there is no evidence of chronic renal disease, hypothyroidism, or other systemic disorder. Bone marrow examination shows severe erythroid hypoplasia initially; subsequently, erythroid hyperplasia develops along with reticulocytosis, and the anemia resolves.

▶ Differential Diagnosis

Transient erythroblastopenia of childhood must be differentiated from Diamond-Blackfan anemia, particularly in infants younger than age 1 year. In contrast to Diamond-Blackfan anemia, transient erythroblastopenia is not associated with macrocytosis, short stature, or congenital anomalies, or with evidence of fetal erythropoiesis prior to the phase of recovery. Also in contrast to Diamond-Blackfan anemia, transient erythroblastopenia is associated with normal levels of red cell adenosine deaminase. Transient erythroblastopenia of childhood must also be differentiated from chronic disorders associated with decreased red cell production, such as renal failure, hypothyroidism, and other chronic states of infection or inflammation. As with other single cytopenias, the possibility of malignancy (ie, leukemia) should always be considered, particularly if fever, bone pain, hepatosplenomegaly, or lymphadenopathy is present. In such cases, examination of the bone marrow is generally diagnostic. Confusion may sometimes arise when the anemia of transient erythroblastopenia is first identified during the early phase of recovery when the reticulocyte count is high. In such cases, the disorder may be confused with the anemia of acute blood loss or with hemolytic disease. In contrast to hemolytic disorders, transient erythroblastopenia of childhood is not associated with jaundice or peripheral destruction of red cells.

▶ Treatment & Prognosis

By definition, this is a transient disorder. Some children require red cell transfusions if cardiovascular compromise is present. Resolution of the anemia is heralded by an increase in the reticulocyte count, which generally occurs within 4–8 weeks of diagnosis. Transient erythroblastopenia of childhood is not treated with corticosteroids because of its short course.

NUTRITIONAL ANEMIAS

1. Iron-Deficiency Anemia

- ▶ Pallor and fatigue.
- ▶ Poor dietary intake of iron (ages 6–24 months).
- ▶ Chronic blood loss (age > 2 years).
- ▶ Microcytic hypochromic anemia.

▶ General Considerations

Long considered the most common cause of anemia in pediatrics, iron deficiency has decreased substantially in incidence due to improved nutrition and the increased availability of iron-fortified infant formulas and cereals. Thus, the current approach to anemia in childhood must take into consideration a relatively greater likelihood of other causes.

Normal-term infants are born with sufficient iron stores to prevent iron deficiency for the first 4–5 months of life. Thereafter, enough iron needs to be absorbed to support the needs of rapid growth. For this reason, nutritional iron deficiency is most common between 6 and 24 months of life. A deficiency earlier than age 6 months may occur if iron stores at birth are reduced by prematurity, small birth weight, neonatal anemia, or perinatal blood loss or if there is subsequent iron loss due to hemorrhage. Iron-deficient children older than age 24 months should be evaluated for blood loss. Iron deficiency, in addition to causing anemia, has adverse effects on multiple organ systems. Thus, the importance of identifying and treating iron deficiency extends past the resolution of any symptoms directly attributable to a decreased hemoglobin concentration.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms and signs vary with the severity of the deficiency. Mild iron deficiency is usually asymptomatic. In infants with more severe iron deficiency, pallor, fatigue, irritability, and delayed motor development are common. Children

whose iron deficiency is due in part to ingestion of unfortified cow's milk may be fat, with poor muscle tone. A history of pica is common.

B. Laboratory Findings

The severity of anemia depends on the degree of iron deficiency, and the hemoglobin level may be as low as 3–4 g/dL in severe cases. Red cells are microcytic and hypochromic, with a low MCV and low mean corpuscular hemoglobin. The red blood cell distribution width is typically elevated, even with mild iron deficiency. The reticulocyte count is usually normal or slightly elevated, but the reticulocyte index or absolute reticulocyte count is decreased. Iron studies show a decreased serum ferritin and a low serum iron, elevated total iron-binding capacity, and decreased transferrin saturation. These laboratory abnormalities are usually present with moderate to severe iron deficiency, but mild cases may be associated with variable laboratory results. The peripheral blood smear shows microcytic, hypochromic red blood cells with anisocytosis, and occasional target, teardrop, elliptical, and fragmented red cells. Leukocytes are normal, and very often platelet count is increased with normal morphology.

The bone marrow examination is not helpful in the diagnosis of iron deficiency in infants and small children because little or no iron is stored as marrow hemosiderin at these ages.

► Differential Diagnosis

The differential diagnosis is that of microcytic, hypochromic anemia. The possibility of thalassemia (α -thalassemia, β -thalassemia, and hemoglobin E disorders) should be considered, especially in infants of African, Mediterranean, or Asian ethnic background. In contrast to infants with iron deficiency, those with thalassemia generally have an elevated number of erythrocytes (the index of the MCV divided by the red cell number is usually less than 13) and are less likely, in mild cases, to have an elevated red blood cell distribution width. Thalassemias are associated with normal or increased levels of serum iron and ferritin and with normal iron-binding capacity. The hemoglobin electrophoresis in β -thalassemia minor typically shows an elevation of hemoglobin A₂ levels, but coexistent iron deficiency may lower the percentage of hemoglobin A₂ into the normal range. Hemoglobin electrophoresis will also identify children with hemoglobin E, a cause of microcytosis common in Southeast Asians. In contrast, the hemoglobin electrophoresis in α -thalassemia trait is normal. Lead poisoning has also been associated with microcytic anemia, but anemia with lead levels less than 40 mg/dL is often due to coexistent iron deficiency.

The anemia of chronic inflammation or infection is normocytic but in late stages may be microcytic. This anemia is usually suspected because of the presence of a chronic systemic disorder. The level of serum iron is low, but the iron-binding capacity is normal, and the serum ferritin level

is normal or elevated. Relatively mild infections, particularly during infancy, may cause transient anemia. As a result, caution should be exercised when the diagnosis of mild iron deficiency is entertained in infants and young children who have had recent viral or bacterial infections. Ideally, screening tests for anemia should not be obtained within 3–4 weeks of such infections.

► Treatment

The recommended oral dose of elemental iron is 6 mg/kg/d in three divided daily doses. Mild cases may be treated with 2 mg/kg/d given once daily before breakfast. Parenteral administration of iron is rarely necessary. Iron therapy results in an increased reticulocyte count within 3–5 days, which is maximal between 5 and 7 days. The hemoglobin level begins to increase thereafter. The rate of hemoglobin rise is inversely related to the hemoglobin level at diagnosis. In moderate to severe cases, an elevated reticulocyte count 1 week after initiation of therapy confirms the diagnosis and documents compliance and response to therapy. When iron deficiency is the only cause of anemia, adequate treatment usually results in a resolution of the anemia within 4–6 weeks. Treatment is generally continued for a few additional months to replenish iron stores.

Hermiston ML: A practical approach to the evaluation of the anemic child. *Pediatr Clin North Am* 2002;49:877 [PMID: 12430617].

2. Megaloblastic Anemias

- Pallor and fatigue.
- Nutritional deficiency or intestinal malabsorption.
- Macrocytic anemia.
- Megaloblastic bone marrow changes.

► General Considerations

Megaloblastic anemia is a macrocytic anemia caused by deficiency of cobalamin (vitamin B₁₂), folic acid, or both. Cobalamin deficiency due to dietary insufficiency may occur in infants who are breast fed by mothers who are strict vegetarians or who have pernicious anemia. Intestinal malabsorption is the usual cause of cobalamin deficiency in children and occurs with Crohn disease, chronic pancreatitis, bacterial overgrowth of the small bowel, infection with the fish tapeworm (*Diphyllobothrium latum*), or after surgical resection of the terminal ileum. Deficiencies due to inborn errors of metabolism (transcobalamin II deficiency

and methylmalonic aciduria) also have been described. Malabsorption of cobalamin due to deficiency of intrinsic factor (pernicious anemia) is rare in childhood.

Folic acid deficiency may be caused by inadequate dietary intake, malabsorption, increased folate requirements, or some combination of the three. Folate deficiency due to dietary deficiency alone is rare but occurs in severely malnourished infants and has been reported in infants fed goat's milk not fortified with folic acid. Folic acid is absorbed in the jejunum, and deficiencies are encountered in malabsorptive syndromes such as celiac disease. Anticonvulsion medications (eg, phenytoin and phenobarbital) and cytotoxic drugs (eg, methotrexate) also have been associated with folate deficiency, caused by interference with folate absorption or metabolism. Finally, folic acid deficiency is more likely to develop in infants and children with increased requirements. This occurs during infancy because of rapid growth and also in children with chronic hemolytic anemia. Premature infants are particularly susceptible to the development of the deficiency because of low body stores of folate.

► Clinical Findings

A. Symptoms and Signs

Infants with megaloblastic anemia may show pallor and mild jaundice as a result of ineffective erythropoiesis. Classically, the tongue is smooth and beefy red. Infants with cobalamin deficiency may be irritable and may be poor feeders. Older children with cobalamin deficiency may complain of paresthesias, weakness, or an unsteady gait and may show decreased vibratory sensation and proprioception on neurologic examination.

B. Laboratory Findings

The laboratory findings of megaloblastic anemia include an elevated MCV and mean corpuscular hemoglobin. The peripheral blood smear shows numerous macro-ovalocytes with anisocytosis and poikilocytosis. Neutrophils are large and have hypersegmented nuclei. The white cell and platelet counts are normal with mild deficiencies, but may be decreased in more severe cases. Examination of the bone marrow typically shows erythroid hyperplasia with large erythroid and myeloid precursors. Nuclear maturation is delayed compared with cytoplasmic maturation, and erythropoiesis is ineffective. The serum indirect bilirubin concentration may be slightly elevated.

Children with cobalamin deficiency have a low serum vitamin B₁₂ level, but decreased levels of serum vitamin B₁₂ may also be found in about 30% of patients with folic acid deficiency. The level of red cell folate is a better reflection of folate stores than is the serum folic acid level. Serum levels of metabolic intermediates (methylmalonic acid and homocysteine) may help establish the correct diagnosis. Elevated methylmalonic acid levels are consistent with cobalamin deficiency, whereas elevated levels of homocysteine occur with both cobalamin and folate deficiency.

► Differential Diagnosis

Most macrocytic anemias in pediatrics are not megaloblastic. Other causes of an increased MCV include drug therapy (eg, anticonvulsants, anti-HIV nucleoside analogues), Down syndrome, an elevated reticulocyte count (hemolytic anemias), bone marrow failure syndromes (Fanconi anemia, Diamond-Blackfan anemia), liver disease, and hypothyroidism.

► Treatment

Treatment of cobalamin deficiency due to inadequate dietary intake is readily accomplished with oral supplementation. Most cases, however, are due to intestinal malabsorption and require parenteral treatment. In severe cases, parenteral therapy may induce life-threatening hypokalemia and require supplemental potassium. Folic acid deficiency is treated effectively with oral folic acid in most cases. Children at risk for the development of folic acid deficiencies, such as premature infants and those with chronic hemolysis, are often given folic acid prophylactically.

ANEMIA OF CHRONIC DISORDERS

Anemia is a common manifestation of many chronic illnesses in children. In some instances, causes may be mixed. For example, children with chronic disorders involving intestinal malabsorption or blood loss may have anemia of chronic inflammation in combination with nutritional deficiencies of iron, folate, or cobalamin. In other settings, the anemia is due to dysfunction of a single organ (eg, renal failure, hypothyroidism), and correction of the underlying abnormality resolves the anemia.

1. Anemia of Chronic Inflammation

Anemia is frequently associated with chronic infections or inflammatory diseases. The anemia is usually mild to moderate in severity, with a hemoglobin level of 8–12 g/dL. In general, the severity of the anemia corresponds to the severity of the underlying disorder, and there may be microcytosis, but not hypochromia. The reticulocyte count is low. The anemia is thought to be due to inflammatory cytokines that inhibit erythropoiesis, and shunting of iron into, and impaired iron release from, reticuloendothelial cells. Levels of erythropoietin are relatively low for the severity of the anemia. The serum iron concentration is low, but in contrast to iron deficiency, anemia of chronic inflammation is not associated with elevated iron-binding capacity and is associated with an elevated serum ferritin level. Treatment consists of correction of the underlying disorder, which, if controlled, generally results in improvement in hemoglobin level.

2. Anemia of Chronic Renal Failure

Severe normocytic anemia occurs in most forms of renal disease that have progressed to renal insufficiency. Although white cell and platelet production remain normal, the bone marrow shows significant hypoplasia of the erythroid series and the reticulocyte count is low. The principal mechanism is deficiency of erythropoietin, a hormone produced in the kidney, but other factors may contribute to the anemia. In the presence of significant uremia, a component of hemolysis may also be present. Recombinant human erythropoietin (epoetin alfa) corrects the anemia, largely eliminating the need for transfusions.

Seeherunvong W: Identification of poor responders to erythropoietin among children undergoing hemodialysis. *J Pediatr* 2001;138:710 [PMID: 11343048].

Yorgin PD: The clinical efficacy of higher hematocrit levels in children with chronic renal insufficiency and those undergoing dialysis. *Semin Nephrol* 2001;21:451 [PMID: 11559886].

3. Anemia of Hypothyroidism

Some patients with hypothyroidism develop significant anemia. Occasionally, anemia is detected before the diagnosis of the underlying disorder. A decreased growth velocity in an anemic child suggests hypothyroidism. The anemia is usually normocytic or macrocytic, but it is not megaloblastic and, hence not due to deficiencies of cobalamin or folate. Replacement therapy with thyroid hormone is usually effective in correcting the anemia.

CONGENITAL HEMOLYTIC ANEMIAS: RED CELL MEMBRANE DEFECTS

The congenital hemolytic anemias are divided into three categories: defects of the red cell membrane; hemoglobinopathies; and disorders of red cell metabolism. Hereditary spherocytosis and elliptocytosis are the most common red cell membrane disorders. The diagnosis is suggested by the peripheral blood smear, which shows characteristic red cell morphology (eg, spherocytes, elliptocytes). These disorders usually have an autosomal dominant inheritance, and the diagnosis may be suggested by a family history. The hemolysis is due to the deleterious effect of the membrane abnormality on red cell deformability. Decreased cell deformability leads to entrapment of the abnormally shaped red cells in the spleen. Many patients have splenomegaly, and splenectomy usually alleviates the hemolysis.

1. Hereditary Spherocytosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Anemia and jaundice.
- ▶ Splenomegaly.
- ▶ Positive family history of anemia, jaundice, or gallstones.

- ▶ Spherocytosis with increased reticulocytes.
- ▶ Increased osmotic fragility.
- ▶ Negative direct antiglobulin test (DAT).

▶ General Considerations

Hereditary spherocytosis is a relatively common inherited hemolytic anemia that occurs in all ethnic groups but is most common in persons of northern European ancestry, in whom the incidence is about 1:5000. The disorder is a heterogeneous one, marked by variable degrees of anemia, jaundice, and splenomegaly. In some persons, the disorder is mild and there is no anemia because erythroid hyperplasia fully compensates for hemolysis. Severe cases are transfusion-dependent prior to splenectomy. The hallmark of hereditary spherocytosis is the presence of microspherocytes in the peripheral blood. The disease is inherited in an autosomal dominant fashion in about 75% of cases; the remaining cases are thought to be autosomal recessive or to be caused by new mutations.

Hereditary spherocytosis is usually the result of a partial deficiency of spectrin, an important structural protein of the red cell membrane skeleton. Spectrin deficiency weakens the attachment of the cell membrane to the underlying membrane skeleton and causes the red cell to lose membrane surface area. This process creates spherocytes that are poorly deformable and have a shortened life span because they are trapped in the microcirculation of the spleen and engulfed by splenic macrophages. The extreme heterogeneity of hereditary spherocytosis is related directly to variable degrees of spectrin deficiency. In general, children who inherit spherocytosis in an autosomal dominant fashion have less spectrin deficiency and mild or moderate hemolysis. In contrast, those with nondominant forms of spherocytosis tend to have greater deficiency of spectrin and more severe anemia.

▶ Clinical Findings

A. Symptoms and Signs

Hemolysis causes significant neonatal hyperbilirubinemia in 50% of affected children. Splenomegaly subsequently develops in the majority and is often present by age 5 years. Jaundice is variably present and in many patients may be noted only during infection. Patients with significant chronic anemia may complain of pallor, fatigue, or malaise. Intermittent exacerbations of the anemia are caused by increased hemolysis or by aplastic crises, and may be associated with severe weakness, fatigue, fever, abdominal pain, or even heart failure.

B. Laboratory Findings

Most patients have mild chronic hemolysis with hemoglobin levels of 9–12 g/dL. In some cases, the hemolysis is fully compensated and the hemoglobin level is in the normal

range. Rare cases of severe disease require frequent transfusions. The anemia is usually normocytic and hyperchromic, and many patients have an elevated mean corpuscular hemoglobin concentration. The peripheral blood smear shows numerous microspherocytes and polychromasia. The reticulocyte count is elevated, often higher than might be expected for the degree of anemia. White blood cell and platelet counts are usually normal. The osmotic fragility is increased, particularly after incubation at 37°C for 24 hours. Serum bilirubin usually shows an elevation in the unconjugated fraction. The DAT is negative.

► Differential Diagnosis

Spherocytes are frequently present in persons with immune hemolysis. Thus, in the newborn, hereditary spherocytosis must be distinguished from hemolytic disease caused by ABO or other blood type incompatibilities. Older patients with autoimmune hemolytic anemia frequently present with jaundice and splenomegaly and with spherocytes on the peripheral blood smear. The DAT is positive in most cases of immune hemolysis and negative in hereditary spherocytosis. Occasionally, the diagnosis is confused in patients with splenomegaly from other causes, especially when hypersplenism increases red cell destruction and when some spherocytes are noted on the blood smear. In such cases, the true cause of the splenomegaly may be suggested by signs or symptoms of portal hypertension or by laboratory evidence of chronic liver disease. In contrast to children with hereditary spherocytosis, those with hypersplenism typically have some degree of thrombocytopenia or neutropenia.

► Complications

Severe jaundice may occur in the neonatal period and, if not controlled by phototherapy, may occasionally require exchange transfusion. Splenectomy is associated with an increased risk of overwhelming bacterial infections, particularly with pneumococci. Gallstones occur in 60–70% of adults who have not undergone splenectomy and may form as early as age 5–10 years.

► Treatment

Supportive measures include the administration of folic acid to prevent the development of red cell hypoplasia due to folate deficiency. Acute exacerbations of anemia, due to increased rates of hemolysis or to aplastic crises caused by infection with human parvovirus, may be severe enough to require red cell transfusions. Splenectomy is performed in many cases and always results in significant improvement. The procedure increases the survival of the spherocytic red cells and leads to complete correction of the anemia in most cases. Patients with more severe disease may show some degree of hemolysis after splenectomy. Except in unusually severe cases, the procedure should be postponed until the child is at least age 5 years because of the greater risk of post-splenectomy sepsis prior to

this age. All patients scheduled for splenectomy should be immunized with pneumococcal, *Haemophilus influenzae* type b, and meningococcal vaccines prior to the procedure, and some clinicians recommend penicillin prophylaxis afterward. Asplenic patients with fever should be promptly evaluated for severe infection. The need for splenectomy in mild cases is controversial. Splenectomy in the middle childhood years prevents the subsequent development of cholelithiasis and eliminates the need for the activity restrictions recommended for children with splenomegaly. However, these benefits must be weighed against the risks of the surgical procedure and the subsequent lifelong risk of post-splenectomy sepsis.

► Prognosis

Splenectomy eliminates signs and symptoms in all but the most severe cases and reduces the risk of cholelithiasis. The abnormal red cell morphology and increased osmotic fragility persist without clinical consequence.

Delhommeau F: Natural history of hereditary spherocytosis during the first year of life. *Blood* 2000;95:393 [PMID: 10627440].

2. Hereditary Elliptocytosis

Hereditary elliptocytosis is a heterogeneous disorder that ranges in severity from an asymptomatic state with almost normal red cell morphology to severe hemolytic anemia. Most affected persons have numerous elliptocytes on the peripheral blood smear, but mild or no hemolysis. Those with hemolysis have an elevated reticulocyte count and may have jaundice and splenomegaly. These disorders are caused by mutations of red cell membrane skeletal proteins, and most have an autosomal dominant inheritance. Because most patients are asymptomatic, no treatment is indicated. Patients with significant degrees of hemolytic anemia may benefit from folate supplementation or from splenectomy.

Some infants with hereditary elliptocytosis present in the neonatal period with moderate to marked hemolysis and significant hyperbilirubinemia. This disorder has been termed transient infantile poikilocytosis because such infants exhibit bizarre erythrocyte morphology with elliptocytes, budding red cells, and small misshapen cells that defy description. The MCV is low, and the anemia may be severe enough to require red cell transfusions. Typically, one parent has hereditary elliptocytosis, usually mild or asymptomatic. The infant's hemolysis gradually abates during the first year of life, and the erythrocyte morphology subsequently becomes more typical of hereditary elliptocytosis.

CONGENITAL HEMOLYTIC ANEMIAS: HEMOGLOBINOPATHIES

The hemoglobinopathies are an extremely heterogeneous group of congenital disorders that occur in many different ethnic groups. The relatively high frequency of these genetic variants is related to the malaria protection afforded to

▲ **Figure 28-3.** Changes in hemoglobin polypeptide chains during human development. (Reproduced, with permission, from Miller DR, Baehner RL: *Blood Diseases of Infancy and Childhood*, 6th ed. Mosby, 1989.)

heterozygous individuals. The hemoglobinopathies are generally classified into two major groups. The first, the thalassemias, are caused by quantitative deficiencies in the production of globin chains. These quantitative defects in globin synthesis cause microcytic and hypochromic anemias. The second group of hemoglobinopathies consists of those caused by structural abnormalities of globin chains. The most important of these, hemoglobins S, C, and E, are all the result of point mutations and single amino acid substitutions in β -globin. Many, but not all, infants with hemoglobinopathies are identified by routine neonatal screening.

Figure 28-3 shows the normal developmental changes that occur in globin-chain production during gestation and the first year of life. At birth, the predominant hemoglobin is fetal hemoglobin (hemoglobin F), which is composed of two α -globin chains and two γ -globin chains. Subsequently, the production of γ -globin decreases and the production of β -globin increases so that adult hemoglobin (two α chains and two β chains) predominates after 2–4 months. Because α -globin chains are present in both fetal and adult hemoglobin, disorders of α -globin synthesis (α -thalassemia) are clinically manifest in the newborn as well as later in life. In contrast, patients with β -globin disorders such as β -thalassemia and sickle cell disease are generally asymptomatic during the first 3–4 months of age and present clinically after γ -chain production—and therefore fetal hemoglobin levels—have decreased substantially.

1. α -Thalassemia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ African, Mediterranean, Middle Eastern, Chinese, or Southeast Asian ancestry.
- ▶ Microcytic, hypochromic anemia of variable severity.
- ▶ Bart's hemoglobin detected by neonatal screening.

▶ General Considerations

Most of the α -thalassemia syndromes are the result of deletions of one or more of the α -globin genes on chromosome 16. Normal diploid cells have four α -globin genes; thus the variable severity of the α -thalassemia syndromes is related to the number of gene deletions (Table 28-1). The severity of the α -thalassemia syndromes varies among affected ethnic groups, depending on the genetic abnormalities prevalent in the population. In persons of African ancestry, α -thalassemia is usually caused by the deletion of only one of the two α -globin genes on each chromosome. Thus, in the African population, heterozygous individuals are silent carriers and homozygous individuals have α -thalassemia trait. In Asians, deletions of one or of both α -globin genes on the same chromosome are common; heterozygous individuals are either silent carriers or have α -thalassemia trait, and homozygous individuals or compound heterozygous individuals have α -thalassemia trait, hemoglobin H disease, or hydrops fetalis. Thus, the presence of α -thalassemia in a child of Asian ancestry may have important implications for genetic counseling, whereas this is not usually the case in families of African ancestry.

▶ Clinical Findings

The clinical findings depend on the number of α -globin genes deleted. Table 28-1 summarizes the α -thalassemia syndromes.

Persons with three α -globin genes (one-gene deletion) are asymptomatic and have no hematologic abnormalities. Hemoglobin levels and MCV are normal. Hemoglobin electrophoresis in the neonatal period shows 0–3% Bart's hemoglobin, which is a variant hemoglobin composed of four γ -globin chains. Hemoglobin electrophoresis after the first few months of life is normal. Thus, this condition is usually suspected only in the context of family studies or when a small amount of Bart's hemoglobin is detected by neonatal screening for hemoglobinopathies.

Table 28-1. The α -Thalassemias.

Usual Genotypes ^a	α -Gene Number	Clinical Features	Hemoglobin Electrophoresis ^b	
			Birth	> 6 mos
$\alpha\alpha/\alpha\alpha$	4	Normal	N	N
$-\alpha/\alpha\alpha$	3	Silent carrier	0-3% Hb Bart's	N
$-\alpha/\alpha\alpha$ or $-\alpha/-\alpha$	2	α -Thal trait	2-10% Hb Bart's	N
$-\alpha/-\alpha$	1	Hb H disease	15-30% Hb Bart's	Hb ₂ ; H present
$-/-$	0	Fetal hydrops	> 75% Hb Bart's	—

^a α indicates presence of α -globin gene, - indicates deletion of α -globin gene.

^bN = normal results, Hb = hemoglobin, Hb Bart's = γ_4 , Hb H = β_4 .

Persons with two α -globin genes (two-gene deletion) are typically asymptomatic. The MCV is usually less than 100 fL at birth. Hematologic studies in older infants and children show a normal or slightly decreased hemoglobin level with a low MCV and a slightly hypochromic blood smear with some target cells. The hemoglobin electrophoresis typically shows 2–10% Bart's hemoglobin in the neonatal period but is normal in older children and adults.

Persons with one α -globin gene (three-gene deletion) have a mild to moderately severe microcytic hemolytic anemia (hemoglobin level of 7–10 g/dL), which may be accompanied by hepatosplenomegaly and some bony abnormalities caused by the expanded medullary space. The reticulocyte count is elevated, and the red cells show marked hypochromia and microcytosis with significant poikilocytosis and some basophilic stippling. Hemoglobin electrophoresis in the neonatal period typically shows 15–30% Bart's hemoglobin. Later in life, hemoglobin H (composed of four β -globin chains) is present. Incubation of red cells with brilliant cresyl blue (hemoglobin H preparation) shows inclusion bodies formed by denatured hemoglobin H.

The deletion of all four α -globin genes causes severe intrauterine anemia and asphyxia and results in hydrops fetalis and fetal demise or neonatal death shortly after delivery. Extreme pallor and massive hepatosplenomegaly are present. Hemoglobin electrophoresis reveals a predominance of Bart's hemoglobin with a complete absence of normal fetal or adult hemoglobin.

► Differential Diagnosis

α -Thalassemia trait (two-gene deletion) must be differentiated from other mild microcytic anemias, including iron deficiency and β -thalassemia minor (see next section). In contrast to children with iron deficiency, children with α -thalassemia trait

show normal or increased levels of ferritin and serum iron. In contrast to children with β -thalassemia minor, children with α -thalassemia trait have a normal hemoglobin electrophoresis after age 4–6 months. Finally, the history of a low MCV (96 fL) at birth or the presence of Bart's hemoglobin on the neonatal hemoglobinopathy screening test suggests α -thalassemia.

Children with hemoglobin H disease may have jaundice and splenomegaly, and the disorder must be differentiated from other hemolytic anemias. The key to the diagnosis is the decreased MCV and the marked hypochromia on the blood smear. With the exception of β -thalassemia, most other significant hemolytic disorders have a normal or elevated MCV and the red blood cells are not hypochromic. Infants with hydrops fetalis due to severe α -thalassemia must be distinguished from those with hydrops due to other causes of anemia, such as alloimmunization.

► Complications

The principal complication of α -thalassemia trait is the needless administration of iron, given in the belief that a mild microcytic anemia is due to iron deficiency. Persons with hemoglobin H disease may have intermittent exacerbations of their anemia in response to oxidant stress or infection, which occasionally require blood transfusions. Splenomegaly may exacerbate the anemia and may require splenectomy. Women pregnant with hydropic α -thalassemia fetuses are subject to increased complications of pregnancy, particularly toxemia and postpartum hemorrhage.

► Treatment

Persons with α -thalassemia trait require no treatment. Those with hemoglobin H disease should receive supplemental folic acid and avoid the same oxidant drugs that cause hemolysis in persons with G6PD deficiency, because exposure to these drugs may exacerbate their anemia. The anemia may also be exacerbated during periods of infection, and transfusions may be required. Hypersplenism may develop later in childhood and require surgical splenectomy. Genetic counseling and prenatal diagnosis should be offered to families at risk for hydropic fetuses.

Clarke GM: Laboratory investigation of hemoglobinopathies and thalassemias: Review and update. *Clin Chem* 2000;46:1284 [PMID: 10926923].

2. β -Thalassemia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

β -Thalassemia minor:

- Normal neonatal screening test.
- African, Mediterranean, Middle Eastern, or Asian ancestry.

- ▶ Mild microcytic, hypochromic anemia.
- ▶ No response to iron therapy.
- ▶ Elevated level of hemoglobin A₂.

β-Thalassemia major:

- ▶ Neonatal screening shows hemoglobin F only.
- ▶ Mediterranean, Middle Eastern, or Asian ancestry.
- ▶ Severe microcytic, hypochromic anemia with marked hepatosplenomegaly.

▶ General Considerations

In contrast to the four α-globin genes, only two β-globin genes are present in diploid cells, one on each chromosome 11. Some β-thalassemia genes produce no β-globin chains and are termed β⁰-thalassemia. Other β-globin genes produce some β-globin, but in diminished quantities, and are termed β⁺-thalassemia. Persons affected by β-thalassemia may be heterozygous or homozygous. Individuals heterozygous for most β-thalassemia genes have β-thalassemia minor. Homozygous individuals have β-thalassemia major (Cooley anemia), a severe transfusion-dependent anemia, or a condition known as thalassemia intermedia, which is more severe than thalassemia minor but is not generally transfusion-dependent. β-Thalassemia major is the most common worldwide cause of transfusion-dependent anemia in childhood. In addition, β-thalassemia genes interact with genes for structural β-globin variants such as hemoglobin S and hemoglobin E to cause serious disease in compound heterozygous individuals. These disorders are discussed further in the sections dealing with sickle cell disease and with hemoglobin E disorders.

▶ Clinical Findings

A. Symptoms and Signs

Persons with β-thalassemia minor are usually asymptomatic with a normal physical examination. Those with β-thalassemia major are normal at birth but develop significant anemia during the first year of life. If the disorder is not identified and treated with blood transfusions, such children grow poorly and develop massive hepatosplenomegaly and enlargement of the medullary space with thinning of the bony cortex. The skeletal changes cause characteristic facial deformities (prominent forehead and maxilla) and predispose the child to pathologic fractures.

B. Laboratory Findings

Children with β-thalassemia minor have normal neonatal screening results but subsequently develop a decreased MCV with or without mild anemia. The peripheral blood smear typically shows hypochromia, target cells, and sometimes basophilic stippling. Hemoglobin electrophoresis performed

after 6–12 months of age is usually diagnostic when levels of hemoglobin A₂, hemoglobin F, or both are elevated. β-Thalassemia major is often initially suspected when hemoglobin A is absent on neonatal screening. Such infants are hematologically normal at birth, but develop severe anemia after the first few months of life. The peripheral blood smear typically shows a severe hypochromic, microcytic anemia with marked anisocytosis and poikilocytosis. Target cells are prominent, and nucleated red blood cells often exceed the number of circulating white blood cells. The hemoglobin level usually falls to 5–6 g/dL or less, and the reticulocyte count is elevated, but the reticulocyte index is normal to decreased. Platelet and white blood cell counts may be increased, and the serum bilirubin level is elevated. The bone marrow shows marked erythroid hyperplasia, but this finding is rarely needed for diagnosis. Hemoglobin electrophoresis shows only fetal hemoglobin and hemoglobin A₂ in children with homozygous β⁰-thalassemia.

Those with β⁺-thalassemia genes make some hemoglobin A but have a marked increase in fetal hemoglobin and hemoglobin A₂ levels. The diagnosis of homozygous β-thalassemia may also be suggested by the finding of β-thalassemia minor in both parents.

▶ Differential Diagnosis

β-Thalassemia minor must be differentiated from other causes of mild microcytic, hypochromic anemias, principally iron deficiency and α-thalassemia. In contrast to patients with iron-deficiency anemia, those with β-thalassemia minor typically have an elevated number of red blood cells, and the index of the MCV divided by the red cell count is under 13. Generally, the finding of an elevated hemoglobin A₂ level is diagnostic; however, the A₂ level is lowered by coexistent iron deficiency. Thus, in children thought to be iron-deficient, hemoglobin electrophoresis with quantitation of hemoglobin A₂ is sometimes deferred until after a course of iron therapy.

β-Thalassemia major is rarely confused with other disorders. Hemoglobin electrophoresis and family studies readily distinguish it from hemoglobin E/β-thalassemia, which is the other important cause of transfusion-dependent thalassemia.

▶ Complications

The principal complication of β-thalassemia minor is the unnecessary use of iron therapy in a futile attempt to correct the microcytic anemia. Children with β-thalassemia major who are inadequately transfused experience poor growth and recurrent infections and may have hepatosplenomegaly, thinning of the cortical bone, and pathologic fractures. Without treatment, most children die within the first decade of life. The principal complications of β-thalassemia major in transfused children are hemosiderosis, splenomegaly, and hypersplenism. Transfusion-related hemosiderosis requires chelation therapy with deferoxamine, given parentally, or deferasirox (Exjade),

given orally, to prevent cardiac, hepatic, and endocrine dysfunction. Noncompliance with chelation in adolescents and young adults may lead to death from congestive heart failure, cardiac arrhythmias, or hepatic failure. Even with adequate transfusions, many patients develop splenomegaly and some degree of hypersplenism. This may require surgical splenectomy because of the increasing transfusion requirements, but the procedure increases the risk of thrombosis and overwhelming septicemia.

▶ Treatment

β -Thalassemia minor requires no specific therapy, but diagnosis of the condition may have important genetic implications for the family. For patients with β -thalassemia major, two treatments are available: chronic transfusion with iron chelation and stem cell transplantation. Programs of blood transfusion are generally targeted to maintain a nadir hemoglobin level of 9–10 g/dL. This approach gives increased vigor and well-being, improved growth, and fewer overall complications. However, maintenance of good health currently requires iron chelation. Small doses of supplemental ascorbic acid may enhance the efficacy of iron chelation. Patients who undergo splenectomy to reduce transfusion requirements, and hence iron loading, should receive pneumococcal vaccine prior to the procedure and prophylactic penicillin and urgent treatment of all febrile illness after splenectomy.

Bone marrow or umbilical cord blood transplantation is an important therapeutic option for children with β -thalassemia major who have an HLA-identical sibling donor. The probability of hematologic cure is greater than 90% when transplantation is performed prior to the development of hepatomegaly or portal fibrosis.

Rund D: Medical progress: β -Thalassemia. *N Engl J Med* 2005;353:1135 [PMID: 16162884].

3. Sickle Cell Disease

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Neonatal screening test with hemoglobins FS, FSC, or FSA.
- ▶ African, Mediterranean, Middle Eastern, Indian, or Caribbean ancestry.
- ▶ Anemia, elevated reticulocyte count, jaundice.
- ▶ Recurrent episodes of musculoskeletal or abdominal pain.
- ▶ Hemoglobin electrophoresis with hemoglobins S and F; hemoglobins S and C; or hemoglobins S, A, and F with $S > A$.
- ▶ Splenomegaly in early childhood with later disappearance.
- ▶ High risk of bacterial sepsis.

▶ General Considerations

A high prevalence of sickle hemoglobin is found in persons of central African origin. It also occurs in other ethnic groups in Italy, Greece, Turkey, Saudi Arabia, and India. Sickle cell anemia is caused by homozygosity for the sickle gene and is the most common form of sickle cell disease. Other clinically important sickling disorders are compound heterozygous conditions in which the sickle gene interacts with genes for hemoglobins C, D_{Punjab}, O_{Arab}, C_{Harlem}, or β -thalassemia.

Overall, sickle cell disease occurs in about 1 of every 400 African American infants. Eight percent of African Americans are heterozygous carriers of the sickle gene and are said to have sickle cell trait.

The protean clinical manifestations of sickle hemoglobinopathies can be linked directly or indirectly to the propensity of deoxygenated hemoglobin S to polymerize. Polymerization of sickle hemoglobin distorts erythrocyte morphology, decreases red cell deformability, causes a marked reduction in red cell life span, increases blood viscosity, and predisposes to episodes of vaso-occlusion.

Neonatal screening for sickle hemoglobinopathies is now routine in most of the United States. The identification of affected infants at birth, when combined with follow-up programs of parental education, comprehensive medical care, and prophylactic penicillin, markedly reduces morbidity and mortality in early childhood.

▶ Clinical Findings

A. Symptoms and Signs

These are related to the hemolytic anemia and to tissue ischemia and organ dysfunction caused by vaso-occlusion. Physical findings are normal at birth, and symptoms are unusual before age 3–4 months because high levels of fetal hemoglobin inhibit sickling. A moderately severe hemolytic anemia may be present by age 1 year. This causes pallor, fatigue, and jaundice, and predisposes to the development of gallstones during childhood and adolescence. Intense congestion of the spleen with sickled cells may cause splenomegaly in early childhood and results in functional asplenia as early as age 3 months. This places children at great risk for overwhelming infection with encapsulated bacteria, particularly pneumococci. Up to 30% of patients experience one or more episodes of acute splenic sequestration, characterized by sudden enlargement of the spleen with pooling of red cells, acute exacerbation of anemia, and, in severe cases, shock and death. Acute exacerbation of anemia also occurs with aplastic crises, usually caused by infection with human parvovirus, and other viruses.

Recurrent episodes of vaso-occlusion and tissue ischemia cause acute and chronic problems. Dactylitis, or hand-and-foot syndrome, is the most common initial symptom of the disease and occurs in up to 50% of children before age 3 years. Recurrent episodes of abdominal and musculoskeletal pain may occur throughout life. Strokes occur in about 8%

Table 28–2. Common clinical manifestations of sickle cell disease.

	Acute	Chronic
Children	Bacterial sepsis or meningitis ^a Splenic sequestration ^a Aplastic crisis Vaso-occlusive events Dactylitis Bone infarction Acute chest syndrome ^a Stroke ^a Priapism	Functional asplenia Delayed growth and development Avascular necrosis of the hip Hyposthenuria Cholelithiasis
Adults	Bacterial sepsis ^a Aplastic crisis Vaso-occlusive events Bone infarction Acute chest syndrome ^a Stroke ^a Priapism Acute multiorgan failure syndrome ^a	Leg ulcers Proliferative retinopathy Avascular necrosis of the hip Cholecystitis Chronic organ failure ^a Liver Lung Kidney Decreased fertility

^aAssociated with significant mortality rate.

of children and tend to be recurrent. The so-called acute chest syndrome, characterized by fever, pleuritic chest pain, and acute pulmonary infiltrates with hypoxemia, is caused by pulmonary infection, infarction, or fat embolism from ischemic bone marrow. All tissues are susceptible to damage from vaso-occlusion, and multiple organ dysfunction is common by adulthood. Table 28–2 lists the common manifestations of sickle cell disease in children and adults.

B. Laboratory Findings

Children with sickle cell anemia (homozygous sickle cell disease) generally show a baseline hemoglobin level of 7–10 g/dL. This value may fall to life-threatening levels at the time of a sequestration or aplastic crisis. The baseline reticulocyte count is elevated markedly. The anemia is usually normocytic or macrocytic, and the peripheral blood smear typically shows the characteristic sickle cells as well as numerous target cells. Patients with sickle β -thalassemia also generally have a low MCV and hypochromia. Those with sickle β^+ -thalassemia tend to have less hemolysis and anemia. Persons with sickle hemoglobin C disease have fewer sickle forms and more target cells, and the hemoglobin level may be normal or only slightly decreased because the rate of hemolysis is much less than in sickle cell anemia.

Most infants with sickle hemoglobinopathies born in the United States are identified by neonatal screening. Results indicative of possible sickle cell disease require prompt confirmation with hemoglobin electrophoresis. Children

with sickle cell anemia and with sickle β^0 -thalassemia have only hemoglobins S and F. Persons with sickle β^+ -thalassemia have a preponderance of hemoglobin S with a lesser amount of hemoglobin A. Persons with sickle hemoglobin C disease have equal amounts of hemoglobins S and C. The use of solubility tests to screen for the presence of sickle hemoglobin should be avoided because a negative result is frequently encountered in infants with sickle cell disease, and because a positive result in an older child does not differentiate sickle cell trait from sickle cell disease. Thus, hemoglobin electrophoresis is always necessary to accurately identify a sickle disorder.

► Differential Diagnosis

Hemoglobin electrophoresis and sometimes hematologic studies of the parents are usually sufficient to confirm the correct diagnosis of a sickle cell disorder. Infants whose neonatal screening test shows only hemoglobins F and S occasionally have disorders other than sickle cell anemia or sickle β^0 -thalassemia. The most important of these disorders is a compound heterozygous condition of sickle hemoglobin and pancellular hereditary persistence of fetal hemoglobin. Such children, when older, typically have 30% fetal hemoglobin and 70% hemoglobin S, but they do not have significant anemia or develop vaso-occlusive episodes.

► Complications

Repeated tissue ischemia and infarction causes damage to virtually every organ system. Table 28–2 lists the most important complications. Patients who require multiple transfusions are at risk of developing transfusion-related hemosiderosis and red cell alloantibodies.

► Treatment

The cornerstone of treatment is enrollment in a program involving patient and family education, comprehensive outpatient care, and appropriate treatment of acute complications. Important to the success of such a program are psychosocial services, blood bank services, and the ready availability of baseline patient information in the setting in which acute illnesses are evaluated and treated. Management of sickle cell anemia and sickle β^0 -thalassemia includes prophylactic penicillin, which should be initiated by age 2 months and continued at least until age 5 years.

The routine use of penicillin prophylaxis in sickle hemoglobin C disease and sickle β^+ -thalassemia is controversial. Pneumococcal conjugate and polysaccharide vaccine should be administered to all children who have sickle cell disease. Other routine immunizations, including yearly vaccination against influenza, should be provided. All illnesses associated with fever greater than 38.5°C should be evaluated promptly, bacterial cultures performed, parenteral broad-spectrum antibiotics administered, and careful inpatient or outpatient observation conducted.

Treatment of painful vaso-occlusive episodes includes the maintenance of adequate hydration (with avoidance of overhydration), correction of acidosis if present, administration of adequate analgesia, maintenance of normal oxygen saturation, and the treatment of any associated infections.

Red cell transfusions play an important role in management. Transfusions are indicated to improve oxygen-carrying capacity during acute severe exacerbations of anemia, as occurs during episodes of splenic sequestration or aplastic crisis. Red cell transfusions are not indicated for the treatment of chronic steady-state anemia, which is usually well tolerated, or for uncomplicated episodes of vaso-occlusive pain. Simple or partial exchange transfusion to reduce the percentage of circulating sickle cells is indicated for some severe acute vaso-occlusive events and may be lifesaving. These events include stroke, moderate to severe acute chest syndrome, and acute life-threatening failure of other organs. Transfusions may also be used prior to high-risk procedures such as surgery with general anesthesia and arteriograms with ionic contrast materials. Some patients who develop severe vaso-occlusive complications may benefit from chronic transfusion therapy. The most common indication for transfusion is stroke. Without transfusions, children with stroke have a 70–80% chance of recurrent stroke within a 2-year period. This risk of recurrent neurologic events is reduced markedly by the transfusion therapy.

Successful stem cell transplantation cures sickle cell disease, but to date its use has been limited because of the risks associated with the procedure, the inability to predict in young children the severity of future complications, and the paucity of HLA-identical sibling donors. Daily administration of oral hydroxyurea increases levels of fetal hemoglobin, decreases hemolysis, and reduces by 50% episodes of pain in severely affected adults with sickle cell anemia. The hematologic effects and short-term toxicity of hydroxyurea in children are similar to those in adults. Thus hydroxyurea is being used increasingly for selected children and adolescents who have frequent, severe complications.

► Prognosis

Early identification by neonatal screening of infants with sickle cell disease, combined with comprehensive care that includes prophylactic penicillin, has markedly reduced mortality in childhood. Most patients now live well into adulthood, but eventually succumb to complications.

4. Sickle Cell Trait

Individuals who are heterozygous for the sickle gene are said to have sickle cell trait. This genetic carrier state occurs in 8% of African Americans and is more common in some areas of Africa and the Middle East. Infants with sickle cell trait are identified by neonatal screening results that show hemoglobin FAS. Accurate identification of older persons with sickle cell trait depends on hemoglobin electrophoresis, which typically shows about 60% hemoglobin A and about 40% hemoglobin S. No anemia or hemolysis is present, and the physical examination is normal. Persons with sickle cell trait are generally healthy, and experience no illness attributable to the presence of sickle hemoglobin in their red cells. Life expectancy is normal.

Sickle trait erythrocytes are capable of sickling, particularly under conditions of significant hypoxemia, and several clinical abnormalities have been linked to this genetic carrier state. Exposure to environmental hypoxia (altitude > 3100 m [10,000 ft] above sea level) may precipitate splenic infarction. However, most persons with sickle cell trait who choose to visit such altitudes for skiing, hiking, or climbing do so without difficulty. Many develop some degree of hyposthenuria, and about 4% experience painless hematuria, usually microscopic but occasionally macroscopic. For the most part, these renal abnormalities are subclinical and do not progress to significant renal dysfunction. The incidence of bacteriuria and pyelonephritis may be increased during pregnancy, but overall rates of maternal and infant morbidity and mortality are not affected by the presence of sickle cell trait in the pregnant woman.

An epidemiologic study of army recruits in military basic training found a higher risk of sudden unexplained death following strenuous exertion in recruits with sickle cell trait than in those with normal hemoglobin. This study has raised concerns about exercise and exertion for persons with the trait. However, considerable evidence suggests that exercise is generally safe and that athletic performance is not adversely affected by sickle cell trait. Exercise tolerance is normal, and the incidence of sickle cell trait in black professional football players is similar to that of the general African-American population, suggesting no barrier to achievement in such a physically demanding profession. Thus, restrictions on athletic competition for children with sickle cell trait are not warranted. Sickle cell trait is most significant for its genetic implications.

5. Hemoglobin C Disorders

Hemoglobin C is detected by neonatal screening. Two percent of African Americans are heterozygous for hemoglobin C and are said to have hemoglobin C trait. Such individuals have no symptoms, anemia, or hemolysis, but the peripheral blood smear may show some target cells. Identification of persons with hemoglobin C trait is important for genetic counseling, particularly with regard to the possibility of sickle hemoglobin C disease in offspring.

Persons with homozygous hemoglobin C have a mild microcytic hemolytic anemia and may develop splenomegaly. The peripheral blood smear shows prominent target cells. As with other hemolytic anemias, complications of homozygous hemoglobin C include gallstones and aplastic crises.

Olson JF: Hemoglobin C disease in infancy and childhood. *J Pediatr* 1994;125:745 [PMID: 7965426].

6. Hemoglobin E Disorders

Hemoglobin E is the second most common hemoglobin variant worldwide, with a gene frequency greater than 10% in some areas of Thailand and Cambodia. In Southeast Asia, an estimated 30 million people have hemoglobin E trait. Persons heterozygous for hemoglobin E show hemoglobin FAE by neonatal screening and are asymptomatic and usually not anemic, but they may develop mild microcytosis. Persons homozygous for hemoglobin E are also asymptomatic but may have mild anemia; the peripheral blood smear shows microcytosis and some target cells.

Hemoglobin E is most important because of its interaction with β -thalassemia. Compound heterozygotes for hemoglobin E and β^0 -thalassemia are normal at birth and, like infants with homozygous E, show hemoglobin FE on neonatal screening. Unlike homozygotes, they subsequently develop mild to severe microcytic hypochromic anemia. Such children may exhibit jaundice, hepatosplenomegaly, and poor growth if the disorder is not recognized and treated appropriately. In some cases, the anemia becomes severe enough to require lifelong transfusion therapy. In certain areas of the United States, hemoglobin E/ β^0 -thalassemia has become a more common cause of transfusion-dependent anemia than homozygous β -thalassemia.

7. Other Hemoglobinopathies

Hundreds of other human globin-chain variants have been described. Some, such as hemoglobins D and G, are relatively common. Heterozygous individuals, who are frequently identified during the course of neonatal screening programs for hemoglobinopathies, are generally asymptomatic and usually have no anemia or hemolysis. The principal significance of most hemoglobin variants is the potential for disease in compound heterozygous individuals who also inherit a gene for β -thalassemia or sickle hemoglobin. For example, children who are compound heterozygous for hemoglobins S and D_{Punjab} (D_{Los Angeles}) have sickle cell disease.

CONGENITAL HEMOLYTIC ANEMIAS: DISORDERS OF RED CELL METABOLISM

Erythrocytes depend on the anaerobic metabolism of glucose for the maintenance of adenosine triphosphate levels sufficient for homeostasis. Glycolysis also produces the 2,3-diphosphoglycerate levels needed to modulate the oxygen

affinity of hemoglobin. Glucose metabolism via the hexose monophosphate shunt is necessary to generate sufficient reduced nicotinamide adenine dinucleotide phosphate (NADH) and reduced glutathione to protect red cells against oxidant damage. Congenital deficiencies of many glycolytic pathway enzymes have been associated with hemolytic anemias. In general, the morphologic abnormalities present on the peripheral blood smear are nonspecific, and the inheritance of these disorders is autosomal recessive or X-linked. Thus, the possibility of a red cell enzyme defect should be considered during the evaluation of a patient with a congenital hemolytic anemia in the following instances: when the peripheral blood smear does not show red cell morphology typical of membrane or hemoglobin defects (eg, spherocytes, sickle forms, target cells); when hemoglobin disorders are excluded by hemoglobin electrophoresis and by isopropanol precipitation tests; and when family studies do not suggest an autosomal dominant disorder. The diagnosis is confirmed by finding a low level of the deficient enzyme.

The two most common disorders of erythrocyte metabolism are G6PD deficiency and pyruvate kinase deficiency.

1. Glucose-6-Phosphate Dehydrogenase (G6PD) Deficiency

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ African, Mediterranean, or Asian ancestry.
- ▶ Neonatal hyperbilirubinemia.
- ▶ Sporadic hemolysis associated with infection or with ingestion of oxidant drugs or fava beans.
- ▶ X-linked inheritance.

▶ General Considerations

Deficiency of G6PD is the most common red cell enzyme defect that causes hemolytic anemia. The disorder has X-linked recessive inheritance and occurs with high frequency among persons of African, Mediterranean, and Asian ancestry. Hundreds of different G6PD variants have been characterized. In most instances, the deficiency is due to enzyme instability; thus, older red cells are more deficient than younger ones, and are unable to generate sufficient NADH to maintain the levels of reduced glutathione necessary to protect the red cells against oxidant stress. Thus, most persons with G6PD deficiency do not have a chronic hemolytic anemia; instead, they have episodic hemolysis at times of exposure to the oxidant stress of infection or of certain drugs or food substances. The severity of the disorder varies among ethnic groups; G6PD deficiency in persons of African ancestry usually is less severe than in other ethnic groups.

Table 28-3. Some common drugs and chemicals that can induce hemolytic anemia in persons with G6PD deficiency.

Acetanilide	Niridazole
Doxorubicin	Nitrofurantoin
Furazolidone	Phenazopyridine
Methylene blue	Primaquine
Nalidixic acid	Sulfamethoxazole

Reproduced, with permission, from Beutler E: Glucose-6-phosphate dehydrogenase deficiency. *N Engl J Med* 1991;324:171.

► Clinical Findings

A. Symptoms and Signs

Infants with G6PD deficiency may have significant hyperbilirubinemia and require phototherapy or exchange transfusion to prevent kernicterus. The deficiency is an important cause of neonatal hyperbilirubinemia in infants of Mediterranean or Asian ancestry, but less so in infants of African ancestry. Older children with G6PD deficiency are asymptomatic and appear normal between episodes of hemolysis. Hemolytic episodes are often triggered by infection or by the ingestion of oxidant drugs such as antimalarial compounds and sulfonamide antibiotics (Table 28-3). Ingestion of fava beans may trigger hemolysis in children of Mediterranean or Asian ancestry but usually not in children of African ancestry. Episodes of hemolysis are associated with pallor, jaundice, hemoglobinuria, and sometimes cardiovascular compromise.

B. Laboratory Findings

The hemoglobin concentration, reticulocyte count, and peripheral blood smear are usually normal in the absence of oxidant stress. Episodes of hemolysis are associated with a variable fall in hemoglobin. “Bite” cells or blister cells may be seen, along with a few spherocytes. Hemoglobinuria is common, and the reticulocyte count increases within a few days. Heinz bodies may be demonstrated with appropriate stains. The diagnosis is confirmed by the finding of reduced levels of G6PD in erythrocytes. Because this enzyme is present in increased quantities in reticulocytes, the test is best performed at a time when the reticulocyte count is normal or near normal.

► Complications

Kernicterus is a risk for infants with significant neonatal hyperbilirubinemia. Episodes of acute hemolysis in older children may be life-threatening. Rare G6PD variants are associated with chronic hemolytic anemia; the clinical course of patients with such variants may be complicated by splenomegaly and by the formation of gallstones.

► Treatment

The most important treatment issue is avoidance of drugs known to be associated with hemolysis (see Table 28-3). For

some patients of Mediterranean, Middle Eastern, or Asian ancestry, the consumption of fava beans must also be avoided. Infections should be treated promptly and antibiotics given when appropriate. Most episodes of hemolysis are self-limiting, but red cell transfusions may be lifesaving when signs and symptoms indicate cardiovascular compromise.

2. Pyruvate Kinase Deficiency

Pyruvate kinase deficiency is an autosomal recessive disorder observed in all ethnic groups but is most common in northern Europeans. The deficiency is associated with a chronic hemolytic anemia of varying severity. Approximately one third of those affected present in the neonatal period with jaundice and hemolysis that require phototherapy or exchange transfusion. Occasionally, the disorder causes hydrops fetalis and neonatal death. In older children, the hemolysis may require red cell transfusions or be mild enough to go unnoticed for many years. Jaundice and splenomegaly frequently occur in the more severe cases. The diagnosis of pyruvate kinase deficiency is occasionally suggested by the presence of echinocytes on the peripheral blood smear, but these findings may be absent prior to splenectomy. The diagnosis depends on the demonstration of low levels of pyruvate kinase activity in red cells.

Treatment of pyruvate kinase depends on the severity of the hemolysis. Blood transfusions may be required for significant anemia, and splenectomy may be beneficial. Although the procedure does not cure the disorder, it ameliorates the anemia and its symptoms. Characteristically, the reticulocyte count increases and echinocytes become more prevalent after splenectomy, despite the decreased hemolysis and increased hemoglobin level.

ACQUIRED HEMOLYTIC ANEMIA

1. Autoimmune Hemolytic Anemia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pallor, fatigue, jaundice, and dark urine.
- Splenomegaly.
- Positive DAT.
- Reticulocytosis and spherocytosis.

► General Considerations

Acquired autoimmune hemolytic anemia is rare during the first 4 months of life but is one of the more common causes of acute anemia after the first year. It may arise as an isolated problem or may complicate an infection (hepatitis, upper respiratory tract infections, mononucleosis, or cytomegalovirus infection); systemic lupus erythematosus and other autoimmune syndromes;

immunodeficiency states, including autoimmune lymphoproliferative syndrome; or, rarely, malignancies.

► Clinical Findings

A. Symptoms and Signs

The disease usually has an acute onset manifested by weakness, pallor, dark urine, and fatigue. Jaundice is a prominent finding, and splenomegaly is often present. Some cases have a more chronic, insidious onset. Clinical evidence of an underlying disease may be present.

B. Laboratory Findings

The anemia is normochromic and normocytic and may vary from mild to severe (hemoglobin concentration < 5 g/dL). The reticulocyte count and index are usually increased but occasionally are normal or low. Spherocytes and nucleated red cells may be seen on the peripheral blood smear. Although leukocytosis and elevated platelet counts are a common finding, thrombocytopenia occasionally occurs. Other laboratory data consistent with hemolysis are present, such as increased indirect and total bilirubin, lactic dehydrogenase, aspartate aminotransferase, and urinary urobilinogen. Intravascular hemolysis is indicated by hemoglobinemia or hemoglobinuria. Examination of bone marrow shows marked erythroid hyperplasia and hemophagocytosis, but is seldom required for the diagnosis.

Serologic studies are helpful in defining pathophysiology, planning therapeutic strategies, and assessing prognosis

(Table 28–4). In almost all cases, the direct and indirect antiglobulin (DAT and IAT) tests are positive. Further evaluation allows distinction into one of three syndromes. The presence of IgG on the patient's red blood cells, maximal in-vitro antibody activity at 37°C, and either no antigen specificity or an Rh-like specificity constitute warm autoimmune hemolytic anemia with extravascular destruction by the reticuloendothelial system. In contrast, the detection of complement alone on red blood cells, optimal reactivity in vitro at 4°C, and I or i antigen specificity are diagnostic of cold autoimmune hemolytic anemia with intravascular hemolysis. Although cold agglutinins are relatively common (~10%) in normal individuals, clinically significant cold antibodies exhibit in-vitro reactivity at 30°C or above.

Paroxysmal cold hemoglobinuria usually has a different cause. The laboratory evaluation is identical to cold autoimmune hemolytic anemia except for antigen specificity (P) and the exhibition of in-vitro hemolysis. Paroxysmal cold hemoglobinuria is almost always associated with significant infections, such as *Mycoplasma*, Epstein-Barr virus (EBV), and cytomegalovirus (CMV). Warm IgM antibodies are rare.

► Differential Diagnosis

Autoimmune hemolytic anemia must be differentiated from other forms of congenital or acquired hemolytic anemias. The DAT discriminates antibody-mediated hemolysis from other causes, such as hereditary spherocytosis. The presence of other cytopenias and antibodies to platelets or neutrophils suggests Evans syndrome.

Table 28–4. Classification of autoimmune hemolytic anemia (AIHA) in children.

Syndrome	Warm AIHA	Cold AIHA	Paroxysmal Cold Hemoglobinuria
Specific antiglobulin test IgG Complement	Strongly positive Negative or mildly positive	Negative Strongly positive	Negative Strongly positive
Temperature at maximal reactivity (in vitro)	37°C	4°C	4°C
Antigen specificity	May be panagglutinin or may have an Rh-like specificity	I or i	P
Other	Positive biphasic hemolysin test
Pathophysiology	Extravascular hemolysis, destruction by the RES (eg, spleen)	Intravascular hemolysis (may have extravascular component)	Intravascular hemolysis (may have extravascular component)
Prognosis	May be more chronic (> 3 mo) with significant morbidity and mortality. May be associated with a primary disorder (lupus, immunodeficiency, etc).	Generally acute (< 3 mo). Good prognosis: often associated with infection.	Acute, self-limited. Associated with infection.
Therapy	Responds to RES blockade, including steroids (prednisone, 2 mg/kg/d), IVIG (1 g/kg/d for 2 d), or splenectomy	May not respond to RES blockade. Severe cases may benefit from plasmapheresis.	Usually self-limited. Symptomatic management.

IVIg, intravenous immune globulin; RES, reticuloendothelial system.

► Complications

The anemia may be very severe and result in cardiovascular collapse, requiring emergency management. The complications of an underlying disease, such as disseminated lupus erythematosus or an immunodeficiency state, may be present.

► Treatment

Medical management of the underlying disease is important in symptomatic cases. Defining the clinical syndrome provides a useful guide to treatment. Most patients with warm autoimmune hemolytic anemia (in which hemolysis is mostly extravascular) respond to prednisone (2–4 mg/kg/d). After the initial treatment, the dose of corticosteroids may be decreased slowly. Patients may respond to 1 g of intravenous immune globulin (IVIG) per kilogram per day for 2 days, but fewer patients respond to IVIG than to prednisone. Although the rate of remission with splenectomy may be as high as 50%, particularly in warm autoimmune hemolytic anemia, this should be carefully considered in younger patients and withheld until other treatments have failed. In severe cases unresponsive to more conventional therapy, immunosuppressive agents such as cyclophosphamide, azathioprine, busulfan, and cyclosporine may be tried alone or in combination with corticosteroids. In refractory cases, rituximab may be a successful alternative, and transplantation has been used in a small number of cases.

Patients with cold autoimmune hemolytic anemia and paroxysmal cold hemoglobinuria are less likely to respond to corticosteroids or IVIG. Because these syndromes are most apt to be associated with infections and have an acute, self-limited course, supportive care may be sufficient. Plasma exchange may be effective in severe cold autoimmune (IgM) hemolytic anemia because the offending antibody has an intravascular distribution.

Supportive therapy is crucial. Patients with cold-reacting antibodies, particularly paroxysmal cold hemoglobinuria, should be kept in a warm environment. Transfusion may be necessary because of the complications of severe anemia but should be used only when there is no alternative. In most patients, cross-match compatible blood will not be found, and the least incompatible unit should be identified. Transfusion must be conducted carefully, beginning with a test dose (see Transfusion Medicine section, later in this chapter). Identification of the patient's phenotype for minor red cell alloantigens may be helpful in avoiding alloimmunization or in providing appropriate transfusions if alloantibodies arise after initial transfusions. Patients with severe intravascular hemolysis may have associated disseminated intravascular coagulation (DIC), and heparin therapy should be considered in such cases.

► Prognosis

The outlook for autoimmune hemolytic anemia in childhood usually is good unless associated diseases are present

(eg, congenital immunodeficiency, AIDS, lupus erythematosus), in which case hemolysis is likely to have a chronic course. In general, children with warm autoimmune hemolytic anemia are at greater risk for more severe and chronic disease with higher morbidity and mortality rates. Hemolysis and positive antiglobulin tests may continue for months or years. Patients with cold autoimmune hemolytic anemia or paroxysmal cold hemoglobinuria are more likely to have acute, self-limited disease (< 3 months). Paroxysmal cold hemoglobinuria is almost always associated with infection (eg, *Mycoplasma* infection, CMV, and EBV).

2. Nonimmune Acquired Hemolytic Anemia

Hepatic disease may alter the lipid composition of the red cell membrane. This usually results in the formation of target cells and is not associated with significant hemolysis.

Occasionally, hepatocellular damage is associated with the formation of spur cells and brisk hemolytic anemia. Renal disease may also be associated with significant hemolysis; hemolytic-uremic syndrome is one example. In this disorder, hemolysis is associated with the presence, on the peripheral blood smear, of echinocytes, helmet cells, fragmented red cells, and spherocytes.

A microangiopathic hemolytic anemia with fragmented red cells and some spherocytes may be observed in several conditions associated with intravascular coagulation and fibrin deposition within vessels. This occurs with DIC such as may complicate severe infection, but it may also occur when the intravascular coagulation is localized, as with giant cavernous hemangiomas (Kasabach-Merritt syndrome). Fragmented red cells may also be seen with mechanical damage (eg, associated with artificial heart valves).

POLYCYTHEMIA & METHEMOGLOBINEMIA

CONGENITAL ERYTHROCYTOSIS (FAMILIAL POLYCYTHEMIA)

In pediatrics, polycythemia is usually secondary to chronic hypoxemia. However, several families with congenital erythrocytosis have been described. The disorder differs from polycythemia vera in that only red blood cells are affected; the

white blood cell and platelet counts are normal. It occurs as an autosomal dominant or recessive disorder. There are usually no physical findings except for plethora and splenomegaly. The hemoglobin level may be as high as 27 g/dL. Patients usually have no symptoms other than headache and lethargy. Studies in a number of families have revealed (1) abnormal hemoglobin with altered oxygen affinity, (2) reduced red cell diphosphoglycerate, (3) autonomous increase in erythropoietin production, or (4) hypersensitivity of erythroid precursors to erythropoietin.

Treatment is not indicated unless symptoms are marked. Phlebotomy is the treatment of choice.

SECONDARY POLYCYTHEMIA

Secondary polycythemia occurs in response to hypoxemia. The most common cause of secondary polycythemia in children is cyanotic congenital heart disease. It also occurs in chronic pulmonary disease such as cystic fibrosis. Persons living at extremely high altitudes, as well as some with methemoglobinemia, develop polycythemia. It has on rare occasions been described without hypoxemia in association with renal tumors, brain tumors, Cushing disease, or hydronephrosis.

Polycythemia may occur in the neonatal period; it is particularly exaggerated in infants who are preterm or small for gestational age. In these infants, polycythemia is sometimes associated with other symptoms. It may occur in infants of diabetic mothers, in Down syndrome, and as a complication of congenital adrenal hyperplasia.

Iron deficiency may complicate polycythemia and aggravate the associated hyperviscosity. This complication should always be suspected when the MCV falls below the normal range. Coagulation and bleeding abnormalities, including thrombocytopenia, mild consumption coagulopathy, and elevated fibrinolytic activity, have been described in severely polycythemic cardiac patients. Bleeding at surgery may be severe.

The ideal treatment of secondary polycythemia is correction of the underlying disorder. When this cannot be done, phlebotomy may be necessary to control symptoms. Iron sufficiency should be maintained. Adequate hydration of the patient and phlebotomy with plasma replacement may be indicated prior to major surgical procedures. These measures prevent the complications of thrombosis and hemorrhage. Isovolumetric exchange transfusion is the treatment of choice in severe cases.

METHEMOGLOBINEMIA

Methemoglobin is continuously formed at a slow rate by the oxidation of heme iron to the ferric state. Normally, it is enzymatically reduced back to hemoglobin. Methemoglobin is unable to transport oxygen and causes a shift in the dissociation curve of the residual oxyhemoglobin. Cyanosis is produced with methemoglobin levels of approxi-

mately 15% or greater. Levels of methemoglobin increase by several mechanisms.

1. Hemoglobin M

The designation M is given to several abnormal hemoglobins associated with methemoglobinemia. Affected individuals are heterozygous for the gene, which is transmitted as an autosomal dominant disorder. The different types of hemoglobin M result from different amino acid substitutions in α -globin or β -globin. Hemoglobin electrophoresis at the usual pH will not always demonstrate the abnormal hemoglobin, and isoelectric focusing may be needed. The patient has cyanosis but is otherwise usually asymptomatic. Exercise tolerance may be normal, and life expectancy is not affected. This type of methemoglobinemia does not respond to any form of therapy.

2. Congenital Methemoglobinemia Due to Enzyme Deficiencies

Congenital methemoglobinemia is caused most frequently by congenital deficiency of the reducing enzyme diaphorase I (coenzyme factor I). It is transmitted as an autosomal recessive trait. Affected patients may have as much as 40% methemoglobin but usually have no symptoms, although a mild compensatory polycythemia may be present. Patients with methemoglobinemia associated with a deficiency of diaphorase I respond readily to treatment with ascorbic acid and methylene blue (see next section), but treatment is not usually indicated.

3. Acquired Methemoglobinemia

Several compounds activate the oxidation of hemoglobin from the ferrous to the ferric state, forming methemoglobin. These include the nitrites and nitrates (contaminated water), chlorates, and quinones. Drugs in this group are the aniline dyes, sulfonamides, acetanilid, phenacetin, bismuth subnitrate, and potassium chlorate. Poisoning with a drug or chemical containing one of these substances should be suspected in any infant or child who presents with sudden cyanosis. Methemoglobin levels in such cases may be extremely high and can produce anoxia, dyspnea, unconsciousness, circulatory failure, and death. Young infants and newborns are more susceptible to acquired methemoglobinemia because their red cells have difficulty reducing hemoglobin, probably because their NADH methemoglobin reductase is transiently deficient. Infants with metabolic acidosis from diarrhea and dehydration or other causes also may develop methemoglobinemia.

Patients with the acquired form of methemoglobinemia respond dramatically to methylene blue in a dose of 1–2 mg/kg intravenously. For infants and young children, a smaller dose (1–1.5 mg/kg) is recommended. Ascorbic acid administered orally or intravenously also reduces methemoglobin, but the response is slower.

DISORDERS OF LEUKOCYTES

NEUTROPENIA

ESSENTIALS OF DIAGNOSIS
& TYPICAL FEATURES

- ▶ Increased frequency of infections.
- ▶ Ulceration of oral mucosa and gingivitis.
- ▶ Normal numbers of red cells and platelets.

▶ General Considerations

Neutropenia is an absolute neutrophil (granulocyte) count of less than 1500/ μL in childhood, or below 1000/ μL between ages 1 week and 2 years. During the first few days of life, an absolute neutrophil count of less than 3500 cells/ μL may be considered neutropenia. Neutropenia results from absent or defective granulocyte stem cells, ineffective or suppressed myeloid maturation, decreased production of hematopoietic cytokines (eg, granulocyte colony-stimulating factor [G-CSF] or granulocyte-macrophage colony-stimulating factor [GM-CSF]), decreased marrow release, increased neutrophil destruction or consumption, or, in pseudo-neutropenia, from an increased neutrophil marginating pool (Table 28–5).

The most severe types of congenital neutropenia include reticular dysgenesis (congenital aleukocytosis), Kostmann syndrome (severe neutropenia with maturation defect in the marrow progenitor cells), Shwachman syndrome (neutropenia with pancreatic insufficiency), neutropenia with immune deficiency states, cyclic neutropenia, and myelokathexis or dysgranulopoiesis. Genetic mutations for Chédiak-Higashi syndrome, Kostmann and Shwachman syndromes, and cyclic neutropenia have been identified. Neutropenia may also be associated with storage and metabolic diseases and immunodeficiency states. The most common causes of neutropenia are viral infection or drugs resulting in decreased neutrophil production in the marrow or increased destruction or both. Severe bacterial infections may be associated with neutropenia. Although rare, neonatal alloimmune neutropenia can be severe and associated with risk for infection. Autoimmune neutropenia in the mother can result in passive transfer of antibody to the fetus and neutropenia in the neonate. Malignancies, osteopetrosis, marrow failure syndromes, and hypersplenism usually are not associated with isolated neutropenia.

▶ Clinical Findings

A. Symptoms and Signs

Acute severe bacterial or fungal infection is the most significant complication of neutropenia. Although the risk is

Table 28–5. Classification of neutropenia of childhood.

Congenital neutropenia with stem cell abnormalities

- Reticular dysgenesis
- Cyclic neutropenia

Congenital neutropenia with abnormalities of committed myeloid progenitor cells

- Neutropenia with immunodeficiency disorders (T cells and B cells)
- Severe congenital neutropenia (Kostmann syndrome)
- Chronic idiopathic neutropenia of childhood
- Myelokathexis with dysmyelopoiesis
- Chédiak-Higashi syndrome
- Shwachman syndrome
- Cartilage-hair hypoplasia
- Dyskeratosis congenita
- Fanconi anemia
- Organic acidemias (eg, propionic, methylmalonic)
- Glycogenosis Ib
- Osteopetrosis

Acquired neutropenias affecting stem cells

- Malignancies (leukemia, lymphoma) and preleukemic disorders
- Drugs or toxic substances
- Ionizing radiation
- Aplastic anemia

Acquired neutropenias affecting committed myeloid progenitors or survival of mature neutrophils

- Ineffective granulopoiesis (vitamin B₁₂, folate, and copper deficiency)
- Infection
- Immune (neonatal alloimmune or autoimmune; autoimmune or chronic benign neutropenia of childhood)
- Hypersplenism

increased when the absolute neutrophil count is less than 500/ μL , the actual susceptibility is variable and depends on the cause of neutropenia, marrow reserves, and other factors. The most common types of infection include septicemia, cellulitis, skin abscesses, pneumonia, and perirectal abscesses. Sinusitis, aphthous ulcers, gingivitis, and periodontal disease also cause significant problems. In addition to local signs and symptoms, patients may have chills, fever, and malaise. In most cases, the spleen and liver are not enlarged. *Staphylococcus aureus* and gram-negative bacteria are the most common pathogens.

B. Laboratory Findings

Neutrophils are absent or markedly reduced in the peripheral blood smear. In most forms of neutropenia or agranulocytosis, the monocytes and lymphocytes are normal and the red cells and platelets are not affected. The bone marrow usually shows a normal erythroid series, with adequate megakaryocytes, but a marked reduction in the myeloid cells or a significant delay in maturation of this series may be noted. Total cellularity may be decreased.

In the evaluation of neutropenia (eg, persistent, intermittent, cyclic), attention should be paid to the duration and pattern of neutropenia, the types of infections and their frequency, and phenotypic abnormalities on physical exam-

ination. A careful family history and blood counts from the parents are useful. If an acquired cause, such as viral infection or drug, is not obvious and no other primary disease is present, white blood cell counts, white cell differential, and platelet and reticulocyte counts should be completed twice weekly for 4–6 weeks to determine the possibility of cyclic neutropenia. Bone marrow aspiration and biopsy are most important to characterize the morphologic features of myelopoiesis. Measuring the neutrophil counts in response to corticosteroid infusion may document the marrow reserves. Other tests that aid in the diagnosis include measurement of neutrophil antibodies, immunoglobulin levels, antinuclear antibodies, and lymphocyte phenotyping to detect immunodeficiency states. Cultures of bone marrow are important for defining the numbers of stem cells and progenitors committed to the myeloid series or the presence of inhibitory factors. Cytokine levels in plasma or mononuclear cells can be measured directly. Some neutropenia disorders have abnormal neutrophil function. Recent studies have documented abnormalities in an antiapoptotic gene, *HAX1*, and the elastase gene, *ELA2*, in Kostmann syndrome and *ELA2* mutations in cyclic neutropenia. A mutation for Shwachman syndrome has been described. Increased apoptosis in marrow precursors or circulating neutrophils has been described in several congenital disorders.

▶ Treatment

Identifiable toxic agents should be eliminated or associated diseases (eg, infections) treated. Prophylactic antimicrobial therapy is not indicated for afebrile, asymptomatic patients. Recombinant G-CSF and GM-CSF will increase neutrophil counts in most patients. Patients may be started on 3–5 mcg/kg/d of G-CSF (filgrastim) given subcutaneously or intravenously once a day. Depending on the counts, the dose may be adjusted. For patients with congenital neutropenia, the dose should be regulated to keep the absolute neutrophil count below 10,000/ μ L. Some patients maintain adequate counts with G-CSF given two to three times a week. Treatment will decrease infectious complications.

▶ Prognosis

The prognosis varies greatly with the cause and severity of the neutropenia. In severe cases with persistent agranulocytosis, the prognosis is poor in spite of antibiotic therapy; in mild or cyclic forms of neutropenia, symptoms may be minimal and the prognosis for normal life expectancy excellent. Up to 50% of patients with Shwachman syndrome may develop aplastic anemia, myelodysplasia, or leukemia during their lifetime. Patients with Kostmann syndrome also have a potential for leukemia.

NEUTROPHILIA

Neutrophilia is an increase in the absolute neutrophil count in the peripheral blood to greater than 7500–8500 cells/ μ L for infants, children, and adults. To support the increased peripheral count, neutrophils may be mobilized from bone marrow storage or peripheral marginating pools. Neutrophilia occurs acutely in association with bacterial or viral infections, inflammatory diseases (eg, juvenile rheumatoid arthritis, inflammatory bowel disease, Kawasaki disease), surgical or functional asplenia, liver failure, diabetic ketoacidosis, azotemia, congenital disorders of neutrophil function (eg, chronic granulomatous disease, leukocyte adherence deficiency), and hemolysis. Drugs such as corticosteroids, lithium, and epinephrine increase the blood neutrophil count. Corticosteroids cause release of neutrophils from the marrow pool, inhibit egress from capillary beds, and postpone apoptotic cell death. Epinephrine causes release of the marginating pool. Acute neutrophilia has been reported after stress such as from electric shock, trauma, burns, surgery, and emotional upset. Tumors involving the bone marrow, such as lymphomas, neuroblastomas, and rhabdomyosarcoma, may be associated with leukocytosis and the presence of immature myeloid cells in the peripheral blood. Infants with Down syndrome have defective regulation of proliferation and maturation of the myeloid series and may develop neutrophilia. At times this process may affect other cell lines and mimic myeloproliferative disorders or acute leukemia.

The neutrophilias must be distinguished from myeloproliferative disorders such as chronic myelogenous leukemia and juvenile chronic myelogenous leukemia. In general, abnormalities involving other cell lines, the appearance of immature cells on the blood smear, and the presence of hepatosplenomegaly are important differentiating characteristics.

DISORDERS OF NEUTROPHIL FUNCTION

Neutrophils play a key role in host defenses. Circulating in capillary beds, they adhere to the vascular endothelium adjacent to sites of infection and inflammation. Moving

between endothelial cells, the neutrophil migrates toward the offending agent. Contact with a microbe that is properly opsonized with complement or antibodies triggers ingestion, a process in which cytoplasmic streaming results in the formation of pseudopods that fuse around the invader, encasing it in a phagosome. During the ingestion phase, the oxidase enzyme system assembles and is activated, taking oxygen from the surrounding medium and reducing it to form toxic oxygen metabolites critical to microbicidal activity. Concurrently, granules from the two main classes (azurophil and specific) fuse and release their contents into the phagolysosome. The concentration of toxic oxygen metabolites (eg, hydrogen peroxide, hypochlorous acid, hydroxyl radical) and other compounds (eg, proteases, cationic proteins, cathepsins, defensins) increases dramatically, resulting in the death and dissolution of the microbe. Complex physiologic and biochemical processes support and control these functions. Defects in any of these processes may lead to inadequate cell function and an increased risk of infection.

► Classification

Table 28–6 summarizes congenital neutrophil function defects. Recently described is a syndrome of severe neutrophil dysfunction and severe infections associated with a mutation in a GTPase signaling molecule, Rac2. New syndromes of innate immune dysfunction include defects in interferon and interleukin-12 receptor and signaling pathways, leading to monocyte and macrophage dysfunction and toll-like receptor signaling pathways (interleukin-1 receptor-associated [IRAK] deficiency) associated with recurrent bacterial infections. Other congenital or acquired causes of mild to moderate neutrophil dysfunction include metabolic defects (eg, glycogen storage disease, diabetes mellitus, renal disease, and hypophosphatemia), viral infections, and certain drugs. Neutrophils from newborn infants have abnormal adherence, chemotaxis, and bactericidal activity. Cells from patients with thermal injury, trauma, and overwhelming infection have defects in cell motility and bactericidal activity similar to those seen in neonates.

► Clinical Findings

Recurrent bacterial or fungal infections are the hallmark of neutrophil dysfunction. Although many patients will have infection-free periods, episodes of pneumonia, sinusitis, cellulitis, cutaneous and mucosal infections (including perianal or peritonsillar abscesses), and lymphadenitis are frequent. As with neutropenia, aphthous ulcers of mucous membranes, severe gingivitis, and periodontal disease are also major complications. In general, *S aureus* or gram-negative organisms are commonly isolated from infected sites; other organisms may be specifically associated with a defined neutrophil function defect. In some disorders, fungi account

for an increasing number of infections. Deep or generalized infections, such as osteomyelitis, liver abscesses, sepsis, meningitis, and necrotic or gangrenous soft-tissue lesions, occur in specific syndromes (eg, leukocyte adherence deficiency or chronic granulomatous disease). Patients with severe neutrophil dysfunction may die in childhood from severe infections or associated complications. Table 28–6 summarizes pertinent laboratory findings.

► Treatment

The mainstays of management of these disorders are anticipation of infections and aggressive attempts to identify the foci and the causative agents. Surgical procedures to achieve these goals may be both diagnostic and therapeutic. Broad-spectrum antibiotics covering the range of possible organisms should be initiated without delay, switching to specific antimicrobial agents when the microbiologic diagnosis is made. When infections are unresponsive or they recur, granulocyte transfusions may be helpful.

Chronic management includes prophylactic antibiotics. Trimethoprim–sulfamethoxazole and some other antibiotics enhance the bactericidal activity of neutrophils from patients with chronic granulomatous disease. Some patients with Chédiak-Higashi syndrome improve clinically when given ascorbic acid. Recombinant γ -interferon decreases the number and severity of infections in patients with chronic granulomatous disease. Demonstration of this activity with one patient group raises the possibility that cytokines, growth factors, and other biologic response modifiers may be helpful in other conditions in preventing recurrent infections. Bone marrow transplantation has been attempted in most major congenital neutrophil dysfunction syndromes, and reconstitution with normal cells and cell function has been documented. Combining genetic engineering with autologous bone marrow transplantation may provide a future strategy for curing these disorders.

► Prognosis

For mild to moderate defects, anticipation and conservative medical management ensure a reasonable outlook. For severe defects, excessive morbidity and significant mortality exist. In some diseases, the development of noninfectious complications, such as the lymphoproliferative phase of Chédiak-Higashi syndrome or inflammatory syndromes in chronic granulomatous disease, may influence prognosis.

Table 28-6. Classification of congenital neutrophil function deficits.

Disorder	Clinical Manifestations	Functional Defect	Biochemical Defect	Inheritance (Chromosome; Gene)
Chédiak-Higashi syndrome	Oculocutaneous albinism, photophobia, nystagmus, ataxia. Recurrent infections of skin, respiratory tract, and mucous membranes with gram-positive and gram-negative organisms. Many patients die during lymphoproliferative phase with hepatomegaly, fever. This may be a viral-associated hemophagocytic syndrome secondary to Epstein-Barr virus infection. Older patients may develop degenerative CNS disease.	Neutropenia. Neutrophils, monocytes, lymphocytes, platelets, and all granule-containing cells have giant granules. Most significant defect is in chemotaxis. Also milder defects in microbicidal activity and degranulation.	Gene deficit identified. Alterations in membrane fusion with formation of giant granules. Other biochemical abnormalities in cAMP and cGMP, microtubule assembly.	Autosomal recessive (1q42.1-.2; <i>CHS1</i>)
Leukocyte adherence deficiency I	Recurrent soft-tissue infections, including gingivitis, otitis, mucositis, periodontitis, skin infections. Delayed separation of the cord in newborn and problems with wound healing.	Neutrophilia. Diminished adherence to surfaces, leading to decreased chemotaxis.	Absence or partial deficiency of CD11/CD18 cell surface adhesive glycoproteins.	Autosomal recessive (12q22.3; <i>ITGB2</i>)
Leukocyte adherence deficiency II	Recurrent infections, mental retardation, craniofacial abnormalities, short stature.	Neutrophilia. Deficient “rolling” interactions with endothelial cells. Red cells have Bombay phenotype.	Deficient fucosyl transferase results in deficient sialyl Lewis X antigen, which interacts with P selectin on endothelial cell to establish neutrophil rolling, a prerequisite for adherence and diapedesis.	Autosomal recessive (11p11.2; <i>SLC35C1</i>)
Chronic granulomatous disease	Recurrent purulent infections with catalase-positive bacteria and fungi. May involve skin, mucous membranes. Patients also develop deep infections (lymph nodes, lung, liver, bones) and sepsis.	Neutrophilia. Neutrophils demonstrate deficient bactericidal activity but normal chemotaxis and ingestion. Defect in the oxidase enzyme system, resulting in absence or diminished production of oxygen metabolites toxic to microbes.	Several molecular defects in oxidase components. Absent cytochrome b_{558} with decreased expression of either (1) or (2): (1) gp91-phox (2) p22-phox Absent p47-phox or p67-phox (cytosolic components).	X-linked in 60–65% of cases (Xp21.1; <i>CYBB</i>) Autosomal recessive in < 5% of cases (16q24; <i>CYBA</i>) Autosomal recessive in 30% of cases (7q11.23; <i>NCF1</i> and 1q25; <i>NCF2</i> , respectively)
Myeloperoxidase deficiency	Generally healthy. Fungal infections when deficiency associated with systemic diseases (eg, diabetes).	Diminished capacity to enhance hydrogen peroxide-mediated microbicidal activity.	Diminished or absent myeloperoxidase; post-translational defect in processing protein.	Autosomal recessive (17q22-23)
Specific granule deficiency	Recurrent skin and deep tissue infections.	Decreased chemotaxis and bactericidal activity.	Failure to produce specific granules or their contents during myelopoiesis. Defect in transcription factor.	Autosomal recessive (14q11.2; <i>CEBPE</i>)

cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; CNS, central nervous system.

LYMPHOCYTOSIS

From the first week up to the fifth year of life, lymphocytes are the most numerous leukocytes in human blood. The ratio then reverses gradually to reach the adult pattern of neutrophil predominance. An absolute lymphocytosis in childhood is associated with acute or chronic viral infections, pertussis, syphilis, tuberculosis, and hyperthyroidism. Other noninfectious conditions, drugs, and hypersensitivity and serum sickness–like reactions cause lymphocytosis.

Fever, upper respiratory symptoms, gastrointestinal complaints, and rashes are clues in distinguishing infectious from noninfectious causes. The presence of enlarged liver, spleen, or lymph nodes is crucial to the differential diagnosis, which includes acute leukemia and lymphoma. Most cases of infectious mononucleosis are associated with hepatosplenomegaly or adenopathy. The absence of anemia and thrombocytopenia helps to differentiate these disorders. Evaluation of the morphology of lymphocytes on peripheral blood smear is crucial. Infectious causes, particularly infectious mononucleosis, are associated with atypical features in the lymphocytes such as basophilic cytoplasm, vacuoles, finer and less-dense chromatin, and an indented nucleus. These features are distinct from the characteristic morphology associated with lymphoblastic leukemia. Lymphocytosis in childhood is most commonly associated with infections and resolves with recovery from the primary disease.

EOSINOPHILIA

Eosinophilia in infants and children is an absolute eosinophil count greater than $300/\mu\text{L}$. Marrow eosinophil production is stimulated by the cytokine interleukin-5. Allergies, particularly eczema, are the most common primary causes of eosinophilia in children. Eosinophilia also occurs in drug reactions, with tumors (Hodgkin and non-Hodgkin lymphomas and brain tumors), and with immunodeficiency and histiocytosis syndromes. Increased eosinophil counts are a prominent feature of many invasive parasitic infections. Gastrointestinal disorders such as chronic hepatitis, ulcerative colitis, Crohn disease, and milk precipitin disease may be associated with eosinophilia. Increased blood eosinophil counts have been identified in several families without association with any specific illness. Rare causes of eosinophilia include the hypereosinophilic syndrome, characterized by counts greater than $1500/\mu\text{L}$ and organ involvement and damage (hepatosplenomegaly, cardiomyopathy, pulmonary fibrosis, and central nervous system injury). This is a disorder of middle-aged adults and is rare in children. Eosinophilic leukemia has been described, but its existence as a distinct entity is controversial.

Eosinophils are sometimes the last type of mature myeloid cell to disappear after marrow ablative chemotherapy. Increased eosinophil counts are associated with graft-versus-host disease after bone marrow transplantation, and eleva-

tions are sometimes documented during rejection episodes in patients who have solid organ grafts.

BLEEDING DISORDERS

Bleeding disorders may occur as a result of (1) quantitative or qualitative abnormalities of platelets, (2) quantitative or qualitative abnormalities in plasma procoagulant factors, (3) vascular abnormalities, or (4) accelerated fibrinolysis. The coagulation cascade and fibrinolytic system are shown in Figures 28–4 and 28–5.

The most critical aspect in evaluating the bleeding patient is obtaining detailed personal and family bleeding histories, including bleeding complications associated with dental interventions, surgeries, suture placement and removal, and trauma. Excessive mucosal bleeding is suggestive of a platelet disorder, von Willebrand disease, dysfibrinogenemia, or vasculitis. Bleeding into muscles and joints may be associated with a plasma procoagulant factor abnormality. In either scenario, the abnormality may be congenital or acquired. A thorough physical examination should be performed with

▲ **Figure 28-4.** The procoagulant system and formation of a fibrin clot. Vascular injury initiates the coagulation process by exposure of tissue factor (TF); the dashed lines indicate thrombin actions in addition to clotting of fibrinogen. special attention to the skin, oro- and nasopharynx, liver, spleen, and joints. Screening and diagnostic evaluation in patients with suspected bleeding disorders should initially include the following laboratory testing:

1. Prothrombin time (PT) to assess clotting function of factors VII, X, V, II, and fibrinogen.
2. Activated partial thromboplastin time (aPTT) to assess clotting function of high molecular weight kininogen, prekallikrein, XII, XI, IX, VIII, X, V, II, and fibrinogen.
3. Platelet count and size determined as part of a CBC.
4. Platelet functional assessment by platelet function analyzer-100 (PFA-100), or template bleeding time.
5. Fibrinogen functional level by clotting assay.

The following laboratory tests may also be useful:

1. Thrombin time to measure the generation of fibrin from fibrinogen following conversion of prothrombin to thrombin, as well as the antithrombin effects of fibrin-split products and heparin. The thrombin time may be prolonged in the setting of a normal fibrinogen concentration if the fibrinogen is dysfunctional (ie, dysfibrinogenemia).
2. Euglobulin lysis time (ELT), if available, to evaluate for accelerated fibrinolysis if the preceding workup is non-revealing despite documented history of pathologic bleeding. If the ELT is shortened, assessment of plasminogen activator inhibitor-1 and α_2 -antiplasmin is warranted, as congenital deficiency in these fibrinolytic inhibitors may cause hyperfibrinolysis. In ill patients, measurement of fibrin degradation products may assist in the diagnosis of DIC.

ABNORMALITIES OF PLATELET NUMBER OR FUNCTION

Thrombocytopenia in the pediatric age range is often immune-mediated (eg, idiopathic thrombocytopenic purpura, neonatal auto- or alloimmune thrombocytopenia, heparin-induced thrombocytopenia), but is also caused by consumptive coagulopathy (eg, DIC, Kasabach-Merritt syndrome), acute leukemias, rare disorders such as Wiskott-Aldrich syndrome and type IIb von Willebrand disease, and artifactually in automated cytometers (eg, Bernard-Soulier syndrome), where giant forms may not be enumerated as platelets by automated cell counters.

1. Idiopathic Thrombocytopenic Purpura

- ▶ Otherwise healthy child.
- ▶ Decreased platelet count.
- ▶ Petechiae, ecchymoses.

▶ General Considerations

Acute idiopathic thrombocytopenic purpura (ITP) is the most common bleeding disorder of childhood. It occurs most frequently in children aged 2–5 years and often follows infection with viruses, such as rubella, varicella, measles, parvovirus, influenza, or EBV. Most patients recover spontaneously within a few months. Chronic ITP (> 6 months' duration) occurs in 10–20% of affected patients. The thrombocytopenia results from clearance of circulating IgM- or IgG-coated platelets by the reticuloendothelial system. The spleen plays a predominant role in the disease by forming the platelet cross-reactive antibodies and sequestering the antibody-bound platelets.

▶ Clinical Findings

A. Symptoms and Signs

Onset of ITP is usually acute, with the appearance of multiple petechiae and ecchymoses. Epistaxis is also common at presentation. No other physical findings are usually present. Rarely, concurrent infection with EBV or CMV may cause hepatosplenomegaly or lymphadenopathy, simulating acute leukemia.

B. Laboratory Findings

1. Blood—The platelet count is markedly reduced (usually < 50,000/ μ L and often < 10,000/ μ L), and platelets frequently are of larger size on peripheral blood smear, suggesting accel-

Table 28-7. Common causes of thrombocytopenia.

Increased Turnover			Decreased Production	
Antibody-Mediated	Coagulopathy	Other	Congenital	Acquired
Idiopathic thrombocytopenic purpura	Disseminated intravascular coagulopathy	Hemolytic-uremic syndrome	Fanconi anemia	Aplastic anemia
Infection	Sepsis	Thrombotic thrombocytopenic purpura	Wiskott-Aldrich syndrome	Leukemia and other malignancies
Immunologic diseases	Necrotizing enterocolitis Thrombosis Cavernous hemangioma	Hypersplenism Respiratory distress syndrome Wiskott-Aldrich syndrome	Thrombocytopenia with absent radii Metabolic disorders Osteopetrosis	Vitamin B ₁₂ and folate deficiencies

erated production of new platelets. The white blood count and differential are normal, and the hemoglobin concentration is preserved unless hemorrhage has been significant.

2. Bone marrow—The number of megakaryocytes is increased. Erythroid and myeloid cellularity is normal.

3. Other laboratory tests—Platelet-associated IgG or IgM, or both, may be demonstrated on the patient's platelets or in the serum. PT and aPTT are normal.

► Differential Diagnosis

Table 28-7 lists common causes of thrombocytopenia. ITP is a diagnosis of exclusion. Family history or the finding of predominantly giant platelets on the peripheral blood smear is helpful in determining whether thrombocytopenia is hereditary. Bone marrow examination should be performed if the history is atypical (ie, the child is not otherwise healthy, or if there is a family history of bleeding), if abnormalities other than purpura and petechiae are present on physical examination, or if other cell lines are affected on the CBC. The importance of performing a bone marrow examination prior to using corticosteroids in the treatment for ITP is controversial.

► Complications

Severe hemorrhage and bleeding into vital organs are the feared complications of ITP. Intracranial hemorrhage is the most serious (but rarely seen) complication, occurring in less than 1% of affected children. The most important risk factors for hemorrhage are a platelet count less than 10,000/ μ L and mean platelet volume less than 8 fL.

► Treatment

A. General Measures

Treatment is optional in most children in the absence of bleeding. Aspirin and other medications that compromise platelet function should be avoided. Bleeding precautions (eg, restriction from physical contact activities, use of helmets, etc)

should be observed. Platelet transfusion should be avoided except in circumstances of life-threatening bleeding, in which case emergent splenectomy is to be pursued. In this setting, administration of corticosteroids and IVIG is also advisable.

B. Corticosteroids

Patients with clinically significant but non-life-threatening bleeding (ie, epistaxis, hematuria, and hematochezia) and those with a platelet count of less than 10,000/ μ L may benefit from prednisone at 2–4 mg/kg orally per day for 3–5 days, decreasing to 1–2 mg/kg/d for a total of 14 days. The dosage is then tapered and stopped. No further prednisone is given regardless of the platelet count unless significant bleeding recurs, at which time prednisone is administered in the smallest dose that achieves resolution of bleeding episodes (usually 2.5–5 mg twice daily). Follow-up continues until the steroid can again be discontinued, spontaneous remission occurs, or other therapeutic measures are instituted.

C. Intravenous Immunoglobulin (IVIG)

IVIG is the treatment of choice for severe, acute bleeding, and may also be used as an alternative or adjunct to corticosteroid treatment in both acute and chronic ITP of childhood. IVIG may be effective even when the patient is resistant to corticosteroids; responses are prompt and may last for several weeks. Most patients receive 1 g/kg/d for 1–3 days. Infusion time is typically 4–6 hours. Platelets may be given simultaneously during life-threatening hemorrhage but are rapidly destroyed. Adverse effects of IVIG are common, including transient neurologic complications (eg, headache, nausea, and aseptic meningitis) in one third of patients. These symptoms may mimic those of intracranial hemorrhage and necessitate radiologic evaluation of the brain. A transient decrease in neutrophil number may also be seen.

D. Anti-Rho(D) Immunoglobulin

This polyclonal immunoglobulin binds to the D antigen on red blood cells. The splenic clearance of anti-D-coated

red cells interferes with removal of antibody-coated platelets, resulting in improvement in thrombocytopenia. This approach is effective only in Rh(+) patients with a functional spleen. The time required for platelet increase is slightly longer than with IVIG. However, approximately 80% of Rh(+) children with acute or chronic ITP respond well. Significant hemolysis may occur transiently with an average hemoglobin concentration decrease of 0.8 g/dL. However, severe hemolysis occurs in 5% of treated children, and clinical and laboratory evaluation approximately 5 days following administration is warranted in all patients. Rho(D) immunoglobulin is less expensive and infused more rapidly than IVIG, but is more expensive than corticosteroids.

E. Splenectomy

Most children with chronic ITP have platelet counts greater than 30,000/ μ L. Up to 70% of such children spontaneously recover with a platelet count greater than 100,000/ μ L within 1 year. For the remainder, corticosteroids, IVIG, and anti-D immunoglobulin are typically effective treatment for acute bleeding. Splenectomy produces a response in 70–90%, but it should be considered only after persistence of significant thrombocytopenia for at least 1 year. Preoperative treatment with corticosteroids, IVIG, or anti-D immunoglobulin is usually indicated. Postoperatively, the platelet count may rise to 1 million/ μ L, but is not often associated with thrombotic complications in the pediatric age group. The risk of overwhelming infection (predominantly with encapsulated organisms) is increased after splenectomy, particularly in the young child. Therefore, the procedure should be postponed, if possible, until age 5 years. Administration of pneumococcal and *H influenzae* type b vaccines at least 2 weeks prior to splenectomy is recommended. Meningococcal vaccine, although controversial, may be considered. Penicillin prophylaxis should be started postoperatively and continued for 1–3 years.

F. Rituximab (Anti-CD20 Monoclonal Antibody)

The efficacy of treating childhood chronic ITP in several series and a phase I/II trial has been demonstrated; remission was observed in 40%. Because of significant adverse events, this therapy may be reserved for refractory cases with significant bleeding.

► Prognosis

Ninety percent of children with ITP will have a spontaneous remission. Features associated with the development of chronic ITP include female gender, age greater than 10 years at presentation, insidious onset of bruising, and the presence of other autoantibodies. Older child- and adolescent-onset ITP is associated with an increased risk of chronic autoimmune diseases. Appropriate screening by history and laboratory studies (eg, antinuclear antibody) is warranted.

2. Thrombocytopenia in the Newborn

Thrombocytopenia is one of the most common causes of neonatal hemorrhage and should be considered in any newborn with petechiae, purpura, or other significant bleeding. Defined as a platelet count less than 150,000/ μ L, thrombocytopenia occurs in approximately 0.9% of unselected neonates. Several specific entities may be responsible (see Table 28–7); however, half of such neonates have alloimmune thrombocytopenia. Infection and DIC are the most common causes of thrombocytopenia in ill full-term newborns and in preterm newborns. In the healthy neonate, antibody-mediated thrombocytopenia (alloimmune or maternal autoimmune), viral syndromes, hyperviscosity, and major-vessel thrombosis are frequent causes of thrombocytopenia. Management is directed toward the underlying etiology.

A. Thrombocytopenia Associated with Platelet Alloantibodies (Neonatal Alloimmune Thrombocytopenia)

Platelet alloimmunization occurs in 1 in approximately 350 pregnancies. Unlike in Rh incompatibility, 30–40% of affected neonates are first-born. Thrombocytopenia is progressive over the course of gestation and worse with each subsequent pregnancy. Alloimmunization occurs when a platelet antigen of the infant differs from that of the mother and the mother is sensitized by fetal platelets that cross the placenta into the maternal circulation. In Caucasians, alloimmune thrombocytopenia is most often due to human platelet antigen (HPA)-1a incompatibility. Sensitization of a mother homozygous for HPA-1b to paternally acquired fetal HPA-1a antigen results in severe fetal thrombocytopenia in 1 in 1200 fetuses. Only 1 in 20 HPA-1a–positive fetuses of HPA-1a–negative mothers develop alloimmunization. The presence of antenatal maternal platelet antibodies on more than one occasion and their persistence into the third trimester is predictive of severe neonatal thrombocytopenia; a weak or undetectable antibody does not exclude thrombocytopenia. Severe intracranial hemorrhage occurs in 10–30% of affected neonates as early as 20 weeks' gestation. Petechiae or other bleeding manifestations are usually present shortly after birth. The disease is self-limited, and the platelet count normalizes within 4 weeks.

If alloimmunization is associated with clinically significant bleeding, transfusion of platelet concentrates harvested

from the mother is more effective than random donor platelets in increasing the platelet count. Transfusion with HPA-matched platelets from unrelated donors or treatment with IVIG or methylprednisolone has also been successful in raising the platelet count and achieving hemostasis. If thrombocytopenia is not severe and bleeding is absent, observation alone is often appropriate.

Intracranial hemorrhage in a previous child secondary to alloimmune thrombocytopenia is the strongest risk factor for severe fetal thrombocytopenia and hemorrhage in a subsequent pregnancy. Amniocentesis or chorionic villus sampling to obtain fetal DNA for platelet antigen typing is sometimes performed if the father is heterozygous for HPA-1a. If alloimmunization has occurred with a previous pregnancy, irrespective of history of intracranial hemorrhage, screening cranial ultrasound for hemorrhage should begin at 20 weeks' gestation and be repeated regularly. In addition, cordocentesis should be performed at approximately 20 weeks' gestation, with prophylactic transfusion of irradiated, leukoreduced, maternal platelet concentrates. If the fetal platelet count is less than 100,000/ μ L, the mother should be treated with weekly IVIG. Delivery by elective cesarean section is recommended if the fetal platelet count is less than 50,000/ μ L, to minimize the risk of intracranial hemorrhage associated with birth trauma.

B. Thrombocytopenia Associated with Idiopathic Thrombocytopenic Purpura in the Mother (Neonatal Autoimmune Thrombocytopenia)

Infants born to mothers with ITP or other autoimmune diseases (eg, antiphospholipid antibody syndrome or systemic lupus erythematosus) may develop thrombocytopenia as a result of transfer of antiplatelet IgG from the mother to the infant. Unfortunately, maternal and fetal platelet counts and maternal antiplatelet antibody levels are unreliable predictors of bleeding risk. Antenatal corticosteroid administration to the mother is generally instituted once maternal platelet count falls below 50,000/ μ L, with or without a concomitant course of IVIG.

Most neonates with neonatal autoimmune thrombocytopenia do not develop clinically significant bleeding, and thus treatment for thrombocytopenia is not often required. The risk of intracranial hemorrhage is 0.2–2%. If diffuse petechiae or minor bleeding are evident, a 1- to 2-week course of oral prednisone, 2 mg/kg/d, may be administered. If the platelet count remains consistently less than 20,000/ μ L or if severe hemorrhage develops, IVIG should be given (1 g/kg daily for 1–3 days). Platelet transfusions are only indicated for life-threatening bleeding, and may only be effective after removal of antibody by exchange transfusion. The platelet nadir is typically between the fourth to sixth day of life and improves significantly by 1 month; full recovery may take 2–4 months. Platelet recovery may be delayed in breast-fed infants because of transfer of IgG to the milk.

C. Neonatal Thrombocytopenia Associated with Infections

Thrombocytopenia is commonly associated with severe generalized infections during the newborn period. Between 50% and 75% of neonates with bacterial sepsis are thrombocytopenic. Intrauterine infections such as rubella, syphilis, toxoplasmosis, CMV, herpes simplex, enteroviruses, and parvovirus are often associated with thrombocytopenia. In addition to specific treatment for the underlying disease, platelet transfusions may be indicated in severe cases.

D. Thrombocytopenia Associated with Kaposiform Hemangioendotheliomas (Kasabach-Merritt Syndrome)

A rare but important cause of thrombocytopenia in the newborn is kaposiform hemangioendotheliomas, a benign neoplasm with histopathology distinct from that of classic infantile hemangiomas. Intense platelet sequestration in the lesion results in peripheral thrombocytopenia and may rarely be associated with a DIC-like picture and hemolytic anemia. The bone marrow typically shows megakaryocytic hyperplasia in response to the thrombocytopenia. Corticosteroids, α -interferon, and vincristine are all useful for reducing the size of the lesion and are indicated if significant coagulopathy is present, the lesion compresses a vital structure, or the lesion is cosmetically unacceptable. If consumptive coagulopathy is present, heparin or aminocaproic acid may be useful. Depending on the site, embolization may be an option. Surgery is often avoided because of the high risk of hemorrhage.

Kaplan RN: Differential diagnosis and management of thrombocytopenia in childhood. *Pediatr Clin North Am* 2004;51:1109 [PMID: 15275991].

3. Disorders of Platelet Function

Individuals with platelet function defects typically develop skin and mucosal bleeding similar to that occurring in persons with thrombocytopenia. Historically, platelet function has been screened by measuring the bleeding time. If this is prolonged, in-vitro platelet aggregation is studied using agonists, such as adenosine diphosphate, collagen, arachidonic acid, and ristocetin, and simultaneous comparison with a normal control subject. While labor-intensive, platelet aggregometry remains important in selected clinical situations. The PFA-100 has become available to evaluate platelet dysfunction and von Willebrand disease, and has replaced the template bleeding time in many clinical laboratories. Unfortunately, none of these tests of platelet function is uniformly predictive of clinical bleeding severity.

Platelet dysfunction may be inherited or acquired, with the latter being more common. Acquired disorders of plate-

let function may occur secondary to uremia, cirrhosis, sepsis, myeloproliferative disorders, congenital heart disease, and viral infections. Many pharmacologic agents decrease platelet function. The most common offending agents in the pediatric population are aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), synthetic penicillins, and valproic acid. In acquired platelet dysfunction, the PFA-100 closure time is typically prolonged with collagen-epinephrine, but normal with collagen-ADP.

The inherited disorders are due to defects in platelet-vessel interaction, platelet-platelet interaction, platelet granule content or release (including defects of signal transduction), thromboxane and arachidonic acid pathway, and platelet-procoagulant protein interaction. Individuals with hereditary platelet dysfunction generally have a prolonged bleeding time with normal platelet number and morphology by light microscopy. PFA-100 closure time, in contrast to that in acquired dysfunction, is typically prolonged with both collagen-ADP and collagen-epinephrine.

Congenital causes of defective platelet-vessel wall interaction include Bernard-Soulier syndrome. This condition is characterized by increased platelet size and decreased platelet number. The molecular defect in this autosomal recessive disorder is a deficiency or dysfunction of glycoprotein Ib-V-IX complex on the platelet surface resulting in impaired von Willebrand factor (vWF) binding, and hence, impaired platelet adhesion to the vascular endothelium.

Glanzmann thrombasthenia is an example of platelet-platelet dysfunction. In this autosomal recessive disorder, glycoprotein IIb-IIIa is deficient or dysfunctional. Platelets do not bind fibrinogen effectively and exhibit impaired aggregation. As in Bernard-Soulier syndrome, acute bleeding is treated by platelet transfusion.

Disorders involving platelet granule content include storage pool disease and Quebec platelet disorder. In individuals with storage pool disease, platelet-dense granules lack adenosine dinucleotide phosphate and adenosine trinucleotide phosphate and are often found to be low in number by electron microscopy. These granules are also deficient in Hermansky-Pudlak, Chédiak-Higashi, and Wiskott-Aldrich syndromes. Whereas deficiency of α -granules results in the gray platelet syndrome, Quebec platelet disorder is characterized by a normal platelet α -granule number, but with abnormal proteolysis of α -granule proteins and deficiency of platelet α -granule multimerin. Epinephrine-induced platelet aggregation is markedly impaired.

Platelet dysfunction has also been observed in other congenital syndromes, such as Down and Noonan syndromes, without a clear understanding of the molecular defect.

► Treatment

Acute bleeding in many individuals with acquired or selected congenital platelet function defects responds to therapy with desmopressin acetate, likely due to an induced release of vWF from endothelial stores. If this therapy is

ineffective, or if the patient has Bernard-Soulier syndrome or Glanzmann syndrome, the mainstay of treatment for bleeding episodes is platelet transfusion. Recombinant VIIa has variable efficacy and may be helpful in platelet transfusion-refractory patients.

Drachman JG: Inherited thrombocytopenia: When a low platelet count does not mean ITP. *Blood* 2004;103:390 [PMID: 14505084].

Sohal AS: Uremic bleeding: Pathophysiology and clinical risk factors. *Thromb Res* 2006;118:417 [PMID: 15993929].

INHERITED BLEEDING DISORDERS

Table 28–8 lists normal values for coagulation factors. The more common factor deficiencies are discussed in this section. Individuals with bleeding disorders should avoid exposure to medications that inhibit platelet function. Participation in contact sports should be considered in the context of the severity of the bleeding disorder.

1. Factor VIII Deficiency (Hemophilia A, Classic Hemophilia)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Bruising, soft-tissue bleeding, hemarthrosis.
- Prolonged activated partial thromboplastin time (aPTT).
- Reduced factor VIII activity.

► General Considerations

Factor VIII activity is reported in units per milliliter, with 1 U/mL equal to 100% of the factor activity found in 1 mL of normal plasma. The normal range for factor VIII activity is 0.5–1.5 U/mL (50–150%). Hemophilia A occurs predominantly in males as an X-linked disorder. One third of cases are due to a new mutation. The incidence of factor VIII deficiency is 1:5000 male births.

► Clinical Findings

A. Symptoms and Signs

Patients with severe hemophilia A (< 1% plasma factor VIII activity) have frequent spontaneous bleeding episodes involving skin, mucous membranes, joints, muscles, and viscera. In contrast, patients with mild hemophilia A (5–40% factor VIII activity) bleed only at times of trauma or surgery. Those with moderate hemophilia A (1% to < 5% factor VIII activity) typically have intermediate bleeding manifestations. The most crippling aspect of factor VIII deficiency is the tendency to develop recurrent hemarthroses that incite joint destruction.

Table 28-8. Physiologic alterations in measurements of the hemostatic system.

Measurement	Normal Adults	Fetus (20 wk)	Preterm (25-32 wk)	Term Infant	Infant (6 mo)	Pregnancy (term)	Exercise (acute)	Aging (70-80 y)

B. Laboratory Findings

Individuals with hemophilia A have a prolonged aPTT, except in some cases of mild deficiency. The prothrombin time (PT) is normal. The diagnosis is confirmed by finding decreased factor VIII activity with normal vWF activity. In two thirds of families of hemophilic patients, the females are carriers and some are mildly symptomatic. Carriers of hemophilia can be detected by determination of the ratio of factor VIII activity to vWF antigen and by molecular genetic techniques. In a male fetus or newborn with a family history of hemophilia A, cord blood sampling for factor VIII activity is accurate and important in subsequent care.

► Complications

Intracranial hemorrhage is the leading disease-related cause of death among patients with hemophilia. Most intracranial hemorrhages in moderate to severe deficiency are spontaneous (ie, not associated with trauma). Hemarthroses begin early in childhood and, if recurrent, result in joint destruction (ie, hemophilic arthropathy). Large intramuscular hematomas can lead to a compartment syndrome with resultant muscle and nerve death. Although these complications are most common in severe hemophilia A, they may be experienced by individuals with moderate or mild disease. A serious complication of hemophilia is the development of an acquired circulating antibody to factor VIII after treatment with factor VIII concentrate. Such factor VIII inhibitors develop in 15–25% of patients with severe hemophilia A, and may be amenable to desensitization with regular factor VIII infusion with or without immunosuppressive therapy. In recent years, recombinant factor VIIa has become a therapy of choice for treatment of acute hemorrhage in patients with hemophilia A and a high-titer inhibitor.

In prior decades, therapy-related complications in hemophilia A have included infection with the human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV). Through more stringent donor selection, the implementation of sensitive screening assays, the use of heat- or chemical viral inactivation methods, and the development of recombinant products, the risk of these infections is minimal. Inactivation methods do not eradicate viruses lacking a lipid envelope, however, so that transmission of parvovirus and hepatitis A remains a concern with the use of plasma-derived products. Immunization with hepatitis A and hepatitis B vaccines is recommended for all hemophilia patients.

► Treatment

The general aim of management is to raise the factor VIII activity to prevent or stop bleeding. Some patients with mild factor VIII deficiency may respond to desmopressin via release of endothelial stores of factor VIII and vWF into plasma; however, most patients require administration of exogenous factor VIII to achieve hemostasis. The in-vivo half-life of factor VIII is generally 8–12 hours but may

exhibit considerable variation among individuals depending on comorbid conditions. Non-life-threatening, non-limb-threatening hemorrhage is treated initially with 20–30 U/kg of factor VIII, to achieve a rise in plasma factor VIII activity to 40–60%. Large joint hemarthrosis and life- or limb-threatening hemorrhage is treated initially with approximately 50 U/kg of factor VIII, targeting a rise to 100% factor VIII activity. Subsequent doses are determined according to the site and extent of bleeding and the clinical response. Doses are rounded to the nearest whole vial size. In circumstances of suboptimal clinical response, recent change in bleeding frequency, or comorbid illness, monitoring the plasma factor VIII activity response may be warranted. For most instances of non-life-threatening hemorrhage in experienced patients with moderate or severe hemophilia A, treatment can be administered at home, provided adequate intravenous access exists and close contact is maintained with the hemophilia clinician team.

Prophylactic factor VIII infusions (eg, two or three times weekly) may prevent the development of arthropathy in severe hemophiliacs, and this approach is becoming more common in pediatric hemophilia care.

► Prognosis

The development of safe and effective therapies for hemophilia A has resulted in improved long-term survival in recent decades. In addition, more aggressive management and the coordination of comprehensive care through hemophilia centers have greatly improved quality of life and level of function.

Manco-Johnson MJ: Prophylaxis versus episodic treatment to prevent joint disease in boys with severe hemophilia. *N Engl J Med* 2007;357:535 [PMID: 17687129].

2. Factor IX Deficiency (Hemophilia B, Christmas Disease)

The mode of inheritance and clinical manifestations of factor IX deficiency are the same as those of factor VIII deficiency. Hemophilia B is 15–20% as prevalent as hemophilia A. As in factor VIII deficiency, factor IX deficiency is associated with a prolonged aPTT, but the PT and thrombin time are normal. However, the aPTT is slightly less sensitive to factor IX deficiency than factor VIII deficiency. Diagnosis of hemophilia B is made by assaying factor IX activity, and severity is determined similarly to factor VIII deficiency. In general, clinical bleeding severity correlates less well with factor activity in hemophilia B than in hemophilia A.

The mainstay of treatment in hemophilia B is exogenous factor IX. Unlike factor VIII, about 50% of the administered dose of factor IX diffuses into the extravascular space. Therefore, 1 U/kg of plasma-derived factor IX concentrate or

recombinant factor IX is expected to increase plasma factor IX activity by approximately 1%. Factor IX typically has a half-life of 20–22 hours in vivo, but due to variability, therapeutic monitoring may be warranted. As for factor VIII products, viral inactivation techniques for plasma-derived factor IX concentrates appear effective in eradicating HIV, HBV, and HCV. Only 1–3% of persons with factor IX deficiency develop an inhibitor to factor IX, but patients may be at risk for anaphylaxis when receiving exogenous factor IX. The prognosis for persons with factor IX deficiency is comparable to that of patients with factor VIII deficiency. Gene therapy research efforts are ongoing for both hemophilias.

 Shapiro AD: The safety and efficacy of recombinant human blood coagulation factor IX in previously untreated patients with severe or moderately severe hemophilia B. *Blood* 2005;105:518 [PMID: 15383463].

3. Factor XI Deficiency (Hemophilia C)

Factor XI deficiency is a genetic, autosomally transmitted coagulopathy, typically of mild to moderate clinical severity. Cases of factor XI deficiency account for less than 5% of all hemophilia patients. Homozygotes generally bleed at surgery or following severe trauma, but do not commonly have spontaneous hemarthroses. In contrast to factor VIII and IX deficiencies, factor XI activity is least predictive of bleeding risk. Although typically mild, pathologic bleeding may be seen in heterozygous individuals with factor XI activity as high as 60%. The aPTT is often considerably prolonged. In individuals with deficiency of both plasma and platelet-associated factor XI, the PFA-100 may also be prolonged. Management typically consists of perioperative prophylaxis and episodic therapy for acute hemorrhage. Treatment includes infusion of fresh frozen plasma (FFP); platelet transfusion may also be useful for acute hemorrhage in patients with deficiency of platelet-associated factor XI. Desmopressin has been used in some cases. The prognosis for an average life span in patients with factor XI deficiency is excellent.

Salomon O: New observations on factor XI deficiency. *Haemophilia* 2004;10:184 [PMID: 15479396].

4. Other Inherited Bleeding Disorders

Other hereditary single clotting factor deficiencies are rare. Transmission is generally autosomal. Homozygous individuals with a deficiency or structural abnormality of prothrombin, factor V, factor VII, or factor X may have excessive bleeding.

Persons with dysfibrinogenemia (ie, structurally or functionally abnormal fibrinogen) may develop recurrent venous thromboembolic episodes or bleeding. Immunologic assay

of fibrinogen is normal, but clotting assay may be low and the thrombin time prolonged. The PT and aPTT may be prolonged. Cryoprecipitate, which is rich in fibrinogen, is the treatment of choice, given the present lack of availability of a plasma-derived or recombinant fibrinogen product in the United States.

Afibrinogenemia resembles hemophilia clinically but has an autosomal recessive inheritance. Affected patients can experience a variety of bleeding manifestations, including mucosal bleeding, ecchymoses, hematomas, hemarthroses, and intracranial hemorrhage, especially following trauma. Fatal umbilical cord hemorrhage has been reported in neonates. The PT, aPTT, and thrombin time are all prolonged. A severely reduced fibrinogen concentration in an otherwise well child is confirmatory of the diagnosis. As in dysfibrinogenemia, cryoprecipitate infusion is used for surgical prophylaxis and for acute hemorrhage.

Acharya SS: Rare Bleeding Disorder Registry: Deficiencies of factors II, V, VII, X, XIII, fibrinogen and dysfibrinogenemias. *J Thromb Haemost* 2004;2:248 [PMID: 14995986].

VON WILLEBRAND DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Easy bruising and epistaxis from early childhood.
- ▶ Menorrhagia.
- ▶ Prolonged PFA-100 (or bleeding time); normal platelet count; absence of acquired platelet dysfunction.
- ▶ Reduced activity or abnormal structure of vWF.

▶ General Considerations

von Willebrand disease (vWD) is the most common inherited bleeding disorder among Caucasians, with a prevalence of 1%. vWF is a protein present as a multimeric complex in plasma, which binds factor VIII and is a cofactor for platelet adhesion to the endothelium. An estimated 70–80% of all patients with vWD have classic vWD (type 1), which is caused by a partial quantitative deficiency of vWF. vWD type 2 involves a qualitative deficiency of (ie, dysfunctional) vWF, and vWD type 3 is characterized by a nearly complete deficiency of vWF. The majority (> 80%) of individuals with type 1 disease are asymptomatic. vWD is most often transmitted as an autosomal dominant trait, but can be autosomal recessive. The disease can also be acquired, developing in association with hypothyroidism, Wilms tumor, cardiac disease, renal disease, or systemic lupus erythematosus and in individuals receiving valproic acid. Acquired vWD is most often caused by the development of an antibody to vWF or increased turnover of vWF.

► Clinical Findings

A. Symptoms and Signs

A history of increased bruising and excessive epistaxis is often present. Prolonged bleeding also occurs with trauma or at surgery. Menorrhagia is often a presenting finding in females.

B. Laboratory Findings

PT is normal, and aPTT is sometimes prolonged. Prolongation of the PFA-100 or bleeding time is usually present since vWF plays a role in platelet adherence to endothelium. Platelet number may be decreased in type 2b vWD. Factor VIII and vWF antigen are decreased in types 1 and 3, but may be normal in type 2 vWD. vWF activity (eg, ristocetin cofactor or collagen binding) is decreased in all types. Since normal vWF antigen levels vary by blood type (type O normally has lower levels), blood type must be determined. Complete laboratory classification requires vWF multimer assay. The diagnosis requires confirmation of laboratory testing and bleeding history is often helpful when present.

► Treatment

The treatment to prevent or halt bleeding for most patients with vWD types 1 and 2 is desmopressin acetate, which causes release of vWF from endothelial stores. Desmopressin may be administered intravenously at a dose of 0.3 mcg/kg diluted in at least 20–30 mL of normal saline and given over 20–30 minutes. This dose typically elicits a three- to fivefold rise in plasma vWF. A high-concentration desmopressin nasal spray (150 mcg/spray), different than the preparation used for enuresis, may alternatively be used. Because response to vWF is variable among patients, factor VIII and vWF activities are typically measured before and 60 minutes after infusion, if no recent response has been measured. Desmopressin may cause fluid shifts, hyponatremia, and seizures in children younger than 2 years of age. Because release of stored vWF is limited, tachyphylaxis often occurs with desmopressin.

If further therapy is indicated, vWF-replacement therapy (eg, plasma-derived concentrate) is recommended; such therapy is also used in patients with type 1 or 2a vWD who exhibit suboptimal laboratory response to desmopressin, and for all individuals with type 2b or 3 vWD. Antifibrinolytic agents (eg, ϵ -aminocaproic acid) may be useful for control of mucosal bleeding. Topical thrombin and fibrin glue may also be of benefit, although antibodies that inhibit clotting proteins have been described. Estrogen-containing contraceptive therapy may be helpful for menorrhagia.

► Prognosis

With the availability of effective treatment and prophylaxis for bleeding, life expectancy in vWD is normal.

ACQUIRED BLEEDING DISORDERS

1. Disseminated Intravascular Coagulation (DIC)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Presence of disorder known to trigger DIC.
- Evidence for consumptive coagulopathy (prolonged aPTT, PT, or thrombin time; increase in FSP [fibrin-fibrinogen split products]; decreased fibrinogen or platelets).

► General Considerations

DIC is an acquired pathologic process characterized by tissue factor–mediated diffuse coagulation activation in the host. DIC involves dysregulated, excessive thrombin generation, with consequent intravascular fibrin deposition and consumption of platelets and procoagulant factors. Microthrombi, composed of fibrin and platelets, may produce tissue ischemia and end-organ damage. The fibrinolytic system is frequently activated in DIC, leading to plasmin-mediated destruction of fibrin and fibrinogen; this results in fibrin-fibrinogen degradation products (FDPs) which exhibit anticoagulant and platelet-inhibitory functions. DIC commonly accompanies severe infection and other critical illnesses in infants and children. Conditions known to trigger DIC include endothelial damage (eg, endotoxin, virus), tissue necrosis (eg, burns), diffuse ischemic injury (eg, shock, hypoxia acidosis), and systemic release of tissue procoagulants (eg, certain cancers, placental disorders).

► Clinical Findings

A. Symptoms and Signs

Signs of DIC may include (1) signs of shock, often including end-organ dysfunction, (2) diffuse bleeding tendency (eg, hematuria, melena, purpura, petechiae, persistent oozing from needle punctures or other invasive procedures), and (3) evidence of thrombotic lesions (eg, major vessel thrombosis, purpura fulminans).

B. Laboratory Findings

Tests that are most sensitive, easiest to perform, most useful for monitoring, and best reflect the hemostatic capacity of the patient are the PT, aPTT, platelet count, fibrinogen, and fibrin-fibrinogen split products. The PT and aPTT are typically prolonged and the platelet count and fibrinogen

concentration may be decreased. However, in children, the fibrinogen level may be normal until late in the course. Levels of fibrin-fibrinogen split products are increased, and elevated levels of D-dimer, a cross-linked fibrin degradation byproduct, may be helpful in monitoring the degree of activation of both coagulation and fibrinolysis. However, D-dimer is nonspecific and may be elevated in the context of a triggering event (eg, severe infection) without concomitant DIC. Often, physiologic inhibitors of coagulation, especially antithrombin III and protein C, are consumed, predisposing to thrombosis. The specific laboratory abnormalities in DIC may vary with the triggering event and the course of illness.

► Differential Diagnosis

DIC can be difficult to distinguish from coagulopathy of liver disease (ie, hepatic synthetic dysfunction), especially when the latter is associated with thrombocytopenia secondary to portal hypertension and hypersplenism. Generally, factor VII activity is decreased markedly in liver disease (due to deficient synthesis of this protein, which has the shortest half-life among the procoagulant factors), but only mildly to moderately decreased in DIC (due to consumption). Factor VIII activity is often normal or even increased in liver disease, but decreased in DIC.

► Treatment

A. Therapy for Underlying Disorder

The most important aspect of therapy in DIC is the identification and treatment of the triggering event. If the pathogenic process underlying DIC is reversed, often no other therapy is needed for the coagulopathy.

B. Replacement Therapy for Consumptive Coagulopathy

Replacement of consumed procoagulant factors with FFP and of platelets via platelet transfusion is warranted in the setting of DIC with hemorrhagic complications, or as periprocedural bleeding prophylaxis. Infusion of 10–15 mL/kg FFP typically raises procoagulant factor activities by approximately 10–15%. Cryoprecipitate can also be given as a rich source of fibrinogen; one bag of cryoprecipitate per 3 kg in infants or one bag of cryoprecipitate per 6 kg in older children typically raises plasma fibrinogen concentration by 75–100 mg/dL.

C. Anticoagulant Therapy for Coagulation Activation

Continuous intravenous infusion of unfractionated heparin is sometimes given in order to attenuate coagulation activation and consequent consumptive coagulopathy. The rationale for heparin therapy is to maximize the efficacy of, and minimize the need for, replacement of procoagulants and

platelets; however, clinical evidence demonstrating benefit of heparin in DIC is lacking. Heparin dosing is provided in the section on thrombosis treatment.

D. Specific Factor Concentrates

A nonrandomized pilot study of antithrombin concentrate in children with DIC and associated acquired antithrombin deficiency demonstrated favorable outcomes, suggesting that replacement of this consumed procoagulant may be of benefit. Protein C concentrate has also shown promise in two small pilot studies of meningococcal-associated DIC with purpura fulminans. Activated protein C has reduced mortality in septic adults in a large randomized multicenter trial; an international pediatric trial is ongoing.

2. Liver Disease

The liver is the major synthetic site of prothrombin, fibrinogen, high molecular weight kininogen, and factors V, VII, IX, X, XI, XII, and XIII. In addition, plasminogen and the physiologic anticoagulants (antithrombin III, protein C, and protein S) are hepatically synthesized. α_2 -Antiplasmin, a regulator of fibrinolysis, is also produced in the liver. Deficiency of factor V and the vitamin K-dependent factors (II, VII, IX, and X) is most often a result of decreased hepatic synthesis and is manifested by a prolonged PT and often a prolonged aPTT. Extravascular loss and increased consumption of clotting factors may contribute to PT and aPTT prolongation. Fibrinogen production is often decreased, or an abnormal fibrinogen (dysfibrinogen) containing excess sialic acid residues may be synthesized, or both. Hypofibrinogenemia or dysfibrinogenemia is associated with prolongation of thrombin time and reptilase time. FDPs and D-dimers may be present because of increased fibrinolysis, particularly in the setting of chronic hepatitis or cirrhosis. Thrombocytopenia secondary to hypersplenism may occur. DIC and coagulopathy of liver disease also mimic vitamin K deficiency; however, vitamin K deficiency has normal factor V activity. Treatment of acute bleeding in the setting of coagulopathy of liver disease consists of replacement with FFP and platelets. Desmopressin may shorten the bleeding time and aPTT in patients with chronic liver disease, but its safety has not been well established. Recombinant VIIa also is efficacious for life-threatening hemorrhage.

3. Vitamin K Deficiency

The newborn period is characterized by physiologically depressed activity of the vitamin K-dependent factors (II, VII, IX, and X). If vitamin K is not administered at birth, a bleeding diathesis previously called hemorrhagic disease of the newborn, now termed vitamin K deficiency bleeding (VKDB), may develop. Outside of the newborn period, vitamin K deficiency may occur as a consequence of inadequate intake, excess loss, inadequate formation of active metabolites, or competitive antagonism.

One of three patterns is seen in the neonatal period:

1. Early VKDB of the newborn occurs within 24 hours of birth and is most often manifested by cephalohematoma, intracranial hemorrhage, or intra-abdominal bleeding. Although occasionally idiopathic, it is most often associated with maternal ingestion of drugs that interfere with vitamin K metabolism (eg, warfarin, phenytoin, isoniazid, and rifampin). Early VKDB occurs in 6–12% of neonates born to mothers who take these medications without receiving vitamin K supplementation. The disorder is often life-threatening.
2. Classic VKDB occurs at 24 hours to 7 days of age and usually is manifested as gastrointestinal, skin, or mucosal bleeding. Bleeding after circumcision may occur. Although occasionally associated with maternal drug usage, it most often occurs in well infants who do not receive vitamin K at birth and are solely breast fed.
