CURRENT

Diagnosis & Treatment

Pediatrics

NINETEENTH EDITION

Edited by

William W. Hay, Jr., MD

Professor, Department of Pediatrics
Section of Neonatology and the Division of Perinatal Medicine
University of Colorado School of Medicine and The Children's Hospital, Denver

Myron J. Levin, MD

Professor, Departments of Pediatrics and Medicine
Section of Pediatric Infectious Diseases
University of Colorado School of Medicine and The Children's Hospital, Denver

Judith M. Sondheimer, MD

Professor Emeritus, Department of Pediatrics
Section of Pediatric Gastroenterology, Hepatology, and Nutrition
University of Colorado School of Medicine and The Children's Hospital, Denver

Robin R. Deterding, MD

Professor, Department of Pediatrics
Section of Pediatric Pulmonary Medicine
University of Colorado School of Medicine and The Children's Hospital, Denver

and Associate Authors

The Department of Pediatrics at the University of Colorado School of Medicine
is affiliated with The Children's Hospital of Denver.

Contents

Authors	x		
Preface	xviii		
1. The Newborn Infant	1		
<i>Elizabeth H. Thilo, MD, & Adam A. Rosenberg, MD</i>			
The Neonatal History	1		
Care of the Well Neonate	7		
Common Problems in the Term Newborn	10		
Neonatal Intensive Care	25		
Cardiac Problems in the Newborn Infant	41		
Gastrointestinal & Abdominal Surgical Conditions in the Newborn Infant	43		
Infections in the Newborn Infant	46		
Hematologic Disorders in the Newborn Infant	55		
Renal Disorders in the Newborn Infant	57		
Neurologic Problems in the Newborn Infant	59		
Metabolic Disorders in the Newborn Infant	60		
2. Child Development & Behavior	63		
<i>Edward Goldson, MD, & Ann Reynolds, MD</i>			
Normal Development	63		
The First 2 Years	63		
Ages 2–4 Years	80		
Early School Years: Ages 5–7 Years	81		
Middle Childhood: Ages 7–11 Years	81		
Behavioral & Developmental Variations	81		
Normality & Temperament	82		
Common Developmental Concerns	83		
Colic	83		
Feeding Disorders	84		
Sleep Disorders	85		
Temper Tantrums & Breath-holding Spells	88		
Well Child Surveillance & Screening	89		
Developmental Disorders	90		
Attention-Deficit/Hyperactivity Disorder	91		
Autism Spectrum Disorders	93		
Intellectual Disability/Mental Retardation	95		
3. Adolescence	101		
<i>David W. Kaplan, MD, MPH, & Kathryn A. Love-Osborne, MD</i>			
Guidelines for Adolescent Preventive Services	103		
Growth & Development	109		
Behavior & Psychological Health	113		
Breast Disorders	118		
Gynecologic Disorders in Adolescence	120		
4. Adolescent Substance Abuse	137		
<i>Paritosh Kaul, MD</i>			
Scope of the Problem	137		
Morbidity Data	141		
Supplement Use & Abuse	142		
Response to the Problem	143		
Predicting the Progression from Use to Abuse	143		
Management of Substance Abuse	144		
Treatment & Referral	147		
Prevention	150		
5. Eating Disorders	152		
<i>Eric J. Sigel, MD</i>			
Etiology	152		
Incidence	153		
Predisposing Factors	153		
Anorexia Nervosa	154		
Bulimia Nervosa	159		
Eating Disorder Not Otherwise Specified	162		
Prognosis	162		
6. Child & Adolescent Psychiatric Disorders & Psychosocial Aspects of Pediatrics	163		
<i>Brian Stafford, MD, MPH, Jennifer Hagman, MD, & Bert Dech, MD</i>			
Mental Health in the Primary Care Setting	163		
Early Identification & Prevention of Developmental & Socioemotional Problems	164		
Identification & Assessment during Health Maintenance Visits	165		
Consultation-Liaison Psychiatry	172		
Psychiatric Disorders of Childhood & Adolescence	176		
Pervasive Developmental Disorders & Autism	177		
Mood Disorders	180		
Suicide	184		
Adjustment Disorders	185		
Schizophrenia	186		
Conduct Disorders	187		
Anxiety Disorders	189		
Obsessive-Compulsive Disorder	191		
Post-Traumatic Stress Disorder	192		
Somatoform Disorders	194		
Elimination Disorders	195		

Overview of Pediatric Psychopharmacology	197	Burns	307
ADHD Medications	198	Disorders Due to Altered Environmental Temperature	308
Antidepressants	200	Submersion Injuries	310
Mood Stabilizers & Atypical Antipsychotics	203	Animal & Human Bites	311
Antipsychotics	205	Procedural Sedation & Analgesia (PSA)	311
Adrenergic Agonists	207		
7. Child Abuse & Neglect	209	12. Poisoning	313
<i>Andrew P. Sirotnak, MD, Richard D. Krugman, MD, & Antonia Chiesa, MD</i>		<i>Barry H. Rumack, MD, & Richard C. Dart, MD, PhD</i>	
Forms of Child Maltreatment	209	Pharmacologic Principles of Toxicology	313
Recognition of Abuse & Neglect	210	Preventing Childhood Poisonings	314
Management & Reporting	213	General Treatment of Poisoning	314
Prevention	214	Management of Specific Common Poisonings	318
		Acetaminophen (Paracetamol)	318
8. Ambulatory & Community Pediatrics	216	Alcohol, Ethyl (Ethanol)	319
<i>Robert M. Brayden, MD, Maya Bunik MD, MSPH, Jeffrey M. Brown, MD, MPH, CPE, & Matthew F. Daley, MD</i>		Amphetamines & Related Drugs	321
Pediatric History	216	Anesthetics, Local	321
Pediatric Physical Examination	217	Antihistamines	321
Health Supervision Visits	219	Arsenic	322
Other Types of General Pediatric Services	229	Barbiturates	322
Common General Pediatric Issues	232	Belladonna Alkaloids	322
		Carbon Monoxide	323
9. Immunization	236	Caustics	323
<i>Matthew F. Daley, MD, Eric A. F. Simoes, MB, BS, DCH, MD, & Ann-Christine Nyquist, MD, MSPH</i>		Cocaine	324
Standards for Pediatric Immunization Practices	236	Contraceptive Pills	324
Routine Childhood & Adolescent Immunizations	238	Cosmetics & Related Products	324
Safe Handling of Vaccines	238	Cyclic Antidepressants	325
Vaccinations for Special Situations	263	Digitalis & Other Cardiac Glycosides	325
Passive Prophylaxis	266	Diphenoxylate with Atropine (Lomotil) & Loperamide (Imodium)	325
		Disinfectants & Deodorizers	326
10. Normal Childhood Nutrition & Its Disorders	268	Disk-Shaped Batteries	326
<i>Nancy F. Krebs, MD, MS, & Laura E. Primak, RD, CNSD, CSP</i>		Ethylene Glycol & Methanol	327
Nutritional Requirements	268	Gamma-Hydroxybutyrate, Gamma-Butyrolactone, & Butanediol	327
Infant Feeding	275	Hydrocarbons (Benzene, Charcoal Lighter Fluid, Gasoline, Kerosene, Petroleum Distillates, Turpentine)	327
Nutrition for the Older Child	282	Ibuprofen	328
Pediatric Under- & Overnutrition	283	Insect Stings (Bee, Wasp, & Hornet)	328
Nutrition Support	286	Insecticides	328
		Iron	329
11. Emergencies & Injuries	294	Lead	330
<i>Maria J. Mandt, MD, & Glenn Faries, MD</i>		Magnets	330
Advanced Life Support for Infants & Children	294	Mushrooms	330
Approach to the Seriously Ill Child	299	Nitrites, Nitrates, Aniline, Pentachlorophenol, & Dinitrophenol	331
Approach to the Pediatric Trauma Patient	301	Opioids (Codeine, Heroin, Methadone, Morphine, Propoxyphene)	331
Head Injury	306	Phenothiazines (Chlorpromazine, Prochlorperazine, Trifluoperazine)	332
		Plants	332
		Psychotropic Drugs	332
		Salicylates	334
		Scorpion Stings	335

Serotonin Reuptake Inhibitors	335	Diseases of the Conjunctiva	408
Snakebite	335	Disorders of the Iris	411
Soaps & Detergents	336	Glaucoma	412
Spider Bites	337	Uveitis	413
Thyroid Preparations (Thyroid Dessicated, Sodium Levothyroxine)	337	Ocular Manifestations of Acquired Immunodeficiency Syndrome	414
Vitamins	337	Disorders of the Cornea	415
Warfarin	337	Disorders of the Lens	416
		Disorders of the Retina	417
		Diseases of the Optic Nerve	419
		Diseases of the Orbit	421
		Nystagmus	422
		Amblyopia & Strabismus	423
		Unexplained Decreased Vision in Infants & Children	425
		The Blind Child	425
		Learning Disabilities & Dyslexia	426
13. Critical Care	339	16. Oral Medicine & Dentistry	427
<i>Todd C. Carpenter, MD, Emily L. Dobyms, MD, Eva N. Grayck, MD, Peter M. Mourani, MD, & Kurt R. Stenmark, MD</i>		<i>Ulrich Klein, DMD, DDS, MS</i>	
Acute Respiratory Failure	339	Issues in Pediatric Oral Health	427
Mechanical Ventilation	343	Oral Examination of the Newborn & Infant	428
Acute Respiratory Distress Syndrome	345	Eruption of the Teeth	430
Indications for Central Venous & Arterial Cannulation	350	Dental Caries	431
Brain Injury & Cerebral Edema	353	Periodontal Disease	432
Ethical Deliberation & End-of-Life Care in the PICU	355	Orofacial Trauma	433
Nutritional Support of the Critically Ill Child	357	Dental Emergencies	434
Asthma (Life-Threatening)	361	Antibiotics in Pediatric Dentistry	434
Shock	364	Special Patient Populations	434
Pain & Anxiety Control	371	Maternal-Fetal Relationship	435
		Dental & Orthodontic Referral	435
14. Skin	375	17. Ear, Nose, & Throat	437
<i>Joseph G. Morelli, MD, & Joanna M. Burch, MD</i>		<i>Peggy E. Kelley, MD, Norman R. Friedman, MD, & Patricia J. Yoon, MD</i>	
General Principles	375	The Ear	437
Disorders of the Skin in Newborns	376	The Nose & Paranasal Sinuses	453
Transient Diseases	376	The Throat & Oral Cavity	459
Birthmarks, Nevi, & Melanoma	378		
Common Skin Diseases in Infants, Children, & Adolescents	381	18. Respiratory Tract & Mediastinum	471
Acne	381	<i>Gwendolyn S. Kerby, MD, Robin R. Deterding, MD, Vivek Balasubramaniam, MD, Scott D. Sagel, MD, Keith L. Cavanaugh, MD, & Monica J. Federico, MD</i>	
Bacterial Infections	383	Respiratory Tract	471
Fungal Infections	384	Growth & Development	471
Viral Infections	385	Diagnostic Aids	472
Insect Infestations	387	General Therapy of Pediatric Lung Diseases	475
Dermatitis (Eczema)	388	Disorders of the Conducting Airways	476
Common Skin Tumors	390	Stridor & Noisy Breathing from Congenital Disorders of the Extrathoracic Airway	477
Papulosquamous Eruptions	391	Stridor & Noisy Breathing from Acquired Disorders of the Extrathoracic Airway	478
Hair Loss	392	Congenital Disorders of the Intrathoracic Airways	481
Reactive Erythemas	393	Acquired Disorders of the Intrathoracic Airways	482
15. Eye	395		
<i>Rebecca Sands Braverman, MD</i>			
Common Nonspecific Signs & Symptoms	395		
Refractive Errors	396		
Ophthalmic Examination	397		
Ocular Trauma	400		
Disorders of the Ocular Structures	404		
Disorders of the Nasolacrimal System	407		

Disorders of Mucociliary Clearance	485	α_1 -Antitrypsin Deficiency Liver Disease	630
Congenital Malformations of the Lung	491	Wilson Disease (Hepatolenticular Degeneration)	631
Acquired Disorders Involving Alveoli	494	Cirrhosis	633
Diseases of the Pulmonary Circulation	506	Portal Hypertension	634
Disorders of the Chest Wall	509	Biliary Tract Disease	637
Sleep-Disordered Breathing	513	Pyogenic & Amebic Liver Abscess	641
Apparent Life-Threatening Events in Infancy	514	Hepatoma	642
Mediastinum	517	Liver Transplantation	644
19. Cardiovascular Diseases	519	Pancreatic Disorders	644
<i>Henry M. Sondheimer, MD, Jeffrey R. Darst, MD, Elizabeth M. Shaffer, MD, & Shelley D. Miyamoto, MD</i>		Acute Pancreatitis	644
Diagnostic Evaluation	519	Chronic Pancreatitis	645
Perinatal & Neonatal Circulation	528	Gastrointestinal & Hepatobiliary Manifestations of Cystic Fibrosis	646
Heart Failure	529	Syndromes with Pancreatic Exocrine Insufficiency	649
Acyanotic Congenital Heart Disease	531	Isolated Exocrine Pancreatic Enzyme Defect	649
Cyanotic Congenital Heart Disease	545	Pancreatic Tumors	649
Acquired Heart Disease	554	22. Kidney & Urinary Tract	651
Cardiac Transplantation	564	<i>Gary M. Lum, MD</i>	
Primary Pulmonary Hypertension	566	Evaluation of the Kidney & Urinary Tract	651
Disorders of Rate & Rhythm	567	Congenital Anomalies of the Urinary Tract	655
20. Gastrointestinal Tract	577	Hematuria & Glomerular Disease	656
<i>Judith M. Sondheimer, MD, & Shikha Sundaram, MD, MSCI</i>		Proteinuria & Renal Disease	658
Disorders of the Esophagus	577	Diseases of the Renal Vessels	660
Disorders of the Stomach & Duodenum	580	Renal Failure	661
Disorders of the Small Intestine	583	Inherited or Developmental Defects of the Kidney	667
Disorders of the Colon	587	Urinary Tract Infections	670
Disorders of the Peritoneal Cavity	591	23. Neurologic & Muscular Disorders	673
Gastrointestinal Tumors & Malignancies	592	<i>Paul G. Moe, MD, Timothy A. Benke, MD, PhD, Tim J. Bernard, MD, & Paul Levisohn, MD</i>	
Major Gastrointestinal Symptoms & Signs	593	Neurologic Assessment & Neurodiagnostic Procedures	673
Malabsorption Syndromes	600	Disorders Affecting the Nervous System in Infants & Children	679
Inflammatory Bowel Disease	605	Infections & Inflammatory Disorders of the Central Nervous System	728
21. Liver & Pancreas	609	Disorders of Childhood Affecting Muscles	736
<i>Ronald J. Sokol, MD, & Michael R. Narkewicz, MD</i>		Miscellaneous Neuromuscular Disorders	745
Liver Disorders	609	24. Orthopedics	750
Prolonged Neonatal Cholestatic Jaundice	609	<i>John D. Polousky, MD, & Robert E. Eilert, MD</i>	
Intrahepatic Cholestasis	609	Disturbances of Prenatal Origin	750
Progressive Familial Intrahepatic Cholestasis (Byler Disease)	617	Growth Disturbances of the Musculoskeletal System	754
Extrahepatic Neonatal Cholestasis	617	Degenerative Problems (Arthritis, Bursitis, & Tenosynovitis)	757
Other Neonatal Hyperbilirubinemic Conditions (Noncholestatic Nonhemolytic)	619	Trauma	757
Hepatitis A	621	Infections of the Bones & Joints	760
Hepatitis B	623	Vascular Lesions & Avascular Necrosis (Osteochondroses)	762
Hepatitis C	625	Neurologic Disorders Involving the Musculoskeletal System	764
Hepatitis D (Delta Agent)	626		
Hepatitis E	626		
Other Hepatitis Viruses	626		
Acute Liver Failure (Fulminant Hepatic Failure)	627		
Autoimmune Hepatitis	628		
Nonalcoholic Fatty Liver Disease	629		

Neoplasia of the Musculoskeletal System	764		
Miscellaneous Diseases of Bone	765		
25. Sports Medicine	768		
<i>Pamela E. Wilson, MD, & K. Brooke Pengel, MD</i>			
Basic Principles	768		
Preparticipation History & Physical Examination	769		
Rehabilitation of Sports Injuries	773		
Common Sports Medicine Issues & Injuries	776		
Infectious Diseases	776		
Head & Neck Injuries	776		
Spine Injuries	777		
Shoulder Injuries	778		
Elbow & Forearm Injuries	780		
Hand & Wrist Injuries	781		
Hip Injuries	781		
Knee Injuries	783		
Foot & Ankle Injuries	786		
Prevention	787		
26. Rehabilitation Medicine	788		
<i>Pamela E. Wilson, MD, & Gerald H. Clayton, PhD</i>			
Pediatric Brain Injury	788		
Spinal Cord Injury	791		
Brachial Plexus Lesions	793		
Common Rehabilitation Problems	794		
27. Rheumatic Diseases	796		
<i>Jennifer B. Soep, MD, & J. Roger Hollister, MD</i>			
Juvenile Idiopathic Arthritis	796		
Enthesitis-Related Arthritis & Spondyloarthropathy	799		
Enteropathic Arthritis	799		
Systemic Lupus Erythematosus	799		
Dermatomyositis	801		
Polyarteritis Nodosa	802		
Scleroderma	802		
Raynaud Phenomenon	802		
Noninflammatory Pain Syndromes	803		
28. Hematologic Disorders	804		
<i>Daniel R. Ambruso, MD, Taru Hays, MD, & Neil A. Goldenberg, MD</i>			
Normal Hematologic Values	804		
Bone Marrow Failure	804		
Anemias	806		
Polycythemia & Methemoglobinemia	824		
Disorders of Leukocytes	826		
Bleeding Disorders	830		
Thrombotic Disorders	842		
Splenic Abnormalities	845		
Transfusion Medicine	846		
29. Neoplastic Disease	853		
<i>Kelly Maloney, MD, Brian S. Greffe, MD, Nicholas K. Foreman, MD, Doug K. Graham, MD, PhD, Roger H. Giller, MD, Ralph R. Quinones, MD, & Amy K. Keating, MD</i>			
Major Pediatric Neoplastic Diseases	853		
Acute Lymphoblastic Leukemia	853		
Acute Myeloid Leukemia	856		
Myeloproliferative Diseases	858		
Brain Tumors	860		
Lymphomas & Lymphoproliferative Disorders	863		
Neuroblastoma	868		
Wilms Tumor (Nephroblastoma)	870		
Bone Tumors	871		
Rhabdomyosarcoma	873		
Retinoblastoma	875		
Hepatic Tumors	876		
Langerhans Cell Histiocytosis	877		
Hematopoietic Stem Cell Transplantation	878		
Late Effects of Pediatric Cancer Therapy	880		
30. Pain Management & Palliative Care	883		
<i>Brian S. Greffe, MD, Jeffrey L. Galinkin, MD, & Nancy A. King, MSN, RN, CPNP</i>			
Pain Management	883		
Pain Assessment	883		
Acute Pain	883		
Chronic Pain	884		
Pediatric Palliative & End-of-Life Care	886		
Pain Management in Palliative Care	888		
Quality-of-Life Adjuncts & Symptom Management	888		
Psychosocial Aspects of Palliative Care	888		
Spiritual & Cultural Support	888		
Advance Care Planning	889		
31. Immunodeficiency	891		
<i>Lora J. Stewart, MD, Richard B. Johnston, Jr., MD, & Andrew H. Liu, MD</i>			
Immunodeficiency Evaluation:			
Primary Considerations	891		
Antibody Deficiency Syndromes	895		
Severe Combined Immunodeficiency Diseases	899		
Interleukin-7-Receptor-Alpha-Chain Deficiency	901		
Other Combined Immunodeficiency Disorders	902		
Phagocytic Defects	904		
Complement Defects	906		
Other Well-Defined Immunodeficiency Syndromes	907		
Genetic Syndromes Associated with Immunodeficiency	908		
Graft-Versus-Host Disease	909		

32. Endocrine Disorders	911		
<i>Philip S. Zeitler, MD, PhD, Sharon H. Travers, MD, Francis Hoe, MD, Kristen Nadeau, MD, & Michael S. Kappy, MD, PhD</i>			
General Concepts	911		
Disturbances of Growth	912		
Disorders of the Posterior Pituitary Gland	920		
Thyroid Gland	921		
Disorders of Calcium & Phosphorus Metabolism	926		
Gonads (Ovaries & Testes)	933		
Adrenal Cortex	940		
33. Diabetes Mellitus	949		
<i>H. Peter Chase, MD, & George S. Eisenbarth, MD, PhD</i>			
General Considerations	949		
Pathogenesis	949		
Prevention	950		
Clinical Findings	950		
Treatment	950		
Acute Complications	953		
Chronic Complications	955		
34. Inborn Errors of Metabolism	956		
<i>Janet A. Thomas, MD, & Johan L. K. Van Hove, MD, PhD, MBA</i>			
Diagnosis	956		
Management of Metabolic Emergencies	960		
Newborn Screening	960		
Disorders of Carbohydrate Metabolism	961		
Disorders of Energy Metabolism	963		
Disorders of Amino Acid Metabolism	965		
Organic Acidemias	970		
Disorders of Fatty Acid Oxidation & Carnitine	973		
Purine Metabolism Disorders	975		
Lysosomal Diseases	975		
Peroxisomal Diseases	978		
Congenital Disorders of Glycosylation	978		
Smith-Lemli-Opitz Syndrome			
& Disorders of Cholesterol Synthesis	979		
Disorders of Neurotransmitter Metabolism	980		
Creatine Synthesis Disorders	980		
35. Genetics & Dysmorphology	982		
<i>Ellen R. Elias, MD, Anne Chun-Hui Tsai, MD, MSc, & David K. Manchester, MD</i>			
Foundations of Genetic Diagnosis	982		
Principles of Inherited Human Disorders	989		
Dysmorphology & Human Embryology	996		
Chromosomal Disorders: Abnormal Number	999		
Chromosomal Abnormalities:			
Abnormal Structure	1003		
Mendelian Disorders	1004		
Nonmendelian Disorders	1008		
Disorders of Multifactorial Inheritance	1011		
		Common Recognizable Disorders with Variable or Unknown Cause	1013
		Evaluation of the Developmentally Delayed Child	1014
		Perinatal Genetics	1016
36. Allergic Disorders	1018		
<i>Mark Boguniewicz, MD, Ronina A. Covar, MD, & David M. Fleischer, MD</i>			
Asthma	1018		
Allergic Rhinoconjunctivitis	1034		
Atopic Dermatitis	1037		
Urticaria & Angioedema	1041		
Adverse Reactions to Drugs & Biologicals	1046		
Food Allergy	1050		
Insect Allergy	1051		
37. Antimicrobial Therapy	1053		
<i>John W. Ogle, MD</i>			
Principles of Antimicrobial Therapy	1053		
Antimicrobial Susceptibility Testing	1054		
Alteration of Dose & Measurement of Blood Levels	1054		
The Use of New Antimicrobial Agents	1058		
Prophylactic Antimicrobial Agents	1058		
Initial Empiric Antimicrobial Choices for Selected Conditions	1062		
Specific Antimicrobial Agents	1064		
38. Infections: Viral & Rickettsial	1071		
<i>Myron J. Levin, MD, & Adriana Weinberg, MD</i>			
Viral Infections	1071		
The Common Cold	1071		
Adenoviruses	1074		
Influenza	1077		
Parainfluenza	1079		
Respiratory Syncytial Virus	1079		
Human Metapneumovirus	1081		
Enteroviruses	1082		
Acute Febrile Illness	1082		
Respiratory Tract Illnesses	1082		
Rashes	1083		
Central Nervous System Illnesses	1083		
Herpesviruses	1086		
Herpes Simplex Infections	1086		
Varicella & Herpes Zoster	1088		
Cytomegalovirus Infections	1091		
Infectious Mononucleosis (Epstein-Barr Virus)	1094		
Viral Infections Spread by Insect Vectors	1096		
Viral Childhood Exanthems	1100		
Hantavirus Cardiopulmonary Syndrome	1104		
Mumps	1105		
Rabies	1106		
Rickettsial Infections	1107		
Ehrlichiosis	1107		
Rocky Mountain Spotted Fever	1108		

Endemic Typhus	1109	Babesiosis	1190
Q Fever	1110	Toxoplasmosis	1190
39. Human Immunodeficiency Virus Infection	1111	Gastrointestinal Infections	1197
<i>Elizabeth J. McFarland, MD</i>		Amebiasis	1197
General Considerations	1111	Giardiasis	1199
Transmission & Epidemiology	1111	Cryptosporidiosis	1200
Pathogenesis	1112	Metazoal Infections	1202
Clinical Findings	1113	Nematodes (Worms)	1202
Differential Diagnosis	1115	Cestodes (Flukes)	1207
Prevention	1115	Trematode Infections	1209
Treatment	1116	Mycotic Infections	1210
Prognosis	1121	Blastomycosis	1211
40. Infections: Bacterial & Spirochetal	1123	Candidiasis	1212
<i>John W. Ogle, MD, & Marsha S. Anderson, MD</i>		Coccidioidomycosis	1215
Bacterial Infections	1123	Cryptococcosis	1217
Streptococcal Infections	1123	Histoplasmosis	1218
Pneumococcal Infections	1131	Sporotrichosis	1219
Staphylococcal Infections	1134	Opportunistic Fungal Infections	1220
Meningococcal Infections	1138	42. Sexually Transmitted Infections	1224
Gonococcal Infections	1140	<i>Ann-Christine Nyquist, MD, MSPH, & Eric J. Sigel, MD</i>	
Botulism	1143	The Most Common Antibiotic-Responsive Sexually Transmitted Infections	1226
Tetanus	1144	The Spectrum of Sexually Transmitted Infections	1233

Preface

The 19th edition of *Current Diagnosis & Treatment: Pediatrics* (CDTP) features practical, up-to-date, well-referenced information on the care of children from birth through infancy and adolescence. CDTP emphasizes the clinical aspects of pediatric care while also covering important underlying principles. CDTP provides a guide to diagnosis, understanding, and treatment of the medical problems of all pediatric patients in an easy-to-use and readable format.

INTENDED AUDIENCE

Like all Lange medical books, CDTP provides a concise yet comprehensive source of current information. Students will find CDTP an authoritative introduction to pediatrics and an excellent source for reference and review. CDTP provides excellent coverage of The Council on Medical Student Education in Pediatrics (COMSEP) curriculum used in pediatric clerkships. Residents in pediatrics (and other specialties) will appreciate the detailed descriptions of diseases as well as diagnostic and therapeutic procedures. Pediatricians, family practitioners, nurses and nurse practitioners, and other health-care providers who work with infants and children will find CDTP a useful reference on management aspects of pediatric medicine.

COVERAGE

Forty-four chapters cover a wide range of topics, including neonatal medicine, child development and behavior, emergency and critical care medicine, and diagnosis and treatment of specific disorders according to major problems and organ systems. A wealth of tables and figures provides quick access to important information, such as acute and critical care procedures in the delivery room, the office, the emergency room, and the critical care unit; anti-infective agents; drug dosages; immunization schedules; differential diagnosis; and developmental screening tests. The final chapter is a handy guide to normal laboratory values.

NEW TO THIS EDITION

The 19th edition of CDTP has been revised comprehensively by the editors and contributing authors. New references as well as up-to-date and useful Web sites have been added, permitting the reader to consult original material and to go beyond the confines of the textbook. As editors and practicing pediatricians, we have tried to ensure that each chapter reflects the needs and realities of day-to-day practice.

CHAPTERS WITH MAJOR REVISIONS INCLUDE:

- 1 The Newborn Infant
- 9 Immunization
- 12 Poisoning
- 16 Oral Medicine & Dentistry
- 19 Cardiovascular Diseases
- 20 Gastrointestinal Tract
- 40 Infections: Bacterial & Spirochetal
- 41 Infections: Parasitic & Mycotic

NEW CHAPTERS INCLUDE:

- 6 Child & Adolescent Psychiatric Disorders & Psychosocial Aspects of Pediatrics
- 25 Sports Medicine
- 26 Rehabilitation Medicine
- 30 Pain Management & Palliative Care

CHAPTER REVISIONS

The eight chapters that have been extensively revised, with new authors added in several cases, reflect the substantially updated material in each of their areas of pediatric medicine. The Gastrointestinal Tract chapter, with contributions from a new author, has been thoroughly revised, particularly the sections on inflammatory bowel disease and gastroesophageal reflux, as well as new sections on cyclic vomiting syndrome and eosinophilic esophagitis. Especially important are updates to the chapters on Infectious Diseases, including information on methicillin-resistant staphylococcus and tropical diseases such as dengue and malaria. The Neonatology chapter includes a major revision on hyperbilirubinemia. The Poisoning chapter has been revised to include more references and guidelines. The Oral Medicine & Dentistry chapter has a new author and a focus on preventive dentistry. The Cardiovascular chapter has been streamlined and includes a thoroughly updated section on ultrasound and a new section on cardiac transplant and treatment of rejection. A new chapter on Pain Management & Palliative Care has been added. The Rehabilitation Medicine & Sports Medicine chapter has been separated into two chapters to clarify and emphasize the unique aspects of each. Child & Adolescent Psychiatric Disorders & Psychosocial Aspects of Pediatrics has been completely revised by two new authors.

All other chapters are substantially revised and references have been updated. Eighteen new authors have contributed to these revisions.

ACKNOWLEDGMENT

The Editors would like to thank Bonnie Savone for her expert assistance in managing the flow of manuscripts and materials among the chapter authors, editors, and publishers. Her attention to detail was enormously helpful.

The Newborn Infant

Elizabeth H. Thilo, MD
Adam A. Rosenberg, MD

1

The newborn period is defined as the first 28 days of life. In practice, however, sick or very immature infants may require neonatal care for many months. There are three levels of newborn care. Level 1 refers to basic care of well newborns, neonatal resuscitation, and stabilization prior to transport. Level 2 refers to specialty neonatal care of premature infants greater than 1500 g or more than 32 weeks' gestation. Level 3 is subspecialty care of higher complexity ranging from 3A to 3D based on newborn size and gestational age, availability of general surgery, cardiac surgery, and extracorporeal membrane oxygenation. Level 3 care is often part of a perinatal center offering critical care and transport to the high-risk mother and fetus as well as the newborn infant.

THE NEONATAL HISTORY

The newborn medical history has three key components: (1) maternal and paternal medical and genetic history, (2) maternal past obstetric history, and (3) current antepartum and intrapartum obstetric history.

The mother's medical history includes chronic medical conditions, medications taken during pregnancy, unusual dietary habits, smoking history, occupational exposure to chemicals or infections of potential risk to the fetus, and any social history that might increase the risk for parenting problems and child abuse. Family illnesses with genetic implications should be sought. The past obstetric history includes maternal age, gravidity, parity, blood type, and pregnancy outcomes. The current obstetric history includes the results of procedures during the current pregnancy such as ultrasound, amniocentesis, screening tests (rubella antibody, hepatitis B surface antigen, serum quadruple screen for genetic disorders, HIV), and antepartum tests of fetal well-being (eg, biophysical profiles, nonstress tests, or Doppler assessment of fetal blood flow patterns). Pregnancy-related maternal complications such as urinary tract infection, pregnancy-induced hypertension, eclampsia, gestational diabetes, vaginal bleeding, and

preterm labor should be documented. Significant peripartum events include duration of ruptured membranes, maternal fever, fetal distress, meconium-stained amniotic fluid, type of delivery (vaginal or cesarean section), anesthesia and analgesia used, reason for operative or forceps delivery, infant status at birth, resuscitative measures, and Apgar scores.

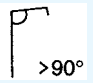

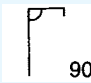

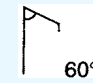

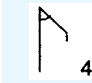

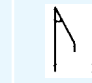

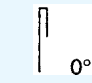

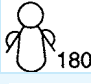

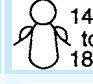

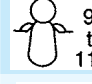

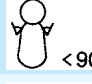

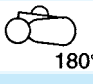

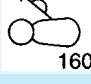

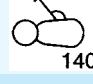

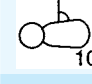

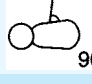

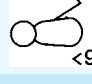

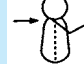

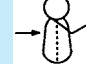

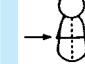

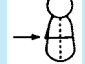

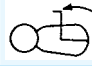

ASSESSMENT OF GROWTH & GESTATIONAL AGE

It is important to know the infant's gestational age because normal behavior and possible medical problems can be predicted on this basis. The date of the last menstrual period is the best indicator of gestational age. Uterine fundal height and early fetal ultrasound provide supporting information. Postnatal physical characteristics and neurologic development are also clues to gestational age. Table 1-1 lists the physical and neurologic criteria of maturity used to estimate gestational age by the Ballard score method. Adding the scores assigned to each neonatal physical and neuromuscular sign yields a score corresponding to gestational age.

Disappearance of the anterior vascular capsule of the lens is also helpful in determining gestational age. Until 27-28 weeks' gestation, the lens capsule is covered by vessels; by 34 weeks, this vascular plexus is completely atrophied. Foot length, from the heel to the tip of the longest toe, also correlates with gestational age in appropriately grown infants. The foot measures 4.5 cm at 25 weeks' gestation and increases 0.25 cm per week until term.

If the physical examination indicates a gestational age within 2 weeks of that predicted by the obstetric dates, the gestational age is as assigned by the obstetric date. Birth weight and gestational age are plotted on standard grids (Figure 1-1) to determine whether the birth weight is appropriate for gestational age (AGA), small for gestational age (SGA) or large for gestational age (LGA). Another term for SGA is intrauterine growth restriction (IUGR). Birth weight for gestational age in normal neonates varies with

race, maternal nutrition, access to obstetric care, and environmental factors such as altitude, smoking, and drug and alcohol use. Whenever possible, standards for newborn weight and gestational age based on data derived from the local or regional population should be used. Birth weight related to gestational age is a screening tool that should be supplemented by clinical data when entertaining a diagnosis of IUGR or excessive fetal growth. These data include the infant's physical examination and other factors such as parental size and the birth weight–gestational age of siblings.

An important distinction, particularly in SGA infants, is whether a growth disorder is symmetrical (weight, length, and occipitofrontal circumference [OFC] all $\leq 10\%$) or asymmetrical (only weight $\leq 10\%$). Asymmetrical growth restric-

tion implies a problem late in pregnancy, such as pregnancy-induced hypertension or placental insufficiency. Symmetrical growth restriction implies an event of early pregnancy: chromosomal abnormality, drug or alcohol use, or congenital viral infections. In general, the outlook for normal growth and development is better in asymmetrically growth-restricted infants whose intrauterine brain growth has been spared (Table 1–2).

The fact that SGA infants have fewer problems (such as respiratory distress syndrome) than AGA infants of the same birth weight but a lower gestational age has led to the misconception that SGA infants have accelerated maturation. SGA infants, when compared with AGA infants of the same gestational age, actually have increased morbidity and mortality rates.

Table 1-2. Causes of variations in neonatal size in relation to gestational age.

Infants large for gestational age
Infant of a diabetic mother
Infants small for gestational age
Asymmetrical
Placental insufficiency secondary to pregnancy-induced hypertension or other maternal vascular disease
Maternal age > 35 years
Poor weight gain during pregnancy
Multiple gestation
Symmetrical
Maternal drug abuse
Narcotics
Cocaine
Alcohol
Chromosomal abnormalities
Intrauterine viral infection (eg, cytomegalovirus)

Knowledge of birth weight in relation to gestational age allows anticipation of some neonatal problems. LGA infants are at risk for birth trauma; LGA infants of diabetic mothers are also at risk for hypoglycemia, polycythemia, congenital anomalies, cardiomyopathy, hyperbilirubinemia, and hypocalcemia. SGA infants are at risk for fetal distress during labor and delivery, polycythemia, hypoglycemia, and hypocalcemia.

EXAMINATION AT BIRTH

The extent of the newborn physical examination depends on the condition of the infant and the setting. Examina-

tion in the delivery room consists largely of observation plus auscultation of the chest and inspection for congenital anomalies and birth trauma. Major congenital anomalies occur in 1.5% of live births and account for 20–25% of perinatal and neonatal deaths. Because infants are physically stressed during parturition, the delivery room examination should not be extensive. The Apgar score (Table 1–3) should be recorded at 1 and 5 minutes of age. In severely depressed infants, a 10-minute score should also be recorded. Although the 1- and 5-minute Apgar scores have almost no predictive value for long-term outcome, serial scores provide a useful description of the severity of perinatal depression and the response to resuscitative efforts.

Skin color is an indicator of cardiac output because of the normal high blood flow to the skin. Stress that triggers a catecholamine response redirects cardiac output away from the skin to preserve oxygen delivery to more critical organs. Cyanosis and pallor are thus two signs of inadequate skin oxygenation and cardiac output.

Skeletal examination at delivery serves to detect obvious congenital anomalies and to identify birth trauma, particularly in LGA infants or those born after a protracted second stage of labor in whom a fractured clavicle or humerus might be found.

The number of umbilical cord vessels should be determined. Normally, there are two arteries and one vein. In 1% of deliveries (5–6% of twin deliveries), the cord has only one artery and one vein. This minor anomaly slightly increases the risk of associated defects. The placenta should be examined at delivery. Small placentas are always associated with small infants. The placental examination includes identification of membranes and vessels (particularly in multiple gestations) as well as placental infarcts or clots (placental abruption) on the maternal side.

Table 1-3. Infant evaluation at birth—Apgar score.^a

	Score		
	0	1	2

EXAMINATION IN THE NURSERY

The examiner should have warm hands and a gentle approach. Start with observation, then auscultation of the chest, and then palpation of the abdomen. Examination of the eyes, ears, throat, and hips should be performed last, as these maneuvers are most disturbing to the infant. The heart rate should range from 120–160 beats/min, and the respiratory rate from 30–60 breaths/min. Systolic blood pressure on day 1 ranges from 50–70 mm Hg and increases steadily during the first week of life. Blood pressure is influenced more significantly by perinatal asphyxia and mechanical ventilation than it is by gestational age. An irregularly irregular heart rate, usually caused by premature atrial contractions, is common, benign, and usually resolves in the first days of life.

Approximately 15–20% of healthy newborns have one minor anomaly. Those with a minor anomaly have a 3% risk of an associated major anomaly. Approximately 0.8% of newborns have two minor anomalies, and 0.5% have three or more, with a risk of 10% and 20%, respectively, of a major malformation. Common minor anomalies requiring no special investigation in healthy infants include preauricular pits, a single sacral dimple without other cutaneous abnormality within 2.5 cm of the anus, a single transverse palmar crease, and three or fewer café-au-lait spots in a white infant or five or fewer in an African-American infant.

Skin

Observe for bruising, petechiae (common over the presenting part), meconium staining, and jaundice. Peripheral cyanosis is commonly present when the extremities are cool or the infant is polycythemic. Generalized cyanosis merits immediate evaluation. Pallor may be caused by acute or chronic blood loss or by acidosis. In dark-skinned infants, pallor and cyanosis should be assessed in the lips, mouth, and nail beds. Plethora suggests polycythemia. Note vernix caseosa (a whitish, greasy material covering the body that decreases as term approaches) and lanugo (the fine hair covering the preterm infant's skin). Dry skin with cracking and peeling of the superficial layers is common in postterm infants. Edema may be generalized (hydrops) or localized (eg, on the dorsum of the feet in Turner syndrome). Check for birthmarks such as capillary hemangiomas (lower occiput, eyelids, and forehead) and mongolian spots (bluish-black pigmentation over the back and buttocks). Milia (small white keratogenous cysts) are common on the cheeks, forehead, nose, and nasolabial folds. Miliaria (blocked ducts of sweat glands) occurs in intertriginous areas and on the face or scalp. Milia can also appear as small vesicles (crystallina), small erythematous papules (rubra), or pustules. Erythema toxicum is a benign rash characterized by fleeting erythematous papules and pustules filled with eosinophils. Pustular melanosis leaves pigmented macules when the pustules rupture. The pustules are noninfectious but contain

neutrophils. Jaundice in the first 24 hours is abnormal and should be evaluated.

Head

Check for cephalohematoma (a swelling over one or both parietal bones contained within suture lines) and caput succedaneum (edema over the presenting part that crosses suture lines). Subgaleal hemorrhages (beneath the scalp) are uncommon but can cause extensive blood loss into this large potential space with hypovolemic shock. Skull fractures may be linear or depressed and may be associated with cephalohematoma. Check for the presence and size of the fontanelles. The anterior fontanelle varies from 1–4 cm in any direction; the posterior fontanelle should be less than 1 cm. A third fontanelle is a bony defect along the sagittal suture in the parietal bones and may be seen in syndromes, such as trisomy 21. Sutures should be freely mobile, but are often overriding just after birth. Craniosynostosis, a prematurely fused suture, is more easily diagnosed a few days or more after birth.

Face

Odd facies may be associated with a specific syndrome. Bruising from birth trauma (especially with face presentation) and forceps application should be identified. Face presentation may cause soft tissue swelling around the nose and mouth and significant facial distortion. Facial nerve palsy is obvious during crying; the unaffected side of the mouth moves normally, giving a distorted grimace.

Eyes

Subconjunctival hemorrhages are a frequent result of birth trauma. Less commonly, a corneal tear may occur and present as a clouded cornea. Ophthalmologic consultation is indicated in such cases. Extraocular movements should be assessed. Occasional uncoordinated eye movements are common, but persistent irregular movements are abnormal. The iris should be inspected for abnormalities such as Brushfield spots (trisomy 21) and colobomas. Retinal red reflexes should be present and symmetrical. Dark spots, unilateral blunted red reflex, absent reflex, or a white reflex all require ophthalmologic evaluation. Leukokoria can be caused by glaucoma (cloudy cornea), cataract, or tumor (retinoblastoma). Infants with suspected or known congenital viral infection should have a retinoscopic examination with pupils dilated to look for chorioretinitis.

Nose

Examine the nose for size and shape. In utero compression can cause deformities. Because infants younger than 1 month of age are obligate nose breathers, any nasal obstruction (eg, bilateral choanal atresia or stenosis) can cause respiratory distress. Unilateral choanal atresia can be diagnosed by

occluding each naris. Patency is best checked by holding a cold metal surface (eg, a chilled laryngoscope blade) under the nose, and observing the fog from both nares on the metal. Purulent nasal discharge at birth suggests congenital syphilis.

Ears

Malformed or malpositioned (low-set or posteriorly rotated) ears are often associated with other congenital anomalies. The tympanic membranes should be visualized. Preauricular pits and tags are common minor variants but may be associated with hearing loss.

Mouth

Epithelial (Epstein) pearls are retention cysts along the gum margins and at the junction of the hard and soft palates. Natal teeth may be present and sometimes must be removed to prevent their aspiration. Check the integrity and shape of the palate. A small mandible and tongue with cleft palate is seen with Pierre Robin syndrome and can result in respiratory difficulty, as the tongue occludes the airway. Prone positioning can be beneficial. A prominent tongue can be seen in trisomy 21 and Beckwith-Wiedemann syndrome. Excessive oral secretions suggest esophageal atresia or a swallowing disorder.

Neck

Redundant neck skin or webbing is seen in Turner syndrome. Cervical sinus tracts may be seen as remnants of branchial clefts. Check for masses: midline (thyroid), anterior to the sternocleidomastoid (branchial cleft cysts), within the sternocleidomastoid (hematoma and torticollis), and posterior to the sternocleidomastoid (cystic hygroma).

Chest & Lungs

Check for fractured clavicles (crepitus, bruising, and tenderness). Increased anteroposterior diameter (barrel chest) can be seen with aspiration syndromes. Check air entry bilaterally and the position of the mediastinum and heart tones. Decreased breath sounds with respiratory distress and a shift in the mediastinum suggests pneumothorax (tension) or a space-occupying lesion (eg, diaphragmatic hernia). Pneumomediastinum causes muffling of the heart sounds. Expiratory grunting and decreased air entry are observed in hyaline membrane disease. Rales are not of clinical significance at this age.

Heart

Cardiac murmurs are common in the first hours and are most often benign. Severe congenital heart disease in the newborn infant may be present with no murmur at all. The two most common presentations of heart disease in the new-

born infant are (1) cyanosis and (2) congestive heart failure with abnormalities of pulses. In hypoplastic left heart and critical aortic stenosis, pulses are diminished at all sites. In aortic coarctation and interrupted aortic arch, pulses are diminished in the lower extremities. Examination of the newborn heart is described in detail in Chapter 19.

Abdomen

Check for softness, distention, and bowel sounds. If polyhydramnios was present or excessive oral secretions are noted, pass a soft catheter into the stomach to rule out esophageal atresia. Most abdominal masses in the newborn infant are associated with kidney disorders (eg, multicystic or dysplastic, and hydronephrosis). When the abdomen is relaxed, normal kidneys may be felt but are not prominent. A markedly scaphoid abdomen plus respiratory distress suggests diaphragmatic hernia. Absence of abdominal musculature (prune belly syndrome) may occur in association with renal abnormalities. The liver and spleen are superficial in the neonate and discernible by light palpation. A distended bladder may be seen and palpated above the pubic symphysis.

Genitalia & Anus

Male and female genitals show characteristics according to gestational age (see Table 1–1). In the female infant during the first few days, a whitish vaginal discharge with or without blood is normal. Check the patency and location of the anus.

Skeleton

Check for obvious anomalies such as absence of a bone, clubfoot, fusion or webbing of digits, and extra digits. Examine for hip dislocation by attempting to dislocate the femur posteriorly and then abducting the legs to relocate the femur. Look for extremity fractures and for palsies (especially brachial plexus injuries). Rule out myelomeningocele and other spinal deformities (eg, scoliosis). Arthrogryposis (multiple joint contractures) results from chronic limitation of movement in utero that may result from lack of amniotic fluid or from congenital neuromuscular disease.

Neurologic Examination

Normal newborns have reflexes that facilitate survival (eg, rooting and sucking reflexes), and sensory abilities (eg, hearing and smell) that allow them to recognize their mother within a few weeks of birth. Although the retina is well developed at birth, visual acuity is poor (20/400) because of a relatively immobile lens. Acuity improves rapidly over the first 6 months, with fixation and tracking becoming well developed by 2 months.

Observe the newborn's resting tone. Normal term newborns should exhibit flexion of the upper and lower extremities and symmetrical spontaneous movements. Extension of the extremities should result in spontaneous recoil to the

flexed position. Assess the character of the cry; a high-pitched cry may indicate disease of the central nervous system (CNS) such as hemorrhage. Hypotonia and a weak cry may indicate systemic disease or congenital neuromuscular disorder. Check the following newborn reflexes:

1. Sucking reflex in response to a nipple or the examiner's finger in the mouth. This reflex is observed by 14 weeks' gestation.
2. Rooting reflex: Head turns to the side of a facial stimulus. This reflex develops by 28 weeks' gestation.
3. Traction response: The infant is pulled by the arms to a sitting position. Initially, the head lags, then with active flexion, comes to the midline briefly before falling forward.
4. Palmar grasp with placement of the examiner's finger in the palm. This reflex develops by 28 weeks' gestation and disappears by age 4 months.
5. Deep tendon reflexes: Several beats of ankle clonus and an upgoing Babinski reflex may be normal.
6. Moro (startle) reflex: Hold the infant supine while supporting the head. Allow the head to drop 1–2 cm suddenly. The arms will abduct at the shoulder and extend at the elbow with spreading of the fingers. Adduction with flexion will follow. This reflex develops by 28 weeks' gestation (incomplete) and disappears by age 3 months.
7. Tonic neck reflex: Forcibly turn the infant's head to one side; the arm and leg on that side will extend while the opposite arm and leg flex ("fencing position"). This reflex disappears by age 8 months.

CARE OF THE WELL NEONATE

The primary responsibility of the Level 1 nursery is care of the well neonate—promoting mother-infant bonding, establishing feeding, and teaching the basics of newborn care. Staff must monitor infants for signs and symptoms of illness, including temperature instability, change in activity, refusal to feed, pallor, cyanosis, early or excessive jaundice, tachypnea, respiratory distress, delayed (beyond 24 hours) first stool or first void, and bilious vomiting. Several preventive measures are routine in the normal newborn nursery.

Prophylactic erythromycin ointment is applied to the eyes within 1 hour of birth to prevent gonococcal ophthalmia. Vitamin K (1 mg) is given intramuscularly or subcutaneously within 4 hours of birth to prevent hemorrhagic disease of the newborn.

All infants should receive hepatitis B vaccine. Both hepatitis B vaccine and hepatitis B immune globulin (HBIG) are administered if the mother is positive for hepatitis B surface antigen (HBsAg). If maternal HBsAg status is unknown, vaccine should be given, maternal blood should be tested for HBsAg, and HBIG should be given to the neonate before 7 days of age if the test is positive.

Cord blood is collected from all infants at birth and used for blood typing and Coombs testing if the mother is type O or Rh-negative.

Rapid glucose testing should be performed in infants at risk for hypoglycemia (infants of diabetic mothers, preterm, SGA, LGA, or stressed infants). Values below 45 mg/dL should be confirmed by laboratory blood glucose testing and treated. Hematocrit should be measured at age 3–6 hours in infants at risk for or those who have symptoms of polycythemia or anemia.

State-sponsored newborn genetic screens (for inborn errors of metabolism such as phenylketonuria [PKU], galactosemia, sickle cell disease, hypothyroidism, and cystic fibrosis) are performed prior to discharge, after 24–48 hours of age if possible. In many states, a repeat test is required at 8–14 days of age because the PKU test may be falsely negative when obtained before 48 hours of age. Not all state-mandated screens include the same panel of diseases. The most recent addition in some states is a screen for congenital adrenal hyperplasia. In infants with prolonged postpartum hospitalization, genetic screening should be performed by 1 week of age. In addition to the state-mandated screen, some centers offer expanded newborn screening by tandem mass spectrometry to look for other inborn errors such as fatty acid oxidation defects.

Infants should routinely be positioned supine to minimize the risk of sudden infant death syndrome (SIDS). Prone positioning is contraindicated unless there are compelling clinical reasons for that position. Bed sharing with adults and prone positioning are associated with increased risk of SIDS.

FEEDING THE WELL NEONATE

A neonate is ready for feeding if he or she is (1) alert and vigorous, (2) has no abdominal distention, (3) has good bowel sounds, and (4) has a normal hunger cry. These signs usually occur within 6 hours after birth, but fetal distress or traumatic delivery may prolong this period. The healthy full-term infant should be allowed to feed every 2–5 hours on demand. The first breast feeding may occur in the delivery room. For formula-fed infants, the first feeding usually occurs by 3 hours of life. The feeding volume generally increases from 0.5–1 oz per feeding initially to 1.5–2 oz per feeding on day 3. By day 3, the average full-term newborn takes about 100 mL/kg/d of milk.

A wide range of infant formulas satisfy the nutritional needs of most neonates. Breast milk is the standard on which

formulas are based (see Chapter 10). Despite low concentrations of several vitamins and minerals in breast milk, bioavailability is high. All the necessary nutrients, vitamins, minerals, and water are provided by human milk for the first 6 months of life except vitamin K (1 mg IM is administered at birth), vitamin D (200–300 IU/d is needed if minimal sunlight exposure), and vitamin B₁₂ (0.3–0.5 mg/d if the mother is a strict vegetarian and takes no B₁₂ supplement). Other advantages of breast milk include (1) immunologic, antimicrobial, and anti-inflammatory factors such as immunoglobulin A (IgA) and cellular, protein, and enzymatic components that decrease the incidence of upper respiratory and gastrointestinal infections; (2) possible decreased frequency and severity of childhood eczema and asthma; (3) improved mother-infant bonding; and (4) improved neurodevelopmental outcome.

Although about 70% of mothers in the United States start by breast feeding, only 33% continue to do so at 6 months. Hospital practices that facilitate successful initiation of breast feeding include rooming-in, nursing on demand, and avoiding unnecessary supplemental formula. Nursery staff must be trained to recognize problems associated with breast feeding and provide help and support for mothers in the hospital. An experienced professional should observe and assist with several feedings to document good latch-on. Good latch-on is important in preventing the common problems of sore nipples, unsatisfied infants, breast engorgement, poor milk supply, and hyperbilirubinemia.

Table 1–4 presents guidelines the nursing mother and health care provider can use to assess successful breast feeding.

EARLY DISCHARGE OF THE NEWBORN INFANT

Discharge at 24–36 hours of age is safe and appropriate for most newborns if there are no contraindications (Table 1–5) and if a follow-up visit within 48 hours is ensured. Most infants with cardiac, respiratory, or infectious disorders are identified in the first 12 hours of life. The exception may be the infant treated intrapartum with antibiotic prophylaxis for maternal group B streptococcal (GBS) colonization or

infection. The Centers for Disease Control and Prevention (CDC) and the American Academy of Pediatrics (AAP) recommend that such infants be observed in hospital for 48 hours because of the possibility of “partial treatment” and delayed onset of symptomatic infection. Recent data show that maternal antibiotics during labor do not change the type or timing of symptoms related to GBS infection in full-term infants. Thus, hospital observation beyond 24 hours may not be necessary for the asymptomatic full-term infant who received intrapartum chemoprophylaxis. Other problems, such as jaundice and breast-feeding problems, typically occur after 48 hours and can usually be dealt with on an outpatient basis.

The AAP recommends a follow-up visit within 48 hours for all newborns discharged before 72 hours of age. Infants who are small or slightly premature—especially if breast feeding—are at particular risk for inadequate intake. Suggested guidelines for the follow-up interview and physical examination are presented in Table 1–6. The optimal timing of discharge must be determined in each case based on medical, social, and financial factors.

CIRCUMCISION

Circumcision is an elective procedure to be performed only in healthy, stable infants. The procedure has medical benefits, including prevention of phimosis, paraphimosis, balanoposthitis, and urinary tract infection. Important later benefits of circumcision include decreased incidence of penile cancer, decreased incidence of sexually transmitted diseases (including HIV), and decreased incidence of cervical cancer in female sexual partners. Most parental decisions regarding circumcision are religious and social, not medical. The risks of circumcision include local infection, bleeding, removal of too much skin, and urethral injury. The combined incidence of complications is less than 1%. Local anesthesia by dorsal penile nerve block or circumferential ring block using 1% lidocaine without epinephrine, or topical anesthetic cream are safe and effective methods that should always be used. Techniques allowing visualization of the glans throughout the procedure (Plastibell and Gomco clamp) are preferred to blind techniques (Mogen clamp) as occasional amputation of the glans occurs with the latter technique. Circumcision is contraindicated in infants with genital abnormalities (eg, hypospadias). A coagulation screen should be performed prior to the procedure in infants with a family history of serious bleeding disorders.

HEARING SCREENING

Normal hearing is critical to normal language development. Significant bilateral hearing loss is present in 1–3 infants per 1000 well neonates and in 2–4 per 100 neonates in the intensive care unit population. Infants should be screened for hearing loss by auditory brainstem evoked responses or

Table 1-4. Guidelines for successful breast feeding.

	First 8 Hours	First 8-24 Hours	Day 2	Day 3	Day 4	Day 5	Day 6 Onward
Milk supply	You may be able to express a few drops of milk.		Milk should come in between the second and fourth days.			Milk should be in. Breasts may be firm or leak milk.	Breasts should feel softer after feedings.
Baby's activity	Baby is usually wide-awake in the first hour of life. Put baby to breast within 30 min after birth.	Wake up your baby. Babies may not wake up on their own to feed.	Baby should be more cooperative and less sleepy.	Look for early feeding cues such as rooting, lip smacking, and hands to face.			Baby should appear satisfied after feedings.
Feeding routine	Baby may go into a deep sleep 2-4 h after birth.	Feed your baby every 1-4 h or as often as wanted—at least 8-12 times a day.			Use chart to write down time of each feeding.	May go one longer interval (up to 5 h between feeds) in a 24-h period.	
Breast feeding	Baby will wake up and be alert and responsive for several more hours after initial deep sleep.	As long as the mother is comfortable, nurse at both breasts as long as baby is actively sucking.	Try to nurse both sides each feeding, aiming at 10 min per side. Expect some nipple tenderness.	Consider hand expressing or pumping a few drops of milk to soften the nipple if the breast is too firm for the baby to latch on.	Nurse a minimum of 10-30 min per side every feeding for the first few weeks of life. Once milk supply is well established, allow baby to finish the first breast before offering the second.		Mother's nipple tenderness is improving or is gone.
Baby's urine output		Baby must have a minimum of one wet diaper in the first 24 h.	Baby must have at least one wet diaper every 8-11 h.	You should see an increase in wet diapers (up to four to six) in 24 h.	Baby's urine should be light yellow.	Baby should have six to eight wet diapers per day of colorless or light yellow urine.	
Baby's stool		Baby may have a second very dark (meconium) stool.	Baby may have a second very dark (meconium) stool.	Baby's stools should be in transition from black-green to yellow.	Baby should have three or four yellow, seedy stools a day.	The number of stools may decrease gradually after 4-6 weeks of life.	

Modified, with permission, from Gabrielski L: Lactation support services. The Children's Hospital, Denver, 1999.

Table 1-5. Contraindications to early newborn discharge.

Contraindications to early newborn discharge

1. Jaundice at ≤ 24 h
2. High risk for infection (eg, maternal chorioamnionitis); discharge allowed after 24 h with a normal transition
3. Known or suspected narcotic addiction or withdrawal
4. Physical defects requiring evaluation
5. Oral defects (clefts, micrognathia)

Relative contraindications to early newborn discharge (infants at high risk for feeding failure, excessive jaundice)

1. Prematurity or borderline prematurity (< 38 weeks' gestation)
2. Birth weight < 2700 g (6 lb)
3. Infant difficult to arouse for feeding; not demanding regularly in nursery
4. Medical or neurologic problems that interfere with feeding (Down syndrome, hypotonia, cardiac problems)
5. Twins or higher multiples
6. ABO blood group incompatibility or severe jaundice in previous child
7. Mother whose previous breast-fed infant gained weight poorly
8. Mother with breast surgery involving periareolar areas (if attempting to nurse)

evoked otoacoustic emissions as early as possible because up to 40% of hearing loss will be missed by risk analysis alone. Primary care providers and parents should be advised of the possibility of hearing loss and offered immediate referral in suspect cases. With the use of universal screening, the average age at which hearing loss is confirmed has dropped from 24–30 months to 2–3 months. If remediation is begun by 6 months, language and social development are commensurate with physical development.

COMMON PROBLEMS IN THE TERM NEWBORN

NEONATAL JAUNDICE

► General Considerations

Sixty-five percent of newborns develop visible jaundice with a total serum bilirubin (TSB) level higher than 6 mg/dL during the first week of life. The normal newborn is deficient in antioxidants such as vitamin E, catalase, and superoxide dismutase. Bilirubin is a potent antioxidant and peroxyl scavenger and may protect the newborn from oxygen toxicity in the

first days of life. Approximately 8–10% of newborns develop excessive hyperbilirubinemia (TSB > 17 mg/dL), and 1–2% have TSB above 20 mg/dL. Extremely high and potentially dangerous TSB levels are rare. Approximately 1 in 700 infants have TSB higher than 25 mg/dL, and 1 in 10,000 have TSB above 30 mg/dL. Such high levels can cause kernicterus, characterized by injury to the basal ganglia and brainstem.

Kernicterus caused by hyperbilirubinemia was common in neonates with Rh-isoimmunization until the institution of exchange transfusion for affected infants and postpartum high-titer Rho (D) immune globulin treatment for sensitized mothers. For several decades after the introduction of exchange transfusion and phototherapy aimed at keeping the neonate's TSB below 20 mg/dL, there were no reported cases of kernicterus in the United States. Since the early 1990s, however, there has been a reappearance of kernicterus, with more than 120 cases reported to a voluntary registry. Common factors in the recent cases are newborn discharge before 48 hours (all but one), breast feeding (100%), delayed measurement of TSB, unrecognized hemolysis, lack of early postdischarge follow-up, and failure to recognize the early symptoms of encephalopathy.

Bilirubin is produced by the breakdown of heme (iron protoporphyrin) in the reticuloendothelial system and bone marrow. Heme is cleaved by heme oxygenase to iron, which is conserved; carbon monoxide, which is exhaled; and biliverdin, which is converted to bilirubin by biliverdin reductase. Each gram of hemoglobin yields 34 mg of bilirubin (1 mg/dL = 17.2 mmol/L of bilirubin). This unconjugated bilirubin is bound to albumin and carried to the liver, where it is taken up by hepatocytes. In the presence of the uridyldiphosphoglucuronyl transferase (UDPGT; glucuronyl transferase), bilirubin is conjugated to one or two glucu-

Table 1-6. Guidelines for early outpatient follow-up evaluation.

History

- Rhythmic sucking and audible swallowing for at least 10 min total per feeding?
- Infant wakes and demands to feed every 2–3 h (at least 8–10 feedings per 24 h)?
- Do breasts feel full before feedings, and softer after?
- Are there at least 6 noticeably wet diapers per 24 h?
- Are there yellow bowel movements (no longer meconium)—at least 4 per 24 h?
- Is infant still acting hungry after nursing (frequently sucks hands, rooting)?

Physical assessment

- Weight, unclothed: should not be more than 8–10% below birth weight
- Extent and severity of jaundice
- Assessment of hydration, alertness, general well-being
- Cardiovascular examination: murmurs, brachial and femoral pulses, respirations

▲ **Figure 1-2.** Risk designation of full-term and near-term newborns based on their hour-specific bilirubin values. (Reproduced, with permission, from Bhutani VK et al: Predictive ability of a pre-discharge hour-specific serum bilirubin test for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. *Pediatrics* 1999;103:6.)

ronide molecules. Conjugated bilirubin is then excreted through the bile to the intestine. In the presence of normal gut flora, conjugated bilirubin is metabolized to stercobilins and excreted in the stool. Absence of gut flora and slow gastrointestinal (GI) motility, both characteristic of the newborn, cause a build up of conjugated bilirubin in the intestinal lumen, where mucosal β -glucuronidase removes the glucuronide molecules and leaves unconjugated bilirubin to be reabsorbed (enterohepatic circulation).

Excess accumulation of bilirubin in blood depends on both the rate of bilirubin production and the rate of excretion. It is best determined by reference to an hour-specific TSB level above the 95th percentile for age in hours (Figure 1-2).

1. Physiologic Jaundice

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Visible jaundice appearing after 24 hours of age.
- ▶ Total bilirubin rises by < 5 mg/dL (86 mmol/L) per day.

- ▶ Peak bilirubin occurs at 3-5 days of age, with a total bilirubin of no more than 15 mg/dL (258 mmol/L).
- ▶ Visible jaundice resolves by 1 week in the full-term infant and by 2 weeks in the preterm infant.

Factors contributing to physiologic jaundice in neonates include low UDPGT activity, relatively high red cell mass, absence of intestinal flora, slow intestinal motility and increased enterohepatic circulation of bilirubin. Hyperbilirubinemia outside of the ranges noted in Figure 1-2 is not physiologic and requires further evaluation.

2. Pathologic Unconjugated Hyperbilirubinemia

Pathologic unconjugated hyperbilirubinemia can be grouped into two main categories: overproduction of bilirubin or decreased conjugation of bilirubin (Table 1-7). The TSB is a reflection of the balance between these processes. Visible jaundice with a TSB greater than 5 mg/dL before 24 hours of age is most commonly a result of significant hemolysis.

Table 1-7. Causes of pathologic unconjugated hyperbilirubinemia.

Overproduction of bilirubin

1. Hemolytic causes of increased bilirubin production (reticulocyte count elevated)
 - a. Immune-mediated: positive direct antibody (DAT, Coombs) test
 - ABO blood group incompatibility, Rh incompatibility, minor blood group incompatibility
 - b. Nonimmune: negative direct antibody (DAT, Coombs) test
 - Abnormal red cell shapes: spherocytosis, elliptocytosis, pyknotocytosis, stomatocytosis
 - Red cell enzyme abnormalities: glucose-6-phosphate dehydrogenase deficiency, pyruvate kinase deficiency, hexokinase deficiency, other metabolic defects
 - c. Patients with bacterial or viral sepsis
2. Nonhemolytic causes of increased bilirubin production (reticulocyte count normal)
 - a. Extravascular hemorrhage: cephalohematoma, extensive bruising, intracranial hemorrhage
 - b. Polycythemia
 - c. Exaggerated enterohepatic circulation of bilirubin: bowel obstruction, functional ileus
 - d. Breast milk-associated jaundice (“lack of breast milk jaundice”)

Decreased rate of conjugation

1. Crigler-Najjar syndrome
 - a. Type I glucuronyl transferase deficiency, autosomal-recessive
 - b. Type II glucuronyl transferase deficiency, autosomal-dominant
2. Gilbert syndrome
3. ?Hypothyroidism

A. Increased Bilirubin Production

Increased bilirubin production may be caused by pathologic destruction of neonatal red blood cells. Destruction may be mediated by maternal antibodies (Coombs test–positive), abnormal red cell membranes (spherocytosis), or abnormal red cell enzymes (glucose-6-phosphate dehydrogenase [G6PD] deficiency) causing decreased red cell life span. Antibodies can be directed against the major blood group antigens (type A or type B infant of a type O mother) or the minor antigens of the Rh system (D, E, C, d, e, c, Kell, Duffy, and others).

1. Antibody-mediated hemolysis (Coombs test–positive)

A. ABO BLOOD GROUP INCOMPATIBILITY—This finding can accompany any pregnancy in a type O mother. Hemolysis is usually mild, but the severity is unpredictable because of variability in the amount of naturally occurring maternal anti-A or anti-B IgG antibodies. Although 20% of pregnancies are “set-ups” for ABO incompatibility (mother O, infant A or B), only 33% of infants in such cases have a positive direct Coombs test and only 20% of these develop jaundice that requires therapy. Persistent maternal antibodies may cause the newborn to gradually become anemic over the first few weeks of life, even to the point of requiring transfusion.

B. RH ISOIMMUNIZATION—This finding is less common than ABO incompatibility. It increases in severity with each immunized pregnancy because of increased maternal IgG antibody production. Most Rh disease can be prevented by giving high-titer Rho (D) immune globulin to the Rh-negative woman after invasive procedures during pregnancy or after miscarriage, abortion, or delivery of an Rh-positive infant. Neonates are often anemic at birth, and hemolysis rapidly causes hyperbilirubinemia and more severe anemia. The most severe form of Rh isoimmunization, erythroblastosis fetalis, is characterized by life-threatening anemia, generalized edema, and fetal or neonatal heart failure. Without antenatal intervention, fetal or neonatal death may result. The cornerstone of antenatal management is transfusion of the fetus with Rh-negative cells, either directly into the umbilical vein or into the fetal abdominal cavity. Phototherapy is usually started in these infants upon delivery, with exchange transfusion given if needed. Intravenous immune globulin (IVIG; 0.5–1 g/kg) given to the infant as soon as the diagnosis is made decreases the need for exchange transfusion. Ongoing hemolysis occurs until all maternal antibody is gone; therefore, these infants require monitoring for 2–3 months for anemia severe enough to require transfusion.

2. Nonimmune hemolysis (Coombs test–negative)

A. HEREDITARY SPHEROCYTOSIS—This condition is the most common of the red cell membrane defects and causes hemolysis by decreasing red cell deformability. Affected infants may have hyperbilirubinemia severe enough to require exchange transfusion. Splenomegaly may be present. Diagnosis is suspected by peripheral blood smear and family history. Because spherocytes are seen in any hemolytic process, confirmation of diagnosis by osmotic fragility testing is required after 2–3 months of age.

B. G6PD DEFICIENCY—This condition is the most common red cell enzyme defect causing hemolysis, especially in infants of African, Mediterranean, or Asian descent. Onset of jaundice is at about 7 days of age, which is later than in physiologic jaundice and isoimmune hemolytic disease. The role of G6PD deficiency in neonatal jaundice is probably underestimated as up to 10–13% of African Americans are G6PD-deficient. Although the disorder is X-linked, even female heterozygotes are at increased risk of hyperbilirubinemia. In most cases, no triggering agent for hemolysis is found. Some infants who develop severe jaundice with G6PD deficiency have been found to have concomitant Gilbert syndrome. Their bilirubin production is exaggerated by a decreased rate of bilirubin conjugation. G6PD enzyme activity is high in reticulocytes. Thus, neonates with a large number of reticulocytes may have falsely normal enzyme tests. A low G6PD level should always raise suspicions. Repeat testing in suspect cases with initially normal results is indicated at 2–3 months of age.

3. Nonhemolytic increased bilirubin production—Enclosed hemorrhage, such as cephalohematoma, intracranial hemorrhage, or extensive bruising in the skin, can lead

to jaundice. Polycythemia leads to jaundice by increased red cell mass, with increased numbers of cells reaching senescence daily. Ileus, either paralytic or mechanical, related to bowel obstruction, leads to increased enterohepatic circulation.

B. Decreased Rate of Conjugation

1. UDPGT deficiency: Crigler-Najjar syndrome type I (complete deficiency, autosomal recessive) and type II (partial deficiency, autosomal dominant)—These two conditions result from mutations in the exon or encoding region of the UDPGT gene that cause complete or nearly complete absence of enzyme activity. Both are rare but can cause severe unconjugated hyperbilirubinemia, bilirubin encephalopathy, and death if untreated. In type II, the enzyme can be induced with phenobarbital, which may lower bilirubin levels by 30–80%. Liver transplantation is curative (see Chapter 21).

2. Gilbert syndrome—This is a mild autosomal dominant disorder characterized by decreased hepatic UDPGT activity caused by genetic polymorphism at the promoter region of the UDPGT gene. Approximately 9% of the population is homozygous, and 42% is heterozygous, with a gene frequency of 0.3. Affected individuals tend to develop hyperbilirubinemia in the presence of conditions that increase bilirubin load. They are also more likely to have prolonged neonatal jaundice and breast milk jaundice.

C. Hyperbilirubinemia Caused by Unknown or Multiple Factors

1. Racial differences—Asians (23%) are more likely than whites (10–13%) or African Americans (4%) to have a peak neonatal TSB greater than 12 mg/dL (206 mmol/L). Some of these differences result from racial variations in prevalence of UDPGT gene polymorphisms or associated G6PD deficiency.

2. Prematurity—Premature infants often have poor enteral intake, delayed stooling, and increased enterohepatic circulation. Red cell life span is shorter in premature infants. Infants at 35–36 weeks' gestation are 13 times more likely than term infants to be readmitted for hyperbilirubinemia. Even near-term infants (37 weeks' gestation) are four times more likely than term neonates to have TSB greater than 13 mg/dL (224 mmol/L).

3. Breast feeding and jaundice

A. BREAST MILK JAUNDICE—Unconjugated hyperbilirubinemia lasting until 2–3 months of age is common in breast-fed infants. An increased prevalence of the Gilbert syndrome promoter genotype is likely involved. Moderate unconjugated hyperbilirubinemia for 6–12 weeks in a thriving breast-fed infant without evidence of hemolysis, hypothyroidism, or other disease strongly suggests this diagnosis.

Table 1–8. Signs of inadequate breast milk intake.

Weight loss of > 8–10% from birth Fewer than six noticeably wet diapers per 24 h by day 3–4 Fewer than four stools per day, or still meconium, by day 3–4 Nursing fewer than eight times per 24 h, or for less than 10 min each feeding
--

B. BREAST FEEDING—ASSOCIATED JAUNDICE—This common entity is also called “lack-of-breast-milk jaundice.” Breast-fed infants have a higher incidence (9%) of unconjugated serum bilirubin levels greater than 13 mg/dL (224 mmol/L) than do formula-fed infants (2%) and are more likely to have bilirubin greater than 15 mg/dL (258 mmol/L) than formula-fed infants (2% versus 0.3%). The pathogenesis is probably poor enteral intake and increased enterohepatic circulation. There is no apparent increase in bilirubin production as measured by carbon monoxide exhalation. Although rarely severe enough to cause bilirubin encephalopathy, nearly 100% of the infants with kernicterus reported to the registry were breast fed, and in 50%, breast feeding was the only known risk factor. Excessive jaundice should be considered a possible sign of failure to establish adequate milk supply and should prompt specific inquiries (Table 1–8). If intake is inadequate, the infant should receive supplemental formula and the mother should be instructed to nurse more frequently and to use an electric breast pump every 2 hours to enhance milk production. Consultation with a lactation specialist should be considered. Because hospital discharge of normal newborns occurs before the milk supply is established and before jaundice peaks, a follow-up visit 2 days after discharge is recommended by the AAP to evaluate adequacy of intake and jaundice.

3. Bilirubin Toxicity

Unconjugated bilirubin anion is the agent of bilirubin neurotoxicity. The anion binds to the phospholipids (gangliosides) of neuronal plasma membranes causing injury, which then allows more anion to enter the neuron. Intracellular bilirubin anion binds to the membrane phospholipids of subcellular organelles, causing impaired energy metabolism, altered excitatory amino acid homeostasis, excitotoxic neuronal injury, and cell death. The blood-brain barrier undoubtedly has a role in protecting the infant from brain damage, but its integrity is impossible to measure clinically. The amount of albumin available to bind the unconjugated bilirubin anion and the presence of other anions that may displace bilirubin from albumin binding sites are also important. It is unknown whether there is a fixed level of bilirubin above which brain damage always occurs. The term *kernicterus* describes the pathologic finding of staining of basal ganglia and brainstem nuclei, as well as the chronic brain injury. The term *acute bilirubin encephalopathy* describes the signs and symptoms of brain damage in the newborn.

Table 1-9. BIND scoring system.

	1 Point (Nonspecific, Subtle)	2 Points (Progressive Toxicity)	3 Points (Advanced Toxicity)
Mental status	Sleepy, poor feeding	Lethargy + irritability	Semi-coma, seizures, apnea
Muscle tone	Slight decrease	Hypertonia or hypotonia, depending on arousal state or Mild arching	Markedly increased (opisthotonus) or decreased or Bicycling
Cry	High-pitched	Shrill	Inconsolable

BIND, bilirubin-induced neurologic dysfunction.

Adapted, with permission, from Bhutani VK, Johnson LH, Keren R: Treating acute bilirubin encephalopathy—before it's too late. *Contemp Pediatr* 2005;22:57.

The risk of bilirubin encephalopathy is small in healthy, term neonates even at bilirubin levels of 25–30 mg/dL (430–516 mmol/L). Risk depends on the duration of hyperbilirubinemia, the concentration of serum albumin, associated illness, acidosis, and the concentrations of competing anions such as sulfisoxazole and ceftriaxone. Premature infants are at greater risk than term infants because of the greater frequency of associated illness affecting the integrity of the blood-brain barrier, reduced albumin levels, and decreased affinity of albumin binding sites. For these reasons, the “exchange level” in premature infants may be lower than that of a term infant.

Correlation between TSB and level of neurotoxicity is poor. Although 65% of cases reported to the registry had TSB levels above 35 mg/dL, 15% had levels below 30 mg/dL, and 8% were below 25 mg/dL. Measurement of free, unbound, unconjugated bilirubin (B_f) may be a more meaningful predictor of risk for brain injury, although this test is not widely available. Currently the best means of assessing neurotoxicity may be the auditory brainstem evoked response, which shows predictable, early effects of bilirubin toxicity.

4. Acute Bilirubin Encephalopathy

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Lethargy, poor feeding.
- ▶ Irritability, high-pitched cry.
- ▶ Arching of the neck (retrocollis) and trunk (opisthotonus).
- ▶ Apnea, seizures, coma (late).

Newborns infants may be described as “sleepy and not interested in feeding.” Although these symptoms are non-specific, they are also the earliest signs of acute bilirubin encephalopathy and should trigger detailed evaluation of the jaundiced infant’s birth and postnatal history, feeding

and elimination history, and perhaps an urgent assessment for signs of bilirubin-induced neurologic dysfunction (BIND). A scoring system has been proposed (Table 1–9) to monitor the severity and progression of bilirubin encephalopathy. A score of 4–6 indicates progressive encephalopathy likely to be reversible with aggressive treatment, whereas a score of 7–9 represents advanced and possibly irreversible damage.

5. Chronic Bilirubin Encephalopathy (Kernicterus)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Extrapyramidal movement disorder (choreoathetoid cerebral palsy).
- ▶ Gaze abnormality, especially limitation of upward gaze.
- ▶ Auditory disturbances (deafness, failed auditory brainstem evoked response with normal evoked otoacoustic emissions, auditory neuropathy, auditory dyssynchrony).
- ▶ Dysplasia of the enamel of the deciduous teeth.

Kernicterus is an irreversible brain injury characterized by choreoathetoid cerebral palsy and hearing impairment. Intelligence is probably normal but may be difficult to assess because of associated hearing, communication, and coordination problems. The diagnosis is clinical but is strengthened if audiologic testing shows auditory neuropathy and auditory dyssynchrony in which the otoacoustic emission test is normal but the auditory brainstem response is absent. Infants with such findings are usually deaf. Infants with milder kernicterus may have normal audiograms but abnormal auditory processing and subsequent problems with speech comprehension. Magnetic resonance imaging (MRI) scanning of the brain is nearly diagnostic if it shows abnormalities isolated to the globus pallidus or the subthalamic nuclei, or both.

Evaluation of Hyperbilirubinemia

Because most newborns are discharged at 24–48 hours of age, before physiologic jaundice peaks and before maternal milk supply is established, a predischarge TSB or a transcutaneous bilirubin measurement (TcB) may help predict which infants are at risk for severe hyperbilirubinemia. In all infants, an assessment of risk for severe hyperbilirubinemia should be performed before discharge (Table 1–10). As recommended by the AAP, follow-up within 24–48 hours for all infants discharged before 72 hours of age (depending on the number of risk factors present) is imperative. Although jaundice is usually visible above a TSB level of 5 mg/dL (86 mmol/L), visual estimation of the bilirubin level is inaccurate. TSB should be measured and interpreted based on the age of the infant in hours at the time of sampling. Infants with a TSB level greater than the 95th percentile for age in hours have a 40% risk of developing significant hyperbilirubinemia (see Figure 1–2). Serial bilirubin levels should be obtained from a single laboratory whenever possible to make interpretation of serial measurements more meaningful.

Infants with visible jaundice on the first day of life or who develop excessive jaundice require further evaluation. The minimal evaluation consists of:

- Feeding and elimination history.
- Birth weight and daily weight change since birth.
- Examination for sources of excessive heme breakdown.
- Assessment of blood type, Coombs testing, complete blood count (CBC) with smear, serum albumin, and TSB.
- G6PD test if jaundice presents later than usual, and in African-American infants with severe jaundice.
- Fractionated bilirubin level in infants who appear ill, those with prolonged jaundice, acholic stool, or dark urine

Treatment of Indirect Hyperbilirubinemia

A. Protoporphyrins

Tin and zinc protoporphyrin or mesoporphyrin (Sn-PP, Zn-PP; Sn-MP, Zn-MP) are inhibitors of heme oxygenase, the enzyme that initiates the catabolism of heme (iron protoporphyrin). Studies are underway involving a single injection of these substances shortly after birth to prevent the formation of bilirubin. Although results are promising, these drugs are not yet approved for use in the United States.

B. Phototherapy

Phototherapy is the most common treatment for indirect hyperbilirubinemia. It is relatively noninvasive and safe. Light of wavelength 425–475 nm (blue-green spectrum) is absorbed by unconjugated bilirubin in the skin and converted to a water-soluble stereoisomer that can be excreted in bile without conjugation. The minimum effective light dose is

Table 1–10. Factors affecting the risk of severe hyperbilirubinemia in infants 35 or more weeks' gestation (in approximate order of importance).

Major risk factors

- Predischarge TSB or TcB level in the high-risk zone (> 95th percentile; see Figure 1–2)
- Jaundice observed in the first 24 h
- Blood group incompatibility with positive direct Coombs test, other known hemolytic disease (eg, G6PD deficiency), or elevated ETCO
- Gestational age 35–36 weeks
- Previous sibling required phototherapy
- Cephalohematoma or significant bruising
- Exclusive breast feeding, particularly if weight loss is excessive
- East Asian race^a

Minor risk factors

- Predischarge TSB or TcB level in the high-intermediate risk zone (75–95th percentile)
- Gestational age 37–38 weeks
- Jaundice observed before discharge
- Previous sibling with jaundice
- Macrosomic infant of a diabetic mother

Decreased risk (these factors are associated with decreased risk of significant jaundice, listed in order of decreasing importance)

- TSB or TcB level in the low-risk zone (see Figure 1–2)
- Gestational age ≥ 41 weeks
- Exclusive bottle feeding
- Black race^a
- Discharge from hospital after 72 h

^aRace as defined by mother's description.

ETCO, end-tidal carbon monoxide; G6PD, glucose-6-phosphate dehydrogenase; TcB, transcutaneous bilirubin; TSB, total serum bilirubin.

10–14 $\mu\text{W}/\text{cm}^2$ irradiance. Intensive phototherapy employs irradiance of 30 $\mu\text{W}/\text{cm}^2$ or higher. Irradiance can be increased by increasing the exposed body surface area or by moving the light source closer to the infant. Special blue fluorescent tubes labeled F20 T12/BB or TL52/20W are most commonly used. Fiberoptic blankets are useful as adjuncts but are not adequate as sole therapy for term infants because they do not cover sufficient surface area. Intensive phototherapy should decrease TSB by 30–40% in the first 24 hours, most significantly in the first 4–6 hours. The infant's eyes should be shielded to prevent retinal damage. Diarrhea, which sometimes occurs during phototherapy, can be treated if necessary by feeding a non-lactose-containing formula.

Phototherapy is started electively when the TSB is approximately 5 mg/dL (86 mmol/L) lower than the exchange level for that infant (eg, at 15–18 mg/dL [258–310 mmol/L] for a full-term infant). AAP guidelines for phototherapy and exchange transfusion in infants of 35 or more weeks' gestation are shown in Figures 1–3 and 1–4. Hyperbilirubinemic infants should be fed by mouth if possible to decrease enterohepatic bilirubin circulation. Casein hydrolysate formula to supplement breast milk decreases enterohepatic circulation by inhibiting mucosal β -glucuronidase

- Use total bilirubin, Do not subtract direct reacting of conjugated bilirubin.
- Risk factors = isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin < 3.0 g/dL (if measured).
- For well infants 35–37 6/7 wk can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 wks and at higher TSB levels for those closer to 37 6/7 wk.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2–3 mg/dL (35–50 μmol/L) below those shown but home phototherapy should not be used in any infant with risk factors.

▲ Figure 1-3. Guidelines for phototherapy in hospitalized infants of 35 or more weeks' gestation. These guidelines are based on limited evidence and levels shown are approximations. The guidelines refer to the use of intensive phototherapy (at least $30 \mu\text{W}/\text{cm}^2$ in the blue-green spectrum), which should be used when the total serum bilirubin (TSB) exceeds the line indicated for each category. If TSB approaches the exchange level, the sides of the incubator or bassinet should be lined with aluminum foil or white material. (Reproduced, with permission, from the AAP Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 2004;114:297.)

activity. IVIG (0.5–1.0 g/kg) in severe antibody-mediated hemolysis interrupts the hemolytic process. Although phototherapy has been shown to decrease the need for exchange transfusion, its long-term benefits, if any, in infants with less severe jaundice are unknown.

C. Exchange Transfusion

Although most infants with indirect hyperbilirubinemia can be treated with phototherapy, extreme indirect hyperbilirubinemia is a medical emergency. Infants should be admitted at once to a neonatal intensive care unit where exchange transfusion can be performed before irreversible neurologic damage occurs. Intensive phototherapy should be instituted immediately, during transport to the hospital if possible.

Double-volume exchange transfusion (approximately 160–200 mL/kg body weight) is most often used in infants with extreme hyperbilirubinemia secondary to Rh isoimmunization, ABO incompatibility, or hereditary spherocytosis. The procedure decreases serum bilirubin acutely by approximately 50% and removes about 80% of sensitized or abnormal

red blood cells and offending antibody so that ongoing hemolysis is decreased. Exchange transfusion is also indicated in any infant with TSB above 30 mg/dL, in infants with signs of encephalopathy, or when intensive phototherapy has not lowered TSB by at least 0.5 mg/dL/h after 4 hours. The decision to perform exchange transfusion should be based on TSB, not on the indirect fraction of bilirubin.

As TSB nears the potentially toxic range, serum albumin should be determined. Albumin (1 g/kg) will aid in binding and removal of bilirubin during exchange transfusion. Table 1–11 illustrates the bilirubin/albumin ratios at which exchange transfusion should be considered.

Exchange transfusion is invasive, risky, and infrequently performed. It should therefore be performed at a referral center. Mortality is 1–5% and is greatest in the smallest, most immature, and unstable infants. Sudden death during the procedure can occur in any infant. There is a 5–10% risk of serious complications such as necrotizing enterocolitis (NEC), infection, electrolyte disturbances, or thrombocytopenia. Isovolemic exchange (withdrawal through an arterial

- The dashed lines for the first 24 hours indicate uncertainty due a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocolitis, opisthotonos, fever, high pitched cry) or if TSB is ≥ 5 mg/dL (85 $\mu\text{mol/L}$) above these lines.
- Risk factors—isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin and calculate B/A ratio (see legend).
- Use total bilirubin. Do not subtract direct reading or conjugated bilirubin.
- If infant is well and 35–37 6/7 wk (median risk) can individualize TSB levels for exchange based on actual gestational age.

▲ **Figure 1-4.** Guidelines for exchange transfusion in infants of 35 or more weeks' gestation. These guidelines represent approximations for which an exchange transfusion is indicated in infants treated with intensive phototherapy. For readmitted infants, if the total serum bilirubin (TSB) level is above the exchange level, repeat TSB measurement every 2–3 hours and consider exchange if the TSB remains above the level after 6 hours of intensive phototherapy. The total serum bilirubin/albumin ratio (TSB [mg/dL]/Alb [g/dL]; 8.0 for infants at lower risk, 7.2 for medium risk, and 6.8 for higher risk) can be used together with, but not in lieu of the TSB level as an additional factor in determining the need for transfusion. If the TSB is at or approaching exchange level, send blood for an immediate type and crossmatch. HYPOGLYCEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Defined as blood glucose < 45 mg/dL.
- ▶ LGA, SGA, preterm, and stressed infants at risk.

- ▶ May be asymptomatic.
- ▶ Infants can present with lethargy, poor feeding, irritability, or seizures.

▶ General Considerations

Blood glucose concentration in the fetus is approximately 15 mg/dL less than maternal glucose concentration. Glucose concentration decreases in the immediate postnatal period. Concentrations below 45 mg/dL are considered hypoglycemic. By 3 hours, the glucose concentration in normal full-term infants stabilizes between 50 and 80 mg/dL. The two groups of full-term newborn infants at high risk for hypoglycemia are infants of diabetic mothers (IDMs) and IUGR infants.

A. Infants of Diabetic Mothers

The IDM has abundant glucose stores in the form of glycogen and fat but develops hypoglycemia because of hyperinsulinemia induced by maternal and fetal hyperglycemia. Increased energy supply to the fetus from the maternal circulation results in a macrosomic infant. The large infant is at increased risk for trauma during delivery. Some infants have cardiomyopathy (asymmetrical septal hypertrophy) which may present with murmur, respiratory distress or cardiac failure. Microcolon is occasionally present in IDMs and causes symptoms of low intestinal obstruction similar to Hirschsprung disease. Other neonatal problems include hypercoagulability and polycythemia, a combination that predisposes the infant to large vein thromboses (especially the renal vein). IDMs are often somewhat immature for their gestational age and are at increased risk for hyaline membrane disease, hypocalcemia, and hyperbilirubinemia. Infants of mothers who were diabetic at conception have a higher incidence of congenital anomalies, probably related to first-trimester glucose control.

Table 1-11. Additional guidelines for exchange transfusion: effects of albumin.

Risk Category	Bilirubin/Albumin Ratio at Which to Consider Exchange Transfusion (TSB [mg/dL]:Albumin [g/dL])
Infants > 38 weeks and well	8.0
Infants 35–38 weeks and well, or > 38 weeks with higher risk (hemolysis, G6PD, sepsis, acidosis)	7.2
Infants 35–38 weeks with higher risk, as above	6.8

G6PD, glucose-6-phosphate dehydrogenase; TSB, total serum bilirubin.

B. Intrauterine Growth-Restricted Infants

The IUGR infant has reduced glucose stores in the form of glycogen and body fat and is prone to hypoglycemia. In addition, marked hyperglycemia and a transient diabetes mellitus–like syndrome occasionally develop, particularly in the very premature IUGR infant. These problems usually respond to adjustment in glucose intake, although insulin is sometimes needed transiently. Some IUGR infants have hyperinsulinemia that persists for a week or more.

C. Other Causes of Hypoglycemia

Hypoglycemia occurs in disorders with islet cell hyperplasia. These include the Beckwith-Wiedemann syndrome, erythroblastosis fetalis, genetic forms of hyperinsulinism, inborn errors of metabolism such as glycogen storage disease and galactosemia, and endocrine disorders such as panhypopituitarism and counterregulatory hormone deficiency. Hypoglycemia also occurs, probably secondary to stress, in infants with birth asphyxia, hypoxia, and bacterial and viral sepsis. Premature infants are at risk for hypoglycemia because of decreased glycogen stores.

▶ Clinical Findings

The signs of hypoglycemia in the newborn infant may be nonspecific and subtle: lethargy, poor feeding, irritability, tremors, jitteriness, apnea, and seizures. Hypoglycemia due to increased insulin is the most severe and most resistant to treatment. Cardiac failure may occur in severe cases, particularly in IDMs with cardiomyopathy. Hypoglycemia in hyperinsulinemic states can develop within the first 30–60 minutes of life.

Blood glucose can be measured by heelstick using a bedside glucometer. All infants at risk should be screened, including IDMs, IUGR infants, premature infants, and any infant with suggestive symptoms. All low or borderline values should be confirmed by laboratory measurement of blood glucose concentration. It is important to continue surveillance of glucose concentration until the baby has been on full enteral feedings without intravenous supplementation for 24 hours. Relapse of hypoglycemia thereafter is unlikely.

Infants with hypoglycemia requiring IV glucose infusions for more than 5 days should be evaluated for less common disorders, including inborn errors of metabolism, hyperinsulinemic states, and deficiencies of counterregulatory hormones.

▶ Treatment

Therapy is based on the provision of enteral or parenteral glucose. Treatment guidelines are shown in Table 1-12. In hyperinsulinemic states, glucose boluses should be avoided and a higher glucose infusion rate used. After initial correction with a bolus of 10% dextrose in water (D₁₀W; 2 mL/kg),

Table 1–12. Hypoglycemia: suggested therapeutic regimens.

Screening Test ^a	Presence of Symptoms	Action
20–45 mg/dL	No symptoms of hypoglycemia	Draw blood glucose ^b ; if the infant is alert and vigorous, feed; follow with frequent glucose monitoring.
		If the infant continues to have blood glucose < 40–45 mg/dL or is unable to feed, provide intravenous glucose at 6 mg/kg/min (D ₁₀ W at 3.6 mL/kg/h).
< 45 mg/dL	Symptoms of hypoglycemia present	Draw blood glucose ^b ; provide bolus of D ₁₀ W (2 mL/kg) followed by an infusion of 6 mg/kg/min (3.6 mL/kg/h).
< 20 mg/dL	With or without symptoms of hypoglycemia	Draw blood glucose ^b ; provide bolus of D ₁₀ W followed by an infusion of 6 mg/kg/min.
		If IV access cannot be obtained immediately, an umbilical vein line should be used.

^aRapid bedside determination.^bLaboratory confirmation.

glucose infusion should be increased gradually as needed from a starting rate of 6 mg/kg/min. IDMs and IUGR infants with polycythemia are at greatest risk for symptomatic hypoglycemia. In such infants, hypoglycemia and polycythemia should be treated with IV glucose and partial exchange transfusion, respectively.

► Prognosis

The prognosis of hypoglycemia is good if therapy is prompt. CNS sequelae are more common in infants with hypoglycemic seizures and in neonates with persistent hyperinsulinemic hypoglycemia. Hypoglycemia may also potentiate brain injury after perinatal depression and should be avoided.

RESPIRATORY DISTRESS IN THE TERM NEWBORN INFANT

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Tachypnea, respiratory rate > 60 breaths/min.
- Intercostal and sternal retractions.
- Expiratory grunting.
- Cyanosis in room air.

► General Considerations

Respiratory distress is one of the most common symptom complexes of the newborn. It may result from cardiopulmonary and noncardiopulmonary causes (Table 1–13). Chest radiography, arterial blood gases, and pulse oximetry are useful in assessing the cause and severity of the distress. It is important to consider the noncardiopulmonary causes (see Table 1–13), because the natural tendency is to focus on the heart and lungs. Most of the noncardiopulmonary causes can be ruled out by the history, physical examination, and a few simple laboratory tests. The most common pulmonary causes of respiratory distress in the full-term infant are transient tachypnea, aspiration syndromes, congenital pneumonia, and air leaks.

A. Transient Tachypnea (Retained Fetal Lung Fluid)

Respiratory distress is typically present at birth, usually associated with a mild to moderate oxygen requirement (25–50% O₂). The infant is usually full term or near term, nonasphyxiated, and born following a short labor or cesarean section without labor. The chest radiograph shows perihilar streaking and fluid in interlobar fissures. Resolution usually occurs within 12–24 hours.

B. Aspiration Syndromes

The infant is typically full-term or near-term with fetal distress prior to delivery or depression at delivery. Blood or meconium is often present in the amniotic fluid. Respiratory distress is present from birth, often manifested by a barrel chest appear-

Table 1-13. Causes of respiratory distress in the newborn.

Noncardiopulmonary	
	Hypothermia or hyperthermia
	Hypoglycemia
	Polycythemia
	Metabolic acidosis
	Drug intoxications or withdrawal
	Insult to the central nervous system
	Asphyxia
	Hemorrhage
	Neuromuscular disease
	Phrenic nerve injury
	Skeletal dysplasia
Cardiovascular	
	Left-sided outflow tract obstruction
	Hypoplastic left heart

ance and coarse breath sounds. Pneumonitis may cause an increasing O_2 need and may require intubation and ventilation. The chest radiograph shows coarse irregular infiltrates, hyperexpansion, and in the worst cases, lobar consolidation. In some cases, because of secondary surfactant deficiency, the radiograph shows a diffuse homogeneous infiltrate pattern.

When amniotic fluid contains meconium or blood, suctioning the infant's mouth and nose prior to delivery of the chest is not recommended as it may provoke aspiration. If the infant is not vigorous at birth, suctioning of the trachea under direct vision is recommended before commencing positive-pressure ventilation (PPV). Although tracheal suctioning is recommended, it does not prevent all cases of meconium or blood aspiration. Aspiration may have

occurred in utero as the stressed infant gasps. Infants who aspirate are at risk of pneumothorax because of uneven aeration with segmental overdistention and are at risk for persistent pulmonary hypertension (see section on Cardiac Problems in the Newborn Infant, later).

C. Congenital Pneumonia

Infants of any gestational age, with or without a history of prolonged rupture of membranes, chorioamnionitis, or maternal antibiotic administration, may be affected. Respiratory distress may begin at birth or may be delayed for several hours. The chest radiograph may resemble that of retained lung fluid or hyaline membrane disease. Rarely, there may be a lobar infiltrate.

The lungs are the most common site of infection in the neonate. Infections usually ascend from the genital tract before or during labor, with the vaginal or rectal flora the most likely agents (group B streptococci, *Escherichia coli*, and *Klebsiella*). Shock, poor perfusion, absolute neutropenia ($< 2000/\text{mL}$), and elevated C-reactive protein provide corroborating evidence for pneumonia. Gram stain of tracheal aspirate may be helpful. Because no signs or laboratory findings can confirm a diagnosis of pneumonia, all infants with respiratory distress should have a blood culture performed and should receive broad-spectrum antibiotic therapy (ampicillin, 100 mg/kg in two divided doses, and gentamicin, 4 mg/kg q24h or 2.5 mg/kg q12h) until the diagnosis of bacterial infection is ruled out.

D. Spontaneous Pneumothorax

Spontaneous pneumothorax occurs in 1% of all deliveries. Risk is increased by manipulations such as PPV in the delivery room. Respiratory distress (primarily tachypnea) is present from birth and typically is not severe. Breath sounds may be decreased on the affected side; heart tones may be shifted toward the opposite side and may be distant. The chest radiograph shows pneumothorax or pneumomediastinum.

Treatment usually consists of supplemental O_2 and watchful waiting. Breathing 100% O_2 for a few hours may accelerate reabsorption of extrapulmonary gas by creating a diffusion gradient for nitrogen across the surface of the lung (nitrogen washout technique). This is effective only if the infant was breathing room air or a small O_2 supplement at the time of the pneumothorax. Drainage by needle thoracentesis or tube thoracostomy is occasionally required. There is a slightly increased risk of renal abnormalities associated with spontaneous pneumothorax. Thus, careful physical examination of the kidneys and observation of urine output are indicated. If pulmonary hypoplasia with pneumothorax is suspected, renal ultrasound is also indicated.

E. Other Pulmonary Causes

Other pulmonary causes of respiratory distress are rare. Bilateral choanal atresia should be suspected if there is no air

movement when the infant breathes through the nose. These infants have good color and heart rate while crying at delivery but become cyanotic and bradycardiac when they resume normal nasal breathing. Other causes of upper airway obstruction usually produce some degree of stridor or poor air movement despite good respiratory effort. Pleural effusion is likely in hydroptic infants. Space-occupying lesions cause a shift of the mediastinum with asymmetrical breath sounds and are apparent on chest radiographs.

► Treatment

Whatever the cause, neonatal respiratory distress is treated with supplemental oxygen sufficient to maintain a P_{aO_2} of 60–70 mm Hg and an oxygen saturation by pulse oximetry (SpO_2) of 92–96%. P_{aO_2} less than 50 mm Hg is associated with pulmonary vasoconstriction, which can exacerbate hypoxemia. P_{aO_2} greater than 100 mm Hg may increase the risk of oxygen toxicity without additional benefit. Oxygen should be warmed, humidified, and delivered through an air blender. Concentration should be measured with a calibrated oxygen analyzer. An umbilical or peripheral arterial line should be inserted in infants requiring more than 45% F_{iO_2} by 4–6 hours of life to allow frequent blood gas determinations. Noninvasive monitoring with pulse oximetry should be used.

Other supportive treatment includes provision of IV glucose and water. Unless infection can be ruled out, blood cultures should be obtained and broad-spectrum antibiotics started. Volume expansion (normal saline) can be given in infusions of 10 mL/kg over 30 minutes for low blood pressure, poor perfusion, and metabolic acidosis. Sodium bicarbonate (1–2 mEq/kg) is given for metabolic acidosis unresponsive to initial oxygen, ventilation, and volume. Other specific testing should be done as indicated by the history and physical examination. In most cases, a chest radiograph, blood gas measurements, CBC, and blood glucose determination allow a diagnosis.

Intubation and ventilation should be undertaken if there is respiratory failure ($P_{aO_2} < 60$ mm Hg in 60–80% F_{iO_2} , P_{aCO_2} greater than 60 mm Hg, or repeated apnea). Peak pressures should be adequate to produce chest wall expansion and audible breath sounds (usually 18–24 cm H_2O). Positive end-expiratory pressure (4–6 cm H_2O) should be used. Ventilation rates of 20–50 breaths/min are usually required. The goal is to maintain a P_{aO_2} of 60–70 mm Hg and a P_{aCO_2} of 45–55 mm Hg.

► Prognosis

Most respiratory conditions of the full-term infant are acute and resolve in the first several days. Meconium aspiration and congenital pneumonia carry a mortality rate of up to 10–20% and produce significant long-term pulmonary morbidity. Mortality has been reduced by use of high-frequency oscillatory ventilation, inhaled nitric oxide for

pulmonary hypertension, and extracorporeal membrane oxygenation (ECMO).

HEART MURMURS (SEE ALSO SECTION ON CARDIAC PROBLEMS IN THE NEWBORN INFANT)

Heart murmurs are common in the first days of life and do not usually signify structural heart problems. If a murmur is present at birth, it should be considered a valvular problem until proved otherwise because the common benign transitional murmurs (eg, patent ductus arteriosus) are not audible until minutes to hours after birth.

If an infant is pink, well-perfused, and in no respiratory distress, with palpable and symmetrical pulses (right brachial pulse no stronger than the femoral pulse), the murmur is most likely transitional. Transitional murmurs are soft (grade 1–3/6), heard at the left upper to midsternal border, and generally loudest during the first 24 hours. If the murmur persists beyond 24 hours of age, blood pressure in the right arm and a leg should be determined. If there is a difference of more than 15 mm Hg (arm > leg) or if the pulses in the lower extremities are difficult to palpate, a cardiologist should evaluate the infant for coarctation of the aorta. If there is no difference, the infant can be discharged home with follow-up in 2–3 days for auscultation and evaluation for signs of congestive failure. If signs of congestive failure or cyanosis are present, the infant should be referred for evaluation without delay. If the murmur persists without these signs, the infant can be referred for elective evaluation at age 2–4 weeks. Some centers now recommend routine pulse oximetry screening in the nursery to identify infants with congenital heart disease. Oxygen saturation less than 95% at sea level is evaluated by echocardiogram.

BIRTH TRAUMA

Most birth trauma is associated with difficult delivery (eg, large fetus, abnormal presenting position, or fetal distress requiring rapid extraction). The most common injuries are soft tissue bruising, fractures (clavicle, humerus, or femur), and cervical plexus palsies. Skull fracture, intracranial hemorrhage (primarily subdural and subarachnoid), and cervical spinal cord injury can also occur.

Fractures are often diagnosed by the obstetrician, who may feel or hear a snap during delivery. Clavicular fractures may cause decreased spontaneous movement of the arm, with local tenderness and crepitus. Humeral or femoral fractures usually cause tenderness and swelling over the shaft with a diaphyseal fracture, and always cause limitation of movement. Epiphyseal fractures are harder to diagnose radiographically owing to the cartilaginous nature of the epiphysis. After 8–10 days, callus is visible on radiographs. Treatment in all cases is gentle handling, with immobilization for 8–10 days: the humerus against the chest with elbow flexed; the femur with a posterior splint from below the knee to the buttock.

Brachial plexus injuries may result from traction as the head is pulled away from the shoulder during delivery. Injury to the C5–C6 roots is most common (Erb-Duchenne palsy). The arm is limp, adducted, and internally rotated, extended and pronated at the elbow, and flexed at the wrist (so-called waiter's tip posture). Grasp is present. If the lower nerve roots (C8–T1) are injured (Klumpke palsy), the hand is flaccid. Isolated involvement of the cervical roots is rare. If the entire plexus is injured, the arm and hand are flaccid, with associated sensory deficit. Early treatment for brachial plexus injury is conservative, because function usually returns over several weeks. Referral should be made to a physical therapist so that parents can be instructed on range-of-motion exercises, splinting, and further evaluation if needed. Return of function begins in the deltoid and biceps, with recovery by 3 months in most cases.

Spinal cord injury can occur at birth, especially in difficult breech extractions with hyperextension of the

neck, or in midforceps rotations when the body fails to turn with the head. Infants are flaccid, quadriplegic, and without respiratory effort at birth. Facial movements are preserved. The long-term outlook for such infants is poor.

Facial nerve palsy is sometimes associated with forceps use but more often results from in-utero pressure of the baby's head against the mother's sacrum. The infant has asymmetrical mouth movements and eye closure with poor facial movement on the affected side. Most cases resolve spontaneously in a few days to weeks.

Subgaleal hemorrhage into the large potential space under the scalp (Figure 1–5) is associated with difficult vaginal deliveries and repeated attempts at vacuum extraction. It can lead to hypovolemic shock and death from blood loss and coagulopathy triggered by consumption of clotting factors and release of thromboplastin from the injured brain. This is an emergency requiring rapid replacement of blood and clotting factors.

INFANTS OF MOTHERS WHO ABUSE DRUGS

Current studies estimate that up to 15% of women use alcohol and 5–15% use illicit drugs during pregnancy, depending on the population studied and the methods of ascertainment. Drugs most commonly used are tobacco, alcohol, marijuana, cocaine, and methamphetamine. Because mothers may abuse many drugs and give an unreliable history of drug usage, it is difficult to pinpoint which drug is causing the morbidity seen in a newborn infant. Early hospital discharge makes recognition of these infants based on physical findings and abnormal behavior difficult.

1. Cocaine & Methamphetamine

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Triad of no prenatal care, premature delivery, placental abruption.
- ▶ Possible intrauterine growth restriction.
- ▶ Irritability.

Cocaine and methamphetamine are currently the most common hard drugs used during pregnancy, often in association with other drugs such as tobacco, alcohol, and marijuana. These stimulants can cause maternal hypertension, decreased uterine blood flow, fetal hypoxemia, uterine contractions, and placental abruption. Rates of stillbirth, placental abruption, IUGR, and preterm delivery are increased two- to fourfold in users compared with nonusers. In the high-risk setting of no prenatal care, placental abruption, and preterm labor, urine toxicology screens should be performed on the mother and infant. Meconium should be sent for drug screening as it enhances diagnosis by indicating cumulative drug exposure from the first trimester forward. Although no specific malformation complex or withdrawal syndrome is described for cocaine and methamphetamine abuse, infants may show irritability and growth restriction.

Children of mothers who use methamphetamines are at particularly high risk for neglect and abuse. Social services evaluation is especially important to assess the home environment for these risks. The risk of SIDS is three to seven times higher in infants of users than in those of nonusers (0.5–1% of exposed infants). The risk may be lessened by environmental interventions such as avoidance of tobacco smoke and supine infant positioning.

2. Opioids

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ CNS—irritability, hyperactivity, hypertonicity, incessant high-pitched cry, tremors, seizures.
- ▶ GI—vomiting, diarrhea, weight loss, poor feeding, incessant hunger, excessive salivation.
- ▶ Metabolic and respiratory—nasal stuffiness, sneezing, yawning, sweating, hyperthermia.
- ▶ Often IUGR.

▶ Clinical Findings

The withdrawal signs of infants born to heroin-addicted mothers or mothers who have been in methadone mainte-

nance programs are similar. The symptoms in infants born to methadone-maintained mothers may be delayed in onset, more severe, and more prolonged than those seen with heroin addiction. Symptoms usually begin within 1–2 days of life. The clinical picture is typical enough to suggest a diagnosis even if a maternal history of narcotic abuse has not been obtained. Confirmation should be made with urine and meconium toxicology screening.

▶ Treatment

If opioid abuse or withdrawal is suspected, the infant is not a candidate for early discharge. Supportive treatment includes swaddling the infant and providing a quiet, dimly lit environment. Specific treatment should be avoided unless the infant has severe symptoms or excessive weight loss. No single drug has been identified as optimally effective. Phenobarbital is used at an initial loading dose of 10–20 mg/kg IM, followed by a maintenance dose of 5 mg/kg/d in two divided doses given orally. Opioids, diazepam, and clonidine have also been used, although the present authors prefer phenobarbital if irritability is the primary symptom because of its safety and predictability. If diarrhea and weight loss are prominent, or if adequate control of symptoms has not been achieved, tincture of opium (25-fold dilution to 0.4 mg/mL morphine equivalent; 0.1 mL/kg q4h to start) titrated to improve symptoms, or methadone (0.05–0.1 mg/kg q6h) are more beneficial than phenobarbital alone. Treatment can be tapered over several days to 2 weeks. Disturbing the infant by procedures should be minimized. It is also important to review maternal tests for HIV, hepatitis B, and hepatitis C, as all are common in intravenous drug users.

▶ Prognosis

These infants often have chronic neurobehavioral handicaps; however, it is difficult to distinguish the effects of in-utero drug exposure from those of the environment. Infants of opioid abusers have a four- to fivefold increased risk of SIDS.

3. Alcohol

Alcohol is the only recreational drug of abuse that is clearly teratogenic and is the most common preventable cause of mental retardation. Prevalence estimates of fetal alcohol syndrome (FAS) in the United States range from 0.5–2 per 1000 live births with up to 1 in 100 having lesser effects (fetal alcohol spectrum disorders). The effects of alcohol on the fetus and newborn are determined by the degree and timing of ethanol exposure and by the maternal, fetal, and placental metabolism of ethanol, which is likely genetically determined. Although there is no clear evidence that minimal amounts of alcohol are harmful, there is no established safe dose. Fetal growth and development are adversely affected if drinking continues throughout the pregnancy, and infants can occasionally experience withdrawal similar to that asso-

Table 1-14. Features observed in fetal alcohol syndrome in the newborn.

Craniofacial

Short palpebral fissures
Thin vermilion of upper lip
Flattened philtrum

Growth

Prenatal and postnatal growth deficiency (small for gestational age, failure to thrive)

Central nervous system

Microcephaly
Partial or complete agenesis of the corpus callosum
Optic nerve hypoplasia
Hypotonia, poor feeding

ciated with maternal opioid abuse. Clinical features of FAS that may be observed in the newborn period are listed in Table 1-14. This diagnosis is usually easier to recognize in older infants and children.

4. Tobacco Smoking

Smoking has a negative effect on fetal growth rate. The more the mother smokes, the greater is the degree of IUGR. There is a twofold increase in low birth weight even in light smokers (< 10 cigarettes per day). Smoking during pregnancy has been associated with mild neurodevelopmental handicaps. The possibility of multiple drug abuse also applies to smokers, and the potential interaction of multiple factors on fetal growth and development must be considered.

5. Toluene Embryopathy

Solvent toxicity may be intentional (paint, lacquer, or glue sniffing) or environmental (dry cleaning industry). The active organic solvent in these agents is toluene. Features attributable to in-utero toluene exposure are prematurity, IUGR, microcephaly, craniofacial abnormalities similar to those associated with in-utero alcohol exposure (see Table 1-14), large anterior fontanelle, hair patterning abnormalities, nail hypoplasia, and renal anomalies. Long-term effects include postnatal growth deficiency and developmental delay.

6. Marijuana

Marijuana is the most frequently used illegal drug. It does not appear to be teratogenic, and although a mild abstinence-type syndrome has been described, infants exposed to marijuana in utero rarely require treatment. Some long-term neurodevelopmental problems, particularly disordered sleep patterns, have been noted.

7. Other Drugs

Drugs with potential effects on the newborn fall in two categories. First are drugs to which the fetus is exposed

because of therapy for maternal conditions. The human placenta is relatively permeable, particularly to lipophilic solutes. If possible, maternal drug therapy should be postponed until after the first trimester to avoid teratogenic effects. Drugs with potential fetal toxicity include antineoplastics, antithyroid agents, warfarin, lithium, and angiotensin-converting enzyme inhibitors (eg, captopril and enalapril). Anticonvulsants, especially high-dose or multiple drug therapy, may be associated with craniofacial abnormalities. The use of selective serotonin reuptake inhibitors, benzodiazepines, and antipsychotic medications appears to be generally safe, and risk should be balanced against the risk of untreated psychiatric conditions in the mother.

In the second category are drugs transmitted to the infant in breast milk. Most drugs taken by the mother achieve some concentration in breast milk, although they usually do not present a problem to the infant. If the drug is one that could have adverse effects on the infant, timing breast feeding to coincide with trough concentrations in the mother may be useful. The AAP (see below) has reviewed drugs contraindicated in the breast-feeding mother.

MULTIPLE BIRTHS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ **Monochorial twins**
 - Always monozygous and same sex.
 - Can be diamniotic or monoamniotic.
 - Risk for twin-to-twin transfusion and higher risk of congenital anomalies, neurodevelopmental problems, and cerebral palsy.
- ▶ **Dichorial twins**
 - Either dizygous or monozygous; same sex or different sex.
 - Can have growth restriction due to abnormal placental implantation.

- Not at risk for twin transfusion syndrome; less risk for anomalies and neurodevelopmental problems than monochorial twins.

Twinning historically occurred at a rate of 1 in 80 pregnancies (1.25%). The incidence of twinning and higher-order multiple births in the United States has increased because of in-vitro fertilization and other assisted reproductive technologies. In 2002, twins occurred in 1 in 32 live births in the United States, with multiple births accounting for 3.3% of all births.

A distinction should be made between dizygous (fraternal) and monozygous (identical) twins. Race, maternal parity, and maternal age affect the incidence of dizygous, but not monozygous, twinning. Drugs used to induce ovulation, such as clomiphene citrate and gonadotropins, increase the incidence of dizygotic or polyzygotic twinning. Monozygous twinning also seems to be more common after assisted reproduction. The incidence of malformations is also increased in identical twins and may affect only one of the twins. If a defect is found in one twin, the other should be examined carefully for lesser degrees of the same defect.

Early transvaginal ultrasound and examination of the placenta after birth can help establish the type of twinning: Two amniotic membranes and two chorionic membranes are found in all dizygous twins and in one third of monozygous twins even when the placental disks appear to be fused into one. A single chorionic membrane always indicates monozygous twins. The rare monochorial, monoamniotic situation (1% of twins) is especially dangerous, with a high risk of antenatal cord entanglement and death of one or both twins. Close fetal surveillance is indicated.

► Complications of Multiple Births

A. Intrauterine Growth Restriction

There is some degree of IUGR in most multiple pregnancies, especially after 32 weeks, although it is usually not clinically significant with two exceptions. First, in monochorial twin pregnancy an arteriovenous shunt may develop between the twins (twin-twin transfusion syndrome). The twin on the venous side (recipient) becomes plethoric and larger than the smaller anemic twin (donor), who may ultimately die or be severely growth restricted. The occurrence of polyhydramnios in the larger twin and oligohydramnios in the smaller may be the first sign of this problem. Second, discordance in size (birth weights that are significantly different) can also occur when separate placentas are present if one placenta develops poorly, because of a poor implantation site. In this instance, no fetal exchange of blood takes place but the growth rates of the two infants are different.

B. Preterm Delivery

Length of gestation tends to be inversely related to the number of fetuses. The mean age at delivery for singletons is 38.8

weeks, for twins 35.3 weeks, for triplets 32.2 weeks, and for quadruplets 29.9 weeks. The prematurity rate in multiple gestations is 5–10 times that of singletons, with 50% of twins and 90% of triplets born before 37 weeks. There is an increased incidence of cerebral palsy in multiple births, more so with monochorial than dichorial infants. Prematurity is the main cause of increased mortality and morbidity in twins, although in the case of monochorial twins, intravascular exchange through placental anastomoses, particularly after the death of one twin, also increases the risk substantially.

C. Obstetric Complications

Polyhydramnios, pregnancy-induced hypertension, premature rupture of membranes, abnormal fetal presentations, and prolapsed umbilical cord occur more frequently in women with multiple fetuses. Multiple pregnancy should always be identified prenatally with ultrasound examinations; doing so allows the obstetrician and pediatrician or neonatologist to plan management jointly. Because neonatal complications are usually related to prematurity, prolongation of pregnancy significantly reduces neonatal morbidity.

NEONATAL INTENSIVE CARE

PERINATAL RESUSCITATION

Perinatal resuscitation refers to the steps taken by the obstetrician to support the infant during labor and delivery and the resuscitative steps taken by the pediatrician after delivery. Intrapartum support includes maintaining maternal blood pressure, maternal oxygen therapy, positioning the mother to improve placental perfusion, readjusting oxytocin infusions or administering a tocolytic if appropriate, minimizing trauma to the infant, obtaining all necessary cord blood samples, and completing an examination of the placenta. The pediatrician or neonatologist focuses on temperature support, initiation and maintenance of effective ventilation, maintenance of perfusion and hydration, and glucose regulation.

A number of conditions associated with pregnancy, labor, and delivery place the infant at risk for birth

asphyxia: (1) maternal diseases such as diabetes, pregnancy-induced hypertension, heart and renal disease, and collagen-vascular disease; (2) fetal conditions such as prematurity, multiple births, growth restriction, and fetal anomalies; and (3) labor and delivery conditions, including fetal distress with or without meconium in the amniotic fluid, and administration of anesthetics and opioid analgesics.

Physiology of Birth Asphyxia

Birth asphyxia can be the result of: (1) acute interruption of umbilical blood flow (eg, prolapsed cord with cord compression), (2) premature placental separation, (3) maternal hypotension or hypoxia, (4) chronic placental insufficiency, and (5) failure to perform resuscitation properly.

The neonatal response to asphyxia follows a predictable pattern (Figure 1-6). The initial response to hypoxia is an increase in respiratory rate and a rise in heart rate and blood pressure. Respirations then cease (primary apnea) as heart rate and blood pressure begin to fall. The initial period of apnea

▲ **Figure 1-6.** Schematic depiction of changes in rhesus monkeys during asphyxia and on resuscitation by positive-pressure ventilation. (Adapted and reproduced, with permission, from Dawes GS: *Fetal and Neonatal Physiology*. Year Book, 1968.)

lasts 30–60 seconds. Gasping respirations (3–6 per minute) then begin, while heart rate and blood pressure gradually decline. Secondary or terminal apnea then ensues, with further decline in heart rate and blood pressure. The longer the duration of secondary apnea, the greater is the risk for hypoxic organ injury. A cardinal feature of the defense against hypoxia is the underperfusion of certain tissue beds (eg, skin, muscle, kidneys, and GI tract), which allows maintenance of perfusion to core organs (ie, heart, brain, and adrenals).

Response to resuscitation also follows a predictable pattern. During the period of primary apnea, almost any physical stimulus causes the infant to initiate respirations. Infants in secondary apnea require PPV. The first sign of recovery is an increase in heart rate, followed by an increase in blood pressure with improved perfusion. The time required for rhythmic, spontaneous respirations to occur is related to the duration of the secondary apnea. As a rough rule, for each minute past the last gasp, 2 minutes of PPV is required before gasping begins, and 4 minutes is required to reach rhythmic breathing. Not until some time later do spinal and corneal reflexes return. Muscle tone gradually improves over the course of several hours.

Delivery Room Management

When asphyxia is anticipated, a resuscitation team of at least two persons should be present, one to manage the airway and one to monitor the heartbeat and provide assistance. The necessary equipment and drugs are listed in Table 1-15.

A. Steps in the Resuscitative Process (see Figure 1-7)

1. Dry the infant well, and place him or her under a radiant heat source. Do not allow the infant to become hyperthermic.
2. Position the infant to open the airway. Gently suction the mouth, then the nose.
3. Quickly assess the infant's condition. The best criteria are the infant's respiratory effort (apneic, gasping or, regular) and heart rate (> 100 or < 100 beats/min). A depressed heart rate—indicative of hypoxic myocardial depression—is the single most reliable indicator of the need for resuscitation.
4. Infants who are breathing and have heart rates above 100 beats/min usually require no further intervention other than supplemental oxygen if cyanotic. Infants with heart rates less than 100 beats/min and apnea or irregular respiratory efforts should be stimulated vigorously. The infant's back should be rubbed with a towel while oxygen is provided near the face.
5. If the infant fails to respond to tactile stimulation within a few seconds, begin bag and mask ventilation, using a soft mask that seals well around the mouth and nose. For the initial inflations, pressures of 30–40 cm H_2O may be necessary to overcome surface-active

Table 1-15. Equipment for neonatal resuscitation.

Clinical Needs	Equipment
Thermoregulation	Radiant heat source with platform, mattress covered with warm sterile blankets, servocontrol heating, temperature probe, occlusive skin cover (preterm)
Airway management	Suction: bulb suction, mechanical suction with sterile catheters (6F, 8F, 10F), meconium aspirator
	Ventilation: manual infant resuscitation bag connected to manometer or with a pressure-release valve capable of delivering 100% oxygen, appropriate masks for term and preterm infants, oral airways, stethoscope
	Intubation: neonatal laryngoscope with No. 0 and No. 1 blades; endotracheal tubes (2.5, 3.0, 3.5 mm outer diameter with stylet); extra bulbs and batteries for laryngoscope; scissors, adhesive tape, gloves, end-tidal CO ₂ detection device
Gastric decompression	Nasogastric tube: 8F with 20-mL syringe
Administration of drugs and volume replacement	Sterile umbilical catheterization tray, umbilical catheters (3.5F and 5F), volume expanders, normal saline, drug box ³ with appropriate neonatal vials and dilutions, sterile syringes, needles, and alcohol sponges
Transport	Warmed transport isolette with oxygen source

³Epinephrine 1:10,000; naloxone hydrochloride 1 mg/mL; sodium bicarbonate 4.2% (5 mEq/10 mL); 10% dextrose.

Modified, with permission, from Rosenberg AA: Neonatal adaptation. In Gabbe SG et al (editors): *Obstetrics: Normal and Problem Pregnancies*. Churchill Livingstone, 1996.

forces in the lungs. Adequacy of ventilation is assessed by observing expansion of the infant's chest accompanied by an improvement in heart rate, perfusion, and color. After the first few breaths, lower the peak pressure to 15–20 cm H₂O. The chest movement should resemble that of an easy breath rather than a deep sigh. The rate of bagging should be 40–60 breaths/min.

- Most neonates can be resuscitated effectively with a bag and mask. If the infant does not respond to bag and mask ventilation, reposition the head (slight extension), reapply the mask to achieve a good seal, consider suctioning the mouth and the oropharynx, and try ventilating with the mouth open. If the infant does not respond within 30 seconds, intubation is appropriate.

Failure to respond to intubation and ventilation can result from (1) mechanical difficulties (Table 1–16), (2) profound asphyxia with myocardial depression, and (3) inadequate circulating blood volume.

Quickly rule out the mechanical causes listed in Table 1–16. Check to ensure that the endotracheal tube passes through the vocal cords. A CO₂ detector placed between the endotracheal tube and the bag can be helpful as a rapid confirmation of proper tube position in the airway. Occlusion of the tube should be suspected when there is resistance to bagging and no chest wall movement. Very few neonates (approximately 0.1%) require either cardiac massage or drugs during resuscitation. Almost all newborns respond to ventilation if done effectively. Although current AAP Neonatal Resuscitation Program (NRP) guidelines recommend 100% oxygen for neonatal resuscitation when PPV is required, there is some evidence that this may increase the risk of postresuscitative oxidative injury. Resuscitation with room air or lower oxygen concentrations may be equally effective. At a minimum, when possible, blended oxygen should be available in the delivery room. Use of lower oxygen concentrations is further supported by review of oxygen saturations after birth in normal newborns. Oxygen saturation rises slowly and does not reach 90% for 5 minutes.

- If mechanical causes are ruled out and the heart rate remains less than 60 beats/min after intubation and PPV for 30 seconds, cardiac compression should be initiated. Simultaneous delivery of chest compressions and PPV is likely to decrease the efficiency of ventilation. Therefore, chest compressions should be interspersed with ventilation at a 3:1 ratio (90 compressions and 30 breaths/min).
- If drugs are needed, the drug and dose of choice is epinephrine 1:10,000 solution (0.1–0.3 mL/kg) given via the endotracheal tube or preferably through an umbilical venous line. If volume loss is suspected, 10 mL/kg of a volume expander (normal saline) should be administered through an umbilical vein line.

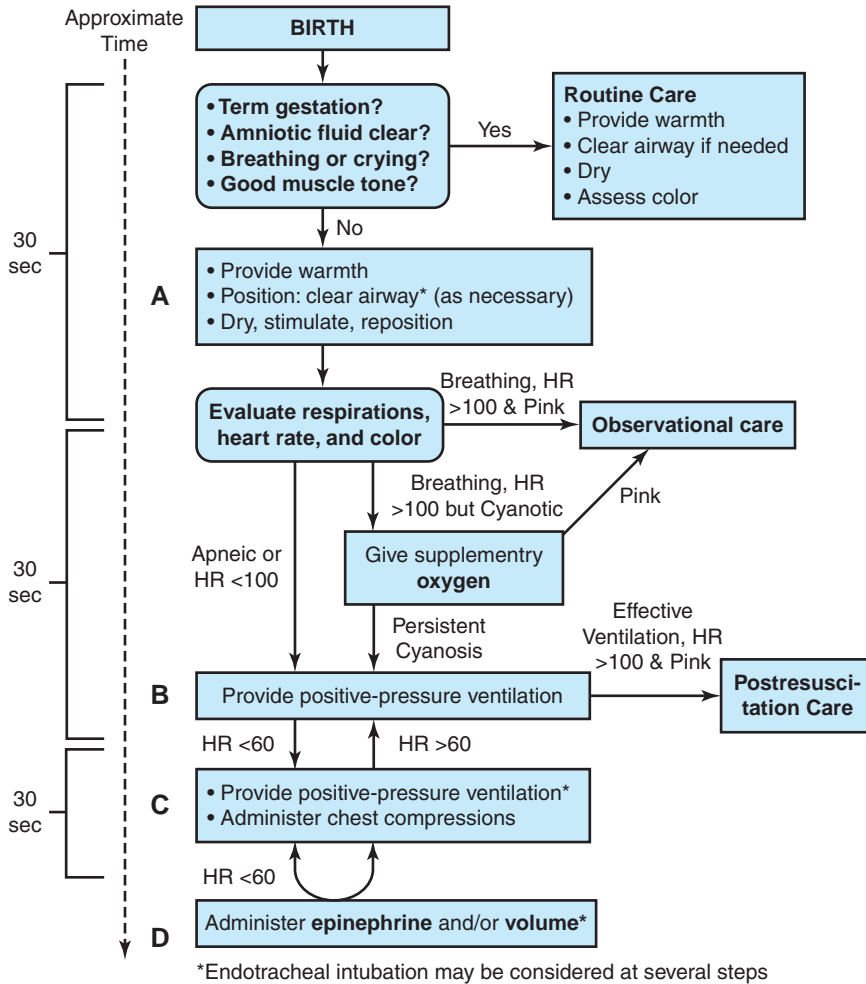

B. Continued Resuscitative Measures

The appropriateness of continued resuscitative efforts should be reevaluated in infants who do not respond to initial measures. In current practice, resuscitative efforts are made even in apparent stillbirths (ie, infants whose Apgar score at 1 minute is 0–1). Modern resuscitative techniques have led to improved survival in such infants, with 60% of survivors showing normal development. Although it is clear that resuscitation of these infants should be performed, subsequent continued support depends on the response to resuscitation. If the Apgar score does not improve markedly in the first 10 minutes of life, the mortality rate and the incidence of severe developmental handicaps among survivors are high.

C. Special Considerations

1. Preterm Infants

A. Minimizing heat loss improves survival. Prewarmed towels should be available. The environmental temperature of

▲ **Figure 1-7.** Delivery room management. (Reproduced, with permission, from Kattwinkel J, et al: *Textbook of Neonatal Resuscitation*, 5th edition, American Heart Association and American Academy of Pediatrics, 2006.)

the delivery suite should be raised to more than 25°C (especially for infants weighing < 1500 g). A polyethylene occlusive skin cover should be used to minimize heat loss in the extremely low birth weight (< 1000 g) infant.

B. The lungs of preterm infants are especially prone to injury from PPV due to volutrauma. For this reason, if possible, ventilation efforts should be supported with nasal continuous positive airway pressure (CPAP) rather than PPV. If PPV is needed, a T-piece resuscitation device should be used to allow precise regulation of pressure delivery.

C. In the infant of extremely low gestational age (< 27 weeks), intubation for administration of surfactant should be considered.

D. Volume expanders should be infused slowly to minimize rapid swings in blood pressure.

2. Narcotic depression—In the case of opioid administration to the mother within 4 hours of delivery, perform the

Table 1-16. Mechanical causes of failed resuscitation.

Cause	Examples
Equipment failure	Malfunctioning bag, oxygen not connected or running
Endotracheal tube malposition	Esophagus, right main stem bronchus
Occluded endotracheal tube	
Insufficient inflation pressure to expand lungs	
Space-occupying lesions in the thorax	Pneumothorax, pleural effusions, diaphragmatic hernia
Pulmonary hypoplasia	Extreme prematurity, oligohydramnios

Reproduced, with permission, from Rosenberg AA: Neonatal adaptation. In Gabbe SG et al (editors): *Obstetrics: Normal and Problem Pregnancies*. Churchill Livingstone, 1996.

resuscitation as described earlier. When the baby is stable with good heart rate, color, and perfusion, but still has poor respiratory effort, a trial of naloxone (0.1 mg/kg IM, SC, IV, or IT) is indicated. Naloxone should not be administered in place of PPV. Naloxone should not be used in the infant of an opioid-addicted mother because it will precipitate withdrawal.

3. Meconium-stained amniotic fluid

A. The obstetrician performs routine suctioning of the mouth and nose after birth.

B. If the infant is active and breathing, requiring no resuscitation, the airway need not be inspected—only further suctioning of the mouth and nasopharynx is required.

C. The airway of any depressed infant requiring ventilation must be checked and cleared (by passage of a tube below the vocal cords) before PPV is instituted. Special adapters are available for use with regulated wall suction to allow suction to be applied directly to the endotracheal tube.

D. Because most severe cases of meconium aspiration syndrome with pulmonary hypertension likely have their origins in utero, resuscitative efforts should not be excessively delayed with attempts to clear the airway of meconium.

4. Universal precautions—In the delivery suite, universal precautions should always be observed.

Treatment of the Asphyxiated Infant

Asphyxia is manifested by multiorgan dysfunction, seizures, hypoxic-ischemic encephalopathy, and metabolic acidemia. The infant with significant perinatal hypoxia and ischemia is at risk for dysfunction of multiple end organs (Table 1–17). The organ of greatest concern is the brain.

The features of hypoxic-ischemic encephalopathy are decreased level of consciousness, poor tone, decreased spontaneous movement, periodic breathing or apnea, and seizures. Brainstem signs (oculomotor and pupillary disturbances, absent gag reflex) may also be present. The severity and duration of clinical signs correlate with the severity of the insult. Other evaluations helpful in assessing severity in the full-term infant include electroencephalogram (EEG) and computed tomography (CT) scan. MRI, particularly diffusion-weighted imaging, is useful, especially in the early evaluation of infants with perinatal asphyxia.

A markedly abnormal EEG with voltage suppression and slowing evolving into a burst-suppression pattern is associated with severe clinical symptoms. Brain CT scan early in the course may demonstrate diffuse hypodensity and loss of gray/white matter tissue differentiation, whereas later scans may demonstrate brain atrophy and focal ischemic lesions. Management is directed at supportive care and treatment of specific abnormalities. Fluids should be restricted initially to 60–80 mL/kg/d; oxygenation should be maintained with mechanical ventilation if necessary; blood pressure should be

Table 1–17. Signs and symptoms caused by asphyxia.

Hypoxic-ischemic encephalopathy, seizures
Respiratory distress due to aspiration or secondary surfactant deficiency, pulmonary hemorrhage
Persistent pulmonary hypertension
Hypotension due to myocardial dysfunction
Transient tricuspid valve insufficiency
Anuria or oliguria due to acute tubular necrosis
Feeding intolerance; necrotizing enterocolitis
Elevated aminotransferases due to liver injury
Adrenal insufficiency due to hemorrhage
Disseminated intravascular coagulation
Hypocalcemia
Hypoglycemia
Persistent metabolic acidemia
Hyperkalemia

supported with judicious volume expansion (if hypovolemic) and pressors; and glucose should be in the normal range of 45–100 mg/dL. Hypocalcemia, coagulation abnormalities, and metabolic acidemia should be corrected and seizures treated with IV phenobarbital (20 mg/kg as loading dose, with total initial 24-hour dosing up to 40 mg/kg). Other anticonvulsants should be reserved for refractory seizures. Hypothermia, either selective head cooling with mild systemic hypothermia or whole body cooling, initiated within 6 hours of birth, has been shown to improve outcome at 18-month follow-up of infants with moderate neurologic symptoms and an abnormal 1-lead amplitude-integrated EEG. Efficacy has not been proved in the most severe cases of neonatal encephalopathy.

Birth Asphyxia: Long-Term Outcome

Fetal heart rate tracings, cord pH, and 1-minute Apgar scores are imprecise predictors of long-term outcome. Apgar scores of 0–3 at 5 minutes in full-term infants are associated with an 18–35% risk of death in the first year of life and an 8% risk of cerebral palsy among survivors. The risks of mortality and morbidity increase with more prolonged depression of the Apgar score. The single best predictor of outcome is the severity of clinical hypoxic-ischemic encephalopathy (severe symptomatology including coma carries a 75% chance of death and a 100% rate of neurologic sequelae among survivors). The major sequela of hypoxic-ischemic encephalopathy is cerebral palsy with or without mental retardation and epilepsy. Other prognostic features are prolonged seizures refractory to therapy, markedly abnormal EEG, and CT or MRI scan with evidence of major ischemic injury. Other clinical features required to support perinatal hypoxia as the cause of cerebral palsy include the presence of fetal distress prior to birth, a low arterial cord pH of less than 7.00, evidence of other end-organ dysfunction, and absence of a congenital brain malformation.

THE PRETERM INFANT

Premature infants comprise the majority of high-risk newborns. The preterm infant faces a variety of physiologic handicaps:

1. The ability to coordinate sucking, swallowing, and breathing is not achieved until 34–36 weeks' gestation. Therefore, enteral feedings must be provided by gavage. Further, preterm infants often have gastroesophageal reflux and an immature gag reflex, which increases the risk of aspiration of feedings.
2. Lack of body fat stores causes decreased ability to maintain body temperature.

3. Pulmonary immaturity–surfactant deficiency is associated with structural immaturity in infants younger than 26 weeks' gestation. This condition is complicated by the combination of noncompliant lungs and extremely compliant chest wall, causing inefficient respiratory mechanics.
4. Immature respiratory control leads to apnea and bradycardia.
5. Persistent patency of the ductus arteriosus compromises pulmonary gas exchange because of overperfusion and edema of the lungs.
6. Immature cerebral vasculature and structure predisposes to subependymal or intraventricular hemorrhage and periventricular leukomalacia.
7. Impaired substrate absorption by the GI tract compromises nutritional management.
8. Immature renal function (including both filtration and tubular functions) complicates fluid and electrolyte management.
9. Increased susceptibility to infection.
10. Immaturity of metabolic processes predisposes to hypoglycemia and hypocalcemia.

1. Delivery Room Care

See section on Perinatal Resuscitation, earlier.

2. Care in the Nursery

A. Thermoregulation

Maintaining stable body temperature is a function of heat production and conservation balanced against heat loss. Heat production in response to cold stress occurs through voluntary muscle activity, involuntary muscle activity (shivering), and thermogenesis not caused by shivering. Newborns produce heat mainly through the last of these three mechanisms. This metabolic heat production depends on the quantity of brown fat, which is very limited in the preterm infant. Heat loss to the environment can occur through: (1) radiation—transfer of heat from a warmer to a cooler object not in contact; (2) convection—transfer of heat to the surrounding gaseous environment, influenced by air movement and temperature; (3) conduction—transfer of heat to a cooler object in contact; and (4) evaporation—cooling secondary to water loss through the skin. Heat loss in the preterm newborn is accelerated because of a high ratio of surface area to body mass, reduced insulation by subcutaneous tissue, and water loss through the immature skin.

The thermal environment of the preterm neonate must be regulated carefully. The infant can be kept warm in an isolette, in which the air is heated and convective heat loss is minimized. The infant can also be kept warm on an open bed with a radiant heat source. Although evaporative and convective heat losses are greater with radiant warmers, this

▲ **Figure 1-8.** Effect of environmental temperature on oxygen consumption and body temperature. (Adapted and reproduced, with permission, from Klaus MH, Fanaroff AA, Martin RJ: The physical environment. In: Klaus MH, Fanaroff AA [editors]: *Care of the High-Risk Neonate*, 5th ed. WB Saunders, 2001.)

system allows better access to an ill neonate. Ideally, the infant should be kept in a neutral thermal environment (Figure 1-8). The neutral thermal environment allows the infant to maintain a stable core body temperature with a minimum of metabolic heat production through oxygen consumption. The neutral thermal environment depends on the infant's size, gestational age, and postnatal age. The neutral thermal environment (for either isolette or radiant warmer care) can be obtained by maintaining an abdominal skin temperature of 36.5°C. Generally, when infants reach 1700–1800 g, they are able to maintain temperature while bundled in an open crib.

B. Monitoring the High-Risk Infant

At a minimum, equipment to monitor heart rate, respirations, and blood pressure should be available. Oxygen saturation can be assessed continuously using pulse oximetry, correlated with arterial oxygen tension (P_{aO_2}) as needed. Transcutaneous PO_2 and PCO_2 can also be used to assess oxygenation and ventilation. Arterial blood gases, electrolytes, glucose, calcium, bilirubin, and other chemistries must be measured on small volumes of blood. Early in the care of a sick preterm infant, the most efficient way to sample blood for tests as well as to provide fluids and monitor blood pressure is through an umbilical arterial line. Once the infant is stable and the need for frequent blood samples is reduced (usually 4–7 days), the umbilical line should be removed. All indwelling lines are associated with morbidity from thrombosis or embolism, infection, and bleeding.

C. Fluid and Electrolyte Therapy

Fluid requirements in preterm infants are a function of (1) insensible losses (skin and respiratory tract), (2) urine output, (3) stool output (< 5% of total), and (4) others, such as nasogastric losses. In most circumstances, the fluid requirement is determined largely by insensible losses plus urine losses. The major contribution to insensible water loss is evaporative skin loss. The rate of water loss is a function of gestational age (body weight, skin thickness, and maturity), environment (losses are greater under a radiant warmer than in an isolette), and the use of phototherapy. Respiratory losses are minimal when humidified oxygen is used. The renal contribution to water requirement is influenced by the limited ability of the preterm neonate either to concentrate the urine and conserve water, or to excrete a water load.

Electrolyte requirements are minimal for the first 24–48 hours until there is significant urinary excretion. Basal requirements thereafter are as follows: sodium, 3 mEq/kg/d; potassium, 2 mEq/kg/d; chloride, 2–3 mEq/kg/d; and bicarbonate, 2–3 mEq/kg/d. In the infant younger than 30 weeks' gestation, sodium and bicarbonate losses in the urine are often elevated, thereby increasing the infant's requirements.

Initial fluid management after birth varies with the infant's size and gestation. Infants of more than 1500 g should start at 80–100 mL/kg/d of $D_{10}W$. Those weighing less should start at 100–120 mL/kg/d of either $D_{10}W$ or 5% dextrose in water (D_5W) (infants < 800 g and born before 26 weeks' gestation often become hyperglycemic on $D_{10}W$). The most critical issue in fluid management is monitoring. Mon-

Table 1-18. Use of parenteral alimentation solutions.

	Volume (mL/kg/d)	Carbohydrate (g/dL)	Protein (g/kg)	Lipid (g/kg)	Calories (kcal/kg)

Target solution	150	D _{12.5} W	3-3.5	3	108
Central: long term (> 10 days)					
Starting solution	100-150	D ₁₀ W	3	1	56-84
Target solution	130	D ₁₅ -D ₂₀ W	3-3.5	3	118-130

Notes:

1. Advance dextrose in central hyperalimentation as tolerated per day as long as blood glucose remains normal.
2. Advance lipids by 0.5-1.0 g/kg/d as long as triglycerides are normal. Use 20% concentration.
3. Total water should be 100-150 mL/kg/d, depending on the child's fluid needs.

Monitoring:

1. Blood glucose two or three times a day when changing dextrose concentration, then daily.
2. Electrolytes daily, then twice a week when the child is receiving a stable solution.
3. Every other week blood urea nitrogen and serum creatinine; total protein and serum albumin; serum calcium, phosphate, magnesium, direct bilirubin, and CBC with platelet counts.
4. Triglyceride level after 24 h at 2 g/kg/d and 24 h at 3 g/kg/d, then every other week.

itoring body weight, urine output, fluid and electrolyte intake, serum and urine electrolytes, and glucose allows fairly precise determination of the infant's water, glucose, and electrolyte needs. Parenteral nutrition should be started early and continued until an adequate enteral intake is achieved.

D. Nutritional Support

The average caloric requirement for the growing premature infant is 120 kcal/kg/d. Expected weight gain is 10-20 g/kg/d. Infants initially require IV glucose infusion to maintain blood glucose concentration in the range of 60-100 mg/dL. Infusions of 5-7 mg/kg/min (approximately 80-100 mL/kg/d of D₁₀W) are usually needed. Aggressive nutritional support in the very low birth weight infant should be started as soon as possible after birth, with parenteral alimentation solutions containing 3 g/kg/d of amino acids, given either peripherally or centrally via an umbilical vein line or percutaneous catheter (Table 1-18). Small-volume trophic feeds with breast milk or 20 kcal/oz premature formula should be started by gavage at 10% or less of the infant's nutritional needs (< 10 mL/kg/d) as soon as possible, generally within the first few days after birth. After several days of trophic feeds the infant can be slowly advanced to full caloric needs over 5-7 days. Even extremely small feedings can enhance intestinal readiness to accept larger feeding volumes. Intermittent bolus feedings are preferred because these appear to stimulate the release of gut-related hormones and may accelerate maturation of the GI tract, although in the extremely low birth weight infant (< 1000 g) or the postsurgical neonate, continuous-drip feeds are sometimes better tolerated. A

more rapid advancement schedule is used for infants weighing more than 1500 g, and the slowest schedule for those weighing less than 1000 g.

In general, long-term nutritional support for infants of very low birth weight consists either of breast milk supplemented to increase protein, caloric density, and mineral content, or of infant formulas modified for preterm infants. In these formulas, protein concentrations (approximately 2 g/dL) and caloric concentrations (approximately 24 kcal/oz) are relatively high. In addition, premature formulas contain some medium-chain triglycerides—which do not require bile for emulsification—as an energy source. Increased calcium and phosphorus are provided to enhance bone mineralization. Formulas for both full-term and premature infants are enriched with long-chain polyunsaturated fatty acids in the hope of enhancing brain and retinal development. The infant should gradually be offered feedings of higher caloric density after a substantial volume (100-120 mL/kg/d) of either breast milk or formula (20 kcal/oz) is tolerated. Success of feedings is assessed by passage of feeds out of the stomach without emesis or large residual volumes, abdominal examination free of distention, and normal stool pattern.

When the preterm infant approaches term, the nutritional source for the bottle-fed infant can be changed to a transitional formula (22 kcal/oz) until age 6-9 months. Additional iron supplementation (2-4 mg/kg/d) is recommended for premature infants, beginning at about age 2 months. In some infants, iron supplementation may be indicated earlier. In particular, infants who are treated with erythropoietin (epoetin alfa) for prevention or treatment of anemia of prematurity require a higher dosage of 4-8 mg/kg/d.

3. Apnea in the Preterm Infant

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Respiratory pause of sufficient duration to result in cyanosis or bradycardia.
- ▶ Most common in infants born before 34 weeks' gestation; onset before 2 weeks of age.
- ▶ Methylxanthines (eg, caffeine) provide effective treatment.

▶ General Considerations

Apnea is defined as a respiratory pause lasting more than 20 seconds—or any pause accompanied by cyanosis and bradycardia. Shorter respiratory pauses associated with cyanosis or bradycardia also qualify as significant apnea but must be differentiated from periodic breathing, which is common in full-term and preterm infants. Periodic breathing is defined as regularly recurring ventilatory cycles interrupted by short pauses not associated with bradycardia or color change. By definition, apnea of prematurity is not associated with a predisposing factor. However, a variety of processes may precipitate apnea (Table 1–19) and should be considered before a diagnosis of apnea of prematurity is established.

Apnea of prematurity is the most frequent cause of apnea. Most apnea of prematurity is mixed apnea characterized by a centrally (brainstem) mediated respiratory pause preceded or followed by airway obstruction. Less common is pure central or pure obstructive apnea. Apnea of prematurity is the result of immaturity of both the central respiratory regulatory centers and protective mechanisms that aid in maintaining airway patency.

▶ Clinical Findings

Onset is typically during the first 2 weeks of life. The frequency of spells gradually increases with time. Pathologic

Table 1–19. Causes of apnea in the preterm infant.

Temperature instability—both cold and heat stress
Response to passage of a feeding tube
Gastroesophageal reflux

Posthemorrhagic hydrocephalus
Seizures
Drugs (eg, morphine)
Apnea of prematurity

apnea should be suspected if spells are sudden in onset, unusually frequent, or very severe. Apnea at birth or on the first day of life is unusual but can occur in the nonventilated preterm infant with respiratory distress syndrome. In the full-term or near-term infant, presentation at birth suggests neuromuscular abnormalities of an acute (asphyxia, birth trauma, or infection) or chronic (eg, congenital hypotonia or structural CNS lesion) nature.

All infants—regardless of the severity and frequency of apnea—require a minimum screening evaluation, including a general assessment of well-being (eg, tolerance of feedings, stable temperature, normal physical examination), a check of the association of spells with feeding, measurement of PaO₂ or SaO₂, blood glucose, hematocrit, and a review of the drug history. Infants with severe apnea of sudden onset require more extensive evaluation for primary causes, especially infection. Other specific tests are dictated by relevant signs, for example, evaluation for necrotizing enterocolitis (NEC) in an infant with apnea and abdominal distention or feeding intolerance.

▶ Treatment

Any underlying cause should be treated. If the apnea is due simply to prematurity, symptomatic treatment is dictated by the frequency and severity of apneic spells. Spells frequent enough to interfere with other aspects of care (eg, feeding), or severe enough to cause cyanosis or bradycardia necessitating bag and mask ventilation require treatment. First-line therapy is methylxanthines. Caffeine citrate (20 mg/kg as loading dose and then 5–10 mg/kg/d) is the drug of choice. Side effects of caffeine include tachycardia and feeding intolerance. The dose used should be the smallest dose necessary to decrease the frequency of apnea and eliminate severe spells. Target drug level is usually 10–20 mcg/mL. Nasal continuous positive airway pressure (CPAP), by treating the

obstructive component of apnea, is effective in some infants. Intubation and ventilation can eliminate apneic spells but carry the risks associated with endotracheal intubation. Although many preterm infants are treated medically for possible reflux-associated apnea, there is little evidence to support this intervention.

► Prognosis

In most premature infants, apneic and bradycardiac spells cease by 34–37 weeks postconception. Spells that require intervention cease prior to self-resolving episodes. In infants born at less than 28 weeks' gestation, episodes may continue past term. Apneic and bradycardiac episodes in the nursery are not predictors of later SIDS, although the incidence of SIDS is slightly increased in preterm infants. Thus, home monitoring in infants who experienced apnea in the nursery is rarely indicated.

4. Hyaline Membrane Disease

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Tachypnea, cyanosis, and expiratory grunting.
- Poor air movement despite increased work of breathing.
- Chest radiograph showing hypoexpansion and air bronchograms.

► General Considerations

The most common cause of respiratory distress in the preterm infant is hyaline membrane disease. The incidence increases from 5% of infants born at 35–36 weeks' gestation to more than 50% of infants born at 26–28 weeks' gestation. This condition is caused by a deficiency of surfactant. Surfactant decreases surface tension in the alveolus during expiration, allowing the alveolus to remain partly expanded and maintain a functional residual capacity. The absence of surfactant results in poor lung compliance and atelectasis. The infant must expend a great deal of effort to expand the lungs with each breath, and respiratory failure ensues (Figure 1–9).

► Clinical Findings

Infants with hyaline membrane disease show all the clinical signs of respiratory distress. On auscultation, air movement is diminished despite vigorous respiratory effort. The chest radiograph demonstrates diffuse bilateral atelectasis, causing a ground-glass appearance. Major airways are highlighted by the atelectatic air sacs, creating air bronchograms. In the unintubated child, doming of the diaphragm and underexpansion occur.

▲ **Figure 1–9.** Pressure–volume relationships for the inflation and deflation of surfactant-deficient and surfactant-treated preterm rabbit lungs. (Reproduced, with permission, from Jobe AH: The developmental biology of the lung. In: Fanaroff AA, Martin RJ [editors]: *Neonatal-Perinatal Medicine: Diseases of the Fetus and Infant*, 6th ed. Mosby, 1997.)

► Treatment

Supplemental oxygen, nasal CPAP, early intubation for surfactant administration and ventilation, and placement of umbilical artery and vein lines are the initial interventions required. A ventilator that can deliver breaths synchronized with the infant's respiratory efforts (synchronized intermittent mandatory ventilation) should be used. High-frequency ventilators are available for rescue of infants doing poorly on conventional ventilation or who have air leak problems.

Surfactant replacement is used both in the delivery room as prophylaxis for infants born before 27 weeks' gestation and with established hyaline membrane disease as rescue, preferably within 2–4 hours of birth. Surfactant therapy decreases both the mortality rate in preterm infants and air leak complications of the disease. During the acute course, ventilator settings and oxygen requirements are significantly lower in surfactant-treated infants than in controls. The dose of the bovine-derived beractant (Survanta) is 4 mL/kg, the calf lung surfactant extract (Infasurf) is 3 mL/kg, and the porcine-derived poractant (Curosurf) is 1.25–2.5 mL/kg, given intratracheally. Repeat dosing is indicated in infants who remain on the ventilator in more than 30–40% oxygen. A total of two to three doses given 8–12 hours apart may be given. As the disease evolves, proteins that inhibit surfactant function leak into the air spaces, making surfactant replacement less effective. In stable infants, a trial of nasal CPAP at 5–6 cm H₂O pressure can be attempted prior to intubation and surfactant administration. For those who require mechanical ventilation, extubation to nasal CPAP should be done as early as possible to minimize lung injury and evolution of chronic lung disease. Antenatal administration of corticosteroids to the mother is an important strategy to accelerate lung maturation. Infants whose mothers were given corticosteroids more than 24 hours prior to preterm birth are less likely to have respiratory distress syndrome and have a lower mortality rate.

5. Chronic Lung Disease in the Premature Infant

► General Considerations

Chronic lung disease, defined as respiratory symptoms, oxygen requirement, and chest radiograph abnormalities at 36 weeks postconception, occurs in about 20% of preterm infants ventilated for surfactant deficiency. The incidence is higher at lower gestational ages and in infants exposed to chorioamnionitis prior to birth. The development of chronic lung disease is a function of lung immaturity at birth, inflammation, and exposure to high oxygen concentrations and ventilator volutrauma. Surfactant replacement therapy or early nasal CPAP has diminished the severity of chronic lung disease. The mortality rate from chronic lung disease is very low, but there is still significant morbidity secondary to reactive airway symptoms and hospital readmissions during the first 2 years of life for intercurrent respiratory infection.

► Treatment

Long-term supplemental oxygen, mechanical ventilation, and nasal CPAP are the primary therapies for chronic lung disease of the premature. Diuretics (furosemide, 1–2 mg/kg/d, or hydrochlorothiazide-spironolactone, 1–2 mg/kg/d), inhaled β_2 -adrenergics, inhaled corticosteroids (fluticasone or budesonide), and systemic corticosteroids (dexamethasone, 0.2–0.5 mg/kg/d, or hydrocortisone, 1–3 mg/kg/d) are used as adjunctive therapy. The use of systemic corticosteroids remains controversial. Although a decrease in lung inflammation can aid infants in weaning from ventilator support, there are data associating dexamethasone use in the first several weeks of life with an increased incidence of cerebral palsy. This risk must be balanced against the higher risk of neurodevelopmental handicap in infants with severe chronic lung disease. There is likely a point in the course of these infants at which the benefit of using systemic corticosteroids for the shortest amount of time at the lowest dose possible outweighs the risk of continued mechanical ventilation. After hospital discharge, some of these infants will require oxygen at home. This can be monitored by pulse oximetry with a target SaO_2 of 94–96%. Some will continue to manifest pulmonary symptomatology into adolescence.

6. Patent Ductus Arteriosus

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Hyperdynamic precordium.
- Widened pulse pressure.
- Hypotension.
- Presence of a systolic heart murmur in many cases.

► General Considerations

Clinically significant patent ductus arteriosus usually presents on days 3–7 as the respiratory distress from hyaline membrane disease is improving. Presentation can be on days 1 or 2, especially in infants born before 28 weeks' gestation and in those who have received surfactant replacement therapy. The signs include a hyperdynamic precordium, increased peripheral pulses, and a widened pulse pressure with or without a systolic heart murmur. Early presentations are sometimes manifested by systemic hypotension without a murmur or hyperdynamic circulation. These signs are often accompanied by an increased need for respiratory support and metabolic acidemia. The presence of patent ductus arteriosus is confirmed by echocardiography.

► Treatment

Treatment of patent ductus arteriosus is by medical or surgical ligation. A clinically significant ductus can be closed

with indomethacin (0.1–0.2 mg/kg IV q12–24h for three doses) in about two thirds of cases. If the ductus reopens or fails to close completely, a second course of drug may be used. If indomethacin fails to close the ductus or if a ductus reopens a second time, surgical ligation is appropriate. In some cases, a more prolonged course of indomethacin can be used to prevent recurrences. In addition, in the extremely low birth weight infant (< 1000 g) who is at very high risk of developing a symptomatic ductus, a prophylactic strategy of indomethacin (0.1 mg/kg q24h for 3–5 days) on the first day of life can be used. The major side effect of indomethacin is transient oliguria, which can be managed by fluid restriction until urine output improves. There may also be an increased incidence of NEC with prolonged therapy. Transient decrease in intestinal and cerebral blood flow caused by indomethacin can be ameliorated by giving the drug as a slow infusion over 1–2 hours. Indomethacin should not be used if the infant is hyperkalemic, if the creatinine is higher than 2 mg/dL, or if the platelet count is less than 50,000/mL. There is an increased incidence of intestinal perforation if used concomitantly with hydrocortisone in extremely low birth weight infants (9% versus 2% for either drug alone). Ibuprofen lysine can be used as an alternative to indomethacin given every 24 hours as an initial dose of 10 mg/kg and then 5 mg/kg for two doses. Oliguria is less severe and less frequent than with indomethacin.

7. Necrotizing Enterocolitis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Feeding intolerance with gastric residuals or vomiting.
- ▶ Bloody stools.
- ▶ Abdominal distention and tenderness.
- ▶ Pneumatosis intestinalis on abdominal radiograph.

▶ General Considerations

NEC is the most common acquired GI emergency in the newborn. It is most common in preterm infants, with an incidence of 10% in infants less than 1500 g. In full-term

infants, it occurs in association with polycythemia, congenital heart disease, and birth asphyxia. The pathogenesis of NEC is multifactorial. Previous intestinal ischemia, bacterial or viral infection, and immunologic immaturity of the gut are all thought to play a role. In up to 20% of affected infants, the only risk factor is prematurity. IUGR infants with a history of absent or reversed end-diastolic flow in the umbilical artery prior to delivery, have abnormalities of splanchnic flow after delivery and have an increased risk of NEC.

▶ Clinical Findings

The most common presenting sign is abdominal distention. Other signs are vomiting, increased gastric residuals, hemepositive stools, abdominal tenderness, temperature instability, increased apnea and bradycardia, decreased urine output, and poor perfusion. There may be an increased white blood cell count with an increased band count or, as the disease progresses, absolute neutropenia. Thrombocytopenia often occurs along with stress-induced hyperglycemia and metabolic acidosis. Diagnosis is confirmed by the presence of pneumatosis intestinalis (air in the bowel wall) on a plain abdominal radiograph. There is a spectrum of disease, and milder cases may exhibit only distention of bowel loops with bowel wall edema.

▶ Treatment

A. Medical Treatment

NEC is managed by nasogastric decompression of the gut, maintenance of oxygenation, mechanical ventilation if necessary, and IV fluids to replace third-space GI losses. Enough fluid should be given to restore good urine output. Other measures include broad-spectrum antibiotics (usually ampicillin, a third-generation cephalosporin or an aminoglycoside, and possibly additional anaerobic coverage), close monitoring of vital signs, serial physical examinations, and laboratory studies (blood gases, white blood cell count, platelet count, and radiographs). Although there are no proven strategies to prevent NEC, use of trophic feedings and cautious advancement of feeds, as well as probiotic agents in sick infants, may provide some protection.

B. Surgical Treatment

Indications for surgery are evidence of perforation (free air present on a left lateral decubitus or cross-table lateral film), a fixed dilated loop of bowel on serial radiographs, abdominal wall cellulitis, or deterioration despite maximal medical support. All of these signs are indicative of necrotic bowel. In the operating room, necrotic bowel is removed and ostomies are created. In extremely low birth weight infants, the initial surgical management may simply be the placement of peritoneal drains. Reanastomosis in infants with ostomies is performed after the disease resolves and the infant is bigger (usually > 2 kg and after 4–6 weeks).

► Course & Prognosis

Infants treated medically or surgically should not be refeed until the disease is resolved (normal abdominal examination and resolution of pneumatosis), usually in 10–14 days. Nutritional support during this time should be provided by total parenteral nutrition.

Death occurs in 10% of cases. Surgery is needed in fewer than 25% of cases. Long-term prognosis is determined by the amount of intestine lost. Infants with short bowel require long-term support with IV nutrition (see Chapter 20). Late strictures—about 3–6 weeks after initial diagnosis—occur in 8% of patients whether treated medically or surgically, and generally require operative management. Infants with surgically managed NEC have an increased risk of poor neurodevelopmental outcome.

8. Anemia in the Premature Infant

► General Considerations

In the premature infant, the hemoglobin concentration reaches its nadir at about 8–12 weeks and is 2–3 g/dL lower than that of the full-term infant. The lower nadir in premature infants appears to be the result of decreased erythropoietin response to the low red cell mass. Symptoms of anemia include poor feeding, lethargy, increased heart rate, poor weight gain, and perhaps periodic breathing.

► Treatment

Transfusion is not indicated in an asymptomatic infant simply because of a low hematocrit. Most infants become symptomatic if the hematocrit drops below 20%. Infants on ventilators and supplemental oxygen are usually maintained with hematocrits above 30%. Alternatively, infants can be treated with erythropoietin (350 U/kg/d for 7–10 days for hematocrits < 28%). The therapeutic goal is to minimize blood draws and use conservative guidelines for transfusion.

Aher S, Ohlsson A: Late erythropoietin for preventing red blood cell transfusion in preterm and low birth weight infants. *Cochrane Database Syst Rev* 2006;(3):CD004868 [PMID: 16856064].

Murray NA, Roberts IAG: Neonatal transfusion practice. *Arch Dis Child Fetal Neonatal Ed* 2004;89:F101 [PMID: 14977890].

9. Intraventricular Hemorrhage

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Large bleeds cause hypotension, metabolic acidosis, and altered neurologic status; smaller bleeds can be asymptomatic.
- Routine cranial ultrasound scanning is essential for diagnosis in infants born before 32 weeks' gestation.

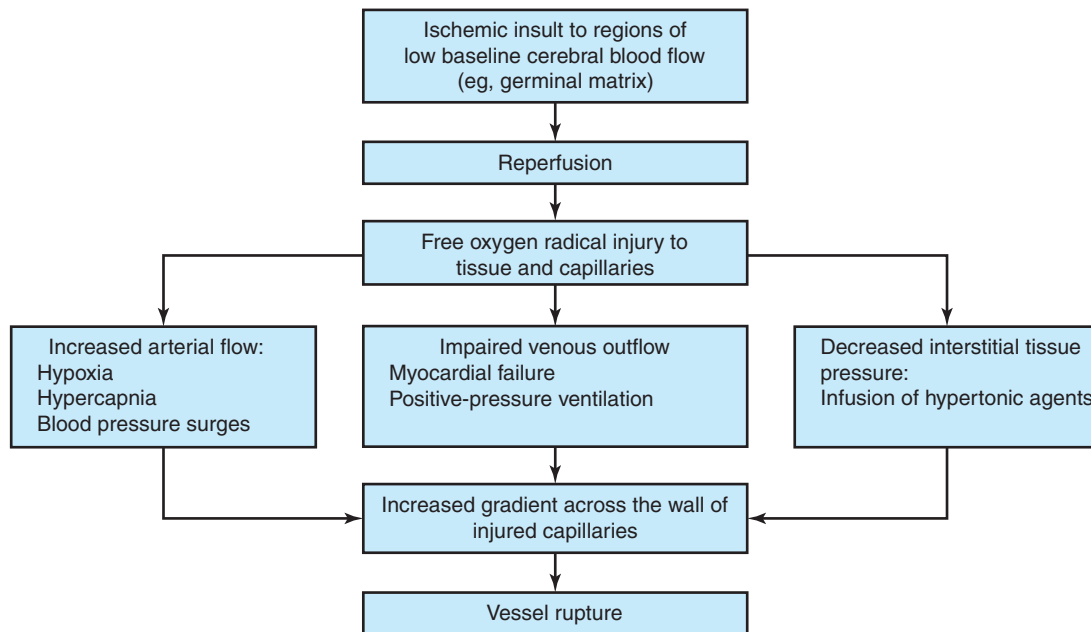

► General Considerations

Periventricular–intraventricular hemorrhage occurs almost exclusively in premature infants. The incidence is 20–30% in infants born before 31 weeks' gestation and weighing less than 1500 g. The highest incidence occurs in infants of the lowest gestational age (< 26 weeks). Bleeding most commonly occurs in the subependymal germinal matrix (a region of undifferentiated cells adjacent to or lining the lateral ventricles). Bleeding can extend into the ventricular cavity. The proposed pathogenesis of bleeding is presented in Figure 1–10. The critical event is ischemia with reperfusion injury to the capillaries in the germinal matrix in the immediate perinatal period. The actual amount of bleeding is also influenced by a variety of factors that affect the pressure gradient across the injured capillary wall. This pathogenetic scheme applies also to intraparenchymal bleeding (venous infarction in a region rendered ischemic) and to periventricular leukomalacia (ischemic white matter injury in a watershed region of arterial supply). CNS complications in preterm infants are more frequent in infants exposed antenatally to intrauterine infection.

► Clinical Findings

Up to 50% of hemorrhages occur before 24 hours of age, and virtually all occur by the fourth day. The clinical syndrome ranges from rapid deterioration (coma, hypoventilation, decerebrate posturing, fixed pupils, bulging anterior fontanelle, hypotension, acidosis, or acute drop in hematocrit), to a more gradual deterioration with more subtle neurologic changes, to absence of any specific physiologic or neurologic signs.

The diagnosis can be confirmed by real-time ultrasound scan. This is performed whenever bleeding is suspected. If symptoms are absent, routine scanning should be done at 10–14 days in all infants born before 29 weeks' gestation. Hemorrhages are graded as follows: grade I, germinal matrix hemorrhage only; grade II, intraventricular bleeding without ventricular enlargement; grade III, intraventricular bleeding with ventricular enlargement; or grade IV, any intraparenchymal bleeding. The amount of bleeding is minor (grade I or II) in 75% of infants and major in the remainder. Follow-

▲ **Figure 1-10.** Pathogenesis of periventricular and intraventricular hemorrhage.

up ultrasound examinations are scheduled based on the results of the initial scan. Infants with no bleeding or germinal matrix hemorrhage require only a single late scan at age 4–6 weeks to look for periventricular leukomalacia. An infant with blood in the ventricular system is at risk for posthemorrhagic ventriculomegaly. This is usually the result of impaired absorption of cerebrospinal fluid (CSF) but can also occur secondary to obstructive phenomena. An initial follow-up scan should be done 1–2 weeks after the initial scan. Infants with intraventricular bleeding and ventricular enlargement should be followed every 7–10 days until ventricular enlargement stabilizes or decreases.

► Treatment

During acute hemorrhage, supportive treatment (restoration of volume and hematocrit, oxygenation, and ventilation) should be provided to avoid further cerebral ischemia. Progressive posthemorrhagic hydrocephalus is treated initially with a subgaleal shunt. When the infant is large enough, this can be converted to a ventriculoperitoneal shunt.

Although the incidence and severity of intracranial bleeding in premature infants have decreased, strategies to prevent this complication are still needed. Maternal antenatal corticosteroids appear to decrease the risk of intracranial bleeding, and phenobarbital may have a role in the mother who has not been prepared with steroids and is delivering before 28 weeks' gestation. The route of delivery may be important as infants delivered by cesarean section have a decreased rate

of intracranial bleed. Postnatal strategies are less effective. Early indomethacin administration may have some benefit in minimizing bleeding, especially in males, with unclear influence on long-term outcome.

► Prognosis

No deaths occur as a result of grade I and grade II hemorrhages. Grade III and grade IV hemorrhages carry a mortality rate of 10–20%. Posthemorrhagic ventricular enlargement is rarely seen with grade I hemorrhages but is seen in 54–87% of grade II–IV hemorrhages. Very few of these infants will require a ventriculoperitoneal shunt. Long-term neurologic sequelae are seen no more frequently in infants with grade I and grade II hemorrhages than in preterm infants without bleeding. In infants with grade III and grade IV hemorrhages, severe sequelae occur in 20–25% of cases, mild sequelae in 35% of cases, and no sequelae in 40% of cases. Severe periventricular leukomalacia, large parenchymal bleeds, and progressive ventriculomegaly greatly increase the risk of neurologic sequelae. It is important to note that extremely low birth weight infants without major ultrasound findings remain at increased risk for both cerebral palsy and cognitive delays. Recent reports using quantitative MRI scans demonstrate that subtle gray and white matter findings not seen with ultrasound are prevalent in preterm survivors and are predictive of neurodevelopmental handicap. This is especially true in infants born weighing less than 1000 g and before 28 weeks' gestation.

Dyett LE et al: Natural history of brain lesions in extremely preterm infants studied with serial magnetic imaging from birth and neurodevelopmental assessment. *Pediatrics* 2006;118:536 [PMID: 16882805].

10. Retinopathy of Prematurity

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Risk of severe retinopathy is greatest in the most preterm infants.
- ▶ Diagnosis depends on screening eye exams in at-risk preterm infants.
- ▶ Examination evaluates stage of abnormal retinal vascular development, extent of retinal detachment, and distribution and amount of retina involved.

Retinopathy of prematurity occurs only in the incompletely vascularized premature retina. The incidence of retinopathy in infants weighing less than 1250 g is 66%, but only 6% have retinopathy severe enough to warrant intervention. The incidence is highest in infants of the lowest gestational age. The condition appears to be triggered by an initial injury to the developing retinal vessels. Hypoxia, shock, asphyxia, vitamin E deficiency, and light exposure have been associated with this initial injury. After the initial injury, normal vessel development may follow or abnormal vascularization may occur, with ridge formation on the retina. The process can regress at this point or may continue, with growth of fibrovascular tissue into the vitreous associated with inflammation, scarring, and retinal folds or detachment. The disease is graded by stages of abnormal vascular development and retinal detachment (I–V), by the zone of the eye involved (1–3, with zone 1 being the posterior region around the macula), and by the amount of the retina involved, in “clock hours” (eg, a detachment in the upper, outer quadrant of the left eye would be defined as affecting the left retina from 12 to 3 o’clock).

Initial eye examination should be performed at 4–6 weeks of age in infants with a birth weight less than 1500 g or in those born before 28 weeks’ gestation, as well as in infants weighing more than 1500 g with an unstable clinical course. Follow-up occurs at 1- to 2-week intervals until the retina is fully vascularized. Laser therapy is used in infants with progressive disease at risk for retinal detachment. Although this treatment does not always prevent retinal detachment, it

reduces the incidence of poor outcomes based on visual acuity and retinal anatomy.

11. Discharge & Follow-Up of the Premature Infant

A. Hospital Discharge

Criteria for discharge of the premature infant include maintaining normal temperature in an open crib, nipping all feeds, gaining weight, and absence of apnea and bradycardia spells requiring intervention. Infants going home on supplemental oxygen should not desaturate below 80% in room air or should demonstrate the ability to arouse in response to hypoxia. Factors such as support for the mother at home and the stability of the family situation play a role in the timing of discharge. Home nursing visits and early physician follow-up can be used to hasten discharge.

B. Follow-Up

With advances in obstetric and maternal care, survival of infants born after 28 weeks’ gestation or weighing as little as 1000 g at birth is now better than 90%. Seventy to 80% survive at 26–27 weeks’ gestation and birth weights of 800–1000 g. Survival at gestational age 25 weeks and birth weight 700–800 g is 50–70%, with a considerable drop-off below this level (Figure 1–11).

These high rates of survival come with some morbidity. Major neurologic sequelae, including cerebral palsy, cognitive delay, and hydrocephalus, occur in 10–25% of survivors of birth weight less than 1500 g. The rate of these sequelae tends to be higher in infants with lower birth weights. Infants with birth weights less than 1000 g also have an increased rate of lesser disabilities, including learning, behavioral, and psychiatric problems. Risk factors for neurologic sequelae include seizures, grade III or IV intracranial hemorrhage, periventricular leukomalacia, ventricular dilation, white matter abnormalities on term-equivalent MRI examinations, severe IUGR, poor early head growth, need for mechanical ventilation, chronic lung disease, NEC, and low socioeconomic class. Maternal fever and chorioamnionitis are associated with an increased risk of cerebral palsy. Other morbidities include chronic lung disease and reactive airway disease, resulting in increased severity of respiratory infections and hospital readmissions in the first 2 years; retinopathy of prematurity with

associated loss of visual acuity and strabismus; hearing loss; and growth failure. All of these issues require close multidisciplinary outpatient follow-up. Infants with residual lung disease are candidates for monthly palivizumab (Synagis) injections during their first winter after hospital discharge to prevent infection with respiratory syncytial virus. Routine immunizations should be given at the appropriate chronological age and should not be age-corrected for prematurity.

THE LATE PRETERM INFANT

The rate of preterm births in the United States has increased 31% since 1981. The largest contribution to this increase is from births between 34 and 36 completed weeks of gestation, which now represent 70% of preterm births in the United States. Compared with term infants, late preterm infants have higher frequencies of respiratory distress, temperature instability, hypoglycemia, kernicterus, apnea, seizures, feed-

ing problems, and rehospitalization after hospital discharge. The respiratory issues are caused by lack of clearance of lung fluid or relative deficiency of pulmonary surfactant, or both. Feeding issues are caused by lack of coordination of suck and swallow, which can interfere with bottle feeding and delay successful breast feeding, putting the infant at risk for poor weight gain and dehydration. Related both to feeding issues and immaturity, these infants have an eightfold increased risk of developing a TSB level above 20 mg/dL when compared with infants born after 40 completed weeks. As a consequence, late preterm infants are overrepresented in the kernicterus registry. Rehospitalizations due to jaundice, proven or suspected infection, feeding difficulties, and failure to thrive are much more common than in term infants. Late preterm infants should be considered preterm rather than near term and require close in-hospital monitoring after birth for complications. After nursery discharge, close outpatient follow-up is indicated, especially if they are sent home within 48–72 hours after birth.

CARDIAC PROBLEMS IN THE NEWBORN INFANT

STRUCTURAL HEART DISEASE

1. Cyanotic Presentations

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Cyanosis, initially without associated respiratory distress.
- ▶ Failure to increase P_{aO_2} with supplemental oxygen.
- ▶ Chest radiograph with decreased lung markings suggests right heart obstruction, while increased lung markings suggest transposition or pulmonary venous obstruction.

▶ General Considerations

The causes of cyanotic heart disease in the newborn are transposition of the great vessels, total anomalous pulmo-

nary venous return, truncus arteriosus (some types), tricuspid atresia, and pulmonary atresia or critical pulmonary stenosis.

▶ Clinical Findings

Infants with these disorders present with early cyanosis. The hallmark of many of these lesions is cyanosis without associated respiratory distress. In most of these infants, tachypnea develops over time either because of increased pulmonary blood flow or secondary to metabolic acidemia from progressive hypoxemia. Diagnostic aids include comparing the blood gas or oxygen saturation in room air to that in 100% FI_{O_2} . Failure of Pa_{O_2} or Sa_{O_2} to increase suggests cyanotic heart disease. **Note:** A Pa_{O_2} , if feasible, is the preferred measure. Saturation in the newborn may be misleadingly high despite pathologically low Pa_{O_2} due to the left-shifted oxyhemoglobin dissociation curve seen with fetal hemoglobin. Other useful aids are chest radiography, electrocardiography, and echocardiography.

Transposition of the great vessels is the most common form of cyanotic heart disease presenting in the newborn. Examination generally reveals a systolic murmur and single S_2 . Chest radiograph shows a generous heart size and a narrow mediastinum with normal or increased lung markings. There is little change in Pa_{O_2} or Sa_{O_2} with supplemental oxygen. Total anomalous pulmonary venous return, in which venous return is obstructed, presents early with severe cyanosis and tachypnea because the pulmonary venous return is obstructed, resulting in pulmonary edema. The chest radiograph typically shows a small to normal heart size with marked pulmonary edema. Infants with right heart obstruction (pulmonary and tricuspid atresia, critical pulmonary stenosis, and some forms of truncus arteriosus) have decreased lung markings on chest radiographs and, depending on the severity of hypoxia, may develop metabolic acidemia. Those lesions with an underdeveloped right heart will have left-sided predominance on electrocardiography. Although tetralogy of Fallot is the most common form of cyanotic heart disease, the obstruction at the pulmonary valve is often not severe enough to result in cyanosis in the newborn. In all cases, diagnosis can be confirmed by echocardiography.

2. Acyanotic Presentations

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Most newborns with acyanotic heart disease have left-sided outflow obstruction.
- ▶ Differentially diminished pulses (coarctation) or decreased pulses throughout (aortic atresia).
- ▶ Metabolic acidemia.

- ▶ Chest radiograph showing large heart and pulmonary edema.

▶ General Considerations

Newborn infants who present with serious acyanotic heart disease usually have congestive heart failure secondary to left-sided outflow tract obstruction. Infants with left-to-right shunt lesions (eg, ventricular septal defect) may have murmurs in the newborn period, but clinical symptoms do not occur until pulmonary vascular resistance drops enough to cause significant shunting and subsequent congestive heart failure (usually at 3–4 weeks of age).

▶ Clinical Findings

Infants with left-sided outflow obstruction generally do well the first day or so until the ductus arteriosus—the source of all or some of the systemic flow—narrows. Tachypnea, tachycardia, congestive heart failure, and metabolic acidosis develop. On examination, all of these infants have abnormalities of the pulses. In aortic atresia (hypoplastic left heart syndrome) and stenosis, pulses are all diminished, whereas in coarctation syndromes, differential pulses (diminished or absent in the lower extremities) are evident. Chest radiographic films in these infants show a large heart and pulmonary edema. Diagnosis is confirmed with echocardiography.

3. Treatment of Cyanotic & Acyanotic Lesions

Early stabilization includes supportive therapy as needed (eg, IV glucose, oxygen, ventilation for respiratory failure, and pressor support). Specific therapy includes infusions of prostaglandin E₁ (0.025–0.1 µg/kg/min) to maintain ductal patency. In some cyanotic lesions (eg, pulmonary atresia, tricuspid atresia, and critical pulmonary stenosis) in which lung blood flow is ductus-dependent, this improves pulmonary blood flow and PaO₂ by allowing shunting through the ductus to the pulmonary artery. In left-sided outflow tract obstruction, systemic blood flow is ductus-dependent; prostaglandins improve systemic perfusion and resolve the acidosis. Further specific management—including palliative surgical and cardiac catheterization procedures—is discussed in Chapter 19. Neurodevelopmental outcome with congenital heart disease depends on the lesion, severity of neonatal presentation, and complications related to palliative and corrective surgery.

PERSISTENT PULMONARY HYPERTENSION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Onset of symptoms on day 1 of life.

- ▶ Hypoxia with poor response to high concentrations of inspired oxygen.
- ▶ Right-to-left shunts through the foramen ovale, ductus arteriosus, or both.
- ▶ Most often associated with parenchymal lung disease.

▶ General Considerations

Persistent pulmonary hypertension of the newborn (PPHN) results when the normal decrease in pulmonary vascular resistance after birth does not occur. Most affected infants are full term or postterm, and many have experienced perinatal asphyxia. Other clinical associations include hypothermia, meconium aspiration syndrome, hyaline membrane disease, polycythemia, neonatal sepsis, chronic intrauterine hypoxia, and pulmonary hypoplasia.

There are three underlying pathophysiologic mechanisms of PPHN: (1) vasoconstriction due to perinatal hypoxia related to an acute event such as sepsis or asphyxia; (2) prenatal increase in pulmonary vascular smooth muscle development, often associated with meconium aspiration syndrome; and (3) decreased cross-sectional area of the pulmonary vascular bed associated with lung hypoplasia (eg, diaphragmatic hernia).

▶ Clinical Findings

Clinically, the syndrome is characterized by onset on the first day of life, usually from birth. Respiratory distress is prominent, and PaO₂ is usually poorly responsive to high concentrations of inspired oxygen. Many infants have associated myocardial depression with systemic hypotension. Echocardiography reveals right-to-left shunting at the level of the ductus arteriosus or foramen ovale, or both. The chest radiograph usually shows lung infiltrates related to associated pulmonary pathology (eg, meconium aspiration and hyaline membrane disease). If the majority of right-to-left shunting is at the ductal level, pre- and postductal differences in PaO₂ and SaO₂ will be observed.

▶ Treatment

Therapy for PPHN involves treatment of other postasphyxia problems such as seizures, renal failure, hypoglycemia, and infection. Specific therapy is aimed at both increasing systemic arterial pressure and decreasing pulmonary arterial pressure to reverse the right-to-left shunting through fetal pathways. First-line therapy includes oxygen and ventilation (to reduce pulmonary vascular resistance) and crystalloid infusions (10 mL/kg, up to 30 mL/kg) to improve systemic pressure. Ideally, systolic pressure should be greater than 50 mm Hg. With compromised cardiac function, systemic pressors can be used as second-line therapy (eg, dopamine, 5–20 mcg/kg/min; dobutamine, 5–20 mcg/kg/min; or both). Metabolic acidemia should be corrected because acidemia exacerbates

bates pulmonary vasoconstriction. In some cases, a mild respiratory alkalosis may improve oxygenation. Pulmonary vasodilation can be enhanced using inhaled nitric oxide, which is identical or very similar to endogenous endothelium-derived relaxing factor, at doses of 5–20 ppm. High-frequency oscillatory ventilation has proved effective in many of these infants, particularly those with severe associated lung disease. Infants for whom conventional therapy is failing (poor oxygenation despite maximum support) may require extracorporeal membrane oxygenation (ECMO). The lungs are essentially at rest during ECMO, and with resolution of pulmonary hypertension infants are weaned from ECMO back to ventilator therapy. Approximately 10–15% of survivors of PPHN have significant neurologic sequelae, with cerebral palsy or cognitive delays. Other sequelae such as chronic lung disease, sensorineural hearing loss, and feeding problems have also been reported.

ARRHYTHMIAS

Irregularly irregular heart rates, commonly associated with premature atrial contractions and less commonly with premature ventricular contractions, are common in the first days of life in well newborns. These arrhythmias are benign. Clinically significant bradyarrhythmias are seen in association with congenital heart block. Heart block can be seen in an otherwise structurally normal heart (associated with maternal lupus) or with structural cardiac abnormalities. In the absence of fetal hydrops, the bradyarrhythmia is often well tolerated. Cardiac pacing may be required if there are symptoms of inadequate cardiac output.

On ECG, tachyarrhythmias can be either wide complex (ventricular tachycardia) or narrow complex (supraventricular tachycardia). Supraventricular tachycardia is the most common neonatal tachyarrhythmia and may be a sign of structural heart disease, myocarditis, left atrial enlargement, and aberrant conduction pathways. Acute treatment is ice to the face, and if unsuccessful, IV adenosine (50–200 mcg/kg). If there is no response, the dose can be increased to 300 mcg/kg. Long-term therapy is with digoxin or propranolol. Digoxin should not be used in infants with Wolff-Parkinson-White syndrome. Cardioversion is rarely needed for supraventricular tachycardia but is needed acutely for hemodynamically unstable ventricular tachycardia.

GASTROINTESTINAL & ABDOMINAL SURGICAL CONDITIONS IN THE NEWBORN INFANT (SEE ALSO CHAPTER 20)

ESOPHAGEAL ATRESIA & TRACHEOESOPHAGEAL FISTULA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Polyhydramnios.
- ▶ Excessive drooling and secretions; choking with attempted feeding.
- ▶ Unable to pass an orogastric tube to the stomach.

General Considerations

Esophageal atresia is characterized by a blind esophageal pouch with or without a fistulous connection between the proximal or distal esophagus (or both) and the airway. In 85% of infants, the fistula is between the distal esophagus and the airway. Polyhydramnios is common because of high GI obstruction. Incidence is approximately 1 in 3000 births.

Clinical Findings

Infants present in the first hours of life with copious secretions, choking, cyanosis, and respiratory distress. Diagnosis is confirmed with chest radiograph after careful placement of a nasogastric (NG) tube to the point at which resistance is met. The tube will be seen radiographically in the blind pouch. If a tracheoesophageal fistula is present to the distal esophagus, gas will be present in the bowel. In esophageal atresia without tracheoesophageal fistula, there is no gas in the bowel.

Treatment

The NG tube in the proximal pouch should be placed on low intermittent suction to drain secretions and prevent aspiration. The head of the bed should be elevated to prevent reflux of gastric contents through the distal fistula into the lungs. IV glucose and fluids should be provided and oxygen administered as needed. Definitive treatment is surgical, and the technique used depends on the distance between the segments of esophagus. If the distance is not too great, the fistula can be ligated and the ends of the esophagus anastomosed. If the ends of the esophagus cannot be brought together, the initial surgery is fistula ligation and a feeding gastrostomy. Echocardiography should be performed prior to surgery to rule out a right-sided aortic arch (for which a left-sided thoracotomy would be preferred).

Prognosis

Prognosis is determined primarily by the presence or absence of associated anomalies. Vertebral, anal, cardiac,

renal, and limb anomalies are the most likely to be observed (VACTERL association). Evaluation for associated anomalies should be initiated early.

INTESTINAL OBSTRUCTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Infants with high intestinal obstruction present soon after birth with emesis.
- ▶ Bilious emesis suggests intestinal malrotation with midgut volvulus until proved otherwise.
- ▶ Low intestinal obstruction is characterized by abdominal distention and late onset of emesis.

▶ General Considerations

A history of polyhydramnios is common, and the fluid, if bile-stained, can easily be confused with thin meconium staining. The higher the location of the obstruction in the intestine, the earlier the infant will develop vomiting and the less prominent the distention will be. The opposite is true for lower intestinal obstructions. Most obstructions are bowel atresias, believed to be caused by an ischemic event during development. Approximately 30% of cases of duodenal atresia are associated with Down syndrome. Meconium ileus is a distal small bowel obstruction caused by the viscous meconium produced in utero by infants with pancreatic insufficiency secondary to cystic fibrosis. Hirschsprung disease is caused by a failure of neuronal migration to the myenteric

plexus of the distal bowel. The distal bowel lacks ganglion cells, causing a lack of peristalsis in that region with a functional obstruction.

Malrotation with midgut volvulus is a surgical emergency that appears in the first days to weeks as bilious vomiting without distention or tenderness. If malrotation is not treated promptly, torsion of the intestine around the superior mesenteric artery will lead to necrosis of the small bowel. For this reason, bilious vomiting in the neonate always demands immediate attention and evaluation.

▶ Clinical Findings

Diagnosis of intestinal obstructions depends on plain abdominal radiographs with either upper GI series (high obstruction suspected) or contrast enema (lower obstruction apparent) to define the area of obstruction. Table 1–20 summarizes the findings expected.

Infants with meconium ileus are presumed to have cystic fibrosis. Infants with pancolonic Hirschsprung disease, colon pseudo-obstruction syndrome, or colonic dysgenesis or atresia may also present with meconium impacted in the distal ileum. Definitive diagnosis of cystic fibrosis is by the sweat chloride test (Na^+ and Cl^- concentration > 60 mEq/L) or by genetic testing. Approximately 10–20% of infants with cystic fibrosis have meconium ileus. Infants with cystic fibrosis and meconium ileus generally have a normal immunoreactive trypsinogen on their newborn screen because of the associated severe exocrine pancreatic insufficiency in utero.

Intestinal perforation in utero results in meconium peritonitis with residual intra-abdominal calcifications. Many perforations are completely healed at birth. If the infant has no signs of obstruction, no immediate evaluation is needed.

Table 1–20. Intestinal obstruction.

Site of Obstruction	Clinical Findings	Plain Radiographs	Contrast Study
Duodenal atresia	Down syndrome (30–50%); early vomiting, sometimes bilious	“Double bubble” (dilated stomach and proximal duodenum, no air distal)	Not needed
Malrotation and volvulus	Bilious vomiting with onset anytime in the first few weeks	Dilated stomach and proximal duodenum; paucity of air distally (may be normal gas pattern)	UGI shows displaced duodenojejunal junction with “corkscrew” deformity of twisted bowel
Jejunioileal atresia, meconium ileus	Bilious gastric contents > 25 mL at birth; progressive distention and bilious vomiting	Multiple dilated loops of bowel; intra-abdominal calcifications if in-utero perforation occurred (meconium peritonitis)	Barium or osmotic contrast enema shows microcolon; contrast refluxed into distal ileum may demonstrate and relieve meconium obstruction (successful in about 50% of cases)
Meconium plug syndrome; Hirschsprung disease	Distention, delayed stooling (> 24 h)	Diffuse bowel distention	Barium or osmotic contrast enema outlines and relieves plug; may show transition zone in Hirschsprung disease; delayed emptying (> 24 h) suggests Hirschsprung disease

UGI, upper gastrointestinal contrast study.

A sweat test to rule out cystic fibrosis should be done at a later date.

Low intestinal obstruction may present with delayed stooling (> 24 hours in term infants is abnormal) with mild distention. Radiographic findings of gaseous distention should prompt contrast enema to diagnose (and treat) meconium plug syndrome. If no plug is found, the diagnosis may be small left colon syndrome (occurring in IDMs) or Hirschsprung disease. Rectal biopsy will be required to clarify these two diagnoses. Imperforate anus is generally apparent on physical examination, although a rectovaginal fistula with a mildly abnormal-appearing anus can occasionally be confused with normal. High imperforate anus in males may be associated with rectourethral or rectovesical fistula.

▶ Treatment

NG suction to decompress the bowel, IV glucose, fluid and electrolyte replacement, and respiratory support as necessary should be instituted. Antibiotics are usually indicated due to the bowel distention and possibility of translocation of bacteria. The definitive treatment for these conditions (with the exception of meconium plug syndrome, small left colon syndrome, and some cases of meconium ileus) is surgical.

▶ Prognosis

Up to 10% of infants with meconium plug syndrome are subsequently found to have cystic fibrosis or Hirschsprung disease. For this reason, it is appropriate to obtain a sweat chloride test and rectal biopsy in all of these infants before discharge. The infant with meconium plug syndrome who is still symptomatic after contrast enema should have a rectal biopsy.

In duodenal atresia associated with Down syndrome, the prognosis depends on associated anomalies (eg, heart defects) and the severity of prestenotic duodenal dilation and subsequent duodenal dysmotility. Otherwise, these conditions usually carry an excellent prognosis after surgical repair.

ABDOMINAL WALL DEFECTS

1. Omphalocele

Omphalocele is a membrane-covered herniation of abdominal contents into the base of the umbilical cord. There is a high incidence of associated anomalies (cardiac, GI, and chromosomal—eg, trisomy 13). The sac may contain liver and spleen as well as intestine.

At delivery, the omphalocele is covered with a sterile dressing soaked with warm saline to prevent fluid loss. NG decompression is performed, and IV fluids, glucose, and antibiotics are given. If the contents of the omphalocele will fit into the abdomen and can be covered with skin, muscle, or both, primary surgical closure is done. If not, staged closure is performed, with placement of a Gore-Tex patch over the exposed contents, and gradual coverage of the patch

by skin over days to weeks. A large ventral hernia is left, which is repaired in the future.

2. Gastroschisis

In gastroschisis, the uncovered intestine extrudes through a small abdominal wall defect lateral to the umbilical cord. There is no membrane or sac and no liver or spleen outside the abdomen. Gastroschisis is associated with intestinal atresia in approximately 10% of infants. The evisceration is thought to be related to abnormal involution of the right umbilical vein, although the exact cause is unknown. The prevalence of gastroschisis has been increasing over the past 20 years, from 0.03% to 0.1%. Environmental factors, including use of drugs such as methamphetamine and cocaine, may be involved.

Therapy initially involves placing the bowel of the infant into a silastic bowel bag to decrease fluid and electrolyte losses as well as to conserve heat. IV fluids, antibiotics, and low intermittent gastric suction are required. The infant is placed right side down to preserve bowel perfusion. Subsequent therapy involves replacement of the bowel into the abdominal cavity. This is done as a single primary procedure if the amount of bowel to be replaced is small. If the amount of bowel is large, staged closure with placement of a silastic silo and gradual reduction of the bowel into the underdeveloped abdominal cavity over several days is the preferred method of treatment. Postoperatively, third-space fluid losses may be extensive; fluid and electrolyte therapy, therefore, must be monitored carefully. Bowel motility, especially duodenal, may be slow to return if the bowel was dilated, thickened, matted together, and covered with a fibrinous “peel” at delivery. Prolonged intravenous nutrition may be required.

DIAPHRAGMATIC HERNIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Respiratory distress from birth.
- ▶ Poor breath sounds; flat or scaphoid abdomen.
- ▶ Bowel loops seen in the chest with mediastinal shift to opposite side on chest radiograph.

This congenital malformation consists of herniation of abdominal organs into the hemithorax (usually left-sided) through a posterolateral defect in the diaphragm. It presents in the delivery room as severe respiratory distress in an infant with poor breath sounds and scaphoid abdomen. The rapidity and severity of presentation depend on several factors: the degree of pulmonary hypoplasia resulting from lung compression by the intrathoracic abdominal contents in utero; degree of associated pulmonary hypertension; and associated anomalies, especially chromosomal abnormalities and con-

genital cardiac defects. Affected infants are prone to development of pneumothorax during attempts at ventilation of the hypoplastic lungs.

Treatment includes intubation, mechanical ventilation, and decompression of the GI tract with an NG tube. An IV infusion of glucose and fluid should be started. A chest radiograph confirms the diagnosis. Surgery to reduce the abdominal contents from the thorax and close the diaphragmatic defect is delayed until after the infant is stabilized and pulmonary hypertension and compliance have improved, usually after 24–48 hours. Both pre- and postoperatively, pulmonary hypertension may require therapy with high-frequency oscillatory ventilation, inhaled nitric oxide, or ECMO. The survival rate for infants with this condition is improving, and now approaches 80–90%, with survival dependent on the degree of pulmonary hypoplasia and presence of congenital heart disease or chromosomal abnormalities. Use of a gentle ventilation style and permissive hypercarbia is recommended to avoid barotrauma and further lung injury.

GASTROINTESTINAL BLEEDING

▶ Upper Gastrointestinal Bleeding

Upper GI bleeding sometimes occurs in the newborn nursery, but is rarely severe. Old blood (“coffee-grounds” material) in the stomach of the newborn may be either swallowed maternal blood or infant blood from gastritis or stress ulcer. Bright red blood from the stomach is most likely from acute bleeding, again due to gastritis. Treatment generally consists of gastric lavage (a sample can be sent for Apt testing or blood typing to determine if it is mother’s or baby’s blood) and antacid medication. If the volume of bleeding is large, intensive monitoring, fluid and blood replacement, and endoscopy are indicated. Coagulation studies should also be sent. (See Chapter 20.)

▶ Lower Gastrointestinal Bleeding

Rectal bleeding in the newborn is less common than upper GI bleeding and is associated with infections (eg, *Salmonella* acquired from the mother perinatally), milk intolerance (blood streaks with diarrhea), or, in ill infants, NEC. An abdominal radiograph should be obtained to rule out pneumatosis intestinalis or other abnormalities in gas pattern suggesting inflammation, infection, or obstruction. If the radiograph is negative and the examination is benign, a protein hydrolysate or predigested formula (eg, Nutramigen or Pregestimil) should be tried. The nursing mother should be instructed to avoid all dairy products in her diet. If the amount of rectal bleeding is large or persistent, endoscopy may be needed.

GASTROESOPHAGEAL REFLUX (SEE ALSO CHAPTER 20)

Physiologic regurgitation is common in infants. Reflux is pathologic and should be treated when it results in failure to thrive owing to excessive regurgitation, poor intake due to

dysphagia and irritability, apnea or cyanotic episodes, or chronic respiratory symptoms of wheezing and recurrent pneumonias. Diagnosis is clinical, with confirmation by pH probe or impedance study. Barium radiography is helpful to rule out anatomic abnormalities but is not diagnostic of pathologic reflux.

Initial steps in treatment include thickened feeds (rice cereal, 1 tbsp/oz of formula) for those with frequent regurgitation and poor weight gain. Gastric acid suppressants such as ranitidine (2 mg/kg bid) or lansoprazole (1.5 mg/kg/d) can also be used, especially if there is associated irritability. Prokinetic agents such as metoclopramide are of little benefit and have significant side effects. Because most infants improve by 12–15 months of age, surgery is reserved for the most severe cases, especially those with chronic neurologic or respiratory conditions that exacerbate reflux, and those who have life-threatening events caused by reflux.

INFECTIONS IN THE NEWBORN INFANT

The fetus and the newborn are susceptible to infections. There are three major routes of perinatal infection: (1) blood-borne transplacental infection of the fetus (eg, cytomegalovirus, rubella, and syphilis); (2) ascending infection with disruption of the barrier provided by the amniotic membranes (eg, bacterial infections after 12–18 hours of ruptured membranes); and (3) infection on passage through an infected birth canal or exposure to infected blood at delivery (eg, herpes simplex, hepatitis B, HIV, and bacterial infections).

Susceptibility of the newborn infant to infection is related to immaturity of both the cellular and humoral immune systems at birth. This feature is particularly evident in the preterm neonate. Passive protection against some organisms is provided by transfer of IgG across the placenta during the third trimester of pregnancy. Preterm infants, especially those born before 30 weeks’ gestation, do not have the full amount of passively acquired antibody.

BACTERIAL INFECTIONS

1. Bacterial Sepsis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Most infants with early-onset sepsis present at < 24 hours of age.
- ▶ Respiratory distress is the most common presenting symptom.
- ▶ Hypotension, acidemia, and neutropenia are associated clinical findings.
- ▶ The presentation of late-onset sepsis is more subtle.

▶ General Considerations

The incidence of early-onset (< 5 days) neonatal bacterial infection is 4–5 in 1000 live births. If rupture of the membranes occurs more than 24 hours prior to delivery, the infection rate increases to 1 in 100 live births. If early rupture of membranes with chorioamnionitis occurs, the infection rate increases further to 1 in 10 live births. Regardless of membrane rupture, infection rates are five times higher in preterm than in full-term infants.

▶ Clinical Findings

Early-onset bacterial infections appear most commonly on day 1 of life, and the majority appear at less than 12 hours. Respiratory distress due to pneumonia is the most common presenting sign. Other features include unexplained low Apgar scores without fetal distress, poor perfusion, and hypotension. Late-onset bacterial infection (> 5 days of age) presents in a more subtle manner, with poor feeding, lethargy, hypotonia, temperature instability, altered perfusion, new or increased oxygen requirement, and apnea. Late-onset bacterial sepsis is more often associated with meningitis or other localized infections.

Low total white count, absolute neutropenia (< 1000/mL), and elevated ratio of immature to mature neutrophils all suggest neonatal bacterial infection. Thrombocytopenia is also a common feature. Other laboratory signs are hypoglycemia or hyperglycemia with no change in glucose administration, unexplained metabolic acidosis, and elevated C-reactive protein. In early-onset bacterial infection, pneumonia is invariably present; chest radiography shows infiltrates, but these infiltrates cannot be distinguished from those resulting from other causes of neonatal lung disease. Presence of a pleural effusion makes a diagnosis of pneumonia more likely. Definitive diagnosis is made by positive cultures from blood, CSF, and the like.

Early-onset infection is most often caused by group B β -hemolytic streptococci (GBS) and gram-negative enteric pathogens (most commonly *Escherichia coli*). Other organ-

isms to consider are *Haemophilus influenzae* and *Listeria monocytogenes*. Late-onset sepsis is caused by coagulase-negative staphylococci (most common in infants with indwelling central venous lines), *Staphylococcus aureus*, GBS, *Enterococcus*, and gram-negative organisms.

▶ Treatment

A high index of suspicion is important in diagnosis and treatment of neonatal infection. Table 1–21 presents guidelines for the evaluation and treatment of full-term infants with risk factors or clinical signs of infection. Because the risk of infection is greater in the preterm infant and because respiratory disease is a common sign of infection, any preterm infant with respiratory disease requires blood cultures and broad-spectrum antibiotic therapy for 48–72 hours pending the results of cultures. Early-onset sepsis is usually caused by GBS or gram-negative enteric organisms; broad-spectrum coverage, therefore, should include ampicillin plus an aminoglycoside or third-generation cephalosporin—for example, ampicillin, 100–150 mg/kg/d divided q12h, and gentamicin, 2.5 mg/kg per dose q12–24h (depending on gestational age), or cefotaxime, 100 mg/kg/d divided q12h. In infants older than 34 weeks' gestation, gentamicin can also be given at a dosage of 4 mg/kg q24h. Late-onset infections can also be caused by the same organisms, but coverage may need

Table 1–21. Guidelines for evaluation of neonatal bacterial infection in the full-term infant.

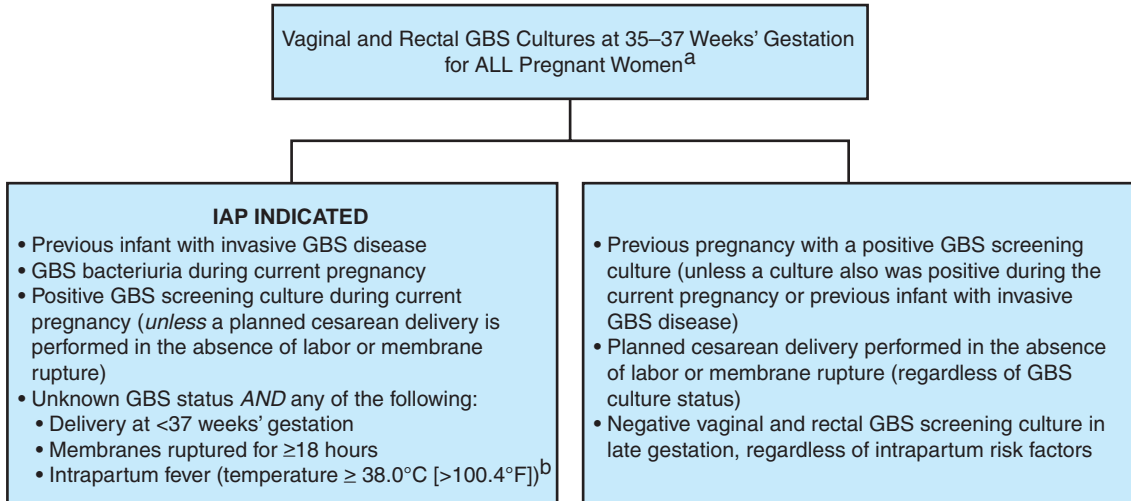

Risk Factor	Clinical Signs of Infection	Evaluation and Treatment
Delivery 12–18 h after rupture of membranes	None	Observation
Delivery > 12–18 h after rupture of membranes, chorioamnionitis	None	CBC, blood culture, broad-spectrum antibiotics for 48–72 h ^a
Delivery > 12–18 h after rupture of membranes, chorioamnionitis, maternal antibiotics ^b	None	CBC, blood culture, broad-spectrum antibiotics for 48–72 h ^a
With or without risk factors	Present	CBC, blood and CSF cultures, perhaps urine culture (see below); broad-spectrum antibiotics ^c

^aIf clinical signs are absent, close observation without treatment may be sufficient.

^bMinimum of 24 h of observation is indicated if no treatment is given.

^cIrrespective of age at presentation, any infant who appears infected by clinical criteria should undergo CSF examination. Urine culture is indicated in the evaluation of infants who were initially well but have developed symptoms after 2–3 days of age.

CBC, complete blood count; CSF, cerebrospinal fluid.

^a Exceptions: women with GBS bacteriuria during the pregnancy or a women with a previous infant with invasive GBS disease.

^b If chorioamnionitis is suspected, broad-spectrum antimicrobial therapy that includes an agent known to be active against GBS should replace GBS IAP. GBS = group B streptococcus, IAP = intrapartum antimicrobial prophylaxis.

▲ **Figure 1–12.** Indications for intrapartum antimicrobial prophylaxis to prevent early-onset group B streptococcal (GBS) disease using a universal prenatal culture screening strategy at 35–37 weeks' gestation for all pregnant women. (Reproduced, with permission, from the American Academy of Pediatrics: Red Book 2003 Report of the Committee on Infectious Disease, 2003.)

to be expanded to include staphylococci. In particular, the preterm infant with an indwelling line is at risk for infection with coagulase-negative staphylococci, for which vancomycin is the drug of choice at a dosage of 10–15 mg/kg q8–24h, depending on gestational and postnatal ages. Initial broad-spectrum coverage should also include a third-generation cephalosporin (cefotaxime or ceftazidime, 100 mg/kg/d divided q12h, when *Pseudomonas aeruginosa* is strongly suspected). To prevent the development of vancomycin-resistant organisms, vancomycin should be stopped as soon as cultures and sensitivities indicate that it is not needed. Other supportive therapy includes IVIG (500–750 mg/kg) in infants with overwhelming infection. The duration of treatment for proved sepsis is 10–14 days of IV antibiotics. In sick infants, the essentials of good supportive therapy should be provided: IV glucose and nutritional support, volume expansion, use of pressors as needed, and oxygen and ventilator support.

Prevention of neonatal GBS infection has been achieved with intrapartum administration of penicillin given more than 4 hours prior to delivery. The current guideline (Figure 1–12) is to perform a vaginal and rectal GBS culture at 35–37 weeks' gestation in all pregnant women. Prophylaxis with penicillin is given to GBS-positive women and to those who have unknown GBS status at delivery with risk factors for infection. Figure 1–13 presents a suggested strategy for the infant born to a mother who received intrapartum prophylaxis for prevention of early-onset GBS or for suspected chorioamnionitis. Some authors also recommend selective neonatal prophylaxis with 50,000 U/kg

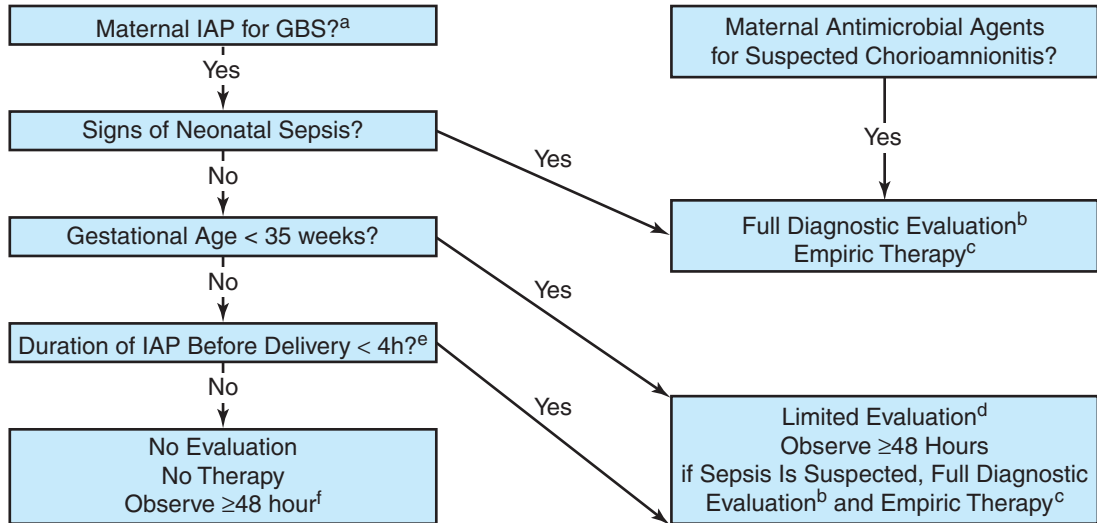

of penicillin G given IM if adequate intrapartum treatment has not been given.

2. Meningitis

Any newborn with bacterial sepsis is at risk for meningitis. The incidence is low in infants with early-onset sepsis and much higher in infants with late-onset infection. The workup for any newborn with possible signs of CNS infection should include a lumbar puncture because blood cultures can be negative in neonates with meningitis. Diagnosis is suggested by a CSF protein level higher than 150 mg/dL, glucose less than 30 mg/dL, leukocytes of more than 25/μL, and a positive Gram stain. The diagnosis is confirmed by culture. The most common organisms are GBS and gram-negative enteric bacteria. Although sepsis can be treated with antibiotics for 10–14 days, meningitis often requires 21 days. The mortality rate of neonatal meningitis is approximately 10%, with significant neurologic morbidity present in one third of the survivors.

3. Pneumonia

The respiratory system can be infected in utero or on passage through the birth canal. Early-onset neonatal infection is usually associated with pneumonia. Pneumonia should also be suspected in older neonates with a recent onset of tachypnea, retractions, and cyanosis. In infants already receiving respiratory support, an increase in the requirement for oxygen or ventilator support may indicate pneumonia. Not

^aIf no maternal IAP for GBS was administered despite an indication being present, data are insufficient on which to recommend a single management strategy.

^bIncludes complete blood cell (CBC) count with differential, blood culture, and chest radiograph if respiratory abnormalities are present. When signs of sepsis are present, a lumbar puncture, if feasible, should be performed.

^cDuration of therapy varies depending on results of blood culture, cerebrospinal fluid findings (if obtained), and the clinical course of the infant. If laboratory results and clinical course do not indicate bacterial infection, duration may be as short as 48 hours.

^dCBC including (WBC) count with differential and blood culture.

^eApplies only to penicillin, ampicillin, or cefazolin and assumes recommended dosing regimens.

^fA healthy-appearing infant who was ≥ 38 weeks gestation at delivery and whose mother received ≥ 4 hours of IAP before delivery may be discharged home after 24 hours if other discharge criteria have been met and a person able to comply fully with instructions for home observation will be present. If any one of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until criteria for discharge are achieved.

▲ **Figure 1-13.** Empiric management of a neonate born to a mother who received intrapartum antimicrobial prophylaxis (IAP) for prevention of early-onset group B streptococcal (GBS) disease or chorioamnionitis. (Reproduced, with permission, from the American Academy of Pediatrics: Red Book 2003 Report of the Committee on Infectious Disease, 2003.)

only common bacteria but also viruses (cytomegalovirus, respiratory syncytial virus, adenovirus, influenza, herpes simplex, parainfluenza) and *Chlamydia* can cause the disease. In infants with preexisting respiratory disease, intercurrent pulmonary infections may contribute to the ultimate severity of chronic lung disease.

4. Urinary Tract Infection

Infection of the urine is uncommon in the first days of life. Urinary tract infection in the newborn can occur in association with genitourinary anomalies and is caused by gram-negative enteric pathogens, *Enterococcus*, or other organisms. Urine should always be evaluated as part of the workup for late-onset infection. Culture should be obtained either by suprapubic aspiration or bladder catheterization. Antibiotic IV therapy is continued for 7–10 days if the blood culture is negative and clinical signs resolve quickly. Evaluation for genitourinary anomalies, starting with an ultra-

sound examination and a voiding cystourethrogram, should be done subsequently.

5. Omphalitis

A normal umbilical cord stump atrophies and separates at the skin level. A small amount of purulent material at the base of the cord is common and can be minimized by keeping the cord open to air and cleaning the base with alcohol several times a day. The cord can become colonized with streptococci, staphylococci, or gram-negative organisms that can cause local infection. Infections are more common in cords manipulated for venous or arterial lines. Omphalitis is diagnosed when redness and edema develop in the soft tissues around the stump. Local and systemic cultures should be obtained. Treatment is with broad-spectrum IV antibiotics (usually nafcillin, 50–75 mg/kg/d divided q8–12h, or vancomycin and a third-generation cephalosporin). Complications are determined by the degree of infection of

the cord vessels and include septic thrombophlebitis, hepatic abscess, necrotizing fasciitis, and portal vein thrombosis. Surgical consultation should be obtained because of the potential for necrotizing fasciitis.

FUNGAL SEPSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Risk factors include low birth weight, indwelling central lines, and multiple antibiotic exposures.
- ▶ Colonization with *Candida* species is common; systemic infection occurs in 2–5% of infants.
- ▶ Presents with often subtle clinical deterioration, thrombocytopenia, and hyperglycemia.

With the survival of smaller, sicker infants, infection with *Candida* species has become more common. Infants of low birth weight with central lines who have had repeated exposures to broad-spectrum antibiotics are at highest risk. For infants of birth weight less than 1500 g, colonization rates of 27–64% have been demonstrated. Many of these infants develop cutaneous lesions, although the GI tract appears to be the initial site of colonization. A much smaller percentage (2–5%) develops systemic disease.

Clinical features of fungal sepsis can be indistinguishable from those of late-onset bacterial sepsis but may be more subtle. Thrombocytopenia may be the earliest and only sign. Deep organ involvement (renal, eye, or endocarditis) is commonly associated with systemic candidiasis. Treatment is with amphotericin B (0.5–1.5 mg/kg/d). In severe infections, flucytosine (50–150 mg/kg/d) can be added for synergistic coverage. (See Chapter 41.) Fluconazole can also be considered as an alternative treatment. Prophylaxis with oral nystatin at 0.5–1 mL PO qid or fluconazole at 3–6 mg/kg/d as a single dose diminishes intestinal colonization with yeast and decreases the frequency of systemic disease.

Malassezia furfur is also seen in infants with central lines receiving IV fat emulsion. To eradicate this organism, as well as *Candida* species, it is necessary to remove the indwelling line.

CONGENITAL VIRAL & PARASITIC INFECTIONS (SEE ALSO CHAPTERS 38 & 41)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Can be acquired in utero, perinatally, and postnatally.
- ▶ Can be asymptomatic in the newborn period.
- ▶ Clinical symptom complexes include IUGR, chorioretinitis, cataracts, cholestatic jaundice, thrombocytopenia, skin rash, and brain calcifications.
- ▶ Diagnosis can be confirmed using polymerase chain reaction (PCR) testing, antigen and antibody studies, and culture.

1. Cytomegalovirus Infection

Cytomegalovirus (CMV) is the most common virus transmitted in utero. The incidence of congenital infection ranges from 0.2–2.2% of live births. Transmission of CMV can occur during either primary or reactivated maternal infection. Children, especially in the day care setting, are an important source of infection. The incidence of primary infection in pregnancy is 1–4%, with a 40% transplacental transmission rate. Of these infants, 85–90% are asymptomatic at birth, while 10–15% have clinically apparent disease—hepatosplenomegaly, petechiae, small size for gestational age, microcephaly, direct hyperbilirubinemia, thrombocytopenia, intracranial calcifications, and chorioretinitis. The risk of neonatal disease is higher when the mother acquires the infection in the first half of pregnancy. The incidence of reactivated infection in pregnancy is less than 1%, with an incidence of clinically apparent disease of 0–1%. Diagnosis in the neonate should be confirmed by culture of the virus from urine. Rapid diagnosis is possible with antigen detection techniques and PCR testing. Diagnosis can also be confirmed in utero from an amniocentesis specimen. Although not routinely recommended, ganciclovir therapy has been used in some severely ill neonates.

The mortality rate in patients with symptomatic congenital CMV may be as high as 20%. Sequelae such as hearing loss, mental retardation, delayed motor development, chorioretinitis and optic atrophy, seizures, language delays, and learning disability occur in 90% of symptomatic survivors. The incidence of complications is 5–15% in asymptomatic infants; the most frequent complication is hearing loss, which can be progressive.

Perinatal infection can also occur when virus is acquired around the time of delivery. These infections generally cause no symptoms or sequelae. Hepatitis, pneumonitis, and neurologic illness may occur in compromised seronegative premature infants. The virus can be acquired postnatally through blood transfusion or ingestion of CMV-infected breast milk. Transfusion risk can be minimized by using frozen, washed red blood cells or CMV antibody–negative donors.

2. Rubella

Congenital rubella infection occurs as a result of maternal rubella infection during pregnancy. The frequency of fetal infection and damage to the fetus is as high as 80% in mothers infected during the first trimester. Fetal infection rates decline in the second trimester before increasing again in the third trimester. Fetal damage generally does not occur in infections acquired after 18 weeks' gestation. Features of congenital rubella include adenopathy, bone radiolucencies, encephalitis, cardiac defects (pulmonary arterial hypoplasia and patent ductus arteriosus), cataracts, retinopathy, growth restriction, hepatosplenomegaly, thrombocytopenia, and purpura. Affected infants can be asymptomatic at birth but develop clinical sequelae during the first year of life. The diagnosis should be suspected in cases of a characteristic clinical illness in the mother (rash, adenopathy, and arthritis) confirmed by serologic testing. Diagnosis can be confirmed by an increase in serum rubella-specific IgM or culture of pharyngeal secretions in the infant. Congenital rubella is now rare because of widespread immunization.

3. Varicella

Congenital varicella infection is rare (< 5% after infection acquired during the first or second trimester) but may cause a constellation of findings, including limb hypoplasia, cutaneous scars, microcephaly, cortical atrophy, chorioretinitis, and cataracts. Perinatal exposure (5 days before to 2 days after delivery) can cause severe to fatal disseminated varicella in the infant. If maternal varicella infection develops within this perinatal risk period, 1 vial of varicella immune globulin should be given to the newborn. If varicella immune globulin is not available, IVIG can be used instead. If this has not been done, the illness can be treated with IV acyclovir (30 mg/kg/d divided q8h).

Hospitalized premature infants of at least 28 weeks' gestation whose mothers have no history of chickenpox—and all infants younger than 28 weeks' gestational age—

should receive varicella immune globulin following any postnatal exposure. Susceptible women of childbearing age should be immunized with varicella vaccine.

4. Toxoplasmosis

Toxoplasmosis is caused by the protozoan *Toxoplasma gondii*. Maternal infection occurs in 0.1–0.5% of pregnancies and is usually asymptomatic. When primary infection occurs during pregnancy, up to 40% of the fetuses become infected, of whom 15% have severe damage. The sources of transmission include exposure to cat feces and ingestion of raw or undercooked meat. Although the risk of transmission increases to 90% near term, fetal damage is most likely to occur when maternal infection occurs in the second to sixth month of gestation.

Clinical findings include growth restriction, chorioretinitis, seizures, jaundice, hydrocephalus, microcephaly, cerebral calcifications, hepatosplenomegaly, adenopathy, cataracts, maculopapular rash, thrombocytopenia, and pneumonia. The majority of affected infants are asymptomatic at birth but show evidence of damage (chorioretinitis, blindness, low IQ, and hearing loss) at a later time. The serologic diagnosis is based on a positive IgA or IgM in the first 6 months of life or a persistent IgG beyond 12 months. Infants with suspected infection should have eye and auditory examinations and a CT scan of the brain. Organism isolation from placenta or cord blood and PCR tests are also available for diagnosis in the neonate and from amniocentesis specimens.

Spiramycin treatment of primary maternal infection is used to try to reduce transmission to the fetus. Neonatal treatment using pyrimethamine and sulfadiazine with folinic acid can improve long-term outcome. (See Chapter 41.)

PERINATALLY ACQUIRED VIRAL INFECTIONS

1. Herpes Simplex (See also Chapter 38)

Herpes simplex virus infection is usually acquired at the birth during transit through an infected birth canal. The mother may have either primary or reactivated secondary infection. Primary maternal infection, because of the high titer of organisms and the absence of antibodies, poses the greatest risk to the infant. The risk of neonatal infection with vaginal delivery in this setting is 33–50%. Seventy percent of mothers with primary herpes at the time of delivery are asymptomatic. The risk to an infant born to a mother with recurrent herpes simplex is much lower (< 0–5%). Time of presentation of localized (skin, eye, or mouth) or disseminated disease (pneumonia, shock, or hepatitis) in the infant is usually 5–14 days of age. CNS disease usually presents at 14–28 days with lethargy and seizures. In about 10% of cases, presentation is as early as day 1 of life, suggesting in-utero infection. In about one third of patients, localized skin, eye, and mouth disease is the first indication of infection. In another third, disseminated or CNS disease precedes skin, eye, and mouth findings, whereas the

remaining third have disseminated or CNS disease in the absence of skin, eye, and mouth disease. Preliminary diagnosis can be made by scraping the base of a vesicle and finding multinucleated giant cells. Viral culture from vesicles, usually positive in 24–72 hours, makes the definitive diagnosis. PCR technology can assist in diagnosis but may be falsely negative in the CSF early in the course. If a lumbar puncture performed shortly after the onset of symptoms is negative, a repeat test should be performed if herpes simplex virus disease is considered a strong possibility.

Acyclovir (60 mg/kg/d given q8h) is the drug of choice for neonatal herpes infection. Localized disease is treated for 14 days, and a 21-day course is used for disseminated or CNS disease. Treatment improves survival of neonates with CNS and disseminated disease and prevents the spread of localized disease. Prevention is possible by not allowing delivery through an infected birth canal (eg, by cesarean section within 6 hours after rupture of the membranes). However, antepartum cervical cultures are poor predictors of the presence of virus at the time of delivery. Furthermore, given the low incidence of infection in the newborn from secondary maternal infection, cesarean delivery is not indicated for asymptomatic mothers with a history of herpes. Cesarean deliveries are performed in mothers with active lesions (either primary or secondary) at the time of delivery. Infants born to mothers with a history of herpes simplex virus infection but no active lesions can be observed closely after birth. Cultures should be obtained and acyclovir treatment initiated only for clinical signs of herpes virus infection. In infants born to mothers with active lesions—regardless of the route of delivery—cultures of the eye, oropharynx, umbilicus, and rectum should be performed 24 hours after delivery. If the infant is colonized (positive cultures) or if symptoms consistent with herpes infection develop, treatment with acyclovir should be started. In cases of maternal primary infection at the time of vaginal delivery, infant specimens should be obtained and acyclovir started pending the results of cultures. The major problem facing perinatologists is the high percentage of asymptomatic primary maternal infection. In these cases, infection in the neonate is not preventable. Therefore, cultures should be obtained and acyclovir started, pending the results of those cultures, in any infant who presents at the right age with symptoms consistent with neonatal herpes.

The prognosis is good for localized skin and mucosal disease that does not progress. The mortality rate for disseminated and CNS herpes is high, with significant morbidity among survivors despite treatment. Recurrences are common, and examination of the CSF should occur each time.

2. Hepatitis B & C (See also Chapter 21)

Infants can be infected with hepatitis B at the time of birth. Clinical illness is rare in the neonatal period, but infants exposed in utero are at high risk of becoming chronic hepatitis B surface antigen (HBsAg) carriers and developing chronic active hepatitis, and later hepatocellular carcinoma. The pres-

ence of HBsAg should be determined in all pregnant women. If the result is positive, the infant should receive hepatitis B immune globulin (HBIG) and hepatitis B vaccine as soon as possible after birth, followed by two subsequent vaccine doses at 1 and 6 months of age. If HBsAg has not been tested prior to birth in a mother at risk, the test should be run after delivery and hepatitis B vaccine given within 12 hours after birth. If the mother is subsequently found to be positive, HBIG should be given as soon as possible (preferably within 48 hours, but not later than 1 week after birth). Subsequent vaccine doses should be given at 1 and 6 months of age. In premature infants born to HBsAg-positive mothers, vaccine and HBIG should be given at birth, but a three-vaccine hepatitis B series should be given after a weight of 2000 g is attained.

Perinatal transmission of hepatitis C occurs in about 5% of infants born to mothers who carry the virus. At present, no prevention strategies exist. Up to 12 months of age, the only reliable screen for hepatitis C infection is PCR. After that time, the presence of hepatitis C antibodies in the infant strongly suggests that infection has occurred.

3. Enteroviral Infection

Enteroviral infections occurs most frequently in the late summer and early fall. Infection is usually acquired in the perinatal period. There is often a history of maternal fever, diarrhea, and rash in the week prior to delivery. The illness appears in the infant in the first 2 weeks of life and is most commonly characterized by fever, lethargy, irritability, diarrhea, and rash. More severe forms occasionally occur, especially if infection occurs before 1 week of age, including meningoencephalitis, myocarditis, hepatitis, pneumonia, shock, and disseminated intravascular coagulation. Diagnosis can be confirmed by culture (rectum, CSF, or blood) or by PCR techniques.

No therapy has proved efficacy. The prognosis is good for all symptom complexes except severe disseminated disease, which carries a high mortality rate.

4. HIV Infection (See also Chapter 39)

Human immunodeficiency virus (HIV) can be acquired in utero or at the time of delivery, or can be transmitted postpartum via breast milk. Transmission of virus occurs in 13–39% of births to infected mothers. Treating the mother with zidovudine starting at 14–34 weeks' gestation and intrapartum, and the infant for the first 6 weeks of life (2 mg/kg PO qid) decreases vertical transmission to 7%. Shorter courses of zidovudine and cesarean delivery are also associated with decreased disease transmission. The combination of zidovudine treatment and cesarean delivery can lower transmission to 2%. The addition of other anti-HIV therapy may further reduce the risk of ante- and intrapartum transmission. Current guidelines for antiretroviral drugs in pregnant HIV-infected women are similar to those for nonpregnant patients (eg, highly active antiretroviral combination therapy). In cases of unknown HIV status at presentation in labor, rapid HIV

testing and intrapartum treatment should be offered. The risk of transmission is increased in mothers with advanced disease, high viral loads, low CD4 counts, and intrapartum events such as chorioamnionitis and prolonged membrane rupture that increase exposure of the fetus to maternal blood.

Newborns with congenitally acquired HIV are often asymptomatic. Jaundice, giant cell hepatitis, and thrombocytopenia have been reported at birth. Failure to thrive, lymphadenopathy, hepatosplenomegaly, oral thrush, chronic diarrhea, bacterial infections with common organisms, and an increased incidence of upper and lower respiratory diseases, including lymphoid interstitial pneumonitis, may appear early or may be delayed for months to years.

Infants of HIV-infected women should be tested by HIV DNA PCR at less than 48 hours, at 1–2 months, and at 2–4 months. If an infant aged 4 months has a negative PCR result, infection can be reasonably excluded. HIV-positive mothers should be counseled not to breast feed their infants.

Protection of health workers caring for infected mothers and infants is important. Testing should be performed in all pregnant women. Because such testing fails to identify some infected patients, universal precautions should always be used. Gloves should be worn during all procedures involving

blood and blood-contaminated fluids, intubation, and procedures using needles. When a splash exposure is possible, mask and eye covers should be used.

OTHER INFECTIONS

1. Congenital Syphilis

The infant is usually infected in utero by transplacental passage of *Treponema pallidum*. Active primary and secondary maternal syphilis leads to fetal infection in nearly 100% of infants, latent disease in 40%, and late disease in 10%. Fetal infection is rare before 18 weeks' gestation. Fetal infection can result in stillbirth or prematurity. Findings of early congenital syphilis (presentation before age 2 years) include mucocutaneous lesions, lymphadenopathy, hepatosplenomegaly, bony changes, and hydrops. Later manifestations (beyond age 2 years) include Hutchinson teeth and mulberry molars, keratitis, chorioretinitis, glaucoma, hearing loss, saddle nose, saber shins, and mental retardation. Newborn infants are often asymptomatic. An infant should be evaluated for congenital syphilis if he or she has proven or probable congenital syphilis, as defined in Table 1–22, or was

Table 1–22. Recommended treatment of neonates (≤ 4 weeks of age) with proven or possible congenital syphilis.

Clinical Status	Antimicrobial Therapy ^a
Proven or highly probable disease ^b	Aqueous crystalline penicillin G, 100,000–150,000 U/kg/d, administered as 50,000 U/kg per dose IV q12h during the first 7 days of life and q8h thereafter for a total of 10 days or Penicillin G procaine, ^c 50,000 U/kg/d, IM in a single dose for 10 days
Normal physical exam and serum quantitative nontreponemal titer the same or less than fourfold the maternal titer:	
1. (a) No penicillin treatment or inadequate or no documentation of penicillin treatment ^d ; (b) mother was treated with erythromycin or other nonpenicillin regimen; (c) mother received treatment ≤ 4 wk before delivery	Aqueous crystalline penicillin G IV for 10 days ^d or Penicillin G procaine, ^c 50,000 U/kg/d, IM in a single dose for 10 days ^d or Clinical, serologic follow-up, and penicillin G benzathine, ^c 50,000 U/kg, IM in a single dose ^d
2. (a) Adequate therapy given > 1 month before delivery; (b) mother has no evidence of reinfection or relapse	Clinical, serologic follow-up, and penicillin G benzathine, 50,000 U/kg, IM in a single dose ^e
3. Adequate therapy before pregnancy and mother's nontreponemal serologic titer remained low and stable during pregnancy and at delivery	None ^f

^aIf more than 1 day of therapy is missed, restart the entire course.

^bAbnormal PE, serum quantitative nontreponemal titer more than fourfold the mother's, or positive darkfield or fluorescent antibody test of body fluids.

^cPenicillin G benzathine and penicillin G procaine are approved for IM administration *only*.

^dA complete evaluation (CSF analysis, CBC and bone radiography) is not needed if administering 10 days of IV therapy, but may be done to support a diagnosis of congenital syphilis. If a single dose is used, evaluation must be done and be normal and follow up must be certain.

^eSome experts would not treat the infant but would provide close serologic follow-up.

^fSome experts would treat with a single IM benzathine penicillin dose if follow-up is uncertain.

CBC, complete blood count; CSF, cerebrospinal fluid; IM, intramuscularly; IV, intravenously.

Reprinted, with permission, from the American Academy of Pediatrics: Red Book 2006 Report of the Committee on Infectious Diseases, 2006.

born to a mother with positive nontreponemal tests confirmed by a positive treponemal test but without documented adequate treatment (parenteral penicillin G), including the expected fourfold decrease in nontreponemal antibody titer. Infants of mothers treated less than 1 month before delivery also require evaluation. Evaluation should include physical examination, a quantitative nontreponemal serologic test for syphilis, CBC, CSF examination for cell count and protein, Venereal Disease Research Laboratory testing, and long bone radiographs. Guidelines for therapy are presented in Table 1–22.

2. Tuberculosis (See also Chapter 40)

Congenital tuberculosis (TB) is rare but may occur in the infant of a mother with hematogenously spread TB or by aspiration of infected amniotic fluid in cases of tuberculous endometritis. Women with pulmonary TB are not likely to infect the fetus until after delivery. Postnatal acquisition is the most common mechanism of neonatal infection. Management in these cases is based on the mother's evaluation.

1. Mother or other household contact with a positive skin test and negative chest radiograph, or mother with an abnormal chest radiograph but no evidence of tuberculous disease after clinical evaluation: Investigate family contacts. Treat the mother or household contact for tuberculosis.
2. Mother has an abnormal chest radiograph consistent with tuberculous disease: Mother and infant should be separated until the mother is evaluated for active TB. Investigate family contacts.
3. Mother with clinical or radiographic evidence of acute and possibly contagious TB: Evaluate the infant for congenital TB (skin test, chest radiograph, lumbar puncture, and cultures) and the mother for HIV. Treat the mother and infant. If the infant is receiving isoniazid and the mother has no risks for multidrug-resistant TB, separation is not necessary.

If congenital TB is suspected, multidrug therapy should be initiated.

3. Conjunctivitis

Neisseria gonorrhoeae may colonize an infant during passage through an infected birth canal. Gonococcal ophthalmitis presents at 3–7 days with copious purulent conjunctivitis. The diagnosis can be suspected when gram-negative intracellular diplococci are seen on a Gram-stained smear and confirmed by culture. Treatment is with IV or IM ceftriaxone, 25–50 mg/kg (not to exceed 125 mg) given once. Prophylaxis at birth is with 0.5% erythromycin ointment. Infants born to mothers with known gonococcal disease should also receive a single dose of ceftriaxone.

Chlamydia trachomatis is another important cause of conjunctivitis, appearing at 5 days to several weeks of age

with congestion, edema, and minimal discharge. The organism is acquired at birth after passage through an infected birth canal. Acquisition occurs in 50% of infants born to infected women, with a 25–50% risk of conjunctivitis. Prevalence in pregnancy is over 10% in some populations. Diagnosis is by isolation of the organism or by rapid antigen detection tests. Treatment is with oral erythromycin (30 mg/kg/d in divided doses q8–12h) for 14 days. Topical treatment alone will not eradicate nasopharyngeal carriage, leaving the infant at risk for the development of pneumonitis.

4. Parvovirus B19 Infection

Parvovirus B19 is a small, nonenveloped, single-stranded DNA virus that causes erythema infectiosum (fifth disease) in children, with a peak incidence at ages 6–7 years. Transmission to the mother is primarily by respiratory secretions. The virus replicates initially in erythroid progenitor cells and induces cell-cycle arrest, resulting in severe anemia, myocarditis, and nonimmune hydrops in approximately 3% and fetal death in up to 10% of fetuses infected in the second trimester. Resolution of the hydrops may occur in utero, either spontaneously or after fetal transfusion. Mothers who have been exposed may have specific serologic testing for antibody response, and serial ultrasound, Doppler exams, and percutaneous umbilical cord blood sampling of the fetus for anemia. If the fetus survives, the long-term outcome is good with no late effects from the infection.

HEMATOLOGIC DISORDERS IN THE NEWBORN INFANT

BLEEDING DISORDERS

Neonatal coagulation is discussed in Chapter 28. Bleeding in the newborn infant may result from inherited clotting deficiencies (eg, factor VIII deficiency) or acquired disorders—hemorrhagic disease of the newborn, disseminated intravascular coagulation, liver failure, and isolated thrombocytopenia.

1. Vitamin K Deficiency Bleeding of the Newborn

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Frequently exclusively breast fed, otherwise clinically well infant.
- ▶ Bleeding from mucous membranes, GI tract, skin, or internal (intracranial).
- ▶ Prolonged prothrombin time (PT), relatively normal partial thromboplastin time (PTT), normal fibrinogen and platelet count.

Vitamin K deficiency bleeding is caused by the deficiency of the vitamin K–dependent clotting factors (II, VII, IX, and X). Bleeding occurs in 0.25–1.7% of newborns who do not receive vitamin K prophylaxis after birth, generally in the

first 5 days to 2 weeks, but as late as 12 weeks in an otherwise well infant. There is an increased risk in infants of mothers receiving therapy with anticonvulsants that interfere with vitamin K metabolism. Early vitamin K deficiency bleeding (0–2 weeks) can be prevented by either parenteral or oral vitamin K administration, whereas late disease is most effectively prevented by administering parenteral vitamin K. Sites of ecchymoses and surface bleeding include the GI tract, umbilical cord, circumcision site, and nose, although devastating intracranial hemorrhage can occur. Bleeding from vitamin K deficiency is more likely to occur in exclusively breast-fed infants because of very low amounts of vitamin K in breast milk, with slower and more restricted intestinal colonization. Differential diagnosis includes disseminated intravascular coagulation and hepatic failure (Table 1–23).

Treatment consists of 1 mg of vitamin K SC or IV. IM injections should be avoided in infants who are actively bleeding. Such infants may also require factor replacement in addition to vitamin K administration.

2. Thrombocytopenia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Generalized petechiae; oozing at cord or puncture sites.
- ▶ Thrombocytopenia, often marked (platelets < 10,000–20,000/mL).
- ▶ In an otherwise well infant, suspect isoimmune thrombocytopenia.
- ▶ In a sick or asphyxiated infant, suspect disseminated intravascular coagulation.

Table 1–23. Features of infants bleeding from vitamin K deficiency (VKDB), disseminated intravascular coagulation (DIC), or liver failure.

	VKDB	DIC	Liver Failure
Clinical	Well infant; no prophylactic vitamin K	Sick infant; hypoxia, sepsis, etc	Sick infant; hepatitis, inborn errors of metabolism, shock liver
Bleeding	GI tract, umbilical cord, circumcision, nose	Generalized	Generalized
Onset	2–3 days to 2 weeks	Any time	Any time
Platelet count	Normal	Decreased	Normal or decreased
Prothrombin time	Prolonged	Prolonged	Prolonged
Partial thromboplastin time	Normal or prolonged	Prolonged	Prolonged
Fibrinogen	Normal	Decreased	Decreased
Factor V	Normal	Decreased	Decreased

GI, gastrointestinal.

Infants with thrombocytopenia have generalized petechiae (not just on the presenting part) and platelet counts less than 150,000/mL (usually < 50,000/mL; may be < 10,000/mL). Neonatal thrombocytopenia can be isolated in a seemingly well infant or may occur in association with a deficiency of other clotting factors in a sick infant. The differential diagnosis for thrombocytopenia is presented in Table 1–24. Treatment of neonatal thrombocytopenia is transfusion of platelets (10 mL/kg of platelets increases the platelet count by approximately 70,000/mL). Indications for transfusion in the full-term infant are clinical bleeding or a total platelet count less than 20,000–30,000/mL. In the preterm infant at risk for intraventricular hemorrhage, transfusion is indicated for counts less than 40,000–50,000/mL.

Isoimmune (alloimmune) thrombocytopenia is analogous to Rh isoimmunization, with a human platelet antigen [HPA]-1a (in 80%) or HPA-5b (in 15%)–negative mother and an HPA-1a or HPA-5b–positive fetus. Transplacental passage of IgG antibody leads to platelet destruction. If platelet transfusion is required for acute bleeding, washed

maternal platelets may be the most readily available antigen-negative platelet source, because 98% of the general population will also be HPA-1a or HPA-5b–positive. Treatment with steroids has been disappointing. Treatment with IVIG infusion, 1 g/kg/d for 2–3 days, until the platelet count has doubled or is over 50,000/mL, is potentially beneficial. Twenty to 30% of infants with isoimmune thrombocytopenia will experience intracranial hemorrhage, half of them before birth. Antenatal therapy of the mother with IVIG with or without steroids may reduce this risk.

Infants born to mothers with idiopathic thrombocytopenic purpura are at low risk for serious hemorrhage despite the thrombocytopenia, and treatment is usually unnecessary. If bleeding does occur, IVIG can be used.

Table 1–24. Differential diagnosis of neonatal thrombocytopenia.

Disorder	Clinical Tips
Immune Passively acquired antibody; idiopathic thrombocytopenic purpura, systemic lupus erythematosus, drug-induced Isoimmune sensitization to HPA-1a antigen	Proper history, maternal thrombocytopenia No rise in platelet count from random donor platelet transfusion. Positive antiplatelet antibodies in baby's serum, sustained rise in platelets by transfusion of mother's platelets
Infections Bacterial infections Congenital viral infections	Sick infants with other signs consistent with infection
Syndromes Absent radii Fanconi anemia	Congenital anomalies, associated pancytopenia
Disseminated intravascular coagulation (DIC)	Sick infants, abnormalities of clotting factors
Giant hemangioma	
Thrombosis	Hyperviscous infants, vascular catheters
High-risk infant with respiratory distress syndrome, pulmonary hypertension, etc	Isolated decrease in platelets is not uncommon in sick infants even in the absence of DIC (? localized trapping)

HPA, human platelet antigen.

ANEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Hematocrit < 45% at term birth.
- ▶ Acute blood loss—signs of hypovolemia, normal reticulocyte count.
- ▶ Chronic blood loss—pallor without hypovolemia, elevated reticulocyte count.
- ▶ Hemolytic anemia—accompanied by excessive hyperbilirubinemia.

The newborn infant with anemia from acute blood loss presents with signs of hypovolemia (tachycardia, poor perfusion, and hypotension), with an initially normal hematocrit that falls after volume replacement. Anemia from chronic blood loss is evidenced by pallor without signs of hypovolemia, with an initially low hematocrit and reticulocytosis.

Anemia can be caused by hemorrhage, hemolysis, or failure to produce red blood cells. Anemia occurring in the first 24–48 hours of life is the result of hemorrhage or hemolysis. Hemorrhage can occur in utero (fetoplacental, fetomaternal, or twin-to-twin), perinatally (cord rupture, placenta previa, placental abruption, or incision through the placenta at cesarean section), or internally (intracranial hemorrhage, cephalohematoma, or ruptured liver or spleen). Hemolysis is caused by blood group incompatibilities, enzyme or membrane abnormalities, infection, and disseminated intravascular coagulation, and is accompanied by significant hyperbilirubinemia.

Initial evaluation should include a review of the perinatal history, assessment of the infant's volume status, and a complete physical examination. A Kleihauer-Betke test for fetal cells in the mother's circulation should be done. A CBC, blood smear, reticulocyte count, and direct and indirect Coombs tests should be performed. This simple evaluation should suggest a diagnosis in most infants. Most infants tolerate anemia quite well due to the increased oxygen

availability in the extrauterine environment; however, treatment with erythropoietin or transfusion might be needed if the infant fails to thrive or develops signs of cardiopulmonary compromise. Additionally, if blood loss is the cause of the anemia, early supplementation with iron will be needed. It is important to remember that hemolysis related to blood group incompatibility can continue for weeks after birth. Serial hematocrits should be followed, because late transfusion may be needed.

POLYCYTHEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Hematocrit > 65% (venous) at term.
- ▶ Plethora, tachypnea, retractions.
- ▶ Hypoglycemia, irritability, lethargy, poor feeding.

Polycythemia in the newborn is manifested by plethora, cyanosis, respiratory distress with tachypnea and oxygen need, hypoglycemia, poor feeding, emesis, irritability, and lethargy. Hyperbilirubinemia is expected. The consequence of polycythemia is hyperviscosity with decreased perfusion of the capillary beds. Clinical symptomatology can affect several organ systems (Table 1–25). Renal vein, other deep vein, or artery thrombosis is a severe complication. Screening can be done by measuring a capillary (heelstick) hematocrit. If the value is greater than 68%, a peripheral venous hematocrit should be measured. Values greater than 65% should be considered consistent with hyperviscosity. The diagnosis of polycythemia should not be based solely on a capillary hematocrit.

Elevated hematocrits occur in 2–5% of live births. Delayed cord clamping is the most common cause of benign neonatal polycythemia. Although 50% of polycythemic infants are AGA, the prevalence of polycythemia is greater in the SGA and LGA populations. Other causes of increased hematocrit

include (1) twin-twin transfusion, (2) maternal-fetal transfusion, and (3) chronic intrauterine hypoxia (SGA infants and LGA infants of diabetic mothers).

Treatment is recommended for symptomatic infants. Treatment for asymptomatic infants based strictly on hematocrit is controversial. Definitive treatment is isovolemic partial exchange transfusion with normal saline, effectively decreasing the hematocrit. The amount to exchange (in milliliters) is calculated using the following formula:

$$\text{Number of Milliliters to exchange} = (\text{PVH} - \text{DH}) / \text{PVH} \times \text{BV}(\text{mL/kg}) \times \text{Wt}(\text{kg})$$

where PVH is peripheral venous hematocrit, DH is desired hematocrit, BV is blood volume in mL/kg, and Wt is weight in kilograms.

Blood is withdrawn at a steady rate from an umbilical venous line while the replacement solution is infused at the same rate through a peripheral IV line over 15–30 minutes. The desired hematocrit value is 50–55%; the assumed blood volume is 80 mL/kg.

Renal	Decreased urinary output, renal vein thrombosis
Metabolic	Hypoglycemia
Hematologic	Hyperbilirubinemia, thrombocytopenia

RENAL DISORDERS IN THE NEWBORN INFANT (SEE ALSO CHAPTER 22)

Renal function depends on postconceptional age. The glomerular filtration rate is 20 mL/min/1.73 m² in full-term neonates and 10–13 mL/min/1.73 m² in infants born at 28–30 weeks' gestation. The speed of maturation after birth also depends on postconceptional age. Creatinine can be used as a clinical marker of glomerular filtration rate. Values in the first month of life are shown in Table 1–26. Creatinine at birth reflects the maternal level and should decrease slowly

Table 1-26. Normal values of serum creatinine (mg/dL).

Gestational Age at Birth (weeks)	Postnatal Age (days)	
	0-2	28
< 28	1.2	0.7
29-32	1.1	0.6
33-36	1.1	0.45
36-42	0.8	0.3

over the first 3–4 weeks. An increasing serum creatinine is never normal.

The ability to concentrate urine and retain sodium also depends on gestational age. Infants born before 28–30 weeks' gestation are compromised in this respect and can easily become dehydrated and hyponatremic. Preterm infants also have an increased bicarbonate excretion and a low tubular maximum for glucose (approximately 120 mg/dL).

RENAL FAILURE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Clinical setting—birth depression, hypovolemia, hypotension, shock.
- ▶ Low or delayed urine output (< 1 mL/kg/h).
- ▶ Rising serum creatinine; hyperkalemia; metabolic acidosis; fluid overload.

Renal failure is most commonly seen in the setting of birth asphyxia, hypovolemia, or shock from any cause. The normal rate of urine flow is 1–3 mL/kg/h. After a hypoxic or ischemic insult, acute tubular necrosis may ensue. Typically, 2–3 days of anuria or oliguria is associated with hematuria, proteinuria, and a rise in serum creatinine. The period of anuria or oliguria is followed by a period of polyuria and then gradual recovery. During the polyuric phase, excessive urine sodium and bicarbonate losses may be seen.

The initial management is restoration of the infant's volume status. Thereafter, restriction of fluids to insensible water loss (40–60 mL/kg/d) without added electrolytes, plus milliliter-for-milliliter urine replacement, should be instituted. Serum and urine electrolytes and body weights should be followed frequently. These measures should be continued through the polyuric phase. After urine output has been reestablished, urine replacement should be decreased to between 0.5 and 0.75 mL for each milliliter of urine output to see if the infant has regained normal function. If that is the case, the infant can be returned to maintenance fluids.

Finally, many of these infants experience fluid overload and should be allowed to lose enough water through urination

to return to birth weight. Hyperkalemia, which may become life-threatening, may occur in this situation despite the lack of added IV potassium. If the serum potassium reaches 7–7.5 mEq/L, therapy should be started with glucose and insulin infusion, giving 1 unit of insulin for every 3 g of glucose administered, in addition to binding resins per rectum. Calcium chloride (20 mg/kg bolus) and correction of metabolic acidosis with bicarbonate are also helpful for arrhythmia resulting from hyperkalemia.

Peritoneal dialysis is occasionally needed for the management of neonatal acute renal failure, for removal of waste products and excess fluid. Hemodialysis, although possible, is difficult due to the small blood volume of the infant and problems with vascular access. Although most acute renal failure in the newborn resolves, ischemic injury severe enough to result in acute cortical necrosis and chronic renal failure can occur.

URINARY TRACT ANOMALIES

Abdominal masses in the newborn are most frequently caused by renal enlargement. Most common is a multicystic or dysplastic kidney; congenital hydronephrosis is second in frequency. Chromosomal abnormalities and syndromes with multiple anomalies frequently include renal abnormalities. An ultrasound examination is the first step in diagnosis. In pregnancies complicated by oligohydramnios, renal agenesis or obstruction secondary to posterior urethral valves should be considered.

Only bilateral disease or disease in a solitary kidney is associated with oligohydramnios, significant morbidity, and death. Such infants will generally also have pulmonary hypoplasia, and die from pulmonary rather than renal insufficiency.

Ultrasonography identifies many infants with renal anomalies (most often hydronephrosis) prior to birth. Postnatal evaluation of infants with hydronephrosis should include renal ultrasound and a voiding cystourethrogram at about 1 week of age, depending on the severity of the antenatal findings. Earlier postnatal ultrasound might underestimate the severity of the hydronephrosis due to low glomerular filtration rates in the first days of life, although cases in which oligohydramnios or severe renal abnormality are suspected will be accurately diagnosed even on the first day of life. Until the presence and severity of vesicoureteral reflux is evaluated, these infants should receive antibiotic prophylaxis with low-dose penicillin or amoxicillin.

RENAL VEIN THROMBOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ History of IDM, birth depression, dehydration.
- ▶ Hematuria, oliguria.
- ▶ Thrombocytopenia, polycythemia.
- ▶ Renal enlargement on exam.

Renal vein thrombosis occurs most often in dehydrated polycythemic newborns. At particular risk is the IDM with polycythemia. If fetal distress is superimposed on polycythemia and dehydration, prompt reduction in blood viscosity is indicated. Thrombosis usually begins in intrarenal venules and can extend into larger veins. Hematuria, oliguria, thrombocytopenia, and possibly an enlarged kidney raise suspicion for this diagnosis. With bilateral renal vein thrombosis, anuria ensues. Diagnosis can be confirmed with an ultrasound examination that includes Doppler flow studies of the kidneys. Treatment involves correcting the predisposing condition and systemic heparinization for the thrombosis. Use of thrombolytics for this condition is controversial. Prognosis for a full recovery is uncertain. Some infants will develop significant atrophy of the affected kidney and systemic hypertension.

NEUROLOGIC PROBLEMS IN THE NEWBORN INFANT

SEIZURES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Usual onset at 12–48 hours.
- ▶ Most common seizure type is characterized by a constellation of findings.
- ▶ Most common causes include hypoxic-ischemic encephalopathy, intracranial bleeds, and infection.

Newborns rarely have well-organized tonic-clonic seizures because of their incomplete cortical organization and a preponderance of inhibitory synapses. The most common type of seizure is characterized by a constellation of findings, including horizontal deviation of the eyes with or without jerking; eyelid blinking or fluttering; sucking, smacking, drooling, and other oral-buccal movements; swimming, rowing, or paddling movements; and apneic spells. Strictly tonic or multifocal clonic episodes are also seen.

▶ Clinical Findings

The differential diagnosis of neonatal seizures is presented in Table 1–27. Most neonatal seizures occur between 12 and 48 hours of age. Later-onset seizures suggest meningitis, benign familial seizures, or hypocalcemia. Information regarding ante-

Table 1–27. Differential diagnosis of neonatal seizures.

Diagnosis	Comment
Hypoxic-ischemic encephalopathy	Most common cause (60%), onset in first 24 h
Intracranial hemorrhage	Up to 15% of cases, periventricular-intraventricular hemorrhage, subdural or subarachnoid bleeding, stroke
Infection	12% of cases
Hypoglycemia	Small for gestational age, infant of a diabetic mother (IDM)
Hypocalcemia, hypomagnesemia	Infant of low birth weight, IDM
Hyponatremia	Rare, seen with syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
Disorders of amino and organic acid metabolism, hyperammonemia	Associated acidosis, altered level of consciousness
Pyridoxine dependency	Seizures refractory to routine therapy; cessation of seizures after administration of pyridoxine
Developmental defects	Other anomalies, chromosomal syndromes
Drug withdrawal	
No cause found	10% of cases
Benign familial neonatal seizures	

natal drug use, the presence of birth asphyxia or trauma, and family history (regarding inherited disorders) should be obtained. Physical examination focuses on neurologic features, other signs of drug withdrawal, concurrent signs of infection, dysmorphic features, and intrauterine growth. Screening workup should include blood glucose, ionized calcium, and electrolytes in all cases. Further workup depends on diagnoses suggested by the history and physical examination. If there is any suspicion of infection, a lumbar puncture should be done. Hemorrhages and structural disease of the CNS can be addressed with ultrasound, CT, and MRI scans. Metabolic workup should be pursued when appropriate. EEG should be done; the presence of spike discharges must be noted and the background wave pattern evaluated. At times correlation between EEG changes and clinical seizure activity is absent.

▶ Treatment

Adequate ventilation and perfusion should be ensured. Hypoglycemia should be treated immediately with a 2-mL/kg infusion of D₁₀W followed by 6 mg/kg/min of D₁₀W (100 mL/kg/d). Other treatments such as calcium or magnesium infusion and antibiotics are indicated to treat hypocalcemia, hypomagnesemia, and suspected infection. Electrolyte

abnormalities should be corrected. Phenobarbital (20 mg/kg IV) should be administered to stop seizures. Supplemental doses of 5 mg/kg can be used if seizures persist, up to a total of 40 mg/kg. In most cases, phenobarbital controls seizures.

If seizures continue, therapy with fosphenytoin, sodium valproate, or lorazepam may be indicated. For refractory seizures, a trial of pyridoxine is indicated.

► Prognosis

Outcome is related to the underlying cause of the seizure. The outcomes for hypoxic-ischemic encephalopathy and intraventricular hemorrhage have been discussed earlier in this chapter. In these settings, seizures that are difficult to control carry a poor prognosis for normal development. Seizures resulting from hypoglycemia, infection of the CNS, some inborn errors of metabolism, and developmental defects also have a high rate of poor outcome. Seizures caused by hypocalcemia or isolated subarachnoid hemorrhage generally resolve without sequelae.

HYPOTONIA

One should be alert to the diagnosis of congenital hypotonia when a mother has polyhydramnios and a history of poor fetal movement. The newborn may present with poor respiratory effort and birth asphyxia. For a discussion of causes and evaluation, see Chapter 23.

INTRACRANIAL HEMORRHAGE¹

1. Subdural Hemorrhage

Subdural hemorrhage is related to birth trauma; the bleeding is caused by tears in the veins that bridge the subdural space. Prospective studies relating incidence to specific obstetric complications are not available.

The most common site of subdural bleeding is in ruptured superficial cerebral veins with blood over the cerebral convexities. These hemorrhages can be asymptomatic or may cause seizures, with onset on days 2–3 of life, vomiting, irritability, and lethargy. Associated findings include retinal hemorrhages and a full fontanelle. The diagnosis is confirmed by CT scan.

Specific treatment entailing needle drainage of the subdural space is rarely necessary. Most infants survive; 75% are normal on follow-up.

2. Primary Subarachnoid Hemorrhage

Primary subarachnoid hemorrhage is the most common type of neonatal intracranial hemorrhage. In the full-term infant, it can be related to trauma of delivery, whereas

subarachnoid hemorrhage in the preterm infant is seen in association with germinal matrix hemorrhage. Clinically, these hemorrhages can be asymptomatic or can present with seizures and irritability on day 2, or rarely, a massive hemorrhage with a rapid downhill course. The seizures associated with subarachnoid hemorrhage are very characteristic—usually brief, with a normal examination interictally. Diagnosis can be suspected on lumbar puncture and confirmed with CT scan. Long-term follow-up is uniformly good.

3. Neonatal Stroke

Focal cerebral ischemic injury can occur in the context of intraventricular hemorrhage in the premature infant and hypoxic-ischemic encephalopathy. Neonatal stroke has also been described in the context of underlying disorders of thrombolysis, maternal drug use (cocaine), a history of infertility, preeclampsia, prolonged membrane rupture, and chorioamnionitis. In some cases, the origin is unclear. The injury often occurs antenatally. The most common clinical presentation of an isolated cerebral infarct is with seizures, and diagnosis can be confirmed acutely with diffusion-weighted MRI scan. The most frequently described distribution is that of the middle cerebral artery.

Treatment is directed at controlling seizures. Long-term outcome is variable, ranging from near-normal to hemiplegias and cognitive deficits.

METABOLIC DISORDERS IN THE NEWBORN INFANT²

HYPERGLYCEMIA

Hyperglycemia may develop in preterm infants, particularly those of extremely low birth weight who are also SGA. Glucose concentrations may exceed 200–250 mg/dL, particularly in the first few days of life. This transient diabetes-like syndrome usually lasts approximately 1 week.

¹Intraventricular hemorrhage is discussed earlier, in the section on the Preterm Infant.

²Hypoglycemia is discussed earlier, in the section on Common Problems in the Term Newborn.

Management may include simply reducing glucose intake while continuing to supply IV amino acids to prevent protein catabolism with resultant gluconeogenesis and worsened hyperglycemia. Intravenous insulin infusions will be needed in infants who remain hyperglycemic despite glucose infusion rates of only 5–6 mg/kg/min or less.

HYPOCALCEMIA (SEE ALSO CHAPTER 32)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Irritability, jitteriness, seizures.
- ▶ Normal blood glucose.
- ▶ Possible dysmorphic features, congenital heart disease (DiGeorge syndrome).

Calcium concentration in the immediate newborn period decreases in all infants. The concentration in fetal plasma is higher than that of the neonate or adult. Hypocalcemia is usually defined as a total serum concentration less than 7 mg/dL (equivalent to a calcium activity of 3.5 mEq/L), although the physiologically active fraction, ionized calcium, should be measured whenever possible. Ionized calcium is usually normal even when total calcium is as low as 6–7 mg/dL. An ionized calcium level above 0.9 mmol/L (1.8 mEq/L; 3.6 mg/dL) is not likely to be detrimental.

▶ Clinical Findings

The clinical signs of hypocalcemia and hypocalcemic tetany include a high-pitched cry, jitteriness, tremulousness, and seizures.

Hypocalcemia tends to occur at two different times in the neonatal period. Early-onset hypocalcemia occurs in the first 2 days of life and has been associated with prematurity, maternal diabetes, asphyxia, and rarely, maternal hypoparathyroidism. Late-onset hypocalcemia occurs at approximately 7–10 days and is observed in infants receiving modified cow's milk rather than infant formula (high phosphorus intake) or in infants with hypoparathyroidism (DiGeorge syndrome, 22q11 deletion). Mothers in underdeveloped countries may have vitamin D deficiency, which can also contribute to late-onset hypocalcemia. Hypomagnesemia should be sought and treated in cases of hypocalcemia that are resistant to treatment.

▶ Treatment

A. Oral Calcium Therapy

The oral administration of calcium salts, often along with vitamin D, is the preferred method of treatment for chronic forms of hypocalcemia resulting from hypoparathyroidism. (See Chapter 32.)

B. Intravenous Calcium Therapy

IV calcium therapy is usually needed for infants with symptomatic hypocalcemia or an ionized calcium level less than 0.9 mmol/L. A number of precautions must be observed when calcium is given intravenously. The infusion must be given slowly so that there is no sudden increase in calcium concentration of blood entering the right atrium, which could cause severe bradycardia and even cardiac arrest. Furthermore, the infusion must be observed carefully, because an IV infiltrate containing calcium can cause full-thickness skin necrosis requiring grafting. For these reasons, IV calcium therapy should be given judiciously and through a central venous line if possible. IV administration of 10% calcium gluconate is usually given as a bolus of 100–200 mg/kg (1–2 mL/kg) over approximately 10–20 minutes, followed by a continuous infusion (0.5–1 g/kg/d) over 1–2 days. Ten percent calcium chloride (20 mg/kg or 0.2 mL/kg per dose) may result in a larger increment in ionized calcium and greater improvement in mean arterial blood pressure in sick hypocalcemic infants and thus may have a role in the newborn. **Note:** Calcium salts cannot be added to IV solutions that contain sodium bicarbonate because they precipitate as calcium carbonate.

▶ Prognosis

The prognosis is good for neonatal seizures entirely caused by hypocalcemia that is promptly treated.

INBORN ERRORS OF METABOLISM (SEE ALSO CHAPTER 34)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Altered level of consciousness (poor feeding, lethargy, seizures) in a previously well-appearing infant.
- ▶ Tachypnea without hypoxemia or distress.
- ▶ Hypoglycemia, respiratory alkalosis, metabolic acidosis.
- ▶ Recurrent “sepsis” without proven infection.

Each individual inborn error of metabolism is rare, but collectively they have an incidence of 1 in 1000 live births. Expanded newborn genetic screening will undoubtedly aid in the diagnosis of these disorders; however, many infants will present prior to these results being available. The diseases are considered in detail in Chapter 34. These diagnoses should be entertained when infants who were initially well present with sepsis-like syndromes, recurrent hypoglycemia, neurologic syndromes (seizures or altered levels of consciousness), or unexplained acidosis (suggestive of organic acidemias).

In the immediate neonatal period, urea cycle disorders present as an altered level of consciousness secondary to

hyperammonemia. A clinical clue that supports this diagnosis is hyperventilation with primary respiratory alkalosis, along with a lower-than-expected blood urea nitrogen. The other major diagnostic category to consider consists of infants with severe acidemia secondary to organic acidemias.

Child Development & Behavior

Edward Goldson, MD
Ann Reynolds, MD

2

The field of developmental and behavioral pediatrics has emerged as a subspecialty that addresses not only typical development but also the diagnosis and evaluation of atypical behavior and development. This chapter provides an overview of typical development, identifies developmental variations, and discusses several developmental disabilities. First, it discusses normal development, but does not cover the newborn period or adolescence (see Chapters 1 and 3, respectively). Second, it addresses behavioral variations, emphasizing that these variations reflect the spectrum of normal development and not pathology. Third, it deals with developmental and behavioral disorders and their treatment. The developmental principle, that is, the concept of ongoing change and maturation, is integral to the daily practice of pediatrics. For example, we recognize that a 3-month-old infant is very different from a 3-year-old and from a 13-year-old adolescent, not only with respect to what the child can do, but also in terms of the kind of illness he or she might have. From the perspective of the general pediatrician all of these areas should be viewed in the context of a “medical home.” The medical home is defined as the setting that provides consistent, continuous, culturally competent, comprehensive and sensitive care to children and their families. It is a setting that advocates for all children, whether they are typical or have developmental challenges or disabilities. By incorporating the principles of child development—the concept that children are constantly changing—the medical home is the optimum setting to understand and enhance typical development and to address variations, delays, and deviations as they may occur in the life-trajectory of the child and family.

NORMAL DEVELOPMENT

Typical children follow a trajectory of increasing physical size (Figures 2–1 through 2–10) and increasing complexity of function (Figures 2–7 and 2–8 and Tables 2–1 and 2–2).

Table 2–3 provides the theoretical perspectives of human behavior, taking into consideration the work of Freud, Erikson, and Piaget.

The first 5 years of life are a period of extraordinary physical growth and increasing complexity of function. The child triples his or her birth weight within the first year and achieves two thirds of his or her brain size by age 2¹/₂–3 years. The child progresses from a totally dependent infant at birth to a mobile, verbal person who is able to express his or her needs and desires by age 2–3 years. In the ensuing 3 years the child further develops the capacity to interact with peers and adults, achieves considerable verbal and physical prowess, and becomes ready to enter the academic world of learning and socialization.

It is critical for the clinician to identify disturbances in development during these early years because there may be windows of time or sensitive periods when appropriate interventions may be instituted to effectively address developmental issues.

THE FIRST 2 YEARS

From a motor perspective, children develop in a cephalocaudal direction. They can lift their heads with good control at 3 months, sit independently at 6 months, crawl at 9 months, walk at 1 year, and run by 18 months. The child learning to walk has a wide-based gait at first. Next, he or she walks with legs closer together, the arms move medially, a heel-toe gait develops, and the arms swing symmetrically by 18–24 months.

Clinicians often focus on gross motor development, but an appreciation of fine motor development and dexterity, particularly the grasp, can be instructive not only in monitoring normal development but also in identifying deviations in development. The grasp begins as a raking motion involving the ulnar aspect of the hand at age 3–4 months. The thumb is added to this motion at about age 5 months as the focus of the movement shifts to the radial side of the

hand. The thumb opposes the fingers for picking up objects just before age 7 months, and the neat pincer grasp emerges at about age 9 months. Most young children have symmetrical movements. Children should not have a significant hand preference before 1 year of age and typically develop handedness between 18 and 30 months.

Language is a critical area to consider as well. Communication is important from birth (Table 2-2 and Figure 2-11), particularly the nonverbal, reciprocal interactions between infant and caregiver. By age 2 months, these interactions

begin to include melodic vowel sounds called cooing and reciprocal vocal play between parent and child. Babbling, which adds consonants to vowels, begins by age 6–10 months, and the repetition of sounds such as “da-da-da-da” is facilitated by the child’s increasing oral muscular control. Babbling reaches a peak at age 12 months. The child then moves into a stage of having needs met by using individual words to represent objects or actions. It is common at this age for children to express wants and needs by pointing to objects or using other gestures. Children usually have 5–10

Table 2-1. Developmental charts.

<p>1-2 months</p> <p>Activities to be observed: Holds head erect and lifts head. Turns from side to back. Regards faces and follows objects through visual field. Drops toys. Becomes alert in response to voice.</p> <p>Activities related by parent: Recognizes parents. Engages in vocalizations. Smiles spontaneously.</p>	<p>Gives toys on request. Tries to build a tower of 2 cubes.</p> <p>Activities related by parent: Points to desired objects. Says 1 or 2 other words.</p>
<p>3-5 months</p> <p>Activities to be observed: Grasps cube—first ulnar then later thumb opposition. Reaches for and brings objects to mouth. Makes “raspberry” sound. Sits with support.</p> <p>Activities related by parent: Laughs. Anticipates food on sight. Turns from back to side.</p>	<p>18 months</p> <p>Activities to be observed: Builds tower of 3-4 cubes. Throws ball. Seats self in chair. Dumps pellet from bottle.</p> <p>Activities related by parent: Walks up and down stairs with help. Says 4-20 words. Understands a 2-step command. Carries and hugs doll. Feeds self.</p>
<p>6-8 months</p> <p>Activities to be observed: Sits alone for a short period. Reaches with one hand. First scoops up a pellet then grasps it using thumb opposition. Imitates “bye-bye.” Passes object from hand to hand in midline. Babbles.</p> <p>Activities related by parent: Rolls from back to stomach. Is inhibited by the word <i>no</i>.</p>	<p>24 months</p> <p>Activities to be observed: Speaks short phrases, 2 words or more. Kicks ball on request. Builds tower of 6-7 cubes. Points to named objects or pictures. Jumps off floor with both feet. Stands on either foot alone. Uses pronouns.</p> <p>Activities related by parent: Verbalizes toilet needs. Pulls on simple garment. Turns pages of book singly. Plays with domestic mimicry.</p>
<p>9-11 months</p> <p>Activities to be observed: Stands alone. Imitates pat-a-cake and peek-a-boo. Uses thumb and index finger to pick up pellet.</p> <p>Activities related by parent: Walks by supporting self on furniture. Follows one-step verbal commands, eg, “Come here,” “Give it to me.”</p>	<p>30 months</p> <p>Activities to be observed: Walks backward. Begins to hop on one foot. Uses prepositions. Copies a crude circle. Points to objects described by use. Refers to self as I. Holds crayon in fist.</p> <p>Activities related by parent: Helps put things away. Carries on a conversation.</p>
<p>1 year</p> <p>Activities to be observed: Walks independently. Says “mama” and “dada” with meaning. Can use a neat pincer grasp to pick up a pellet. Releases cube into cup after demonstration.</p>	<p>3 years</p> <p>Activities to be observed: Holds crayon with fingers. Builds tower of 9-10 cubes.</p>

(continued)

Table 2-1. Developmental charts. (Continued)

<p>Imitates 3-cube bridge. Copies circle. Gives first and last name.</p> <p>Activities related by parent: Rides tricycle using pedals. Dresses with supervision.</p>	<p>Knows right and left hand. Draws recognizable person with at least 8 details. Can describe favorite television program in some detail.</p> <p>Activities related by parent: Does simple chores at home (eg, taking out garbage, drying silverware). Goes to school unattended or meets school bus. Good motor ability but little awareness of dangers.</p>
<p>3-4 years</p> <p>Activities to be observed: Climbs stairs with alternating feet. Begins to button and unbutton. “What do you like to do that’s fun?” (Answers using plurals, personal pronouns, and verbs.) Responds to command to place toy <i>in, on, or under</i> table. Draws a circle when asked to draw a person. Knows own sex. (“Are you a boy or a girl?”) Gives full name. Copies a circle already drawn. (“Can you make one like this?”)</p> <p>Activities related by parent: Feeds self at mealtime. Takes off shoes and jacket.</p>	<p>6-7 years</p> <p>Activities to be observed: Copies a Δ. Defines words by use. (“What is an orange?” “To eat.”) Knows if morning or afternoon. Draws a person with 12 details. Reads several one-syllable printed words. (My, dog, see, boy.)</p>
<p>4-5 years</p> <p>Activities to be observed: Runs and turns without losing balance. May stand on one leg for at least 10 seconds. Buttons clothes and laces shoes. (Does not tie.) Counts to 4 by rote. “Give me 2 sticks.” (Able to do so from pile of 4 tongue depressors.) Draws a person. (Head, 2 appendages, and possibly 2 eyes. No torso yet.) Knows the days of the week. (“What day comes after Tuesday?”) Gives appropriate answers to: “What must you do if you are sleepy? Hungry? Cold?” Copies + in imitation.</p> <p>Activities related by parent: Self-care at toilet. (May need help with wiping.) Plays outside for at least 30 minutes. Dresses self except for tying.</p>	<p>7-8 years</p> <p>Activities to be observed: Counts by 2s and 5s. Ties shoes. Copies a ◊ Knows what day of the week it is. (Not date or year.) No evidence of sound substitution in speech (eg, <i>fr</i> for <i>thr</i>). Draws a man with 16 details. Reads paragraph #1 Durrell:</p> <p>Reading: Muff is a little yellow kitten. She drinks milk. She sleeps on a chair. She does not like to get wet.</p> <p>Corresponding arithmetic:</p> $\begin{array}{r} 7 \\ +4 \\ \hline \end{array} \quad \begin{array}{r} 6 \\ +7 \\ \hline \end{array} \quad \begin{array}{r} 6 \\ -4 \\ \hline \end{array} \quad \begin{array}{r} 8 \\ -3 \\ \hline \end{array}$ <p>Adds and subtracts one-digit numbers.</p>
<p>5-6 years</p> <p>Activities to be observed: Can catch ball. Skips smoothly. Copies a + already drawn. Tells age. Concept of 10 (eg, counts 10 tongue depressors). May recite to higher number by rote.</p>	<p>8-9 years</p> <p>Activities to be observed: Defines words better than by use. (“What is an orange?” “A fruit.”) Can give an appropriate answer to the following: “What is the thing for you to do if . . . —you’ve broken something that belongs to someone else?” —a playmate hits you without meaning to do so?” Reads paragraph #2 Durrell:</p> <p>Reading: A little black dog ran away from home. He played with two big dogs. They ran away from him. It began to rain. He went under a tree. He wanted to go home, but he did not know the way. He saw a boy he knew. The boy took him home.</p>

comprehensible words by 12–18 months; by age 2 years they are putting 2–3 words into phrases, 50% of which their caregivers can understand (see Tables 2–1 and 2–2 and Figure 2–11). The acquisition of expressive vocabulary varies greatly between 12 and 24 months of age. As a group, males and children who are bilingual tend to develop expressive language more slowly during that time. It is important to note, however, that for each individual, milestones should still fall within the expected range. Gender and exposure to two languages should never be used as an excuse for failing to refer a child who has significant delay in the acquisition of speech and language for further evaluation. It is also important to note that most children are not truly bilingual. Most

children have one primary language, and any other languages are secondary.

Receptive language usually develops more rapidly than expressive language. Word comprehension begins to increase at age 9 months, and by age 13 months the child's receptive vocabulary may be as large as 20–100 words. After age 18 months, expressive and receptive vocabularies increase dramatically, and by the end of the second year there is typically a quantum leap in language development. The child begins to put together words and phrases and begins to use language to represent a new world, the symbolic world. Children begin to put verbs into phrases and focus much of their language on describing their new abil-

Table 2-2. Normal speech and language development.

Age	Speech	Language	Articulation
1 month	Throaty sounds		Vowels: \ah\, \uh\, \ee\
2 months	Vowel sounds (“eh”), coos		
2½ months	Squeals		
3 months	Babbles, initial vowels		
4 months	Guttural sounds (“ah,” “go”)		Consonants: m, p, b
5 months			Vowels: \o\, \u\
7 months	Imitates speech sounds		
8 months			Syllables: da, ba, ka
10 months		“Dada” or “mama” nonspecifically	Approximates names: baba/bottle
12 months	Jargon begins (own language)	One word other than “mama” or “dada”	Understandable: 2-3 words
13 months		Three words	
16 months		Six words	Consonants: t, d, w, n, h
18-24 months		Two-word phrases	Understandable 2-word phrases
24-30 months		Three-word phrases	Understandable 3-word phrases
2 years	Vowels uttered correctly	Approximately 270 words; uses pronouns	Approximately 270 words; uses phrases
3 years	Some degree of hesitancy and uncertainty common	Approximately 900 words; intelligible 4-word phrases	Approximately 900 words; intelligible 4-word phrases
4 years		Approximately 1540 words; intelligible 5-word phrases or sentences	Approximately 1540 words; intelligible 5-word phrases
6 years		Approximately 2560 words; intelligible 6- or 7-word sentences	Approximately 2560 words; intelligible 6- or 7-word sentences
7-8 years	Adult proficiency		

Data on articulation from Berry MF: *Language Disorders of Children*. Appleton-Century-Crofts, 1969; and from Bzoch K, League R: *Receptive-Expressive Emergent Language Scale*. University Park Press, 1970.

ties, for example, “I go out.” They begin to incorporate prepositions, such as “I” and “you” into speech and ask “why?” and “what?” questions more frequently. They also begin to appreciate time factors and to understand and use this concept in their speech (see Table 2-1).

The Early Language Milestone Scale (see Figure 2-11) is a simple tool for assessing early language development in the pediatric office setting. It is scored in the same way as the Denver II (Figure 2-12) but tests receptive and expressive language areas in greater depth.

One may easily memorize the developmental milestones that characterize the trajectory of the typical child; however, these milestones become more meaningful and clinically useful if placed in empirical and theoretical contexts. The work of Piaget and others is quite instructive and provides some insight into behavioral and affective development (see Table 2-3). Piaget described the first 2 years of life as the sensorimotor period, during which infants learn with increasing sophistication how to link sensory input from the environment with a motor response. Infants build on prim-

itive reflex patterns of behavior (termed schemata; sucking is an example) and constantly incorporate or assimilate new experiences. The schemata evolve over time as infants accommodate new experiences and as new levels of cognitive ability unfold in an orderly sequence. Enhancement of neural networks through dendritic branching and pruning (apoptosis) occurs.

In the first year of life, the infant’s perception of reality revolves around itself and what it can see or touch. The infant follows the trajectory of an object through the field of vision, but before age 6 months the object ceases to exist once it leaves the infant’s field of vision. At age 9–12 months, the infant gradually develops the concept of object permanence, or the realization that objects exist even when not seen. The development of object permanence correlates with enhanced frontal activity on the electroencephalogram. The concept attaches first to the image of the mother or primary caregiver because of his or her emotional importance and is a critical part of attachment behavior (discussed later). In the second year, children extend their ability to manipulate

Table 2-3. Perspectives of human behavior.

Age	Theories of Development			Skill Areas		Psychopathology
	Freud	Erikson	Piaget	Language	Motor	
Birth to 18 months	Oral	Basic trust versus mistrust	Sensorimotor	Body actions; crying; naming; pointing	Reflex sitting, reaching, grasping, walking	Autism; anaclitic depression, colic; disorders of attachment; feeding, sleeping problems
18 months-3 years	Anal	Autonomy versus shame, doubt	Symbolic (pre-operational)	Sentences; telegraph jargon	Climbing, running	Separation issues; negativism; fearfulness; constipation; shyness, withdrawal
3-6 years	Oedipal	Initiative versus guilt	Intuition (pre-operational)	Connective words; can be readily understood	Increased coordination; tricycle; jumping	Enuresis; encopresis; anxiety; aggressive acting out; phobias; nightmares
6-11 years	Latency	Industry versus inferiority	Concrete operational	Subordinate sentences; reading and writing; language reasoning	Increased skills; sports, recreational cooperative games	School phobias; obsessive reactions; conversion reactions; depressive equivalents
12-17 years	Adolescence (genital)	Identity versus role confusion	Formal operational	Reason abstract; using language; abstract manipulation	Refinement of skills	Delinquency; promiscuity; schizophrenia; anorexia nervosa; suicide

objects by using instruments, first by imitation and later by trial and error.

Freud described the first year of life as the oral stage because so many of the infant's needs are fulfilled by oral means. Nutrition is obtained through sucking on the breast or bottle, and self-soothing occurs through sucking on fingers or a pacifier. During this stage of symbiosis with the mother, the boundaries between mother and infant are blurred. The infant's needs are totally met by the mother, and the mother has been described as manifesting "narcissistic possessiveness" of the infant. This is a very positive interaction in the bidirectional attachment process called bonding. The parents learn to be aware of and to interpret the infant's cues, which reflect its needs. A more sensitive emotional interaction process develops that can be seen in the mirroring of facial expressions by the primary caregiver and infant and in their mutual engagement in cycles of attention and inattention, which further develop into social play. A parent who is depressed or cannot respond to the infant's expressions and cues can have a profoundly adverse effect on the child's future development. Erikson's terms of basic trust versus mistrust are another way of describing the reciprocal interaction that characterizes this stage. Turn-taking games, which occur between ages 3 and 6 months, are a pleasure for both the parents and the infant and are an extension of mirroring behavior. They also represent an early form of imitative behavior, which is important in later social and cognitive development. More sophisticated games, such

as peek-a-boo, occur at approximately age 9 months. The infant's thrill at the reappearance of the face that vanished momentarily demonstrates the emerging understanding of object permanence. Age 8-9 months is also a critical time in the attachment process because this is when separation anxiety and stranger anxiety become marked. The infant at this stage is able to appreciate discrepant events that do not match previously known schemata. These new events cause uncertainty and subsequently fear and anxiety. The infant must be able to retrieve previous schemata and incorporate new information over an extended time. These abilities are developed by age 8 months and give rise to the fears that may subsequently develop: stranger anxiety and separation anxiety. In stranger anxiety, the infant analyzes the face of a stranger, detects the mismatch with previous schemata or what is familiar, and responds with fear or anxiety, leading to crying. In separation anxiety, the child perceives the difference between the primary caregiver's presence and his or her absence by remembering the schema of the caregiver's presence. Perceiving the inconsistency, the child first becomes uncertain and then anxious and fearful. This begins at age 8 months, reaches a peak at 15 months, and disappears by the end of 2 years in a relatively orderly progression as central nervous system (CNS) maturation facilitates the development of new skills. A parent can put the child's understanding of object permanence to good use by placing a picture of the mother (or father) near the child or by leaving an object (eg, her sweater) where the child can see it during her

absence. A visual substitute for the mother's presence may comfort the child.

Once the child can walk independently, he or she can move away from the parent and explore the environment. Although the child uses the parent, usually the mother, as "home base," returning to her frequently for reassurance, he or she has now taken a major step toward independence. This is the beginning of mastery over the environment and an emerging sense of self. The "terrible twos" and the frequent self-asserting use of "no" are the child's attempt to develop a better idea of what is or might be under his or her control. The child is starting to assert his or her autonomy. Ego development during this time should be fostered but with appropriate limits. As children develop a sense of self, they begin to understand the feelings of others and develop empathy. They hug another child who is in perceived distress or become concerned when one is hurt. They begin to understand how another child feels when he or she is harmed, and this realization helps them to inhibit their own aggressive behavior. Children also begin to understand right and wrong and parental expectations. They recognize that they have done something "bad" and may signify that awareness by saying "uh-oh" or with other expressions of distress. They also take pleasure in their accomplishments and become more aware of their bodies.

An area of child behavior that has often been overlooked is play. Play is the child's work and a significant means of learning. Play is a very complex process whose purpose can include the practice and rehearsal of roles, skills, and relationships; a means of revisiting the past; a means of actively mastering a range of experiences; and a way to integrate the child's life experiences. It involves emotional development (affect regulation and gender identification and roles), cognitive development (nonverbal and verbal function and executive functioning and creativity), and social/motor development (motor coordination, frustration tolerance, and social interactions such as turn-taking). Of interest is the fact that play has a developmental progression. The typical 6- to 12-month-old engages in the game of peek-a-boo, which is a form of social interaction. During the next year or so, although children engage in increasingly complex social interactions and imitation, their play is primarily solitary. However, they do begin to engage in symbolic play such as by drinking from a toy cup and then by giving a doll a drink from a toy cup. By age 2–3 years children begin to engage in parallel play (engaging in behaviors that are imitative). This form of play gradually evolves into more interactive or collaborative play by age 3–4 years and is also more thematic in nature. There are of course wide variations in the development of play, reflecting cultural, educational, and socioeconomic variables. Nevertheless, the development of play does follow a sequence that can be assessed and can be very informative in the evaluation of the child.

Brain maturation sets the stage for toilet training. After age 18 months, toddlers have the sensory capacity for awareness of a full rectum or bladder and are physically able to control bowel and urinary tract sphincters. They also take great pleasure in their accomplishments, particularly in appropriate elimination, if it is reinforced positively. Children must be given some control over when elimination occurs. If parents impose severe restrictions, the achievement of this developmental milestone can become a battle between parent and child. Freud termed this period the anal stage because the developmental issue of bowel control is the major task requiring mastery. It encompasses a more generalized theme of socialized behavior and overall body cleanliness, which is usually taught or imposed on the child at this age.

AGES 2–4 YEARS

Piaget characterized the 2- to 6-year-old stage as preoperational. This stage begins when language has facilitated the creation of mental images in the symbolic sense. The child begins to manipulate the symbolic world; sorts out reality from fantasy imperfectly; and may be terrified of dreams, wishes, and foolish threats. Most of the child's perception of the world is egocentric or interpreted in reference to his or her needs or influence. Cause-effect relationships are confused with temporal ones or interpreted egocentrically. For example, children may focus their understanding of divorce on themselves ("My father left because I was bad" or "My mother left because she didn't love me"). Illness and the need for medical care are also commonly misinterpreted at this age. The child may make a mental connection between a sibling's illness and a recent argument, a negative comment, or a wish for the sibling to be ill. The child may experience significant guilt unless the parents are aware of these misperceptions and take time to deal with them.

At this age, children also endow inanimate objects with human feelings. They also assume that humans cause or create all natural events. For instance, when asked why the sun sets, they may say, "The sun goes to his house" or "It is pushed down by someone else." Magical thinking blossoms between ages 3 and 5 years as symbolic thinking incorporates more elaborate fantasy. Fantasy facilitates development of role playing, sexual identity, and emotional growth. Children test new experiences in fantasy, both in their imagination and in play. In their play, children often create magical stories and novel situations that reflect issues with which they are dealing, such as aggression, relationships, fears, and control. Children often invent imaginary friends at this time, and nightmares or fears of monsters are common. At this stage, other children become important in facilitating play, such as in a preschool group. Play gradually becomes more cooperative; shared fantasy leads to game playing. Freud described the oedipal phase between ages 3 and 6 years, when there is

strong attachment to the parent of the opposite sex. The child's fantasies may focus on play-acting the adult role with that parent, although by age 6 years oedipal issues are usually resolved and attachment is redirected to the parent of the same sex.

EARLY SCHOOL YEARS: AGES 5–7 YEARS

Attendance at kindergarten at age 5 years marks an acceleration in the separation-individuation theme initiated in the preschool years. The child is ready to relate to peers in a more interactive manner. The brain has reached 90% of its adult weight. Sensorimotor coordination abilities are maturing and facilitating pencil-and-paper tasks and sports, both part of the school experience. Cognitive abilities are still at the preoperational stage, and children focus on one variable in a problem at a time. However, most children have mastered conservation of length by age 5½ years, conservation of mass and weight by 6½ years, and conservation of volume by 8 years.

By first grade, there is more pressure on the child to master academic tasks—recognizing numbers, letters, and words and learning to write. Piaget described the stage of concrete operations beginning after age 6 years, when the child is able to perform mental operations concerning concrete objects that involve manipulation of more than one variable. The child is able to order, number, and classify because these activities are related to concrete objects in the environment and because these activities are stressed in early schooling. Magical thinking diminishes greatly at this time, and the reality of cause-effect relationships is better understood. Fantasy and imagination are still strong and are reflected in themes of play.

MIDDLE CHILDHOOD: AGES 7–11 YEARS

Freud characterized ages 7–11 years as the latency years, during which children are not bothered by significant aggressive or sexual drives but instead devote most of their energies to school and peer group interactions. In reality, throughout this period there is a gradual increase in sex drive, manifested by increasingly aggressive play and interactions with the opposite sex. Fantasy still has an active role in dealing with sexuality before adolescence, and fantasies often focus on movie and music stars. Organized sports, clubs, and other activities are other modalities that permit preadolescent children to display socially acceptable forms of aggression and sexual interest.

For the 7-year-old child, the major developmental tasks are achievement in school and acceptance by peers. Academic expectations intensify and require the child to concentrate on, attend to, and process increasingly complex auditory and visual information. Children with significant learning disabilities or problems with attention, organization, and impulsivity may have difficulty with academic tasks and subsequently may receive negative reinforcement

from teachers, peers, and even parents. Such children may develop a poor self-image manifested as behavioral difficulties. The pediatrician must evaluate potential learning disabilities in any child who is not developing adequately at this stage or who presents with emotional or behavioral problems. The developmental status of school-aged children is not documented as easily as that of younger children because of the complexity of the milestones. In the school-aged child, the quality of the response, the attentional abilities, and the child's emotional approach to the task can make a dramatic difference in success at school. The clinician must consider all of these aspects in the differential diagnosis of learning disabilities and behavioral disorders.

BEHAVIORAL & DEVELOPMENTAL VARIATIONS

Behavioral and developmental variations and disorders encompass a wide range of issues of importance to pediatricians. Practitioners will be familiar with most of the problems discussed in this chapter; however, with increasing knowledge of the factors controlling normal neurologic and behavioral development in childhood, new perspectives on these disorders and novel approaches to their diagnosis and management are emerging.

Variations in children's behavior reflect a blend of intrinsic biologic characteristics and the environments with which the children interact. The next section focuses on some of the more common complaints about behavior encountered by those who care for children. These behavioral complaints are by and large normal variations in behavior, a reflection of each child's individual biologic and temperament traits and the parents' responses. There are no cures for these behaviors, but management strategies are available that can enhance the parents' understanding of the child and the child's relationship to the environment. These strategies also facilitate the parents' care of the growing infant and child.

The last section of this chapter discusses developmental disorders of cognitive and social competence. Diagnosis and management of these conditions requires a comprehensive and often multidisciplinary approach. The health care provider can play a major role in diagnosis, in coordinating the child's evaluation, in interpreting the results to the family, and in providing reassurance and support.

NORMALITY & TEMPERAMENT

The physician confronted by a disturbance in physiologic function rarely has doubts about what is abnormal. Variations in temperament and behavior are not as straightforward. Labeling such variations as disorders implies that a disease entity exists.

The behaviors described in this section are viewed as part of a continuum of responses by the child to a variety of internal and external experiences. Variations in temperament have been of interest to philosophers and writers since ancient times. The Greeks believed there were four temperament types: choleric, sanguine, melancholic, and phlegmatic. In more recent times, folk wisdom has defined temperament as a genetically influenced behavioral disposition that is stable over time. Although a number of models of temperament have been proposed, the one usually used by pediatricians in clinical practice is that of Thomas and Chess, who describe temperament as being the “how” of behavior as distinguished from the “why” (motivation) and the “what” (ability). Temperament is an independent psychological attribute that is expressed as a response to an external stimulus. The influence of temperament is bidirectional: The effect of a particular experience will be influenced by the child's temperament, and the child's temperament will influence the responses of others in the child's environment. Temperament is the style with which the child interacts with the environment.

The perceptions and expectations of parents must be considered when a child's behavior is evaluated. A child that one parent might describe as hyperactive might not be characterized as such by the other parent. This truism can be expanded to include all the dimensions of temperament. Thus, the concept of “goodness of fit” comes into play. For example, if the parents want and expect their child to be

Table 2-4. Theories of temperament.

Thomas and Chess	Temperament is an independent psychologic attribute, biologically determined, which is expressed as a response to an external stimulus. It is the child's behavioral style: an interactive model.
Rothbart	Temperament is a function of biologically based individual differences in reactivity and self-regulation. It is subsumed under the concept of “personality” and goes beyond mere “behavioral style.”
Buss and Plomin	Temperament is a set of genetically determined personality traits that appear early in life and are different from other inherited and acquired personality traits.
Goldsmith and Campos	Temperament is the individual's differences in the probability of experiencing emotions and arousal.

predictable but that is not the child's behavioral style, the parents may perceive the child as being bad or having a behavioral disorder rather than as having a developmental variation. An appreciation of this phenomenon is important because the physician may be able to enhance the parents' understanding of the child and influence their responses to the child's behavior. When there is goodness of fit, there will be more harmony and a greater potential for healthy development not only of the child but also of the family. When goodness of fit is not present, tension and stress can result in parental anger, disappointment, frustration, and conflict with the child.

Other models of temperament include those of Rothbart, Buss and Plomin, and Goldsmith and Campos (Table 2-4). All models seek to identify intrinsic behavioral characteristics that lead the child to respond to the world in particular ways. One child may be highly emotional and another less so (ie, calmer) in response to a variety of experiences, stressful or pleasant. The clinician must recognize that each child brings some intrinsic, biologically based traits to its environment and that such characteristics are neither good nor bad, right nor wrong, normal nor abnormal; they are simply part of the child. Thus, as one looks at variations in development, one should abandon the illness model and consider this construct as an aid to understanding the nature of the child's behavior and its influence on the parent-child relationship.

COMMON DEVELOPMENTAL CONCERNS

COLIC

ESSENTIALS OF DIAGNOSIS
& TYPICAL FEATURES

- ▶ An otherwise healthy infant aged 2–3 months seems to be in pain, cries for > 3 hours a day, for > 3 days a week, for > 3 weeks (“rule of threes”).

Infant colic is characterized by severe and paroxysmal crying that occurs mainly in the late afternoon. The infant’s knees are drawn up and its fists are clenched, flatus is expelled, the facies is pained, and there is minimal response to attempts at soothing. Studies in the United States have shown that among middle-class infants, crying occupies about 2 hours per day at 2 weeks of age, about 3 hours per day by 6 weeks, and gradually decreases to about 1 hour per day by 3 months. The word “colic” is derived from Greek *kolikos* (“pertaining to the colon”). Although colic has traditionally been attributed to gastrointestinal disturbances, this has never been proved. Colic is a behavioral sign or symptom that begins in the first few weeks of life and peaks at age 2–3 months. In about 30–40% of cases, colic continues into the fourth and fifth months.

A colicky infant, as defined by Wessel, is one who is healthy and well fed but cries for more than 3 hours a day, for more than 3 days a week, and for more than 3 weeks—commonly referred to as the rule of threes. The important word in this definition is “healthy.” Thus, before the diagnosis of colic can be made, the pediatrician must rule out diseases that might cause crying. With the exception of the few infants who respond to elimination of cow’s milk from its own or the mother’s diet, there has been little firm evidence of an association of colic with allergic disorders. Gastroesophageal reflux is often suspected as a cause of colicky crying in young infants. Undetected corneal abrasion, urinary tract infection, and unrecognized traumatic injuries, including child abuse, must be among the physical causes of crying considered in evaluating these infants. Some attempts have been made to eliminate gas with simethicone and to slow gut motility with dicyclomine. Simethicone has not been shown to ameliorate colic. Dicyclomine has been associated with apnea in infants and is contraindicated.

This then leaves characteristics intrinsic to the child (ie, temperament) and parental caretaking patterns as contributing to colic. Behavioral states have three features: (1) they are self-organizing—that is, they are maintained until it is necessary to shift to another one; (2) they are stable over several minutes; and (3) the same stimulus elicits a state-specific response that is different from other states. The behavioral states are (among others) a crying state, a quiet alert state, an active alert state, a transitional state, and a state of deep sleep.

The states of importance with respect to colic are the crying state and the transitional state. During transition from one state to another, infant behavior may be more easily influenced. Once an infant is in a stable state (eg, crying), it becomes more difficult to bring about a change (eg, to soothe). How these transitions are accomplished is probably influenced by the infant’s temperament and neurologic maturity. Some infants move from one state to another easily and can be diverted easily; other infants sustain a particular state and are resistant to change.

The other component to be considered in evaluating the colicky infant is the feeding and handling behavior of the caregiver. Colic is a behavioral phenomenon that involves interaction between the infant and the caregiver. Different caregivers perceive and respond to crying behavior differently. If the caregiver perceives the crying infant as being spoiled and demanding and is not sensitive to or knowledgeable about the infant’s cues and rhythms—or is hurried and “rough” with the infant—the infant’s ability to organize and soothe him- or herself or respond to the caregiver’s attempts at soothing may be compromised. Alternatively, if the temperament of an infant with colic is understood and the rhythms and cues deciphered, crying can be anticipated and the caregiver can intervene before the behavior becomes “organized” in the crying state and more difficult to extinguish.

▶ Management

Several approaches can be taken to the management of colic.

1. Parents may need to be educated about the developmental characteristics of crying behavior and made aware that crying increases normally into the second month and abates by the third to fourth month.
2. Parents may need reassurance, based on a complete history and physical examination, that the infant is not sick. Although these behaviors are stressful, they are a normal variant and are usually self-limited. This discussion can be facilitated by having the parent keep a diary of crying and weight gain. If there is a diurnal pattern and adequate weight gain, an underlying disease process is less likely to be present. Parental anxiety must be relieved, because it may be contributing to the problem.
3. For parents to effectively soothe and comfort the infant, they need to understand the infant’s cues. The pediatrician can help by observing the infant’s behavior and devising interventions aimed at calming both the infant and the parents. One can encourage a quiet environment without excessive handling. Rhythmic stimulation such as gentle swinging or rocking, soft music, drives in the car, or walks in the stroller may be helpful, especially if the parents are able to anticipate the onset of crying. Another approach is to change the feeding habits so that the infant is not rushed, has ample opportunity to burp, and if necessary can be fed more frequently so as to

decrease gastric distention if that seems to be contributing to the problem.

4. Medications such as phenobarbital elixir and dicyclomine have been found to be somewhat helpful, but their use is to be discouraged because of the risk of adverse reactions and overdose. A trial of ranitidine hydrochloride might be of help if gastroesophageal reflux is contributing to the child's discomfort.
5. For colic that is refractory to behavioral management, a trial of changing the feedings, and eliminating cow's milk from the formula or from the mother's diet if she is nursing, may be indicated.

FEEDING DISORDERS IN INFANTS & YOUNG CHILDREN

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Inadequate or disordered intake of food due to any of the following conditions:
 - Poor oral motor coordination.
 - Fatigue resulting from a chronic disease.
 - Lack of appetite.
 - Behavioral issues relating to parent-child interaction.
 - Pain associated with feeding.

Children have feeding problems for various reasons including oral motor dysfunction, cardiopulmonary disorders leading to fatigue, gastrointestinal disturbances causing pain, social or emotional issues, and problems with regulation. The common denominator, however, is usually food refusal. Infants and young children may refuse to eat if they find

eating painful or frightening. They may have had unpleasant experiences (emotional or physiologic) associated with eating, they may be depressed, or they may be engaged in a developmental conflict with the caregiver that is being played out in the arena of feeding. The infant may refuse to eat if the rhythm of the feeding experience with the caregiver is not harmonious. The child who has had an esophageal atresia repair and has a stricture may find eating uncomfortable. The very young infant with severe oral candidiasis may refuse to eat because of pain. The child who has had a choking experience associated with feeding may be terrified to eat (oral motor dysfunction or aspiration). The child who is forced to eat by a maltreating parent or an overzealous caregiver may refuse feeds. Children who have required nasogastric feedings or who have required periods of fasting and intravenous nutrition in the first 1–2 months of life are more likely to display food refusal behavior upon introduction of oral feedings.

Depression in children may be expressed through food refusal. Food refusal may develop when the infant's cues around feeding are not interpreted correctly by the parent. The infant who needs to burp more frequently or who needs time between bites but instead is rushed will often passively refuse to eat. Some will be more active refusers, turning their heads away to avoid the feeder, spitting out food, or pushing away food.

Chatoor and coworkers have proposed a developmental and interactive construct of the feeding experience. The stages through which the child normally progresses are establishment of homeostasis (0–2 months), attachment (2–6 months), and separation and individuation (6 months to 3 years). During the first stage, feeding can be accomplished most easily when the parent allows the infant to determine the timing, amount, pacing, and preference of food intake. During the attachment phase, allowing the infant to control the feeding permits the parent to engage the infant in a positive manner. This paves the way for the separation and individuation phase. When a disturbance occurs in the parent-child relationship at any of these developmental levels, difficulty in feeding may ensue, with both the parent and the child contributing to the dysfunctional interaction. One of the most striking manifestations of food refusal occurs during the stage of separation and individuation. Conflict may arise if the parent seeks to dominate the child by intrusive and controlling feeding behavior at the same time the child is striving to achieve autonomy. The scenario then observed is of the parent forcing food on the child while the child refuses to eat. This often leads to extreme parental frustration and anger, and the child may be inadequately nourished and developmentally and emotionally thwarted.

When the pediatrician is attempting to sort out the factors contributing to food refusal, it is essential first to obtain a complete history, including a social history. This should include information concerning the parents' percep-

tion of the child's behavior and their expectations of the child. Second, a complete physical examination should be performed, with emphasis on oral-motor behavior and other clues suggesting neurologic, anatomic, or physiologic abnormalities that could make feeding difficult. The child's emotional state and developmental level must be determined. This is particularly important if there is concern about depression or a history of developmental delays. If evidence of oral-motor difficulty is suspected, evaluation by an occupational therapist is warranted. Third, the feeding interaction needs to be observed live, if possible. Finally, the physician needs to help the parents understand that infants and children may have different styles of eating and different food preferences and may refuse foods they do not like. This is not necessarily abnormal but reflects temperamental differences and variations in the child's way of processing olfactory, gustatory, and tactile stimuli.

► Management

The goal of intervention is to identify factors contributing to the disturbance and to work to overcome them. The parents may be encouraged to view the child's behavior differently and try not to impose their expectations and desires. Alternatively, the child's behavior may need to be modified so that the parents can provide adequate nurturing.

When the chief complaint is failure to gain weight, a different approach is required. The differential diagnosis should include not only food refusal but also medical disorders and maltreatment. The most common reason for failure to gain weight is inadequate caloric intake. Excessive weight loss may be due to vomiting or diarrhea, to malabsorption, or to a combination of these factors. In this situation more extensive diagnostic evaluation may be needed. Laboratory studies may include a complete blood count; erythrocyte sedimentation rate; urinalysis and urine culture; blood urea nitrogen; serum electrolytes and creatinine; and stool examination for fat, occult blood, and ova and parasites. Some practitioners also include liver and thyroid profiles. Occasionally an assessment of swallowing function or evaluation for the presence of gastroesophageal reflux may be indicated. Because of the complexity of the problem, a team approach to the diagnosis and treatment of failure to thrive, or poor weight gain, may be most appropriate. The team should include a physician, nurse, social worker, and dietitian. Occupational and physical therapists, developmentalists, and psychologists may be required.

The goals of treatment of the child with poor weight gain are to establish a normal pattern of weight gain and to establish better family functioning. Guidelines to accomplishing these goals include the following: (1) establish a comprehensive diagnosis that considers all factors contributing to poor weight gain; (2) monitor the feeding interaction and ensure appropriate weight gain; (3) monitor the developmental progress of the child and the changes in the family dynamics that facilitate optimal weight gain and psychoso-

cial development; and (4) provide support to the family as they seek to help the child.

SLEEP DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Children younger than age 12 years:
 - Difficulty initiating or maintaining sleep that is viewed as a problem by the child or caregiver.
 - May be characterized by its severity, chronicity, frequency, *and* associated impairment in daytime function in the child *or* family.
 - May be due to a primary sleep disorder or occur in association with other sleep, medical, or psychiatric disorders.
- Adolescents—difficulty initiating or maintaining sleep, or early morning awakening, or nonrestorative sleep, or a combination of these problems.

Sleep is a complex physiologic process influenced by intrinsic biologic properties, temperament, cultural norms and expectations, and environmental conditions. Between 20% and 30% of children experience sleep disturbances at some point in the first 4 years of life. The percentage decreases to 10–12% in school-aged children. Sleep disorders fall into two categories. **Dyssomnias** refer to problems with initiating and maintaining sleep or to excessive sleepiness. **Parasomnias** refer to abnormalities of arousal, partial arousal, and transitions between stages of sleep.

Sleep is controlled by two different biologic clocks. The first is a circadian rhythm—daily sleep-wake cycle. The second is an ultradian rhythm that occurs several times per night—the stages of sleep. Sleep stages cycle every 50–60 minutes in infants to every 90 minutes in adolescents. The circadian clock is longer than 24 hours. Environmental cues entrain the sleep-wake cycle into a 24-hour cycle. The cues are light-dark, ambient temperature, core body temperature, noise, social interaction, hunger, pain, and hormone production. Without the ability to perceive these cues (ie,

blindness or autism) a child might have difficulty entraining a 24-hour sleep-wake cycle.

Two major sleep stages have been identified clinically and with the use of polysomnography (electroencephalography, electro-oculography, and electromyography): rapid eye movement (REM) and nonrapid eye movement (NREM) sleep. In REM sleep, muscle tone is relaxed, the sleeper may twitch and grimace, and the eyes move erratically beneath closed lids. In adults and children, REM sleep occurs throughout the night but is increased during the latter half of the night. NREM sleep is divided into four stages. In the process of falling asleep, the individual enters stage 1, light sleep, characterized by reduced bodily movements, slow eye rolling, and sometimes opening and closing of the eyelids. Stage 2 sleep is characterized by slowing of eye movements, slowing of respirations and heart rate, and relaxation of the muscles but with repositioning of the body. Most mature individuals spend about half of their sleep time in this stage. Stages 3 and 4 (also called delta or slow-wave sleep) are the deepest NREM sleep stages, during which the body is relaxed, breathing is slow and shallow, and the heart rate is slow. The deepest NREM sleep occurs during the first 1–3 hours after going to sleep. Most parasomnias occur early in the night during deep NREM sleep. Dreams and nightmares that occur later in the night occur during REM sleep.

Sleep is clearly a developmental phenomenon. Infants are not born with a sleep-wake cycle. REM sleep is more common than NREM sleep in newborns and decreases by 3–6 months of age. Sleep spindles and vertex waves are usually not seen until 9 weeks of age. By 3–6 months, stage 1 through 4 NREM sleep can be seen. By 6–12 months an infant's electroencephalogram (EEG) can be read using adult criteria. Infants also do not make melatonin until 9–12 weeks of age. Melatonin is a hormone that decreases core body temperature, which appears to play a role in sleep onset and sleep maintenance. This hormone is sensitive to light. It crosses the placenta and is present in breast milk.

Like the sleep EEG, sleep patterns slowly mature throughout infancy, childhood, and adolescence until they become adultlike. Newborns sleep 16–20 hours per day in 2- to 5-hour blocks. Over the first year of life the infant slowly consolidates sleep at night into a 9- to 12-hour block and naps gradually decrease to one per day by about 12 months. Most children stop napping between 3 and 5 years of age. School-aged children typically sleep 10–11 hours per night without a nap. Adolescents need 9–9½ hours per night but often only get 7–7¼ hours per night. This is complicated by an approximate 2-hour sleep phase delay in adolescence that is due to physiologic changes in hormonal regulation of the circadian system. Often adolescents are not tired until 2 hours after their typical bedtime but still must get up at the same time in the morning. Some school districts have implemented later start times for high-school students because of this phenomenon.

1. Parasomnias

Parasomnias, consisting of arousal from deep NREM sleep, are probably the most frightening for parents. They include night terrors, sleepwalking, and sleepwalking (somnambulism).

A. Night Terrors and Sleepwalking

Night terrors commonly occur within 2 hours after falling asleep, during the deepest stage of NREM sleep, and are often associated with sleepwalking. They occur in about 3% of children. During a night terror, the child may sit up in bed screaming, thrashing about, and exhibiting rapid breathing, tachycardia, and sweating. The child is often incoherent and unresponsive to comforting. The episode may last up to half an hour, after which the child goes back to sleep and has no memory of the event the next day. The parents must be reassured that the child is not in pain and that they should let the episode run its course.

Management of night terrors is by reassurance of the parents plus measures to avoid stress, irregular sleep schedule, or sleep deprivation which prolongs deep sleep when night terrors occur. Scheduled awakening (awakening the child 30–45 minutes before the time the night terrors usually occur) can be used in children with nightly or frequent night terrors.

Sleepwalking also occurs during slow-wave sleep and is common between 4 and 8 years of age. It is typically benign except that injuries can occur while the child is walking around. Steps should be taken to ensure that the environment is free of obstacles and that doors to the outside are locked. Parents may also wish to put a bell on their child's door to alert them that the child is out of bed. As with night terrors, steps should be taken to avoid stress and sleep deprivation. Scheduled awakenings may also be used if the child sleep walks frequently and at a predictable time.

B. Nightmares

Nightmares are frightening dreams that occur during REM sleep, typically followed by awakening, which usually occurs in the latter part of the night. The peak occurrence is between ages 3 and 5 years, with an incidence between 25% and 50%. A child who awakens during these episodes is usually alert. He or she can often describe the frightening images, recall the dream, and talk about it during the day. The child seeks and will respond positively to parental reassurance. The child will often have difficulty going back to sleep and will want to stay with the parents. Nightmares are usually self-limited and need little treatment. They can be associated with stress, trauma, anxiety, sleep deprivation that can cause a rebound in REM sleep, and medications that increase REM sleep.

2. Dyssomnias

The dyssomnias comprise problems with going to sleep and maintaining sleep, and nighttime awakenings. Although

parasomnias are frightening, dyssomnias are frustrating. They can result in daytime fatigue for both the parents and the child, parental discord about management, and family disruption.

Several factors contribute to these disturbances. The quantity and timing of feeds in the first years of life will influence nighttime awakening. Most infants beyond age 6 months can go through the night without being fed. Thus, under normal circumstances, night waking for feeds is probably a learned behavior and is a function of the child's arousal and the parents' response to that arousal.

Bedtime habits can influence settling in for the night as well as nighttime awakening. If the child learns that going to sleep is associated with pleasant parental behavior such as rocking, singing, reading, or nursing, going back to sleep after nighttime arousal without these pleasant parental attentions may be difficult. This is called a sleep onset association disorder and usually is the reason for night waking. Every time that the child gets to the light sleep portion of the sleep-wake cycle he or she may wake up. This is usually brief and not remembered the next morning, but for the child who does not have strategies for getting to sleep, getting back to sleep may require the same interventions needed to get to sleep initially, such as rocking, patting, and drinking or sucking. Most of these interventions require a parent. Night waking occurs in 40–60% of infants and young children. Parents need to set limits for the child while acknowledging the child's individual biologic rhythms. They should resist the child's attempts to put off bedtime or to engage them during nighttime awakenings. The goal is to establish clear bedtime rituals, to put the child to bed while still awake, and to create a quiet, secure bedtime environment.

The child's temperament is another factor contributing to sleep. It has been reported that children with low sensory thresholds and less rhythmicity (regulatory disorder) are more prone to night waking. Night waking often starts at about 9 months as separation anxiety is beginning. Parents should receive anticipatory guidance prior to that time so that they know to reassure their child without making the interaction prolonged or pleasurable.

Finally, psychosocial stressors and changes in routine can play a role in night waking.

3. Sleep-Disordered Breathing

Sleep-disordered breathing or obstructive sleep apnea is characterized by obstructed breathing during sleep accompanied by loud snoring, chest retractions, morning headaches and dry mouth, and daytime sleepiness. Obstructive sleep apnea occurs in 1–3% of preschoolers. It has its highest peak in childhood between the ages of 2 and 6 years, which corresponds with the peak in adenotonsillar hypertrophy. It has been associated with daytime behavioral disorders, including attention-deficit/hyperactivity disorder. A thorough physical examination is important to look for ade-

notonsillar hypertrophy, hypotonia, and facial anomalies that may predispose the child to obstruction during sleep. Lateral neck films may be helpful. The gold standard for diagnosis is polysomnography. (See also Chapter 17.)

4. Restless Legs Syndrome & Periodic Limb Movement Disorder

Restless legs syndrome and periodic limb movement disorder are common disorders in adults and frequently occur together. The frequency of these disorders in children is unknown. Restless legs syndrome is associated with an uncomfortable sensation in the lower extremities that occurs at night when trying to fall asleep, is relieved by movement, and is sometimes described by children as “creepy-crawly” or “itchy bones.” Periodic limb movement disorder is stereotyped, repetitive limb movements often associated with a partial arousal or awakening. The etiology of these disorders is unknown but there has been some association with iron deficiency. A diagnosis of restless legs syndrome is generally made by history and a diagnosis of periodic limb movement disorder can be made with a sleep study.

A complete medical and psychosocial history should be obtained and a physical examination performed. A detailed sleep history and diary should be maintained to which both parents contribute. Lateral neck films and polysomnography may be indicated to complete the evaluation, especially if sleep-disordered breathing is suspected. It is important to consider disorders such as gastroesophageal reflux, which may cause discomfort or pain when recumbent.

Management of Sleep Disorders

The key to treatment of children who have difficulty going to sleep or who awaken during the night and disturb others is to recognize that both the child and the parents play significant roles in initiating and sustaining what may be an undesirable behavior. Thus, it becomes important for the physician and parents to understand normal sleep patterns, the parents' responses that inadvertently reinforce undesirable sleep behavior, and the child's individual temperament traits. It is also important to remember that individual circadian rhythms do not change immediately; they require consistency and regularity over a period of time before change will occur. Keeping sleep logs or diaries and patience are essential. There is currently little evidence base for pharmacologic management of sleep disorders. It is important to review adequate sleep hygiene and underlying causes such as sleep-disordered breathing, acute or chronic pain, allergies, and developmental or psychiatric disorders before considering any type of pharmacologic management.

TEMPER TANTRUMS & BREATH-HOLDING SPELLS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Behavioral responses to stress, frustration, and loss of control.
- ▶ Tantrum—child may throw him- or herself on the ground, kick, scream, or strike out at others.
- ▶ Breath-holding spell—child engages in a prolonged expiration that is reflexive and may become pale or cyanotic.
- ▶ Rule out underlying organic disease in children with breath-holding spells (eg, CNS abnormalities, Rett syndrome, seizures).

1. Temper Tantrums

Temper tantrums are common between ages 12 months and 4 years, occurring about once a week in 50–80% of children in this age group. The child may throw him- or herself down, kick and scream, strike out at people or objects in the room, and hold his or her breath. These behaviors may be considered normal as the young child seeks to achieve autonomy and mastery over the environment. They are often a reflection of immaturity as the child strives to accomplish age-appropriate developmental tasks and meets with difficulty because of inadequate motor and language skills, impulsiveness, or parental restrictions. In the home, these behaviors may be annoying. In public, they are embarrassing.

Some children tolerate frustration well, are able to persevere at tasks, and cope easily with difficulties; others have a much greater problem dealing with experiences beyond their developmental level. Parents can minimize tantrums by understanding the child's temperament and what he or she is trying to communicate. Parents must also be committed to supporting the child's drive to master his or her feelings.

▶ Management

Appropriate intervention can provide an opportunity for enhancing the child's growth. The tantrum is a loss of control on the child's part that may be a frightening event and a blow to the child's self-image. The parents and the physician need to view these behaviors within the child's developmental context rather than from a negative, adversarial, angry perspective.

Several suggestions can be offered to parents and physicians to help manage tantrums:

1. Minimize the need to say “no” by “child-proofing” the environment so that fewer restrictions need to be enforced.
2. Use distraction when frustration increases; direct the child to other, less frustrating activities; and reward the positive response.
3. Present options within the child's capabilities so that he or she can achieve mastery and autonomy.
4. Fight only those battles that need to be won, and avoid those that arouse unnecessary conflict.
5. Do not abandon the preschool child when a tantrum occurs. Stay nearby during the episode without intruding. A small child may need to be restrained. An older child can be asked to go to his or her room. Threats serve no purpose and should not be used.
6. Do not use negative terms when the tantrum is occurring. Instead, point out that the child is out of control and give praise when he or she regains control.
7. Never let a child hurt him- or herself or others.
8. Do not “hold a grudge” after the tantrum is over, but do not grant the child's demands that led to the tantrum.
9. Seek to maintain an environment that provides positive reinforcement for desired behavior. Do not overreact to undesired behavior, but set reasonable limits and provide responsible direction for the child.
10. Approximately 5–20% of young children have severe temper tantrums that are frequent and disruptive. Such tantrums may result from a disturbance in the parent-child interaction, poor parenting skills, lack of limit-setting, and permissiveness. They may be part of a larger behavioral or developmental disorder or may emerge under adverse socioeconomic conditions, in circumstances of maternal depression and family dysfunction, or when the child is in poor health. Referral to a psychologist or psychiatrist is appropriate while the pediatrician continues to support and work with the family.

2. Breath-Holding Spells

Whereas temper tantrums can be frustrating to parents, breath-holding spells can be terrifying. The name for this behavior may be a misnomer in that it connotes prolonged inspiration. In fact, breath-holding occurs during expiration and is reflexive—not volitional—in nature. It is a paroxysm-

mal event occurring in 0.1–5% of healthy children from age 6 months to 6 years. The spells usually start during the first year of life, often in response to anger or a mild injury. The child is provoked or surprised, starts to cry—briefly or for a considerable time—and then falls silent in the expiratory phase of respiration. This is followed by a color change. Spells have been described as either pallid (acyanotic) or cyanotic, with the latter usually associated with anger and the former with an injury such as a fall. The spell may resolve spontaneously, or the child may lose consciousness. In severe cases, the child may become limp and progress to opisthotonos, body jerks, and urinary incontinence. Only rarely does a spell proceed to asystole or a seizure.

► Management

For the child with frequent spells, underlying disorders such as seizures, orthostatic hypotension, obstructive sleep apnea, abnormalities of the CNS, tumors, familial dysautonomia, and Rett syndrome need to be considered. An association exists among breath-holding spells, pica, and iron-deficiency anemia. These conditions can be ruled out on the basis of the history, physical examination, and laboratory studies. Once it has been determined that the child is healthy, the focus of treatment is behavioral. Parents should be taught to handle the spells in a matter-of-fact manner and monitor the child for any untoward events. The reality is that parents cannot completely protect the child from upsetting and frustrating experiences and probably should not try to do so. Just as in temper tantrums, parents need to help the child control his or her responses to frustration. Parents need to be careful not to be too permissive and submit to the child's every whim for fear the child might have a spell.

If loss of consciousness occurs, the child should be placed on his or her side to protect against head injury and aspiration. Maintaining a patent oral airway is essential, but cardiopulmonary resuscitation should be avoided. There are no prophylactic medications. Atropine, 0.01 mg/kg given subcutaneously, has been used with some benefit in spells accompanied by bradycardia or asystole.

risk for a developmental disorder and involves asking parents if they have concerns about their child's development. The PEDS (Pediatric Evaluation of Developmental Status) can be used for this purpose. Screening involves use of a standardized tool to clarify identified risk. An evaluation would be done by a specialist and would involve a more definitive evaluation of a child's development.

Surveillance should occur at all well child visits. Screening of development should occur at 9, 18, and 30 months. Because a 30-month visit is not part of the standard well child visit schedule and may not be reimbursed, screening may occur at 24 months instead. It is also recommended that autism-specific screening should occur at the 18-month visit. Clinicians should keep in mind that if they are administering a screen because they are concerned and the child passes the screen, they should still schedule an early follow-up visit to ensure that appropriate progress has been made and that there are no further concerns.

Although an autism-specific screen was only recommended at the 18-month visit in the AAP guidelines, the Autism Workgroup of the AAP has recommended a second autism-specific screen at 24–30 months in order to pick up children missed at the 18-month screen. Because the average age of regression is 20 months, some children may be missed by a single screen at 18 months. Screening for autism earlier than 14 months, with the tools that are currently available, yields too many false-positive results. Development of screening tools for children younger than 18 months are ongoing.

Implementation of screening requires planning for timing of screening administration during office visits, defining the process for referral, and designing handouts prior to beginning screening. Aside from the important process of seeking to optimize the child's development with the use of these screenings they also demonstrate to the parent the interest their caretaker has not only for the child's physical wellbeing but also for the child's developmental and psychosocial wellbeing. Parents of children who received a developmental assessment expressed greater satisfaction with their care provider.

DEVELOPMENTAL DISORDERS

Developmental disorders include abnormalities in one or more aspects of development, such as verbal, motor, visual-spatial, attentional, and social abilities. These problems are diagnosed by comparing the child's performance level with norms accumulated from observation and testing of children of the same age. Problems with development are often noted by parents when a child does not meet typical motor and language milestones. Developmental disorders may also include difficulties with behavior or attention. Attention-deficit/hyperactivity disorder (ADHD) is the most common neurodevelopmental disorder. ADHD occurs in 2–10% of school-aged children and may occur in combination with a variety of other learning or developmental issues. Mild developmental disorders are often not noted until the child is of school age.

Many biologic and psychosocial factors may influence a child's performance on developmental tests. In the assessment of the child, it is important to document adverse psychosocial factors, such as neglect or poverty, which can negatively influence developmental progress. Many of the biologic factors that influence development are genetic and are discussed throughout this section.

Evaluation

The neurodevelopmental evaluation must focus on (1) defining the child's level of developmental abilities in a variety of domains, including language, motor, visual-spatial, attentional, and social abilities; (2) attempting to determine the etiology for the child's developmental delays; and (3) planning a treatment program. These objectives are best achieved by a multidisciplinary team that includes the physician, a psychologist, a speech or language therapist, an occupational therapist, and an educational specialist. The psychologist will usually carry out standardized testing of intellectual ability appropriate to the child's age. The motor and language specialists will also carry out clinical testing to document the deficits in their areas and to organize a treatment program. The educational specialist will usually carry out academic testing for the school-aged child and plan a course of special education support through the school. The physician is usually the integrator of the information from the team and must also obtain a detailed medical and developmental history and conduct the physical and neurologic examinations.

Medical & Neurodevelopmental Examination

The medical history should begin with pregnancy, labor, and delivery to identify conditions that might compromise the

child's CNS function. The physician must ask the child's parents about prenatal exposures to toxins, medications, alcohol, drugs, smoking, and infections; maternal chronic illness; complications of pregnancy or delivery and neonatal course. Problems such as failure to thrive, chronic illnesses, hospitalizations, and abuse can interfere significantly with normal development. Major illnesses or hospitalizations should be discussed. Any CNS problems, such as trauma, infection, or encephalitis should be documented. The presence of metabolic diseases, such as diabetes or phenylketonuria, and exposure to environmental toxins such as lead should be determined. Chronic diseases such as chronic otitis media, hyper- or hypothyroidism, and chronic renal failure can interfere with normal development. The presence of motor or vocal tics, seizures, or sleep disturbances should be documented. In addition, parents should be questioned about any motor, cognitive, or behavioral regression.

The physician should review and document the child's temperament, difficulties with feeding, and subsequent developmental milestones. The child's difficulties with tantrums, poor attention, impulsivity, hyperactivity, or aggression should be documented.

A detailed history of school-related events should be recorded, including previous special education support, evaluations through the school, history of repeating grades, difficulties with specific academic areas, problems with peers, and the teacher's impressions of the child's difficulties, particularly related to attentional problems, impulsivity, or hyperactivity. Input from teachers can be invaluable and should be sought prior to the evaluation.

Perhaps the most important aspect of the medical history is a detailed family history of learning strengths and weaknesses, emotional or behavioral problems, learning disabilities, mental retardation, or psychiatric disorders. Parental learning strengths and weaknesses, temperament difficulties, or attentional problems may be passed on to the child. For instance, dyslexia (deficits in decoding skills that result in reading difficulties) is often inherited.

The neurodevelopmental examination should include a careful assessment of dysmorphic features such as epicanthal folds, palpebral fissure size, shape of the philtrum, low-set or posteriorly rotated ears, prominent ear pinnae, unusual dermatoglyphics (eg, a single palmar crease), hyperextensibility of the joints, syndactyly, clinodactyly, or other unusual features. A detailed physical and neurologic examination needs to be carried out with an emphasis on both soft and hard neurologic findings. Soft signs can include motor incoordination, which can relate to handwriting problems and academic delays in written language or drawing. Visual motor coordination abilities can be assessed by having the child write, copy designs, or draw a person.

The child's growth parameters, including height, weight, and head circumference, need to be assessed, along with hearing and visual acuity. Cranial nerve abnormalities and oral-motor coordination problems need to be noted. The

examiner should watch closely for motor or vocal tics. Both fine and gross motor abilities should be assessed. Dyspraxia (motor planning difficulties or imitating complex motor movements) and disorders of fine motor coordination are fairly common. Tandem walking, one-foot balancing, and coordinating a skip may often show surprising abnormalities. Tremors can be noted when watching a child stack blocks or draw.

The developmental aspects of the examination can include an assessment of auditory processing and perceptual ability with simple tasks, such as twofold to fivefold directions, assessing right and left directionality, memory for a series of spoken words or digit span, and comprehension of a graded paragraph. In assessing expressive language abilities, the examiner should look for difficulties with word retrieval, formulation, and articulation, and adequacy of vocabulary. Visual-perceptual abilities can be assessed by simple visual memory tasks, puzzles, or object assembly, and evaluating the child's ability to decode words or organize math problems. Visual-motor integration and coordination can be assessed again with handwriting, design copying, and drawing a person. Throughout the assessment the clinician should pay special attention to the child's ability to focus attention and concentrate, and to other aspects of behavior such as evidence of depression or anxiety.

Additional questionnaires and checklists—such as the Child Behavior Checklist by Achenbach; ADHD scales such as the Conners' Parent/Teacher Rating Scale; and the Swanson, Nolan and Pelham Questionnaire-IV, which includes the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)* criteria for ADHD—can be used to help with this assessment.

Referral of family to community resources is critical, as is a medical home (described earlier in the chapter).

ATTENTION-DEFICIT/ HYPERACTIVITY DISORDER

Attention-deficit/hyperactivity disorder (ADHD) is a common neurodevelopmental disorder that may affect 2–10% of school-aged children and may persist into adolescence and adulthood. It is associated with a triad of symptoms: impulsivity, inattention, and hyperactivity. DSM-IV-TR has described three ADHD subtypes: hyperactive-impulsive, inattentive, and combined. To be classified according to

Table 2-5. Attention-deficit/hyperactivity disorder subtypes.

Subtype	Symptoms ^a
Hyperactive-impulsive	Fidgetiness Difficulty remaining seated in the class Excessive running or climbing Difficulty in engaging in quiet activities Excessive talking and blurting out answers before questions have been completed Difficulty awaiting turns Interrupting and intruding on others
Inattentive	Failure to give close attention to detail Difficulty sustaining intention in task Failure to listen when spoken to directly Failure to follow instructions Difficulty organizing tasks and activities Reluctance to engage in tasks Losing utensils necessary for tasks or activities Easy distractibility Forgetfulness in daily activities

^aThe child must exhibit six or more of these symptoms.

Adapted, with permission, from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. American Psychiatric Association, 1994.

either subtype, the child must exhibit six or more of the symptoms listed in Table 2-5.

The majority of children with ADHD have a combined type with symptoms of inattention as well as hyperactivity and impulsivity. Although symptoms begin in early childhood, they can diminish between ages 10 and 25 years. Hyperactivity declines more quickly, and impulsivity and inattentiveness often persist into adolescence and adulthood. ADHD may be combined with other psychiatric conditions, such as mood disorder in approximately 20% of patients, conduct disorders in 20%, and oppositional defiant disorder in up to 40%. Up to 25% of children with ADHD seen in a referral clinic have tics or Tourette syndrome. Conversely, well over 50% of individuals with Tourette syndrome also have ADHD.

ADHD has a substantial genetic component. Several candidate genes have been identified, although there is strong evidence that ADHD is a disorder involving multiple genes. ADHD is also associated with a variety of genetic disorders related to developmental disorders, including fragile X syndrome, Williams syndrome, Angelman syndrome, XXY syndrome (Klinefelter syndrome), and Turner syndrome. Fetal alcohol syndrome (FAS) is also strongly associated with ADHD. CNS trauma, CNS infections, prematurity, and a difficult neonatal course with brain injury can also be associated with later ADHD. Metabolic problems such as hyperthy-

roidism can sometimes cause ADHD. These organic causes of ADHD should be considered in the evaluation of any child presenting with attentional problems, hyperactivity, or impulsivity. However, in the majority of children who have ADHD the cause remains unknown.

► Management

The treatment of ADHD varies depending on the complexity of the individual case, including comorbid disorders such as anxiety and learning disabilities. It is important to educate the family regarding the symptoms of ADHD and to clarify that it is a neurologic disorder that at times is difficult for the child to control. Behavior modification techniques usually help these children and should include structure with consistency in daily routine, positive reinforcement whenever possible, and time out for negative behaviors. It is important to try to boost the child's self-esteem because psychological complications are common in ADHD. A variety of educational interventions can be helpful, including preferential seating in the classroom, a system of consistent positive behavior reinforcement, consistent structure, the repetition of information when needed, and the use of instruction that incorporates both visual and auditory modalities. Many children with ADHD have significant social difficulties, and social skills training can be helpful. Individual counseling is beneficial in alleviating poor self-esteem, oppositional behavior, and conduct problems.

The National Institute of Mental Health Collaborative Multisite Multimodal Treatment Study of Children With Attention-Deficit/Hyperactivity Disorder (MTA) evaluated 579 children with ADHD who were randomly assigned to four treatment groups: state-of-the-art medication management, intensive behavioral intervention, a combination of medication and behavior management, and a community treatment control group. This study found that children treated with state-of-the-art medication management, which included blinded placebo-controlled dosage adjustment, monthly visits, and parent and teacher questionnaires, had better outcomes than children in the other groups. All groups improved over the course of the study, with those receiving intensive medication management and combined therapy doing better than children receiving behavioral intervention alone and community management. Combined therapy was not significantly better than intensive medication management alone for core ADHD symptoms. However, only the combined group showed significant improvement over the controls in other symptoms such as parent-child interaction, aggression, and social skills.

Stimulant medications (methylphenidate and dextroamphetamine) are available in short- and long-acting preparations. A newer medication, atomoxetine, has been found to be effective in some children with ADHD as a second-line drug. Alternative medications for the treatment of ADHD include clonidine or guanfacine, which are α_2 -adrenergic presynaptic agonists that decrease norepinephrine levels.

They are particularly helpful for individuals who are hyperreactive to stimuli and may decrease motor tics in patients who have Tourette syndrome.

It is most important that, no matter what medication is used, the diagnosis is correct and the correct dosage is prescribed. A recent study has demonstrated that one of the major factors contributing to treatment failure is inadequate dosing or the failure to recognize the presence of comorbid conditions such as learning disability, anxiety disorders, and depression.

Seventy to 90% of children with normal intellectual abilities respond well to stimulant medications. Stimulants enhance both dopamine and norepinephrine neurotransmission, which seems to improve impulse control, attention, and hyperactivity. The main side effects of methylphenidate and dextroamphetamine include appetite suppression and resulting weight loss, as well as sleep disturbances. Atomoxetine is a selective inhibitor of the presynaptic norepinephrine transporter, which increases norepinephrine and dopamine, and has a similar side-effect profile to the stimulants. Cardiovascular effects of stimulant medications have undergone significant scrutiny over the past 2 years. It is unclear whether stimulants increase the risk of sudden death over the risk in the general population, especially in children without any underlying risk. Prior to beginning a stimulant medication, it is recommended that clinicians obtain any history of syncope, palpitations, chest pain, and family history of sudden death prior to age 30 that may predispose a child to sudden death. Some individuals experience increased anxiety, particularly with higher doses of stimulant medications. Stimulants may exacerbate psychotic symptoms. They may also exacerbate motor tics in 30% of patients, but in 10% motor tics may be improved.

Long-acting and short-acting forms of stimulant medications are available. The initial dose of methylphenidate can be 5, 10, 15, or 20 mg daily divided two or three times a day. Adderall, a stimulant that combines four dextro- and levoamphetamine salts, is a more long-acting medication, and often a single morning dose suffices for the day. Starting doses can be 5, 7.5, 10, 12.5, or 15 mg, although higher doses may also be used.

Alternative medications for the treatment of ADHD include clonidine or guanfacine, which are α_2 -adrenergic presynaptic agonists that decrease norepinephrine levels. They are particularly helpful for individuals who are hyperreactive to stimuli and may be helpful in decreasing motor tics in patients who have Tourette syndrome. Tricyclic antidepressant medications such as imipramine may also be effective treatment for ADHD, but the cardiovascular side effects at high dosages can include severe arrhythmias. Bupropion is an antidepressant medication that can also be effective for treatment of ADHD symptoms. Its use is contraindicated in patients with a history of seizures, because it will lower the seizure threshold. It has also been

known to cause seizures in individuals who have anorexia or bulimia. It is used more commonly in adolescents and adults with ADHD than in children with the disorder.

AUTISM SPECTRUM DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Three core deficits:

- Qualitative impairments in communication
- Qualitative impairments in reciprocal social interaction
- Presence of stereotypic, restrictive, and repetitive patterns of behavior, interests, and activities.

Autism is a neurologic disorder characterized by (1) qualitative impairments in social interaction; (2) qualitative impairments in communication; and (3) restricted repetitive and stereotyped patterns of behavior, interests, and activities. Autism is currently grouped under the Pervasive Developmental Disorders in the DSM-IV with Asperger Disorder, Pervasive Developmental Disorder Not Otherwise Specified, Childhood Disintegrative Disorder, and Rett Syndrome. Asperger disorder is characterized by impairment in social interaction and restricted interest/repetitive behaviors. Individuals with Asperger disorder should not have significant delays in cognitive, language, or self-help skills. Pervasive

developmental disorder not otherwise specified is characterized by impairment in reciprocal social interaction along with impairment in communication skills, or restricted interest or repetitive behaviors. Children with pervasive developmental disorder not otherwise specified do not meet full criteria for autism due to mild or atypical symptoms. Childhood disintegrative disorder is characterized by typical development for at least 2 years followed by a regression in at least two of the following three areas: social interaction, communication, and behavior (characterized by restricted interests or repetitive behaviors.) Rett syndrome is a genetic syndrome caused by a mutation on the X chromosome that is characterized by regression in skills in the first year of life. Table 2–6 lists the DSM-IV-TR criteria for diagnosis of an autism spectrum disorder.

Autism spectrum disorders are relatively common, occurring in approximately 1 in 150 children. Males are overrepresented 3–4:1, with reports as high as 9.5:1 (especially when higher functioning individuals are included). No known etiology can be found in 80–90% of cases. A genetic syndrome such as fragile X syndrome or chromosome 15q duplication is found in 10–20% of cases. There is a strong familial component. Parents of one child with autism of unknown etiology have a 2–9% chance of having a second child with autism. The concordance rate among monozygotic twins is high, and there is an increased incidence of speech, language, reading, attention, and affective disorders in family members of children with autism.

► Evaluation & Management

Children with autism are often not diagnosed until age 3–4 years, when their disturbances in reciprocal social interaction

Table 2–6. Criteria for diagnosis of an autism spectrum disorder.

Qualitative impairment in social interaction (at least 2)

- Impairment in nonverbal behaviors such as eye contact
- Failure to develop peer relationships
- Lack of seeking to share enjoyment or interests
- Lack of social or emotional reciprocity

Qualitative impairment in communication (at least 1)

- Delay in or lack of spoken language
- If speech is present, lack of ability to initiate or sustain conversation
- Stereotyped and repetitive/idiosyncratic language
- Lack of pretend/social imitative play

Restricted interests/repetitive behavior (at least 1)

- Preoccupation with restricted interest
- Inflexible adherence to nonfunctional routines or rituals
- Stereotyped and repetitive motor mannerisms (hand flapping)
- Persistent preoccupation with parts of objects

Reprinted, with permission, from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed, text revision. American Psychiatric Association, 2000.

and communication become more apparent. However, impairments in communication and behavior can often be recognized in the first 12–18 months of life. The most common characteristics during the first year are a consistent failure to orient to one's name, regard people directly, use gestures, and to develop speech. Even if one of these skills is present, it is often diminished in frequency, inconsistent, or fleeting. On the contrary, for all children every interaction should be an opportunity to engage. Sharing affect or enjoyment is an important precursor to social interaction. By 18 months a child should have “joint attention,” which occurs when two people attend to the same thing at the same time. This is usually accomplished by shifting eye gaze, pointing, or saying “look.” Toddlers should point to get needs met (“I want that”) and to show (“look at that”) by 1 year of age and they should do it regularly. By 18 months a toddler should be able to follow a point, imitate others, and engage in functional play (using toys in the way that they are intended to be used, such as rolling a car, throwing a ball, or holding a baby doll). Restricted interests and repetitive behaviors sometimes do not emerge until after age 2, but usually are present before age 2.

There is mounting evidence that a diagnosis of autism spectrum disorder can be made reliably by age 2 years and is stable over time. Because there is evidence that early intervention is particularly important for children with autism, great interest has arisen in developing a screening instrument that can be used in very young children. The Modified Checklist for Autism in Toddlers (M-CHAT) is designed for children 16–30 months of age. It is a parent report measure with 23 yes/no questions. This test is still undergoing study to determine sensitivity and specificity but preliminary outcomes show good sensitivity and specificity. Specificity is greater if parents of children who screen positive on the M-CHAT receive a follow-up phone call asking for specific examples of failed items to confirm accuracy. The M-CHAT has also been evaluated in both low-risk and high-risk groups.

An autism-specific screen is recommended at 18 months. A second autism-specific screen has been recommended at 24–30 months. The second screen was recommended because some of the symptoms may be more obvious in an older child, and because about 30% of children with autism spectrum disorders experience a regression in skills, on average at 20 months. Screening at 18 months would miss many of these children.

When behaviors raising concern for autism are noted, the child should be referred to a team of specialists experienced in the assessment of autism spectrum disorders. The child should also be referred to a local early intervention program and to a speech and language pathologist to begin therapy as soon as possible. All children with autism should have a formal audiology evaluation. Laboratory tests such as high-resolution chromosome analysis, DNA for fragile X syndrome, and fluorescence in situ hybridization (FISH) for 15q duplication should be considered. Metabolic screening, lead level, thyroid studies, and a Wood lamp test for tuberous

sclerosis may also be done if indicated by findings in the history and physical examination. Neuroimaging is not routinely indicated even in the presence of macrocephaly because children with autism often have relatively large heads. Neuroimaging should be done if microcephaly or focal neurologic signs are noted.

Approximately 15–30% of children with autism demonstrate plateauing or loss of skills (usually language and social skills only) between 12 and 24 months of age. The loss is usually gradual. It can co-occur with atypical development and can be fluctuating. It usually occurs before the child attains a vocabulary of 10 words. If a child presents with regression, he or she should be referred to a child neurologist. A sleep-deprived EEG or an overnight EEG should be considered when there is a history of regression. The EEG must have adequate sampling of slow-wave sleep to rule out epileptiform discharges during slow-wave sleep. It should be noted that the recommendations for treatment of that type of EEG abnormality are still being debated.

According to the National Research Council, “A substantial subset of children with autistic spectrum disorders are able to make marked progress during the period that they receive intensive early intervention, and nearly all children with autistic spectrum disorders appear to show some benefit. Children with ASD who begin treatment before age 3 to 3½ years make the greatest gains with intervention.” As with any child, treatment should be based on the individual needs of the child. It is clear, however, that intervention must begin early and must be comprehensive and intensive. Many specialists advocate 20–25 hours or more per week of structured behavioral treatments such as applied behavioral analysis, that target development of social attention, peer interactions, functional language, and appropriate play. There are many models for this type of intervention and much variability in what is available in different areas of the country. Families should be encouraged to find a model that best suits the needs of the child and the family.

Many complementary and alternative treatments for autism have been proposed. Research is currently underway to evaluate some of these treatments.

INTELLECTUAL DISABILITY/ MENTAL RETARDATION

The field of developmental disabilities has been evolving and redefining the constructs of disability and intellectual disability and thereby using new terms to reflect that evolution. The term *retardation* was first used in an educational context to describe educationally compromised students. Indeed, during the early 20th century, educators and psychologists struggled to identify the causes of the problems these students encountered. Interestingly, their “differential diagnoses” included biologic, environmental, and emotional etiologies, not dissimilar to those we deal with in the 21st century. In addition, it was—and continues to be—acknowledged that the term *mental retardation* and earlier terms such as *idiocy*, *feeble-mindedness*, and *mental deficiency* are pejorative, demeaning, and dehumanizing.

Recently, a rethinking of the construct of disability has emerged that shifts the focus from limitations in intellectual

functioning and adaptive capability (a person-centered trait) to a human phenomenon with its source in biologic or social factors and contexts. The current view is a social-ecological conception of disability that articulates the role of disease or disorder leading to impairments in structure and function, limitations in activities, and restriction in participation in personal and environmental interactions. The term *intellectual disability*, which is consistent with this broader view, is increasingly being used and reflects an appreciation of the humanness and potential of the individual. The diagnostic criteria currently remain the same; however, the construct and context has changed.

Having noted this, it is important to acknowledge that significant delays in the development of language, motor skills, attention, abstract reasoning, visual-spatial skills, and academic or vocational achievements are associated with intellectual disability/mental retardation (ID/MR). Deficits on standardized testing in cognitive and adaptive functioning greater than two standard deviations below the mean for the population are considered to fall in the range of ID/MR (Table 2–7). The most common way of reporting the results of these tests is by using an intelligence quotient. The intelligence quotient is a statistically derived number reflecting the ratio of age-appropriate cognitive function and the child’s actual level of cognitive function. A number of accepted standardized measurement tools, such as the Wechsler Intelligence Scale for Children, third edition, can be used to assess these capacities. To receive a diagnosis of ID/MR a child must not only have an intelligence quotient of less than 70, but also must demonstrate adaptive skills more than two standard deviations below the mean. Adaptive function refers to the child’s ability to function in his or her environment and can be measured by a parent or teacher interview recorded using an instrument such as the Vineland Adaptive Behavior Scales.

The prevalence of ID/MR is approximately 3% in the general population, although some states have reported a prevalence of less than 2%. Mild levels of ID/MR are more common and more likely to have a sociocultural cause than are more severe levels. Poverty, deprivation, or a lack of exposure to a stimulating environment can contribute to developmental delays and poor performance on standardized tests. In addition, physical problems such as hearing loss, blindness, and brain trauma can lead to developmental delays

Table 2–7. Categories of intellectual disability/mental retardation (ID/MR).

Mental ID/MR Range	Intelligence Quotient (IQ)
Mild ID/MR	50–69
Moderate ID/MR	35–49
Severe ID/MR	20–34
Profound ID/MR	< 20

Table 2-8. Causes of intellectual disability/mental retardation (ID/MR).

Cause	Percentage of Cases
Chromosomal abnormalities	4-28
Fragile X syndrome	2-5
Monogenetic conditions	4-14
Structural CNS abnormalities	7-17
Complications of prematurity	2-10
Environmental or teratogenic causes	5-13
“Cultural-familial” ID/MR	3-12
Metabolic or endocrine causes	1-5
Unknown	30-50

Adapted from Curry CJ et al: Evaluation of mental retardation: Recommendations of a consensus conference. *Am J Med Genet* 1997;72:468.

and low intelligence quotient test scores. Great strides in our identification of genetic causes of ID/MR have been made since the 1990s because of the Human Genome Project. More than 750 genetic disorders have been associated with ID/MR, and over 200 of those disorders are carried on the X chromosome alone. In approximately 60% of cases, the cause of the mental retardation can be identified. Table 2-8 summarizes the findings of several studies examining the causes of mental retardation.

Evaluation

Children who present with developmental delays should be evaluated by a team of professionals as described at the beginning of this section. For children 0–3½ years of age, the Bayley Scales of Infant Development, second edition, is a well-standardized developmental test. For children older than 3 years of age standardized cognitive testing, such as the Wechsler Preschool and Primary Scale of Intelligence-Revised; the Wechsler Intelligence Scale for Children, third edition; the Stanford-Binet IV; or the Kaufman Assessment Battery for Children should be administered to assess cognitive function over a broad range of abilities, including verbal and nonverbal scales. For the nonverbal patient, a scale such as the Leiter-R will assess skills that do not involve language.

A full psychological evaluation in school-aged children should include an emotional assessment if psychiatric or emotional problems are suspected. Such problems are common in children with developmental delays or ID/MR. A hearing test and a vision screening or ophthalmologic evaluation are important to determine whether hearing and vision are normal.

Diagnostic testing should be carried out in an effort to find the cause of ID/MR. Because chromosomal abnormalities occur in 4–28% of patients with ID/MR, cytogenetic

testing is important in cases without a known cause. A consensus panel has recommended a high-resolution karyotype so that small deletions or duplications can be visualized. In addition, FISH studies are available. These studies use a fluorescent DNA probe that hybridizes to a region of DNA where a deletion or duplication is suspected. Microdeletion syndromes—such as Prader-Willi syndrome or Angelman syndrome, caused by a deletion at 15q; velocardiofacial syndrome, caused by a deletion at 22q; Smith-Magenis syndrome, caused by a deletion at 17p; and Williams syndrome, caused by a 7p deletion—can be assessed with FISH studies. Sometimes the deletion is so small that it may not be visualized through the microscope even with high-resolution cytogenetic studies. If clinical features consistent with any of the microdeletion syndromes are present, then FISH studies should be ordered to look for a small deletion in a specific region. In addition, duplications may be present. For example, duplication at 15q has been associated with pervasive developmental disorder or autistic spectrum disorders and with ID/MR. This duplication can be identified by FISH testing.

Structural abnormalities of the brain can occur in many individuals with ID/MR. Magnetic resonance imaging is superior to computed tomography in identifying structural and myelination abnormalities. Computed tomography is the study of choice in evaluation of intracranial calcifications, such as those seen in congenital infections or tuberous sclerosis. The value of computed tomography and magnetic resonance imaging studies in a child with a normal-sized head and no focal neurologic signs is unclear, and they are not routinely carried out. Neuroimaging is important in patients with microcephaly, macrocephaly, seizures, loss of psychomotor skills, or specific neurologic signs such as spasticity, dystonia, ataxia, or abnormal reflexes. Neuroimaging is not routinely carried out in children with known genetic disorders such as Down syndrome, fragile X syndrome, or microdeletion syndromes because the CNS abnormalities have been well described and documentation of the abnormalities usually does not affect management.

Metabolic screening has a relatively low yield (0–5%) in children who present with developmental delay or ID/MR. Many patients with metabolic disorders such as hypothyroidism, phenylketonuria, and galactosemia are identified through newborn screening. Most patients with metabolic problems will present with specific indications for more focused testing, such as failure to thrive, recurrent unexplained illnesses, plateauing or loss of developmental skills, coarse facial features, cataracts, recurrent coma, abnormal sexual differentiation, arachnodactyly, hepatosplenomegaly, deafness, structural hair abnormalities, muscle tone changes, and skin abnormalities. Thyroid function studies should be carried out in any patient who has a palpably abnormal thyroid or exhibits clinical features associated with hypothyroidism. Serum amino acids, urine organic acid, and mucopolysaccharide screens should be considered in children with

developmental delays and a suggestive history. Preliminary laboratory findings such as lactic acidosis, hyperuricemia, hyperammonemia, or a low or high cholesterol level require additional metabolic workup.

Serial follow-up of patients is important as the physical and behavioral phenotype changes over time and diagnostic testing improves with time. Although cytogenetic testing may have been negative 10 years earlier, advances in high-resolution techniques, FISH testing, and fragile X DNA testing may now reveal an abnormality that was not identified previously. A stepwise approach to diagnostic testing may also be more cost-effective, so that the test most likely to be positive is done first.

► Management

Once a diagnosis of ID/MR is made, treatment should include a combination of individual therapies, such as speech and language therapy, occupational therapy or physical therapy, special education support, behavioral therapy or counseling, and medical intervention, which may include psychopharmacology. To illustrate how these interventions work together, three disorders are described in detail in the next section.

SPECIFIC FORMS OF INTELLECTUAL DISABILITY & ASSOCIATED TREATMENT ISSUES

1. Fragile X Syndrome

The most common inherited cause of mental retardation is fragile X syndrome, which is caused by a trinucleotide expansion (CGG repeated sequence) within the fragile X mental retardation I (*FMR1*) gene. Individuals with mental retardation of unknown origin should receive *FMR1* DNA testing to see if they have an expansion of the CGG repeat causing dysfunction of this gene. The CGG sequence at *FMR1* in the normal population includes 5–50 repeats. Carriers of the premutation have 54–200 repeats, and have been considered unaffected. However, there is mounting evidence for a specific phenotype in these individuals. Women with the premutation have a higher incidence of premature ovarian failure, anxiety, and mild

facial dysmorphisms. Individuals with the premutation have normal levels of *FMR1* protein but increased levels of mRNA. It should be noted that seemingly unaffected females can pass an expansion of the CGG repeat to the next generation. Approximately 1 in 250 women and 1 in 700 men in the general population are premutation carriers. When a premutation of more than 90 repeats is passed on by a female to her offspring, it will expand to a full mutation (more than 200 repeats) 100% of the time, which usually causes mental retardation or learning disabilities. The full mutation is associated with methylation of the gene, which turns off transcription, resulting in a deficiency in the *FMR1* protein product. These deficiencies result in mental retardation or significant learning and emotional problems.

Fragile X syndrome includes a broad range of symptoms. Patients can present with shyness, social anxiety, and learning problems, or they can present with mental retardation. Girls are usually less affected by the syndrome because they have a second X chromosome that is producing *FMR1* protein. Approximately 70% of girls with the full mutation have cognitive deficits in addition to emotional problems, such as mood lability, ADHD, anxiety, and shyness. Approximately 85% of males with the syndrome have mental retardation and autistic-like features, such as poor eye contact, hand flapping, hand biting, and tactile defensiveness. About 20% of fragile X males meet the criteria for autism.

Children with fragile X syndrome usually present with language delays, hyperactivity, and tantrum behavior in early childhood. Although prominent ears and hyperextensible finger joints are common, approximately 30% of children with the syndrome may not have these features, and the diagnosis must be suspected because of behavioral problems and developmental delays alone. As the boys move into puberty, macroorchidism develops with an average adult volume of 50 mL, or twice the normal volume. The child's face may become longer during puberty, and the majority of these children continue to have prominent ears.

► Management

All young children with fragile X syndrome benefit from language and motor therapy because delays in these areas are universal. Because approximately 10% of boys with the syndrome will be nonverbal at age 5 years, the use of augmentative communication techniques—such as signing; the use of pictures to represent food, toys, or activities; or the use of computers that can be programmed for communication—are helpful. Tantrums and hyperarousal to stimuli, along with hyperactivity, are common. Sensory integrative occupational therapy can be helpful in calming hyperarousal to stimuli and in improving the child's fine and gross motor coordination and motor planning. Speech and language therapy can decrease oral hypersensitivity, improve articulation, enhance verbal output and comprehension, and stimulate abstract reasoning skills.

If the behavioral problems are severe, it can be helpful to involve a behavioral psychologist who emphasizes positive reinforcement, time outs, consistency in routine, and the use of both auditory and visual modalities, such as a picture sequence, to help with difficult transition times and new situations.

Psychopharmacology can also be useful to treat ADHD, aggression, anxiety, or severe mood instability. Clonidine or guanfacine may be helpful in low doses, beginning in the preschool period to treat hyperarousal, tantrums, or severe hyperactivity. Stimulant medications such as methylphenidate, dextroamphetamine, and Adderall are usually beneficial by age 5 years and occasionally earlier. Relatively low doses are used (eg, 0.2–0.3 mg/kg per dose of methylphenidate) because irritability is often a problem with higher doses.

Shyness and social anxiety combined with mild ADHD are commonly seen in girls who have fragile X syndrome. The social anxiety is sometimes so severe that selective mutism (refusal to speak in some environments, especially school) is seen in girls who have the full mutation. The treatment for selective mutism includes fluoxetine, language therapy, and counseling.

Anxiety may also be a significant problem for boys with fragile X syndrome, and the use of a selective serotonin reuptake inhibitor (SSRI) such as fluoxetine, sertraline, fluvoxamine, or paroxetine is often helpful. SSRIs may also decrease aggression or moodiness, although in approximately 25% of cases, an increase in agitation or even hypomania may occur. The use of a more limited serotonin agent, buspirone, may also be helpful for anxiety, particularly if the patient cannot tolerate SSRIs.

Anticonvulsants such as carbamazepine, valproic acid, and gabapentin can be used to treat seizures, which occur in 20% of children with fragile X syndrome. They can also be helpful in treating more severe mood instability that does not improve with an SSRI, clonidine, or a stimulant medication. The use of carbamazepine and valproic acid requires careful monitoring of blood levels, liver function studies, electrolytes, blood count, and platelet level.

Aggression may become a significant problem in childhood or adolescence for boys with fragile X syndrome. Counseling can often be helpful, although medication may be needed. Stimulants, clonidine, and an SSRI may decrease aggression, although sometimes an atypical antipsychotic may be needed. If psychotic features are present, such as paranoia, delusions, or hallucinations, or if thinking is severely disorganized, then an atypical antipsychotic is usually helpful. Risperidone has been used most frequently in pediatrics and has a low risk for extrapyramidal symptoms. Side effects include sedation, excessive appetite and subsequent weight gain, and an increase in prolactin, which can cause breast tenderness and gynecomastia in boys. Usually a low dose of risperidone is well tolerated, and 0.5–2 mg at bedtime usually improves aggression, decreases hyperactivity, and stabilizes mood.

An important component of treatment is genetic counseling. Parents should meet with a genetic counselor after the diagnosis of fragile X syndrome is made because there is a high risk that other family members are carriers or may be affected by the syndrome. A detailed family history is essential, and all siblings of the proband should have *FMRI* DNA testing. If the mother received the gene from her father, then all of her sisters are obligate carriers, and their children are at 50% risk of having the fragile X mutation.

It is also helpful to link up a newly diagnosed family to a parent support group. Educational materials and parent support information may be obtained by calling the National Fragile X Foundation at 1-800-688-8765.

2. Fetal Alcohol Spectrum Disorders

Alcohol exposure in utero is associated with a broad spectrum of developmental problems, ranging from learning disabilities to severe mental retardation. Fetal alcohol spectrum disorders (FASD) is an umbrella term describing the range of effects that can occur in an individual exposed to alcohol prenatally. The Institute of Medicine in 1996 defined the diagnostic categories in individuals with documented prenatal maternal alcohol exposure as follows.

A. Fetal Alcohol Syndrome

Fetal alcohol syndrome (FAS) refers to the full syndrome associated with prenatal alcohol exposure. The diagnosis of FAS requires the presence of a characteristic pattern of facial abnormalities (short palpebral fissures, thin upper lip, and indistinct or smooth philtrum, for which there are standard measurements), growth deficiency, and evidence of CNS damage and neurodevelopmental abnormalities.

B. Partial Fetal Alcohol Syndrome

The diagnosis of partial fetal alcohol syndrome requires the presence of some but not all components of the facial anomalies as well as growth retardation, CNS neurodevelopmental abnormalities, or behavioral or cognitive abnormalities that are inconsistent with the child's developmental level and cannot be explained by familial background or environment.

Partial fetal alcohol syndrome is a category that has been controversial, and some clinicians feel that the criteria are too vague and imprecise to be of clinical help. What is most important, if the child does not have all of the criteria for FAS, is the documentation of prenatal alcohol exposure and the presence of neurodevelopmental dysfunction (encephalopathy).

C. Alcohol-Related Neurodevelopmental Disorder

Alcohol-related neurodevelopmental disorder does not require the presence of dysmorphic facial features, but it does require the presence of neurodevelopmental abnormalities or evidence of a pattern of behavioral or cognitive abnormalities. These abnormalities may include learning disabilities; poor impulse control; and problems in memory, attention, and judgment.

D. Alcohol-Related Birth Defects

The diagnosis of alcohol-related birth defects requires the presence of congenital anomalies, including malformations and dysplasias in cardiac, skeletal, renal, ocular, or auditory areas (ie, sensorineural hearing loss).

Animal and human data support these diagnostic categories, including the controversial alcohol-related neurodevelopmental disorder diagnosis, which does not include dysmorphic features. The prevalence of FAS, partial fetal alcohol syndrome, and alcohol-related neurodevelopmental disorder combined is approximately 1 per 100 in the general population. These are common problems. Thus, the physician should always ask about alcohol (and other drug) intake during pregnancy. This is particularly true when evaluating a child presenting with developmental disturbances. The exact amount of alcohol consumption that leads to teratogenesis remains unclear. However, there is strong evidence that binge drinking during the first trimester, the critical period of embryogenesis, leads to FASD.

► Evaluation & Management

Essential to the evaluation of a child with FASD, or one suspected of having FASD, is an assessment by a multidisciplinary team. Growth deficiency, facial features, brain dysfunction, and the documentation of prenatal alcohol exposure are the most significant areas to be assessed.

The majority of children with alcohol-related syndromes present with ADHD symptoms, with or without significant developmental delays. To adequately assess involvement in other organs the following tests are recommended: an ophthalmologic examination, a hearing test, and a careful cardiac examination, with ultrasonography if abnormalities are detected. A careful examination for dysmorphic features and bony abnormalities is necessary. Renal function studies (ie, creatinine) should be conducted and a renal ultrasound obtained. Mental health problems are observed in over 90% of children and adolescents affected by alcohol in utero. Depression, panic attacks, anxiety, and mood instability are common. Because psychotic ideation is present in 20–40% of individuals with alcohol-related syndromes, a thorough emotional or psychiatric evaluation is essential. Long-term therapy and special education services are usually needed, and psychopharmacologic intervention may be helpful.

For treatment of ADHD symptoms, a dextroamphetamine preparation should be tried initially, although methylphenidate may also be helpful. SSRIs can help relieve anxiety, panic attacks, and depression, although mania or hypomanias, a side effect, may occur in 25–50% of patients. Mood instability may be severe, although it usually responds to a mood stabilizer such as valproate or carbamazepine. One should be cautious with lithium because kidney dysfunction, secondary to malformations or hypoplasia, occasionally occurs. Psychotic features can be treated with an atypical or typical antipsychotic agent. However, consultation with a psychiatrist is advised under these circumstances. A speech and language evaluation and an occupational therapy evaluation in childhood usually lead to documentation of problems, and ongoing therapy is usually helpful. The most significant problem in FASD is the high rate of legal problems, incarceration, and alcohol or drug abuse in adolescence and adulthood. A coordinated intensive treatment program must be put in place early on if the outcome for these children is to be improved. Long-term counseling and advocacy, along with intensive job training can be of help in preventing social and legal problems for children with FASD.

Adolescence

David W. Kaplan, MD, MPH
Kathryn A. Love-Osborne, MD

3

Adolescence is a period of rapid physical, emotional, cognitive, and social growth and development. Generally, adolescence begins at age 11–12 years and ends between ages 18 and 21. Most teenagers complete puberty by age 16–18 years; in western society, however, for educational and cultural reasons, the adolescent period is prolonged to allow for further psychosocial development before the individual assumes adult responsibilities.

The developmental passage from childhood to adulthood encompasses the following steps: (1) completing puberty and somatic growth; (2) developing socially, emotionally, and cognitively, and moving from concrete to abstract thinking; (3) establishing an independent identity and separating from the family; and (4) preparing for a career or vocation.

DEMOGRAPHY

In the United States in 2006, there were 21.3 million adolescents aged 15–19 years and 21.1 million aged 20–24 years. Adolescents and young adults (ages 15–24 years) constitute 14% of the U.S. population. In the next several decades, the proportion of racial and ethnic minority adolescents is expected to increase. It is projected that by 2040 the percentage of non-Hispanic whites will drop below 50%. Hispanics are becoming the second most populous racial and ethnic group.

MORTALITY DATA

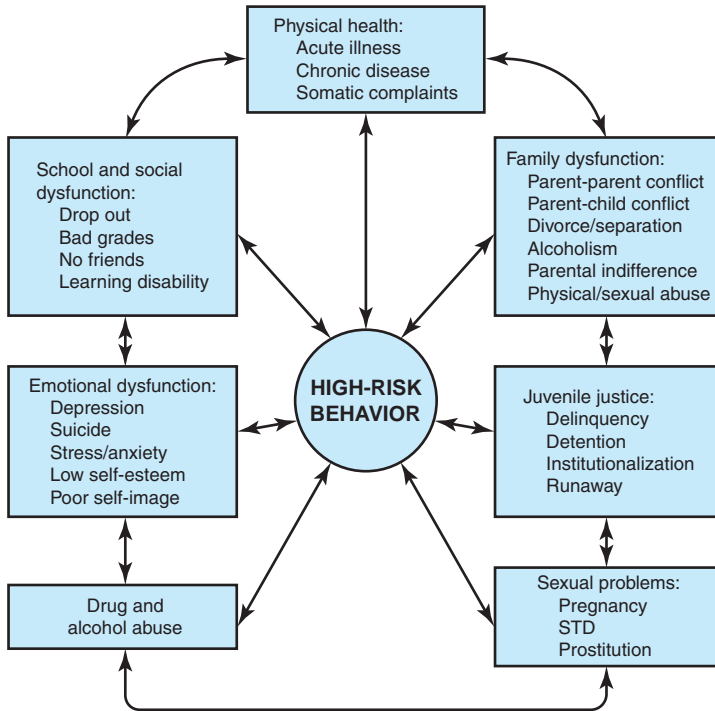

In adolescents, cultural and environmental rather than organic factors pose the greatest threats to life. The three leading causes of death in the adolescents aged 15–19 years in 2004 were unintentional injury (50.0%), homicides (14.1%), and suicides (12.4%). These three causes of violent death accounted for 76.5% of all adolescent deaths. Although deaths from automobile crashes have decreased in the past decade, alcohol use remains the underlying cause of most teenage motor vehicle

deaths. Almost two thirds of motor vehicle deaths involving young drinking drivers occur on Friday, Saturday, or Sunday, and 70% occur between 8:00 PM and 4:00 AM.

There is continued concern with the problem of youth violence in the United States. The concern is stimulated by the high rate of homicides involving handguns among young males, the number of firearm-related suicides, and school shootings. Youths 12–17 years old are twice as likely as adults to be victims of serious violent crimes, including aggravated assault, rape, robbery, and homicide. Violent crimes committed by juveniles constitute about 25% of all violent crimes. Nationally, 18.5% of high-school students reported carrying a weapon at least once in the preceding 30 days. Violent crime victimization among adolescents has declined substantially since the early 1990s. In 2005, adolescents aged 12–19 were victimized at an all time low rate of 44.0 per 1000. This rate is less than half that reported for 1994. Adolescents who have been violently victimized are more likely to have physical and mental health problems, substance abuse problems, and problems at school.

MORBIDITY DATA

Demographic and economic changes in the American family have had a profound effect on children and adolescents. Between 1955 and 1990, the divorce rate rose from about 400,000 to nearly 1.2 million per year. Between 1960 and 1990, the number of children involved in divorce increased from 460,000 to 1.1 million per year. The percentage of children and adolescents living in two-parent households has decreased significantly, from 79% in 1980 to 68% in 2004. After peaking at 22% in 1992, the percentage of children living in families whose income was below the official poverty threshold fell during the late 1990s to 17%. However, the rate of poverty differs significantly by race and family structure. In 2005, 34% of black children and 28% of Hispanic children lived in families with incomes below the official poverty threshold. In 2005, 43% of children living in

▲ **Figure 3-1.** Interrelation of high-risk adolescent behavior.

single-mother families were poor, compared with 9% of children living in married-couple families.

The major causes of morbidity during adolescence are psychosocial and often correlated with poverty: unintended pregnancy, sexually transmitted infections (STIs), substance abuse, smoking, dropping out of school, depression, running away from home, physical violence, and juvenile delinquency. High-risk behavior in one area is frequently associated with problems in another (Figure 3-1). For example, teenagers who live in a dysfunctional family (eg, problems related to drinking or physical or sexual abuse) are much more likely than other teenagers to be depressed. A depressed teenager is at greater risk for drug and alcohol abuse, academic failure, inappropriate sexual activity, STIs, pregnancy, and suicide.

Early identification of the teenager at risk for these problems is important in preventing immediate complications and future associated problems. Early indicators for problems related to depression include the following:

1. Decline in school performance.
2. Excessive school absences or cutting class.
3. Frequent or persistent psychosomatic complaints.
4. Changes in sleeping or eating habits.
5. Difficulty in concentrating or persistent boredom.
6. Signs or symptoms of depression, extreme stress, or anxiety.

7. Withdrawal from friends or family, or change to a new group of friends.
8. Unusually severe violent or rebellious behavior, or radical personality change.
9. Conflict with parents.
10. Sexual acting-out.
11. Conflicts with the law.
12. Suicidal thoughts or preoccupation with themes of death.
13. Drug and alcohol abuse.
14. Running away from home.

DELIVERY OF HEALTH SERVICES

How, where, why, and when adolescents seek health care depends on ability to pay, distance to health care facilities, availability of transportation, accessibility of services, time away from school, and privacy. Many common teenage health problems, such as unintended pregnancy and the need for contraception; STIs; and substance abuse, depression, and other emotional problems, have moral, ethical, and legal implications. Teenagers are often reluctant to confide in their parents for fear of punishment or disapproval. Recognizing this reality, health care providers have established specialized programs such as teenage family planning clinics, drop-in centers, STI clinics, hotlines, and adolescent clinics. Establishing a trusting and confidential relationship with adolescents is basic to meeting their health care needs. Patients who sense that the physician will inform their parents about a confidential problem may lie or fail to disclose information essential for proper diagnosis and treatment.

GUIDELINES FOR ADOLESCENT PREVENTIVE SERVICES

The American Medical Association guidelines for adolescent preventive services and the American Academy of Pediatrics' *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents* cover health screening and guidance, immunization, and health care delivery. The goals of these guidelines are (1) to deter adolescents from participating in behaviors that jeopardize health; (2) to detect physical, emotional, and behavioral problems early and intervene promptly; (3) to reinforce and encourage behaviors that promote healthful living; and (4) to provide immunization against infectious diseases. The guidelines recommend that adolescents between ages 11 and 21 years have annual routine health visits. Health services should be developmentally appropriate and culturally sensitive, and confidentiality between patient and physician should be ensured.

RELATING TO THE ADOLESCENT PATIENT

Adolescence is one of the physically healthiest periods in life. The challenge of caring for adolescents lies not in managing complex organic disease, but in accommodating the cognitive, emotional, and psychosocial growth that influences health behavior. How the physician initially

approaches the adolescent may determine the success or failure of the visit. The physician should behave simply and honestly, without an authoritarian or excessively professional manner. Because the self-esteem of many young adolescents is fragile, the physician must be careful not to overpower and intimidate the patient. To establish a comfortable and trusting relationship, the physician should strive to present the image of an ordinary person who has special training and skills.

Because individuals vary in the onset and termination of puberty, chronologic age may be a poor indicator of physical, physiologic, and emotional development. In communicating with an adolescent, the physician must be sensitive to the patient's developmental level, recognizing that outward appearance and chronologic age may not give an accurate assessment of cognitive development.

Working with teenagers can be emotionally draining. Adolescents have a unique ability to identify hidden emotional vulnerabilities. The physician who has a personal need to control patients or foster dependency may be disappointed in caring for teenagers. Because teenagers are consumed with their own emotional needs, they rarely provide the physician with the ego rewards that younger or older patients do.

The physician should be sensitive to the issue of countertransference, the emotional reaction elicited in the physician by the adolescent. How the physician relates to the adolescent patient often depends on the physician's personal characteristics. This is especially true of physicians who treat families that are experiencing parent-adolescent conflicts. It is common for young physicians to overidentify with the teenage patient and for older physicians to see the conflict from the parents' perspective.

Overidentification with the parents is readily sensed by the teenager, who is likely to view the physician as just another authority figure who cannot understand the problems of being a teenager. Assuming a parental-authoritarian role may jeopardize the establishment of a working relationship with the patient. In the case of the young physician, overidentification with the teenager may cause the parents to become defensive about their parenting role and discount the physician's experience and ability.

THE SETTING

Adolescents respond positively to settings and services that communicate sensitivity to their age. A pediatrician's waiting room with toddlers' toys and infant-sized examination tables makes adolescent patients feel they have outgrown the practice. A waiting room filled with geriatric or pregnant patients can also make a teenager feel out of place.

It is not uncommon to see a teenage patient who has been brought to the office against his or her wishes, especially for evaluations of drug and alcohol use, parent-child conflict, school failure, depression, or a suspected eating disorder.

Even in cases of acute physical illness, the adolescent may feel anxiety about having a physical examination. If future visits are to be successful, the physician must spend time on the first visit to foster a sense of trust and an opportunity to feel comfortable.

CONFIDENTIALITY

It is helpful at the beginning of the visit to talk with the adolescent and the parents about what to expect. The physician should address the issue of confidentiality, telling the parents that two meetings, one with the teenager alone and one with only the parents, will take place. Adequate time must be spent with both the patient and the parents, or important information may be missed. At the beginning of the interview with the patient, it is useful to say, “I am likely to ask you some personal questions. This is not because I am trying to pry into your personal affairs, but because these questions may be important to your health. I want to assure you that what we talk about is confidential, just between the two of us. If there is something I feel we should discuss with your parents, I will ask your permission first unless I feel it is life-threatening.”

THE STRUCTURE OF THE VISIT

Caring for adolescents is time-intensive. In many adolescent practices, a 40–50% no-show rate is not unusual. The stated chief complaint often conceals the patient’s real concern. For example, a 15-year-old girl may say she has a sore throat but actually may be worried about being pregnant.

By age 11 or 12 years, patients should be seen alone. This gives them an opportunity to ask questions they may be embarrassed to ask in front of a parent. Because of the physical changes that take place in early puberty, some adolescents are too self-conscious to undress in front of a parent. If an adolescent comes in willingly, for an acute illness or for a routine physical examination, it may be helpful to meet with the adolescent and parent together to obtain the history. In angry adolescents brought in against their will, it is useful to meet with the parents and patient for 3–5 minutes to allow the parents to describe the conflict and voice their concerns. The adolescent should then be seen alone. This approach conveys that the physician is primarily interested in the adolescent patient, yet gives the physician an opportunity to acknowledge the parents’ concerns.

The Interview

The first few minutes may dictate whether or not a trusting relationship can be established. A few minutes just getting to know the patient is time well spent. For example, immediately asking “Do you smoke marijuana?” when a teenager is brought in for suspected marijuana use confirms the adolescent’s negative preconceptions about the physician and the purpose of the visit. It is preferable to spend a few minutes asking nonthreat-

ening questions, such as “Tell me a little bit about yourself so I can get to know you,” “What do you like to do most?” “Least?” and “What are your friends like?” Neutral questions help defuse some of the patient’s anger and anxiety. Toward the end of the interview, the physician can ask more directed questions about psychosocial concerns.

Medical history questionnaires for the patient and the parents are useful in collecting historical data (Figure 3–2). The history should include an assessment of progress with psychosocial tasks and of behaviors potentially detrimental to health. The review of systems should include questions about the following:

1. Nutrition: number and balance of meals; calcium, iron, and cholesterol intake; body image.
2. Sleep: number of hours, problems with insomnia or frequent waking.
3. Seat belt or helmet: regularity of use.
4. Self-care: knowledge of testicular or breast self-examination, dental hygiene, and exercise.
5. Family relationships: parents, siblings, relatives.
6. Peers: best friend, involvement in group activities, gangs, boyfriends, girlfriends.
7. School: attendance, grades, activities.
8. Educational and vocational interests: college, career, short-term and long-term vocational plans.
9. Tobacco: use of cigarettes, snuff, chewing tobacco.
10. Substance abuse: frequency, extent, and history of alcohol and drug use.
11. Sexuality: sexual activity, contraceptive use, pregnancies, history of STI, number of sexual partners, risk for HIV infection.
12. Emotional health: signs of depression and excessive stress.

The physician’s personal attention and interest is likely to be a new experience for the teenager, who has probably received medical care only through a parent. The teenager should leave the visit with a sense of having a personal physician.

Physical Examination

During early adolescence, many teenagers may be shy and modest, especially with a physician of the opposite sex. The examiner should address this concern directly, because it can be allayed by acknowledging the uneasiness verbally and by explaining the purpose of the examination, for example, “Many boys that I see who are your age are embarrassed to have their penis and testes examined. This is an important part of the examination for a couple of reasons. First, I want to make sure that there aren’t any physical problems, and second, it helps me determine if your development is proceeding normally.” This also introduces the subject of sexual development for discussion.

A pictorial chart of sexual development is useful for showing the patient how development is proceeding and

▲ Figure 3-2. (Continued)

▲ **Figure 3-3.** Adolescent male sexual maturation and growth.

what changes to expect. Figure 3–3 shows the relationship between height, penis and testes development, and pubic hair growth in the male, and Figure 3–4 shows the relationship between height, breast development, menstruation, and pubic hair growth in the female. Although teenagers may not admit that they are interested in this subject, they are usually attentive when it is raised. This discussion is particularly useful in counseling teenagers who lag behind their peers in physical development.

Because teenagers are sensitive about their changing bodies, it is useful to comment during the examination: “Your heart sounds fine. I feel a small lump under your right breast. This is very common during puberty in boys. It is called gynecomastia and should disappear in 6 months to a year. Don’t worry, you are not turning into a girl.”

If a teenage girl has not been sexually active and has no gynecologic complaints or abnormalities, a pelvic examination is usually not necessary until about age 18 years. The following are indications for a pelvic examination in a younger teenage girl:

1. A history of sexual intercourse. (The pelvic examination should be done for purposes of contraceptive counseling and to rule out STI.)
2. Abnormal vaginal discharge.

3. Menstrual irregularities.
4. Suspicion of anatomic abnormalities, such as imperforate hymen.
5. Pelvic pain.
6. Patient request for an examination.

GROWTH & DEVELOPMENT

PUBERTY

Pubertal growth and physical development are a result of activation of the hypothalamic-pituitary-gonadal axis in late childhood. Before puberty, pituitary and gonadal hormone levels are low. At onset of puberty, the inhibition of gonadotropin-releasing hormone in the hypothalamus is removed, allowing pulsatile production and release of the gonadotropins: luteinizing hormone (LH) and follicle-stimulating hor-

▲ **Figure 3-4.** Adolescent female sexual maturation and growth.

mone (FSH). In early to middle adolescence, pulse frequency and amplitude of LH and FSH secretion increase, stimulating the gonads to produce estrogen or testosterone. In females, FSH stimulates ovarian maturation, granulosa cell function, and estradiol secretion. LH is important in ovulation and also is involved in corpus luteum formation and progesterone secretion. Initially, estradiol inhibits the release of LH and FSH. Eventually, estradiol becomes stimulatory, and the secretion of LH and FSH becomes cyclic. Estradiol levels progressively increase, resulting in maturation of the female genital tract and breast development.

In males, LH stimulates the interstitial cells of the testes to produce testosterone. FSH stimulates the production of spermatoocytes in the presence of testosterone. The testes also produce inhibin, a Sertoli cell protein that inhibits the secretion of FSH. During puberty, circulating testosterone levels increase more than 20-fold. Levels of testosterone correlate with the physical stages of puberty and the degree of skeletal maturation.

PHYSICAL GROWTH

A teenager's weight almost doubles in adolescence, and height increases by 15–20%. During puberty, major organs double in size, except for lymphoid tissue, which decreases in mass. Before puberty, there is little difference in the muscular strength of boys and girls. The body's musculature increases both in size and in strength during puberty, with maximal strength lagging behind the increase in size by many months. Boys attain greater strength and mass, and strength continues to increase into late puberty. Although motor coordination lags behind growth in stature and musculature, it continues to improve as strength increases.

The pubertal growth spurt begins nearly 2 years earlier in girls than in boys. Girls reach peak height velocity between ages 11½ and 12 years, and boys, between ages 13½ and 14 years. Linear growth at peak velocity is 9.5 cm/y ± 1.5 cm in boys and 8.3 cm/y ± 1.2 cm in girls. Pubertal growth lasts

about 2–4 years and continues longer in boys than in girls. By age 11 years in girls and age 12 years in boys, 83–89% of ultimate height is attained. An additional 18–23 cm in females and 25–30 cm in males is achieved during late pubertal growth. Following menarche, growth is rarely more than 5–7.5 cm.

In boys, the quantity of body fat increases before onset of the height spurt, continues until the growth spurt has finished, and then gradually increases. Muscle mass doubles between 10 and 17 years. Girls, by contrast, store fat gradually from about 6 years of age and do not decrease the quantity of fat, although its location changes. There is an increase in subcutaneous fat in the pelvis, breasts, and upper back.

SEXUAL MATURATION

Sexual maturity rating (SMR) is useful for categorizing genital development. SMR staging includes age ranges of normal development and specific descriptions for each stage of pubic hair growth, penis and testis development in boys, and breast maturation in girls. Figures 3–3 and 3–4 show this chronologic development. SMR 1 is prepuberty and SMR 5 is adult maturity. In SMR 2 the pubic hair is sparse, fine, nonpigmented, and downy; in SMR 3, the hair becomes pigmented and curly and increases in amount; and in SMR 4, the hair is adult in texture but limited in area. The appearance of pubic hair precedes axillary hair by more than 1 year. Male genital development begins with SMR 2, in which the testes become larger and the scrotal skin reddens and coarsens. In SMR 3, the penis lengthens; and in SMR 4, the penis enlarges in overall size and the scrotal skin becomes pigmented.

Female breast development follows a predictable sequence. Small, raised breast buds appear in SMR 2. In SMR 3, the breast and areolar tissue generally enlarge and become elevated. The areola and nipple form a separate mound from the breast in SMR 4, and in SMR 5 the areola assumes the same contour as the breast.

There is great variability in the timing and onset of puberty and growth, and psychosocial development does not always parallel physical changes. Chronologic age, therefore, may be a poor indicator of physiologic and psychosocial development. Skeletal maturation correlates well with growth and pubertal development.

Teenagers began entering puberty at earlier ages in the last century because of better nutrition and socioeconomic conditions. In the United States, the average age at menarche is 12.16 years in African-American girls and 12.88 in white girls. Among girls reaching menarche, the average weight is 48 kg, and the average height is 158.5 cm. Menarche may be delayed until age 16 years or may begin as early as age 10. Although the first measurable sign of puberty in girls is the beginning of the height spurt, the first conspicuous sign usually is development of breast buds between 8 and 11 years. Although breast development usually precedes the growth of pubic hair, the sequence may be reversed. A common concern for girls at this

time is whether the breasts will be of the right size and shape, especially because initial breast growth is often asymmetrical. The growth spurt starts at about age 9 years in girls and peaks at age 11½, usually at SMR 3–4 breast development and stage 3 pubic hair development. The spurt usually ends by age 14 years. Girls who mature early will reach peak height velocity sooner and attain their final height earlier. Girls who mature late will attain a greater final height because of the longer period of growth before the growth spurt. Final height is related to skeletal age at onset of puberty as well as genetic factors. The height spurt correlates more closely with breast developmental stages than with pubic hair stages.

The first sign of puberty in the male, usually between ages 10 and 12 years, is scrotal and testicular growth. Pubic hair usually appears early in puberty but may do so any time between ages 10 and 15 years. The penis begins to grow significantly a year or so after the onset of testicular and pubic hair development, usually between ages 10 and 13½. The first ejaculation usually occurs about 1 year after initiation of testicular growth, but its timing is highly variable. About 90% of boys have this experience between ages 11 and 15 years. Gynecomastia, a hard nodule under the nipple, occurs in a majority of boys, with a peak incidence between ages 14 and 15 years. Gynecomastia usually disappears within 6 months to 2 years. The height spurt begins at age 11 years but increases rapidly between ages 12 and 13, with the peak height velocity reached at age 13½ years. The period of pubertal development lasts much longer in boys and may not be completed until age 18 years. The height velocity is higher in males (8–11 cm/y) than in females (6.5–9.5 cm/y). The development of axillary hair, deepening of the voice, and the development of chest hair in boys usually occur in midpuberty, about 2 years after onset of growth of pubic hair. Facial and body hair begin to increase at age 16–17 years.

PSYCHOSOCIAL DEVELOPMENT

Adolescence is a period of progressive individuation and separation from the family. Adolescents must learn who they are, decide what they want to do, and identify their personal strengths and weaknesses. Because of the rapidity of physical,

emotional, cognitive, and social growth during adolescence, it is useful to divide it into three phases. Early adolescence is roughly from 10 to 13 years of age; middle adolescence, from 14 to 16 years; and late adolescence, 17 years and later.

Early Adolescence

Early adolescence is characterized by rapid growth and development of secondary sex characteristics. Body image, self-concept, and self-esteem fluctuate dramatically. Concerns about how personal growth and development deviate from that of peers may be a great worry, especially short stature in boys and delayed breast development or delayed menarche in girls. Although there is a certain curiosity about sexuality, young adolescents generally feel more comfortable with members of the same sex. Peer relationships become increasingly important. Young teenagers still think concretely and cannot easily conceptualize about the future. They may have vague and unrealistic professional goals, such as becoming a movie star or a lead singer in a rock group.

Middle Adolescence

During middle adolescence as rapid pubertal development subsides, teenagers become more comfortable with their new bodies. Intense emotions and wide swings in mood are typical. Although some teenagers go through this experience relatively peacefully, others struggle. Cognitively, the mid-adolescent moves from concrete thinking to formal operations and abstract thinking. With this new mental power comes a sense of omnipotence and a belief that the world can be changed by merely thinking about it. Sexually active teenagers may believe they do not need to worry about using contraception because they can't get pregnant ("it won't happen to me"). Sixteen-year-old drivers believe they are the best drivers in the world and think the insurance industry is conspiring against them by charging high rates for automobile insurance. With the onset of abstract thinking, teenagers begin to see themselves as others see them and may become extremely self-centered. Because they are establishing their own identities, relationships with other people, including peers, are narcissistic. Experimenting with different images is common. As sexuality increases in importance, adolescents may begin dating and experimenting with sex. Relationships tend to be one-sided and narcissistic. Peers determine the standards for identification, behavior, activities, and fashion and provide emotional support, intimacy, empathy, and the sharing of guilt and anxiety during the struggle for autonomy. The struggle for independence and autonomy is often a stressful period for both teenagers and parents.

Late Adolescence

During late adolescence, the young person generally becomes less self-centered and more caring of others. Social relationships shift from the peer group to the individual. Dating becomes much more intimate. By 10th grade, 43% of

adolescents have had sexual intercourse, and by 12th grade, 63%. Abstract thinking allows older adolescents to think more realistically about their plans for the future. Older adolescents have rigid concepts of what is right or wrong. This is a period of idealism.

Sexual Orientation

Sexual orientation develops during early childhood. One's gender identity is established by age 2 years, and a sense of masculinity or femininity usually solidifies by age 5 or 6 years. Homosexual adults describe homosexual feelings during late childhood and early adolescence, years before engaging in overt homosexual acts.

Although only 5–10% of American young people acknowledge having had homosexual experiences and only 5% feel that they are or could be gay, homosexual experimentation is common, especially during early and middle adolescence. Experimentation may include mutual masturbation and fondling the genitals and does not by itself cause or lead to adult homosexuality. Theories about the causes of homosexuality include genetic, hormonal, environmental, and psychological models.

The development of homosexual identity in adolescence commonly progresses through two stages. The adolescent feels different, develops a crush on a person of the same sex without clear self-awareness of a gay identity, and then goes through a coming-out phase in which the homosexual identity is defined for the individual and revealed to others. The coming-out phase may be a difficult period for the young person and the family. The young adolescent is afraid of society's bias and seeks to reject homosexual feelings. This struggle with identity may include episodes of both homosexual and heterosexual promiscuity, STIs, depression, substance abuse, attempted suicide, school avoidance and failure, running away from home, and other crises.

In a clinical setting, the issue of homosexual identity most often surfaces when the teenager is seen for an STI, family conflict, school problem, attempted suicide, or substance abuse rather than as a result of a consultation about sexual orientation. Pediatricians should be aware of the psychosocial and medical implications of homosexual identity and be sensitive to the possibility of these problems in gay adolescents. Successful management depends on the physician's ability to gain the trust of the gay adolescent and on the physician's knowledge of the wide range of medical and psychological problems for which gay adolescents are at risk. Pediatricians must be nonjudgmental in posing sexual questions if they are to be effective in encouraging the teenager to share concerns. Physicians who for religious or other personal reasons cannot be objective must refer the homosexual patient to another professional for treatment and counseling.

BEHAVIOR & PSYCHOLOGICAL HEALTH

It is not unusual for adolescents to seek medical attention for seemingly minor complaints. In early adolescence, teenagers may worry about normal developmental changes such as gynecomastia. They may present with vague symptoms, but have a hidden agenda of concerns about pregnancy or an STI. Adolescents with emotional disorders often present with somatic symptoms such as abdominal pain, headaches, dizziness, syncope, fatigue, sleep problems, and chest pain that appear to have no biologic cause. The emotional basis of such complaints may be varied: somatoform disorder, depression, or stress and anxiety.

PSYCHOPHYSIOLOGIC SYMPTOMS & CONVERSION REACTIONS

The most common somatoform disorder of adolescence is conversion disorder or conversion reaction. (A conversion reaction is a psychophysiologic process in which unpleasant feelings, especially anxiety, depression, and guilt, are communicated through a physical symptom.) Psychophysiologic symptoms result when anxiety activates the autonomic nervous system, causing tachycardia, hyperventilation, and vasoconstriction. The emotional feeling may be threatening or unacceptable to the individual, who expresses it as a physical symptom rather than verbally. The process is unconscious, and the anxiety or unpleasant feeling is dissipated by the somatic symptom. The degree to which the conversion symptom lessens anxiety, depression, or the unpleasant feeling is referred to as primary gain. Conversion symptoms not only diminish unpleasant feelings but also release the adolescent from conflict or an uncomfortable situation. This is called secondary gain. Secondary gain may intensify the symptoms, especially with increased attention from concerned parents and friends. Adolescents with conversion symptoms tend to have overprotective parents and become increasingly dependent on their parents as the symptom becomes a major focus of concern in the family.

Clinical Findings

Symptoms may appear at times of stress. Nervous, gastrointestinal, and cardiovascular symptoms are common and

include paresthesias, anesthesia, paralysis, dizziness, syncope, hyperventilation, abdominal pain, nausea, and vomiting. Specific symptoms may reflect existing or previous illness (eg, pseudoseizures in adolescents with epilepsy) or modeling of a close relative's symptom (eg, chest pain in a boy whose grandfather died of a heart attack).

Conversion symptoms are more common in girls than in boys. Although they occur in patients from all socioeconomic levels, the complexity of the symptom may vary with the sophistication and cognitive level of the patient.

Differential Diagnosis

History and physical findings are usually inconsistent with a physical cause of symptoms. Conversion symptoms occur most frequently during stress and in the presence of individuals meaningful to the patient. The common personality traits of these patients include egocentricity, emotional lability, and dramatic and attention-seeking behaviors.

Conversion reactions must be differentiated from hypochondriasis, which is a preoccupation with developing or having a serious illness despite medical reassurance that there is no evidence of disease. Over time, the fear of one disease may give way to concern about another. In contrast to patients with conversion symptoms, who seem relieved if an organic cause is considered, patients with hypochondriasis become more anxious when such a cause is considered.

Malingering is uncommon during adolescence. The malingering patient consciously and intentionally fabricates false or exaggerated physical or psychological symptoms. Such patients are motivated by external incentives such as avoiding work, evading criminal prosecution, obtaining drugs, or obtaining financial compensation. These patients may be hostile and aloof. Parents of patients with conversion disorders and malingering have a similar reaction to illness. They have an unconscious psychological need to have sick children and reinforce their child's behavior.

Somatic delusions are physical symptoms, often bizarre, that accompany other signs of mental illness. Examples are visual or auditory hallucinations, delusions, incoherence or loosening of associations, rapid shifts of affect, and confusion.

Treatment

The physician must emphasize from the outset that both physical and emotional causes of the symptom will be considered. The relationship between physical causes of emotional pain and emotional causes of physical pain should be described to the family, using examples such as stress causing an ulcer or making a severe headache worse. The patient should be encouraged to understand that the symptom may persist and that at least a short-term goal is to continue normal daily activities. Medication is rarely helpful. If the family will accept it, psychological referral is often the best initial step toward psychotherapy. If the family resists psychiatric or psychological referral, the pediatrician may need to begin to

deal with some of the emotional factors responsible for the symptom while building rapport with the patient and family. Regular appointments should be scheduled. During visits, the teenager should be seen first and encouraged to talk about school, friends, the relationship with the parents, and the stresses of life. Discussion of the symptom itself should be minimized; however, the physician should be supportive and must never suggest that the pain is not real. As parents gain insight into the cause of the symptom, they will become less indulgent and facilitate resumption of normal activities. If management is successful, the adolescent will gain coping skills and become more independent, while decreasing secondary gain.

If the symptom continues to interfere with daily activities and if the patient and parents feel that no progress is being made, psychological referral is indicated. A psychotherapist experienced in treating adolescents with conversion reactions is in the best position to establish a strong therapeutic relationship with the patient and family. After referral is made, the pediatrician should continue to follow the patient to ensure compliance with psychotherapy.

DEPRESSION (SEE ALSO CHAPTER 6)

Symptoms of clinical depression (lethargy, loss of interest, sleep disturbances, decreased energy, feelings of worthlessness, and difficulty concentrating) are common during adolescence. The intensity of feelings, often in response to seemingly trivial events such as a poor grade on an examination or not being invited to a party, makes it difficult to differentiate severe depression from normal sadness or dejection. In less severe depression, sadness or unhappiness associated with problems of everyday life is generally short-lived. The symptoms usually result in only minor impairment in school performance, social activities, and relationships with others. Symptoms respond to support and reassurance.

► Clinical Findings

The presentation of serious depression in adolescence may be similar to that in adults, with vegetative signs such as depressed mood, crying spells or inability to cry, discouragement, irritability, a sense of emptiness and meaninglessness, negative expectations of oneself and the environment, low self-esteem, isolation, helplessness, diminished interest or pleasure in activities, weight loss or weight gain, insomnia or hypersomnia, fatigue or loss of energy, feelings of worthlessness, and diminished ability to think or concentrate. However, it is not unusual

for a serious depression to be masked because the teenager cannot tolerate the severe feelings of sadness. Such a teenager may present with recurrent or persistent psychosomatic complaints, such as abdominal pain, chest pain, headache, lethargy, weight loss, dizziness, syncope, or other nonspecific symptoms. Other behavioral manifestations of masked depression include truancy, running away from home, defiance of authorities, self-destructive behavior, vandalism, drug and alcohol abuse, sexual acting out, and delinquency.

► Differential Diagnosis

A complete history and physical examination, including a careful review of the patient's medical and psychosocial history, should be performed. The family history should be explored for psychiatric problems.

The teenager should be questioned about the previously listed symptoms of depression, and specifically about suicidal ideation or preoccupation with thoughts of death. The history should include an assessment of school performance, looking for signs of academic deterioration, excessive absence or cutting class, changes in work or other outside activities, and changes in the family (eg, separation, divorce, serious illness, loss of employment by a parent, a recent move to a new school, increasing quarrels or fights with parents, or the death of a close relative). The teenager may have withdrawn from friends or family or switched allegiance to a new group of friends. The physician should inquire about possible physical and sexual abuse, drug and alcohol abuse, conflicts with the police, sexual acting out, running away from home, unusually violent or rebellious behavior, or radical personality changes. Patients with vague somatic complaints or concerns about having a fatal illness may have an underlying affective disorder.

Adolescents presenting with symptoms of depression require a thorough medical evaluation to rule out any contributing or underlying medical illness. Among the medical conditions associated with affective disorders are eating disorders, organic central nervous system disorders (tumors, vascular lesions, closed head trauma, and subdural hematomas), metabolic and endocrinologic disorders (systemic lupus erythematosus, hypothyroidism, hyperthyroidism, Wilson disease, hyperparathyroidism, Cushing syndrome, Addison disease, or premenstrual syndrome), infections (infectious mononucleosis or syphilis), and mitral valve prolapse. Marijuana use, phencyclidine abuse, amphetamine withdrawal, and excessive caffeine intake can cause symptoms of depression. Common prescription and over-the-counter medications, including birth control pills, anticonvulsants, and β -blockers, may cause depressive symptoms.

Some routine laboratory studies are indicated to rule out organic disease: a complete blood count and erythrocyte sedimentation rate, urinalysis, serum electrolytes, blood urea nitrogen, serum calcium, thyroxine and thyroid-stimulating hormone (TSH), Venereal Disease Research Laboratory or rapid plasma reagin, and liver enzymes. Although metabolic

markers such as abnormal secretion of cortisol, growth hormone, and thyrotropin-releasing hormone have been useful in confirming major depression in adults, these neurobiologic markers are less reliable in adolescents.

The risk of depression appears to be greatest in families with a history of early-onset and chronic depression. Depression of early onset and bipolar illness are more likely to occur in families with a multigenerational history of depression. The lifetime risk of depressive illness in first-degree relatives of adult depressed patients is between 18% and 30%.

► Treatment

The primary care physician may be able to counsel adolescents and parents if depression is mild or is the result of an acute personal loss or frustration and if the patient is not contemplating suicide or other life-threatening behaviors. If there is evidence of a long-standing depressive disorder, suicidal thoughts, or psychotic thinking, or if the physician does not feel prepared to counsel the patient, psychological referral should be made.

Counseling involves establishing and maintaining a positive supportive relationship; following the patient at least weekly; remaining accessible to the patient at all times; encouraging the patient to express emotions openly, defining the problem, and clarifying negative feelings, thoughts, and expectations; setting realistic goals; helping to negotiate interpersonal crises; teaching assertiveness and social skills; reassessing the depression as it is expressed; and staying alert to the possibility of suicide.

Patients with bipolar disease or those with significant depression that is unresponsive to supportive counseling should be referred to a psychiatrist for evaluation and antidepressant medication. The Food and Drug Administration has issued a “black box warning” alerting providers that using antidepressants in children and adolescents may increase the risk of suicidal thoughts and behavior. Adolescents taking these medications should be monitored closely.

Simon GE: The antidepressant quandary—considering suicide risk when treating adolescent depression. *N Engl J Med* 2006;355:2722 [PMID: 17192536].

ADOLESCENT SUICIDE (SEE ALSO CHAPTER 6)

In 2004, 4316 adolescents and young adults 15–24 years committed suicide. There were 1700 suicides among those

aged 15–19 years, and 2616 among those aged 20–24 years. In the younger group, males had a suicide rate five times higher than females, and white males had the highest rate, 15.5 per 100,000. The incidence of unsuccessful suicide attempts is three times higher in females than in males. The estimated ratio of attempted suicides to actual suicides is estimated to be 100:1–50:1. Firearms account for 50% of suicide deaths in both males and females.

Mood swings are common in adolescence. Short periods of depression are common and may be accompanied by thoughts of suicide. Normal adolescent mood swings rarely interfere with sleeping, eating, or normal activities. Acute depressive reactions (transient grief responses) to the loss of a family member or friend may cause depression lasting for weeks or even months. An adolescent who is unable to work through this grief can become increasingly depressed. A teenager who is unable to keep up with schoolwork, does not participate in normal social activities, withdraws socially, has sleep and appetite disturbances, and has feelings of hopelessness and helplessness should be considered at increased risk for suicide.

Angry teenagers attempting to influence others by their actions may be suicidal. They may be only mildly depressed and may not have any long-standing wish to die. Teenagers in this group, usually females, may attempt suicide or make an impulsive suicidal gesture as a way of getting back at someone or gaining attention by frightening another person. Adolescents with serious psychiatric disease such as acute schizophrenia or psychotic depressive disorder are also at risk for suicide.

► Risk Assessment

The physician must determine the extent of the teenager's depression and the risk that he or she might inflict self-injury. Evaluation should include interviews with both the teenager and the family. The history should include the medical, social, emotional, and academic background. The physician should inquire about:

1. Common signs of depression
2. Recent events that could be the cause of an underlying depression
3. Evidence of long-standing problems in the home, at school, or with peers
4. Drug or substance use and abuse
5. Signs of psychotic thinking, such as delusions or hallucinations
6. Evidence of masked depression, such as rebellious behavior, running away from home, reckless driving, or other acting-out behavior

The physician should always ask depressed patients about thoughts of suicide, for example by asking, “Are things ever so bad that life doesn't seem worth living?” If the response is affirmative, a more specific question should be asked, for

example, “Have you thought of taking your life?” If the patient has thoughts of suicide, the immediacy of risk can be assessed by determining if the patient has a concrete, feasible plan. Although patients who are at greatest risk have a concrete plan that can be carried out in the near future, especially if they have rehearsed the plan, the physician should not dismiss the potential risk of suicide in the adolescent who does not describe a specific plan. The physician should pay attention to his or her own instincts. Subtle nonverbal signs may indicate that the patient is at greater risk than may be apparent.

▶ Treatment

The primary care physician is often in a unique position to identify an adolescent at risk for suicide, because many teenagers who attempt suicide seek medical attention in the weeks preceding the attempt. These visits are often for vague somatic complaints. If the patient shows evidence of depression, the physician must assess the severity of the depression and suicidal risk. The pediatrician should always seek emergency psychological consultation for any teenager who is severely depressed, psychotic, or acutely suicidal. It is the psychologist's or psychiatrist's responsibility to assess the seriousness of suicidal ideation and decide whether hospitalization or outpatient treatment is most appropriate. Adolescents with mild depression and low risk for suicide should be followed closely, and the extent of the depression should be assessed on an ongoing basis. If it appears that the patient is worsening or is not responding to supportive counseling, referral should be made.

SUBSTANCE ABUSE

Substance abuse is a complex problem for adolescents and the broader society. See Chapter 4 for an in-depth look at this issue.

EATING DISORDERS (SEE CHAPTER 5)

OVERWEIGHT (SEE ALSO CHAPTER 10)

Obesity is defined as body mass index (BMI) greater than the 95th percentile for age. Overweight is defined as BMI greater than the 85th percentile for age. (Growth charts are available

at the Centers for Disease Control and Prevention web site, <http://www.cdc.gov/growthcharts>; see also Chapter 2). These definitions have changed to reflect adult obesity definitions. It is important to note that mean BMI changes with age. For a 13-year-old, a BMI above 25 constitutes obesity, whereas in adolescents older than 18 years, BMI above 30 defines obesity.

▶ Background

The National Health and Nutrition Examination Survey reported an increase in overweight among adolescents aged 12–19 from 5% in 1966–1970 to 17% in 2003–2004. The changes in BMI during and after adolescence are important predictors of adult adiposity. Generally, the longer a child remains overweight, the more likely obesity will persist into adulthood. The medical risks associated with obesity are discussed in Chapter 10. The psychosocial hazards of overweight are great in adolescence, causing alienation, distorted peer relations, poor self-esteem, guilt, depression, or altered body image.

▶ Diagnosis

BMI should be recorded for all adolescents at the time of their annual physical examination. When overweight or obesity is diagnosed, additional information should be documented: blood pressure; condition of the skin, thyroid, heart, and abdomen. In patients with BMI in the 85–95% range, waist circumference at the umbilicus should be measured. Athletes with increased muscle mass may have elevated BMI but normal waist circumference, indicating that their weight may be normal for their muscular build. Acanthosis nigricans is a cutaneous finding characterized by velvety hyperpigmentation, most prominent behind the neck, in the axilla, and in the groin. Acanthosis nigricans is more common in dark-skinned persons and is a marker for insulin resistance. Endocrine causes of obesity, such as hypothyroidism and Cushing disease, can generally be excluded by the history and physical examination. If an adolescent is healthy and has no delay of growth or sexual maturation, an underlying endocrinologic, neurologic, or genetic cause is unlikely. Laboratory evaluation should include fasting lipids, glucose, and liver function tests to assess for nonalcoholic fatty liver disease.

▶ Treatment

Poorly motivated adolescents may be alienated by an aggressive discussion of weight loss. Instead, providers may give basic information about healthy diet and regular exercise and be available for future visits if patients become interested in weight loss. For the highly motivated patient, treatment should be appropriate to age and developmental level. The adolescent should be taught appropriate eating and exercise habits to maintain weight reduction yet meet nutritional needs for growth and development. Providers are more likely to engage the adolescents by helping them to choose concrete, attainable goals (decreasing soda or other sugared drinks from three to two per day, decreasing portion sizes, or moderate

exercise for 30 minutes 3 days a week). If patients are successful with these goals, they may be more likely to continue positive lifestyle changes. Appetite-suppressing drugs such as sibutramine have been used in older adolescents but are expensive and not usually covered by insurance. Bypass surgery has been used in some centers when the overweight adolescent has severe comorbidities of obesity. An age-appropriate behavior modification program incorporating dietary counseling and exercise is optimal, although a report from the U.S. Preventive Services Task Force did not find sufficient evidence that behavioral counseling is effective. In fact some studies indicate that increased activity is more important than dietary changes in long-term weight management. Lifestyle activity recommendations, such as walking and taking the stairs, may be more effective in the long run than regimented exercise programs. Avoiding labeling any food as “forbidden” improves long-term success with healthful eating behaviors. Behavioral treatment involving parents improves long-term maintenance of weight loss in children; parental involvement in adolescent weight loss programs has produced mixed results. In general, the most important factor in successful weight loss and weight maintenance is motivation. Monthly follow-up visits may help to maintain motivation, especially initially. Unfortunately, no program has been proven effective for long-term weight reduction.

SCHOOL AVOIDANCE

A teenager who has missed more than 1 week of school for a physical illness or symptom, and whose clinical picture is inconsistent with serious illness, should be suspected of having primary or secondary emotional factors that contribute to the absence. Investigation of absences may show a pattern, such as missing morning classes or missing the same days at the beginning or end of the week.

School avoidance should be suspected in children who are consistently absent in spite of parents' and professionals' attempts to encourage school attendance. Adolescents with school avoidance often have a history of excessive school absences or separation difficulties as a younger child. They may have a record of recurrent somatic complaints. Parents of a school avoider often feel helpless to compel their adolescent to attend school, may lack the sophistication to distinguish malingering from illness, or may have an underlying need to keep the teenager at home.

A complete history and physical examination should be performed, reviewing the patient's medical, educational, and psychiatric history. Signs of emotional problems should be explored. After obtaining permission from the patient and parents, the physician may find it helpful to speak directly with school officials and some key teachers. The adolescent may be having problems with particular teachers or subjects or experiencing adversity at school (eg, school-yard bullying or an intimidating instructor). Some students get so far behind academically that they see no way of catching up and feel overwhelmed. Separation anxiety, sometimes of long duration, may be manifested in subconscious worries that something may happen to the mother while the teenager is at school.

The school nurse may give useful information, including the number of visits to the nurse during the last school year. An important part of the history is how the parents respond to the absences and somatic complaints. The parent(s) may be making a subconscious attempt to keep the adolescent at home, which may be coupled with secondary gains for the patient, such as increased parental attention.

▶ Treatment

The importance of returning to school quickly after a period of avoidance needs to be emphasized. The pediatrician should facilitate this process by offering to speak with school officials to excuse missed examinations, homework, and papers. The pediatrician should speak directly with teachers who are punitive with the objective of making the transition back to school as easy as possible. The longer adolescents stay out of school, the more anxious they may become about returning and the more difficult the return becomes. If an illness or symptom becomes so severe that an adolescent cannot go to school, the patient and the parents must be informed that a visit to a medical office is necessary. The physician focuses visits on the parents as much as on the adolescent to alleviate parental guilt about sending the child to school. If the adolescent cannot stay in school, hospitalization should be recommended for in-depth medical and psychiatric evaluation. Parents should be cautioned about the possibility of relapse after school holidays, summer vacation, or an acute illness.

SCHOOL FAILURE

The amount and complexity of course work increase significantly in middle school, at about the same time as the rapid physical, social, and emotional changes of puberty. To perform well academically, young adolescents must have the

necessary cognitive capacity, study habits, concentration, motivation, interest, and emotional focus. Academic failure presenting at adolescence has a broad differential:

1. Limited intellectual abilities
2. Specific learning disabilities
3. Depression or emotional problems
4. Physical causes such as visual or hearing problems
5. Excessive school absenteeism secondary to chronic disease such as asthma or neurologic dysfunction
6. Lack of ability to concentrate
7. Attention-deficit/hyperactivity disorder
8. Lack of motivation
9. Drug and alcohol problems

Each of these causes must be explored. Evaluation requires a careful history, physical examination, and appropriate laboratory tests, as well as standardized educational and psychological testing.

▶ Treatment

Management must be individualized to address specific needs, foster strengths, and implement a feasible program. For children with specific learning disabilities, an individual prescription for regular and special education courses, teachers, and extracurricular activities is important. Counseling helps these adolescents gain coping skills, raise self-esteem, and develop socialization skills. If the patient has hyperactivity or attention-deficit disorder along with poor ability to concentrate, a trial of stimulant medication (eg, methylphenidate or dextroamphetamine) may be useful. If the teenager appears depressed or if other serious emotional problems are uncovered, psychological evaluation should be recommended.

BREAST DISORDERS

The breast examination should become part of the routine physical examination in girls as soon as breast budding occurs. The preadolescent thus comes to accept breast examination as a routine part of health care, and the procedure serves as an opportunity to offer reassurance about patient concerns. The breast examination begins with inspection of the breasts for symmetry and Tanner or sexual maturity rating (SMR) stage. Asymmetrical breast development is common in young adolescents, and is generally transient, although 25% of women may continue to have some degree of asymmetry into adulthood. Organic causes

of breast asymmetry include unilateral breast hypoplasia, amastia, absence of the pectoralis major muscle, and unilateral virginal hypertrophy (massive enlargement of the breast during puberty).

Palpation of the breasts is performed with the patient supine and the ipsilateral arm placed behind the head. The examiner palpates the breast tissue with the flat of the fingers in concentric circles from the sternum, clavicle, and axilla in to the areola. The areola should be compressed gently to check for discharge.

Instructions for breast self-examination and its purpose can be given to older adolescents during this portion of the physical examination, and the patient older than 18 years should be encouraged to begin monthly self-examination after each menstrual flow. Because the vast majority of breast lesions in teens are benign, teaching younger adolescents breast self-examination may lead to unnecessary anxiety and overconcern with normal variants.

BREAST MASSES

Most breast masses in adolescents are benign (Table 3–1). Rare malignancies of adolescent girls include hemangiosarcoma, rhabdomyosarcoma, ductal carcinoma, cystosarcoma phyllodes, and metastatic tumor.

Table 3–1. Breast masses in adolescent females.

Common
Fibroadenoma
Fibrocystic changes
Breast cysts (including retroareolar cysts)
Breast abscess or mastitis
Fat necrosis (after trauma)
Less common or rare (benign)
Lymphangioma
Hemangioma
Juvenile papillomatosis
Giant fibroadenoma
Neurofibromatosis
Nipple adenoma or keratoma
Mammary duct ectasia
Intramammary lymph node
Lipoma
Hematoma
Hamartoma
Galactocele
Rare (malignant potential)
Adenocarcinoma
Juvenile secretory carcinoma
Fibrosarcoma
Fibrous histiocytoma
Cystosarcoma phyllodes
Intraductal carcinoma
Rhabdomyosarcoma, lymphoma, neuroblastoma
Lymphosarcoma, hemangiosarcoma
Metastatic cancer

1. Fibroadenoma

Fibroadenoma accounts for about two thirds of all breast masses in adolescents. It presents as a rubbery, well-demarcated, slowly growing, nontender mass in any quadrant, but is most common in the upper outer quadrant. The natural history of fibroadenomas is growth over 6–12 months followed by stabilization. The average size is 2–3 cm in diameter. In 10–25% of cases, multiple or recurrent lesions occur.

2. Cysts

Breast cysts are generally tender and spongy, with exacerbation of symptoms premenstrually and improvement after menses. Often they are multiple. Spontaneous regression occurs over two or three menstrual cycles in about 50% of cases.

It is reasonable to follow suspected fibroadenoma or cyst in adolescents for two or three menstrual cycles. About 25% of fibroadenomas become smaller, and about 50% of cysts resolve. If a presumed fibroadenoma does not change after two to three cycles, ultrasound will differentiate a solid tumor from a cyst. Patients with solid tumors larger than 2.5 cm in diameter should be referred for fine-needle aspiration or excisional biopsy. Those with tumors less than 2.5 cm in diameter may be followed every 3–6 months, because many of these tumors will shrink or remain the same. Persistent cystic lesions may be drained by needle aspiration. Patients with suspicious lesions should be referred immediately to a breast surgeon (Table 3–2).

3. Fibrocystic Breasts

Fibrocystic breast disease sometimes occurs in older adolescents and becomes more common with age. It is characterized by cyclic tenderness and nodularity bilaterally and is believed to be influenced by the estrogen-progesterone balance. Reassuring the young woman about the benign nature of the process and emphasizing the importance of breast self-examination as she becomes an adult may be all that is needed. Support bras may provide symptomatic relief. Oral contraceptive pills (OCPs) often improve symptoms. Studies have shown no association between methylxanthines and fibrocystic breasts; however, some women report reduced symptoms when they discontinue caffeine. The efficacy of vitamins E, B₁, and A is unknown. Evening primrose oil was beneficial in 44% of patients in one study. A trial of 1000 mg three times a day for 3 months may be helpful.

4. Breast Abscess

The female with a breast abscess usually complains of unilateral breast pain, and examination reveals overlying inflammatory changes. The examination may be misleading in that the infection may extend much deeper than suspected. A palpable mass is found only late in the course. Although breast feeding is the most common cause of mastitis, trauma and eczema involving the areola are factors in teenagers. *Staphylococcus aureus* is the most common pathogen. Other

Table 3–2. Breast lesions.

Fibroadenoma	Rubbery, well demarcated, nontender, slowly growing; most commonly found in the upper outer quadrant of the breast. Usually < 5 cm.
Adenocarcinoma	Hard, nonmobile, well-circumscribed, painless mass; generally indolent clinical course; occurs also in males but less frequently.
Cystosarcoma phyllodes	Firm, rubbery mass that may suddenly enlarge; associated with skin necrosis; most often benign.
Giant juvenile fibroadenoma	Remarkable large fibroadenoma with overlying dilated superficial veins; accounts for 5–10% of fibroadenomas in adolescents; benign but requires excision to prevent breast atrophy and for cosmetic reasons.
Intraductal papilloma	A cylindrical tumor arising from the ductal epithelium; often subareolar but may be in the periphery of the breast in adolescents, with associated nipple discharge. Most are benign but require excision for cytologic diagnosis.
Fat necrosis	Localized inflammatory process in one breast; follows trauma in about half of cases. Subsequent scarring may be confused with cancer.
Virginal or juvenile hypertrophy	Massive enlargement of both breasts or, less often, one breast; attributed to end-organ hypersensitivity to normal hormonal levels just before or within a few years after menarche.
Miscellaneous	Fibroma, galactocele, hemangioma, intraductal granuloma, interstitial fibrosis, keratoma, lipoma, granular cell myoblastoma, papilloma, sclerosing adenosis.

aerobic and anaerobic organisms have also been implicated. Fluctuant abscesses should be surgically incised and drained. Fluid should be sent for culture. Oral antibiotics with appropriate coverage for methicillin-resistant *S aureus* should be given for 2–4 weeks. Ice packs for the first 24 hours and heat thereafter may relieve symptoms.

Cyclic mastodynia, fibrocystic disease, or chest wall pain may also be causes of breast pain, but no associated inflammatory signs are present in these conditions.

GALACTORRHEA

In teenagers, nipple discharge can be white, clear, red, brown, yellow, or green. Galactorrhea is most often benign; however, a careful history and workup are necessary. The most common causes of galactorrhea are medications, stimulation or irritation of the nipple, or pregnancy. Prolactinomas are the most common pathologic cause of galactorrhea in adolescents of both sexes and generally present as amenorrhea or failure of sexual maturation. Hypothyroidism is the second most common cause in adolescence but has been

Table 3-3. Medications and herbs associated with galactorrhea.

Amphetamines
Antidepressants (selective serotonin reuptake inhibitors, tricyclic antidepressants)

Metoclopramide
Muscle relaxants (eg, cyclobenzaprine)
Opiates
Rimantadine
Sumatriptan
Valproic acid

reported only in girls, usually prepubertally. Ductal ectasia, with dilation of the mammary ducts, fibrosis, and inflammation, is benign and can present with bloody or brown nipple discharge. Bloody discharge with a mass can also result from papillomatosis, which has malignant potential.

Galactorrhea may be present postpartum and after spontaneous or induced abortions. Numerous prescribed and illicit drugs are possible causes (Table 3-3). Stimulation of the intercostal nerves (following surgery or due to herpes zoster infection), stimulation of the nipples, central nervous system disorders (hypothalamic injury), or emotional distress may produce galactorrhea.

► Clinical Findings

TSH and serum prolactin levels should be determined. Elevated TSH confirms the diagnosis of hypothyroidism. Elevated prolactin and normal TSH, often accompanied by amenorrhea, in the absence of medications suggest a hypothalamic or pituitary tumor, and a magnetic resonance imaging scan is indicated. When the prolactin level is normal, uncommon causes such as adrenal, renal, or ovarian tumors should be considered. Males with a negative workup and normal puberty need to be followed intensively. Males with elevated prolactin levels require a magnetic resonance imaging scan every 12–18 months even if the galactorrhea resolves, because of the significant risk of a small pituitary adenoma that may become apparent with serial examinations.

► Treatment

Treatment depends on the underlying cause. Prolactinomas may be removed surgically or suppressed with dopamine agonists such as bromocriptine. Bromocriptine may also be beneficial to some amenorrheic females with normal serum

prolactin levels. The female with a negative workup and persistent galactorrhea may be followed with menstrual history and serum prolactin level every 6–12 months. In many cases, symptoms resolve spontaneously and no diagnosis is made. The female with an elevated serum prolactin concentration but negative prolactinoma workup may be treated with bromocriptine if her symptoms are bothersome or may be observed with a magnetic resonance imaging scan every 1–2 years for several years.

GYNECOMASTIA

Gynecomastia is a common concern of male adolescents, 60–70% of whom have transient subareolar breast tissue during SMR stages 2 and 3. Causes include testosterone-estrogen imbalance, increased serum prolactin level, and abnormal serum protein binding levels.

► Clinical Findings

In type I idiopathic gynecomastia, the adolescent has a unilateral (20% bilateral) tender, firm mass beneath the areola. Generalized breast enlargement is classified as type II. Pseudogynecomastia refers to excessive fat tissue or prominent pectoralis muscles.

► Differential Diagnosis

Gynecomastia may be drug-induced (Table 3-4). Testicular, adrenal, or pituitary tumors, Klinefelter syndrome, primary hypogonadism, thyroid or hepatic dysfunction, or malnutrition may also be associated with gynecomastia (Table 3-5). Onset of gynecomastia in late (rather than early or middle) adolescence is more likely to be indicative of organic disease.

► Treatment

If gynecomastia is idiopathic, reassurance about the common and benign nature of the process can be given. Resolution may take up to 2 years. Surgery is reserved for those with significant psychological trauma or severe breast enlargement.

luteal (days 16–28). During the follicular phase, pulsatile gonadotropin-releasing hormone from the hypothalamus stimulates anterior pituitary secretion of FSH and LH. Under the influence of FSH and LH, a dominant ovarian follicle emerges by days 5–7 of the menstrual cycle, and the other follicles become atretic. Rising estradiol levels produced by the maturing

follicle cause proliferation of the endometrium. By the midfollicular phase, FSH is beginning to decline secondary to estradiol-mediated negative feedback, whereas LH continues to rise as a result of estradiol-mediated positive feedback.

The rising LH initiates progesterone secretion and luteinization of the granulosa cells of the follicle. Progesterone in turn further stimulates LH and FSH. This leads to the LH surge, which causes the follicle to rupture and expel the oocyte.

During the luteal phase, LH and FSH gradually decline. The corpus luteum secretes progesterones. The endometrium enters the secretory phase in response to rising levels of estrogen and progesterone, with maturation 8–9 days after ovulation. If no pregnancy occurs or placental human chorionic gonadotropin is released, luteolysis begins; estrogen and progesterone levels decline; and the endometrial lining is shed as menstrual flow approximately 14 days after ovulation.

During the first 2 years after menarche, the majority of cycles are anovulatory (50–80%). Between 10% and 20% of cycles remain anovulatory for up to 5 years after menarche.

PELVIC EXAMINATION

A pelvic examination may be indicated to evaluate abdominal pain or menstrual disorders or to detect a suspected STI in the sexually active adolescent. Urine STI screening can be utilized in asymptomatic patients. The first Papanicolaou (Pap) smear should be performed within 3 years of the initiation of sexual activity or age 21 years, whichever comes first. Pap smears should be performed earlier in adolescents with a history of sexual abuse with penile penetration. The adolescent may be apprehensive about the first examination. It should not be rushed, and an explanation of the procedure and its purpose should precede it. The patient can be encouraged to relax by slow, deep breathing and by relaxation of her lower abdominal and inner thigh muscles. A young adolescent may wish to have her mother present during the examination, but the history should be taken privately. A female chaperone should be present with male examiners.

The pelvic examination begins by placing the patient in the dorsal lithotomy position after equipment and supplies are ready (Table 3-6). The examiner inspects the external genitalia, noting the pubic hair maturity rating, the size of the clitoris (2–5 mm is normal), Skene glands just inside the urethral meatus, and Bartholin glands at 4 o'clock and 8 o'clock outside the hymenal ring. In cases of alleged sexual abuse or assault, the presence of any lacerations, bruises, scarring, or synechiae about the hymen, vulva, or anus should be noted.

A vaginal speculum is then inserted at a 45-degree twist and angled 45 degrees downward. (A medium Pedersen speculum is most often used in sexually experienced patients; a narrow Huffman is used for virginal patients.) The vaginal walls are inspected for estrogen effects, inflammation, or lesions. The cervix should be dull pink. Cervical ectropion is commonly observed in adolescents; the columnar epithelium

Table 3-6. Items for pelvic exam tray.

Medium and vaginal speculums (use warm water before exam)
Gloves
Applicator sticks, sterile
Large swabs to remove excess discharge
Cervical spatulas and brushes and available PAP media or slides

Test tube (if swab is to be placed in saline and prepared elsewhere)
NaCl and KOH if provider is to perform tests
Gonorrhea test media
<i>Chlamydia</i> test media
Lubricant
Facial tissue

extends outside the cervical os onto the face of the cervix until later adolescence, when it recedes.

Specimens are obtained, including a wet preparation for leukocytes, trichomonads, and clue cells (vaginal epithelial cells stippled with adherent bacteria); potassium hydroxide preparation for yeast and whiff test; cervical swab for gonorrhea and *Chlamydia*; and endocervical and cervical samples for Pap smear testing if indicated. A cervical brush and spatula are typically used together. Pap smears should be interpreted by a cytopathologist at a laboratory using the Bethesda system of classification. Liquid-based Pap testing is often used with reflex human papillomavirus testing if the Pap result is atypical squamous cells of uncertain etiology.

The speculum is then removed, and bimanual examination is performed to assess uterine size and position, adnexal enlargement or tenderness, or cervical motion tenderness. Bimanual examination may reveal beading in the adnexa secondary to endometriosis.

MENSTRUAL DISORDERS

1. Amenorrhea

Amenorrhea is the absence of menarche when normally anticipated. Primary amenorrhea is defined as no menstrual periods or secondary sex characteristics by age 14 years or no menses in the presence of secondary sex characteristics by age 15 years. Constitutional delay is normal pubertal progression at a delayed onset or rate. Secondary amenorrhea is the absence of menses for at least three cycles after regular cycles have been present. In some instances, evaluation should begin immediately, without waiting for the specified age or duration of lapsed periods, such as in patients with suspected pregnancy, short stature with the stigmata of Turner syndrome, or an anatomic defect.

A. Evaluation for Primary Amenorrhea

Primary amenorrhea may be the result of anatomic abnormalities, chromosomal deviations, or physiologic delay (Table 3-7).

Table 3-7. Causes of amenorrhea.

Hypothalamic-pituitary axis
Hypothalamic suppression
Emotional stress
Depression
Chronic disease
Weight loss
Obesity
Severe dieting
Strenuous athletics
Drugs (post-birth control pills, phenothiazines)
Central nervous system lesion
Pituitary lesion: adenoma, prolactinoma
Craniopharyngioma, brainstem, or parasellar tumors
Head injury with hypothalamic contusion
Infiltrative process (sarcoidosis)
Vascular disease (hypothalamic vasculitis)
Congenital conditions ^a
Kallmann syndrome
Ovaries
Gonadal dysgenesis ^a
Turner syndrome (XO)
Mosaic (XX/XO)
Injury to ovary
Autoimmune disease
Infection (mumps, oophoritis)
Toxins (alkylating chemotherapeutic agents)
Irradiation
Trauma, torsion (rare)
Polycystic ovary syndrome
Ovarian failure
Premature menopause
Resistant ovary
Uterovaginal outflow tract
Müllerian dysgenesis ^a
Congenital deformity or absence of uterus, uterine tubes, or vagina
Imperforate hymen, transverse vaginal septum, vaginal agenesis, agenesis of the cervix ^a
Testicular feminization (absent uterus) ^a
Uterine lining defect
Asherman syndrome (intrauterine synechiae postcurettage or endometritis)
Tuberculosis, brucellosis
Defect in hormone synthesis or action (virilization may be present)
Adrenal hyperplasia ^a
Cushing disease
Adrenal tumor
Ovarian tumor (rare)
Drugs (steroids, ACTH)

^aIndicates condition that usually presents as primary amenorrhea. ACTH, adrenocorticotropic hormone.

The history should include whether puberty has commenced, level of exercise, nutritional intake, presence of stressors, and the age at menarche for female relatives. Adrenal androgens are largely responsible for axillary and pubic hair; estrogen is responsible for breast development, maturation of the external genitalia, vagina, and uterus, and menstruation.

A careful physical examination should be done, noting the percentage of ideal body weight for height and age, SMR stage, vaginal patency, presence of the uterus (assessed through rectoabdominal examination or ultrasonography if pelvic examination is not appropriate), signs of virilization (acne, clitoromegaly of > 5 mm, or hirsutism), or stigmata of Turner syndrome (< 152 cm tall, shieldlike chest, widely spaced nipples, increased carrying angle of the arms, and webbed neck). If pelvic examination reveals normal female external genitalia and pelvic organs, the patient should be given a challenge of medroxyprogesterone, 10 mg orally twice daily for 5 days (or 10 mg/d for 7–10 days) (Figure 3–5). If withdrawal bleeding occurs within 7 days after administration of medroxyprogesterone, normal anatomy and adequate estrogen effect are implied. If physical examination reveals an absent uterus (Figure 3–6), karyotyping should be performed to differentiate testicular feminization from müllerian duct defect, because these two entities are managed differently.

Laboratory studies should include complete blood count, erythrocyte sedimentation rate, and TSH. If systemic illness is suspected, a urinalysis and a chemistry panel (including renal and liver function tests) should be obtained. If short stature is present, a bone age should be done. If the diagnosis remains unclear after preliminary evaluation, or if no withdrawal bleeding occurs after a medroxyprogesterone challenge, FSH, LH, and prolactin levels should be obtained. Low levels of gonadotropins indicate a more severe hypothalamic suppression, caused by anorexia nervosa, chronic disease, or a central nervous system tumor. Involvement of a gynecologist or endocrinologist is helpful at this point. If gonadotropin levels are high, ovarian failure or gonadal dysgenesis is implied, and a karyotype should be obtained.

B. Evaluation and Treatment of Secondary Amenorrhea

Secondary amenorrhea results when estrogen stimulation is unopposed, maintaining the endometrium in the proliferative phase. The most common causes are pregnancy, stress, and polycystic ovary syndrome (PCOS). Ovarian failure can also present as secondary amenorrhea, caused by mosaic Turner syndrome or autoimmune oophoritis.

The history should focus on issues of stress, chronic illness, drugs, weight change, strenuous exercise, sexual activity, and contraceptive use. A review of systems should include questions about headaches, visual changes, hirsutism, constipation, cold intolerance, and galactorrhea.

Physical examination should include ophthalmoscopic and visual field examination, palpation of the thyroid, determination of blood pressure and heart rate, compression of the areola to check for galactorrhea, and a search for signs of androgen excess (eg, hirsutism, clitoromegaly, severe acne, or ovarian enlargement).

The first laboratory study obtained is a pregnancy test, even if the patient denies sexual activity. If the teenager is not

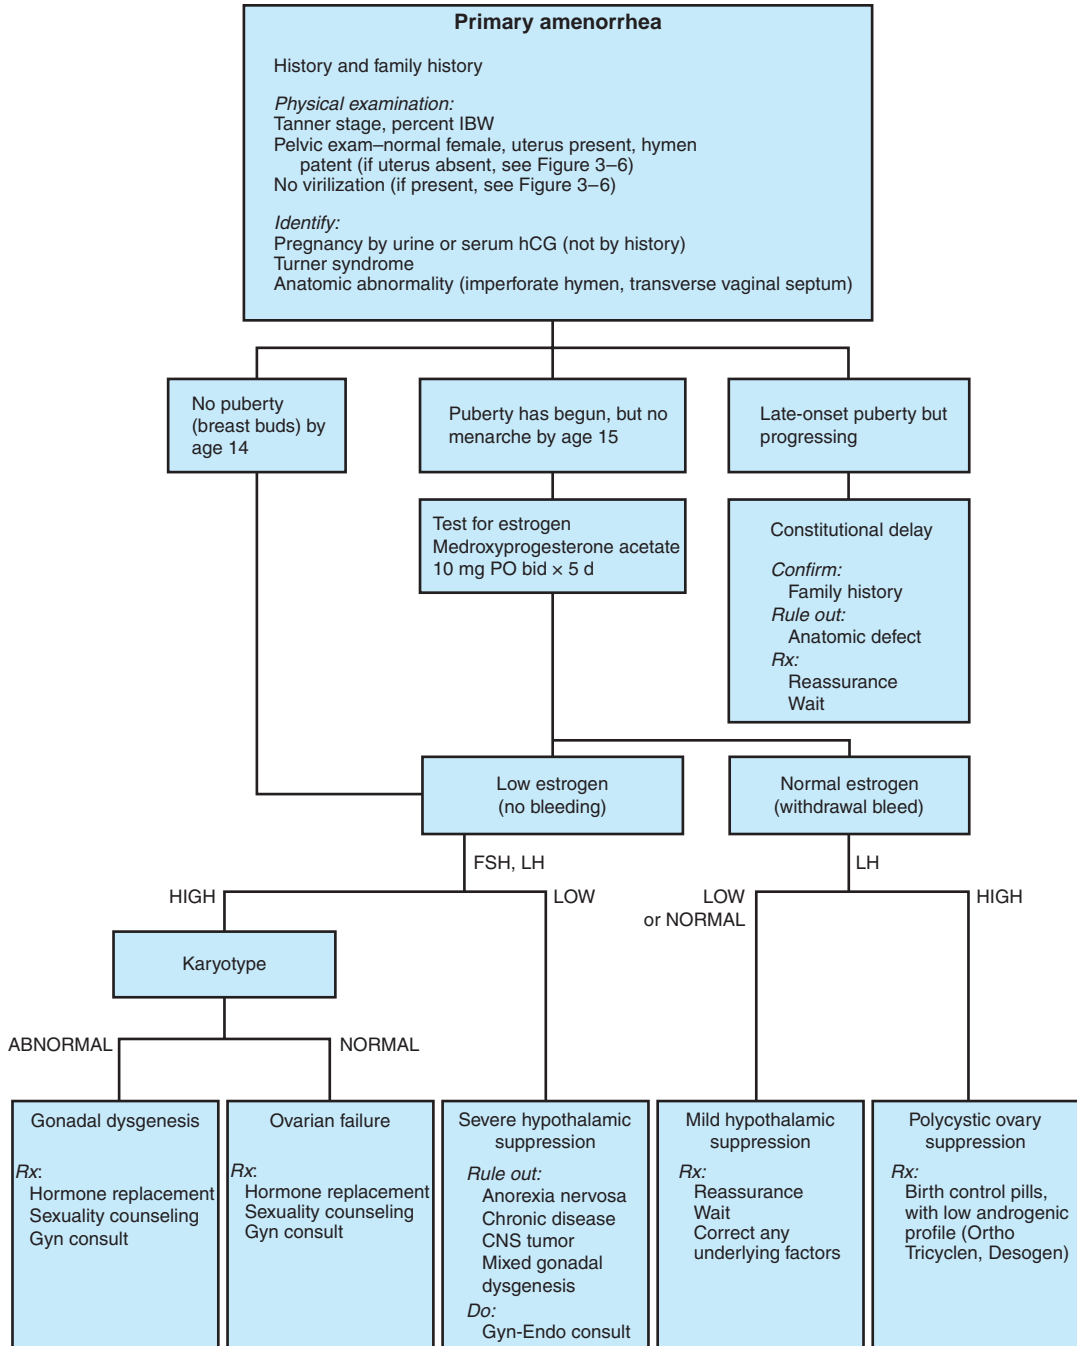

pregnant, a progesterone challenge (medroxyprogesterone, 10 mg orally bid for 5 days or 10 mg/d for 7–10 days) should be done to determine whether the uterus is primed with estrogen (Figure 3–7).

Most patients who have withdrawal flow after progesterone challenge have mild hypothalamic suppression due to weight change, athletics, stress, or illness; however, disorders such as PCOS, adrenal disorders, ovarian tumors, thyroid disease, and diabetes mellitus should be excluded by history and physical examination and appropriate laboratory studies. (See Primary Amenorrhea, earlier, and Figure 3–6.)

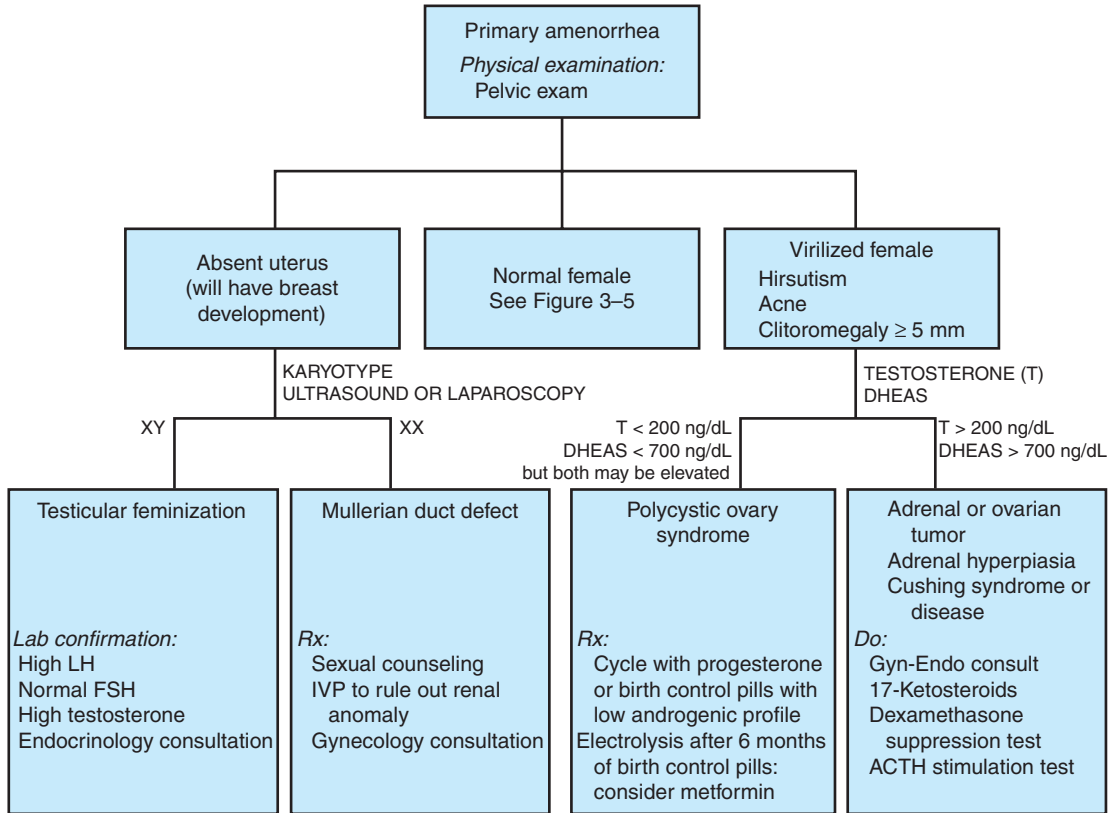

If withdrawal flow occurs after the progesterone challenge (see Figure 3–5), but the adolescent continues to have problems with amenorrhea, serum levels of estradiol, FSH, LH, and prolactin should be checked. An elevated FSH level accompanied by a low estrogen level implies ovarian failure, in which case blood for karyotype and antiovarian antibodies (if the karyotype is normal) should be obtained and laparoscopy considered. If gonadotropin levels are low or normal and the estradiol level is low, hypothalamic amenorrhea is likely; however, one must consider the possibilities of a central nervous system tumor (prolactinoma or craniopharyngioma), pituitary infarction from postpartum hemorrhage or sickle cell anemia, uterine synechiae, or chronic disease. Further evaluation may be necessary.

If signs of virilization are present (see Figure 3–6), determining levels of free testosterone, 17-hydroxyprogesterone, and dehydroepiandrosterone sulfate will help to distinguish PCOS from adrenal causes of virilization and amenorrhea. Although elevation of testosterone and dehydroepiandrosterone sulfate may occur in patients with PCOS, the elevation is not as dramatic as with androgen-producing adrenal or ovarian tumors, adrenal hyperplasia, or Cushing syndrome. Endocrinologic consultation will assist in differentiating the cause of significantly elevated androgens.

PCOS is a spectrum of disorders accompanied by symptoms of obesity, insulin resistance, hirsutism, acne, oligomenorrhea, and infertility. PCOS is very common, with a prevalence estimated at 5–10%. Although a classic LH:FSH ratio of more than 2.5:1 is described in PCOS, up to 40% of patients do not have elevated LH levels. Because of insufficient FSH, androstenedione cannot be converted to estradiol in the ovarian follicle, and anovulation and production of excess androgens result. OCPs containing a low androgenic progestin (desogestrel or norgestimate) help to regulate menses and improve acne and hirsutism. Patients who do not wish to take an OCP can be given progesterone (10 mg daily) for the first 10 days of each month to allow withdrawal flow; however, this treatment does not suppress ovarian androgen production. Hirsute patients should have a lipid profile checked, because PCOS patients have an increased risk of dyslipidemias. OCPs may reduce terminal hair growth, but antiandrogens such as spironolactone reduce the growth and diameter of terminal hair and may be useful for more severe hirsutism. Weight loss in obese patients helps to suppress ovarian androgen production. Insulin-sensitizing medications,

▲ **Figure 3-5.** Evaluation of primary amenorrhea in a normal female. CNS, central nervous system; FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; IBW, ideal body weight; LH, luteinizing hormone.

such as metformin, have been shown to improve menstrual regularities in adolescents with PCOS.

2. Dysmenorrhea

Dysmenorrhea is the most common gynecologic complaint of adolescent girls, with an incidence of about 80% by age 18 years. Yet many teenage girls do not seek help from a physician, relying instead on female relatives, friends, and the media for advice. Therefore, the physician should ask about menstrual cramps when taking a review of systems.

Dysmenorrhea can be divided into primary and secondary dysmenorrhea on the basis of whether underlying pelvic disease exists (Table 3-8). Primary dysmenorrhea accounts for 80% of cases of adolescent dysmenorrhea and most often affects women younger than age 25 years.

Pelvic examination is normal in females with primary dysmenorrhea. The pelvic examination has diagnostic benefits and provides an opportunity to educate and reassure the patient about her normal reproductive function. However, if the patient has never been sexually active and the history is consis-

tent with primary dysmenorrhea, a trial of a nonsteroidal anti-inflammatory drug is justified. Patients should be instructed to begin nonsteroidal anti-inflammatory drugs at the first sign of menses or dysmenorrhea and continue them for 2-3 days. Recommended doses are ibuprofen, 400-800 mg every 6 hours, or naproxen, 220-550 mg twice a day. If the patient does not respond to nonsteroidal anti-inflammatory drugs, OCPs are an effective treatment for primary dysmenorrhea. If patients do not respond to either of these treatments, secondary dysmenorrhea is more likely and a pelvic examination is indicated.

Secondary dysmenorrhea is menstrual pain due to an underlying pelvic lesion (see Table 3-8). Although uncommon in adolescents, when present it is most often due to infection or endometriosis. In one study of adolescent females with chronic pelvic pain, more than 40% who had not received a definitive diagnosis by the third visit were found to have endometriosis.

The clinician evaluating a patient with secondary dysmenorrhea should take a sexual history and conduct a pelvic examination even if the patient is not sexually active. Testing for gonorrhea and *Chlamydia*, a complete blood count and

▲ **Figure 3-7.** Evaluation of secondary amenorrhea. CBC, complete blood count; CT, computed tomography; DHEAS, dehydroepiandrosterone sulfate; FSH, follicle-stimulating hormone; LH, luteinizing hormone; MRI, magnetic resonance imaging scan; 17-OH-P, 17-hydroxyprogesterone; T_4 , thyroxine.

erythrocyte sedimentation rate, and a pregnancy test should be done. Gynecologic consultation is indicated to look for endometriosis or congenital problems by ultrasonography or laparoscopy. Treatment depends on the cause (see Table 3-8).

3. Dysfunctional Uterine Bleeding

Dysfunctional uterine bleeding may consist of menorrhagia (normal intervals with excessive flow) or metrorrhagia (irregular intervals with excessive flow). It results when an endometrium that has proliferated under unopposed estro-

gen stimulation finally begins to slough, but does so incompletely, causing irregular, painless bleeding. The unopposed estrogen stimulation occurs during anovulatory cycles, common in younger adolescents who have not been menstruating for long. Anovulation may also occur in older adolescents during times of stress or illness (Figure 3-8).

► Clinical Findings

Typically, the adolescent has had several years of regular cycles and then begins to have menses every 2 weeks, or

Table 3–8. Dysmenorrhea in the adolescent.

	Etiology	Onset and Duration	Symptoms	Pelvic Exam	Treatment
Primary Dysmenorrhea^a					
Primary	Excessive amount of prostaglandin F _{2α} , which attaches to myometrium, causing uterine contractions, hypoxia, and ischemia. Also, directly sensitizes pain receptors.	Begins with onset of flow or just prior and lasts 1–2 d. Does not start until 6–18 mo after menarche, when cycles become ovulatory.	Lower abdominal cramps radiating to lower back and thighs. Associated nausea, vomiting, diarrhea, and urinary frequency also due to excess prostaglandins.	Normal. May wait to examine if never sexually active and history is consistent with primary dysmenorrhea.	Mild—heating pad, warm baths, NSAIDs. Moderate to severe—NSAIDs at onset of flow or pain. Consider OCPs.
Secondary Dysmenorrhea^b					
Infection	Most often due to an STI such as chlamydia or gonorrhea.	Recent onset of pelvic cramps.	Pelvic cramps, excessive bleeding, intermenstrual spotting or vaginal discharge.	Mucopurulent or purulent discharge from cervical os, cervical friability, cervical motion tenderness, adnexal tenderness, positive test for STI.	Appropriate antibiotics.
Endometriosis	Aberrant implants of endometrial tissue in pelvis or abdomen; may result from reflux.	Generally starts more than 2 y after menarche.	Pelvic pain, may occur intermenstrually.	Two thirds are tender on exam, especially during late luteal phase.	Hormonal suppression by OCPs, DMPA or danazol. Surgery may be necessary for extensive disease.
Complication of pregnancy	Spontaneous abortion, ectopic pregnancy.	Acute onset.	Pelvic cramps associated with a delay in menses.	Positive hCG, enlarged uterus or adnexal mass.	Immediate gynecologic consult.
Congenital anomalies	Transverse vaginal septum, septate uterus, or cervical stenosis.	Onset at menarche.	Pelvic cramps.	Underlying congenital anomaly may be apparent. May require exam under anesthesia.	Gynecologic consult for ultrasound, hysteroscopy, or laparoscopy.
IUD	Increased uterine contractions, or increased risk for pelvic infection.	Onset after placement of IUD or acutely if due to infection.	Pelvic cramps, heavy menstrual bleeding, may have vaginal discharge.	Normal, or see infection above.	NSAIDs or mefenamic acid may be drug of choice because they also reduce flow. Appropriate antibiotics and consider removal of IUD if infection is present.
Pelvic adhesions	Previous abdominal surgery or pelvic inflammatory disease.	Delayed onset after surgery or PID.	Abdominal pain, may or may not be associated with menstrual cycles; possible alteration in bowel pattern.	Variable.	Surgery. Consider a trial of tricyclic antidepressants.

^aNo pelvic pathology.

^bUnderlying pathology present. (Always perform pelvic exam if secondary dysmenorrhea suspected or patient is sexually active. Tests for *Chlamydia* and gonorrhea, complete blood test, and erythrocyte sedimentation rate should be obtained.)

complains of bleeding for 2–3 weeks after 2–3 months of amenorrhea. A history of painless, irregular periods at intervals of less than 3 weeks may also be elicited. Bleeding for

more than 10 days should be considered abnormal. Dysfunctional uterine bleeding must be considered a diagnosis of exclusion (Table 3–9).

▶ Treatment

A pregnancy test and pelvic examination with appropriate tests for sexually transmitted infections should be performed in sexually active patients. A complete blood count, including a platelet count, should be obtained. The history and physical findings may suggest the need for additional coagulation or hormonal studies. Coagulation studies should be done if the patient presents with severe anemia, especially within 1 year after menarche. Management depends on the severity of the problem (Table 3-10). It is important to treat for a minimum of 3–4 months to progressively reduce the endometrium to baseline thickness.

4. Mittelschmerz

Mittelschmerz is midcycle pain caused by irritation of the peritoneum due to spillage of fluid from the ruptured follicular cyst at the time of ovulation. The patient presents with a history of midcycle, unilateral dull or aching abdominal pain lasting a few minutes to as long as 8 hours. This pain rarely mimics the abdominal findings of acute appendicitis, torsion or rupture of an ovarian cyst, or ectopic pregnancy. The patient should be reassured and treated symptomatically. If the findings are severe enough to warrant consideration of the previously mentioned diagnoses, laparoscopy may be done.

5. Premenstrual Syndrome

Premenstrual syndrome (PMS) is a cluster of physical and psychological symptoms temporally related to the luteal phase of the menstrual cycle and alleviated by the onset of menses. PMS should be distinguished from major depression, idiopathic cyclic edema, fibromyalgia, chronic fatigue syndrome, and psychosomatic disorders. This may be difficult because of the diversity of symptoms ascribed to PMS and the variability from month to month in the same patient. Premenstrual behavioral symptoms include emotional lability, anxiety, depression, irritability, impulsivity, hostility, and impaired social function. Physical symptoms include bloating, breast tenderness, fatigue, and appetite changes. Previously thought to be a disorder limited to adult women, studies indicate that adolescents also experience premenstrual symptoms. Although several causes have been proposed (progesterone deficiency, hyperprolactinemia, estrogen excess or imbalance of the estrogen-progesterone ratio, vitamin B₁₂ deficiency, fluid retention, low levels of endorphins and prostaglandins, hypoglycemia, and psychosomatic factors), none has been proved. Hormones may play a role; women who have undergone hysterectomy but not oophorectomy may have cyclic symptoms resembling PMS, whereas postmenopausal women have no such symptoms.

Several treatments have been advocated but are without consistent benefits. OCPs or nonsteroidal anti-inflammatory drugs may be beneficial for some women. Sertraline (50–100 mg) has been shown to be significantly better than placebo for treatment of premenstrual dysphoria.

6. Ovarian Cysts

Functional cysts account for 20–50% of ovarian tumors in adolescents and are a result of the normal physiologic process of ovulation. They may be asymptomatic or may cause menstrual irregularity, constipation, or urinary frequency. Functional cysts, unless large, rarely cause abdominal pain; however, torsion or hemorrhage of an ovarian cyst may present as an acute abdomen. Follicular cysts account for the majority of ovarian cysts. They are produced every cycle but occasionally are not resorbed. Follicular cysts are unilateral, usually not larger than 4 cm in diameter, and resolve spontaneously. If the patient is asymptomatic, she can be reexamined monthly. The patient should be referred to a gynecologist for laparoscopy if she is premenarcheal, if the cyst has a solid component or is larger than 5 cm by ultrasonography, if she has symptoms or signs suggestive of hemorrhage or torsion, or if the cyst fails to regress within 2 months. Luteal cysts occur less commonly and may be 5–10 cm in diameter. The patient may have associated amenorrhea, or as the cyst becomes atretic, heavy vaginal bleeding. The patient may be monitored for 3 months but should have a laparoscopy if the cyst is larger than 5 cm, does not resolve within 2 months, or if there is pain or bleeding from the cyst.

Table 3-10. Management of dysfunctional uterine bleeding.^a

	Mild	Moderate	Severe
Hemoglobin (Hgb) value	Hgb > 12 g/dL	Hgb 9–12 g/dL	Hgb < 9 g/dL (or dropping); orthostatic symptoms and signs
Acute treatment	Menstrual calendar; iron supplementation. NSAID with menses may help reduce flow. Consider OCPs if patient is sexually active and desires contraception.	Monophasic OCPs, up to four pills per day, and taper over 2–3 wk; may need antiemetic. Bleeding should stop in a few days. Begin tapering dose 2–3 d after bleeding stops. Expect withdrawal flow a few days after last dose.	Fluids, blood transfusion as needed, admit to hospital if Hgb < 7 g/dL or patient is hemodynamically unstable. For hemostasis, consider: conjugated estrogens, 25 mg IV every 4–6 h for 24 h or until bleeding stops. Provide antiemetic medication. Then, OCPs: 4 pills/d for 4 d 3 pills/d for 4 d 2 pills/d for 17 d withdrawal bleeding for 7 d ^b
Long-term management	Monitor menstrual calendar and Hgb. Follow-up in 2–3 mo.	Cycle with either: (1) Provera, ^c 10 mg PO daily for 10 d starting on day 14 of each cycle for 3–6 mo, or (2) OCPs for 3–6 mo beginning the Sunday after withdrawal bleeding starts. Provide iron supplementation. Monitor Hgb. Follow-up within 2–3 wk and every 3 mo.	Next: OCPs cycle (using 28-d packs) for 3 mo. Begin the Sunday after withdrawal bleeding begins. Length of use depends on resolution of anemia. Monitor Hgb. Follow-up within 2–3 wk and every 3 mo.

^aDiagnosis: Prolonged (> 8 d) painless menses; heavy flow (> 6 tampons/pads per day); short cycles (< 21 d); no cause found.

^bThis schedule will use three 21-d packages.

^cProvera = medroxyprogesterone acetate.

CONTRACEPTION

According to the Youth Risk Behavior Survey of high school students in 2005, 46.8% have had sexual intercourse; 62.8% reported they used a condom at last intercourse. According to the 2002 National Survey of Family Growth, teens were more likely to use contraception when they began having intercourse; 79% in 1999–2002, up from 61% in the 1980s. Teens were also more likely to have used contraception at their most recent intercourse in 2002 (83% in 2002 compared with 71% in 1995). Still, many adolescent pregnancies occur within the first 6 months of initiation of sexual activity. Adolescents often delay seeing a clinician for prescription contraceptives after initiating sexual activity.

Abstinence & Decision Making

Many adolescents have given little thought to their developing sexuality or how they will handle sexual situations. Talking with teenagers about sexual intercourse and its implications, and alternatives to intercourse, can help teens

make informed decisions before they find themselves with an unplanned pregnancy or an STI.

If an adolescent chooses to remain abstinent, the clinician should reinforce that decision. Encouraging adolescents to use contraception when they do engage in sexual intercourse does not lead to higher rates of sexual activity. Another approach to decreasing teen pregnancy is to educate adolescent males on the importance of hormonal contraception and emergency contraception for their partners, in addition to condom use. The teen pregnancy, birth, and abortion rates are higher in the United States than in any other developed country, despite similar rates of sexual experience.

Emergency Contraception

A discussion of emergency contraception (EC), which could potentially prevent 50–90% of unintended pregnancies and elective abortions, should be part of anticipatory guidance given to both female and male teenagers. Indications for EC include unprotected intercourse within the past 120 hours (5 days), condom breakage, more than two missed OCPs, or more than 14 weeks since the last depot medroxyprogesterone acetate (DMPA) injection. The pregnancy rate after EC is 1.8%, compared with 6.8% without such intervention. (See Table 3–11 for dosages.) EC works best within 24 hours of intercourse but can be taken up to 120 hours afterward. It

Table 3–11. Emergency postcoital contraception regimens.

Pill	Dosage	Each Dose Achieves:
Plan B ^a	Two tablets orally	Levonorgestrel, 1.5 mg
Nordette ^b	Four tablets orally and repeat in 12 h	Levonorgestrel, 0.6 mg
Lo-Ovral ^b	Four tablets orally and repeat in 12 h	Norgestrel, 1.2 mg
Alesse ^b	Five pink pills orally and repeat in 12 h	Levonorgestrel, 0.5 mg
Triphasil ^b	Four yellow pills orally and repeat in 12 h	Levonorgestrel, 0.5 mg

^aBoth doses can be given at the same time.

^bAn antiemetic drug taken 30 minutes before the dose may help reduce nausea.

should be verified that other instances of unprotected intercourse beyond 120 hours have not occurred. The only contraindication to the use of EC is pregnancy. Plan B is a progestin-only method that causes significantly less nausea and vomiting than combined estrogen-progesterone methods. It is available over the counter for patients older than age 18. The two pills can be given at the same time if there is a single episode of unprotected intercourse; patients with multiple episodes of unprotected intercourse should receive the doses 12 hours apart. If this method is not available, certain combined OCPs can be used for EC. It is important to note that some progestin-containing contraceptives are *not* approved for EC. A follow-up appointment should be held in 2–3 weeks, to test for pregnancy if menses have not occurred, to screen for STIs if indicated, and to counsel regarding contraceptive use.

Condoms & Spermicides

Condoms have been used more widely in the last several decades as a result of educational and marketing efforts driven by the AIDS epidemic. Regardless of whether another method is used, all sexually active adolescents should be counseled to use condoms. Condoms offer protection against STIs by decreasing (but not eliminating) the transmission of gonorrhea, *Chlamydia*, syphilis, herpes simplex, hepatitis, and HIV. Spermicides containing nonoxynol-9 are no longer recommended, as evidence suggests that repeated use of spermicide increases transmission of HIV. Aside from the diaphragm and cervical cap, barrier methods do not require a medical visit or prescription and are widely available. The polyurethane vaginal pouch, or female condom, is also available. Although it has pregnancy and STI prevention properties similar to those of the male condom, its higher cost and greater difficulty of insertion make it less appealing to adolescents.

Oral & Cutaneous Contraceptives

OCPs have a three-pronged mechanism of action: (1) suppression of ovulation; (2) thickening of the cervical mucus, thereby making sperm penetration more difficult; and (3) atrophy of the endometrium, which diminishes the chance of implantation. The latter two actions are progestin effects.

Combination OCPs contain both estrogen and progestin. Ethinyl estradiol is the estrogen currently used in nearly all OCPs in the United States. A number of progestins are used in OCPs and differ in their estrogenic, antiestrogenic, and androgenic effects. As estrogen doses decreased in OCPs, the androgenic side effects of progestins became more apparent, leading to the development of two progestins (desogestrel and norgestimate) with lower androgenic potential. All of the lower androgenic pills improve acne and may especially benefit patients with polycystic ovary syndrome. Reports of increased risk of thromboembolism associated with the newer progestins are likely related to an excess of first-time users among desogestrel patients. Factor V Leiden has been identified as a risk factor for venous thrombosis; 5% of patients of European ancestry are carriers of factor V Leiden. Carriers have a 30- to 50-fold increased risk for thrombosis. Testing family members with a history of venous thrombosis for factor V Leiden and other conditions such as the prothrombin gene mutation, proteins C and S, and antithrombin III before prescribing estrogen-containing OCPs to the adolescent may prevent these complications. OCPs have many noncontraceptive benefits, including improvement of dysmenorrhea, menorrhagia, acne, and PMS; suppression of ovarian and breast cysts; and lower risk of anemia, pelvic inflammatory disease, and ectopic pregnancy. A pill containing 30–35 mg of ethinyl estradiol with norgestimate, desogestrel, or 0.5 mg norethindrone is recommended for most adolescents beginning OCPs.

Ortho Evra is a combined estrogen-progesterone patch, which is worn 3 weeks out of every 4. It releases 150 mcg of norelgestromin and 20 mcg of ethinyl estradiol per day. Side effects are similar to those of combined OCPs. Reports of increased thrombotic events reinforce the importance of screening patients for risk factors for thrombosis (personal or family history of thrombosis) prior to prescription of the patch. Five percent of patients report having a patch come off. Two percent report skin irritation. Efficacy may be reduced in patients weighing more than 200 pounds. The patch is an attractive alternative to OCPs for adolescents who have difficulty remembering to take a pill every day, as compliance is increased. The failure rate for the patch is reported to be 1%.

Progestin-only pills contain no estrogen. Their chief use is in women who experience unacceptable estrogen-related side effects with combination OCPs or who have a contraindication to estrogen-containing pills. Their lack of estrogen, however, is also responsible for the main side effect, less predictable menstrual patterns. For this reason, progestin-only pills are not often desirable for adolescents. Their mechanism of action relies on the progestin-mediated actions, and ovulation is suppressed in only 15–40% of cycles.

A. Indications and Contraindications

Combined OCPs may be the method of choice for sexually active adolescents who frequently have unplanned intercourse; however, the patient must be able to comply with a daily dosing regimen. Most states allow OCPs to be prescribed to minors confidentially. Ideally, it is best to wait until 6–12 regular menstrual cycles have occurred before beginning hormonal contraception; however, if the teenager is already sexually active, the medical and social risks of pregnancy outweigh the risks of hormonal contraception.

OCPs or the contraceptive patch may also be used to treat dysmenorrhea, menorrhagia, dysfunctional uterine bleeding, and acne (see previous discussion).

Contraindications to combined OCPs or the contraceptive patch can be categorized as absolute and relative (Table 3–12). When use of estrogenic agents is contraindicated, progestin-only pills and DMPA are alternatives.

B. Beginning Oral Contraceptive Pills or the Contraceptive Patch and Follow-up

Before a patient begins taking OCPs or the patch, a careful menstrual history, medical history, and family medical history should be taken. In addition, baseline weight and blood pressure should be established. If time constraints are present and a patient has no symptoms suggesting an STI, OCPs or the patch may be started and a follow-up appointment for STI screening can be scheduled as soon as possible.

If the teen has no contraindications (see Table 3–12), she may begin her first pack of pills or the patch with her next menstrual period (either the first Sunday after flow begins or

Table 3–12. Contraindications to combined birth control pills.

Absolute contraindications
Pregnancy
Lactation (first 6 wk postpartum to allow milk supply to become established)
History of thrombophlebitis, thromboembolic disorder, cerebrovascular disease, or ischemic heart disease
Structural heart disease with endocarditis, atrial fibrillation, or pulmonary hypertension
Breast cancer
Migraine headaches with neurologic changes (numbness or unilateral weakness)
History of active liver disease or tumor
Hypertension SBP > 160 mm Hg or DBP > 100 mm Hg
Prolonged immobilization after surgery on legs or pelvis
Relative contraindications
First 3 wk postpartum due to increased risk of thromboembolism
Lactation (6 wk–6 mo)
Active gallbladder disease
Use of drugs that affect liver enzymes (rifampin, griseofulvin, phenytoin, carbamazepine, barbiturates)

DBP, diastolic blood pressure; SBP, systolic blood pressure.

Dysmenorrhea
Irregular cycles
Functional ovarian cysts
Premenstrual syndrome
Acne
Mounting evidence
Improved bone density

the first day of flow, depending on the brand). An alternate approach, termed “quick start,” allows adolescents to begin their contraception on the day of the appointment. This approach may lead to increased adherence with the method of choice. A low-dose monophasic combined oral contraceptive or a triphasic pill of low androgenic profile is used for those without contraindications to use of estrogen. The patient should be instructed on the use of her pills and on the possible risks and side effects and their warning signs. In addition, the patient should be advised to use condoms at every intercourse to prevent STIs. A follow-up visit every 3 months for the first year may improve adherence, because teenagers often discontinue birth control pills because of nonmedical reasons or minor side effects. Teenagers may need reassurance about the safety of birth control pills and their added benefits (Table 3–13).

C. Management of Side Effects

A different type of combined oral contraceptive should be tried if a patient has a persistent minor side effect for more than the first 2–3 months. Adjustments should be made on the basis of hormonal effects desired (Table 3–14). Changes are most often made for persistent breakthrough bleeding not related to missed pills.

Injectable Hormonal Contraceptives

The depot form of medroxyprogesterone acetate (DMPA), or Depo-Provera, is a long-acting injectable progestational contraceptive. It is given as a deep intramuscular injection of 150 mg into the gluteal or deltoid muscle every 13 weeks. The first injection should be given within the first 5 days of the menstrual cycle to ensure immediate contraceptive protection. The quick-start method may also be used with DMPA. Adolescents who have been sexually active within the previous 2 weeks should be informed of the chance of pregnancy and instructed

Table 3-14. Estrogenic, progestogenic, and androgenic effects of oral contraceptive pills.

Estrogenic Effects	Progestogenic Effects	Androgenic Effects
Nausea	Breast tenderness	Decreased production of testosterone, improved acne, less oily skin, and improved hirsutism. The progestin component may have androgenic as well as progestational effects:
Increased breast size (ductal and fatty tissue)	Headaches	Increased appetite and weight gain
Cyclic weight gain due to fluid retention	Hypertension	Depression, fatigue
Leukorrhea	Myocardial infarction (rare)	Decreased libido
Cervical eversion or ectopy		Increased breast tenderness or breast size
Hypertension		Increased LDL cholesterol levels
Telangiectasia		Decreased HDL cholesterol levels
Thromboembolic complications, including pulmonary emboli (rare), deep venous thrombosis, cerebrovascular accident, or myocardial infarction (rare)		Decreased carbohydrate tolerance; increased insulin resistance Pruritus

HDL, high density lipoprotein; LDL, low-density lipoprotein.

Adapted, with permission, from Hatcher RA et al: *Contraceptive Technology*, 17th ed. Ardent Media, 1998.

to return for a repeat pregnancy test 2 weeks after initiating DMPA. DMPA works chiefly by blocking the LH surge, thereby suppressing ovulation, but it also thickens cervical mucus and alters the endometrium to inhibit implantation. With a failure rate of less than 0.3%, minimal compliance issues, long-acting nature, reversibility, lack of interference with intercourse, and lack of estrogen-related side effects, it may be an attractive contraceptive for many adolescents. Patients should be warned about unpredictable menstrual patterns, the possibility of weight gain or mood changes, and the potential for decreased bone density. The Food and Drug Administration has issued a black box warning about decreased bone density with DMPA. Whether this decrease in bone density is reversible remains under investigation. Current recommendations are for adolescents to consider another method of contraception after 2 years of DMPA. Providers must take into consideration the risk of pregnancy, including deleterious effects on bone density with pregnancy. DMPA may reduce intravascular sickling and increase hemoglobin and red cell survival in patients with sickle cell disease. Moreover, DMPA may be the preferred method for patients with seizure disorders, because it has been found to reduce the number of seizures in some patients. DMPA may also be helpful for adolescents with von Willebrand disease, since amenorrhea (which decreases blood loss) is a common effect of DMPA. Studies have shown no increased risk of liver cancer, breast cancer, or invasive squamous cell cervical cancer among users of DMPA, and the risk of endometrial and ovarian cancers is also reduced.

Implantable Contraceptive Methods

Implanon is a single implant, effective for 3 years. It contains etonogestrel. It has a failure rate approaching 0%. Side effects include irregular bleeding, headache, nausea, breast

pain, and depression. Return to fertility is rapid following removal. Insertion and removal are reportedly significantly easier than with Norplant. The implantable contraceptives do not lead to decreased bone density, likely due to lower levels of progestins. Providers must complete formal training in order to be able to insert Implanon.

Contraceptive Vaginal Ring

The NuvaRing is a vaginal ring that releases 15 mcg of ethinyl estradiol and 120 mcg of etonogestrel per day. The ring is placed inside the vagina for 3 weeks, followed by 1 week without the ring to allow for withdrawal bleeding. A new ring is inserted each month. The failure rate is 1%. Side effects include vaginitis in 5%, headache in 6%, and foreign body sensation in 2.5%. The vaginal ring is easier to insert correctly than the diaphragm. However, like the diaphragm, adolescents are often reluctant to use contraception requiring insertion into the vagina.

Contraceptive Methods Not Usually Recommended for Teenagers

Adolescents should understand the menstrual cycle and be taught that ovulation typically occurs 2 weeks before the next menstrual period and may be difficult to predict. Because teenagers frequently have irregular cycles, the rhythm, or calendar, method is not effective. Adolescents also need to be taught that withdrawal is not a reliable method of contraception. Diaphragms and cervical caps require professional fitting and skill with insertion and are not popular among teenagers. Adolescents who have never been pregnant or who engage in behaviors that carry a risk of STIs should not use an intrauterine device.

PREGNANCY

Approximately 750,000 adolescents younger than age 19 become pregnant every year. The birth rate fell to 40.4 births per 1000 females 15–19 years of age in 2005. The decline in the birth rate for younger teens, 15–17 years of age, fell to 21.4 births per 1000 females in 2005, dropping 45% since 1991.

Abortions in adolescents have also decreased over the past decade, down to 215,000 in 2002. Despite decreasing rates, the United States still has the highest adolescent pregnancy rate of any developed country. Lower socioeconomic status and lower maternal education are risk factors for teen pregnancy regardless of racial or ethnic group.

Presentation

Adolescents report delayed or missed menses or may request a pregnancy test, but often they present with an unrelated concern. The level of denial is high. The complaint may be abdominal pain, urinary frequency, dizziness, or other nonspecific symptoms, and the adolescent may not have considered the possibility of pregnancy. A history of weight gain, nausea, painful or engorged breasts, an unusually light or mistimed period, or urinary frequency may be present. Denial contributes to delay in seeking prenatal care. Clinicians need to have a low threshold for suspecting pregnancy. If any suspicion exists, a urine pregnancy test should be obtained.

Diagnosis

The history and physical examination assists in making the diagnosis. Bluish coloring and softening of the cervix appear on speculum examination. The uterine fundus may be palpable on abdominal examination after about 14 weeks' gestation. If uterine size on bimanual examination does not correspond to dates, one must consider ectopic pregnancy, incomplete or missed abortion, twin gestation, or inaccurate dates.

Enzyme-linked immunosorbent assay test kits specific for the β -human chorionic gonadotropin subunit and sensitive to less than 50 mIU/mL of human chorionic gonadotropin can be performed on urine (preferably the first morning-voided specimen, because it is more concentrated) in less than 5 minutes and are accurate by the expected date of the

missed period in almost all patients. Serum radioimmunoassay is also specific for the β subunit, is accurate within 7 days after conception, and is helpful in ruling out ectopic pregnancy or threatened abortion.

The timing of pregnancy tests is important, because human chorionic gonadotropin levels rise initially after conception, peak at about 60–70 days, then drop to levels not detected by routine office slide tests after 16–20 weeks.

Management

A. Counseling at the Time of Pregnancy Testing

When an adolescent presents for pregnancy testing, it is helpful, before performing the test, to find out what she hopes the result will be and what she thinks she will do if the test is positive. If she wants to be pregnant and the test is negative, further counseling about the implications of teen pregnancy should be offered. Prenatal vitamins should be prescribed. For those who do not wish to be pregnant, contraception should be discussed, because teens with a negative pregnancy test have a high risk of pregnancy within the next 2 years.

If the adolescent is pregnant, the physician must discuss her support systems and her options with her (abortion, adoption, or raising the infant). If providers are not comfortable discussing the option of abortion, the adolescent should be referred to a provider comfortable with options counseling. Many teenagers need help in telling and involving their parents. It is important to be available for further assistance with decision making. Patients should be informed of the gestational age and time frames required for the different options. If the patient knows what she wants to do, she should be referred to the appropriate resources. If a teenager is ambivalent about her plans, it is helpful to follow up in 1 week to be certain that a decision has been made. Avoiding a decision reduces the adolescent's options and may result in poor pregnancy outcomes. Providers can help ensure that the patient obtains prenatal care if she has chosen to continue the pregnancy. In addition, brief counseling about healthful diet; folic acid supplementation (400 mcg/d); and avoiding alcohol, tobacco, and other drugs is important.

B. Fathers of Infants Born to Adolescent Mothers

Statistics regarding the age of fathers of infants born to adolescent mothers are limited due to fear of statutory rape prosecution and also the inclusion of 18- and 19-year-old women in statistics of teen pregnancy. Data have shown that adult males impregnated 27–40% of 15–17-year-old adolescent mothers. These data vary by race and ethnicity, with larger age differences typical in Hispanic and Asian couples. Regardless of age, fathers of children born to adolescent mothers have lower academic achievement, lower income, and higher rates of substance abuse and involvement with the law than fathers of children born to adult women. The majority of these fathers do not provide long-term support

for their children. Most do not continue a romantic relationship with the adolescent mother.

C. Pregnancy Outcomes

Young maternal age, low maternal prepregnancy weight, poor weight gain, delay in prenatal care, maternal depression, and low socioeconomic status contribute to low birth weight and poor fetal outcome. The poor nutritional status of some teenagers, substance abuse, and high incidence of STIs also play a role. Teenagers are at greater risk than adult women for preeclampsia, eclampsia, iron-deficiency anemia, cephalopelvic disproportion, prolonged labor, premature labor, and maternal death.

Maternal risk factors are linked to adverse neonatal outcome, including higher rates of low birth weight babies (< 2500 g) and neonatal mortality. Specific risk factors leading to adverse outcomes include poverty, maternal depression, exposure to domestic violence, and inadequate support. Good family support, early prenatal care, and good nutrition can make a difference with several of these problems. The psychosocial consequences for the teenage mother and her infant are listed in Table 3–15. Teenagers who are pregnant require additional support from their caregivers. Multidisciplinary clinics for young mothers, if available, may be the best providers for pregnant adolescents.

Adolescent mothers tend to be more negative and authoritative when disciplining their children. They may have inadequate knowledge of normal behavior and development. Providers can help by educating the adolescent mother during routine visits regarding appropriate discipline and expectations of her child’s behavior.

Postpartum contraceptive counseling and follow-up may help prevent additional pregnancies. In untreated girls, the risk of a second unintended pregnancy within the next 2 years is approximately 30%. Combined OCPs, the vaginal ring, or the contraceptive patch can be started 6 weeks after delivery in non–breast-feeding adolescents; progestin-only methods can be started immediately postpartum, even in breast-feeding adolescents.

Ectopic Pregnancy

In the United States, approximately 2% of pregnancies are ectopic. Adolescents have the highest mortality rate from ectopic pregnancy, most likely related to delayed entry into health care. Risk factors include history of pelvic inflammatory disease or STIs. Repeat infections with *Chlamydia* increase risk for ectopic pregnancy, as does cigarette smoking. Conception while on progestin-only methods of contraception also increases the risk of ectopic pregnancy, because of the progestin-mediated decrease in tubal motility. Providers should have a high level of suspicion when any adolescent presents with vaginal bleeding and abdominal pain. Patients typically present 6–8 weeks after their last menstrual period. Urine pregnancy test is usually positive by the time of presentation. Patients should be referred urgently to a gynecologist. Diagno-

Table 3–15. Psychosocial consequences of pregnancy for the adolescent mother and her infant.

Mother	Infant
<p>Increased morbidity related to pregnancy</p> <ul style="list-style-type: none"> Greater risk of eclampsia, anemia, prolonged labor, premature labor Increased chance of miscarriages, stillbirths Increased chance of maternal mortality <p>Decreased educational attainment</p> <ul style="list-style-type: none"> Less likely to get high school diploma, go to college, or graduate Delayed education (average 2 y) <p>Lower occupational attainment and prestige</p> <ul style="list-style-type: none"> Less chance of stable employment (some resolution over time) Lower job satisfaction Lower income and wages Greater dependence on public assistance <p>Less stable marital relationships</p> <ul style="list-style-type: none"> Higher rates of single parenthood Earlier marriage (though less common than in the past) Accelerated pace of marriage, separation, divorce, and remarriage <p>Faster pace of subsequent childbearing</p> <ul style="list-style-type: none"> High rate of repeat unintended pregnancy More births out of marriage Closer spacing of births Larger families 	<p>Greater health risks</p> <ul style="list-style-type: none"> Increased chance of low birth weight or prematurity Increased risk of infant death Increased risk of injury and hospitalization by age 5 y <p>Decreased academic achievement</p> <ul style="list-style-type: none"> Lower cognitive scores Decreased development Greater chance of being behind grade or needing remedial help Lower chance of advanced academics Lower academic aptitude as a teenager and perhaps a higher probability of dropping out of school <p>Psychosocial consequences</p> <ul style="list-style-type: none"> Greater risk of behavior problems Poverty Higher probability of living in a nonintact home while in high school Greater risk of adolescent pregnancy

VULVOVAGINITIS

Vaginitis may be due to pathogens or to indigenous flora after a change in milieu of the vagina. Candidal vulvovaginitis and bacterial vaginosis (formerly called *Gardnerella*, *Haemophilus*, or nonspecific vaginitis) may occur in patients who are not sexually active. These are examples of indigenous flora that may cause symptoms. Bacterial vaginosis, however, is more prevalent in those who are sexually active. In sexually active patients, *Trichomonas* infection or cervicitis due to sexually transmitted pathogens must be considered (see Chapter 42). For this reason, appropriate specimens should be obtained from sexually active patients or suspected victims of sexual abuse in order to detect STIs, even if yeast forms are present or bacterial vaginosis is identified.

1. Physiologic Leukorrhea

Leukorrhea is the normal vaginal discharge that begins around the time of menarche. The discharge is typically clear or white, and its consistency may vary according to cyclic hormonal influences. There should be no odor. Girls in early adolescence may have concerns about such a discharge and need reassurance that it is normal. This may be a good time to tell girls that there is no need for douching. If a vaginal wet preparation is examined, a few squamous epithelial cells may be revealed, but there should be fewer than five polymorphonuclear cells per high-power field.

2. Candidal Vulvovaginitis

Candidal vulvovaginitis is caused by yeast (*Candida albicans* or less commonly *C. glabrata* or *tropicalis*). It may occur following a course of antibiotics, after which the normal perineal flora are altered and yeast is allowed to proliferate. Diabetic patients, those with compromised immune systems, and those who are pregnant or receiving OCPs are more prone to develop candidal infections. *Candida* are normal flora; therefore, only symptomatic patients should be treated.

► Clinical Findings

The patient usually complains of vulvar pruritus and a thick vaginal discharge, frequently beginning the week before menses. Dysuria or dyspareunia may also be present. Examination of the vulva reveals erythematous mucosa, sometimes with excoriation, and a thick, white, cheesy discharge. The discharge may be adherent to the walls of the vagina. Leukocytes may be seen on a wet preparation, and a potassium hydroxide preparation may reveal budding yeast or mycelia. The vaginal preparations are often not helpful, and the patient should be treated on the basis of the clinical examination.

► Treatment

Clotrimazole, miconazole, terconazole, or tioconazole vaginal creams or suppositories designed for seven nightly doses are effective in most patients. Patients with recurrent infections may benefit from 10–14 days of treatment. Fluconazole

(150 mg once orally) is also effective and may be beneficial in virginal adolescents. Patients with recurrent episodes may be given prophylactic treatment whenever they take antibiotics. It may be helpful to simultaneously treat the partners of sexually active patients with recurrent candidal infections.

3. Bacterial Vaginosis

Bacterial vaginosis may be caused by any of the indigenous vaginal flora, such as *Gardnerella*, *Bacteroides*, *Peptococcus*, *Mycoplasma hominis*, lactobacilli, or other anaerobes.

► Clinical Findings

The patient generally complains of a malodorous discharge or wetness. On examination, a thin, homogeneous, grayish-white discharge is found adhering to the vaginal wall. A whiff test, in which a drop of potassium hydroxide is added to a smear of the discharge on a slide, results in the release of amines, causing a fishy odor. Wet preparation reveals more than 20% of epithelial cells as clue cells and small pleomorphic rods.

► Treatment

Treatment for bacterial vaginosis should be reserved for symptomatic patients. First-line treatment is with metronidazole (500 mg orally twice daily for 7 days), which results in 95% cure, or clindamycin (300 mg orally twice daily for 7 days). Patients who are prescribed metronidazole should be warned that a disulfiram-type reaction of nausea and vomiting may occur when alcohol is consumed. Topical metronidazole or clindamycin may also be effective. Ampicillin (500 mg orally 4 times daily for 7 days) is the alternative for pregnant patients.

4. Other Causes of Vulvovaginitis

A. Sexually Transmitted Infections

STIs are a common cause of vaginal discharge in adolescents (see Chapter 42). *Chlamydia* and gonorrhea testing should be done whenever a sexually active adolescent complains of vaginal discharge even when the cervix appears normal.

B. Foreign Body Vaginitis

Foreign bodies (most commonly retained tampons or condoms) cause extremely malodorous vaginal discharges. Treatment consists of removal, for which ring forceps may be useful. Further treatment is generally not necessary.

C. Allergic or Contact Vaginitis

Bubble baths, feminine hygiene sprays, or vaginal contraceptive foams or suppositories may cause chemical irritation of the vaginal mucosa. Discontinuing use of the offending agent is indicated.

Adolescent Substance Abuse

4

Paritosh Kaul, MD

The use and abuse of mood-altering substances—alcohol, marijuana, opioids, cocaine, amphetamines, sedative-hypnotics, hallucinogens, inhalants, nicotine, anabolic steroids, γ -hydroxybutyrate (GHB), methylenedioxymethamphetamine (ecstasy), and recently, prescription drugs—is a serious public health problem. The short- and long-term health, social, emotional, legal, and behavioral consequences of substance abuse are particularly damaging during childhood and adolescence. Not only does early substance use portend chronic, severe polysubstance abuse later in life, but substance use may also compromise physical, cognitive, and psychosocial aspects of adolescent development if this maladaptive behavior becomes the preferred response to environmental stressors.

Substance abuse tends to be a chronic, progressive disease. The first or initiation stage—from nonuser to user—is such a common feature of becoming an American adult that many authorities call it normative behavior. At this stage, substance use is typically limited to experimentation with tobacco or alcohol (so-called gateway substances). During adolescence, young people are expected to establish an independent, autonomous identity. They try out a variety of behaviors within the safety of their family circles and peer groups. This process often involves experimentation with psychoactive substances, usually in culturally acceptable circumstances. Progression to the second or continuation stage of substance abuse is a nonnormative risk behavior with the potential to compromise adolescent development. The American Psychiatric Association has outlined criteria that can be used to judge the severity of substance use that progresses beyond the experimentation stage to substance abuse or substance dependency (the former being more severe). Maintenance and progression within a class of substances (eg, from beer to liquor) and progression across classes of substances (eg, from alcohol to marijuana) represent the third and fourth stages of substance abuse. Individuals at these stages are polysubstance abusers, and most manifest one or more of the

symptoms of dependency such as tolerance or withdrawal. The transition from one stage to the next is typically a cyclic process of regression, cessation, and relapse. Common symptoms and physiologic effects of intoxication (which can occur at any stage) and withdrawal (a symptom of dependency) for the major classes of substances are presented in Tables 4–1 and 4–2.

SCOPE OF THE PROBLEM

The best source of information about the prevalence of substance abuse among American children and adolescents is the annual Monitoring the Future Study, which tracks health-related behaviors in a sample of 50,000 8th, 10th, and 12th graders in more than 400 schools across the United States. This study probably understates the magnitude of the problem of substance abuse because it excludes two high-risk adolescent groups—school dropouts and runaways. Although the exclusion of these youngsters may minimize prevalence estimates only moderately for the entire population, errors in estimating drug use among subgroups with high rates of school dropout (eg, urban minority youths) are thought to be substantial. Data from this survey and others show that alcohol is the most frequently abused substance in our society. Experimentation with alcohol typically begins in or before middle school; is more common among boys than girls; and is most common among whites, less common among Hispanics and Native Americans, and least common

Table 4-1. Physiologic effects of commonly abused mood-altering substances.

EYES/PUPILS	
Mydriasis	Amphetamines, MDMA, or other stimulants; cocaine; glutethimide; jimson weed; LSD. Withdrawal from alcohol and opioids
Miosis	Alcohol, barbiturates, benzodiazepines, opioids, PCP
Nystagmus	Alcohol, barbiturates, benzodiazepines, inhalants, PCP
Conjunctival injection	LSD, marijuana
Lacrimation	Inhalants, LSD. Withdrawal from opioids
CARDIOVASCULAR	
Tachycardia	Amphetamines, MDMA, or other stimulants; cocaine; LSD; marijuana; PCP. Withdrawal from alcohol, barbiturates, benzodiazepines
Hypertension	Amphetamines, MDMA, or other stimulants; cocaine; LSD; marijuana; PCP. Withdrawal from alcohol, barbiturates, benzodiazepines
Hypotension	Barbiturates, opioids. Orthostatic: marijuana. Withdrawal from depressants
Arrhythmia	Amphetamines, MDMA, or other stimulants; cocaine; inhalants; opioids; PCP
RESPIRATORY	
Depression	Opioids, depressants, GHB
Pulmonary edema	Opioids, stimulants
CORE BODY TEMPERATURE	
Elevated	Amphetamines, MDMA, or other stimulants; cocaine; PCP. Withdrawal from alcohol, barbiturates, benzodiazepines, opioids
Decreased	Alcohol, barbiturates, benzodiazepines, opioids, GHB
PERIPHERAL NERVOUS SYSTEM RESPONSE	
Hyperreflexia	Amphetamines, MDMA, or other stimulants; cocaine; LSD; marijuana; methaqualone; PCP. Withdrawal from alcohol, barbiturates, benzodiazepines
Hyporeflexia	Alcohol, barbiturates, benzodiazepines, inhalants, opioids
Tremor	Amphetamines or other stimulants, cocaine, LSD. Withdrawal from alcohol, barbiturates, benzodiazepines, cocaine
Ataxia	Alcohol, amphetamines, MDMA, or other stimulants; barbiturates; benzodiazepines; inhalants; LSD; PCP; GHB
CENTRAL NERVOUS SYSTEM RESPONSE	
Hyperalertness	Amphetamines, MDMA, or other stimulants; cocaine
Sedation, somnolence	Alcohol, barbiturates, benzodiazepines, inhalants, marijuana, opioids, GHB
Seizures	Alcohol, amphetamines, MDMA, or other stimulants; cocaine; inhalants; methaqualone; opioids (particularly meperidine, propoxyphene). Withdrawal from alcohol, barbiturates, benzodiazepines
Hallucinations	Amphetamines, MDMA, or other stimulants; cocaine; inhalants; LSD; marijuana; PCP. Withdrawal from alcohol, barbiturates, benzodiazepines
GASTROINTESTINAL	
Nausea, vomiting	Alcohol, amphetamines or other stimulants, cocaine, inhalants, LSD, opioids, peyote, GHB. Withdrawal from alcohol, barbiturates, benzodiazepines, cocaine, opioids

GHB, γ -hydroxybutyrate; LSD, lysergic acid diethylamide; MDMA, methylenedioxyamphetamine (ecstasy); PCP, phencyclidine hydrochloride. Adapted, with permission, from Schwartz B, Alderman EM: Substance abuse. *Pediatr Rev* 1997;18:215.

among blacks and Asians. Over 50% of children consume alcohol before high school, and over 90% do so before graduation. Over 25% of eighth graders and over 50% of high-school students seen in an average American pediatric practice have used alcohol within the last 30 days, and half have consumed five or more drinks on at least one occasion. Use of tobacco, marijuana, and other mood-altering substances is less common. Marijuana is the most commonly

used illicit drug in the United States. First experiences with marijuana and the substances listed in Table 4-2 typically occur during middle school and early high school. Initiation of substance abuse is rare after age 20 years.

The level of substance abuse among American youth rose in the 1960s and 1970s, declined in the 1980s, rose again in the early 1990s, and has declined somewhat since then. Between 1999 and 2006, substance use initiation

Table 4-2. Effects of commonly abused mood-altering substances.

Substance	Pharmacology	Intoxication	Withdrawal	Chronic Use
Alcohol (ethanol)	Depressant; 10 g/drink Drink: 12 oz beer, 4 oz wine, 1 ¹ / ₂ oz liquor; one drink increases blood level by approximately 0.025 g/dL (varies by weight)	Legal: 0.05–0.1 g/dL (varies by state) Mild (< 0.1 g/dL): disinhibition, euphoria, mild sedation and impaired coordination Moderate (0.1–0.2 g/dL): impaired mentation and judgment, slurred speech, ataxia Severe: > 0.3 g/dL: confusion, stupor > 0.4 g/dL: coma, depressed respiration	Mild: headache, tremors, nausea and vomiting (“hangover”) Severe: fever, sweaty, seizure, agitation, hallucination, hypertension, tachycardia Delirium tremens (chronic use)	Hepatitis, cirrhosis, cardiac disease, Wernicke encephalopathy, Korsakoff syndrome
Marijuana (cannabis)	δ-9-Tetrahydrocannabinol (THC); 4–6% in marijuana; 20–30% in hashish	Low: euphoria, relaxation, impaired thinking High: mood changes, depersonalization, hallucinations Toxic: panic, delusions, paranoia, psychosis	Irritability, disturbed sleep, tremor, nystagmus, anorexia, diarrhea, vomiting	Cough, gynecomastia, low sperm count, infertility, amotivational syndrome, apathy
Cocaine	Stimulant; releases biogenic amines; concentration varies with preparation and route of administration	Hyperalert, increased energy, confident, insomnia, anxiety, paranoia, dilated pupils, tremors, seizures, hypertension, arrhythmia, tachycardia, fever, dry mouth Toxic: coma, psychosis, seizure, myocardial infarction, stroke, hyperthermia, rhabdomyolysis	Drug craving, depression, dysphoria, irritability, lethargy, tremors, nausea, hunger	Nasal septum ulceration, epistaxis, lung damage, intravenous drug use
Opioids (heroin, morphine, codeine, methadone, opium, fentanyl, meperidine, propoxyphene)	Depressant; binds central opioid receptor; variable concentrations with substance	Euphoria, sedation, impaired thinking, low blood pressure, pinpoint pupil, urinary retention Toxic: hypotension, arrhythmia, depressed respiration, stupor, coma, seizure, death	Only after > 3 weeks of regular use: drug craving, rhinorrhea, lacrimation, muscle aches, diarrhea, anxiety, tremors, hypertension, tachycardia	Intravenous drug use: cellulitis, endocarditis, embolisms, HIV
Amphetamines	Stimulant; sympathomimetic	Euphoria, hyperalert state, hyperactive, hypertension, arrhythmia, fever, flushing, dilated pupils, tremor, ataxia, dry mouth	Lethargy, fatigue, depression, anxiety, nightmares, muscle cramps, abdominal pain, hunger	Paranoia, psychosis
MDMA (ecstasy)	Stimulant, psychedelic; releases serotonin, dopamine, and norepinephrine; inhibits reuptake of neurotransmitters; increases dopamine synthesis; inhibits MAO	Enhanced empathy, euphoria, increased energy and self-esteem, tachycardia, hypertension, increased psychomotor drive, sensory enhancement, illusions, difficulty concentrating and retaining information, headaches, palpitations, flushing, hyperthermia	None	Paranoid psychosis

(continued)

Table 4-2. Effects of commonly abused mood-altering substances. (Continued)

Substance	Pharmacology	Intoxication	Withdrawal	Chronic Use
		Toxic: frank psychosis, coma, seizures, intracranial hemorrhage, cerebral infarction, asystole, pulmonary edema, multisystem organ failure, acute renal or hepatic failure, ARDS, DIC, SIADH, death		
GHB (liquid ecstasy)	Depressant, endogenous CNS transmitter; influences dopaminergic activity, higher levels of GABA-B activity	10 mg/kg: sleep 30 mg/kg: memory loss 50 mg/kg: general anesthesia Toxic: CNS and respiratory depression, aggressiveness, seizures, bradycardia, apnea	Only after chronic use with dosing every 3 h Early: mild tremor, tachycardia, hypertension, diaphoresis, moderate anxiety, insomnia, nausea, vomiting Progressive: confusion, delirium, hallucinations, autonomic instability, death	Wernicke-Korsakoff syndrome
Sedative-hypnotics (barbiturates, benzodiazepines, methaqualone)	Depressant	Sedation, lethargy, slurred speech, pinpoint pupils, hypotension, psychosis, seizures Toxic: stupor, coma, cardiac arrest, seizure, pulmonary edema, death	Only after weeks of use: agitation, delirium, psychosis, hallucinations, fever, flushing, hyper- or hypotension, death	Paranoia
Hallucinogens (LSD, peyote, mescaline, mushrooms, nutmeg, jimson weed)	Inhibition of serotonin release	Illusions, depersonalization, hallucination, anxiety, paranoia, ataxia, dilated pupils, hypertension, dry mouth Toxic: coma, terror, panic, "crazy feeling"	None	Flashbacks
Phencyclidine	Dissociative anesthetic	Low dose (< 5 mg): illusions, hallucinations, ataxia, hypertension, flushing Moderate dose (5-10 mg): hyperthermia, salivation, myoclonus High dose: (> 10 mg): rigidity, seizure, arrhythmia, coma, death	None	Flashbacks
Inhalants (toluene, benzene, hydrocarbons and fluorocarbons)	Stimulation progressing to depression	Euphoria, giddiness, impaired judgment, ataxia, rhinorrhea, salivation, hallucination Toxic: respiratory depression, arrhythmia, coma, stupor, delirium, sudden death	None	Permanent damage to nerves, liver, heart, kidney, brain
Nicotine	Releases dopamine, 1 mg nicotine per cigarette	Relaxation, tachycardia, vertigo, anorexia	Drug craving, irritability, anxiety, hunger, impaired concentration	Permanent damage to lung, heart, cardiovascular system

(continued)

Table 4-2. Effects of commonly abused mood-altering substances. (Continued)

Substance	Pharmacology	Intoxication	Withdrawal	Chronic Use
Anabolic steroids ^a	Bind steroid receptor Stacking: use many types simultaneously; pyramiding: increase dosage	Increased muscle bulk, strength, endurance, increased drive, hypogonadism, low sperm count, gynecomastia, decreased libido, virilization, irregular menses, hepatitis, early epiphysial closure, aggressiveness	Drug craving, dysphoria, irritability, depression	Tendon rupture, cardiomyopathy, atherosclerosis, peliosis hepatis (orally active C17 derivatives of testosterone are especially hepatotoxic)

^aDespite conventional assumptions, scientific studies show that anabolic steroids do not improve aerobic athletic performance and improve strength only in athletes trained in weight lifting before they begin using steroids who continue to train and consume a high-protein diet.

ARDS, acute respiratory distress syndrome; CNS, central nervous system; DIC, disseminated intravascular coagulation; GABA, γ -aminobutyric acid; GHB, γ -hydroxybutyrate; HIV, human immunodeficiency virus; LSD, lysergic acid diethylamide; MAO, monoamine oxidase; MDMA, methylenedioxyamphetamine; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

among adolescents has decreased. Despite the overall decline, there is still a significant pattern of drug use among adolescents. The use of alcohol, tobacco, and illicit drugs doubles from 8th grade to 12th grade. The rate of alcohol and cigarette use more than triples from adolescence (12–17 years) to young adulthood (18–25 years). The prevalence of marijuana use among 12th graders in 2006 was 32%. In the past decade, LSD, ecstasy, and methamphetamine use decreased but cocaine use increased. The most disturbing trend among adolescents is the recreational use of prescription medications, particularly psychotherapeutic agents. Studies indicate that the rise and fall in use of a substance is heralded by changes in the perceived risks and benefits of using the substance. The use of inhalants had been rising until 2006, when both experience and educational efforts resulted in a perception of these substances as being “dangerous.”

MORBIDITY DATA

Use and abuse of alcohol or other mood-altering substances is tightly linked with the leading causes of death among adolescents in the United States (ie, motor vehicle accidents, unintentional injury, homicide, and suicide). Substance abuse is also associated with physical and sexual abuse. Up to two thirds of sexual assaults and acquaintance or date rapes are linked to alcohol or other drug use. Drug use and abuse also contribute to other high-risk behaviors, such as unsafe sexual activity, unintended pregnancy, and sexually transmitted diseases. The use of drugs during periods of low self-esteem and depression increases the risk of suicide. Adolescents are also involved with selling of drugs.

The risks associated with tobacco, alcohol, and cocaine are listed in Table 4-2. Less well known are the long- and short-term adolescent morbidities connected with the currently most popular illicit drugs, marijuana and ecstasy. The active ingredient in marijuana, δ -9-tetrahydrocannabinol (THC), transiently causes tachycardia, mild hypertension, and bronchodilation. Regular use can cause lung changes similar to those seen in tobacco smokers. Heavy use decreases fertility in both sexes and immunocompetence. It is also associated with

damage to the hippocampus and basal ganglia, which causes abnormalities of cognition, learning, coordination, and memory. It is possible that heavy marijuana use is the cause of the so-called amotivational syndrome, characterized by inattention to environmental stimuli and impaired goal-directed thinking and behavior. Analysis of confiscated marijuana has shown increasing THC concentration and adulteration with other substances.

Ecstasy is gaining in both popularity and accessibility among adolescents. Chronic use destroys the serotonin system of the brain and is associated with progressive decline of immediate and delayed memory and with alterations in mood, sleep, and appetite that may be permanent. Even first-time users may develop frank psychosis indistinguishable from schizophrenia. Irreversible cardiomyopathy, noncardiogenic pulmonary edema, and pulmonary hypertension may occur with long-term use. Acute overdose can cause hyperthermia and multiorgan system failure.

A growing problem is the abuse of prescribed and over-the-counter (OTC) medications by adolescents. Medication used in the medical management of chronic pain, depression, anxiety, and attention-deficit/hyperactivity disorder can be drugs of abuse either by the patients or by those they supply with the drug.

Environmental and prenatal exposure to abused substances carries health risks. Parental tobacco smoking is associated with low birth weight in newborns, sudden infant death syndrome, bronchiolitis, asthma, otitis media, and fire-related injuries. Paternal use of marijuana during pregnancy is associated with an increased risk of sudden infant death syndrome. In utero exposure to cocaine and alcohol may produce fetal malformations, intrauterine growth restriction, and brain injury.

SUPPLEMENT USE & ABUSE

Use of supplements or special diets to enhance athletic performance dates to antiquity. Today, many elite and casual athletes use ergogenic supplements in an attempt to improve performance. The most popular products used by adolescents are protein supplements, creatine, and the prohormones. Strength athletes (ie, weight lifters) use protein powders and shakes to enhance muscle repair and mass. The amount of protein consumed by athletes often greatly exceeds the recommended daily allowance for weight lifters and other resistance-training athletes (1.6–1.7 g/kg/d). The American Academy of Pediatrics (AAP) condemns the use of performance-enhancing substances. Excess consumption of protein provides no added strength or muscle mass and can provoke renal failure in teens with underlying renal dysfunction.

Sales of creatine supplements are over \$400 million (U.S.) per year. Creatine—a combination of glycine, arginine, and methionine that is produced naturally in the liver, kidneys, and pancreas—facilitates production of adenosine triphosphate and increases free energy for muscle contraction. It maximizes power during short-duration, intense exercise and improves baseline strength in adults. Creatine does not improve performance in longer-duration, aerobic exercise nor has its effectiveness been analyzed in children. Although the American College of Sports Medicine discourages its use by people younger than 18 years of age, recent studies show that creatine is extensively used by athletes in grades 6–12. Side effects include weight gain, headache, abdominal pain, diarrhea, and increased muscle strain. There are conflicting reports about the risk of renal damage.

There has been a disturbing increase in the availability and use of prohormones, specifically dehydroepiandrosterone (DHEA) and androstenedione. Sold as dietary supplements, these precursors to testosterone and other sex hormones are sold without federal regulation. Endogenous DHEA is produced in the adrenal cortex as a precursor of gonadal hormones. Putative benefits of DHEA are increased fat catabolism; increased muscle mass; increased libido; "improved" immune function; and decreased memory loss, heart disease, cancer, type 2 diabetes mellitus, and Alzheimer and Parkinson disease. Although its effects on strength and performance in athletes remain unstudied and unproven, the advertised

benefits are attractive to many athletes. Its effect on young, healthy individuals (ie, those with higher baseline DHEA levels) has not been studied. In adults, two studies have shown that doses of 50–100 mg/d cause increased androgenic steroid plasma levels and increased subjective perception of physical and psychological well-being. Users of DHEA report few adverse effects.

Androstenedione, which is banned by the International Olympic Committee, National Collegiate Athletic Association, and National Football League, is converted to testosterone in the liver. A recent study of young athletes concluded that oral androstenedione does not increase plasma testosterone concentration. In young eugonadal men it has no anabolic effect on muscle protein metabolism. Other studies have shown increased biologically active estrogen levels. No long-term studies have been conducted. Its side effects are believed to be similar to those of other anabolic and androgenic agents. Most side effects are secondary to androgen excess—hyperlipidemia, hypertension, insulin resistance, hyperinsulinism, depression, aggression, paranoia, acne, male pattern baldness, alopecia, and priapism. Most effects are reversible with cessation of use. Irreversible side effects include virilization in females (hair loss, clitoromegaly, hirsutism, and voice-deepening) and gynecomastia in males.

As the use of supplements and herbs increases, it will be increasingly important for pediatric care providers to be familiar with their common side effects. The Internet has become a source for information about and distribution of these products. The easy accessibility, perceived low risk, and low cost of these products significantly increase the likelihood that they will become substances of abuse by the pediatric population.

RESPONSE TO THE PROBLEM

Federal, state, and local governments attempt to control the damage caused by substance abuse by prohibiting use and by legislating against associated high-risk behaviors (eg, enacting drunk-driving laws and nighttime curfews). However, neither these legal actions nor the large sums of money spent on school- and community-based drug abuse prevention and treatment programs have curbed the problem. Hence, the AAP recommends that pediatricians become knowledgeable about the extent and nature of drugs used in their community, provide anticipatory guidance to parents starting with the first prenatal visit, and be aware of community referral and treatment resources.

The Internet has made the task of limiting drug use more difficult. For example, poor methods for age verification make it easy for minors to purchase tobacco products online. The media also glamorize use of tobacco and alcohol. Pro-tobacco marketing and media stimulate tobacco use among youth while recent state budget crises have cut anti-tobacco advertising. Exposure to tobacco company youth-targeted smoking prevention advertising generally has had no beneficial outcomes for youths.

PREDICTING THE PROGRESSION FROM USE TO ABUSE

Most adolescents use mood-altering substances intermittently or experimentally at the start. The challenge to pediatric health care providers is to recognize the warning signs, identify potential abusers early, and intervene in an effective and timely fashion before acute or chronic use results in morbidity. The

Table 4-3. Factors that influence the progression from substance use to substance abuse.

Enabling Risk Factors	Potentially Protective Factors
SOCIETAL AND COMMUNITY	
Experimentation encouraged by media Illicit substances available Extreme economic deprivation Neighborhood disorganization, crowding Tolerance of licit and illicit substance use	Regular involvement in church activities Support for norms and values of society Strict enforcement of laws prohibiting substance use among minors and abuse among adults Neighborhood resources, supportive adults
SCHOOL	
Lack of commitment to school or education Truancy Academic failure Early, persistent behavior problems	Strong commitment to school or education Future-oriented goals Achievement oriented
FAMILY	
Models of substance abuse and other unconventional behavior Dysfunctional parenting styles; excessive authority or permissiveness High family conflict; low bonding	Models of conventional behavior Attachment to parents Cohesive family Nurturing parenting styles
PEERS	
Peer rejection in elementary grades Substance use prevalent among peers Peer attitudes favorable to substance abuse and unconventional behavior	Popular with peers Abstinent friends Peer attitudes favor conventional behavior
INDIVIDUAL	
Genetic predisposition Psychological diagnoses (attention-deficit/hyperactivity disorder; antisocial personality) Depression and low self-esteem Alienation and rebelliousness Sexual or physical abuse Early onset of deviant behavior or delinquency Early onset of sexual behavior Aggressive	Positive self-concept, good self-esteem Intolerance of deviance Internally motivated, takes charge of problems

best predictors of ethanol and drug abuse are male sex, young age at first use, and associating with drug-using peers. It is still unclear why only a minority of the young people exhibiting the high-risk characteristics listed in Table 4-3 go on to abuse substances. Substance abuse is a symptom of personal and social maladjustment as often as it is a cause. Because there is a direct relationship between the number of risk factors listed in Table 4-3 and the frequency of substance abuse, a combination of risk factors is the best indicator of risk. Even so, most teenagers with multiple risk characteristics never develop a substance abuse problem, presumably because the protective factors listed in Table 4-3 give them enough resilience to cope with stress in more socially adaptive ways. Being aware of the risk domains in Table 4-3 will help physicians identify youngsters most apt to need counseling about substance abuse.

MANAGEMENT OF SUBSTANCE ABUSE

Office Screening

The AAP Committee on Substance Abuse recommends that pediatricians include discussions of substance abuse as part of their anticipatory care, starting with parents at the first prenatal visit. Given the high incidence of substance abuse and the subtlety of its early signs and symptoms, a general psychosocial assessment is the best way to screen for substance abuse among adolescents. Interviewing and counseling techniques and methods for taking a psychosocial history are discussed in

Chapter 3. In an atmosphere of trust and confidentiality, physicians must ask routine screening questions of all patients and be alert for addictive diseases, recognizing the high level of denial often present in addicted patients. The universal screening approach outlined in the American Medical Association (AMA) Guidelines for Adolescent Preventive Services (GAPS) is a good guide for routine screening and diagnosis. Clues to possible substance abuse include truancy, failing grades, problems with interpersonal relationships, delinquency, depressive affect, chronic fatigue, recurrent abdominal pains, chest pains or palpitations, headache, chronic cough, persistent nasal discharge, and recurrent complaints of sore throat. Substance abuse should be included in the differential diagnosis of all behavioral, family, psychosocial, and medical problems. Pediatricians seeing patients in emergency departments, trauma units, or prison must have an especially high index of suspicion. A family history of drug addiction or abuse should raise the level of concern about drug abuse in the pediatric patient. Possession of promotional products such as T-shirts and caps with cigarette or alcohol logos should also be a red flag because teenagers who own these items are more likely to use the products they advertise.

Diagnosis

Although few children and adolescents will have been abusing substances long enough to have developed overt signs and symptoms, it is important to look for them on physical examination. Positive physical findings can be a tool to penetrate a patient’s denial and convince him or her of the significance of the alcohol or drug use.

When the psychosocial history suggests the possibility of substance use, the primary tasks of the diagnostic interview are the same as for the evaluation of other medical problems (Table 4–4).

First, specific information about the extent of the problem must be gathered. Eliciting multiple-choice answers is a useful technique. For example, “Has anything really good ever happened to you when you are high?” or “Some of my

Table 4–4. Causes of false-positive drug screens.

<p>I. Define the extent of the problem by determining: Age at onset of substance use Which substances are being used Circumstances of use Where? When? With whom? To what extent substances are being used How frequently? How much (quantity)? With what associated symptoms (eg, tolerance, withdrawal)? With what result? What does the patient gain from becoming high? Does the patient get into risky situations while high? Does the patient engage in behaviors while high that are later regretted?</p> <p>II. Define the cause of the problem by developing a differential diagnosis</p>
--

patients like to get high because they feel good; others find it helps them relax and be sociable with friends; and some find it helps them forget their problems. Are any of these things true for you?”

Second, the provider needs to determine why the patient has progressed from initiation to the continuation or maintenance phase of substance abuse. The cause may be different at different periods of development. Although peer group characteristics are one of the best predictors of substance use among early and middle adolescents, this is not so among older adolescents and young adults.

In the primary care setting, insufficient time and lack of training in management of positive screens are the greatest barriers to screening adolescents for substance abuse. Brief questionnaires can be used if time does not allow for more detailed investigation. A screening instrument that has been rigorously studied in primary care settings is the CAGE questionnaire. CAGE is a mnemonic derived from the first four questions listed in Table 4–5. A score of 2 or more is highly suggestive of substance abuse.

Although constructed as a screening tool for alcohol abuse in adults, the CAGE questionnaire can be adapted to elicit similar information about use of other mood-altering substances by pediatric patients and by their close contacts (eg, parents and older siblings). Finally, clinicians may find it helpful to use such questionnaires to stimulate discussion of the patient’s self-perception of his or her substance use. For example, if an adolescent admits to a previous attempt to cut down on drinking, this provides an opportunity to inquire about events that may have led to the attempt.

Knight JR et al: Motivational interviewing for adolescent substance use: a pilot study. *J Adolesc Health* 2005;37:167 [PMID: 16026730].

Table 4-5. CAGE questionnaire.

CUT DOWN: Have you ever felt you ought to cut down on your drinking (drug use)?

ANNOYED: Have people annoyed you by criticizing your drinking (drug use)?

GUILTY: Have you ever felt bad about your drinking (drug use)?

EYE OPENER: Have you ever had a drink (used drugs) to steady your nerves in the morning?

(Score 1 point for each positive answer; refer if total points ≥ 2)

Comorbidity

There are often numerous comorbidities among substance-abusing patients. Substance abusers are more likely to have another psychiatric disorder. Affective disorder, anxiety disorder, and mania are most strongly associated with alcohol and drug dependence. Adolescents with depression are likely to use drugs in an attempt to feel pleasure, but this type of self-medication may exacerbate their condition. Attention-deficit/hyperactivity has been closely linked with adolescent substance abuse. In addition to identifying psychiatric comorbidities, it is imperative that providers look for medical conditions that mimic symptoms of drug withdrawal or intoxication. Patients with significant primary medical conditions may use illicit substances to relieve symptoms (severe pain or chemotherapeutic side effects). Although it is often difficult to determine which diagnosis is primary, it is important for pediatric health care providers to recognize the possibility of a comorbid condition and provide appropriate treatment.

Barkley RA et al: Does the treatment of attention-deficit/hyperactivity disorder with stimulants contribute to drug use/abuse? A 13-year prospective study. *Pediatrics* 2003;111:97 [PMID: 12509561].

Pharmacologic Screening

The use of urine and blood testing for detecting substance abuse is controversial. The consensus is that pharmacologic screening should be reserved for situations in which behavioral dysfunction is of sufficient concern to outweigh the practical and ethical drawbacks of testing. The AAP recommends screening under certain circumstances (eg, an inexplicably obtunded patient in the emergency department) but discourages routine screening for the following reasons: (1) Voluntary screening programs are rarely truly voluntary owing to the negative consequences for those who decline to participate; (2) infrequent users or individuals who have not used substances recently may be missed; (3) confronting substance-abusing individuals with objective evidence of their use has little or no effect on their behavior; (4) the AAP reminds providers that their role is counseling and treatment, not law enforcement, so drug testing should not be done for the purpose of detecting illegal use. If testing is to be performed, the provider should discuss the plan for screening with the patient, explain the reasons for it, and obtain informed consent. The AAP does not consider parental request and permission sufficient justification for involuntary screening of mentally competent minors.

Beyond the ethical concerns, there are also practical concerns. If testing is to be performed, it is imperative that it be done accurately and that the limitations of testing be understood by all parties. Tests range from inexpensive, chromatographic spot tests, which can be performed in the office, to gas chromatography and mass spectrometry, which require specialized laboratory equipment and are usually reserved for forensic investigations. Most commercial medical laboratories use the enzyme multiplication immunoassay technique, in which a sample of the fluid to be tested is added to a test reagent containing a known quantity of the radiolabeled index drug under question. If the index drug is also present in the patient’s urine or serum, it competes with the radiolabeled drug for binding sites on the test kit antibody. The unbound or excess drug can then be quantified with a spectrophotometer. Most of the commonly abused mood-altering substances, with the exception of solvents and inhalants, can be detected by this method.

Interpretation of results is complicated by false-positives resulting from antibody cross-reactions with some medications and substances (Table 4-6) or from a patient’s passive exposure to illicit substances. The most common cause of false-negative tests is infrequent use. Table 4-7 shows the duration of detectability in the urine after last use by class of substance and duration of use. Detectability ranges from a few hours for alcohol to several weeks for regular marijuana use. False-negative results can occur if the patient alters or adulterates the specimen. Some of the commercial products

tive and potentially dangerous way to prevent drug detection in the urine.) Close observation during collection and pre-testing the temperature, specific gravity, and pH of urine samples may detect attempts at deception.

Internet-based home drug-testing products are available for parents; however, these products have limitations and potential risks. The AAP recommends that home and school-based drug testing not be implemented until the safety and efficacy of these procedures can be established. It further recommends that parents be encouraged to consult the adolescent’s primary care provider rather than relying on home drug-testing products.

TREATMENT & REFERRAL

Office-Based Treatment

The AMA and the AAP recommend that all children and adolescents receive counseling about the dangers of substance use and abuse from their primary care providers. By offering confidential health care services and routinely counseling about the risks associated with drug abuse, primary care providers can help most patients avoid the adverse consequences of experimentation with mood-altering substances. However, more intervention is required for youngsters in environments where substance abuse is regarded as acceptable recreational behavior. Counseling strategies appropriate for patients who wish to change their behavior may be ineffective for patients who do not consider use of mood-altering substances to be a problem. It may therefore be preferable to begin discussions about treatment by helping youngsters consider alternative ways of meeting the needs that substance use is currently providing. The clinician

may in this way help the patient devise alternatives that are more attractive than substance use. Realistically, few substance-abusing teenagers will choose to quit because of a single conversation even with a highly respected health care provider. The message is most effective when offered repeatedly from many sources—family, peers, guidance counselors, and teachers. Brief interventions for adolescents have shown some improvement among high-risk youth. Motivational interviewing for substance-abusing teens has shown some promise.

Assessment of the patient's readiness to change is the critical first step in office-based intervention. Clinicians should consider the construct presented in Table 4–8. In theory, individuals pass through this series of stages in the course of changing problem behaviors. Thus, to be maximally effective, providers should tailor their counseling messages to the patient's stage of readiness to change.

Once it has been established that a patient is prepared to act on information about treatment, the next step is to select the program that best fits his or her individual needs. Most drug treatment programs are not designed to recognize and act on the individual vulnerabilities that have predisposed the patient to substance abuse. When programs are individualized, even brief (5- to 10-minute) counseling sessions may promote reductions in cigarette smoking and drinking. This strategy appears to be most effective when the health care provider's message is part of an office-wide program so that the entire staff reinforces the cessation message with every patient.

Table 4–8. Stages of change and intervention tasks.

Patient Stage	Motivation Tasks
Precontemplation	Create doubt, increase the patient's awareness of risks and problems with current patterns of substance use
Contemplation	Help the patient weigh the relative risks and benefits of changing substance use; evoke reasons to change and risks of not changing; strengthen the patient's self-efficacy for changing current use
Determination	Help the patient determine the best course of action to change substance use from among available alternatives
Action	Help the patient establish a clear plan of action toward changing substance use
Maintenance	Help the patient identify and use strategies to prevent relapse
Relapse	Help the patient renew the process of change starting at contemplation

Smoking Cessation in Pediatrics

Although more than half of adolescents who smoke regularly say they want to quit and have tried to quit, only a minority report that they have been advised or helped to do so by a health care provider. Practitioners unfamiliar with approaches to smoking cessation may feel that smoking cessation interventions are time-consuming, nonreimbursable, and impractical in a busy office. An easy guideline for health care providers is the “Five As” for tobacco cessation (Table 4–9), published by the Public Health Service and endorsed by the AAP.

Smoking cessation is a process that takes time. Relapse must be regarded as a normal part of quitting rather than evidence of personal failure or a reason to forgo further attempts. Patients can actually benefit from relapses if they are helped to identify the circumstances that led to the relapse and to devise strategies to prevent subsequent relapses or respond to them in a different manner.

Nicotine is a physically and psychologically addictive substance. Replacement therapy improves smoking cessation rates and may relieve withdrawal symptoms. Two types of nicotine replacement therapies are available. Nicotine gum and transdermal nicotine patches are recommended for teens.

Providers should be aware that adolescents may not exhibit the same symptoms of nicotine dependence as adults, and that dependence may be established within as little as 4 weeks. Those who are not comfortable prescribing and monitoring nicotine replacement therapies should limit their involvement with patients who smoke to those who do not exhibit signs of nicotine dependency (eg, patients who smoke less than a pack of cigarettes a day or do not feel a

Referral

There is no consensus about which substance-abusing patients can be adequately treated in the office, which require referral, and which require hospitalization. Factors to be considered are summarized in Table 4–10. When doubt exists about the seriousness of the problem or the advisability of office management, consultation with a specialist should be sought.

Although most primary pediatric providers will not assume responsibility for the treatment of substance-abusing youngsters, clinicians can be instrumental in motivating their patients to seek treatment and in guiding them to appropriate treatment resources. Substance-abusing teenagers must be treated in teen-oriented treatment facilities. Despite the similarities between adult and adolescent substance abuse, adult programs are usually developmentally inappropriate and ineffective for adolescents. As discussed in Chapter 3, many adolescents are concrete thinkers. Their inability to reason deductively, especially about emotionally charged issues, makes it difficult for them to understand the abstract concepts (such as denial) that are an integral component of most adult-oriented programs. This invariably

Table 4–10. Factors to consider prior to referral for substance abuse.

Duration and frequency of substance use
The type of substances being used
Presence of other psychological disorders
Attention-deficit/hyperactivity disorder
Depression
Antisocial personality disorder
Presence of other social morbidities
School failure
Delinquency
Homelessness
Ongoing or past physical or sexual abuse
Program evaluation
View on substance abuse as primary disorder vs symptom
Offers comprehensive evaluation of patient and can manage associated problems identified in initial assessment (eg, comorbid conditions)
Adherence to abstinence philosophy
Patient-to-staff ratios
Separate adolescent and adult treatment programs
Follow-up and continuing care

frustrates counselors who misinterpret lack of comprehension as resistance to therapy, and concrete responses as evidence of deceit.

Treatment programs range from low-intensity, outpatient, school-based student assistance programs, which rely heavily on peers and nonprofessionals, to residential, hospital-based programs staffed by psychiatrists and other professionals. Outpatient counseling programs are most appropriate for motivated patients who do not have significant mental health or behavioral problems and are not at risk for withdrawal. Some investigators have raised the concern that in pediatric settings, low-problem users may actually experience a strengthening of the drug subculture by associating with high-problem users in group therapy. More intensive day treatment programs are available for those who require a structured environment. Inpatient treatment should be considered for patients who need medical care and detoxification in addition to counseling, education, and family therapy.

Finally, special dual-diagnosis facilities are available for substance-abusing patients who also have other psychological conditions. These patients are difficult to diagnose and treat because it is often unclear whether their symptoms are a consequence of substance use or a symptom of a comorbid psychological disorder. Recognition of such disorders is critical because they must be treated in programs that include psychiatric expertise.

Approaches to the treatment of substance abuse in children and adolescents are typically modeled after adult treatment programs. Key elements of an effective adolescent drug treatment program include: assessment and treatment matching, comprehensive, integrated treatment approach,

family involvement, developmentally appropriate program, engaging and retaining teens, qualified staff, gender and cultural competence, continuing care, and treatment outcomes. Several studies of adolescent substance abuse treatment programs have shown that many do not adequately address all of the important components of therapy.

PREVENTION

Prevention of substance abuse has been a public health priority since the 1980s. Pediatric health care providers are important as advocates and educators of the community and government on developmentally appropriate programs. *Primary level* programs focus on preventing the initiation of substance use. The Drug Awareness and Resistance Education (D.A.R.E.) program is a familiar example of a primary prevention program that attempts to educate elementary and middle school students about the adverse consequences of substance abuse and enable them to resist peer pressures.

Secondary level programs target populations at increased risk for substance use. The aim is to prevent progression from initiation to continuance and maintenance, relying on individualized intervention to reduce the risk and enhance the protective factors listed in Table 4–3. This approach enables the provider to focus scarce resources on those who are most likely to benefit from them. Alateen, which supports the children of alcoholic parents, typifies secondary level prevention.

Tertiary level prevention programs target young people who have been identified as substance abusers. The aim is to prevent the morbid consequences of substance use. One example is identifying adolescents who misuse alcohol and drugs at parties and providing them with a safe ride home. Because prevention is more effective when targeted at reducing the initiation of substance use than at decreasing use, tertiary prevention is the least effective approach.

Very few population-based programs undergo rigorous scientific evaluation. It is the consensus among drug educators that primary prevention programs, such as D.A.R.E., have minimal effect in decreasing the use of illicit substances.

During the 1990s, when these programs were most popular, a smaller proportion of middle- and high-school students perceived illicit drug and alcohol use as dangerous, and substance use actually increased. Even when knowledge- and resistance-based programs do increase student understanding of adverse consequences, there is no evidence that they change attitudes or abuse rates.

The failure of resistance education programs has fostered interest in a potentially more effective type of program, exemplified by the Adolescents Training and Learning to Avoid Steroids program. This program, a same-sex, peer-educator program designed to simultaneously reduce the use of steroids and improve dietary and exercise habits of teen athletes has proven effective in randomized controlled trials. Pediatric health care providers should promote developmentally appropriate prevention programs like this one that address the social and psychological problems predisposing youngsters to substance abuse and provide realistic alternative solutions.

Parents and others should understand that most adolescents who abuse alcohol and drugs do not do so just for the high. Rather, these behaviors are often purposeful, developmentally appropriate coping strategies. To the extent that these behaviors meet young peoples' developmental needs, they are not apt to be abandoned unless equally attractive alternatives are available. For example, even though many teenagers cite stress and anxiety as reasons for smoking, teen-oriented smoking cessation programs rarely address the young smoker's need for alternative coping strategies by offering stress management training. Similarly, for the youngster growing up in an impoverished urban environment, the real costs of substance abuse may be too low and the rewards too high to be influenced by talk and knowledge alone. It is unreasonable to expect a talk-based intervention to change attitudes and behaviors in a direction that is opposite to that of the child's own social milieu. The efficacy of the most promising prevention models and interventions is apt to decay over time unless changes in the social environment provide substance-abusing children and adolescents with realistic alternative ways to meet their developmental needs.

Eating Disorders

Eric J. Sigel, MD

Teenagers and younger children continue to develop eating disorders at a significant rate. The spectrum of eating disorders includes anorexia nervosa (AN), bulimia nervosa (BN), eating disorders not otherwise specified (EDNOS), and binge-eating disorder. The relationship between genetics and environment in the development of eating disorders is complex. These disorders are best defined in a biopsychosocial context.

ETIOLOGY

A genetic susceptibility to develop eating disorders probably exists. The incidence of AN is 7% in first-degree relatives of anorexic patients compared with 1–2% in the general population. The concordance rate in monozygotic twins is 55%, compared with 7% in dizygotic twins. Twin studies estimate the heritability of AN as 33–84%, and BN as 28–83%. First-degree female relatives of males with AN have a 20-fold relative risk of AN. Most studies have found a higher incidence of eating disorders among first-degree relatives of bulimic patients as well. Genomic regions on chromosome 1 (for AN) and chromosome 10 (for BN) appear to harbor susceptibility genes.

Abnormalities of leptin, a hormone secreted by adipocytes that regulates energy homeostasis and satiety signaling, do not appear to cause AN primarily, but may mediate energy changes that affect the hypothalamic-pituitary axis and play a role in perpetuating AN. Leptin physiology is deranged in patients with AN. Leptin levels increase to excessive levels as individuals regain weight. The idiosyncratic higher levels of leptin may contribute to the difficulty AN patients have when trying to regain weight, as higher leptin levels signal the body to decrease energy intake. Leptin also plays a significant role in some of the sequelae of AN, with low levels signaling the hypothalamus to inhibit reproductive hormone production.

There is evidence of persistently altered serotonergic and dopaminergic function in AN. Other alterations in neu-

ropeptides and gut peptides are found both in AN and BN. Adiponectin appears elevated in AN, although it is unclear whether this is due to the malnourished state, or elevated independently of malnutrition. Cholecystokinin is decreased in BN, perhaps contributing to the lack of post-ingestion satiety that perpetuates a binge. An alteration in dopamine has also been recognized, although its significance is not clear. Ghrelin, a gut peptide, is elevated in patients with AN and does not decrease in the normal fashion after a meal in these patients.

Despite significant research into the neurobiology of eating disorders, it remains unclear whether alterations contribute to the development of eating disorders or are present as a consequence of the physiologic changes associated with the disorders. Patients with BN or binge-eating disorder appear to have a blunted serotonin response to eating and satiety. With a decreased satiety response, patients continue to eat, leading to a binge. Treatment with selective serotonin reuptake inhibitors (SSRIs) tends to equilibrate satiety regulation. More research is needed to determine which factors are causative and which are results of the eating disorder.

Traditional psychological theory has suggested many environmental factors that might promote the development of eating disorders. Enmeshment of mother with daughter to the point that the teenager cannot develop her own identity (a key developmental marker of adolescence) may be a predisposing factor. The teenager may cope by asserting control over food, as she senses her lack of control in the developmental realm. A second theory involves father-daughter distancing. As puberty progresses and a girl's sexuality blossoms, a father may experience difficulty in dealing with his daughter as a sexual being and may respond by withdrawing both emotionally and physically. The teenage girl may intuitively recognize this and subconsciously decrease her food intake in order to become prepubertal again. A third theory is related to puberty itself. Some teenagers may fear or dislike their changing bodies. By

restricting food intake they lose weight, stop menstruating, and effectively reverse pubertal development.

Society has provided the message that being thin or muscular is necessary for attractiveness and success. The ease of access to diet products—foods and diet pills—as well as internet instructions (pro-anorexia sites) makes it simple for adolescents to embark on a quest for thinness or muscularity.

Genetic predisposition, psychological factors, and environmental factors combine to create a milieu that promotes adolescent eating disorders.

INCIDENCE

AN is the third most common chronic illness of teenaged girls in the United States. The incidence has been increasing steadily in the United States since the 1930s. Although ascertaining exact incidence is difficult, most studies show that 1–2% of teenagers develop AN and 2–4% develop BN. Adolescents outnumber adults 5 to 1, although the number of adults with eating disorders is rising. Incidence is also increasing among younger children. Prepubertal patients often have significant associated psychiatric diagnoses. Males comprise about 10% of the patients with eating disorders, and this prevalence appears to be increasing. Prevalence of full or partial syndrome BN is 1.1% in males and 3.2% in females (1:2.9 male-to-female ratio). Prevalence of full or partial syndrome AN is 0.9% in males and 1.8% in females (1:2 ratio). The increasing number of males with eating disorders correlates with the increased media emphasis on muscular, chiseled appearance as the male ideal.

Recent literature on preadolescents with eating disorders suggests that patients younger than 13 years are more likely to be male and more likely to have EDNOS. Younger patients are less likely to engage in behaviors characteristic of BN. They present with more rapid weight loss and lower percentile body weight than adolescents.

Many youth engage in some eating disorder behaviors. In the most recent Youth Risk Behavior Survey of U.S. teenagers published by the Centers for Disease Control and Prevention (Eaton et al, 2005), 62% of females and 30% of males had attempted to lose weight during the 30 days preceding the survey. Twelve percent had fasted for more than 24 hours to lose weight, and 6.1% had used diet pills, powders, or liquids to lose weight (8.1% of girls and 4.6% of boys). Self-induced vomiting or laxative use was common; 6.2% of females and 2.8% of males used one or the other. Forty-six percent of females and 30% of males reported at least one bingeing episode during their lifetime. Although the number of youth with full-blown eating disorders is low, it is alarming that so many youth experiment with unhealthy weight control habits. These signs may be precursors to the development of eating disorders, and clinicians should explore these practices with all of their adolescent patients.

PREDISPOSING FACTORS

In the past, the typical anorexic patient was described as a high-achieving, athletic, straight-A student from a middle-class family. Demographics have changed, and eating disorders now occur across all racial and ethnic groups. There is no difference among blacks, Asians, Hispanics, and whites in the frequency of eating disorder symptoms or eating disorder risk factors. Children involved in gymnastics, figure skating, and ballet—activities that emphasize (and in which coaches often require) thin bodies—are at higher risk for anorexia than are children in sports that do not emphasize body image. Adolescents who believe that being thin represents the ideal frame for a female, those who are dissatisfied with their bodies, and those with a history of dieting are at increased risk for eating disorders. Sudden changes in dietary habits, such as becoming vegetarian, may be a first sign of anorexia, especially if the change is abrupt and without good reason.

The typical bulimic patient is more impulsive, tending to engage in risk-taking behavior such as alcohol use, drug use, and sexual experimentation. Bulimic patients are often an appropriate weight for height or slightly overweight. They have average academic performance. Some studies report that 50% of bulimic patients have been sexually abused. Youth with diabetes have an increased risk of BN. In males, wrestling predisposes to BN, and homosexual orientation is associated with binge eating.

ANOREXIA NERVOSA

Table 5–1 lists the diagnostic criteria for AN, according to the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR). There are two forms of AN. In the restricting type, patients do not regularly engage in binge eating or purging. In the purging type, classic AN is combined with binge eating or purging behavior, or both. Distinguishing between the two is important as they carry different implications for prognosis and treatment. There is ongoing debate about the criteria for AN. Some experts suggest eliminating amenorrhea as a specific criterion. Though patients may not demonstrate all features of AN, they may still exhibit the deleterious symptoms associated with AN.

► Clinical Findings

A. Symptoms and Signs

Clinicians should recognize the early symptoms and signs of AN because early intervention may prevent the full-blown syndrome from developing. Patients may show some of the behaviors and psychology of AN, such as reduction in dietary fat and intense concern with body image, even before weight loss or amenorrhea occurs.

Making the diagnosis of AN can be challenging because adolescents may try to conceal their illness. Assessing the patient's body image is essential to determining the diagno-

Table 5–1. Diagnostic criteria for anorexia nervosa.

- A. Refusal to maintain body weight at or above a minimally normal weight for age and height (eg, weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during a period of growth, leading to body weight less than 85% of that expected).
- B. Intense fear of gaining weight or becoming fat, even though underweight.
- C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
- D. In postmenarchal females, amenorrhea, ie, the absence of at least three menstrual cycles. (A woman is considered to have amenorrhea if her periods occur only following hormone, eg, estrogen, administration.)

Reprinted, with permission, from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed, text revision. Copyright 2000. American Psychiatric Association.

Table 5–2. Screening questions to help diagnose anorexia and bulimia nervosa.

How do you feel about your body?
 Are there parts of your body you might change?
 When you look at yourself in the mirror, do you see yourself as overweight, underweight, or satisfactory?
 If overweight, how much do you want to weigh?
 If your weight is satisfactory, has there been a time that you were worried about being overweight?
 If overweight [underweight], what would you change?
 Have you ever been on a diet?
 What have you done to help yourself lose weight?
 Do you count calories or fat grams?
 Do you keep your intake to a certain number of calories?
 Have you ever used nutritional supplements, diet pills, or laxatives to help you lose weight?
 Have you ever made yourself vomit to get rid of food or lose weight?

sis. Table 5–2 lists screening questions that help tease out a teenager's perceptions of body image. Other diagnostic screening tools (eg, Eating Attitudes Test) assess a range of eating and dieting behaviors. Parental observations are critical in determining whether a patient has expressed dissatisfaction over body habitus and determining which weight loss techniques the child has used. If the teenager is unwilling to share his or her concerns about body image, the clinician may find clues to the diagnosis by carefully considering other presenting symptoms. Weight loss from a baseline of normal body weight is an obvious red flag and should raise the clinical suspicion for the presence of an eating disorder. Additionally, AN should be considered in any girl with secondary amenorrhea who has lost weight.

Physical symptoms are usually secondary to weight loss and proportional to the degree of malnutrition. The body effectively goes into hibernation, becoming functionally hypothyroid (euthyroid sick) to save energy. Body temperature decreases, and patients report being colder than normal. Patients become bradycardic, especially in the supine position. Dizziness, lightheadedness, and syncope may occur as a result of orthostasis and hypotension secondary to impaired cardiac function. Left ventricular mass is decreased (as is the mass of all striated muscle), stroke volume is compromised, and peripheral resistance is increased, contributing to left ventricular systolic dysfunction. Patients can develop prolonged QTc syndrome and increased QT dispersion, putting them at risk for cardiac arrhythmias. Peripheral circulation is reduced. Hands and feet may be blue and cool. Hair thins, nails become brittle, and skin becomes dry. Lanugo develops as a primitive response to starvation. The gastrointestinal (GI) tract may be affected. Inability to take in normal quantities of food, early satiety, and gastroesophageal reflux can develop as the body adapts to reduced intake. The normal gastrocolic reflex may be lost due to lack of stimulation by food, causing bloating and constipation. One study

showed that delayed gastric emptying is present in restricting type and purging type AN. Long-term physical rehabilitation improves gastric emptying and dyspeptic symptoms in AN restricting type, but not purgers.

Neurologically, patients may experience decreased cognition, inability to concentrate, increased irritability, and depression, which may be related to structural brain changes and decreased cerebral blood flow.

A combination of malnutrition and stress causes hypothalamic hypogonadism. The hypothalamic-pituitary-gonadal axis shuts down as the body struggles to survive, directing finite energy resources to vital functions. This may be mediated by the effect of low serum leptin on the hypothalamic-pituitary axis. Both males and females experience decreased libido and interruption of pubertal development, depending on the timing of the illness. Skeletal growth may be interrupted.

Nutritional assessment is vital. Often patients eliminate fat from their diets and may eat as few as 100–200 kcal/d. A gown-only weight after urination is the most accurate way to assess weight. Patients tend to wear bulky clothes and may hide weights in their pockets or drink excessive fluid (water-loading) to trick the practitioner. Calculating body mass index (BMI)—weight in kilograms divided by height in meters squared—is an efficient way to interpret degree of malnutrition. BMI below the 25th percentile indicates risk for malnutrition, and one below the fifth percentile significant malnutrition. Ideal body weight (IBW) for height should be calculated, using the 50th percentile of BMI for age. A weight less than 85% IBW is one of the diagnostic criteria for AN.

A hallmark physical sign of girls with AN is amenorrhea, which occurs for two reasons. The hypothalamic-pituitary-ovarian axis shuts down under stress, causing hypothalamic amenorrhea. Additionally, adipose tissue is needed to convert estrogen to its activated form. When weight loss is significant, adipose tissue is lost and there is not enough substrate to activate estrogen. Resumption of normal menses occurs only when both body weight and body fat increase. Approximately 73% of postmenarchal girls will resume menstruating if they reach 90% of IBW. An adolescent female needs about 17% body fat to restart menses and 22% body fat if she has primary amenorrhea. One study demonstrated that target weight gain for return of menses is approximately 1 kg higher than the weight at which menses ceased.

B. Laboratory Findings

Most organ systems can suffer some degree of damage in the anorexic patient, related both to severity and duration of illness (Table 5–3). Initial screening should include complete blood count with differential; serum levels of electrolytes, blood urea nitrogen, creatinine, phosphorus, calcium, magnesium, and thyroid-stimulating hormone; liver function tests; and urinalysis. An electrocardiogram should be performed, because significant electrocardiographic abnormalities may be present, most importantly prolonged QTc syn-

Table 5–3. Laboratory findings: anorexia nervosa.

Increased blood urea nitrogen and creatinine secondary to renal insufficiency
Decreased white blood cells, platelets, and less commonly red blood cells and hematocrit secondary to bone marrow suppression or fat atrophy of the bone marrow
Increased AST and ALT secondary to malnutrition
Increased cholesterol, thought to be related to fatty acid metabolism
Decreased alkaline phosphatase secondary to zinc deficiency
Low to low-normal thyroid-stimulating hormone and thyroxine
Decreased follicle-stimulating hormone, luteinizing hormone, estradiol, and testosterone secondary to shutdown of hypothalamic-pituitary-gonadal axis
Abnormal electrolytes related to hydration status
Decreased phosphorus
Decreased insulin-like growth factor
Increased cortisol
Decreased urine specific gravity in cases of intentional water intoxication

ALT, alanine aminotransferase; AST, aspartate aminotransferase.

drome. Bone densitometry should be done if amenorrhea has persisted for 6 months, as patients begin to accumulate risk for osteoporosis.

► Differential Diagnosis

If the diagnosis is unclear (ie, the patient has lost a significant amount of weight but does not have typical body image distortion or fat phobia), then the clinician must consider the differential diagnosis for weight loss in adolescents. This includes inflammatory bowel disease, diabetes, hyperthyroidism, malignancy, and depression. Less common diagnoses include adrenal insufficiency and malabsorption syndromes such as celiac disease. The history and physical examination should direct specific laboratory and radiologic evaluation.

► Complications (Table 5–4)

A. Short-Term Complications

1. Early satiety—Patients may have significant difficulty tolerating even modest quantities of food as their bodies adapt to increased caloric intake. Gastric emptying is poor. Pancreatic and biliary secretion is diminished. Patients may benefit from a gastric-emptying agent such as metoclopramide. This complication usually resolves after a patient has become used to larger meals.

2. Superior mesenteric artery syndrome—As patients become malnourished, the fat pad between the superior mesenteric artery and the duodenum may shrink, compressing the transverse duodenum and causing vomiting and intolerance of oral intake, especially solids. Diagnosis is made by an upper GI series showing to and fro movement of barium in the descending and transverse duodenum proximal to the obstruction. Treatment involves a liquid diet or

nasoduodenal feedings until restoration of the fat pad has occurred, coincident with weight gain.

3. Constipation—Patients may have prolonged constipation, often not having a bowel movement for several weeks. Two mechanisms contribute: loss of the gastrocolic reflex and loss of colonic muscle tone. Typically stool softeners are not effective because the colon has decreased peristaltic amplitude. Agents that induce peristalsis, such as bisacodyl, as well as osmotic agents, such as polyethylene glycol-electrolyte solution (MiraLax), are helpful. Constipation can persist for up to 6–8 weeks after refeeding. Occasionally enemas are required.

4. Refeeding syndrome—This is described in the Treatment section.

B. Long-Term Complications

1. Osteoporosis—Approximately 50% of females with AN have reduced bone mass at one or more sites. The causes of osteopenia and osteoporosis are multiple. Estrogen and testosterone are essential to potentiate bone development. Higher

ghrelin level is an independent predictor of bone density in healthy adolescents; however, it does not appear to contribute to bone loss in patients with AN. Teenagers are particularly at risk as they accrue 40% of their bone mineral during adolescence. Low body weight is most predictive of bone loss. Amenorrhea, an indicator of estrogen deficiency and hypothalamic amenorrhea, is highly correlated with osteoporosis. Bone minerals begin to resorb without estrogen. Elevated cortisol levels and decreased insulin-like growth factor-1 also contribute to bone resorption. Studies show that as few as 6 months of amenorrhea can lead to osteopenia or osteoporosis. In one study, 44% of adolescents with anorexia had osteopenia of the lumbar spine. Males also can develop osteoporosis due to decreased testosterone and elevated cortisol.

A recent finding has shown that depression in adolescent females with AN is associated with a higher risk of osteoporosis, compared with AN alone. The reason for this association is unknown.

The only proven treatment for osteoporosis in girls with AN is regaining sufficient weight and body fat to restart the menstrual cycle. Most studies do not support use of hormone replacement therapy to improve bone recovery; however, some

evidence indicates that use of hormone replacement therapy may stop further bone loss and may be of particular benefit for patients with extremely low body weight (< 70% IBW). Some practitioners use hormone replacement therapy if amenorrhea has been present for more than 1 year and the patient is not able to achieve normal body weight. Bisphosphonates used to treat postmenopausal osteoporosis are currently being studied in adolescents. Two small randomized controlled trials have shown small positive effects on bone density with alendronate and risedronate, although clinical effectiveness has not yet been determined. Newer treatments with possible effectiveness, including recombinant insulin-like growth factor-1 injection and dehydroepiandrosterone, are still under investigation.

2. Brain changes—As malnutrition becomes more pronounced, brain tissue—both white and gray matter—is lost, with a compensatory increase in cerebrospinal fluid in the sulci and ventricles. Follow-up studies of weight-recovered anorexic patients show a persistent loss of gray matter, although white matter returns to normal. Functionally there does not seem to be a direct relationship between cognition and brain tissue loss, although studies have shown a decrease in cognitive ability and decreased cerebral blood flow in very malnourished patients. Making patients and family aware that brain tissue can be lost may improve their perception of the seriousness of this disorder.

C. Mortality

Patients with eating disorders are at a higher risk of death than the general population. Meta-analysis shows that the risk of dying is 5.9% in such patients. Mortality estimates vary between 0% and 18%, depending on the patient population and the duration of follow-up. One study showed the risk of dying to be 0.56% per year. Death in anorexic patients is due to suicide, abnormal electrolytes, and cardiac arrhythmias.

▶ Treatment

A. General Approach

Factors that determine treatment interventions are severity of illness, duration of illness, specific manifestations of disease, previous treatment approaches and outcomes, program availability, financial resources, and insurance coverage. Treatment options include outpatient management, day treatment hospitalization, and inpatient medical or psychiatric hospitalization. Residential treatment is most often used when outpatient management or short-term hospitalization fails and the eating disorder becomes chronic. Residential treatment usually lasts 2–6 months. Day treatment programs are a good intervention for patients who do not yet need inpatient care but who are not improving with outpatient management. Treatment is costly. Many patients do not have insurance benefits that adequately cover the cost of treatment, leaving parents and practitioners with profound dilemmas as to how to best provide treatment in the face of financial constraints.

Regardless of the treatment program, a multidisciplinary approach is most effective and should include medical monitoring, nutrition therapy, and individual and family psychotherapy by experienced practitioners. Family therapy is especially helpful with younger teenagers, whereas older teenagers tend to benefit more from individual therapy. Family therapy is an important means of helping families understand the development of the disease and addressing issues that may be barriers to recovery. Both types of therapy are encouraged in most treatment programs, and recovery without psychotherapy is unusual. The average length of therapy is roughly 6–9 months, although some individuals continue therapy for extended periods. Adjunctive modalities include art and horticulture therapy, therapeutic recreation, and massage therapy.

A newer family therapy approach, manualized family therapy, developed in Britain by Maudsley and adapted by Lock and LeGrange, has shifted the therapeutic approach to adolescents with AN. Traditional therapy allowed the adolescent to control his or her eating, and the parents to remain uninvolved with the food-portion of recovery. The manualized approach gives power and control back to parents. Treatment is prescribed for 20 weekly sessions. The first 10 weeks are devoted to empowering parents, putting them in control of their child's nutrition and exercise. Parents are educated about the dangers of malnutrition and are instructed to supervise each meal. The next phase—sessions 11–16—returns control over eating to the adolescent once he or she accepts the demands of the parents. The last phase of treatment, sessions 17–20, occurs when the patient is maintaining a healthy weight, and shifts the focus away from the eating disorder, examining instead the impact that the eating disorder has had on establishing a healthy adolescent identity. This approach is reported to result in good or intermediate outcomes in 90% of treated adolescents.

Careful instruction in nutrition helps the teenager and family dispel misconceptions about nutrition, identify realistic nutritional goals, and normalize eating. Initially, nutrition education may be the most important intervention as the teenager slowly works through his or her fears of fat-containing foods and weight gain. The teenager begins to trust the nutrition therapist and restore body weight, eventually eating in a well-balanced, healthy manner.

The key to determining level of intervention is the degree of malnutrition, the rapidity of weight loss, the degree of medical compromise, and the presence of life-threatening electrolyte abnormalities. No absolute criteria determine level of intervention. The practitioner must examine the degree of medical compromise and consider immediate risks and the potential for an individual to reverse the situation on his or her own.

B. Inpatient Treatment

Table 5–5 lists the criteria for hospital admission generally used in the medical community. It is usually quite difficult for a patient who is losing weight rapidly (> 2 lb/wk) to reverse the weight loss because the body is in a catabolic state.

Goals of hospitalization include arresting weight loss and stabilizing hemodynamics. Nutrition is the most vital inpatient medicine. Clinicians can safely begin with a meal plan containing approximately 250 kcal more than the patient has been routinely eating, which can usually be accomplished orally. Ideally, with the help of a nutritionist, patients should start with a well-balanced meal plan, with appropriate proportions of carbohydrate, protein, and fat. Usually patients tolerate oral meals. If the patient resists, nasogastric or intravenous alimentation can be used for a short time. Aside from caloric needs, the clinician needs to consider the patient's hydration and include the appropriate amount of fluid with the meal plan. Dehydration should be corrected slowly. The oral route is usually adequate. Aggressive intravenous fluid administration should be avoided because left ventricular mass is compromised and a rapid increase in volume may not be tolerated. Regulating fluid intake is important, because water intoxication can contribute to abnormal electrolytes and falsified weights.

During the initial introduction of food, the clinician should monitor the patient for refeeding syndrome, a phe-

nomenon that occurs if caloric intake is increased too rapidly. Signs of refeeding syndrome are decreased serum phosphorus (as the body resumes synthesis of adenosine triphosphate), decreased serum potassium (as increased insulin causes K^+ to shift from extracellular fluid into K^+ -depleted cells), and rarely, edema related to fluid shifts or congestive heart failure.

Although specific guidelines do not exist, many practitioners begin phosphorus supplementation if patients are severely malnourished ($< 70\%$ IBW) or their intake has been consistently less than 500 kcal/d.

Caloric intake can be increased 250 kcal/d as long as refeeding syndrome does not occur. Weight goals vary depending on programmatic approach. Typically intake is adjusted to reach a goal of 0.1–0.25 kg/d weight gain.

Overnight monitoring for bradycardia is helpful in assessing degree of metabolic compromise. Usually the more rapid and severe the weight loss is, the worse the bradycardia. Improving bradycardia correlates with weight recovery. Orthostatic hypotension is most severe around hospital day 4, improving steadily and correcting by the third week of nutritional rehabilitation. An electrocardiogram should be obtained because the patient is at risk for prolonged QTc syndrome and junctional arrhythmias related to the severity of bradycardia.

It usually takes 2–3 weeks to reach the initial goals of hospitalization—steady weight gain, toleration of oral diet without signs of refeeding syndrome, corrected bradycardia (heart rate > 45 beats/min for three consecutive nights), and correction of orthostasis. Specific weight criteria are used by many programs when considering discharge. This depends partly on admission weight. Ideally a patient gains at least 5% of his or her ideal weight. Some programs set discharge at 80%, 85%, or 90% IBW. Patient outcomes are improved with discharge at a higher body weight. One study has shown that patients do better if discharged at 95% IBW. Frequently, insurance companies do not pay for hospital stays beyond strict medical stabilization (normal vital signs and normal electrolytes). In many practitioners' experience, relapse rate is high if patients are discharged at less than 75% IBW.

Extremely malnourished patients may not benefit from individual psychotherapy or nutritional instruction initially because of their cognitive impairment. Beginning family psychotherapy at first, with the addition of individual psychotherapy after the first week of refeeding, may be more effective.

C. Pharmacotherapy

Use of psychotropic medications is common in treatment of AN, despite lack of solid proof of efficacy. The most promising class of medication is the atypical antipsychotics. Several open label trials support the use of atypical antipsychotics (risperidone, olanzapine, quetiapine), which target specifically the body image distortion of these patients. One review found that olanzapine (2.5–15 mg/d) was associated with improved

Table 5–5. Criteria for inpatient treatment of anorexia nervosa.

Body weight $< 75\%$ of ideal body weight
Supine heart rate < 45 /min
Symptomatic hypotension or syncope
Hypokalemia: $K^+ < 2.5$ mEq/L
Rapid weight loss that cannot be interrupted as outpatient
Failure of outpatient management
Acute food refusal

body weight, decreased delusional thinking, improvement in body image, and decreased agitation and premeal anxiety. There have not yet been any published randomized placebo-controlled trials of the atypical antipsychotics, although several are pending.

SSRIs repeatedly have been shown to not be helpful in the initial therapy of AN. However, once the patient has achieved approximately 85% IBW, then SSRIs (fluoxetine, citalopram, or sertraline) may help prevent relapse.

Zinc deficiency is common in AN, and several studies support its use as a supplement during the initial phases of treatment. Because zinc deficiency adversely affects neurotransmitters, administering zinc helps restore neurotransmitter action to baseline. Additionally zinc may restore appetite and improve depressive mood. Zinc should be administered for approximately 2 months from the beginning of therapy, with at least 14 mg of elemental zinc daily.

Due to global nutritional deficits, a multivitamin with iron is also recommended daily. Symptomatic treatment for disturbances in the GI system should be used appropriately until symptoms resolve.

D. Outpatient Treatment

Not all patients with AN need inpatient treatment, especially if parents and clinicians recognize the warning signs early. These patients can receive treatment as outpatients, employing the same multidisciplinary team approach. Manualized family-based treatment, described earlier under General Approach, is ideal for the outpatient setting, if a trained therapist is available. Appropriate nutrition counseling is vital in guiding a patient and family through the initial stages of recovery. As the nutrition therapist is working at increasing the patient's caloric intake, a practitioner needs to monitor the patient's weight and vital signs. Often activity level needs to be decreased to help reverse the catabolic state. A reasonable weight gain goal may be 0.2–0.5 kg/wk. If weight loss persists, careful monitoring of vital signs, including supine heart rate, is important in determining whether an increased level of care is needed. Concomitantly, the patient should be referred to a psychotherapist, and if indicated, assessed by a psychiatrist.

BULIMIA NERVOSA

Table 5–6 lists the diagnostic criteria for BN. Binge eating is either eating excessive amounts of food during a normal mealtime or having a meal that lasts longer than usual. Bulimic individuals feel out of control while eating, unable or unwilling to recognize satiety signals. Any type of food may be eaten in a binge, although typically it is either carbohydrates or junk food. Extreme guilt is often associated with the episode. At some point, either prior to or during a binge, bulimic individuals often decide to purge as a means of preventing weight gain. The most common ways to purge are self-induced vomiting, exercise, and laxative use. Some individuals will vomit multiple times during a purge episode, after using large amounts of water to cleanse their system. This can induce significant electrolyte abnormalities such as hyponatremia and hypokalemia, which may put the patient at acute risk for arrhythmia or seizure. Other methods of purging include diuretics, diet pills, cathartics, and nutritional supplements, including Metabolife.

Diagnosing BN can be difficult unless the teenager is forthcoming or parents or caregivers can supply direct observations. Bulimic patients are usually average or slightly above average in body weight and have no physical abnormalities. Screening all teenagers for body image concerns is crucial. If the teenager

Table 5–6. Diagnostic criteria for bulimia nervosa.

- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
 - (1) eating, in a discrete period of time (eg, within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
 - (2) a sense of lack of control over eating during the episodes (eg, a feeling that one cannot stop eating or control what or how much one is eating).
- B. Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.
- C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months.
- D. Self-evaluation is unduly influenced by body shape and weight.
- E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

Reprinted, with permission, from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. Text Revision. Copyright 2000. American Psychiatric Association.

expresses concern about being overweight, then the clinician needs to screen the patient about dieting methods. Asking whether patients have binged, feel out of control while eating, or whether they cannot stop eating can clarify the diagnosis. Parents may report that significant amounts of food are missing or disappearing more quickly than normal. If the physician is suspicious, direct questioning about all the ways to purge should follow. Indicating first that the behavior is not unusual can make questioning less threatening and more likely to elicit a truthful response. For example, the clinician might say, “Some teenagers who try to lose weight make themselves vomit after eating. Have you ever considered or done that yourself?” (See Table 5–2 for additional screening questions.)

► Clinical Findings

A. Symptoms and Signs

Symptoms are related to the mechanism of purging. GI problems are most prominent. Abdominal pain is common. This can be due to gastroesophageal reflux, as the lower esophageal sphincter is compromised due to repetitive vomiting. Frequent vomiting may result in esophagitis or gastritis, as the mucosa is irritated from increased acid exposure. Early satiety, involuntary vomiting, and complaints of food “coming up” on its own are frequent. Less common but more serious is hematemesis or esophageal rupture. Patients may report diarrhea or constipation, especially if laxatives have been used. Sialadenitis (parotid pain and enlargement) may be caused by frequent vomiting. Erosion of dental enamel results from increased oral acid exposure during vomiting. Because comorbid depression is common in BN, patients may report difficulty sleeping, decreased energy, decreased motivation, and headaches. Lightheadedness or syncope may develop secondary to dehydration.

It is important to note that most purging methods are ineffective. When patients binge, they may consume thousands of calories. Digestion begins rapidly. Although the patient may be able to vomit some of the food, much is actually digested and absorbed. Laxatives work in the large intestine, leading to fluid and electrolyte loss. Consumed calories are still absorbed from the small intestine. Use of diuretics may result in decreased fluid weight and electrolyte imbalance.

On physical examination, bulimic patients may be dehydrated and have orthostatic hypotension. Sialadenitis, tooth enamel loss, dental caries, and abdominal tenderness are the most common findings. Abrasion of the proximal interphalangeal joints may occur secondary to scraping the fingers against teeth while inducing vomiting. Rarely a heart murmur is heard. Irreversible cardiomyopathy can develop secondary to ipecac use. Tachycardia and hypertension may occur secondary to caffeine and diet pill use.

B. Laboratory Findings

Electrolyte disturbances are common in bulimic patients. The method of purging results in specific abnormalities.

Vomiting causes metabolic alkalosis, hypokalemia, and hypochloremia. If laxatives are used, then a metabolic acidosis develops with hypokalemia and hypochloremia. Amylase may be increased secondary to chronic parotid stimulation.

► Complications

A. Short-Term Complications

Complications in normal-weight bulimic patients are related to the mechanisms of purging, and many of these complications are listed under Symptoms and Signs, earlier. If the bulimic patient is significantly malnourished, complications may be the same as those encountered in the anorexic patient. Other complications of bulimia include esophageal rupture, acute or chronic esophagitis, and rarely, Barrett syndrome. Chronic vomiting can lead to metabolic alkalosis, and laxative abuse may cause metabolic acidosis. Patients may develop aspiration pneumonia from vomiting. Diet pill use can cause insomnia, hypertension, tachycardia, palpitations, seizures, and sudden death.

Patients who stop taking laxatives can have severe constipation. Treating constipation can be difficult psychologically, because the practitioner may need to prescribe agents similar to the drugs of abuse used during the eating disorder.

B. Mortality

The mortality rate in bulimic patients is similar to that in anorexic patients. Death usually results from suicide or electrolyte derangements.

► Treatment

Treatment of BN depends on the frequency of bingeing and purging and the severity of biochemical and psychiatric derangement. If K^+ is less than 3.0 mEq/L, inpatient medical admission is warranted. Typically extracellular K^+ is spared at the expense of intracellular K^+ , so a patient may become hypokalemic several days after the serum K^+ concentration appears to be corrected. Usually cessation of purging is sufficient to correct K^+ concentration and is the recommended intervention for K^+ above 3.0 mEq/L. If K^+ is 2.5–2.9 mEq/L, oral supplementation is suggested. If K^+ is less than 2.5 mEq/L, then intravenous therapy is recommended. Supplements can be stopped once K^+ levels are more than 3.5 mEq/L. Total body K^+ can be assumed to be normal when serum K^+ corrects and remains normal 2 days after supplements are stopped. Continued hospitalization depends on the patient’s psychological status.

Many bulimic patients abuse laxatives and may be chronically dehydrated. The renin-angiotensin-aldosterone axis and the antidiuretic hormone level may be elevated to compensate. These systems do not shut down automatically when laxatives are stopped, and fluid retention of up to 10 kg/wk may result. This puts patients at risk for congestive heart failure and can scare them as their weight increases

dramatically. Diuresis often occurs after 7–10 days. Parents and patients should be advised of this possible complication of initial therapy to help maintain their confidence in the care plan.

Another reason to hospitalize bulimic patients is failure of outpatient management. The binge-purge cycle is addictive and can be difficult for patients to interrupt on their own. Hospitalization can offer a forced break from the cycle, allowing patients to normalize their eating, interrupt the addictive behavior, and regain the ability to recognize satiety signals.

Outpatient management can be pursued if patients are medically stable. Cognitive-behavioral therapy is crucial to help bulimic patients understand their disease and to offer suggestions for decreasing bingeing and purging. Nutrition therapy offers patients ways to regulate eating patterns so that they can avoid the need to binge. Medical monitoring should be done to check electrolytes periodically, depending on the purging method used.

SSRIs are generally helpful in treating the binge-purge cycle. Fluoxetine has been studied most extensively; a dose of 60 mg/d is most efficacious in teenagers. Other SSRIs appear to be effective as well and may be used in patients experiencing side effects of fluoxetine. Treatment for gastroesophageal reflux and gastritis should be used when appropriate. The pain and swelling of enlarged parotid glands can be helped by sucking on tart candy and by the application of heat.

BINGE-EATING DISORDER

The diagnostic category of binge-eating disorder was created in DSM-IV. Officially, it is still considered a research diagnosis. Studies show that most adults who have binge-eating disorder (a prevalence of 2–4%) develop symptoms during adolescence. Table 5–7 lists the diagnostic criteria.

► Clinical Findings

A. Symptoms and Signs

Binge-eating disorder most often occurs in overweight or obese individuals. Eighteen percent of such patients report bingeing at least once in the past year. Patients with binge-eating disorder have an increased incidence of depression

Table 5–7. Diagnostic criteria for binge-eating disorder.

- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
 - (1) eating, in a discrete period of time (eg, within any 2-hour period), an amount of food that is definitely larger than most people would eat in a similar period of time under similar circumstances.
 - (2) a sense of lack of control over eating during the episode (eg, a feeling that one cannot stop eating or control what or how much one is eating).
- B. The binge-eating episodes are associated with three (or more) of the following:
 - (1) eating much more rapidly than normal
 - (2) eating until feeling uncomfortably full
 - (3) eating large amounts of food when not feeling physically hungry
 - (4) eating alone because of being embarrassed by how much one is eating
 - (5) feeling disgusted with oneself, depressed, or very guilty after overeating
- C. Marked distress regarding binge eating at present.
- D. The binge eating occurs, on average, at least 2 days a week for 6 months.
- E. The binge eating is not associated with regular use of inappropriate compensatory behaviors (eg, purging, fasting, excessive exercise) and does not occur exclusively during the course of anorexia nervosa or bulimia nervosa.

Reprinted, with permission, from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed, text revision. Copyright 2000. American Psychiatric Association.

and substance abuse. Using the DSM-IV-TR diagnostic criteria as a guide for evaluation, the possibility of binge-eating disorder should be raised for any significantly overweight patient. Specific questionnaires are available for evaluating patients suspected of binge-eating disorder.

B. Laboratory Findings

The clinician should assess causes and complications of obesity, and laboratory evaluation should include thyroid function tests and measurement of cholesterol and triglyceride levels.

Johnson WG et al: Measuring binge eating in adolescents: Adolescent and parent versions of the questionnaire of eating and weight patterns. *Int J Eat Disord* 1999;26:301 [PMID: 10441246].

Schneider M: Bulimia nervosa and binge eating disorder in adolescents. *Adolesc Med State Art Rev* 2003;14:119 [PMID: 12529196].

► Treatment

A combination of cognitive-behavioral therapy and antidepressant medication has been helpful in treating binge-eating disorder in adults. Use of SSRIs for binge-eating

disorder in adolescents has not been studied, but in adults, fluoxetine and citalopram help decrease binge episodes, improve depressive symptoms, and possibly decrease appetite. This evidence suggests that SSRIs in adolescents with binge-eating disorder may be helpful as well.

McElroy SL et al: Citalopram in the treatment of binge-eating disorder: A placebo-controlled trial. *J Clin Psychiatry* 2003;64:807 [PMID: 12934982].

EATING DISORDER NOT OTHERWISE SPECIFIED

An additional DSM-IV-TR diagnostic category is eating disorder not otherwise specified (EDNOS). Patients do not meet all the criteria for either AN or BN, but have features of either or both. Table 5–8 lists the diagnostic criteria. This has become a “catch-all” category and some researchers describe this as an atypical eating disorder or partial syndrome eating disorder. EDNOS is estimated to affect 0.5–14% of the general adolescent population. Careful attention by clinicians to patient concerns about body weight and dieting behavior can provide clues to the diagnosis. Symptoms and sequelae depend on patient behaviors. Some patients with EDNOS will go on to develop full-blown AN or BN, and early recognition and treatment may decrease further complications.

Chamay-Weber C et al: Partial eating disorders among adolescents: A review. *J Adolesc Health* 2005;37:417 [PMID: 16227132].

PROGNOSIS

Outcome in eating disorders, especially AN, has been studied extensively. Unfortunately, most studies have focused on specific inpatient treatment programs, and few have evaluated the less ill patients who do not need hospitalization. About 40–50% of patients receiving treatment recover; 20–30% have intermittent relapses; and 20% have chronic, unremitting illness. As time from initial onset lengthens, the recovery rate decreases and mortality associated with AN and BN increases.

The course of AN often includes significant weight fluctuations over time, and it may be a matter of years until recovery is certain. The course of BN often includes relapses of bingeing and purging, although bulimic patients initially recover faster than do anorexic patients. Up to 50% of anorexic patients may develop bulimia, as well as major psychological complications, including depression, anxiety, and substance abuse disorders. Bulimic patients also develop similar psychological illness but rarely develop anorexia. Long-term medical sequelae, aside from low body weight and amenorrhea, have not been studied in an outcome format, although AN is known to have multiple medical consequences, including osteoporosis and structural brain changes.

It is unclear whether age at onset affects outcome, but shorter length of time between symptom onset and ther-

Table 5–8. Diagnostic criteria for eating disorder not otherwise specified.

- The eating disorder not otherwise specified category is for disorders of eating that do not meet the criteria for any specific eating disorder. Examples include
1. For females, all of the criteria for anorexia nervosa are met except that the individual has regular menses.
 2. All of the criteria for anorexia nervosa are met except that, despite significant weight loss, the individual's current weight is in the normal range.
 3. All of the criteria for bulimia nervosa are met except that the binge eating and inappropriate compensatory mechanisms occur at a frequency of less than twice a week or for a duration of less than 3 months.
 4. The regular use of inappropriate compensatory behavior by an individual of normal body weight after eating small amounts of food (eg, self-induced vomiting after the consumption of two cookies).
 5. Repeatedly chewing and spitting out, but not swallowing, large amounts of food.

Reprinted, with permission, from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed, text revision. Copyright 2000. American Psychiatric Association.

apy tends to improve outcome. Various treatment modalities can be equally effective. Favorable outcomes have been found with brief medical hospitalization and long psychiatric or residential hospitalization. Higher discharge weight seems to improve the initial outcome. It is difficult to compare treatment regimens, because the numbers are small and the type of patient and illness varies between studies. No existing studies compare outpatient to inpatient treatment or the effects of day treatment on recovery.

Binge-eating disorder has been recognized only recently, and outcomes have not been studied. Intervention with an SSRI appears to help the bingeing, but little is known regarding long-term prognosis.

Child & Adolescent Psychiatric Disorders & Psychosocial Aspects of Pediatrics

Brian Stafford, MD, MPH
Jennifer Hagman, MD
Bert Dech, MD

6

Mental illness affects between 14% and 20% of children and adolescents. The prevalence is higher for those juveniles living in poor socioeconomic circumstances. Unfortunately, the shortage of mental health providers, stigma attached to receiving mental health services, chronic underfunding, institutional barriers of the public mental health system, and disparate insurance benefits have contributed to the fact that only 2% of these children are actually seen by mental health specialists. About 75% of children with psychiatric disturbances are seen in primary care settings, and half of all pediatric office visits involve behavioral, psychosocial, or educational concerns. Parents and children often prefer discussing these issues with someone they already know and trust. As a result, primary care physicians are compelled to play an important role in the identification, initiation, management, and coordination of mental health care in children and adolescents.

Despite being strategically positioned as the gatekeeper for identifying these concerns, primary care physicians identify fewer than 20% of children with emotional and behavioral problems during health supervision visits when these concerns are also present. In addition, these problems are not identified when they begin (and are more readily amenable to treatment). This gatekeeper role has become more important over the past decade as advances in mental health awareness and treatment have improved opportunities for early identification and intervention. This role is especially critical since child psychiatry remains an underserved medical specialty, with only 7000 board-certified child and adolescent psychiatrists in the United States. In contrast, the more than 50,000 board-certified pediatricians in the United States are in a unique position to identify issues affecting the emotional health of children and to initiate treatment or referrals to other providers.

Emotional problems that develop during childhood and adolescence can have a significant impact on development and may continue into adulthood; in fact, most “adult” psychiatric disorders have their onset during childhood.

Most disorders do not present as an “all-or-none” phenomenon; rather, they progress from adjustment concerns to perturbations in functioning to significant disturbances and severe disorders. Pediatricians have the capacity to manage emotional problems and behavioral conditions early on, when improvement can be achieved with less intensive interventions. If pediatricians and schools do not appropriately identify mental health problems, provide education about the benefits of intervention, and encourage and initiate intervention, childhood-onset disorders are more likely to persist, cause worsening impairment, and lead to a downward spiral of school and social difficulties, poor employment opportunities, and poverty in adulthood.

Pediatricians and other primary care providers may be the first or sometimes only medical professional in a position to identify a mental health problem. This chapter reviews prevention, surveillance, and screening for mental illness; situations that may arise in the context of such assessments; illnesses that are often diagnosed during childhood or adolescence; current recommendations for interventions and use of psychotropic medications; and indications for referral to mental health professionals.

MODELS OF CARE ENCOMPASSING MENTAL HEALTH IN THE PRIMARY CARE SETTING

Given the many barriers to receiving mental health care, new approaches to providing mental health professional services have been recently explored.

Usual or typical pediatric care of emotional and behavioral problems is related to the comfort level of the individual pediatric provider and available resources. The efficacy of

surveillance in the form of developmentally appropriate anticipatory guidance and counseling is variable; the average time spent is 2.5 minutes. However, as stated earlier, the majority of emotional and behavioral problems are not identified in this model of care. In addition, when they are identified, the logistics of referral can be problematic. Although pediatricians often refer to mental health providers, only 50% of families will actually attend an appointment and the average number of appointments attended is only slightly greater than one. Based on level of comfort and training, the primary clinician in this model is more likely to be responsible for psychiatric medications if prescribed.

Among the technological interventions that can enhance identification of problems and target specific symptoms for assessment is the **Child Health and Interactive Developmental System (CHADIS)** (<http://www.childhealthcare.org>). In this system, parents use a computer kiosk to note their level of concern about various behaviors, which triggers algorithmic interviews for each concern based on psychiatric diagnostic criteria. The CHADIS system provides an electronic worksheet of analyzed results, school communication tools, as well as other resources.

Enhanced care is a model of care in which a pediatric developmental or behavioral specialist is embedded in the clinic, thus making for improved referral and communication and management. This “co-location” creates easier access for patients and improved communication with mental health professionals.

Collaborative care provides high-quality, multidisciplinary and collaborative care through the co-location of educators, consultants, or direct service providers in the clinic. Successful collaborative care results in greater specialist involvement by negating identification and referral and other system-of-care barriers. Successful components include a leadership team, primary clinicians, mental health and developmental specialists, administrators, clinical informatics specialists, and care managers. Collaborative care implies that nearly all visits are done jointly and that mental health professionals are always available for consultation, in contrast to the approach in the enhanced care model, which requires the scheduling of an appointment with a mental health specialist in the practice. These interventions can be accomplished through collaboration among mental health and primary care providers, mental health systems and primary care practices, and in academic settings with interdepartmental collaboration. Typically, philanthropic or other foundation grants are necessary to start a collaborative program so that reimbursement and sustainability concerns can be identified and remedied.

EARLY IDENTIFICATION & PREVENTION OF DEVELOPMENTAL & SOCIOEMOTIONAL PROBLEMS

The role of the primary care pediatrician continues to expand to include public health, mental health, and community concerns. The American Academy of Pediatrics (AAP) Policy Statement on Community Pediatrics addresses the fact that today’s children and families live in a period of rapid social change. In addition, the economic organization of the health care and social service systems in the United States is undergoing profound changes. For many pediatricians, efforts to promote the health of children have been directed at attending to the needs of particular children in a practice setting, on an individual basis, and providing them with a medical home. This approach, in combination with pediatricians’ own personal community interests and commitments, has been dramatically successful. Increasingly, however, the major threats to the health of U.S. children—the new morbidity—arise from problems that cannot be adequately addressed by the practice model alone. These problems include unacceptably high infant mortality rates in certain communities, extraordinary levels of intentional and unintentional injuries, chemical dependency, behavioral and developmental consequences of inappropriate care and experience, family dysfunction, sexually transmitted diseases, unplanned pregnancies and out-of-wedlock births, and lack of a medical home. The Policy Statement concludes that “We must become partners with others, or we will become increasingly irrelevant to the health of children.”

Today’s community pediatrician seeks to provide a far more realistic and complete clinical picture by taking responsibility for all children in a community, providing preventive and curative services, and understanding the determinants and consequences of child health and illness, as well as the effectiveness of services provided.

Bright Futures

The Bright Futures Task Force, a partnership initiated by the Maternal and Child Health Bureau (MCHB) over a decade ago, is a philosophy and approach that is dedicated to the principle that every child deserves to be healthy, and that optimal health involves a trusting relationship between the health professional, the child, the family, and the community. As part of this initiative, *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents* was developed to provide comprehensive health supervision guidelines, including recommendations on immunizations, routine health screenings, and anticipatory guidance. In addition, Bright Futures for Mental Health provides numerous guidelines, tools, and strategies for improving mental health identification, assessment, initiation, management, and coordination.

Surgeon General's National Action Plan

The U.S. Surgeon General also recommends that pediatrics continue to evolve and include lifestyle, health system, and other psychosocial areas. The U.S. Surgeon General's National Action Agenda on Mental Health includes several calls to primary care pediatricians, including the following: engage other professional organizations in educating new frontline providers in various systems (eg, teachers, physicians, nurses, hospital emergency personnel, day care providers, probation officers, and other child health care providers) in child development; equip them with skills to address and enhance children's mental health; and train them to recognize early symptoms of emotional or behavioral problems for proactive intervention. Such training must focus on developmental and cultural differences in cognitive, social, emotional, and behavioral functioning, and understanding these issues in familial and ecological context.

Summary of the Pediatrician's Role

Given these calls for a new pediatric role as the gatekeeper for socioemotional health, the expanding role of the primary care pediatric provider encompasses the following broad categories: identification, assessment, initiation, management, coordination, and collaboration (Table 6–1).

IDENTIFICATION & ASSESSMENT DURING HEALTH MAINTENANCE VISITS

Most families seek help from their primary care providers when they are concerned about a child's health, growth, or development. Historically, the most efficient indicator in eliciting psychosocial problems is the history provided by parents or guardians, and interview and observation of the child. The possible approaches to identification of problems include surveillance, screening, and assessment

Surveillance consists of the following elements: checking in, eliciting concerns, asking open-ended questions, watching and waiting, listening for red flags, identifying risk factors, and monitoring closely over time. Like vital signs, which represent an essential component of the physical evaluation, the essential components of the primary care surveillance for mental health concerns should generally include a review of the youth's general functioning in different aspects of their life. Five questions forming the mnemonic **PSYCH** can be addressed to parents and youth as a surveillance means of uncovering areas of concern.

1. Parent-child interaction: How are things going with you and your parents? Or you and your infant (or toddler)?

Table 6–1. The pediatric primary care provider's role in mental health.

Role	Specific Activities
Identification	Shared family concern Surveillance Screening
Assessment	Interview Assessment tools Comorbid conditions
Initiation	Psychoeducation about condition and treatment options <ul style="list-style-type: none"> • Wait and watch • Refer to mental health for further evaluation • Refer for therapy • Start medication
Management	Monitor condition for improvement Monitor for side effects
Coordination	With social work, therapist, psychologist, or psychiatrist
Collaboration	With mental health service providers With child protection With local schools

2. School: How are things going in school (or day care)? (academically and behaviorally)
3. Youth: How are things going with peer relationships?
4. Casa: How are things going at home? (including siblings, family stresses, and relationship with parents)
5. Happiness: How would you describe your mood?

Many pediatric practices are strapped by lack of continuity and not enough time to do in-depth surveillance. In addition, surveillance is notoriously tied to office and provider characteristics. Given current time constraints for current pediatric visits, and the fact that only 18% of parents reporting elevated behavior problems in children actually told their providers about it, surveillance is currently considered nonoptimal. Although part of the clinical interview with families, surveillance is not, under current Medicaid and insurance reimbursement plans, a separate and billable service, whereas formal screening is.

Screening is the process of using standardized instruments to determine the existence of a problem. Newborn, hearing, vision, and developmental screenings are common in today's pediatric practice. However, the morbidity associated with developmental, emotional, and psychosocial problems requires that socioemotional screening to identify the presence of symptoms of emotional, behavioral, or relationship disorders be performed, as well. Screening tools are brief, easy to use, and can be administered as a questionnaire

or using an interview format. A positive screen warrants a more complete assessment. The use of screening tools can also lead to early identification and interrupt the adjustment-perturbation-disturbance-disorder pathway. Newer methods of eliciting socioemotional and behavior concerns have been developed (see next sections). Helpful information can also be obtained from broad screening checklists and symptom-specific questionnaires (such as depression or anxiety self-report inventories). Questions can be incorporated into the general pediatric office screening forms, or specific questionnaires can be used.

Tools for Mental Health Screening in the Office Setting

Given the low rates of identification of psychosocial problems by pediatric surveillance, the use of standardized screening tools has become standard practice. Typically, broad screeners that elicit information from multiple domains are employed first and are followed by targeted screens to address symptomatology, severity, impairment, and context.

A. General or Broad Screening Tools

1. Strengths and Difficulties Questionnaires (SDQ)—

The SDQ are brief behavioral screening questionnaires targeting patients 3–16 years old. They exist in several versions to meet the needs of researchers, clinicians, and educators. They have been well validated and are available on the Internet without cost. The findings can then influence how the assessment is carried out and which professionals may need to be involved in that assessment. The SDQ are available in over 40 languages. For further information, refer to the following web site: <http://sdqinfo.com>.

Muris P et al: The Strengths and Difficulties Questionnaire (SDQ)—further evidence for its reliability and validity in a community sample of Dutch children and adolescents. *Eur Child Adolesc Psychiatry* 2003;12:1 [PMID: 12601558].

2. Pediatric Symptoms Checklist (PSC)—

The PSC is a one-page questionnaire listing a broad range of children's emotional and behavioral problems that reflects parents' impressions of their children's psychosocial functioning. An adolescent self-report version is also available for children older than age 11 years. The PSC was developed initially for children older than age 5, but cutoff scores for preschool and school-aged children indicating clinical levels of dysfunction have been empirically derived. The questionnaire is easy to score, is free of charge, and is available in English and Spanish from the following web sites: http://brightfutures.org/mentalhealth/pdf/professionals/ped_symptom_chklst.pdf; http://psc.partners.org/psc_order.htm.

Reijneveld SA et al: Use of the Pediatric Symptom Checklist for the detection of psychosocial problems in preventive child health-care. *BMC Public Health* 2006;6:197 [PMID: 16872535].

3. Parents Evaluation of Developmental Status (PEDS)—

The PEDS is a valid screener for socioemotional, developmental, and behavioral issues in children aged 1 month to 8 years. It requires more time to score than other general screening tools and must be purchased. Its benefits include extensive validity data and useful pathways for level of concern and referral. It is available in English, Vietnamese, and Spanish. For further information, see the following web site: <http://www.pedstest.com>.

Brothers KT et al: PEDS: Developmental milestones—an accurate brief tool for surveillance and screening. *Clin Pediatr (Phila.)* 2007; Dec 5 [Epub ahead of print] [PMID: 18057141].

4. Ages and Stages, Socio-Emotional (SE)—

The Ages and Stages, SE is a companion to the Ages and Stages Developmental Screen. It is an easy-to-use tool with a deep, exclusive focus on infant, toddlers, and younger children's social and emotional behavior and is cost-effective, photocopiable, and culturally sensitive for use in pediatric clinics. Screens are available for the 6, 12, 18, 24, 36, 48, and 60 month visits, and in English, French, Spanish, and Korean.

Squires J et al: Revision of a parent-completed developmental screening tool: Ages and Stages Questionnaires. *J Pediatr Psychol* 1997;22:313 [PMID: 9212550].

Ages and Stages, SE (technical data): <http://www.brookespublishing.com/store/books/bricker-asq/asq-technical.pdf>

Assessment of Behavioral & Emotional Signs & Symptoms

When an emotional problem or mental illness is mentioned by the patient or parents, elicited by an interview, or identified by a screening instrument, a thorough evaluation is indicated. At least 30 minutes should be scheduled, and additional appointments may be necessary to gather information or perform tests to clarify a diagnosis. Examples of more thorough questions and observation are given in Table 6–2. Targeted assessment screening tools are also useful in determining severity, comorbidity, and context of impairment.

It is useful to see both parents and the child first together, then the parents alone, and then the child alone. This sequence enables the physician to observe interactions among family members and gives the parents and the child an opportunity to talk confidentially about their concerns. Parents and children often feel shame and guilt about some personal inadequacy they perceive to be causing the problem. The physician can facilitate the assessment by acknowledging that the family is trying to cope and that the ultimate task of assessment is to seek solutions and not to assign blame. An attitude of nonjudgmental inquiry can be communicated with supportive statements such as, “Let’s see if we can figure out what might be happening here and find some ways to make things better.”

---	--

A. History of the Presenting Problem

First, obtain a detailed description of the problem.

- When did it start?
- Were there unusual stresses at that time?
- How are the child's life and the family's functioning affected?
- What does the child say about the problem?
- What attempts have been made to alleviate the problem?
- Do the parents have any opinions about the cause of the problem?

B. Techniques for Interviewing Children and Adolescents

1. Interviewing the preschool child—Preschool children should be interviewed with their parents. As the parents

discuss their concerns, the physician can observe the child's behavior, including their activity level and any unusual behaviors or symptoms. It is helpful to have toy human figures, animals, or puppets, and crayons and paper available that the child can use to express him- or herself. After hearing the history from the parents and observing and talking with the child, the physician can begin to develop an impression about the problem and formulate a treatment plan to discuss with the family.

2. Interviewing the school-aged child—Most school-aged children have mastered separation anxiety sufficiently to tolerate at least a brief interview alone with the physician. In addition, they may have important information to share about their own worries. The child should be told beforehand by the parents or physician (or both) that the doctor will want to talk to the child about his or her feelings. School-

aged children understand and even appreciate parental concern about unhappiness, worries, and difficulty in getting along with people. At the outset, it is useful to explore the child's thoughts about certain issues raised by the parents and ask whether the child thinks that a problem exists (eg, unhappiness, anxiety, or sleep disturbance) and any other concerns the child may have. The physician should ask the child to describe the problem in his or her own words and ask what he or she thinks is causing the problem. It is important to ask the child how the problem affects the child and the family. At the end of the interview with the child, it is important to share or reiterate the central points derived from the interview and to state that the next step is to talk with the parents about ways to make things better for the child. At that time, it is good to discuss any concerns or misgivings the child might have about sharing information with parents so that the child's right to privacy is not arbitrarily violated. Most children want to make things better and thus will allow the physician to share appropriate concerns with the parents.

3. Interviewing the adolescent—The physician usually begins by meeting briefly with the parents and adolescent together to define the concerns. Because the central developmental task of adolescence is to create an identity separate from that of the parents, the physician must show respect for the teen's point of view. The physician should then meet alone with the adolescent. After the physician has interviewed the adolescent and talked further with the parents, he or she should formulate thoughts and recommendations. Whenever possible, it is helpful to discuss these with the adolescent before presenting them to the parents and teen together. The issue of confidentiality must be discussed early in the interview: "What we talk about today is between you and me unless we decide together that someone should know or unless it appears to me that you might be in a potentially dangerous situation."

The interview with the adolescent alone might start with a restatement of the parents' concerns. The teen should be encouraged to describe the situation in his or her own words and say what he or she would like to be different. The physician should ask questions about the adolescent's primary concerns, predominant mood state, relationships with family members, level of satisfaction with school and peer relationships, plans for the future, drug and alcohol use, and sexual activity.

In concluding the interview, the physician should summarize his or her thoughts and develop a plan with the teenager to present to the parents. If teenagers participate in the solution, they are more likely to work with the family to improve the situation. This should include a plan either for further investigation or for ways of dealing with the problem and arranging subsequent appointments with the physician or an appropriate referral to a mental health care provider.

C. Targeted Screening Tools and Assessment Measures

As with broad screening tools, targeted screening tools or assessment instruments can be very valuable in the clinic since they are standardized and allow for the assessment of current symptoms and severity. They can also be useful for following or reassessing a patient's progress after initiation of treatment.

1. Vanderbilt Assessment Scales for Attention-Deficit/Hyperactivity Disorder—These scales are included in the American Academy of Pediatrics/National Initiative for Children's Health Quality (AAP/NICHQ) Attention-Deficit/Hyperactivity Disorder Practitioner's Toolkit, available at: <http://www.nichq.org/resources/toolkit/> or <http://www.schoolpsychiatry.org>.

2. Center for Epidemiologic Scales Depression Scale for Children (CESD-C)—Available at: <http://www.brightfutures.org/mentalhealth/pdf/tools.html>.

3. Self-Report for Childhood Anxiety Related Emotional Disorders (SCARED)—Available at: <http://www.wpic.pitt.edu/research/>.

4. Other tools

A. BRIGHT FUTURES—The Bright Futures Tool Kit has numerous guidelines, tools, and other resources for identifying mental health concerns. Available at: <http://www.brightfutures.org/mentalhealth/pdf/tools.html>.

B. CHADDIS—See earlier discussion of models of health care.

C. DISORDER-SPECIFIC SCREENING TOOLS—Useful tools for evaluating other mental health concerns, such as obsessive-compulsive disorder (OCD), post-traumatic stress disorder (PTSD), and pervasive developmental disorder (PDD), can be found at the following web site: <http://www.schoolpsychiatry.org>.

Diagnostic Formulation & Interpretation of Findings

Diagnosis, the final product of the assessment, starts with a description of the presenting problem, which is then evaluated within the context of the child's age, developmental needs, the stresses and strains on the child and the family, and the functioning of the family system.

The physician's first task is to decide whether a problem exists. For example, how hyperactive must a 5-year-old child be before he or she is too hyperactive? When a child's functioning is impaired in major domains of life, such as learning, peer relationships, family relationships, authority relationships, and recreation, or when a substantial deviation from the trajectory of normal developmental tasks occurs, a differential diagnosis should be sought based on the symptom profile. The physician then develops an etiologic hypothesis based on the information gathered:

1. The behavior falls within the range of normal given the child's developmental level.
2. The behavior is a temperamental variation.
3. The behavior is related to central nervous system impairment (eg, prematurity, exposure to toxins in utero, seizure disorder, or genetic disorders).
4. The behavior is a normal reaction to stressful circumstances (eg, medical illness, change in family structure, or loss of a loved one).
5. The problem is primarily a reflection of family dysfunction (eg, the child is the symptom bearer, scapegoat, or the identified patient for the family).
6. The problem indicates a possible psychiatric disorder.
7. The problem is complicated by an underlying medical condition.
8. Some combination of the above.

Sharing of the diagnosis is also the beginning of initiating treatment. The physician's interpretation of the complaint and diagnosis is then presented to the family. The interpretive process includes the following components:

1. Psychoeducation: an explanation of how the presenting problem or symptom is a reflection of a suspected cause and typical outcomes both with and without intervention.
2. A discussion of possible interventions, including the following options:
 - a. Close monitoring.
 - b. Counseling provided by the primary care provider.
 - c. Referral to a mental health professional.
 - d. Initiation of medication.
 - e. Some combination of the above.
3. A discussion of the parent's and adolescent's response to the diagnosis and potential interventions.

A joint plan involving the physician, parents, and child is then negotiated to address the child's symptoms and developmental needs in light of the family structure and stresses. If an appropriate plan cannot be developed, or if the physician feels that further diagnostic assessment is required, referral to a mental health practitioner should be recommended.

Situations Requiring Emergent or More Extensive Psychiatric Assessment

If there is any concern about the child's safety the provider must also evaluate the risk of danger to self (suicidal attempts or ideation), danger to others (assault, aggression, or homicidal ideation), and screen for other factors that could heighten the risk of danger to self or others, such as physical or sexual abuse or illicit substance use or abuse. The presence of drug or alcohol abuse in adolescent patients may require referral to community resources specializing in the treatment of these addictive disorders.

The following questions should be asked of the youth. The parents should be asked similar questions about what they have observed. Specific details about the circumstances should be asked if any question below is answered with "yes."

1. Have you ever been sad for more than a few days at a time such that it affected your sleep or appetite?
2. Have you ever been so sad that you wished you weren't alive?
3. Have you ever thought of ways of killing yourself or made a suicide attempt?
4. Have you ever thought about killing someone else, or tried to kill someone?
5. Has anyone ever hit you and left marks? (If yes, ask who, when, and under what circumstances, and if it was reported.)
6. Has anyone ever touched your private areas when they weren't supposed to, or in a way that made you feel uncomfortable? (If yes, ask who, when, and under what circumstances, and if it was reported.)
7. Do you use alcohol, tobacco, or illicit drugs? (If yes, ask what, when, with whom, and how much.)

A. Civil Commitment and Involuntary Mental Health "Holds"

If further assessment indicates a need for inpatient hospitalization, it is optimal if the patient and guardian give consent for this care. In a situation in which the guardian is unwilling or unable to give consent for emergency department-based assessment or inpatient hospitalization of a child or adolescent, an involuntary mental health "hold" may become necessary.

The term involuntary mental health "hold" refers to a legal process that can be initiated by physicians, police officers, and certified mental health professionals, that allows the individual to be prevented from leaving the emergency department or hospital for up to 72 hours. This allows the physician to

establish a safe environment and prevent the individual from harming themselves or others, and allows sufficient time to determine if the individual is a risk to him- or herself or others due to mental illness. Each state has laws specifying rules and regulations that must be followed as part of this process. A specific form must be completed and the patient and family informed of their rights. As this involves revoking the civil rights of a patient or their guardian, it is critical to implement the procedure correctly. All physicians should be familiar with their state laws regulating this process.

Although the precise wording and conditions of involuntary mental health holds may vary slightly from state to state, they are generally quite similar. A 72-hour involuntary mental health hold is obtained for the purpose of acute evaluation and determination of the patient's safety when the evaluator elicits sufficient information to confirm a significant risk exists of danger to self or others. Additional criteria for involuntary psychiatric admission include a determination that the patient is "gravely disabled" by virtue of impaired judgment, which renders the patient unable to provide food, clothing, or shelter for him- or herself, or in the case of a child or adolescent, that he or she is unable to eat and perform normal activities of daily living.

B. Circumstances Under Which a Mental Health Hold May Be Discontinued

At any time after a patient's acute admission but within 72 hours, one of three possibilities must be chosen by the physician or psychiatric treatment team.

1. The clinician may determine that the patient is safe for further treatment in a less restrictive setting and may decide to end the 72-hour mental health hold and discharge the patient from the emergency department or the inpatient psychiatric setting. This requires assessment and documentation that the patient is now safe and a physician signature on an order form to discontinue the hold.
2. The patient or his or her guardian may agree to inpatient psychiatric treatment and offer to remain in the hospital as a voluntary psychiatric inpatient. In this case, the mental health hold is discontinued and the patient and guardian sign a request for voluntary mental health treatment.
3. Finally, the clinician and patient or guardian may continue to disagree about the need for inpatient psychiatric treatment. In this case, when the psychiatrist believes the patient continues to be a risk to him- or herself or others or is gravely disabled, the psychiatrist may petition the mental health court to place the patient on a "short term certification" (this is the term in use in Colorado, but other states have different terms and processes) for continued involuntary mental health treatment on an inpatient psychiatric unit by completing the appropriate evaluation and paperwork. In Colorado a short term

certification can remain in effect for up to 90 days or be discontinued at any time at the clinician's discretion or by a judge. Short term certification also mandates that a patient has access to legal representation in the form of his or her own lawyer or, if the patient is unable to afford legal council, a court-appointed attorney. Patients have the right to contest their involuntary commitment in front of a mental health judge. If the case goes to court, the health care providers must also be present at the hearing. It is always preferable to work with the guardian and the patient to obtain informed consent for treatment and to minimize the need for legal proceedings. Figure 6–1 outlines the steps in identifying the need for involuntary mental health treatment.

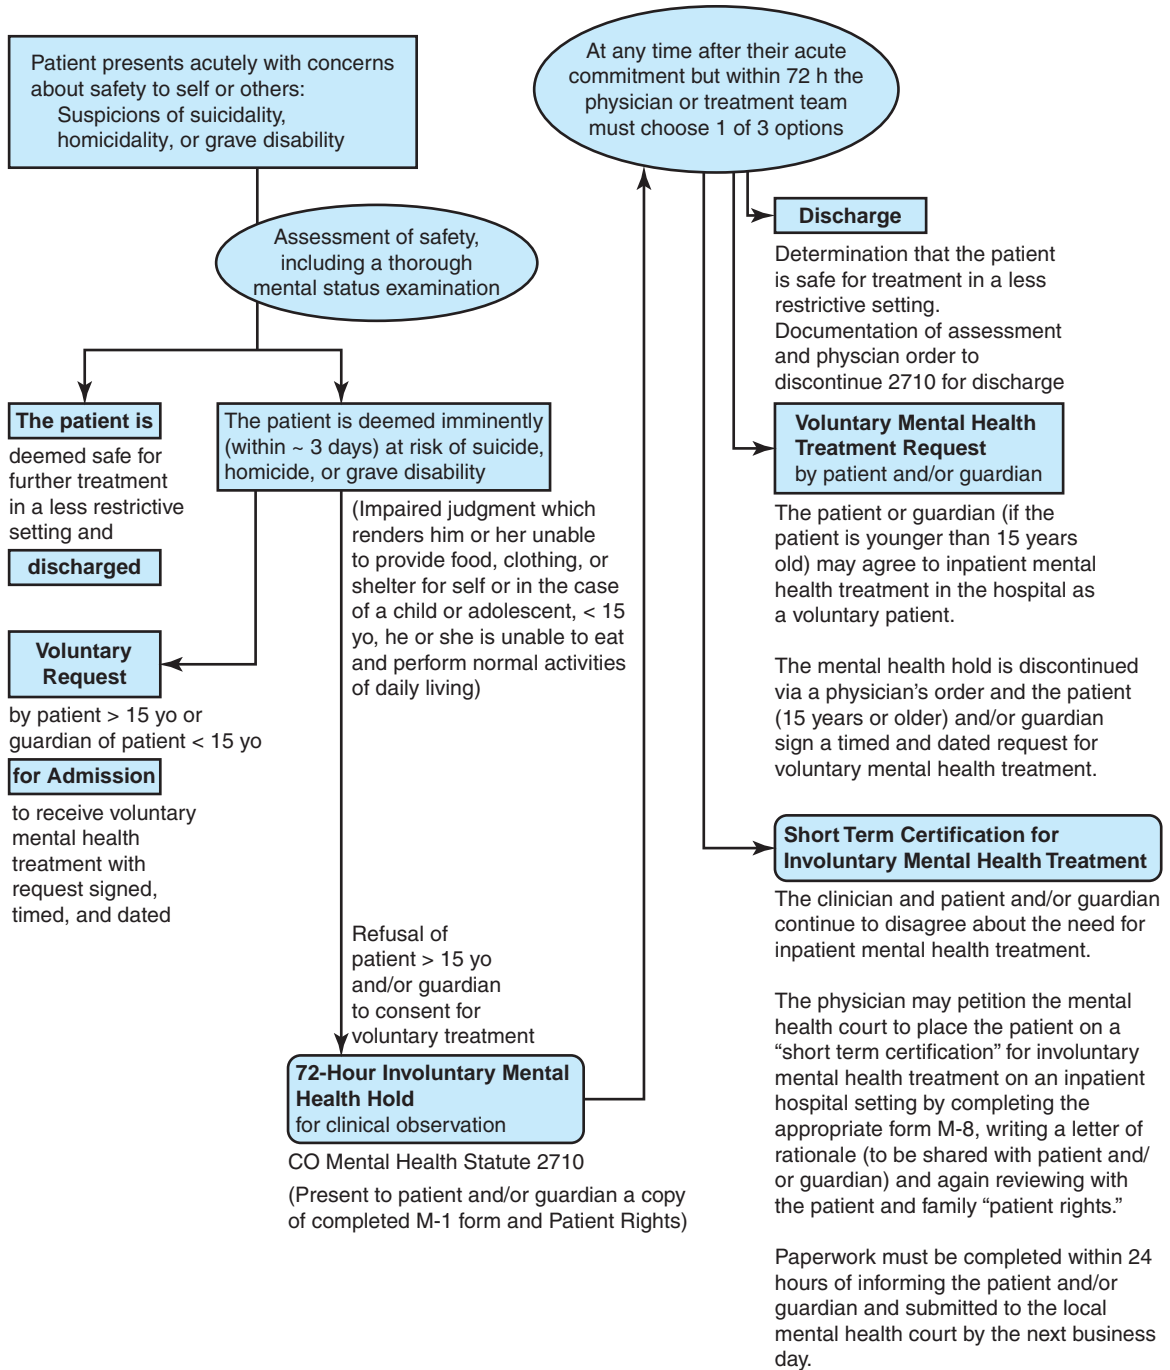

C. Mandatory Reporting of Abuse or Neglect or Threat to Others

Mandatory reporting by a physician of suspicion of physical or sexual abuse or neglect to the local human services agency is discussed in greater detail in Chapter 7. The "Tarasoff Rule" refers to a California legal case that led to a "duty to warn": Physicians are mandated to warn potential victims of harm when plans are disclosed to them about serious threats to harm specific individuals. Documentation of a phone call and registered letter to the individual being threatened are mandated. Under such circumstances, arrangement for the involuntary civil commitment of the potential perpetrator of harm is likely to be in order as well.

D. Referral of Patients to Mental Health Care Professionals

Primary care physicians often refer patients to a child and adolescent psychiatrist or other qualified child mental health professional when the diagnosis or treatment plan is uncertain, or when medication is indicated and the pediatrician prefers that a specialist initiate or manage treatment of the mental illness (Table 6–3). For academic difficulties not associated with behavioral difficulties, a child or educational psychologist may be most helpful in assessing patients for learning disorders and potential remediation. For cognitive difficulties associated with head trauma, epilepsy, or brain tumors, a referral to a pediatric neuropsychologist may be indicated.

Patients with private mental health insurance need to contact their insurance company for a list of local mental health professionals trained in the assessment and treatment of children and adolescents who are on their insurance panel. Patients with Medicaid or without mental health insurance coverage can usually be assessed and treated at their local mental health care center. The referring pediatrician or staff should assist the family by providing information to put them in touch with the appropriate services. Personal relationships with community mental health administrators and clinicians improve the success of referrals. Additionally, new delivery systems in which mental

▲ **Figure 6-1.** Steps in the process of civil commitment and involuntary mental health treatment in Colorado.

Table 6-3. When to consider consultation or referral to a child and adolescent psychiatrist.

<p>The diagnosis is not clear</p> <p>The pediatrician feels that further assessment is needed</p> <p>The pediatrician believes medication may be needed, but will not be prescribing it</p> <p>The pediatrician has started medications and needs further psychopharmacologic consultation</p> <p>Individual, family, or group psychotherapy is needed</p> <p>Psychotic symptoms (hallucinations, paranoia) are present</p> <p>Bipolar affective disorder is suspected</p> <p>Chronic medical regimen nonadherence has a risk of lethality</p> <p>Delirium is suspected</p>

health professionals are “co-located” in the clinic remove barriers and improve access and care (see earlier discussion).

Pediatricians who feel comfortable implementing the recommendations of a mental health professional with whom they have a collaborative relationship should consider remaining involved in the management and coordination of treatment of mental illness in their patients. The local branches of the American Academy of Child and Adolescent Psychiatry and the American Psychological Association should be able to provide a list of mental health professionals who are trained in the evaluation and treatment of children and adolescents.

CONSULTATION-LIAISON PSYCHIATRY

The field of consultation-liaison psychiatry was developed to address the need for mental health assessment and intervention of medically hospitalized pediatric patients. Psychiatric consultation on the medical floor and in the intensive care units can be complex and often requires assessment and intervention beyond the individual patient. The psychiatric consultation, in addition to evaluating the patient’s symptom presentation, should also include assessment of family dynamics as related to the patient, and may include evaluation of how the medical team is addressing care of the patient and family. The psychiatric consultation focuses on the various hierarchies related to the interaction of the patient and staff, or staff and staff, in addition to the patient per se; this evaluation can be quite enlightening and may lead to more productive interventions.

When requesting a psychiatric consultation, as with any medical specialty it is critical that the concern and focus of the consultation request be as specific as possible. Psychiatric consultation on the medical floor is often requested when the patient’s emotional state is affecting his or her response to medical care, or when an underlying mental illness may be contributing to the presenting symptoms. Patients admitted to the intensive care unit or a medical floor after a suicide attempt or supposed unintentional overdose should be evaluated by a psychiatric consultant before discharge.

Another common reason for requesting a psychiatric consultation on the medical floor is change in mental status. Be alert to the likelihood that acute mental status changes in the medical setting can represent delirium, as this has significant assessment and treatment implications. Delirium is defined as an acute and fluctuating disturbance of the sensorium (ie, alertness and orientation). Delirium can be manifested by a variety of psychiatric symptoms including paranoia, hallucinations, anxiety, and mood disturbances. However, aside from dementia and possibly dissociation and malingering, primary psychiatric presentations do not typically involve disturbances of alertness and orientation that are always present in delirium.

THE CHRONICALLY ILL CHILD

Advances in the treatment of pediatric and adolescent illness have transformed several previously fatal conditions into life-threatening but potentially survivable conditions. These include advances in the fields of neonatal medicine, cardiac surgery, and hematology-oncology, including bone marrow transplantation. Additionally, solid organ transplantation, including heart, liver, kidney, and lung, among others, has revolutionized the potential treatment options for a whole host of once-fatal illnesses.

However, the intensity of treatment can in itself be highly stressful and even traumatic physically, financially, and psychologically, for children as well as their parents and siblings. Survivors are at risk of long-term medical and psychological sequelae. Those who are fortunate enough to survive the initial treatment of a potentially life-threatening condition often exchange a life-threatening biologic illness for a chronic emotional condition.

Phase-Oriented Intervention

Psychosocial interventions should vary depending on the developmental level of the patient, siblings, and family, and the phase of the illness. A first crisis is dealt with differently than interventions made during a long course of illness, or a period of stabilization or remission. With this in mind, the Organ Procurement and Transplantation Network/United Network for Organ Sharing established new by-laws in August 2004 which set minimum requirements for the psychosocial services available as part of an accredited solid organ transplant program. Included in these guidelines is the establishment of a team comprising a transplantation psychiatrist, psychologist, nurse practitioner, and psychiatric social worker. Additional guidelines include a formal psychiatric and substance abuse evaluation of prospective transplantation candidates as well as evaluation of any potential renal or hepatic living donors. These guidelines include the availability of individual supportive counseling, crisis intervention, support groups, and death, dying, and bereavement counseling to transplantation patients and their families.

Reactions to Chronic Physical or Mental Illness & Disability

Between 5% and 10% of individuals experience a prolonged period of medical illness or disability during childhood and another 5–10% experience the onset of mental illness in childhood. The psychosocial effects for the child and the family are often profound. Although the specific effect of illness on children and their families depends on the characteristics of the illness, the age of the child, and premorbid functioning, it can be expected that both the child and the parents will go through stages toward eventual acceptance of the disease state. It may take months for a family to accept the diagnosis, to cope with the stresses, and to resume normal life to the extent possible. These stages resemble those that follow the loss of a loved one. If anxiety and guilt remain prominent within the family, a pattern of overprotection can evolve. Likewise, when the illness is not accepted as a reality to be dealt with, a pattern of denial may become prominent. The clinical manifestations of these patterns of behavior are presented in Table 6–4.

Children are very observant and intuitive when it comes to understanding their illness and its general prognosis. At the same time, their primary concerns usually are the effects of the illness on everyday life, feeling sick, and limitations on normal activities. Children are also keenly aware of the family's reactions and may be reluctant to bring up issues they know are upsetting to their parents. Whenever possible, parents should be encouraged to discuss the child's illness and to answer questions openly and honestly, including exploration of the child's fears and fantasies. Such interactions promote closeness and relieve the child's sense of isolation. Even with these active attempts to promote effective sharing between the child and the family, ill children frequently experience fear, anxiety, irritability, and anger over their illness, and guilt over causing family distress. Sleep disturbances, tears, and clinging, dependent behavior are not infrequent or abnormal. Parents frequently need support in an individual or group format to help them cope with the diagnosis and stress caused by the disease, its treatments, and its affect on the afflicted child and other family members.

The Vicious Cycle of Disease Empowerment

Submission to the power of illness, resulting, for example, in staying in bed longer than strictly necessary or withdrawing from friends and family, reduces a variety of opportunities to experience normal life. When reinforced by further relapses, increased helplessness and apprehension about symptoms raise the idea that symptoms and relapse strike unpredictably and cannot be influenced by the patient. Consequently, the patient experiences an increase in fear of illness and a reduction of activity because it can be interrupted at any time by unpredictable relapse. This submission to fear of illness by waiting for relapse reinforces the status of the

Table 6–4. Patterns of coping with chronic illness.

Overprotection
Persistent anxiety or guilt
Few friends and peer activities
Poor school attendance
Overconcern with somatic symptoms
Secondary gain from the illness
Effective coping
Realistic acceptance of limits imposed by illness
Normalization of daily activities with peers, play, and school
Denial
Lack of acceptance of the illness
Poor medical compliance
Risk-taking behaviors
Lack of parental follow-through with medical instructions
General pattern of acting-out behavior

chronically ill with increased helplessness. Both cycles result in lowering of self-esteem and disempowerment.

Families of chronically ill patients sometimes continue to use the same behavior and strategies, favoring rigidity and predictable long-standing habits. Although such rigidity is constraining, families often consider change as being unsafe. Past, present, and future collapse into a timeless dimension under the tyranny of illness. Rituals and metaphors serve the purpose of introducing distinctions in time. Rituals have always been used to demarcate different phases in life and to celebrate significant moments. Introducing different rituals that are consistent with family growth and helping the family to seek out their developmental priorities can represent an important intervention.

Discussions and interventions that take into account both emotional and medical symptoms will help the child and family better understand their experiences and attitude toward illness and life. The family and child will benefit from discussions about such questions as “What is the real nature of this illness? Why has it affected us? What will be our future? What does the treatment do to me?” Such discussions can be quite enlightening and empowering, as they encourage open discussion for the child and parents and an active role in treatment.

Patient-reported and parent-reported outcome tools, known either as Health Status or Health Related Quality of Life (HRQOL) measures, can also be routinely used in pediatric specialty clinics. These measures adopt the World Health Organization's definition of health as “a state of complete physical, mental, and social well-being and not merely the absence of disease.” Health-related quality of life refers to the subjective and objective impact of dysfunction associated with an illness or injury and is multidimensional, including four core domains: disease state and physical symptoms, functional status, psychological functioning, and social functioning. A team approach is often necessary when providing care to complex and chronically ill children. Including these measures during annual visits and incorpo-

rating a mental health professional on the team can improve overall adjustment and quality of care.

THE TERMINALLY ILL CHILD

The diagnosis of a potentially fatal illness in a child is a severe blow even to families who have reason to suspect that outcome. The discussion with parents and the child about terminal illness is one of the most difficult tasks for a physician working with children and adolescents. Although parents want and need to know the truth, they are best told in stepwise fashion beginning with temporizing phrases such as “The news is not good” and “This is a life-threatening illness.” The parents’ reactions and questions can then be observed for clues about how much they want to be told at any one time. The physician must also attempt to gauge how much of the information the parents are able to comprehend during the initial discussion and consider involvement of appropriate support services. Some parents may dissociate during the sharing of frightening and overwhelming news, and crucial information may need to be addressed again when the parents are in a less-traumatized and more receptive state. Parents’ reactions may proceed in a grief sequence, including initial shock and disbelief lasting days to weeks, followed by anger, despair, and guilt over weeks to months, and ending in acceptance of the reality of the situation. These responses vary in their expression, intensity, and duration for each member of the family. Even when the illness is cured, some parents may continue to suffer from post-traumatic stress symptoms related to the diagnosis and treatment.

Developmental and phase-oriented perspectives of patients, siblings, parents, and caretakers are reviewed in Table 6–5. Although most children do not fully understand the permanency of death until about age 8, most ill children experience a sense of danger and doom that is associated with death before that age. Even so, the question of whether to tell a child about the fatal nature of a disease should in most cases be answered in the affirmative unless the parents object. When the parents object, this should alert the physician to involve the unit social worker, who can work with the family to ensure their decision is in the best interest of the child. Refusal of the adults to tell the child, especially when the adults themselves are very sad, leads to a conspiracy of silence that increases fear of the unknown in the child and leads to feelings of loneliness and isolation at the time of greatest need. In fact, children who are able to discuss their illness with family members are less depressed, have fewer behavior problems, have higher self-esteem, feel closer to their families, and adapt better to the challenges of their disease and its treatment.

The siblings of dying children are also significantly affected. They may feel neglected and deprived because of the time their parents must spend with the sick child. Anger and jealousy may then give rise to feelings of guilt over having such feelings about their sick sibling. Awareness of the emotional responses, coping abilities, and available

resources for support of other family members can diminish these feelings and make a significant difference in the family’s overall ability to cope with the illness.

After the child dies, the period of bereavement may last for years. Family members may need outside help in dealing with their grief through supportive counseling services or peer-support groups. Bereavement usually does not substantially interfere with overall life functioning for more than 2–3 months. Most parents and siblings are able to return to work and school within a month, although their emotional state and thoughts may continue to be dominated by the loss for some time. When the individual is unable to function in his or her societal and family role beyond this time frame, a diagnosis of complicated bereavement, major depression, post-traumatic stress disorder (PTSD), or adjustment disorder should be considered and appropriate interventions recommended, such as referral for counseling or psychotherapy and possibly antidepressant medication.

Long-Term Coping

The process of coping with a chronic or terminal illness is complex and varies with the dynamics of each individual child and family. Each change in the illness course and each new developmental stage present different challenges for the child and family. It is important for health care providers to continually assess the family’s and child’s needs and coping abilities over time and to provide appropriate support, information, and access to interventions.

Assistance from Health Care Providers

A. Educate the Patient and Family

Children and their families should be given information about the illness, including its course and treatment, at frequent intervals. Factual, open discussions minimize anxieties. The explanation should be comprehensible to all, and time should be set aside for questions and answers. The setting can be created with an invitation such as “Let’s take some time together to review the situation again.”

B. Prepare the Child for Changes and Procedures

The physician should explain, in an age-appropriate manner, what is expected with a new turn in the illness or with upcoming medical procedures. This explanation enables the child to anticipate and in turn to master the new development and promotes trust between the patient and the health care providers.

C. Encourage Normal Activities

The child should attend school and play with peers as much as the illness allows. Individual education plans should be requested from the school if accommodation beyond the regular classroom is necessary. At the same time, parents should be encouraged to apply the same rules of discipline and behavior to the ill child as to the siblings.

Table 6-5. Death and childhood.

	Before		During			After			
	Developmental Concerns		Sudden	Acute	Chronic				
Child									
0-5 y	Ideas on death Abandonment; punishment	Death and stage anxieties Fear of loss of love		Avoidance of pain; need for love	Withdrawal; separation anxiety				
5-10 y	Concepts of inevitability; confusion	Castration anxiety		Guilt (bad), regression, denial	Guilt (religious), regression, denial				
10-15 y	Reality	Control of body and other developmental tasks		Depression; despair for future	Depression; despair, anxiety, anger				
	Sudden	Acute	Chronic			Sudden	Acute	Chronic	
Parents		Anxiety; concern; hopelessness	Premature mourning, guilt, anticipatory grief, reaction formation and displacements, need for information	Disbelief; displaced rage; accelerated grief; prolonged numbness	Desperate concern; denial; guilt	Denial; remorse; resurgence of love	Guilt; mourning	Anger at doctors; need for follow-up, over-idealizing, fantasy loss	Remorse; relief and guilt
Siblings									
0-5 y		Reactions to changes in parents (sense of loss of love and withdrawal)			1. Respond to reaction of parents				
5-10 y		Concern about their implications; fearful for themselves			2. Survivor guilt				
10-15 y		Generally supportive							
Staff	Anxiety; conspiracy of silence		Reaction: withdraw Tasks: 1. Correct distortions (e.g., "Am I safe?"; "Will someone be with me?"; "Will I be helped to feel better?") 2. Comfort parents 3. Allow hope and promote feeling of actively coping 4. Protect dignity of patient			Need for aftercare of survivors; autopsy request tactful; accurate information regarding disposal of body; delay billing

D. Encourage Compensatory Activities, Interests, and Skill Development

Children who experience disability or interruption of their usual activities and interests should be encouraged to explore new interests, and the family should be supported in adapting the child's interests for their situation, and in presenting new opportunities.

E. Promote Self-Reliance

Children often feel helpless when others must do things for them, or assist with their daily needs. The health care provider should guide and encourage parents in helping ill children assume responsibility for some aspects of their medical care and continue to experience age-appropriate independence and skills whenever possible.

F. Periodically Review Family Coping

Families are often so immersed in the crisis of their child's illness that they neglect their own needs or the needs of other family members. From time to time, the physician should ask "How is everyone doing?" The feelings of the patient, the parents, and other children in the family are explored. Parents should be encouraged to stay in touch with people in their support system, and to encourage their children in such efforts as well. Feelings of fear, guilt, anger, and grief should be monitored and discussed as normal reactions to difficult circumstances. If these experiences are interfering with the family's functioning, involvement of the pediatric social worker or a therapist can be helpful.

Appropriate lay support groups for the patient and family should be recommended. Many hospitals have such groups, and hospital social workers can facilitate participation for the patient and family.

PSYCHIATRIC DISORDERS OF CHILDHOOD & ADOLESCENCE

A psychiatric disorder is defined as a characteristic cluster of signs and symptoms (emotions, behaviors, thought patterns, and mood states) that are associated with subjective distress or maladaptive behavior. This definition presumes that the individual's symptoms are of such intensity, persistence, and duration that the ability to adapt to life's challenges is compromised.

Psychiatric disorders have their origins in neurobiologic, genetic, psychological (life experience), or environmental sources. The neurobiology of childhood disorders is one of the most active areas of investigation in child and adolescent psychiatry. Although much remains to be clarified, data from genetic studies point to heritable transmission of attention-deficit/hyperactivity disorder (ADHD), schizophrenia, mood and anxiety disorders, eating disorders, pervasive developmental disorders, learning disorders, and tic disorders, among others. About 3–5% of children and 10–15% of adolescents will experience psychiatric disorders.

The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)* is the formal reference text for psychiatric disorders and includes the criteria for each of the mental illnesses, including those that begin in childhood and adolescence. Psychiatric diagnoses are given on five axes to allow the physician to address the developmental, medical, psychosocial, and overall adaptive issues that contribute to the primary diagnosis on axis I or II.

Axis I: Clinical disorders

Axis II: Personality disorders, mental retardation, learning disabilities

Axis III: General medical conditions

Axis IV: Psychosocial and environmental problems

Axis V: Global assessment of functioning (on a scale of 0–100, with 100% being the highest level of functioning)

Unfortunately, available mental health classification systems are infrequently used in pediatric primary care settings since they address the more severe and extensive conditions. As previously stated, primary care providers frequently see a spectrum of disturbances in their clinical practice, many not achieving full DSM-IV-TR criteria. In order to combat the fact that current nosologies do not provide enough detail about common problems and situations that primary care pediatric providers come across, the AAP and the American Psychiatric Association (APA) collaboratively developed the DSM-IV Primary Care (DSM-PC), including a child and adolescent version. The key assumptions of the DSM-PC (C&A) are based on the fact that children's environments have an impact on their mental health, and that children demonstrate a continuum of symptoms from normality to severe disorders. The DSM-PC is compatible with the DSM-IV-TR, is clear and concise, and is available for research testing and subsequent refinement. It is organized into sec-

tions covering environmental situations, child manifestations, and severity (Table 6–6). Categories of the major environmental factors that may affect a child, ranging from economic issues to family violence, are described and given V codes. Specific behavioral manifestations are listed under broad groupings and include complaints, definitions, symptoms, differential diagnosis, developmental variation, and etiology. Severity, in the DSM-PC, has several dimensions including symptoms, functioning, burden of suffering, and risk and protective factors. The DSM-PC has a great deal of promise, not only as a mechanism to classify the complexities of children’s behavior problems, but also as a mechanism for the future to facilitate financial reimbursement for early identification of and intervention for children’s behavioral problems. Pediatricians should find this manual to be a valuable tool in the care of children and their families.

The descriptions of disorders in this chapter follow the DSM-IV-TR nosology rather than the DSM-PC criteria. Pediatricians are encouraged to become familiar with the DSM-PC, perhaps mastering one section at a time. A revised DSM-PC is being developed.

PERVASIVE DEVELOPMENTAL DISORDERS & AUTISM

Pervasive developmental disorders (PDDs) and childhood autism are early-onset, severe neuropsychiatric disorders that were once referred to as childhood psychoses. PDDs (including autistic disorder) are now distinguished from childhood schizophrenia on the basis of clinical differences and family histories. The term *pervasive developmental disorder* denotes a group of disorders with the common findings of impairment of socialization skills and characteristic behavioral abnormalities (Table 6–7). Speech and language deficits are common as well.

1. Autistic Disorder

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Severe deficits in social responsiveness and interpersonal relationships.
- ▶ Abnormal speech and language development.
- ▶ Behavioral peculiarities such as ritualized, repetitive, or stereotyped behaviors; rigidity; and poverty of age-typical interests and activities.
- ▶ Onset in infancy or early childhood (before age 3 years).

Table 6–6. Areas of focus in the Diagnostic and Statistical Manual, Primary Care (DSM-PC).

DSM-PC Section	Area of Focus
Environmental situations	Challenges to primary support group Changes in caregiving Community or social changes Educational challenges Parent or adolescent occupational challenges Housing challenges Economic challenges Inadequate access to health or mental health services Legal system or crime problem Other environmental situations Health-related situations
Child manifestations	Developmental competencies Impulsive, hyperactive, and inattentive behaviors Negative and antisocial behaviors Substance use and abuse Emotions and moods, and emotional behaviors Somatic behaviors Feeding, eating, and elimination Illness-related behaviors Sexual behaviors Atypical behaviors
Severity of disorder	
Mild	Unlikely to cause serious developmental difficulties or impairment in functioning
Moderate	May cause, or is causing, some developmental difficulties or impairment. Further evaluation and intervention planning are warranted.
Severe	Is causing serious developmental difficulties and dysfunction in one or more key areas of the child’s life. Mental health referral and comprehensive treatment planning are often indicated, possibly on an urgent basis.

▶ General Considerations

Improved identification of autistic disorder has led to earlier interventions as well as confusion about etiology and fear about supposed rising incidence. Autism is more common than was once thought, with an incidence of approximately 16–40 cases per 10,000 school-aged children. More boys than girls are affected (3–4:1). Although the cause of autism is unknown, central nervous system dysfunction is suggested by its higher incidence in populations affected by perinatal disorders: rubella, phenylketonuria, tuberous sclerosis, infantile spasms, encephalitis, and fragile X syndrome. Studies of twins reveal over 90% concordance for autistic disorder in

Table 6-7. Characteristics of pervasive developmental disorders.

Disorder	Age at Onset	Clinical Features
Asperger syndrome	Early childhood	“Odd” individuals (probably more common in males) with normal intelligence, motor clumsiness, eccentric interests, and a limited ability to appreciate social nuances
Childhood disintegrative disorder	3–4 y	Profound deterioration to severe autistic disorder
Pervasive developmental disorder	Early childhood	Two to three times more common than autistic disorder, with similar but less severe symptoms
Rett syndrome	5 mo–4 y	Females with reduced head circumference and loss of social relatedness who develop stereotyped hand movements and have impaired language and mental functioning
Autistic disorder	Before age 1 y	Severe deficit in social interaction, poor language development, abnormal eating and sleeping patterns.

monozygotic twins compared with 24% in dizygotic twins. Twenty-five percent of families with an autistic child have other family members with language-related disorders. Although there has been much debate over the past decade about a possible link between vaccines or dietary factors and the onset of autism spectrum disorders, research studies have not supported these as causal factors.

► Clinical Findings

Severe deficits in reciprocal social interaction (eg, delayed or absent social smile, failure to anticipate interaction with caregivers, and a lack of attention to a primary caregiver’s face) are often evident even in the first year of life. In toddlers, findings include deficiencies in imitative play and a relative lack of interest in interactions with others. Language development is often quite delayed. In fact, children are often first referred for audiologic evaluation because of failure to respond as expected to sounds. When speech does begin to develop, it may be echolalic or nonsensical. Children with

autism often display peculiar interests; bizarre responses to sensory stimuli; repetitive, stereotypical motor behaviors (eg, twirling and hand-flapping); odd posturing; self-injurious behavior; abnormal patterns of eating and sleeping; and unpredictable mood changes. Thematic pretend play is often impaired. An intense preoccupation with an age-unusual interest (eg, power poles) may replace the usual broad range of interests of the child’s age-mates. About 40–60% of children with autism have intelligence quotients (IQs) below 70.

► Differential Diagnosis

A hearing or visual impairment must be ruled out with appropriate screening. Children with developmental speech and language disorders typically show better interpersonal interactions than children with autism. Evaluation should include investigations for metabolic disorders and fragile X syndrome. As stated, early identification usually predicts a better response to treatment. Use of the Ages and Stages and the Ages and Stages-SE will likely improve detection of early language or socioemotional disturbance. A formal screen with the Modified Checklist for Autism in Toddlers (M-CHAT) may help further guide the pediatric provider in making an early referral to appropriate early childhood evaluation services. (See also Chapter 2.)

► Complications

Approximately 30% of individuals with autism develop a seizure disorder, with the onset often occurring during puberty. The onset of puberty can also be associated with worsening of aggression, hyperactivity and self-destructive behaviors. These symptoms, along with the development of a seizure disorder, are more common in individuals who have a low IQ associated with their autism diagnosis. Comorbid psychiatric disorders should be screened for if significant changes in mood and behavior occur. Some adolescents with autism who have higher cognitive skills become distressed and possibly depressed as their awareness of their differences from their peers increases.

► Treatment

Parents and families need strong support as well as education in caring for a child with autism. Early interventions to facilitate the development of reciprocal interactions, language, and social skills are critical. Occupational therapy for sensory integration is also an integral component of the comprehensive assessment. Sensory integration interventions help the family better support the child and adapt the environment to their specific needs.

Behaviorally oriented special education classes or day treatment programs are vital in supporting the development of more appropriate social, linguistic, self-care, and cognitive skills.

No specific medications are available to treat the core symptoms of autistic disorder. Pharmacotherapy is aimed at

reducing specific target symptoms and must be continually assessed and reevaluated for efficacy and side effects. Coexisting diagnoses must be carefully considered. Antipsychotic medications (eg, risperidone, olanzapine, and haloperidol) may modify a variety of disruptive symptoms, including hyperactivity and aggressiveness. Stimulants may improve inattentive or hyperactive symptoms but can sometimes worsen behavior or mood. Antidepressants—especially the selective serotonin reuptake inhibitors (SSRIs)—may benefit both mood symptoms and symptoms of excessive rigidity or obsessive behavior. Mood stabilizers may diminish irritability, mood swings, or episodic dyscontrol. Naltrexone may help control severe self-injurious behavior or stereotypes. Controlled studies do not support the use of secretin or chelation therapy for autism.

► Prognosis

Autism is a lifelong disorder. The best prognosis is for children who have normal intelligence and have developed symbolic language skills by age 5 years. Individuals with autism may not be able to live independently and may require significant support and supervision throughout their lives. Approximately one-sixth of children with autism become gainfully employed as adults, and another one-sixth are able to function in sheltered workshops or special work and school environments. Placement in specialized residential homes or programs may be necessary for some individuals whose guardians are unable to meet their special needs or provide a secure and safe home environment.

2. Nonautistic Pervasive Developmental Disorders

These disorders comprise Asperger syndrome, childhood disintegrative disorder, pervasive developmental disorder

not otherwise specified (PDD-NOS), and Rett syndrome (see Table 6–7).

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Substantial social impairment, either primary or representing a loss of previously acquired social skills.
- Abnormalities in speech and language development or behavior resembling autistic disorder.
- Onset by early childhood (may be as late as age 9 years in childhood disintegrative disorder).

► General Considerations

Children with nonautistic PDDs display a wide range of deficits in social, language, and behavioral skills that are similar to those in children with autistic disorder. However, these children deviate from the clinical profile for autistic disorder by failing to meet all the necessary diagnostic criteria, by failing to fulfill the severity threshold (ie, milder functional impairment), by manifesting atypical symptomatology (eg, the characteristic hand-wringing or gender distribution [female] in Rett syndrome), or by experiencing onset at a later age. In the past, many of these children would have been classified in the group manifesting so-called atypical development. Children with nonautistic PDDs probably outnumber autistic children by as much as 2–3:1. The majority of Rett syndrome cases are now known to be due to a mutation in the *MECP2*, an X-linked gene.

► Differential Diagnosis

Specific developmental speech and language disorders should be distinguished. Hearing impairment should be ruled out with appropriate screening.

► Treatment

The backbone of treatment for Asperger syndrome and PDD-NOS is a cognitive-behavioral approach aimed at teaching and reinforcing more appropriate social and language skills and behaviors. Rett syndrome and childhood disintegrative disorder have much worse prognoses and call for multidisciplinary, often milieu-based interventions (as for autistic disorder). Occupational therapy for sensory integration interventions may be helpful. In all cases, family education and support are important.

Children should be screened for the presence of other psychiatric conditions, including mood disorders, obsessive-compulsive disorder (OCD), ADHD, and anxiety disorders, and appropriate interventions should be initiated. Medications may be helpful for treating specific target symptoms as described for autistic disorder.

► Prognosis

These are lifelong disorders. The prognosis is variable depending on the severity of social and language deficits and response to treatment interventions.

MOOD DISORDERS

1. Depression in Children & Adolescents

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Dysphoric mood, mood lability, irritability or depressed appearance, persisting for days to months at a time.
- Characteristic neurovegetative signs and symptoms (changes in sleep, appetite, concentration, and activity levels).
- Suicidal ideation, feeling of hopelessness.

► General Considerations

The incidence of depression in children increases with age, from 1–3% before puberty to around 8% for adolescents. The rate of depression in females approaches adult levels by age 15. The lifetime risk of depression ranges from 10–25% for women and 5–12% for men. The incidence of depression in children is higher when other family members have been affected by depressive disorders. The sex incidence is equal in childhood, but with the onset of puberty the rates of depression for females begin to exceed those for males by 5:1.

► Clinical Findings

Clinical depression can be defined as a persistent state of unhappiness or misery that interferes with pleasure or productivity. The symptom of depression in children and adolescents is as likely to be an irritable mood state accompanied by tantrums or verbal outbursts as it is to be a sad mood. Typically, a child or adolescent with depression begins to look unhappy and may make comments such as “I have no friends,” “Life is boring,” “There is nothing I can do to make things better,” or “I wish I were dead.” A change in behavior patterns usually takes place that includes social isolation, deterioration in schoolwork, loss of interest in usual activities, anger, and irritability. Sleep and appetite patterns commonly change, and the child may complain of tiredness and nonspecific pain such as headaches or stomach aches (Table 6–8).

Table 6–8. Clinical manifestations of depression in children and adolescents.

Depressive Symptom	Clinical Manifestations
Anhedonia	Loss of interest and enthusiasm in play, socializing, school, and usual activities; boredom; loss of pleasure
Dysphoric mood	Tearfulness; sad, downturned expression; unhappiness; slumped posture; quick temper; irritability; anger
Fatigability	Lethargy and tiredness; no play after school
Morbid ideation	Self-deprecating thoughts, statements; thoughts of disaster, abandonment, death, suicide, or hopelessness
Somatic symptoms	Changes in sleep or appetite patterns; difficulty in concentrating; bodily complaints, particularly headache and stomach ache

► Differential Diagnosis

Clinical depression can usually be identified simply by asking about the symptoms. Children are often more accurate than their caregivers in describing their own mood state. When several depressive symptoms cluster together over time, are persistent (2 weeks or more) and cause impairment, a major depressive disorder may be present. When depressive symptoms are of lesser severity but have persisted for 1 year or more, a diagnosis of dysthymic disorder should be considered. Milder symptoms of short duration in response to some stressful life event may be consistent with a diagnosis of adjustment disorder with depressed mood.

The Center for Epidemiologic Study of Depression–Child Version (CESD-C), Child Depression Inventory (CDI), Beck Depression Rating Scale, and Reynolds Adolescent Depression Scale are self-report rating scales that are easily used in primary care to assist in assessment and monitoring response to treatment.

Depression often coexists with other mental illnesses such as ADHD, conduct disorders, anxiety disorders, eating disorders, and substance abuse disorders. Medically ill patients also have an increased incidence of depression. Every child and adolescent with a depressed mood state should be asked directly about suicidal ideation and physical and sexual abuse. Depressed adolescents should also be screened for hypothyroidism and substance abuse.

► Complications

The risk of suicide is the most significant risk associated with depressive episodes. In addition, adolescents are likely to self-medicate their feelings through substance abuse, or indulge in self-injurious behaviors such as cutting or burning themselves (without suicidal intent). School performance usually suffers during a depressive episode, as children are unable to

concentrate or motivate themselves to complete homework or projects. The irritability, isolation, and withdrawal that often result from the depressive episode can lead to loss of peer relationships and tense dynamics within the family.

► Treatment

Treatment includes developing a comprehensive plan to treat the depressive episode and help the family to respond more effectively to the patient's emotional needs. Referrals should always be made for individual and family therapy. Cognitive-behavioral therapy has been shown to effectively improve depressive symptoms in children and adolescents. Cognitive-behavioral therapy includes a focus on building coping skills to change negative thought patterns that predominate in depressive conditions. It also helps the young person to identify, label, and verbalize feelings and misperceptions. In therapy, efforts are also made to resolve conflicts between family members and improve communication skills within the family.

When the symptoms of depression are moderate to severe and persistent, and have begun to interfere with relationships and school performance, antidepressant medications may be indicated (Table 6–9). Mild depressive symptoms often do not require antidepressant medications and may improve with psychotherapy alone. A positive family history of depression increases the risk of early-onset depression in children and adolescents and the chances of a positive response to antidepressant medication. Depression in toddlers and young children is best approached with parent-child relational therapies.

Controversy continues regarding the efficacy and safety of antidepressants in children and adolescents. (See Psychopharmacology section, later.) Following the addition of a “black box warning” for all antidepressants in October 2005, a 20% decrease in prescriptions for those under age 20 was noted with a corresponding 18% increase in suicides. Also supporting treatment is the finding that suicide rates in children and adolescents were lowest in areas of the country that had had the highest rate of SSRI prescriptions. These debates will continue, but best practice is to educate the family and monitor carefully, especially in the first 4 weeks and subsequent 3 months, watching carefully for any increase in suicidal ideation or self-injurious urges, as well as improvement in target symptoms of depression.

► Prognosis

A comprehensive treatment intervention, including psychoeducation for the family, individual and family psychotherapy, medication assessment, and evaluation of school and home environments, often leads to complete remission of depressive symptoms over a 1- to 2-month period. If medications are started and prove effective, they must be continued for 6–9 months after remission of symptoms to prevent relapse. Early-onset depression (before age 15) is associated

Table 6–9. Interventions for the treatment of depression.

Disorder	Interventions	
Adjustment disorder with depressed mood	Refer for psychotherapy	Medications usually not needed
Mild depression	Refer for psychotherapy	Medications may not be needed
Moderate depression	Refer for psychotherapy	Consider antidepressant medication
Severe depression	Refer for psychotherapy	Strongly encourage antidepressant medication

with increased risk of recurrent episodes and the potential need for longer term treatment with antidepressants. Education of the family and child (or adolescent) will help them identify depressive symptoms sooner and limit the severity of future episodes with earlier interventions. Some studies suggest that up to 30% of preadolescents with major depression manifest bipolar disorder at 2-year follow-up. It is important to reassess the child or adolescent with depressive symptoms regularly for at least 6 months and to maintain awareness of the depressive episode in the course of well-child care.

2. Bipolar Affective Disorder

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Periods of abnormally and persistently elevated, expansive, or irritable mood, and heightened levels of energy and activity.
- ▶ Associated symptoms: grandiosity, diminished need for sleep, pressured speech, racing thoughts, impaired judgment.
- ▶ Not caused by prescribed or illicit drugs.

▶ General Considerations

Bipolar affective disorder (previously referred to as manic-depressive disorder) is an episodic mood disorder manifested by alternating periods of mania and major depressive episodes or, less commonly, manic episodes alone. Children and adolescents often exhibit a variable course of mood instability combined with aggressive behavior and impulsivity. At least 20% of bipolar adults experience onset of symptoms before age 20 years. Onset of bipolar disorder before puberty is uncommon; however, symptoms often begin to develop and may be initially diagnosed as ADHD or other disruptive behavior disorders. The lifetime prevalence of bipolar disorder in middle to late adolescence approaches 1%.

▶ Clinical Findings

In about 70% of patients, the first symptoms are primarily those of depression; in the remainder, manic, hypomanic, or mixed states dominate the presentation. Patients with mania display a variable pattern of elevated, expansive, or irritable mood along with rapid speech, high energy levels, difficulty in sustaining concentration, and a decreased need for sleep. The child or adolescent may also have hypersexual behavior, usually in the absence of a history or sexual abuse. (It is critical to rule out abuse, or be aware of abuse factors contributing to the clinical presentation.) Patients often do not acknowledge any problem with their mood or behavior. The clinical picture can be quite dramatic, with florid psychotic symptoms of delusions and hallucinations accompanying extreme hyperactivity and impulsivity. Other illnesses on the bipolar spectrum are bipolar type II, which is characterized by recurrent major depressive episodes alternating with hypomanic episodes (lower intensity manic episodes that do not cause social impairment and do not typically last as long as manic episodes) and cyclothymic

disorder, which is diagnosed when the child or adolescent has had 1 year of hypomanic symptoms alternating with depressive symptoms that do not meet criteria for major depression.

It is also common for individuals diagnosed with bipolar spectrum disorders to have a history of attentional and hyperactivity problems in childhood, and some will have a diagnosis of ADHD as well. ADHD and bipolar disorder are highly comorbid; however, it is also felt that attentional and hyperactivity problems accompanied by mood swings can be an early sign of bipolar disorder before full criteria for the disorder have emerged and clustered together in a specific pattern.

▶ Differential Diagnosis

Differentiating ADHD, bipolar disorder, and major depressive disorder can be a challenge even for the seasoned clinician, and confusion about the validity of the disorder in younger children still exists. The situation is further complicated by the potential for the coexistence of ADHD and mood disorders in the same patient.

A history of the temporal course of symptoms can be most helpful. ADHD is typically a chronic disorder of life-long duration. However, it may not be a problem until the patient enters the classroom setting. Mood disorders are typically characterized by a normal baseline followed by an acute onset of symptoms usually associated with acute sleep, appetite, and behavior changes. If inattentive, hyperactive, or impulsive behavior was not a problem a year ago, it is unlikely to be ADHD. Typically, all of these disorders are quite heritable, so a positive family history for other affected individuals can be enlightening. Successful treatment of relatives can offer guidance for appropriate treatment.

In prepubescent children, mania may be difficult to differentiate from ADHD and other disruptive behavior disorders. In both children and adolescents, preoccupation with violence, decreased need for sleep, impulsivity, poor judgment, intense and prolonged rages or dysphoria, hypersexuality, and some cycling of symptoms suggest bipolar disorder. Table 6–10 further defines points of differentiation between ADHD, conduct disorder, and bipolar disorder.

Physical or sexual abuse and exposure to domestic violence can also cause children to appear mood labile, hyperactive, and aggressive, and PTSD should be considered by reviewing the history for traumatic life events in children with these symptoms. Diagnostic considerations should also include substance abuse disorders, and an acute organic process, especially if the change in personality has been relatively sudden, or is accompanied by other neurologic changes. Individuals with manic psychosis may resemble those with schizophrenia. Psychotic symptoms associated with bipolar disorder should clear with resolution of the mood symptoms, which should also be prominent. Hyperthyroidism should be ruled out. The Young Mania Rating Scale and The Child Mania Rating Scale may be helpful in eliciting concerning symptoms and educating families and patients, and in aiding timely referral to local mental health resources.

Table 6–10. Differentiating behavior disorders.

	ADHD	Conduct Disorder	Bipolar Disorder
School problems	Yes	Yes	Yes
Behavior problems	Yes	Yes	Yes
Defiant attitude	Occasional	Constant	Episodic
Motor restlessness	Constant	May be present	May wax and wane
Impulsivity	Constant	May be present	May wax and wane
Distractibility	Constant	May be present	May wax and wane
Anger expression	Short-lived (minutes)	Plans revenge	Intense rages (minutes to hours)
Thought content	May be immature	Blames others	Morbid or grandiose ideas
Sleep disturbance	May be present	No	May wax and wane
Self-deprecation	Briefly, with criticism	No	Prolonged, with or without suicidal ideation
Obsessed with ideas	No	No	Yes
Hallucinations	No	No	Diagnostic, if present
Family history	May be a history of school problems	May be a history of antisocial behavior	May be a history of mood disorders

ADHD, attention-deficit/hyperactivity disorder.

► Complications

Children and adolescents with bipolar disorder are more likely to be inappropriate or aggressive toward peers and family members. Their symptoms almost always create significant interference with academic learning and peer relationships. The poor judgment associated with manic episodes predisposes to dangerous, impulsive, and sometimes criminal activity. Legal difficulties can arise from impulsive acts, such as excessive spending, and acts of vandalism, theft, or aggression, that are associated with grandiose thoughts. Affective disorders are associated with a 30-fold greater incidence of successful suicide. Substance abuse may be a further complication, often representing an attempt at self-medication for the mood problem.

► Treatment & Prognosis

Most patients with bipolar disorder respond to pharmacotherapy with mood stabilizers, such as lithium, or atypical antipsychotics. The recent data on the mood stabilizers carbamazepine and valproate have been less promising. The atypical neuroleptics are increasingly being used as primary mood stabilizers to treat bipolar disorder as primary agents, and olanzapine, risperidone, quetiapine, aripiprazole, and ziprasidone have been approved by the Food and Drug Administration (FDA) for the treatment of bipolar affective disorder in adults. If the individual is being treated primarily for manic episodes with a non-antipsychotic mood stabilizer (such as lithium) the addition of a neuroleptic medication may be necessary if psychotic symptoms (hallucinations, paranoia, or delusions) or significant aggression is also present. In cases of severe impairment, hospitalization is required to maintain

safety and initiate treatment. Dual use of mood stabilizers and antipsychotics is still used in most settings, although the only approved medication for treatment of acute mania in youth aged 12 and older is lithium. It is often possible to discontinue the antipsychotic after remission of psychotic symptoms, it is usually necessary to continue treatment with a mood stabilizer for at least a year, and longer if the individual has had recurrent episodes. It is not uncommon for the patient to need lifelong medication. Supportive psychotherapy for the patient and family and education about the recurrent nature of the illness are critical. Family therapy should also include improving skills for conflict management and appropriate expression of emotion.

In its adult form, bipolar disorder is an illness with a remitting course of alternating depressive and manic episodes. The time span between episodes can be years or months depending on the severity of illness and ability to comply with medication interventions. In childhood, the symptoms may be more pervasive and not fall into the intermittent episodic pattern until after puberty.

SUICIDE IN CHILDREN & ADOLESCENTS

The suicide rate in young people has remained high for several decades. In 2007, suicide was the third leading cause of death among children and adolescents aged 10–24 years in the United States. The suicide rate among adolescents aged 15–19 years quadrupled from approximately 2.7 to 11.3 per 100,000 since the 1960s. It is estimated that each year, approximately 2 million U.S. adolescents attempt suicide, yet only 700,000 receive medical attention for their attempt. Suicide and homicide rates for children in the United States are two to five times higher than those for the other 25 industrialized countries combined, primarily due to the prevalence of firearms in the United States. For children younger than 10 years old, the rate of completed suicide is low, but from 1980 to 1992 it increased by 120%, from 0.8 to 1.7 per 100,000.

Adolescent girls make three to four times as many suicide attempts as boys of the same age, but the number of completed suicides is three to four times greater in boys. Firearms are the most commonly used method in successful suicides, accounting for 40–60% of cases; hanging, carbon monoxide poisoning, and drug overdoses each account for approximately 10–15% of cases.

Suicide is almost always associated with a psychiatric disorder and should not be viewed as a philosophic choice about life or death or as a predictable response to overwhelming stress. Most commonly it is associated with a mood disorder and the hopelessness that accompanies a severe depressive episode. Suicide rates are higher for Native American and Native Alaskan populations than for white, black, and Latinos/Hispanic populations. Although suicide attempts are more common in individuals with a history of behavior problems and academic difficulties, other suicide victims are high achievers who are temperamentally anxious and perfectionistic and who commit suicide impulsively after a failure or rejection, either real or perceived. Mood disorders (in both sexes, but especially in females), substance abuse disorders (especially in males), and conduct disorders

are commonly diagnosed at psychological autopsy in adolescent suicide victims. Some adolescent suicides reflect an underlying psychotic disorder, with the young person usually committing suicide in response to auditory hallucinations or psychotic delusions.

The vast majority of young people who attempt suicide give some clue to their distress or their tentative plans to commit suicide. Most show signs of dysphoric mood (anger, irritability, anxiety, or depression). Over 60% make comments such as “I wish I were dead” or “I just can’t deal with this any longer” within the 24 hours prior to death. In one study, nearly 70% of subjects experienced a crisis event such as a loss (eg, rejection by a girlfriend or boyfriend), a failure, or an arrest prior to completed suicide.

Assessment of Suicide Risk

Any clinical assessment for depression must include direct questions about suicidal ideation. If a child or adolescent expresses suicidal thinking, the physician must ask if he or she has an active plan. Suicidal ideation accompanied by any plan warrants immediate referral for a psychiatric crisis assessment. This can usually be accomplished at the nearest emergency department.

Assessment of suicide risk calls for a high index of suspicion and a direct interview with the patient and his or her parents or guardians. The highest risk of suicide is among white adolescent boys. High-risk factors include previous suicide attempts, a suicide note, and a viable plan for suicide with the availability of lethal means, close personal exposure to suicide, conduct disorder, and substance abuse. Other risk factors are signs and symptoms of major depression or dysthymia, a family history of suicide, a recent death in the family, and a view of death as a relief from the pain in the patient's life.

Intervention

Suicidal ideation and any suicide attempt must be considered a serious matter. The patient should not be left alone, and the physician should express concern and convey a desire to help. The physician should meet with the patient and the family, both alone and together, and listen carefully to their problems and perceptions. It should be made clear that with the assistance of mental health professionals, solutions can be found.

The majority of patients who express suicidal ideation and all who have made a suicide attempt should be referred for psychiatric evaluation and possible hospitalization. Most providers feel uncomfortable and have little experience in evaluating suicidality and risk. In addition, this evaluation frequently takes considerable time and requires contact with multiple informants. **The physician should err on the side of caution as referral for further assessment is always appropriate when there is concern about suicidal thinking and behavior.**

An evaluation in a psychiatrist's office or the emergency department will help determine level of risk and disposition. If the patient has suicidal ideation without a plan, has a therapist he or she can see the next day, is able to "contract for safety," and the family is able to provide supervision and support, then the evaluating physician can consider sending the patient and family home that day from the office or emergency department without need for hospitalization. If there appears to be potential for suicide as determined by suicidal ideation with a plan, there are no available resources for therapy, and the patient is not able to cooperate with a plan to ensure safety; if the patient is severely depressed or intoxicated; if the family does not appear to be appropriately concerned; or if there are practical limitations on providing supervision and support to ensure safety, the individual should be hospitalized on an inpatient psychiatric unit. **Any decision to send the patient home from the emergency department without hospitalization should be made only after consultation with a mental health expert.** The decision should be based on lessening of the risk of suicide and assurance of the family's ability to follow through with outpatient therapy and provide appropriate support and supervision. Guns, knives, and razor blades should be removed from the home, and as much as possible, access to them outside the home must be denied. Medications and over-the-counter drugs should be kept locked in a safe place with all efforts made to minimize the risk of the patient having access (eg, key kept with a parent, or use of combination lock on the medicine chest). The patient should be restricted from driving for at least the first 24 hours to lessen the chance of impulsive motor vehicle crashes. Instructions and phone numbers for crisis services should be given, and the family must be committed to a plan for mental health treatment.

Suicide prevention efforts include heightened awareness in the community and schools to promote identification of at-risk individuals and increasing access to services, including hotlines and counseling services. Restricting young people's access to firearms is also a critical factor, as firearms are responsible for 85% of deaths due to suicide or homicide in youth in the United States.

Finally, the physician should be aware of his or her own emotional reactions to dealing with suicidal adolescents and their families. Because the assessment can require considerable time and energy, the physician should be on guard against becoming tired, irritable, or angry. The physician should not be afraid of precipitating suicide by direct and frank discussions of suicidal risk. Reviewing difficult cases with colleagues, developing formal or informal relationships with psychiatrists, and attending workshops on assessment and management of depression and suicidal ideation can decrease the anxiety and improve competence for primary care providers.

ADJUSTMENT DISORDERS

The most frequent and most disturbing stresses for children and adolescents are marital discord, separation and divorce, family illness, the loss of a loved one, a change of residence, and for adolescents, peer relationship problems. When faced with stress, children can experience many different symptoms, including changes in mood, changes in behavior, anxiety symptoms, and physical complaints. Key findings for the diagnosis of an adjustment disorder include the following:

- The precipitating event or circumstance is identifiable.
- The symptoms have appeared within 3 months after the occurrence of the stressful event.
- Although the child experiences distress or some functional impairment, the reaction is not severe or disabling.
- The reaction does not persist more than 6 months after the stressor has terminated.

► Differential Diagnosis

When symptoms are a reaction to an identifiable stressor but are severe, persistent, or disabling, depressive disorder, anxiety disorder, and conduct disorders must be considered.

► Treatment

The mainstay of treatment is the physician's genuine empathy and assurance to the parents and the patient that the emotional or behavioral change is a predictable consequence of the stressful event. This validates the child's reaction and encourages the child to talk about the stressful occurrence and its aftermath. Parents are encouraged to help the child with appropriate verbal expression of feelings, while defining boundaries for behavior that prevent the child from feeling out of control.

► Prognosis

The duration of symptoms in adjustment reactions depends on the severity of the stress; the child's personal sensitivity to

stress and vulnerability to anxiety, depression, and other psychiatric disorders; and the available support system.

SCHIZOPHRENIA

The incidence of schizophrenia is about 1 per 10,000 per year. The onset of schizophrenia is typically between the middle to late teens and early 30s, with onset before puberty being relatively rare. Symptoms usually begin after puberty, although a full “psychotic break” may not occur until the young adult years. Childhood onset (before puberty) of psychotic symptoms due to schizophrenia is uncommon and usually indicates a more severe form of the spectrum of schizophrenic disorders. Childhood-onset schizophrenia is more likely to be found in boys.

Schizophrenia is a biologically based disease with a strong genetic component. Other psychotic disorders that may be encountered in childhood or adolescence include schizoaffective disorder and psychosis not otherwise specified (psychosis NOS). Psychosis NOS may be used as a differential diagnosis when psychotic symptoms are present, but the cluster of symptoms is not consistent with a schizophrenia diagnosis.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Delusional thoughts.
- ▶ Disorganized speech (rambling or illogical speech patterns).
- ▶ Disorganized or bizarre behavior.
- ▶ Hallucinations (auditory, visual, tactile, olfactory).
- ▶ Paranoia, ideas of reference.
- ▶ Negative symptoms (ie, flat affect, avolition, alogia).

▶ Clinical Findings

Children and adolescents display many of the symptoms of adult schizophrenia. Hallucinations or delusions, bizarre and morbid thought content, and rambling and illogical speech are typical. Affected individuals tend to withdraw into an internal world of fantasy and may then equate fantasy with external reality. They generally have difficulty with schoolwork and with peer relationships. Adolescents may have a prodromal period of depression prior to the onset of psychotic symptoms. The majority of patients with childhood-onset schizophrenia have had nonspecific psychiatric symptoms or symptoms of delayed development for months or years prior to the onset of their overtly psychotic symptoms.

▶ Differential Diagnosis

Obtaining the family history of mental illness is critical when assessing children and adolescents with psychotic symptoms.

Psychological testing is often helpful in identifying or ruling out psychotic thought processes. Psychotic symptoms in children younger than age 8 years must be differentiated from manifestations of normal vivid fantasy life or abuse-related symptoms. Children with psychotic disorders often have learning disabilities and attention difficulties in addition to disorganized thoughts, delusions, and hallucinations. In psychotic adolescents, mania is differentiated by high levels of energy, excitement, and irritability. Any child or adolescent exhibiting new psychotic symptoms requires a medical evaluation that includes physical and neurologic examinations (including consideration of magnetic resonance imaging and electroencephalogram), drug screening, and metabolic screening for endocrinopathies, Wilson disease, and delirium.

▶ Treatment

The treatment of childhood and adolescent schizophrenia focuses on four main areas: (1) decreasing active psychotic symptoms, (2) supporting development of social and cognitive skills, (3) reducing the risk of relapse of psychotic symptoms, and (4) providing support and education to parents and family members. Antipsychotic medications (neuroleptics) are the primary psychopharmacologic intervention. In addition, a supportive, reality-oriented focus in relationships can help to reduce hallucinations, delusions, and frightening thoughts. A special school or day treatment environment may be necessary depending on the child's or adolescent's ability to tolerate the school day and classroom activities. Support for the family emphasizes the importance of clear, focused communication and an emotionally calm climate in preventing recurrences of overtly psychotic symptoms.

▶ Prognosis

Schizophrenia is a chronic disorder with exacerbations and remissions of psychotic symptoms. It is generally believed that earlier onset (prior to age 13 years), poor premorbid functioning (oddness or eccentricity), and predominance of negative symptoms (withdrawal, apathy, or flat affect) over positive symptoms (hallucinations or paranoia) predict more severe disability, while later age of onset, normal social and school functioning prior to onset, and predominance of positive symptoms are generally associated with better outcomes and life adjustment to the illness.

CONDUCT DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ A persistent pattern of behavior that includes the following:
 - Defiance of authority.
 - Violating the rights of others or society's norms.
 - Aggressive behavior toward persons, animals, or property.

▶ General Considerations

Disorders of conduct affect approximately 9% of males and 2% of females younger than 18 years. This is a very heterogeneous population, and overlap occurs with ADHD, substance abuse, learning disabilities, neuropsychiatric disorders, mood disorders, and family dysfunction. Many of these individuals come from homes where domestic violence, child abuse, drug abuse, shifting parental figures, and poverty are environmental risk factors. Although social learning partly explains this correlation, the genetic heritability of aggressive conduct and antisocial behaviors is currently under investigation.

▶ Clinical Findings

The typical child with conduct disorder is a boy with a turbulent home life and academic difficulties. Defiance of authority, fighting, tantrums, running away, school failure, and destruction of property are common symptoms. With increasing age, fire-setting and theft may occur, followed in adolescence by truancy, vandalism, and substance abuse. Sexual promiscuity, sexual perpetration, and other criminal behaviors may develop. Hyperactive, aggressive, and uncooperative behavior patterns in the preschool and early school years tend to predict conduct disorder in adolescence with a high degree of accuracy, especially when ADHD goes untreated. A history of reactive attachment disorder is an additional childhood risk factor. The risk for conduct disorder increases with inconsistent and severe parental disciplinary techniques, parental alcoholism, and parental antisocial behavior.

▶ Differential Diagnosis

Young people with conduct disorders, especially those with more violent histories, have an increased incidence of neurologic signs and symptoms, psychomotor seizures, psychotic symptoms, mood disorders, ADHD, and learning disabilities. Efforts should be made to identify these associated disorders (see Table 6–10) because they may suggest specific therapeutic interventions. Conduct disorder is best conceptualized as a final common pathway emerging from a variety of underlying psychosocial, genetic, environmental, and neuropsychiatric conditions.

▶ Treatment

Effective treatment can be complicated by the psychosocial problems often found in the lives of children and adolescents with conduct disorders, and the related difficulty achieving compliance with treatment recommendations. Efforts should be made to stabilize the environment and improve functioning within the home, particularly as it relates to parental functioning and disciplinary techniques. Identification of learning disabilities and placement in an optimal school environment is also critical. Any associated neurologic and psychiatric disorders should be addressed.

Residential treatment may be needed for some individuals whose symptoms do not respond to lower level interventions, or whose environment is not able to meet their needs for supervision and structure. It is not unusual for the juvenile justice system to be involved when conduct disorder behaviors lead to illegal activities, theft, or assault.

Medications such as mood stabilizers, neuroleptics, stimulants, and antidepressants have all been studied in youth with conduct disorders, yet none has been found to be consistently effective in this population. Early involvement in programs such as Big Brothers, Big Sisters, scouts, and team sports in which consistent adult mentors and role models interact with youth decreases the chances that the youth with conduct disorders will develop antisocial personality disorder. Multisystemic therapy (MST) is being used increasingly as an intervention for youth with conduct disorders and involvement with the legal system. Multisystemic therapy is an intensive home-based model of care that seeks to stabilize and improve the home environment and to strengthen the support system and coping skills of the individual and family.

▶ Prognosis

The prognosis is based on the ability of the child's support system to mount an effective treatment intervention consistently over time. The prognosis is generally worse for children in whom the disorder presents before age 10 years; those who display a diversity of antisocial behaviors across multiple settings; and those who are raised in an environment characterized by parental antisocial behavior, alcoholism or other substance abuse, and conflict. Nearly half of

individuals with a childhood diagnosis of conduct disorder develop antisocial personality disorder as adults.

1. Oppositional Defiant Disorder

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ A pattern of negativistic, hostile, and defiant behavior lasting at least 6 months.
- ▶ Loses temper, argues with adults, defies rules.
- ▶ Blames others for own mistakes and misbehavior.
- ▶ Angry, easily annoyed, vindictive.
- ▶ Does not meet criteria for conduct disorder.

Oppositional defiant disorder usually is evident before 8 years of age and may be an antecedent to the development of conduct disorder. The symptoms usually first emerge at home, but then extend to school and peer relationships. The disruptive behaviors of oppositional defiant disorder are generally less severe than those associated with conduct disorder and do not include hurting other individuals or animals, destruction of property, or theft.

Oppositional defiant disorder is more common in families in whom caregiver dysfunction is present, and in children with a history of multiple changes in caregivers; inconsistent, harsh, or neglectful parenting; or serious marital discord.

Interventions include careful assessment of the psychosocial situation and recommendations to support parenting skills and optimal caregiver functioning. Assessment for comorbid psychiatric diagnoses such as learning disabilities, depression, and ADHD should be pursued and appropriate interventions recommended.

2. Violent Behavior in Youth

Of particular concern to physicians today, as well as to society at large, is the tragic increase in teen violence, including school shootings. There is strong evidence that screening and initiation of interventions by primary care providers can make a significant difference in violent behavior in youth. Although the prediction of violent behavior remains a difficult and imprecise endeavor, physicians can support and encourage several important prevention efforts.

- The vast majority of the increase in youth violence including suicides and homicides involves the use of firearms. Thus the presence of firearms in the home, the method of storage and safety measures taken when present, and access to firearms outside the home should be explored regularly with all adolescents as part of their routine medical care.
- Violent behavior is often associated with suicidal impulses. In the process of screening for violent behavior, suicidal ideation should not be overlooked. In general, the suicidal youth is somewhat easier to identify than the homicidal youth, and in many cases may be one and the same (see the section on Suicide in Children and Adolescents, earlier). Any comment about wishes to be dead or hopelessness should be taken seriously and help sought.
- Parents and guardians should be aware of their child's school attendance and performance and peer groups. They should know their children's friends and be aware of who they are going out with, where they will be, what they will be doing, and when they will be home. Any concerns should be discussed with the teen and interventions sought if necessary.
- Most students involved in school violence could have benefited from earlier interventions to address problems in social and educational functioning in the school environment. Many communities and school districts have increased their efforts to identify and intervene with students whom teachers, peers, or parents recognize as having difficulty.

ANXIETY DISORDERS

1. Anxiety-Based School Refusal (School Avoidance)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ A persistent pattern of school avoidance related to symptoms of anxiety.
- ▶ Somatic symptoms on school mornings, with symptoms resolving if the child is allowed to remain at home.
- ▶ No organic medical disorder that accounts for the symptoms.
- ▶ High levels of parental anxiety are commonly observed.

▶ General Considerations

Anxiety-based school refusal should be considered if a child presents with a medically unexplained absence from school for more than 2 weeks. Anxiety-based school refusal is a persistent behavioral symptom rather than a diagnostic entity. It refers to a pattern of school nonattendance resulting from anxiety, which may be related to a dread of leaving home (separation anxiety), a fear of some aspect of school, or a fear of feeling exposed or embarrassed at school (social phobia). In all cases, a realistic cause of the fear (eg, an intimidating teacher or a playground bully) should be ruled out. In most cases, anxiety-based school refusal is related to developmentally inappropriate separation anxiety. The incidence between males and females is about equal, and there are peaks of incidence at ages 6–7 years, again at ages 10–11 years, and in early adolescence.

▶ Clinical Findings

In the preadolescent years, school refusal often begins after some precipitating stress in the family. The child's anxiety is then manifested either as somatic symptoms or in displacement of anxiety onto some aspect of the school environment. The somatic manifestations of anxiety include dizziness, nausea,

and stomach distress. Characteristically, the symptoms become more severe as the time to leave for school approaches and then remit if the child is allowed to remain at home for the day. In older children, the onset is more insidious and often associated with social withdrawal and depression. The incidence of anxiety and mood disorders is increased in these families.

▶ Differential Diagnosis

The differential diagnosis of school nonattendance is presented in Table 6–11. Medical disorders that may be causing the somatic symptoms must be ruled out. Children with learning disorders may wish to stay home to avoid the sense of failure they experience at school. Children may also have transient episodes of wanting to stay at home during times of significant family stress or loss. The onset of school avoidance in middle or late adolescence may be related to the onset of schizophrenia. Children who are avoiding school for reasons related to oppositional defiant disorder or conduct disorder can be differentiated on the basis of their chronic noncompliance with adult authority and their preference for being with peers rather than at home.

▶ Complications

The longer a child remains out of school, the more difficult it is to return and the more strained the relationship between

Table 6-11. Differential diagnosis of school nonattendance.^a

I. Emotional or anxiety-based refusal^b
A. Separation anxiety disorder (50–80% of anxious refusers)
B. Generalized anxiety disorder
C. Mood or depressive disorder (with or without combined anxiety)
D. Social phobia
E. Specific phobia
F. Panic disorder
G. Psychosis
II. Truancy^c behavior disorders
A. Oppositional defiant disorder, conduct disorder
B. Substance abuse disorders
III. Situation-specific school refusal
A. Learning disability, unaddressed or undetected
B. Bullying or gang threat
C. Psychologically abusive teacher
D. Family-sanctioned nonattendance
1. For companionship
2. For child care
3. To care for the parent (role-reversal)
4. To supplement family income
E. Socioculturally sanctioned nonattendance (school is not valued)
F. Gender concerns
IV. Undiagnosed medical condition (including pregnancy)

^aMedically unexplained absence of more than 2 weeks.

^bSubjectively distressed child who generally stays at home.

^cNonsubjectively distressed and not at home.

child and parent becomes. Many parents of nonattending children feel tyrannized by their defiant, clinging child. Children often feel accused of making up their symptoms, leading to further antagonism between the child, parents, and medical caregivers.

► Treatment

Once the comorbid diagnoses and situations related to school avoidance or refusal have been identified and interventions begun (ie, educational assessment if learning disabilities are suspected, medication if necessary for depression or anxiety, or addressing problems in the home), the goal of treatment is to help the child confront anxiety and overcome it by returning to school. This requires a strong alliance between the parents and the health care provider. The parent must understand that no underlying medical disorder exists, that the child's symptoms are a manifestation of anxiety, and that the basic problem is anxiety that must be faced to be overcome. Parents must be reminded that being good parents in this case means helping a child cope with a distressing experience. Children must be reassured that their symptoms are caused by worry and that they will be overcome on return to school.

A plan for returning the child to school is then developed with parents and school personnel. Firm insistence on full compliance with this plan is essential. The child is brought to school by someone not likely to give in, such as the father or an older sibling. If symptoms develop at school, the child should be checked by the school nurse and then returned to class after a brief rest. The parents must be reassured that school staff will handle the situation at school and that school personnel can reach the primary health care provider if any questions arise.

If these interventions are ineffective, increased involvement of a therapist and consideration of a day treatment program may be necessary. For children with persistent symptoms of separation that do not improve with behavioral interventions, medications such as SSRIs should be considered. Comorbid diagnoses of panic disorder, generalized anxiety disorder, or major depression should be carefully screened for, and if identified, treated appropriately.

► Prognosis

The vast majority of preadolescent children improve significantly with behavioral interventions and return to school. The prognosis is worsened by the length of time the child remains out of school. Long-term outcomes are influenced by comorbid diagnoses and responsiveness to behavioral or medication interventions. A history of school refusal is more common in adults with panic and anxiety disorders and agoraphobia than in the general population.

Connolly SD, Bernstein GA; Work Group on Quality Issues: Practice parameter for the assessment and treatment of children and adolescents with anxiety disorders. *J Am Acad Child Adolesc Psychiatry* 2007;46:267 [PMID: 17242630].

Table 6–12. Signs and symptoms of anxiety in children.

Psychological

- Fears and worries
- Increased dependence on home and parents
- Avoidance of anxiety-producing stimuli
- Decreased school performance
- Increased self-doubt and irritability
- Frightening themes in play and fantasy

Psychomotor

- Motoric restlessness and hyperactivity
- Sleep disturbances
- Decreased concentration
- Ritualistic behaviors (eg, washing, counting)

Psychophysiological

- Autonomic hyperarousal
- Dizziness and lightheadedness
- Palpitations
- Shortness of breath
- Flushing, sweating, dry mouth
- Nausea and vomiting
- Panic
- Headaches and stomach aches

Masi G et al: Separation anxiety disorder in children and adolescents: Epidemiology, diagnosis, and management. *CNS Drugs* 2001;15:93 [PMID: 11460893].

2. Generalized Anxiety Disorder & Panic Disorder

Anxiety can be manifested either directly or indirectly, as shown in Table 6–12. The characteristics of anxiety disorders in childhood are listed in Table 6–13. Community-based studies of school-aged children and adolescents suggest that nearly 10% of children have some type of anxiety disorder. The differential diagnosis of symptoms of anxiety is presented in Table 6–14.

The evaluation of anxiety symptoms in children must consider the age of the child, the developmental fears that can normally be expected at that age, the form of the symptoms and their duration, and the degree to which the symptoms disrupt the child's life. The family and school environment should be evaluated for potential stressors, marital discord, family violence, harsh or inappropriate disciplinary methods, sexual abuse, neglect, and emotional overstimulation. The child's experience of anxiety and its relationship to life events should be explored, and therapy to incorporate specific cognitive and behavioral techniques to diminish the anxiety should be recommended. Finally, when panic attacks or anxiety symptoms do not remit with cognitive, behavioral, and environmental interventions, and they significantly affect life functioning, psychopharmacologic agents may be helpful. SSRIs may be effective across a broad spectrum of anxiety symptoms.

Table 6-13. Anxiety disorders in children and adolescents.

Disorder	Major Clinical Manifestations
Generalized anxiety disorder	Intense, disproportionate or irrational worry, often about future events
Panic disorder	Unprovoked, intense fear with sympathetic hyperarousal, and often palpitations or hyperventilation
Post-traumatic stress disorder	Fear of a recurrence of an intense, anxiety-provoking traumatic experience, causing sympathetic hyperarousal, avoidance of reminders, and the reexperiencing of aspects of the traumatic event
Separation anxiety disorder	Developmentally inappropriate wish to maintain proximity with caregivers; morbid worry of threats to family integrity or integrity of self upon separation; intense homesickness
Social phobia	Painful shyness or self-consciousness; fear of humiliation with public scrutiny
Specific phobia	Avoidance of specific feared stimuli

► Prognosis

There is continuity between high levels of childhood anxiety and anxiety disorders in adulthood. Anxiety disorders are thus likely to be lifelong conditions, yet with effective interventions, individuals can minimize their influence on overall life functioning.

OBSESSIVE-COMPULSIVE DISORDER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Recurrent obsessive thoughts, impulses, or images that are not simply excessive worries about real-life problems.
- Obsessions and compulsions cause marked distress, are time-consuming, and interfere with normal routines.
- Repetitive compulsive behaviors or mental acts are performed to prevent or reduce distress stemming from obsessive thoughts.

Obsessive-compulsive disorder (OCD) is an anxiety disorder that often begins in early childhood but may not be diagnosed until the teen or even young adult years. The essential features of OCD are recurrent obsessions or compulsions that are severe enough to be time-consuming or cause marked distress and functional impairment. Obsessions are persistent ideas, thoughts, or impulses that are intrusive and often inappropriate. Children may have obsessions about contamination or cleanliness; ordering and compulsive behaviors will follow, such as frequent hand-washing, counting, or ordering objects. The goal of the compulsive behavior for the individual with OCD is to reduce anxiety and distress. There may be significant avoidance of situations due to obsessive thoughts or fears of contamination. OCD is often associated with major depressive disorder. OCD is a biologically based disease and has a strong genetic/familial component. Pediatric autoimmune disorders associated with group B streptococci have also been implicated in the development of OCD for some children. The prevalence of OCD is estimated to be around 2%, and the rates are equal between males and females.

Trichotillomania, while technically classified as an impulse disorder, is also thought to be related to OCD. It involves the recurrent pulling out of hair, often to the point of bald patches, and can also involve pulling out eyelashes, eyebrows, and hair from any part of the body. Trichotillomania should be considered in the differential diagnosis for any patient with alopecia. Treatment often includes the same medications used to treat OCD, and behavior therapy to decrease hair-pulling and restore normal social functioning.

► Treatment

OCD is best treated with a combination of cognitive-behavioral therapy specific to OCD and medications in more severe cases. SSRIs are effective in diminishing OCD symptoms. Fluvoxamine and sertraline have FDA approval for the treatment of pediatric OCD. The tricyclic antidepressant (TCA) clomipramine has FDA approval for the treatment of OCD in adults.

► Prognosis

Although OCD is usually a lifelong condition, most individuals can achieve significant remission of symptoms with the combination of cognitive-behavioral therapy and medications. A minority of individuals with OCD are completely disabled by their symptoms.

POST-TRAUMATIC STRESS DISORDER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Signs and symptoms of autonomic hyperarousal such as easy startle, increased heart rate, and hypervigilance.
- Avoidant behaviors and numbing of responsiveness.
- Flashbacks to a traumatic event, such as nightmares and intrusive thoughts.
- Follows traumatic events such as exposure to violence, physical or sexual abuse, natural disasters, car accidents, dog bites, and unexpected personal tragedies.

► General Considerations

Factors that predispose individuals to the development of post-traumatic stress disorder (PTSD) include proximity to the traumatic event or loss, a history of exposure to trauma, preexisting depression or anxiety disorder, and lack of an adequate support system. PTSD can develop in response to natural disasters, terrorism, motor vehicle crashes, and significant personal injury, in addition to physical, sexual, and emotional abuse. Natural disasters such as hurricanes, fires, flooding, and earthquakes, for example, can create situations in which large numbers of affected individuals are at height-

ened risk for PTSD. Individuals who have a previous history of trauma, or an unstable social situation are at greatest risk of PTSD.

Long overdue, attention is now being paid to the substantial effects of family and community violence on the psychological development of children and adolescents. Abused children are most likely to develop PTSD and to suffer wide-ranging symptoms and impaired functioning. As many as 25% of young people exposed to violence develop symptoms of PTSD.

Heightened concern about terrorism in the United States has created increased awareness of PTSD and community-based interventions to decrease the risk of PTSD. Studies after the terrorist attacks of September 11, 2001, and the Oklahoma City bombing reported up to 40% of children and adolescents experienced PTSD symptoms. Studies after the Space Shuttle *Challenger* explosion and the Oklahoma City bombing strongly suggested that overexposure to media coverage of these tragic events also led to symptoms of PTSD for some children and adults.

► Clinical Findings

Children and adolescents with PTSD show persistent evidence of fear and anxiety and are hypervigilant to the possibility of repetition. They may regress developmentally and experience fears of strangers, of the dark, and of being alone, and avoid reminders of the traumatic event. Children also frequently reexperience elements of the events in nightmares and flashbacks. In their symbolic play, one can often notice a monotonous repetition of some aspect of the traumatic event. Children with a history of traumatic experiences or neglect in infancy and early childhood are likely to show signs of reactive attachment disorder and have difficulty forming relationships with caregivers.

► Treatment

The cornerstone of treatment for PTSD is education of the child and family regarding the nature of the disorder so that the child's emotional reactions and regressive behavior are not mistakenly viewed as crazy or manipulative. Support, reassurance, and repeated explanations and understanding are needed. It is critical that the child be living in a safe environment, and if caregivers have been abusive, concerns must be reported to social services. Efforts should be made to establish or maintain daily routines as much as possible, especially after a trauma or disaster that interrupts the family's environment. In the case of media coverage of a disaster or event, children's viewing should be avoided or limited. Interventions to maintain safety of the child are imperative. Individual and family psychotherapy are central features of treatment interventions. Specific fears usually wane with time, and behavioral desensitization may help. Cognitive-behavioral therapy is considered first-line treatment for PTSD, and there is some preliminary evidence eye movement desensitization and reprocessing (EMDR) may also be useful.

A supportive relationship with a caregiving adult is essential. Frequently caregivers also have PTSD and need referral for treatment so that they can also assist in their child's recovery.

For children with more severe and persistent symptoms, assessment for treatment with medication is indicated. Sertraline has approval for the treatment of PTSD in adults. Target symptoms (eg, anxiety, depression, nightmares, and aggression) should be clearly identified and appropriate medication trials initiated with close monitoring. Some of the medications used to treat children with PTSD include clonidine or guanfacine (Tenex), mood stabilizers, antidepressants, and neuroleptics. Children who have lived for an extended time in abusive environments or who have been exposed to multiple traumas are more likely to require treatment with medications. Occupational therapy for sensory integration can also be effective in decreasing reactivity to stimuli and helping the child and caregivers develop and implement self-soothing skills. Individuals who have suffered single-episode traumas usually benefit significantly from psychotherapy and may require limited treatment with medication to address symptoms of anxiety, nightmares, and sleep disturbance.

► Prognosis

At 4- to 5-year follow-up investigations, many children who have been through a traumatic life experience continue to have vivid and frightening memories and dreams and a pessimistic view of the future. The effects of traumatic experiences can be far-reaching. The ability of caregivers to provide a safe, supportive, stable, empathic environment enhances the prognosis for individuals with PTSD. Timely access to therapy and use of therapy over time to work through symptoms also enhance prognosis. Evidence is growing to support a connection between victimization in childhood and unstable personality and mood disorders in later life.

SOMATOFORM DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ A symptom suggesting physical dysfunction.
- ▶ No physical disorder accounting for the symptom.
- ▶ Symptoms causing distress, dysfunction, or both.
- ▶ Symptoms not voluntarily created or maintained, as in malingering.

▶ Clinical Findings

Hypochondriasis, somatization, and conversion disorders involve an unhealthy overemphasis and preoccupation with somatic experiences and symptoms. Somatoform disorders are defined by the presence of physical illness or disability for which no organic cause can be identified, although neither the patient nor the caregiver is consciously fabricating the symptoms. The category includes body dysmorphic disorder, conversion disorder, hypochondriasis, somatization disorder, and somatoform pain disorder (Table 6–15).

Conversion symptoms most often occur in school-aged children and adolescents. The exact incidence is unclear, but in pediatric practice they are probably seen more often as transient symptoms than as chronic disorders requiring help from mental health practitioners. A conversion symptom is thought to be an expression of underlying psychological conflict. The specific symptom may be symbolically determined by the underlying conflict; the symptom may resolve the dilemma created by the underlying wish or fear (eg, a seemingly paralyzed child need not fear expressing his underlying rage or aggressive retaliatory impulses). Although children can present with a variety of symptoms, the most common include neurologic and gastrointestinal complaints. Children with conversion disorder may be surprisingly unconcerned about the substantial disability deriving from their symptoms. Symptoms include unusual sensory phenomena, paralysis, vomiting, abdominal pain, intractable headaches, and movement or seizure-like disorders.

Table 6–15. Somatoform disorders in children and adolescents.

Disorder	Major Clinical Manifestations
Body dysmorphic disorder	Preoccupation with an imagined defect in personal appearance
Conversion disorder	Symptom onset follows psychologically stressful event; symptoms express unconscious feelings and result in secondary gain
Hypochondriasis	Preoccupation with worry that physical symptoms manifest unrecognized and threatening condition; medical assurance does not provide relief from worry
Somatization disorder	Long-standing preoccupation with multiple somatic symptoms
Somatoform pain disorder	Preoccupation with pain that results in distress or impairment beyond what would be expected from physical findings

In the classic case of conversion disorder, the child's symptoms and examination findings are not consistent with the clinical manifestations of any organic disease process. The physical symptoms often begin within the context of a family experiencing stress, such as serious illness, a death, or family discord. On closer examination, the child's symptoms are often found to resemble symptoms present in other family members. Children with conversion disorder may have some secondary gain associated with their symptoms. Several reports have pointed to the increased association of conversion disorder with sexual overstimulation or sexual abuse. As with other emotional and behavioral problems, health care providers should always screen for physical and sexual abuse.

▶ Differential Diagnosis

It is sometimes not possible to rule out medical disease as a source of the symptoms. Medical follow-up is required to monitor for changes in symptoms and response to recommended interventions.

Somatic symptoms are often associated with anxiety and depressive disorders (see Tables 6–8 and 6–12). Occasionally, psychotic children have somatic preoccupations and even somatic delusions.

▶ Treatment & Prognosis

In most cases, conversion symptoms resolve quickly when the child and family are reassured that the symptom is a way of reacting to stress. The child is encouraged to continue with normal daily activities, knowing that the symptom will abate when the stress is resolved. Treatment of conversion disorders includes acknowledging the symptom rather than telling the child that the symptom is not medically justified

and responding with noninvasive interventions such as physical therapy while continuing to encourage normalization of the symptoms. If the symptom does not resolve with reassurance, further investigation by a mental health professional is indicated. Comorbid diagnoses such as depression and anxiety disorders should be addressed, and treatment with psychopharmacologic agents may be helpful.

Patients presenting with somatoform disorders are often resistant to mental health treatment, in part fearing that any distraction from their vigilance will put them at greater risk of succumbing to a medical illness. Psychiatric consultation is often helpful and for severely incapacitated patients, referral psychiatric consultation is always indicated.

Somatoform disorder is not associated with the increased morbidity and mortality associated with other psychiatric disorders such as mood disorders or psychotic illness. Somatoform patients are best treated with regular, short, scheduled medical appointments to address the complaints at hand. In this way they do not need to precipitate emergencies to elicit medical attention. Avoid invasive procedures unless clearly indicated and offer sincere concern and reassurance. Avoid telling the patient “it’s all in your head” and do not abandon or avoid the patient, as somatoform patients are at great risk of seeking multiple alternative treatment providers and potentially unnecessary treatments.

ELIMINATION DISORDERS

Elimination disorders are defined as problems with age-appropriate bowel and bladder control. These disorders are often identified and addressed by primary care providers. Enuresis and encopresis are not always associated with mental health problems and can simply be due to delayed development of consistent bowel and bladder control, or parental difficulty in managing this developmental stage. Elimination disorders may also be treated by child psychiatrists when they are found to be comorbid with other mental health problems, such as PTSD, anxiety disorders, and developmental disabilities.

1. Enuresis

It is important for the primary care provider to carefully assess the developmental age of the child and the situation in which enuresis is occurring, and to screen for medical concerns before deciding that the enuresis or encopresis is

attributable to a behavioral or emotional disorder. It is not uncommon for parents to have unrealistic expectations about toilet training young children. In many cases of enuresis, the child is simply not developmentally ready or sometimes is unable to remain dry at night. Most children with enuresis are able to remain dry by age 9 years.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Urinary incontinence in a child age 5 years (or developmental equivalent) or older.
- ▶ Not due to medication or a medical disorder.

▶ General Considerations

Enuresis is the passage of urine into bedclothes or undergarments, whether involuntary or intentional. At least 90% of enuretic children have primary nocturnal enuresis—that is, they wet only at night during sleep and have never had a sustained period of dryness. Diurnal enuresis (daytime wetting) is much less common, as is secondary enuresis, which develops after a child has had a sustained period of bladder control. The latter two varieties are much more commonly associated with emotional stress, anxiety, and psychiatric disorders. Primary nocturnal enuresis is most often a parasomnia, a deep-sleep (stage 3 or stage 4) event. Etiologically, it is generally viewed as a developmental disorder or maturational lag that children will outgrow. Only infrequently is it associated with a serious psychopathologic disorder.

▶ Clinical Findings

Primary nocturnal enuresis is common (Table 6–16). The incidence is three times higher in boys than in girls. Most children with enuresis become continent by adolescence or earlier. The family history in such cases frequently reveals other members, especially fathers, who have had prolonged nighttime bedwetting problems. Although the cause of primary nocturnal enuresis is not established, it appears to be related to maturational delay of sleep and arousal mechanisms or to delay in development of increased bladder capacity.

Daytime wetting most often occurs in timid and shy children or in children with ADHD. It occurs with about equal frequency in boys and girls, and 60–80% of daytime wetters also wet at night. Secondary enuresis typically follows a stressful event, such as the birth of a sibling, a loss, or discord within the family. The symptom can be seen as the result of regression in response to stress or as a more symbolic expression of the child’s feelings.

▶ Differential Diagnosis

The differential diagnosis includes urinary tract infections, neurologic diseases, seizure disorders, diabetes mellitus, and

Table 6-16. Incidence of enuresis in children.

Age (y)	Primary Nocturnal Enuresis (%)	Occasional Daytime Enuresis (%) ^a
5	15	8
7-8	7	—
10	3-5	—
12	2-3	1
14	1	—

^aDiurnal (daytime) enuresis tends to resolve by developmental age 6 y, with a slight recurrence around age 12 y in early adolescence.

structural abnormalities of the urinary tract. Urinalysis and urine culture and observing the child's urinary stream can rule out the majority of organic causes of enuresis.

► Complications

The most common complication of enuresis is low self-esteem in response to criticism from caregivers and embarrassment if peers are aware of the problem. Older children with enuresis may be reluctant to attend sleep-overs and be self-conscious with peers.

► Treatment

Treatment should emphasize that the symptom of nocturnal enuresis is a developmental lag and often will be outgrown even without treatment. Even with these interventions, many children will have difficulty remaining dry. If the child chooses to pursue treatment, a program of bladder exercises can be prescribed: fluids should be limited after dinner; the child should attempt to hold urine as long as possible during the day and then start and stop the stream at the toilet bowl; the child is instructed to practice getting up from bed and going to the bathroom at bedtime before sleep. These procedures are helpful in perhaps 30–40% of children with nighttime wetting. Another option is a “potty pager.” This is a beeper-like object that attaches to the child's underwear and vibrates when the child is wet in an attempt to rouse the child into a wakeful state and increase awareness of the need to urinate.

Desmopressin acetate (DDAVP), administered intranasally at bedtime, can result in complete remission of nocturnal enuresis in 50% of children as long as they continue the treatment. DDAVP is expensive, but can be useful until the child develops the ability to hold urine through the night or awaken to use the bathroom. For others, a trial of the TCA imipramine is worthwhile, at dosages of 25–50 mg at bedtime for children younger than age 12 years and 50–75 mg for older children. Because many patients relapse once the drug is stopped, its primary use is for camp attendance or overnight visits. Mental health treatment is more often needed for children with daytime wetting or secondary

enuresis. The focus is on the verbal expression of feelings that may be associated with perpetuation of the symptom and behavioral interventions to work toward dryness and cope with episodes of wetting.

2. Encopresis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fecal incontinence in a child age 4 years (or developmental equivalent) or older.
- Not due to medication or a medical disorder.

► General Considerations

Functional encopresis is defined as the repeated passage of feces in inappropriate places by a child of at least the developmental equivalent of age 4 years. It may be either involuntary or intentional, although most often it is involuntary. It affects approximately 1–1.5% of school-aged children, boys four times more often than girls. Functional fecal incontinence is rare in adolescence.

► Clinical Findings

Functional encopresis can be divided into four types: retentive, continuous, discontinuous, and toilet phobia.

A. Retentive Encopresis

In retentive encopresis, also called psychogenic megacolon, the child withholds bowel movements, leading to the development of constipation, fecal impaction, and the seepage of soft or liquid feces around the margins of the impaction into the underclothing. Marked constipation and painful defecation often contribute to a vicious cycle of withholding, thus creating larger impaction and further seepage. These children often have a history of crossing their legs to resist the urge to defecate and of infrequent bowel movements large enough to stop up the toilet, and they are found on examination to have large fecal masses in their rectal vaults. The soiling that occurs distresses most of these children.

B. Continuous Encopresis

Children with continuous encopresis have never gained primary control of bowel function. The bowel movement is usually randomly deposited in underclothing without regard to social norms. Typically, the family structure does not encourage organization and skill training, and for that reason the child has never had adequate bowel training. These children and their parents are more apt to be socially or intellectually disadvantaged.

C. Discontinuous Encopresis

Children with discontinuous encopresis have a history of normal bowel control for an extended period. Loss of control often occurs in response to a stressful event, such as the birth of a sibling, a separation, family illness, or marital disharmony. These children may soil their pants or on occasion defecate on the floor or smear feces as an expression of anger or of a wish to be perceived as younger. They typically display relative indifference to the symptom.

D. Toilet Phobia

In the infrequent case of toilet phobia, a young child views the toilet as a frightening structure to be avoided. These children may view the bowel movement as an extension of themselves, which is then swept away in a frightening manner. They may think that they, too, may be swept away down the toilet.

► Differential Diagnosis

Differential diagnosis includes the medical causes of constipation and retentive encopresis. Hirschsprung disease can be ruled out with reasonable certainty by the history of passing large-caliber bowel movements in the past and by the presence of palpable stool in the rectal vault. Neurologic disorders, hypothyroidism, hypercalcemia, and diseases of smooth muscle must be considered as well. The child should be examined for anal fissures, which tend to encourage the withholding of bowel movements.

► Treatment

Identifying the type of encopresis is important in treatment planning. Another important variable is the child's own concern about the symptom. Encopresis in children who display denial or indifference is much harder to treat. Children with coexisting illnesses need to receive treatment for those conditions before focusing treatment on soiling. Parents should be given guidance on responding calmly and firmly to this behavior.

With the most common type of encopresis, the retentive type, efforts are made to soften stool so that constipation and painful defecation do not perpetuate the behavior. These children are then taught to adopt a regular schedule of sitting on the toilet after meals. A system of positive reinforcement can be added in which the child is rewarded for each day with

no soiled underclothes. The responsibility for rinsing soiled clothing and depositing it in the appropriate receptacle rests with the child. In the case of continuous encopresis, the family is taught to train the child. For toilet phobia, a progressive series of rewarded desensitization steps is necessary. Children with discontinuous encopresis that persists over several weeks often need psychotherapy to help them recognize and verbally express their anger and wish to be dependent, rather than express themselves through fecal soiling.

► Prognosis

Although the ultimate prognosis is excellent, parental distress and parent-child conflict may be substantial prior to the cessation of symptoms. The natural history of soiling is that it resolves by adolescence in all but the most severely disturbed teenagers.

OTHER PSYCHIATRIC CONDITIONS

Several psychiatric conditions are covered elsewhere in this book. Refer to the following chapters for detailed discussion:

- Attention-deficit/hyperactivity disorder (ADHD): see Chapter 2.
- Eating disorders: see Chapter 5.
- Intellectual disability/mental retardation: see Chapter 2.
- Substance abuse: see Chapter 4.
- Sleep disorders: see Chapter 2.
- Tourette syndrome: see Chapter 23.

OVERVIEW OF PEDIATRIC PSYCHOPHARMACOLOGY

Pediatric psychopharmacology has improved significantly over the past decade with increasing study of the effect of psychoactive medications on mental illness in childhood and adolescence. Although relatively few medications are approved for use in children, many of the same psychopharmacologic agents used in adults are used in children and adolescents.

As with any medication, the risks as well as the benefits of administering psychoactive medications must be discussed with the child's parent or guardian and with the child or adolescent, as is age-appropriate. A recommendation for medication is warranted if the symptoms observed and reported by the child and family are associated with a psychiatric diagnosis known to respond to a particular medication or class of medications. Medication is more likely to be recommended if the disorder is interfering with psychosocial development, interpersonal relationships, daily functioning, or the patient's sense of personal well-being, and if there is significant potential for benefit with the medication and relatively low risk of harm. Informed consent should be given by the parent or guardian and noted in the record. The recommendation and target symptoms for medication should be discussed with both children and adolescents, and adolescents should also provide informed consent for treatment. In some states adolescents aged 15 and older must give informed consent. Informed consent includes a discussion of the diagnosis, target symptoms, possible common side effects, any side effects that should be closely monitored, potential benefits associated with the medication, and documentation of informed consent in the medical record. Psychopharmacologic agents are seldom the only treatment for a psychiatric disorder. They are best used in combination with other interventions such as individual therapy, family psychotherapy, and other psychosocial interventions, including assessment of school functioning and special needs.

When considering the use of psychoactive medications, specific target symptoms of the medication should be identified and followed to evaluate the efficacy of treatment. These symptoms should be also measured either by self-report rating scales (child, family, or both) and clinician-rated scales. When initiating treatment, start with low doses and increase slowly (in divided doses, if indicated) while monitoring for side effects along with therapeutic effects. When a medication is discontinued, it should usually be tapered over 2–4 weeks to minimize withdrawal effects. When multiple choices exist, one should select the medication that has a pediatric FDA approval (Table 6–17), or has been studied for the specific indication for which it is being prescribed, ideally in the age range of the patient. The side-effect profile of each option should be carefully considered, and the medication selected with the fewest and least serious risks and side effects. Polypharmacy should be avoided by choosing one drug that might diminish most or all of the target symptoms before considering the simultaneous administration of two or more agents. General guidelines regarding comfort level for pediatric providers in initiating and managing psychotropic classes of medications are outlined in Table 6–18.

In the text that follows, the major classes of psychopharmacologic agents with clinical indications in child and adolescent psychiatry are represented. The more commonly prescribed drugs from each class are reviewed with reference

Table 6–17. Psychoactive medications approved by the FDA for use in children and adolescents.^a

Drug	Indication	Age for Which Approved (y)
Mixed amphetamine salts (Adderall)	ADHD	3 and older
Dextroamphetamine (Dexedrine, Dextrostat)	ADHD	3 and older
Methylphenidate (Concerta, Ritalin, others)	ADHD	6 and older
Clomipramine (Anafranil)	OCD	10 and older
Fluvoxamine (Luvox)	OCD	8 and older
Sertraline (Zoloft)	OCD	6 and older
Risperidone (Risperdal)	Aggression and autism	5 and older
	Schizophrenia and mania	10 and older
Pimozide (Orap) ^b	Tourette syndrome	12 and older
Lithium (Eskalith, Lithobid, Lithotabs)	Bipolar disorder	12 and older
Fluoxetine (Prozac)	Depression	12 and older
	OCD	6 and older
Imipramine (Norpramin)	Enuresis	6 and older

^aHaloperidol and chlorpromazine have an indication for use in psychotic disorders. Their use in children, however, is not currently recommended.

^bUse of pimozide in the treatment of extrapyramidal disorders is discussed in Chapter 23.

ADHD, attention-deficit/hyperactivity disorder; FDA, Food and Drug Administration; OCD, obsessive-compulsive disorder.

to indications, relative contraindications, initial medical screening procedures (in addition to a general pediatric examination), dosage, adverse effects, drug interactions, and medical follow-up recommendations. This is meant to be a brief reference guide, and the physician should consult a child and adolescent psychopharmacology textbook for additional information on specific medications.

MEDICATIONS FOR ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

Dextroamphetamine (Dexedrine, Dextrostat)
 Mixed amphetamine salts (Adderall, Adderall XR)
 Methylphenidate (Concerta, Metadate, Methylin, Ritalin, Ritalin LA, Ritalin SR, Daytrana, Transdermal)
 Dexmethylphenidate (Focalin, Focalin XR)
 Clonidine (Catapres); guanfacine (Tenex)
 Atomoxetine (Strattera)
 Lisdexamfetamine (Vyvanse)

Table 6-18. Guidelines for management of psychiatric medications by the pediatrician.

Drug or Class	Comfort Initiating	Comfort Managing
Stimulants	+++	+++
Alpha agonists	++	+++
Antidepressants	+/-	++
Atypical antipsychotics	Recommend psychiatrist involvement	++
Typical antipsychotics	Requires psychiatrist involvement	+/-
Clozapine (Clozaril)	Requires psychiatrist involvement	Requires psychiatrist involvement
Mood stabilizers	Recommend psychiatrist involvement	+
Lamotrigine (Lamictal)	Requires psychiatrist involvement	++
Sleep medicines	+	++
Tricyclic antidepressants	+	++

Symbols: +++, high comfort; ++, comfort; +, mild caution; +/-, caution required.

1. Indications—Approximately 75% of children with ADHD experience improved attention span, decreased hyperactivity, and decreased impulsivity when given stimulant medications. Children with ADHD who do not respond favorably to one stimulant may respond well to another. Children and adolescents with ADHD without prominent hyperactivity (ADHD, predominantly inattentive type) are also likely to be responsive to stimulant medications. Atomoxetine (Strattera) and bupropion (Wellbutrin) are nonstimulant medications used to treat ADHD. Atomoxetine has FDA approval for the treatment of ADHD and is a selective noradrenergic reuptake inhibitor. Bupropion is primarily used as an antidepressant, and blocks serotonin, dopamine, and norepinephrine reuptake.

2. Contraindications—Although there has been much debate about stimulants causing sudden death in children, the FDA reviewed the literature and found no risk, except in cases of an underlying cardiac conduction or structural abnormality. Stimulants should also be used cautiously in individuals with a personal or family history of motor tics or Tourette syndrome, as these medications may cause or worsen motor tics. Caution should also be taken if there is a personal or family history of substance abuse or addictive disorders, as these medications can be abused or sold as drugs of abuse. Stimulants are also contraindicated for individuals with psychotic disorders, as they can significantly worsen psychotic symptoms. Stimulants should be used with

caution in individuals with comorbid bipolar affective disorder and ADHD and consideration of concurrent mood stabilization is critical.

3. Initial medical screening—The child should be observed for involuntary movements. Height, weight, pulse, and blood pressure should be recorded. (See also Chapter 2.)

4. Adverse effects—These are often dose-related and time-limited.

A. COMMON ADVERSE EFFECTS—Anorexia, weight loss, abdominal distress, headache, insomnia, dysphoria and tearfulness, irritability, lethargy, mild tachycardia, and mild elevation in blood pressure.

B. LESS COMMON EFFECTS—Interdose rebound of ADHD symptoms, emergence of motor tics or Tourette syndrome, behavioral stereotypy, tachycardia or hypertension, depression, mania, and psychotic symptoms. Reduced growth velocity occurs only during active administration. Growth rebound occurs during periods of discontinuation. Ultimate height is not usually noticeably compromised. Treatment with stimulant medications does not predispose to future substance abuse.

5. Drug interactions—Additive stimulant effects are seen with sympathomimetic amines (ephedrine and pseudoephedrine).

6. Medical follow-up—Pulse, blood pressure, height, and weight should be recorded every 3–4 months and at times of dosage increases. Assess for abnormal movements such as motor tics at each visit.

7. Dosage

A. METHYLPHENIDATE—The usual starting dose is 5 mg once or twice a day, before school and at noon (or 2.5 mg twice a day for children aged 4–6 years), gradually increasing as clinically indicated. The maximum daily dose should not exceed 60 mg, and a single dose should not exceed 0.7 mg/kg. Administration on weekends and during vacations is determined by the need at those times. The duration of action is approximately 3–4 hours. Extended-release forms can prevent the need for taking medication at school. Dexmethylphenidate (Focalin) is typically administered at a dose of 2.5 mg twice a day (8 AM and noon, for example), to a maximum of 20 mg.

B. DEXTROAMPHETAMINE SULFATE—The dose is 2.5–10 mg twice daily, before school and at noon, with or without another dose at 4 PM. A sustained-release preparation may have clinical effects for up to 8 hours. There is also an extended-release form.

C. PEMOLINE—Pemoline is generally not recommended for the treatment of ADHD due to a significant risk of liver failure.

D. ATOMOXETINE HYDROCHLORIDE—The starting dose for children and adolescents up to 70 kg is 0.5 mg/kg, with titration to a maximum dose of 1.2 mg/kg, in single or divided dosing.

ANTIDEPRESSANTS

The “black box warning” that was issued in October 2005 for all antidepressants has had a significant impact on prescription of these medications for children. The black box warning reads “Pooled analysis of short term (4–16 weeks) placebo-controlled trials of antidepressant drugs (SSRIs and others) in children and adolescents with Major Depressive Disorder (MDD), Obsessive-Compulsive Disorder (OCD) and other psychiatric disorders (a total of 24 trials involving more than 4400 patients) has revealed a greater risk of adverse events representing suicidal thinking or behavior (suicidality) during the first few months of treatment in those receiving antidepressants. The average risk of such events was 4%, twice the placebo risk of 2%. No suicides occurred in these trials.”

The “medication guide” created for consumers along with the black box warning that now appears in all antidepressant packaging recommends the following monitoring schedule for health care providers when starting an antidepressant:

- Once every week for the first 4 weeks
- Every 2 weeks for the next 4 weeks
- After taking the antidepressant for 12 weeks
- After 12 weeks, follow your health care provider’s advice on how often to come back.

The Treatment of Adolescent Depression Study found that cognitive-behavioral therapy combined with fluoxetine led to the best outcomes in the treatment of pediatric depression.

It is important to be cognizant of evidence-based medical practice when prescribing for any indication. Target symptoms should be carefully monitored for improvement or worsening, and it is important to ask and document the responses about any suicidal thinking and self-injurious behaviors. When recommending an antidepressant, the physician should also firmly recommend cognitive-behavioral therapy and discuss the options for medication treatment, including which medications have FDA approval for pediatric indications (see Table 6–17). Recent findings suggest that fluoxetine has the best evidence for improvement in depressive symptoms.

1. Selective Serotonin Reuptake Inhibitors

Citalopram, escitalopram (Celexa, Lexapro)

Fluvoxamine (Luvox)

Paroxetine (Paxil)

Sertraline (Zoloft)

1. Indications—The SSRIs have become the agents of first choice for the treatment of depression and anxiety. Fluvoxamine and sertraline both have approval from the FDA for treatment of pediatric OCD and fluoxetine has approval for pediatric depression. Although no other SSRIs have FDA approval for pediatric indications, some published

studies support the efficacy of SSRIs for the treatment of depression, anxiety, and OCD in pediatric populations. Each SSRI has different FDA indications. However, once an indication is obtained for one SSRI, it is widely believed that other SSRIs are likely to be effective as well for the same indication. The FDA-approved indications for SSRIs are the following:

Major depression: fluoxetine (age 6 years and older); citalopram, escitalopram, paroxetine, sertraline (18 and older).

Panic disorder: sertraline (18 and older), paroxetine (18 and older).

OCD: fluvoxamine (6 and older), sertraline (6 and older).

Bulimia: fluoxetine (18 and older).

PTSD: sertraline (18 and older).

Premenstrual dysphoric disorder: fluoxetine (18 and older).

2. Contraindications—Caution should be used in cases of known liver disease or chronic or severe illness where multiple medications may be prescribed, because all SSRIs are metabolized in the liver. Caution should be used when prescribing for an individual with a family history of bipolar disorder, or when the differential diagnosis includes bipolar disorder, because antidepressants can induce manic or hypomanic symptoms.

3. Initial medical screening—General medical examination.

4. Adverse effects—Often dose-related and time-limited: gastrointestinal (GI) distress and nausea (can be minimized by taking medication with food), headache, tremulousness, decreased appetite, weight loss, insomnia, sedation (10%), sexual dysfunction (25%). Irritability, social disinhibition, restlessness, and emotional excitability can occur in approximately 20% of children taking SSRIs. Monitor for improvement and onset or worsening of suicidal or self-injurious thinking, in addition to other target symptoms.

5. Drug interactions—All SSRIs inhibit the efficiency of the hepatic microsomal enzyme system. The order of inhibition is: fluoxetine > fluvoxamine > paroxetine > sertraline > citalopram > escitalopram. This can lead to higher-than-expected blood levels of other drugs, including antidepressants, antiarrhythmics, antipsychotics, β -blockers, opioids, and antihistamines. Taking tryptophan while on an SSRI may result in a serotonergic syndrome of psychomotor agitation and GI distress. A potentially fatal interaction that clinically resembles neuroleptic malignant syndrome may occur when SSRIs are administered concomitantly with monoamine oxidase inhibitors. Fluoxetine has the longest half-life of the SSRIs and should not be initiated within 14 days of the discontinuation of a monoamine oxidase inhibitor, or a monoamine oxidase inhibitor initiated within at least 5 weeks of the discontinuation of fluoxetine.

Table 6-19. Medications used to treat depression in adolescents.

Generic	Trade Name	Adolescent Starting Dose	Target Dose (Average Effective Dose)	Maximum Dose
Selective serotonin reuptake inhibitors				
Citalopram	Celexa	20 mg q AM	20 mg q AM	40-60 mg q AM
Escitalopram	Lexapro	10 mg	10 mg	30 mg
Fluoxetine ^a	Prozac	10 mg q AM	20 mg q AM	60 mg q AM
Fluvoxamine	Luvox	50 mg qhs	100-150 mg qd	100 mg bid
Paroxetine	Paxil	10 mg q AM	20 mg q AM	60 mg q AM
Paroxetine CR	Paxil CR	25 mg	25 mg	50 mg
Sertraline	Zoloft	25 mg q AM	50 mg q AM	150 mg q AM
Other antidepressants				
Bupropion	Wellbutrin	75 mg q AM	150 mg bid	200 mg bid
Bupropion SR	Wellbutrin SR	100 mg q AM	100 mg bid	150 mg bid
Duloxetine	Cymbalta	20 mg bid	20 mg bid	60 mg qd
Mirtazapine	Remeron	7.5 mg qhs	15 mg qhs	30 mg qhs
Venlafaxine	Effexor	37.5 mg q AM	75 mg bid	150 mg bid
Venlafaxine XR	Effexor XR	37.5 mg q AM	150 mg qd	225 mg qd

^aFDA approved for depression in children older than age 12 y. bid, twice a day; q AM, every morning; qd, every day; qhs, every night at bedtime.

6. Dosage (Table 6-19)—Therapeutic response should be expected 4–6 weeks after a therapeutic dose has been reached. The starting dose for a child younger than 12 years old is generally half the starting dose for an adolescent.

A. SSRIs—The SSRIs are usually given once a day, in the morning with breakfast. One in ten individuals may experience sedation and prefer to take the medication at bedtime. Fluoxetine is the only SSRI with FDA approval and replicable efficacy.

B. ALTERNATIVE ANTIDEPRESSANTS AND FLUVOXAMINE—The alternative antidepressants (see below) and fluvoxamine are usually given in twice-daily dosing. Paroxetine, bupropion, and venlafaxine are now available in a sustained- and extended-release form.

2. Other Antidepressants

Bupropion (Wellbutrin), bupropion SR (sustained-release), bupropion XL (extended-release)

Duloxetine (Cymbalta)

Mirtazapine (Remeron)

Venlafaxine (Effexor), venlafaxine XR (extended-release)

A. Bupropion

1. Indications—Bupropion is an antidepressant that inhibits reuptake of primarily serotonin, but also norepinephrine

and dopamine. It is approved for treatment of major depression in adults, but is receiving favorable attention for its therapeutic effects in adolescents with major depressive disorder and in children and adolescents with ADHD. Like the SSRIs, bupropion has very few anticholinergic or cardiotoxic effects.

2. Contraindications—History of seizure disorder or bulimia nervosa.

3. Initial medical screening and follow-up—General medical examination.

4. Adverse effects—Psychomotor activation (agitation or restlessness), headache, GI distress, nausea, anorexia with weight loss, insomnia, tremulousness, precipitation of mania, and induction of seizures with doses above 450 mg/d.

B. Venlafaxine

Venlafaxine is an antidepressant that primarily inhibits reuptake of serotonin and norepinephrine.

1. Indications—It is approved for the treatment of major depression in adults.

2. Contraindications—Hypertension.

3. Initial medical screening and follow-up—General medical examination.

4. Adverse effects—The most common adverse effects are nausea, nervousness, and sweating. Hypertension is likely with doses over 300 mg or over 225 mg of the extended-release version. Venlafaxine must be discontinued slowly to minimize withdrawal symptoms: severe headaches, dizziness, and significant flu-like symptoms. It is also available in an extended-release form.

C. Mirtazapine

Mirtazapine is an α_2 -antagonist that enhances central noradrenergic and serotonergic activity.

1. Indications—It is approved for the treatment of major depression in adults.

2. Contraindications—Mirtazapine should not be given in combination with monoamine oxidase inhibitors. Very rare side effects are acute liver failure (1 case per 250,000–300,000), neutropenia, and agranulocytosis.

3. Initial medical screening and follow-up—General medical examination.

4. Adverse effects—Dry mouth, increased appetite, constipation, weight gain.

D. Duloxetine

Duloxetine is a selective serotonin and norepinephrine reuptake inhibitor.

1. Indications—It is approved for the treatment of major depression, generalized anxiety disorder, and diabetic peripheral neuropathic pain in adults.

2. Contraindications—Duloxetine should not be given in combination with monoamine oxidase inhibitors. Very rare side effects are orthostatic hypotension and liver toxicity.

3. Initial medical screening and follow-up—General medical examination.

4. Adverse effects—Nausea, dizziness, dry mouth, and fatigue.

3. Tricyclic Antidepressants

Imipramine
Desipramine
Clomipramine
Nortriptyline
Amitriptyline

With the introduction of the SSRIs and alternative antidepressants, use of the TCAs has become uncommon for the treatment of depression and anxiety disorders. The TCAs have more significant side-effect profiles, require more substantial medical monitoring, and are quite cardiotoxic in overdose. For these reasons, in general, SSRIs or alternative antidepressants

should be considered before recommending a TCA. In some countries, where access to newer and more costly medications is difficult, TCAs are still frequently employed for certain behavioral, emotional, and functional conditions.

1. Indications—TCAs have been prescribed for chronic pain syndromes, migraines, headache, depression, anxiety, enuresis, bulimia nervosa, OCD, and PTSD in children and adolescents. Imipramine and desipramine have FDA approval for the treatment of major depression in adults and for enuresis for children age 6 years and older. Some published studies have demonstrated clinical efficacy in the treatment of ADHD, panic disorder, anxiety-based school refusal, separation anxiety disorder, bulimia, night terrors, and sleepwalking. But as yet, the FDA has not approved their use for these indications. **Studies have not supported efficacy in major depression in children and adolescents.** Nortriptyline has FDA approval for the treatment of major depression in adults. Clomipramine has FDA approval for the treatment of depression and OCD in adults and may be helpful for obsessive symptoms in autism.

2. Contraindications—Known cardiac disease or arrhythmia, undiagnosed syncope, known seizure disorder, family history of sudden cardiac death or cardiomyopathy, known electrolyte abnormality (with bingeing and purging).

3. Initial medical screening—The family history should be examined for sudden cardiac death; the patient's history for cardiac disease, arrhythmias, syncope, seizure disorder, or congenital hearing loss (associated with prolonged QT interval). Other screening procedures include serum electrolytes and blood urea nitrogen in patients who have eating disorders, cardiac examination, and a baseline electrocardiogram (ECG).

4. Medical follow-up—Measure pulse and blood pressure (monitor for tachycardia and orthostatic hypotension) with each dosage increase, and obtain an ECG to monitor for arteriovenous block with each dosage increase; after reaching steady state, record pulse, blood pressure, and ECG every 3–4 months.

5. Adverse effects

A. CARDIOTOXIC EFFECTS—The cardiotoxic effects of TCAs appear to be more common in children and adolescents than in adults. In addition to anticholinergic effects, TCAs have quinidine-like effects that result in slowing of cardiac conduction. Increased plasma levels appear to be weakly associated with an increased risk of cardiac conduction abnormalities. Steady-state plasma levels of desipramine or of desipramine plus imipramine should therefore not exceed 300 ng/mL. In addition, for each dosage increase above 3 mg/kg/d, pulse and blood pressure must be carefully checked, and repeated ECGs obtained to monitor for arteriovenous block. Upper limits for cardiovascular parameters when administering TCAs to children and adolescents are listed in Table 6–20.

Table 6–20. Upper limits of cardiovascular parameters with tricyclic antidepressants.

Heart rate	130/min
Systolic blood pressure	130 mm Hg
Diastolic blood pressure	85 mm Hg
PR interval	0.2 s
QRS interval	0.12 s, or no more than 30% over baseline
QT corrected	0.45 s

B. ANTICHOLINERGIC EFFECTS—Tachycardia, dry mouth, stuffy nose, blurred vision, constipation, sweating, vasomotor instability, withdrawal syndrome (GI distress and psychomotor activation).

C. OTHER EFFECTS—Orthostatic hypotension and dizziness, lowered seizure threshold, increased appetite and weight gain, sedation, irritability and psychomotor agitation, rash (often associated with yellow dye No. 5), headache, abdominal complaints, sleep disturbance and nightmares, mania.

6. Drug interactions—TCAs may potentiate the effects of central nervous system depressants and stimulants; barbiturates and cigarette smoking may decrease plasma levels; phenothiazines, methylphenidate, and oral contraceptives may increase plasma levels; SSRIs given in combination with TCAs will result in higher TCA blood levels due to inhibition of TCA metabolism by liver enzymes (eg, cytochrome P-450 isoenzymes).

7. Dosage—Refer to a pediatric psychopharmacology text for dosages. Daily dosage requirements vary considerably with different clinical disorders.

MOOD STABILIZERS AND ATYPICAL ANTIPSYCHOTICS

► Mood Stabilizers

Carbamazepine (Tegretol), oxycarbamazepine (Trileptal)
 Gabapentin (Neurontin)
 Lamotrigine (Lamictal)
 Lithium carbonate (Eskalith, Eskalith CR, Lithobid, Lithotabs)
 Valproic acid (Depakote, Depakote ER)

► Atypical Antipsychotics

Aripiprazole (Abilify)
 Olanzapine (Zyprexa)
 Risperidone (Risperdal)
 Quetiapine (Seroquel)
 Ziprasidone (Geodon)

Lithium and antiepileptic medications have historically been the drugs of choice for mood stabilization in bipolar mood disorder. New research also finds that the atypical antipsychotic medications are also effective. Lithium, valproic acid, olanzapine, risperidone, aripiprazole, and ziprasidone are FDA approved for the treatment of adult bipolar disorder. Carbamazepine and oxcarbazepine, although not FDA approved for treatment of bipolar disorder, may also be effective and carry less risk of weight gain. Lamotrigine (Lamictal) was recently approved for the treatment of bipolar depression in adults. Other antiepileptic medications, such as gabapentin and topiramate, have also been used with varying efficacy. Medications that are effective as mood stabilizers may be helpful also in the treatment of severe aggressive symptoms.

A. Lithium

1. Indications—Lithium remains a front-line drug in the treatment of bipolar disorder and has been shown to have an augmenting effect when combined with SSRIs for treatment-resistant depression and OCD.

2. Contraindications—Lithium is contraindicated in patients with known renal, thyroid, or cardiac disease; those at high risk for dehydration and electrolyte imbalance (eg, vomiting and purging); and those who may become pregnant (teratogenic effects).

3. Initial medical screening—General medical screening with pulse, blood pressure, height, and weight; complete blood cell count (CBC); serum electrolytes, blood urea nitrogen, and creatinine; and thyroid function tests, including thyroid-stimulating hormone levels.

4. Dosage—For children the starting dose is usually 150 mg once or twice a day, with titration in 150- to 300-mg increments. (Dose may vary with the brand of lithium used; consult a psychopharmacology textbook for medication-specific information.) Oral doses of lithium should be titrated to maintain therapeutic blood levels of 0.8–1.2 mEq/L. The drug is generally given in two doses. Blood samples should be drawn 12 hours after the last dose.

5. Adverse effects

A. LITHIUM TOXICITY—Lithium has a narrow therapeutic index. Blood levels required for therapeutic effects are close to those associated with toxic symptoms. Mild toxicity may be indicated by increased tremor, GI distress, neuromuscular irritability, and altered mental status (confusion), and can occur when blood levels exceed 1.5 mEq/L. Moderate to severe symptoms of lithium toxicity are associated with blood levels above 2 mEq/L. Acute renal failure can occur at levels over 2.5–3 mEq/L.

B. SIDE EFFECTS—Lithium side effects include intention tremor, GI distress (including nausea and vomiting and sometimes diarrhea), hypothyroidism, polyuria and polydipsia, drowsiness, malaise, weight gain, acne, and granulocytosis.

6. Drug interactions—Excessive salt intake and salt restriction should be avoided. Thiazide diuretics and nonsteroidal anti-inflammatory agents (except aspirin and acetaminophen) can lead to increased lithium levels. Ibuprofen should be avoided by individuals who take lithium due to combined renal toxicity. Precautions against dehydration are required in hot weather and during vigorous exercise.

7. Medical follow-up—Serum lithium levels should be measured 5–7 days following a change in dosage and then quarterly at steady state; serum creatinine and thyroid-stimulating hormone concentrations should be determined every 3–4 months.

B. Valproic Acid

1. Indications—Valproate has FDA approval for the treatment of bipolar disorder in adults. Its efficacy in acute mania equals that of lithium, but it is generally better tolerated. Valproate is more effective than lithium in patients with rapid-cycling bipolar disorder (more than four cycles per year) and in patients with mixed states (coexisting symptoms of depression and mania). Valproate may be more effective than lithium in adolescents with bipolar disorder because they often have rapid cycling and mixed states.

2. Contraindications—Liver dysfunction.

3. Initial medical screening—CBC and liver function tests (LFTs).

4. Dosage—The starting dose is usually 15 mg/kg/d. This is increased in increments of 5–10 mg/kg/d every 1–2 weeks to a range of 500–1500 mg/d in two or three divided doses. Trough levels in the range of 80–120 mg/mL are thought to be therapeutic.

5. Adverse effects—Between 10% and 20% of patients experience sedation or anorexia, especially early in treatment or if the dose is increased too rapidly. GI upset occurs in 25% of patients, and when severe, can usually be treated with cimetidine. Increased appetite and weight gain can be troublesome for children and adolescents. Blurred vision, headache, hair loss, and tremor occur occasionally. Slight elevations in aminotransferases are frequent. Severe idiosyncratic hepatitis, pancreatitis, thrombocytopenia, and agranulocytosis occur only rarely.

6. Medical follow-up—LFTs should be checked monthly for 3–4 months; subsequently, LFTs, a CBC, and trough valproate levels should be obtained every 3–4 months.

C. Carbamazepine

1. Indications—Similarly to lithium and valproate, carbamazepine may be effective for treating bipolar disorder or for the target symptoms of mood instability, irritability, or behavioral dyscontrol. Some data suggest that it is more effective than valproate for the depressive phases of bipolar

disorder. A new form of carbamazepine—oxcarbazepine (Trileptal)—is also rarely being used for pediatric mood disorders; however, its efficacy has not been established. Reportedly, it does not have the worrisome side effects of bone marrow suppression and liver enzyme induction. Blood levels cannot be monitored, and the dose range is similar to that of carbamazepine.

2. Contraindications—History of previous bone marrow depression or adverse hematologic reaction to another drug; history of sensitivity to a TCA.

3. Initial medical screening—Obtain a CBC with platelets, reticulocytes, serum iron, and blood urea nitrogen; LFTs; urinalysis.

4. Dosage—The drug is usually started at 10–20 mg/kg/d, in two divided doses, in children younger than 6 years; 100 mg twice daily in children aged 6–12 years; and 200 mg twice daily in children older than 12 years. Doses may be increased weekly until there is effective symptom control. Total daily doses should not exceed 35 mg/kg/d in children younger than 6 years; 1000 mg/d in children aged 6–15 years; and 1200 mg/d in adolescents older than 15 years. Plasma levels in the range of 4–12 mg/mL are thought to be therapeutic.

5. Adverse effects—Nausea, dizziness, sedation, headache, dry mouth, diplopia, and constipation reflect the drug's mild anticholinergic properties. Rashes are more common with carbamazepine than with other mood stabilizers. Aplastic anemia and agranulocytosis are rare. Leukopenia and thrombocytopenia are more common, and if present, should be monitored closely for evidence of bone marrow depression. These effects usually occur early and transiently and then spontaneously revert toward normal. Liver enzyme induction may significantly change the efficacy of medications given concurrently.

6. Medical follow-up—Hematologic, hepatic, and renal parameters should be followed at least every 3 months for the first year. White blood cell counts below 3000/mL and absolute neutrophil counts below 1000/mL call for discontinuation of the drug and referral for hematology consultation.

D. Lamotrigine

Lamotrigine is approved for the treatment of bipolar depression in adults. The most concerning side effects of this medication are serious rashes that can require hospitalization and can include Stevens-Johnson syndrome (0.8% incidence). Lamotrigine should be used very carefully. The starting dose is 25 mg, with a slow titration of increasing the dose by 25 mg per week to a target dose (as clinically indicated) of 300 mg/d.

E. Gabapentin

Like valproate and carbamazepine, gabapentin is an anticonvulsant that has been used as a mood stabilizer in some adult

populations. It may be used along with either valproate or carbamazepine in individuals with treatment-resistant disorders. The usual adult dose range for seizure disorders is 900–1800 mg/d in three divided doses and may need to be adjusted downward in individuals with renal impairment. Although its use among adolescents and even children is increasing, gabapentin is not approved for this indication, and reports of its efficacy remain largely anecdotal. Some reports suggest it may worsen behavioral parameters in children with underlying ADHD.

ANTIPSYCHOTICS

▶ Atypical Antipsychotics

- Aripiprazole (Abilify)
- Clozapine (Clozaril)
- Olanzapine (Zyprexa)
- Risperidone (Risperdal)
- Quetiapine (Seroquel)
- Ziprasidone (Geodon)

▶ Conventional Neuroleptics

- Chlorpromazine
- Haloperidol
- Molindone
- Perphenazine
- Thioridazine
- Thiothixene
- Trifluoperazine

The antipsychotics, formerly known as neuroleptics, are indicated for psychotic symptoms in patients with schizophrenia. Some now have an FDA-approved indication for bipolar affective disorder in adults (risperidone and olanzapine). They are also used for acute mania and as adjuncts to antidepressants in the treatment of psychotic depression (with delusions or hallucinations). The antipsychotics may be used cautiously in refractory PTSD, in refractory OCD, and in individuals with markedly aggressive behavioral problems unresponsive to other interventions. They may also be useful for the body image distortion and irrational fears about food and weight gain associated with anorexia nervosa.

The “atypical antipsychotics” differ from conventional antipsychotics in their receptor specificity and effect on serotonin receptors. Conventional antipsychotics are associated with a higher incidence of movement disorders and extrapyramidal symptoms (EPS) due to their wider effect on dopamine receptors. The introduction of the atypical antipsychotics has significantly changed neuroleptic prescribing patterns. The atypical antipsychotics have a better side-effect profile for most individuals and comparable efficacy for the treatment of psychotic symptoms and aggression. Atypical

antipsychotics have a decreased incidence of EPS and tardive dyskinesia (TD). Significant side effects can include substantial weight gain and sedation. Because of their increased use over conventional antipsychotics, this section focuses primarily on the atypical antipsychotics.

A. Aripiprazole

Aripiprazole (Abilify) is the newest atypical neuroleptic and is indicated for the treatment of adults with schizophrenia and bipolar disorder. It is a partial dopamine blocker and a serotonin agonist. Side effects include nausea and vomiting and fatigue. It is associated with minimal weight gain. Doses over 30 mg are more likely to be associated with EPS. The dose range is 5–30 mg, and pills can be split.

B. Olanzapine

The FDA has approved this agent for the treatment of schizophrenia and bipolar disorder in adults. Olanzapine (Zyprexa) has greater affinity for type 2 serotonin receptors than dopamine-2 receptors and also has an effect on muscarinic, histaminic, and α -adrenergic receptors. As with the other atypical antipsychotics, it may be more helpful for treating the negative symptoms of schizophrenia (flat affect, isolation and withdrawal, and apathy) than conventional antipsychotics. Anecdotal and case report data support its utility in child and adolescent psychotic disorders. The adult dose range of 5–15 mg/d administered in a single bedtime dose is probably applicable to adolescents as well. Weight gain can be a significant side effect. The starting dose for children is usually 1.25 mg.

C. Quetiapine

Quetiapine (Seroquel) is an antagonist at multiple receptor sites, including serotonin (5-HT_{1A} and 5-HT₂), dopamine (D₁ and D₂), histamine, and adrenergic receptors. Quetiapine is given in 25- to 50-mg increments up to 800 mg for the treatment of psychotic symptoms. It is thought to be a weight-neutral medication, and the primary side effect is sedation.

D. Risperidone

Risperidone (Risperdal) blocks type 2 dopamine receptors (similarly to haloperidol) and type 2 serotonin receptors. It is approved for the treatment of schizophrenia and bipolar affective disorder in adults. Risperidone has also demonstrated clinical efficacy in the treatment of Tourette syndrome. The initial dose is 1–2 mg/d. It is typically titrated up in 0.5–1 mg increments to a maximum dose of 4–10 mg for psychotic disorders. Side effects include weight gain and sedation.

E. Ziprasidone

Ziprasidone (Geodon) has affinity for multiple serotonin receptors (5-HT₂, 5-HT_{1A}, 5-HT_{1D}, and 5-HT_{2C}) and dopa-

mine-2 receptors, and it moderately inhibits norepinephrine and serotonin reuptake. It also has moderate affinity for H₁ and α_1 receptors. Ziprasidone has a greater effect on cardiac QT intervals and requires a baseline ECG and ECG monitoring when a dose of 80 mg is reached and with each dose change above 80 mg to monitor for QT prolongation. Ziprasidone is reported to cause minimal weight gain. The initial dose is 20 mg, with dose changes in 20-mg increments to a total daily dose of 140 mg for the treatment of psychotic symptoms in adults. There are no studies of ziprasidone in children and adolescents at this time.

F. Clozapine

Clozapine (Clozaril) is usually reserved for individuals who have not responded to multiple other antipsychotics due to its side effect of agranulocytosis. Clozapine blocks type 2 dopamine receptors weakly and is virtually free of EPS, apparently including TD. It was very effective in about 40% of adult patients with chronic schizophrenia who did not respond to conventional antipsychotics.

Non-dose-related agranulocytosis occurs in 0.5–2% of subjects. Some case reports note benefit from clozapine in child and adolescent schizophrenic patients who were resistant to other treatment. Contraindications are concurrent treatment with carbamazepine and any history of leukopenia. Initial medical screening should include a CBC and LFTs. The daily dose is 200–600 mg in two divided doses. Because of the risk of neutropenia, patients taking clozapine must be registered with the Clozapine Registry and a white blood cell count must be obtained biweekly before a 2-week supply of the drug is dispensed. If the white count falls below 3000/mL, clozapine is usually discontinued. Other side effects include sedation, weight gain, and increased salivation. The incidence of seizures increases with doses above 600 mg/d.

General Antipsychotic Information

The following adverse effects of antipsychotics apply to both typical and atypical antipsychotics, but are thought to have a significantly lower incidence with the atypical antipsychotics.

1. Initial medical screening—One should observe and examine for tremors and other abnormal involuntary movements and establish baseline values for CBC and LFTs. An ECG should be obtained if there is a history of cardiac disease or arrhythmia, and to establish a baseline QT interval (cardiac repolarization) prior to initiation of the antipsychotics that have a greater effect on the QT interval (eg, ziprasidone and thioridazine). Antipsychotics can cause QT prolongation leading to ventricular arrhythmias, such as torsades de pointes. Medications that affect the cytochrome P-450 isoenzyme pathway (including SSRIs) may increase the neuroleptic plasma concentration and increase risk of QTc prolongation.

2. Adverse effects—The most troublesome adverse effects of the atypical antipsychotics are cognitive slowing, sedation,

orthostasis, and weight gain. The conventional antipsychotics have an increased incidence of EPS and TD. Sedation, cognitive slowing, and EPS all tend to be dose-related. Because of the risk of side effects, neuroleptic medications should be used with caution and monitored regularly. The risk-benefit ratio of the medication for the identified target symptom should be carefully considered and reviewed with the parent or guardian.

A. EXTRAPYRAMIDAL SIDE EFFECTS—EPS and acute dystonic reactions are tonic muscle spasms, often of the tongue, jaw, or neck. EPS symptoms can be mildly uncomfortable or may result in such dramatically distressing symptoms as oculogyric crisis, torticollis, and even opisthotonos. Onset is usually within days after a dosage change and symptoms may occur in up to 25% of children treated with conventional antipsychotics. Acute neuroleptic-induced dystonias are quickly relieved by anticholinergics such as benztropine (Cogentin) and diphenhydramine.

B. TARDIVE DYSKINESIAS—TDs are involuntary movement disorders that are often irreversible and may appear after long-term use of neuroleptic medications. Choreoathetoid movements of the tongue and mouth are most common, but the extremities and trunk may also be involved. The risk of TD is small in patients on atypical antipsychotics, and those on conventional antipsychotics for less than 6 months. There is no universally effective treatment.

C. PSEUDOPARKINSONISM—Pseudoparkinsonism is usually manifested 1–4 weeks after the start of treatment. It presents as muscle stiffness, cogwheel rigidity, masklike facial expression, bradykinesia, drooling, and occasionally pill-rolling tremor. Anticholinergic medications or dosage reductions are helpful.

D. AKATHISIA—Akathisia is usually manifested after 1–6 weeks of treatment. It presents as an unpleasant feeling of driven motor restlessness that ranges from vague muscular discomfort to a markedly dysphoric agitation with frantic pacing. Anticholinergic agents or β -blockers are sometimes helpful.

E. NEUROLEPTIC MALIGNANT SYNDROME—Neuroleptic malignant syndrome is a very rare medical emergency associated primarily with the conventional antipsychotics, although it has also been reported with atypical antipsychotics. It is manifested by severe muscular rigidity, mental status changes, fever, autonomic lability, and myoglobinemia. Neuroleptic malignant syndrome can occur without muscle rigidity in patients taking atypical antipsychotics and should be considered in the differential diagnosis of any patient on antipsychotics who presents with high fever and altered mental status. Mortality as high as 30% has been reported. Treatment includes immediate medical assessment, withdrawal of the neuroleptic, and may require transfer to an intensive care unit.

F. WITHDRAWAL DYSKINESIAS—Withdrawal dyskinesias are reversible movement disorders that appear following withdrawal of neuroleptic medications. Dyskinetic movements develop within 1–4 weeks after withdrawal of the drug and may persist for months.

G. OTHER ADVERSE EFFECTS—These include cardiac arrhythmias, irregular menses, gynecomastia and galactorrhea due to increased prolactin, sexual dysfunction, photosensitivity, rashes, lowered seizure threshold, hepatic dysfunction, and blood dyscrasias.

3. Drug interactions—Potentiation of central nervous system depressant effects or the anticholinergic effects of other drugs may occur, as well as increased plasma levels of antidepressants.

4. Medical follow-up—The patient should be examined at least every 3 months for signs of the side effects listed. An Abnormal Involuntary Movement Scale can be used to monitor for TD in patients taking antipsychotics. Most antipsychotic treatments seem to be associated with relevant weight gain, which increases the risk of the development of metabolic syndrome and future cardiovascular morbidity and mortality. New recommendations include quarterly monitoring of blood pressure, weight gain, abdominal circumference, dietary and exercise habits, and, if indicated, fasting blood glucose and lipid panels. In cases of significant weight gain or abnormal laboratory values, patients should either be switched to an agent with a decreased risk for these adverse events or should receive additional treatments to reduce specific adverse events in cases in which discontinuation of the offending agent is clinically contraindicated or unfeasible.

ADRENERGIC AGONISTS

Clonidine (Catapres) & Guanfacine (Tenex)

1. Indications—Clonidine is a nonselective α -adrenergic agonist that is clinically useful in decreasing states of hyperarousal seen in children and adolescents with PTSD and ADHD. Guanfacine is a selective agonist for α_2 -adrenergic receptors with advantages over the nonselective agonist clonidine. Guanfacine is less sedating and less hypotensive than clonidine and has a longer half-life, allowing for twice-daily dosing. Case reports find guanfacine effective in ADHD and in Tourette syndrome with comorbid ADHD. Bedtime doses of adrenergic agonists can be helpful for the delayed onset of sleep and nightmares that can occur with PTSD, for the difficulty settling for sleep seen in ADHD, or for ameliorating the side effects of stimulant medications. These agents are also effective in the treatment of tics in Tourette syndrome.

2. Contraindications—Adrenergic agonists are contraindicated in patients with known renal or cardiovascular disease and in those with a family or personal history of depression.

3. Initial medical screening—The pulse and blood pressure should be recorded prior to starting an adrenergic agonist.

4. Dosage—The initial dosage of clonidine is usually 0.025–0.05 mg at bedtime. The dosage can be increased after 3–5 days by giving 0.05 mg in the morning. Further dosage increases are made by adding 0.05 mg first in the morning, then at noon, and then in the evening every 3–5 days to a maximum total daily dose of 0.3 mg in three or four divided doses per day. The half-life of clonidine is in the range of 3–4 hours. Although a clinical response generally becomes apparent by about 4 weeks, treatment effects may increase over 2–3 months. Therapeutic doses of methylphenidate can frequently be decreased by 30–50% when used in conjunction with clonidine. Transdermal administration of clonidine using a skin patch can be quite effective but may result in skin irritation in 40% of patients. Patches are generally changed every 5 days.

The starting dosage of guanfacine is usually 0.5–1 mg once a day, increasing as clinically indicated after 3–5 days to 2–4 mg/d in two or three divided doses per day. Adverse effects include transient headaches and stomach aches in 25% of patients. Sedation and hypertension are mild. For medical follow-up, pulse and blood pressure should be checked every 1–2 weeks for 2 months and then at 3-month intervals.

5. Adverse effects—Sedation can be prominent. Side effects include fatigability, dizziness associated with hypotension, increased appetite and weight gain, headache, sleep disturbance, GI distress, skin irritation with transdermal clonidine administration, and rebound hypertension with abrupt withdrawal. Bradycardia can occasionally be marked.

6. Drug interactions—Increased sedation with central nervous system depressants; possible increased anticholinergic toxicity. Several case reports have mentioned cardiac toxicity with clonidine when combined with methylphenidate, although other medications and clinical factors were present in each case.

7. Medical follow-up—Pulse and blood pressure should be recorded every 2 weeks for 2 months and then every 3 months. The discontinuation of clonidine or guanfacine should occur gradually, with stepwise dosage decreases every 3–5 days to avoid rebound hypertension. Blood pressure should be monitored during withdrawal.

Child Abuse & Neglect

Andrew P. Sirotnak, MD
Richard D. Krugman, MD
Antonia Chiesa, MD

The problem of child abuse and neglect, barely recognized as a significant problem in the early editions of this textbook, has grown to such serious proportions that in 1990 the U.S. Advisory Board on Child Abuse and Neglect called the present state of the nation's ability to protect children a "national emergency." Over a decade later and into the 21st century, the emergency is still with us. What Dr. Henry Kempe and his colleagues first called battered child syndrome was thought to affect 749 children in the United States in 1960. In 2005 an estimated 3.3 million referrals were made to child protective service agencies involving the alleged maltreatment of approximately 6 million children. This translates to an approximate national referral rate of 43.9 referrals per 1000 children. Just under 900,000 of these cases were substantiated by child protective services in 2005, yielding an abuse victimization rate of 12.1 per 1000 American children. At least 1500 children are victims of fatal child abuse each year, and in 2005 the rate of child abuse death was 1.96 per 100,000 children. This dramatic increase in cases has resulted from increased recognition of the problem by professionals, partly in response to statutory reporting mandates, a broadening of the definitions of abuse and neglect from the original battered child concept, and changes in the demography and social structure of families and neighborhoods over the past several decades. Substance abuse, poverty and economic strains, parental capacity and skills, and domestic violence are cited as the most common presenting problems in abusive families.

Abuse and neglect of children are best considered in an ecological perspective, which recognizes the individual, family, social, and psychological influences that come together to contribute to the problem. Kempe and Helfer termed this the *abusive pattern*, in which the child, the crisis, and the caregiver's potential to abuse are components in the event of maltreatment. For most pediatric health care professionals, however, their involvement will be limited to individual cases. This chapter focuses on the knowledge necessary for

the recognition, intervention, and follow-up of the more common forms of child maltreatment and highlights the role of pediatric professionals in prevention.

FORMS OF CHILD MALTREATMENT

Child maltreatment may occur either within or outside the family. The proportion of intrafamilial to extrafamilial cases varies with the type of abuse as well as the gender and age of the child. Each of the following conditions may exist as separate or concurrent diagnoses. Neglect is the most commonly reported and substantiated form of child maltreatment annually.

Physical Abuse

Physical abuse of children is most often inflicted by a caregiver or family member but occasionally by a stranger. The most common manifestations include bruises, burns, fractures, head trauma, and abdominal injuries. A small but significant number of unexpected pediatric deaths, particularly in infants and very young children (eg, sudden unexpected infant death), are related to physical abuse.

Sexual Abuse

Sexual abuse is defined as the engaging of dependent, developmentally immature children in sexual activities that they do not fully comprehend and to which they cannot give consent, or activities that violate the laws and taboos of a society. It includes all forms of incest, sexual assault or rape, and pedophilia. This includes fondling, oral-genital-anal contact, all forms of intercourse or penetration, exhibitionism, voyeurism, exploitation or prostitution, and the involvement of children in the production of pornography. Although over the past decade there has been a small downward trend in total reports of sexual abuse cases, exploitation and enticement of children and adolescents via the Internet remains a growing trend.

Emotional Abuse & Neglect

Emotional or psychological abuse has been defined as the rejection, ignoring, criticizing, isolation, or terrorizing of children, all of which have the effect of eroding their self-esteem. The most common form is verbal abuse or denigration. Children who witness domestic violence should be considered emotionally abused. The most common feature of emotional neglect is the absence of normal parent-child attachment and a subsequent inability to recognize and respond to an infant's or child's needs. A common manifestation of emotional neglect in infancy is nutritional (nonorganic) failure to thrive.

Physical Neglect

Physical neglect is the failure to provide the necessary food, clothing, and shelter and a safe environment in which children can grow and develop. Although often associated with poverty or ignorance, physical neglect involves a more serious problem than just lack of resources. There is often a component of emotional neglect and either a failure or an inability, intentionally or otherwise, to recognize and respond to the needs of the child.

Medical Care Neglect

Medical care neglect is failure to provide the needed treatment to infants or children with life-threatening illness or other serious or chronic medical conditions.

Münchhausen Syndrome by Proxy

Münchhausen syndrome by proxy is a relatively unusual disorder in which a caregiver, usually the mother, either simulates or creates the symptoms or signs of illness in a child. The disorder has recently been termed *factitious disorder by proxy*. The child can present with a long list of medical problems or often bizarre, recurrent complaints. Persistent doctor shopping and enforced invalidism (eg, not accepting that the child is healthy and reinforcing that the child is somehow ill) are also described in the original definition of Münchhausen syndrome by proxy. Fatal cases have been reported.

RECOGNITION OF ABUSE & NEGLECT

The most common features suggesting a diagnosis of child abuse are summarized in Tables 7–1 and 7–2. Obvious signs of injury, sexual abuse, or neglect may be present. Classic radiographic and laboratory findings are discussed later in this chapter. Psychosocial factors may indicate risk for or confirm child maltreatment.

Recognition of any form of abuse and neglect of children can occur only if child abuse is considered in the differential diagnosis of the child's presenting medical condition. The approach to the family should be supportive, nonaccusatory, and empathetic. The individual who brings the child in for care may not have any involvement in the abuse. Approximately one third of child abuse incidents occur in extrafamilial settings. Neverthe-

Table 7-1. Common historical features in child abuse cases.

<ul style="list-style-type: none"> Discrepant, evolving, or absent history Delay in seeking care Event or behavior by child that triggers a loss of control of caregiver History of abuse in the caregiver's childhood Inappropriate affect of the caregiver Pattern of increasing severity or number of injuries if no intervention Social or physical isolation of the child or the caregiver Stress or crisis in the family or the caregiver Unrealistic expectations of caregiver for the child
--

less, the assumption that the caregiver is "nice," combined with the failure to consider the possibility of abuse, can be costly and even fatal. Raising the possibility that a child has been abused is not the same as accusing the caregiver of being the abuser. The health professional who is examining the child can explain to the family that several possibilities might explain the child's injuries or abuse-related symptoms. If the family or presenting caregiver is not involved in the child's maltreatment, they may actually welcome the necessary report and investigation.

History

In all cases of abuse and neglect, a detailed psychosocial history is important. This should include information on who lives in the home, other caregivers, domestic violence, substance abuse, and prior family history of physical or sexual abuse. Inquiring about any previous involvement with social services or law enforcement can help to determine risk.

Table 7-2. Presentations of sexual abuse.

<ul style="list-style-type: none"> General or direct statements about sexual abuse Sexualized knowledge, play, or behavior in developmentally immature children Sexual abuse of other children by the victim Behavioral changes <ul style="list-style-type: none"> Sleep disturbances (eg, nightmares and night terrors) Appetite disturbances (eg, anorexia, bulimia) Depression, social withdrawal, anxiety Aggression, temper tantrums, impulsiveness Neurotic or conduct disorders, phobias or avoidant behaviors Guilt, low self-esteem, mistrust, feelings of helplessness Hysterical or conversion reactions Suicidal, runaway threats or behavior Excessive masturbation Medical conditions <ul style="list-style-type: none"> Recurrent abdominal pain or frequent somatic complaints Genital, anal, or urethral trauma Recurrent complaints of genital or anal pain, discharge, bleeding Enuresis or encopresis Sexually transmitted infections Pregnancy Promiscuity or prostitution, sexual dysfunction, fear of intimacy School problems or truancy Substance abuse

A. Physical Abuse

The medical diagnosis of physical abuse is based on the presence of a discrepant history, in which the history offered by the caregiver is not consistent with the clinical findings. The discrepancy may exist because the history is absent, partial, changing over time, or simply illogical or improbable. The presence of a discrepant history should prompt a request for consultation with a multidisciplinary child protection team or a report to the child protective services agency. This agency is mandated by state law to investigate reports of suspected child abuse and neglect. Investigation by social services and possibly law enforcement officers, as well as a home visit, may be required to sort out the circumstances of the child's injuries. Other common historical features in child abuse cases are listed in Table 7-1.

B. Sexual Abuse

Sexual abuse may come to the clinician's attention in different ways: (1) The child may be brought in for routine care or for an acute problem, and sexual abuse may be suspected by the medical professional as a result of the history or the physical examination. (2) The parent or caregiver, suspecting that the child may have been sexually abused, may bring the child to the health care provider and request an examination to rule in or rule out abuse. (3) The child may be referred by child protective services or the police for an evidentiary examination following either disclosure of sexual abuse by the child or an allegation of abuse by a parent or third party. Table 7-2 lists the presentations of child sexual abuse. It should be emphasized that with the exception of acute trauma, certain sexually transmitted infections (STIs), or forensic laboratory evidence, none of these presentations is specific. The presentations listed should arouse suspicion of the possibility of sexual abuse and lead the practitioner to ask the appropriate questions—again, in a compassionate and nonaccusatory manner. Asking the child nonleading, age-appropriate questions is important and is often best handled by the most experienced interviewer after a report is made. Community agency protocols may exist for child advocacy centers that help in the investigation of these reports. Concerns expressed about sexual abuse in the context of divorce and custody disputes should be handled in the same manner, with the same objective, nonjudgmental documentation. The American Academy of Pediatrics has published guidelines for the evaluation of child sexual abuse as well as other guidelines relating to child maltreatment.

C. Emotional Abuse

Emotional abuse may cause nonspecific symptoms in children. Loss of self-esteem or self-confidence, sleep disturbances, somatic symptoms (eg, headaches and stomach aches), hypervigilance, or avoidant or phobic behaviors (eg, school refusal or running away) may be presenting com-

plaints. These complaints may also be seen in children who experience domestic violence. Emotional abuse can occur in the home or day care, school, sports team, or other settings.

D. Neglect

Even though in 2005 there were three times as many reports of neglect of children as of physical abuse, neglect is not easily documented on history. Physical neglect—which must be differentiated from the deprivations of poverty—will be present even after adequate social services have been provided to families in need. Emotionally neglectful parents appear to have an inability to recognize the physical or emotional states of their children. For example, an emotionally neglectful parent may ignore an infant's cry if the cry is perceived incorrectly as an expression of anger. This misinterpretation leads to inadequate nutrition and failure to thrive. The clinician must evaluate the psychosocial history and family dynamics when neglect is a consideration, and a careful social services investigation of the home and entire family may be required.

E. Failure to Thrive

The history offered in cases of growth failure (failure to thrive) is often discrepant with the physical findings. Infants who have experienced a significant deceleration in growth are probably not receiving adequate amounts or appropriate types of food despite the dietary history provided. Medical conditions causing poor growth in infancy and early childhood can be ruled out with a detailed history and physical examination with minimal laboratory tests. A psychosocial history may reveal maternal depression, family chaos or dysfunction, or other previously unknown social risk factors (eg, substance abuse, violence, poverty, or psychiatric illness). Placement of the child with another caregiver is usually followed by a dramatic weight gain. Hospitalization of the severely malnourished patient is sometimes required, but most cases are managed on an outpatient basis.

Physical Findings

A. Physical Abuse

The findings on examination of physically abused children may include abrasions, alopecia, bites, bruises, burns, dental trauma, fractures, lacerations, ligature marks, or scars. Injuries may be in multiple stages of healing. Bruises in physically abused children are sometimes patterned (eg, belt marks, looped cord marks, or grab or pinch marks) and are typically found over the soft tissue areas of the body. Toddlers or older children typically sustain accidental bruises over bony prominences such as shins and elbows. Any bruise in an infant not developmentally mobile should be viewed with concern. (Other child abuse emergencies are listed in Table 7-3.) Lacerations of the frenulum or tongue and bruising of the lips may be associated with force feeding. Pathognomonic burn pat-

Table 7-3. Potential child abuse medical emergencies.

Any infant with bruises (especially head, facial, or abdominal), burns, or fractures
Any infant or child younger than age 2 years with a history of suspected “shaken baby” head trauma or other inflicted head injury
Any child who has sustained suspicious or known inflicted abdominal trauma
Any child with burns in stocking or glove distribution or in other unusual patterns, burns to the genitalia, and any unexplained burn injury
Any child with disclosure or sign of sexual assault within 48–72 h after the alleged event if the possibility of acute injury is present or if forensic evidence exists

terns include stocking or glove distribution; immersion burns of the buttocks, sometimes with a “doughnut hole” area of sparing; and branding burns such as with cigarettes or hot objects (eg, grill, curling iron, or lighter). The absence of splash marks or a pattern consistent with spillage may be helpful in differentiating accidental from nonaccidental scald burns.

Head and abdominal trauma may present with signs and symptoms consistent with those injuries. Inflicted head trauma (eg, shaken baby syndrome) and abdominal injuries may have no visible findings on examination. Symptoms can be subtle and may mimic other conditions such as gastroenteritis. Studies have documented that cases of inflicted head injury will be missed when practitioners fail to consider the diagnosis. The finding of retinal hemorrhages in an infant without an appropriate medical condition (eg, leukemia, congenital infection, or clotting disorder) should arouse concern about possible inflicted head trauma. Retinal hemorrhages are not commonly seen after cardiopulmonary resuscitation in either infants or children.

B. Sexual Abuse

The genital and anal findings of sexually abused children, as well as the normal developmental changes and variations in prepubertal female hymens, have been described in journal articles and visual diagnosis guides. To maintain a sense of comfort and routine for the patient, the genital examination should be conducted in the context of a full body checkup. For non–sexually active, prepubertal girls, an internal speculum examination is rarely necessary unless there is suspicion of internal injury; the external female genital structures can be well visualized using labial separation and traction with the child in the supine frog leg or knee-chest position. The majority of victims of sexual abuse exhibit no physical findings. The reasons for this include delay in disclosure by the child, abuse that may cause no physical trauma (eg, fondling, oral-genital contact, or exploitation by pornographic photography), or rapid healing of minor injuries such as labial, hymenal, or anal abrasions, contusions, or lacerations. Nonspecific abnormalities of the genital and

rectal regions such as erythema, rashes, and irritation may not suggest sexual abuse in the absence of a corroborating history, disclosure, or behavioral changes. Finally, some medical conditions may be misdiagnosed as sexual abuse (eg, vulvovaginitis, lichen sclerosus, dermatitis, labial adhesions, congenital urethral or vulvar disorders, Crohn’s disease, and accidental straddle injuries to the labia) and can be ruled out by careful history and examination.

Certain STIs should strongly suggest sexual abuse. *Neisseria gonorrhoeae* infection or syphilis beyond the perinatal period is diagnostic of sexual abuse. *Chlamydia trachomatis*, herpes simplex virus, trichomoniasis, and human papillomavirus are all sexually transmitted, although the course of these perinatally acquired infections may be protracted. In the case of human papillomavirus, an initial appearance of venereal warts beyond the toddler age should prompt a discussion regarding concerns of sexual abuse. Human papillomavirus is a ubiquitous virus and can be spread innocently by caregivers with hand lesions; biopsy and viral typing is rarely indicated and often of limited availability. Finally, sexual abuse must be considered with the diagnosis of HIV infection when other modes of transmission (eg, transfusion or perinatal acquisition) have been ruled out. Postexposure prophylaxis medications for HIV in cases of acute sexual assault should be considered only after assessment of risk of transmission and consultation with an infectious disease expert.

Although sensitivity and specificity of nonculture tests such as nucleic acid amplification tests (NAATs) have improved, they have not yet been approved for the screening of STIs in sexual abuse victims or for children younger than 12 years of age. If an NAAT is positive, a confirmatory test is needed. Specimens from symptomatic patients should still be cultured. Finally, the Centers for Disease Control and Prevention and many sexual abuse atlases list guidelines for the screening and treatment of STIs in the context of sexual abuse.

C. Neglect and Nonorganic Failure to Thrive

Infants and children with nonorganic failure to thrive have a relative absence of subcutaneous fat in the cheeks, buttocks, and extremities. Other conditions associated with poor nutrient and vitamin intake may be present. If the condition has persisted for some time, these patients may also appear and act depressed. Older children who have been chronically emotionally neglected may also have short stature (ie, deprivation dwarfism). The head circumference is usually normal in cases of nonorganic failure to thrive. Microcephaly may signify a prenatal condition, congenital disease, or chronic nutritional deprivation and increases the likelihood of more serious and possibly permanent developmental delay.

D. Münchausen Syndrome by Proxy

Children with Münchausen syndrome by proxy may present with the signs and symptoms of whatever illness is factitiously

produced or simulated. They may be actually ill or, more often, are reported to be ill and have a normal clinical appearance. Among the most common reported presentations are recurrent apnea, dehydration from induced vomiting or diarrhea, sepsis when contaminants are injected into a child, change in mental status, fever, gastrointestinal bleeding, and seizures.

Radiologic & Laboratory Findings

A. Physical Abuse

Certain radiologic findings are strong indicators of physical abuse. Examples are metaphyseal “corner” or “bucket handle” fractures of the long bones in infants, spiral fracture of the extremities in nonambulatory infants, rib fractures, spinous process fractures, and fractures in multiple stages of healing. Skeletal surveys in children aged 3 years or younger should be performed when a suspicious fracture is diagnosed. Computed tomography or magnetic resonance imaging findings of subdural hemorrhage in infants—in the absence of a clear accidental history—are highly correlated with abusive head trauma, especially after the advent of infant seat restraint laws that have reduced the incidence of head trauma in infants. Abdominal computed tomography is the preferred test in suspected abdominal trauma. Any infant or very young child with suspected abuse-related head or abdominal trauma should be evaluated immediately by an emergency physician or trauma surgeon.

Coagulation studies and a complete blood cell count with platelets are useful in children who present with multiple or severe bruising in different stages of healing. Coagulopathy conditions may confuse the diagnostic picture but can be excluded with a careful history, examination, laboratory screens, and hematologic consultation if necessary.

The differential diagnosis of all forms of physical abuse can be considered in the context of a detailed trauma history, family medical history, radiographic findings, and laboratory testing. The diagnosis of osteogenesis imperfecta or other collagen disorders, for example, may be considered in the child with skin and joint findings or multiple fractures with or without the classic radiographic presentation and is best made in consultation with a geneticist, an orthopedic surgeon, and a radiologist. Trauma—accidental or inflicted—leads the differential diagnosis list for subdural hematomas. Coagulopathy; disorders of copper, amino acid, or organic acid metabolism (eg, Menkes syndrome and glutaric acidemia type 1); chronic or previous central nervous system infection; birth trauma; or congenital central nervous system malformation (eg, arteriovenous malformations or cerebrospinal fluid collections) may need to be ruled out in some cases. It should be recognized, however, that children with these rare disorders can also be victims of abuse or neglect.

B. Sexual Abuse

The forensic evaluation of sexually abused children should be performed in a setting that prevents further emotional

distress. If the history indicates that the child may have had contact with the ejaculate of a perpetrator within 72 hours, an examination to look for semen or its markers (eg, acid phosphatase) should be performed according to established protocols. This should occur in an emergency department or clinic where chain of custody for specimens can be assured. More important, if there is a history of possible sexual abuse within the past 48–72 hours, and the child reports a physical complaint or a sign is observed (eg, genital or anal bleeding or discharge), the child should be examined for signs of trauma. The most experienced examiner (pediatrician, nurse examiner, or child advocacy center) is preferable. The laboratory and serologic evaluation of STIs should be guided by the type of contact reported and the epidemiology of these infections in the community.

C. Neglect and Growth Failure

Children with failure to thrive or malnutrition may not require an extensive workup. Assessment of the patient’s growth curve, as well as careful plotting of subsequent growth parameters after treatment, is critical. Complete blood cell count, urinalysis, electrolyte panel, and thyroid and liver function tests are sufficient screening. Newborn screening should be documented as usual. Other tests should be guided by any aspect of the clinical history that points to a previously undiagnosed condition. A skeletal survey and head computed tomography scan may be helpful if concurrent physical abuse is suspected. The best screening method, however, is placement in a setting in which the child can be fed and monitored. Hospital or foster care placement may be required. Weight gain may not occur for several days to a week in severe cases.

D. Münchhausen Syndrome by Proxy

Recurrent polymicrobial sepsis (especially in children with indwelling catheters), recurrent apnea, chronic dehydration of unknown cause, or other highly unusual unexplained laboratory findings should raise the suspicion of Münchhausen syndrome by proxy.

MANAGEMENT & REPORTING

Physical abuse injuries, STIs, and medical sequelae of neglect should be treated immediately. Children with failure to thrive related to emotional and physical neglect need to be placed in a setting in which they can be fed and cared for. Likewise, the child in danger of recurrent abuse or neglect needs to be placed in a safe environment.

In the United States, clinicians and many other professionals who come in contact with or care for children are mandated reporters. If abuse or neglect is suspected, a report must be made to the local or state agency designated to investigate such matters. In most cases, this will be the child protective services agency. Law enforcement agencies may

also receive such reports. The purpose of the report is to permit professionals to gather the information needed to determine whether the child's environment (eg, home, school, day care setting, or foster home) is safe. Recent backlash against physicians in Great Britain involved in high-profile child abuse cases should not deter anyone in the United States from following the state-specific child abuse reporting laws. Many hospitals and communities make child protection teams or consultants available when there are questions about the diagnosis and management in a child abuse case. A listing of pediatric consultants in child abuse is available from the American Academy of Pediatrics.

Except in extreme cases, the reporting of emotional abuse is not likely to generate an immediate response from child protection agencies. This should not deter reporting, especially if there is also concern for domestic violence or other forms of abuse or neglect. Practitioners can encourage parents to become involved with parent effectiveness training programs (eg, Healthy Families America or Parents Anonymous) or to seek mental health consultation. Support for the child may also include mental health counseling or age-appropriate peer and mentoring activities in school or the community. Finally, communication with social services, case management, and careful follow-up by primary care providers is crucial to ensuring ongoing safety of child.

PREVENTION

Physical abuse is preventable in many cases. Extensive experience with and evaluation of high-risk families have shown that the provision of home visitor services to families at risk can prevent abuse and neglect of children. These services can be provided by public health nurses or trained paraprofessionals, although more data are available describing public health nurse intervention. The availability of these services could make it as easy for a family to pick up the telephone and ask for help before they abuse a child as it is for a neighbor or physician to report an episode of abuse after it has occurred. Parent education and anticipatory guidance are also helpful, with attention to handling situations that stress parents (eg, colic, crying behavior, and toilet training), age-appropriate discipline, and general developmental issues. Prevention of abusive injuries perpetrated by nonparent caregivers (eg, babysitters, nannies, and unrelated adults in the home) may be addressed by education and counseling of mothers about safe child care arrangements and advocating for affordable day care for all families. Promising new data suggest the efficacy of hospital-based programs that teach parents about the dangers of shaking an infant and how to respond to a crying infant.

The prevention of sexual abuse is more difficult. Most efforts in this area involve teaching children to protect themselves and their "private parts" from harm or interference. The age of toilet training is a good time to provide anticipatory guidance to encourage parents to consider this

discussion. The most rational approach is to place the burden of responsibility of prevention on the adults who supervise the child and the medical providers rather than on the children themselves. Knowing the parents' own history of any victimization is important, as the ability to engage in this anticipatory guidance discussion with a provider and their child may be affected by that history. Promoting Internet safety and limiting exposure to sexualized materials and media should be part of this anticipatory guidance. Finally, many resource books on this topic for parents can be found in the parenting and health sections of most bookstores.

Efforts to prevent emotional abuse of children have been undertaken through extensive media campaigns. No data are available to assess the effectiveness of this approach. The primary care physician can promote positive, nurturing, and nonviolent behavior in parents. The message that they are role models for a child's behavior is important. Screening for domestic violence during anticipatory guidance discussions on discipline, home, and safety can be effective in identifying parents and children at risk.

Ambulatory & Community Pediatrics

Robert M. Brayden, MD

Maya Bunik, MD, MSPH

Jeffrey M. Brown, MD, MPH, CPE

Matthew F. Daley, MD

Pediatric ambulatory outpatient services provide children and adolescents with preventive health care and acute and chronic care management services and consultations. In this chapter, special attention is given to the pediatric history and physical examination, normal developmental stages, office telephone management, and community pediatrics.

The development of a physician–patient–parent relationship is crucially important if the patient and parent are to effectively confide their concerns. This relationship develops over time, with increasing numbers of visits, and is facilitated by the continuity of clinicians and other staff members. This clinical relationship is based on trust that develops as a result of several experiences in the context of the office visit. Perhaps the greatest factor facilitating the relationship is for patients or parents to experience advice as valid and effective. Important skills include choosing vocabulary that communicates understanding and competence, demonstrating commitment of time and attention to the concern, and showing respect for areas that the patient or parent does not wish to address (assuming there are no concerns relating to physical or sexual abuse or neglect). Parents and patients expect that their concerns will be managed confidentially and that the clinician understands and sympathizes with those concerns. The effective physician–patient–parent relationship is one of the most satisfying aspects of ambulatory pediatrics.

PEDIATRIC HISTORY

A unique feature of pediatrics is that the history represents an amalgam of parents' objective reporting of facts (eg, fever for 4 days), parents' subjective interpretation of their child's symptoms (eg, infant crying interpreted by parents as abdominal pain), and for older children their own history of events. Parents and patients may provide a specific and detailed history, or a vague history that necessitates more focused probing. Parents may or may not be able to distinguish whether symptoms are caused by organic illness or a psycho-

logical concern. It is often helpful to ask what problems the parents specifically wish to address in order to determine what really prompted the office visit. Some visits are occasioned by problems at school, such as low grades or troublesome peer relationships. Understanding the family and its hopes for and concerns about the child can help in the process of distinguishing organic illness from emotional or behavioral conditions, thus minimizing unnecessary testing and intervention.

Although the parents' concerns need to be understood, it is essential also to obtain as much of the history as possible directly from the patient. Direct histories not only provide firsthand information but also give the child a degree of control over a potentially threatening situation and may reveal important information about the family.

Obtaining a comprehensive pediatric history is time-consuming. Many offices provide questionnaires for parents to complete before the clinician sees the child. Data from questionnaires can make an outpatient visit more productive, allowing the physician to address problems in detail while more quickly reviewing areas that are not of concern. Questionnaires may be more productive than face-to-face interviews in revealing sensitive parts of the history. However, failure to review and assimilate this information prior to the interview may cause a parent or patient to feel that the time and effort have been wasted.

Elements of the history that will be useful over time should be readily accessible in the medical record. Such information can be accumulated on a summary sheet, as illustrated in Figure 8–1. Demographic data; a problem list; information about chronic medications, allergies, and previous hospitalizations; and the names of other physicians providing care for the patient are commonly included. Documentation of immunizations, including all data required by the National Childhood Vaccine Injury Act, should be kept on a second page.

The components of a comprehensive pediatric history are listed in Table 8–1. The information should, ideally, be obtained at the first office visit. The first seven items may be included on a summary sheet at the front of the medical

Table 8-1. Components of the pediatric historical database.^a

1. Demographic data	Patient's name and nickname, date of birth, social security number, sex, race, parents' names (first and last), siblings' names, and payment mechanism.
2. Problem list	Major or significant problems, including dates of onset and resolution.
3. Allergies	Triggering allergen, nature of the reaction, treatment needed, and date allergy diagnosed.
4. Chronic medications	Name, concentration, dose, and frequency of chronically used medications.
5. Birth history	Maternal health during pregnancy, medications, street drugs used, complications of pregnancy; duration and ease of labor; form of delivery; analgesics and anesthetics used; need for monitoring; and labor complications. Infant's birth weight, gestational age, Apgar scores, and problems in the neonatal period.
6. Screening procedures	Results of newborn screening, vision and hearing screening, any health screen, or screening laboratory tests. (Developmental screening results are maintained in the development section; see item 14, below.)
7. Immunizations	Date of each immunization administered, vaccine manufacturer and lot number, and name and title of the person administering the vaccine; previous reaction and contraindication to immunization (eg, immunodeficiency or an evolving neurologic problem).
8. Reasons for visit	The patient's or parents' concerns, stated in their own words, serve as the focus for the visit.
9. Present illness	A concise chronologic summary of the problems necessitating a visit, including the duration, progression, exacerbating factors, ameliorating interventions, and associations.
10. Medical history	A statement regarding the child's functionality and general well-being, including a summary record of significant illnesses, injuries, hospitalizations, and procedures.
11. Diet	Eating patterns, likes and dislikes, use of vitamins, and relative amounts of carbohydrates, fat, and protein in the diet.
12. Family history	Information about the illnesses of relatives, preferably in the form of a family tree.
13. Social history	Family constellation, relationships, parents' educational background, religious preference, and the role of the child in the family; socioeconomic profile of the family to identify resources available to the child, access to services that may be needed, and anticipated stressors.
14. Development	(1) Attainment of developmental milestones (including developmental testing results); (2) social habits and milestones (toilet habits, play, major activities, sleep patterns, discipline, peer relationships); (3) school progress and documentation of specific achievements and grades.
15. Sexual history	Family's sexual attitudes, sex education, sexual development and activity, sexually transmitted diseases, and birth control measures.
16. Review of systems (ROS)	This area tends to be overlooked because of the work required to obtain a complete ROS and integrate data into the patient's problems list and care plan. A focused ROS is essential if any problem is to be addressed adequately.

^aThe components of this table should be included in a child's medical record and structured to allow easy review and modification. The practice name and address should appear on all pages.

Because young children may fear the examination and become fussy, simple inspection is important. For example, during an acute-care visit for fever, the examiner should observe the child's skin color and work of breathing prior to beginning the examination. During a health supervision visit, observation will provide the examiner with an opportunity to assess parent-child interactions.

Clothing should be removed slowly and gently to avoid threatening the child. A parent or the child is usually the best person to do this. Modesty should always be respected, and gown or drapes should be provided. Examinations of adolescents should be chaperoned whenever a pelvic examination or a stressful or painful procedure is performed.

Examination tables are convenient, but a parent's lap is a comfortable location for a young child. For most purposes,

an adequate examination can be conducted on a "table" formed by the parent's and examiner's legs as they sit facing each other.

Although a thorough physical examination is important at every age, at some ages the examination tends to focus on specific issues and concerns. At any age, an astute clinician can detect signs of important clinical conditions in an asymptomatic child. In infancy, for example, physical examination can reveal the presence of craniosynostosis, congenital heart disease, or developmental dysplasia of the hip. Similarly, examination of a toddler may reveal pallor (possible iron-deficiency anemia) or strabismus. The routine examination of an adolescent may reveal scoliosis or acanthosis nigricans (a finding associated with insulin resistance).

HEALTH SUPERVISION VISITS

One of several timetables for recommended health supervision visits is illustrated in Figure 8–2. (**Note:** A PDF printable format of this figure is available from the American Academy of Pediatrics [AAP].) The federal Maternal and Child Health Bureau has developed comprehensive health supervision guidelines through their Bright Futures program. In areas where evidence-based information is lacking, expert opinion has been used as the basis for these plans. For example, immunizations are proven to be effective and necessary (Centers for Disease Control and Prevention [CDC]), whereas there is disagreement about whether screening for certain metabolic diseases is universally warranted. Practitioners should remember that guidelines are not meant to be rigid; services should be individualized according to the child's needs.

During health supervision visits, the practitioner should review child development and acute and chronic problems, conduct a complete physical examination, order appropriate screening tests, and anticipate future developments. New historical information should be elicited through an interval history. Development should be assessed by parental report and clinician observation at each visit. Developmental surveillance is augmented with systematic use of parent-directed questionnaires or screening tests. Growth is carefully recorded, and the growth chart is brought up to date (see Chapter 2). Vision and hearing should be assessed subjectively at each visit, with objective assessments at intervals beginning after the child is old enough to cooperate with the screening test, usually at age 3 or 4 years. Various laboratory screening tests may also be part of the visit.

Because fewer than 4% of asymptomatic children have physical findings on routine health maintenance visits, a major portion of the health supervision visit is devoted to anticipatory guidance. This portion of the visit enables the health care provider to address behavioral, developmental, injury prevention, and nutritional issues; school problems; and other age-appropriate issues that will arise before the next well-child visit.

DEVELOPMENTAL & BEHAVIORAL ASSESSMENT

Addressing developmental and behavioral problems is one of the central features of pediatric primary care. The term *developmental delay* refers to the circumstance in which a child has not demonstrated a developmental skill (such as walking independently) by an age at which the vast majority of normally developing children have accomplished this task. Developmental delays are, in fact, quite common:

approximately 18% of children younger than age 18 years either have developmental delays or have conditions that place them at risk of developmental delays.

Pediatric practitioners are in a unique position to assess the development of their patients. This developmental assessment should ideally take the form of *developmental surveillance*, in which a skilled individual monitors development over time as part of providing routine care. Developmental surveillance includes several key elements: listening to parent concerns; obtaining a developmental history; making careful observations during office visits; periodically screening all infants and children for delays using validated screening tools; recognizing conditions and circumstances that place children at increased risk of delays; and referring children who fail screening tests for further evaluation and intervention.

The prompt recognition of children with developmental delays is important for several reasons. The presence of delays may lead practitioners to diagnose unsuspected but important conditions, such as genetic syndromes or metabolic disorders. Children with delays can be referred for a wide range of developmental therapies, such as those provided by physical therapists and speech/language therapists. Importantly, children with delays, regardless of the cause, make better developmental progress if they receive appropriate developmental therapies than if they do not. Finally, many infants and toddlers younger than age 3 years with developmental delays are eligible to receive a range of therapies and other services, often provided in the home, at no cost to families. Children aged 3 years and older with delays are also eligible for developmental services, at no cost, through the local school system.

Although the benefits of early detection of developmental delays are clear, it is often difficult to incorporate developmental surveillance into busy outpatient practice. Only 30% of pediatricians routinely use formal screening tests; most rely on clinical judgment alone. However, when screening tests are not used, delays are often not detected until school age, particularly when the delays are not severe. There are several practical barriers to performing routine surveillance using standardized screening tools: perceived lack of time to screen all children at every well child visit; lack of familiarity with the various screening tools; not wanting to concern parents by identifying a possible delay; and not knowing where in the community to refer patients with suspected delays. There are some solutions to these barriers, such as using parent developmental questionnaires rather than provider-administered tests to save time, become familiar with one or two screening tests, and making use of Internet-based resources. For example, the National Information Center for Children and Youth with Disabilities maintains a web site with links to a wide variety of resources in each state (<http://www.nichcy.org>).

Several parent-administered and physician-administered developmental screening tools are available. The Parents' Evaluation of Developmental Status, the Ages and Stages Questionnaires, and the Child Development Inventories are

● = to be performed ★ = risk assessment to be performed, with appropriate action to follow, if positive ←●→ = range during which a service may be provided, with the symbol indicating the preferred age

- a If a child comes under care for the first time at any point on the schedule, or if any items are not accomplished at the suggested age, the schedule should be brought up to date at the earliest possible time.
- b A prenatal visit is recommended for parents who are at high risk, for first-time parents, and for those who request a conference. The prenatal visit should include anticipatory guidance, pertinent medical history, and a discussion of benefits of breastfeeding and planned method of feeding per AAP statement “The Prenatal Visit” (2001) [URL:<http://aappolicy.aappublications.org/cgi/content/full/pediatrics;107/6/1456>].
- c Every infant should have a newborn evaluation after birth, breastfeeding encouraged, and instruction and support offered.
- d Every infant should have an evaluation within 3 to 5 days of birth and within 48 to 72 hours after discharge from the hospital, to include evaluation for feeding and jaundice. Breastfeeding infants should receive formal breastfeeding evaluation, encouragement, and instruction as recommended in AAP statement “Breastfeeding and the Use of Human Milk” (2005) [URL:<http://aappolicy.aappublications.org/cgi/content/full/pediatrics;115/2/496>]. For newborns discharged in less than 48 hours after delivery, the infant must be examined within 48 hours of discharge per AAP statement “Hospital Stay for Healthy Term Newborns” (2004) [URL:<http://aappolicy.aappublications.org/cgi/content/full/pediatrics;113/5/1434>].
- e Blood pressure measurement in infants and children with specific risk conditions should be performed at visits before age 3 years.
- f If the patient is uncooperative, rescreen within 6 months per AAP statement “Eye Examination and Vision Screening in Infants, Children, and Young Adults” (1996) [URL:<http://aappolicy.aappublications.org/cgi/reprint/pediatrics;98/1/153.pdf>].
- g All newborns should be screened per AAP statement “Year 2000 Position Statement: Principles and Guidelines for Early Hearing Detection and Intervention Programs” (2000) [URL:<http://aappolicy.aappublications.org/cgi/content/full/pediatrics;106/4/798>]. Joint Committee on Infant Hearing. Year 2007 position statement: principles and guidelines for early hearing detection and intervention programs. *Pediatrics*. 2007;120:898–921.
- h AAP Council on Children With Disabilities, AAP Section on Developmental Behavioral Pediatrics, AAP Bright Futures Steering Committee. AAP Medical Home Initiatives for Children With Special Needs Project Advisory Committee. Identifying infants and young children with developmental disorders in the medical home: an algorithm for developmental surveillance and screening. *Pediatrics*. 2006;118:405–420 [URL:<http://aappolicy.aappublications.org/cgi/content/full/pediatrics;118/1/405>].
- i Gupta VB, Hyman SL, Johnson CP, et al. Identifying children with autism early? *Pediatrics*, 2007;119:152–153 [URL:<http://pediatrics.aappublications.org/cgi/content/full/119/1/152>].
- j At each visit, age-appropriate physical examination is essential, with infant totally unclothed, older child undressed and suitably draped.
- k These may be modified, depending on entry point into schedule and individual need.
- l Newborn metabolic and hemoglobinopathy screening should be done according to state law. Results should be reviewed at visits and appropriate retesting or referral done as needed.
- m Schedules per the Committee on Infectious Diseases, published annually in the January issue of *Pediatrics*. Every visit should be an opportunity to update and complete a child’s immunizations.
- n See AAP *Pediatric Nutrition Handbook*, 5th Edition (2003) for a discussion of universal and selective screening options. See also Recommendations to prevent and control iron deficiency in the United States. *MMWR Recomm Rep*. 1998; 47(RR-3):1–36.
- o For children at risk of lead exposure, consult the AAP statement “Lead Exposure in Children: Prevention, Detection, and Management” (2005) [URL:aappolicy.aappublications.org/cgi/content/full/pediatrics;116/4/1036]. Additionally, screening should be done in accordance with state law where applicable.
- p Perform risk assessments or screens as appropriate, based on universal screening requirements for patients with Medicaid or high prevalence areas.
- q Tuberculosis testing per recommendations of the Committee on Infectious Diseases, published in the current edition of *Red Book: Report of the Committee on Infectious Diseases*. Testing should be done in recognition of high-risk factors.
- r “Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III) Final Report” (2002) [URL:<http://circ.ahajournals.org/cgi/content/full/106/25/3143>] and “The Expert Committee Recommendations on the Assessment, Prevention, and Treatment of Child and Adolescent Overweight and Obesity.” Supplement to *Pediatrics*. In press.
- s All sexually active patients should be screened for sexually transmitted infections (STIs).
- t All sexually active girls should have screening for cervical dysplasia as part of a pelvic examination beginning within 3 years of onset of sexual activity or age 21 (whichever comes first).
- u Referral to dental home, if available. Otherwise, administer oral health risk assessment. If the primary water source is deficient in fluoride, consider oral fluoride supplementation.
- v At the visits for 3 years and 6 years of age, it should be determined whether the patient has a dental home. If the patient does not have a dental home, a referral should be made to one. If the primary water source is deficient in fluoride, consider oral fluoride supplementation.
- w Refer to the specific guidance by age as listed in Bright Futures Guidelines. (Hagan JF, Shaw JS, Duncan PM, eds. *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents*, 3rd ed. Elk Grove Village, IL: American Academy of Pediatrics: 2008.)

▲ **Figure 8-2.** Recommendations for preventive health care. (Hagan JF, Shaw JS, Duncan PM, eds. *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents*. 3rd ed. American Academy of Pediatrics, 2008.)

screening tests that rely on parent report. The Denver II screening test (reproduced in Chapter 2, Figure 2–12), the Early Language Milestone Scale (see Chapter 2, Figure 2–11), and the Bayley Infant Neurodevelopmental Screener all involve the direct observation of a child's skills by a care provider. All developmental screening tests have their strengths and weaknesses. The Denver II is familiar to many pediatric providers and is widely used. However, whereas the Denver II has relatively high sensitivity for detecting possible developmental delays, the specificity is poorer, and this may lead to the over-referral of normal children for further developmental testing.

Regardless of the approach taken to developmental screening, there are number of important considerations: (1) the range of normal childhood development is broad, and therefore a child with a single missing skill in a single developmental area is less likely to have a significant developmental problem than a child showing multiple delays in several developmental areas (eg, gross motor *and* language delays); (2) continuity of care is important, because development is best assessed over time; (3) it is beneficial to routinely use formal screening tests to assess development; (4) if developmental delays are detected in primary care, these patients need referral for further testing and likely will benefit from receiving developmentally focused therapies; (5) parents appreciate when attention is paid to their child's development, and generally react positively to referrals for appropriate developmental therapies.

Several developmental charts with age-based expectations for normal development are presented in Chapter 2 (see Tables 2–1, 2–2, and 2–3), as well as a discussion of the recommended medical and neurodevelopmental evaluation of a child with a suspected developmental disorder.

In addition to developmental issues, pediatric providers are an important source of information and counseling for parents regarding a broad range of behavioral issues. The nature of the behavioral problems, of course, varies with the child's age. Some common issues raised by parents, discussed in detail in Chapter 2, include colic, feeding disorders, sleep problems, temper tantrums, breath-holding spells, and noncompliance. Behavioral issues in adolescents are discussed in Chapter 3.

GROWTH PARAMETERS

Monitoring appropriate growth is pivotal in ambulatory pediatric practice. Pediatric growth charts are based on a

broad sampling of the U.S. population, with representation of young infants, breast-fed infants, and certain ethnic minorities. The 2- to 18-year growth charts include a chart of body mass index (BMI) for age. The BMI is calculated as the weight (in kilograms) divided by the squared height (in meters). The BMI is useful for determining obesity (BMI \geq 95th percentile for age) and underweight status (BMI \leq 5th percentile for age). The BMI is highly correlated with secondary complications of obesity.

Height, weight, and head circumference are carefully measured and plotted at each visit during the first 3 years (see growth charts in Chapter 2). For children older than 3 years, height and weight should be measured at each well child examination. To ensure accurate weight measurements for longitudinal comparisons, infants should be undressed completely, and young children should be wearing underpants only. Recumbent length is plotted on the chart from birth to 3 years (see Figures 2–1 and 2–3). When the child is old enough to be measured upright, height should be plotted on the charts for ages 2–18 years (see Figures 2–5 and 2–7). If circumferential head growth has been steady for the first 2 years, routine measurements may be suspended. However, if a central nervous system problem exists or develops, or if the child has growth deficiency, this measurement continues to be useful. Tracking the growth velocity for each of these parameters allows early recognition of deviations from normal.

Kuczumski RJ et al: *CDC Growth Charts: United States. Advance Data from Vital and Health Statistics*, No. 314. National Center for Health Statistics, 2000. Available at: <http://www.cdc.gov/growthcharts/default.htm>.

BLOOD PRESSURE

Blood pressure screening at well-child visits starts at age 3 years. If the child has a renal or cardiovascular abnormality, a blood pressure reading should be obtained at each visit regardless of age. Accurate determination of blood pressure requires proper equipment (stethoscope, manometer and inflation cuff, or an automated system) and a cooperative, seated subject in a quiet room. Although automated blood pressure instruments are widely available and easy to use, blood pressure readings from these devices are typically 5 mm Hg higher for diastolic and 10 mm Hg higher for systolic blood pressure compared with auscultatory techniques. Therefore, the diagnosis of hypertension should not be made on the basis of automated readings alone. Additionally, blood pressure varies somewhat by the height and weight of the individual. Consequently, hypertension is diagnosed as a systolic or diastolic blood pressure greater than the 95th percentile based on the age and height (or weight) percentile of the patient.

The width of the inflatable portion of the cuff should be 40–50% of the circumference of the limb. Obese children need a larger cuff size to avoid a falsely elevated blood pressure reading. Cuffs that are too narrow will overestimate

and those that are too wide will underestimate the true blood pressure. Repeated measurements at different visits over time should be tracked using flow charts in an electronic medical record or equivalent in a paper chart. Blood pressure norms are provided in Chapter 19.

VISION & HEARING SCREENING

Examination of the eyes and an assessment of vision should be performed at every health supervision visit. Parents should be queried about any concerns regarding vision, eye alignment, or any other eye problems. For example, parental observation of photophobia or excessive tearing may be suggestive of glaucoma.

In children from birth to 3 years of age, the eyes and eyelids should be inspected, the movement and alignment of the eyes assessed, and the pupils and red reflexes examined. The red reflex, performed on each pupil individually and then on both eyes simultaneously, is used to detect eye opacities (eg, cataracts or corneal clouding) and retinal abnormalities (eg, retinal detachment or retinoblastoma). In children younger than 3 years of age or in nonverbal children of any age, vision can be assessed by testing a child's ability to fixate on and follow an object.

In children aged 3 years and older, in addition to the eye evaluations, formal testing of visual acuity should be done. This can be performed in the office with a variety of tests, including the tumbling E chart or picture tests such as Allen cards. Each eye is tested separately, with the nontested eye completely covered. Credit is given for any line on which the child gets more than 50% correct. Children 4 years of age and older who are unable to cooperate should be retested, ideally within 1 month, and those who cannot cooperate with repeated attempts should be referred to an ophthalmologist. Because visual acuity improves with age, results of the test are interpreted using the cutoff values in Table 8–2. However, any two-line discrepancy between the two eyes, even within the passing range (eg, 20/20 in one eye, 20/30 in the other in a child aged 6 years or older) should be referred to an ophthalmologist. Throughout childhood and adolescence, clinicians should screen for undetected strabismus (ocular misalignment) and decreased visual acuity. The random dot E test is recommended for detecting strabismus. The corneal light reflex test, the cover test, and visual acuity tests are described further in Chapter 15.

Table 8–2. Age-appropriate visual acuity.^a

Age (years)	Minimal Acceptable Acuity
3–5	20/40
6 and older	20/30

^aRefer to an ophthalmologist if minimal acuity is not met at a given age or if there is a difference in scores of two or more lines between the eyes.

Hearing loss, if undetected, can lead to substantial impairments in speech, language, and cognitive development. Because significant bilateral hearing loss is one of the more common major anomalies found at birth, and early detection and intervention of hearing loss leads to better outcomes for children, universal hearing screening of all infants is required in many parts of the United States. Hearing in infants is assessed using either auditory brainstem evoked responses or evoked otoacoustic emissions. Because universal newborn hearing screening will inevitably be associated with some false-positive test results, confirmatory audiologic testing is required for all abnormal tests.

Informal behavioral testing of hearing, such as observing an infant's response to a shaken rattle, may be unreliable. In fact, parental concerns about hearing are of greater predictive value than the results of informal tests, and such concerns should be taken seriously. Pure tone audiometry in the office is feasible beginning at age 3 years. Any evidence of hearing loss should be substantiated by repeated testing, and if still abnormal, a referral for a formal hearing evaluation should be made. A number of inherited or acquired conditions increase the risk of hearing loss. Children with any risk factors for hearing loss should be closely followed and periodically screened. Additional details regarding hearing assessment are provided in Chapter 17.

LABORATORY SCREENING

Newborn Screening

Newborn screening involves population-wide testing for metabolic and genetic diseases. Blood samples are collected by heelstick from newborns before hospital discharge, and results are usually available within 1 week. Some states routinely repeat blood testing between 7 and 14 days of life, while others recommend it if the child is discharged in less than 24 hours. Repeat testing may be necessary to detect

diseases of protein (eg, phenylketonuria [PKU]) or sugar metabolism (eg, galactosemia), which may not be discovered if the first newborn blood screen is performed before the child has had substantial milk intake.

All state newborn screening programs include tests for PKU and congenital hypothyroidism. If undiagnosed, both diseases result in severe mental retardation. Early treatment maintains cognitive function in the normal range. All states also test for classical galactosemia and sickle cell disease. Additional diseases screened for in the majority of states include congenital adrenal hyperplasia, homocystinuria, maple syrup urine disease, and biotinidase deficiency. Tests for tyrosinemia, cystic fibrosis, toxoplasmosis, and HIV are conducted in some states.

Infants with a positive screening result should receive close follow-up, with additional confirmatory studies performed at a center with experience in doing these tests. Screening tests are usually accurate, but the sensitivity and specificity of a particular screening test must be carefully considered. If symptoms of a disease are present despite a negative result on a screening test, the infant should be tested further. Once a diagnosis is confirmed, the infant will need further evaluation and treatment.

Advances in science and technology, such as tandem mass spectroscopy and the Human Genome Project, have created the potential to test for numerous additional inherited diseases. Treatments for these additional diseases vary from highly effective to ineffective. The risks and benefits of early detection of these conditions have been little studied but widely speculated upon. Preliminary results suggest that the early identification of rare metabolic diseases by screening leads to improved child health outcomes and reduced parent stress. The long-term effect of false-positive screens on parents is unknown.

Lead Screening

The developing infant and child are at risk of lead poisoning or toxicity because of their propensity to place objects in the mouth and their efficient absorption of the metal. High blood levels (> 70 mcg/dL) can cause severe health problems such as seizures and coma. Numerous neuropsychological deficits have been associated with increased lead levels. Blood lead levels less than 10 mcg/dL have been correlated with lower intelligence quotients. The primary source of lead exposure in this country remains lead-based paint, even though most of its uses have been banned since 1977. Lead levels have declined nationally from a mean of 16 mcg/dL in 1976 to 2 mcg/dL in 2001. However, considerable variation in lead levels exists in different regions of the United States, and a majority of children at risk of lead toxicity are not currently screened. To eliminate childhood lead poisoning by 2010 (one of the Healthy People 2010 national health objectives), health care providers need to be vigilant about this environmental health threat.

Despite the wide variation in the prevalence of lead toxicity, the CDC recommends universal lead screening for children at ages 1 and 2 and targeted screening for older children living in communities with a high percentage of old housing ($> 27\%$ of houses built before 1950) or a high percentage of children with elevated blood lead levels ($> 12\%$ of children with levels above 10 mcg/dL).

Communities with inadequate data regarding local blood lead levels should also undergo universal screening. Medicaid requires that all children aged 1–5 years be screened twice. Caregivers of children between 6 months and 6 years of age may be interviewed by questionnaire about environmental risk factors for lead exposure (Table 8–3), although the data to support the use of this screening are inconclusive. If risk factors are present, a blood lead level should be obtained.

A venous blood sample is preferred over a capillary specimen. An elevated capillary (fingerstick) blood sample should always be confirmed by a venous sample. No action is required for blood lead levels less than 10 mcg/dL. The cognitive development of children with confirmed blood levels higher than 14 mcg/dL should be evaluated and attempts made to identify the environmental source. Iron deficiency should be treated if present. Chelation of lead is indicated for levels of 45 mcg/dL and higher and is urgently required for levels above 70 mcg/dL. All families should receive education to decrease the risk of lead exposure. With any elevated lead level (> 10 mcg/dL) rescreening should be performed at recommended intervals.

Iron Deficiency

Iron deficiency is the most common nutritional deficiency in the United States. Severe iron deficiency causes anemia,

Table 8–3. Elements of a lead risk questionnaire.

Recommended questions

1. Does your child live in or regularly visit a house built before 1950? This could include a day care center, preschool, the home of a baby-sitter or relative, and so on.
2. Does your child live in or regularly visit a house built before 1978 with recent, ongoing, or planned renovation or remodeling?
3. Does your child have a sister or brother, housemate, or playmate being followed for lead poisoning?

Questions that may be considered by region or locality

1. Does your child live with an adult whose job (eg, at a brass/copper foundry, firing range, automotive or boat repair shop, or furniture refinishing shop) or hobby (eg, electronics, fishing, stained-glass-making, pottery-making) involves exposure to lead?
2. Does your child live near a work or industrial site (eg, smelter, battery recycling plant) that involves the use of lead?
3. Does your child use pottery or ingest medications that are suspected of having a high lead content?
4. Does your child have exposure to burning lead-painted wood?

behavioral problems, and cognitive effects, but recent evidence suggests that even iron deficiency without anemia may cause behavioral and cognitive difficulties. Furthermore, the developmental effects of iron deficiency may persist for 10 years, even if iron deficiency is corrected in infancy. Risk factors for iron deficiency include preterm or low birth weight births, multiple pregnancy, iron deficiency in the mother, use of nonfortified formula or cow's milk before age 12 months, and an infant diet that is low in iron-containing foods. Infants and toddlers consuming more than 24 oz/d of cow's milk are at risk, as are children with chronic illness, restricted diet, or extensive blood loss.

Primary prevention of iron deficiency should be achieved through dietary means, including feeding infants iron-containing cereals by age 6 months, avoiding low-iron formula during infancy, and limiting cow's milk to 24 oz/d in children aged 1–5 years. Selective early screening for iron deficiency should be considered with the presence of any of the preceding risk factors. A screening hemoglobin or hematocrit should be obtained for high-risk children between ages 9 and 12 months and again at 15–18 months, and it should be considered annually through age 5 years. Premature and low birth weight infants may need testing before 6 months of age. Universal anemia screening at 9 and 15 months of age is appropriate for children in communities or patient populations in which anemia is found in 5% or more of those tested. Biochemical tests of iron deficiency, including ferritin (low in the absence of inflammation), transferrin saturation (low), and erythrocyte protoporphyrin (elevated), are sensitive measures. Lead poisoning can cause iron-deficiency anemia and should be explored as a cause for at-risk infants and children. A screening hematocrit is recommended for pregnant teenagers.

Hypercholesterolemia & Hyperlipidemia

The benefits of screening and treatment for hypercholesterolemia and hyperlipidemia in children are not fully known. However, the AAP and the American Heart Association recommend obtaining a total cholesterol measurement in children older than 2 years who have a parent with elevated cholesterol (> 240 mg/dL). If there is a family history of cardiovascular disease before age 55 years, a complete lipoprotein analysis (fasting cholesterol, high-density lipoproteins, low-density lipoproteins, triglycerides) is recommended. For all children, a prudent diet is advised (see section on Nutrition Counseling, later).

Tuberculosis

According to the CDC, 13,779 cases of tuberculosis were reported in the United States in 2006. Risk of tuberculosis should be assessed at well-child visits, and screening should be based on high-risk status. High risk is defined as contact with a person with known or suspected tuberculosis; having symptoms or radiographic findings suggesting tuberculosis; birth, residence, or travel to a region with high tuberculosis

prevalence (Asia, Middle East, Africa, Latin America); contact with a person with AIDS or HIV; or contact with a prisoner, migrant farm worker, illicit drug user, or a person who is or has been recently homeless. The Mantoux test (5 tuberculin units of purified protein derivative) is the only recommended screening test. It can be done as early as 3 months of age and should be repeated annually if the risk persists. The tine test should not be used. Previous vaccination with bacille Calmette-Guérin (BCG) is not a contraindication to tuberculosis skin testing.

Screening of Adolescent Patients

Screening adolescents for blood cholesterol, tuberculosis, and HIV should be offered based on high-risk criteria outlined in this chapter and in Chapter 39. Females with heavy menses, weight loss, poor nutrition, or athletic activity should have a screening hematocrit. During routine visits, adolescents should be questioned sensitively about risk factors (eg, multiple partners; early onset of sexual activity, including child sexual abuse) and symptoms (eg, genital discharge, infectious lesions, pelvic pain) of sexually transmitted diseases (STDs). A dipstick urinalysis for leukocytes is generally recommended for sexually active adolescents. Teenage girls who are sexually active and all girls aged 18 years and older, regardless of sexual experience, should have a pelvic examination with Papanicolaou (Pap) smear. A Pap smear should be performed at least every 3 years thereafter and more frequently in patients with STD risk factors. Because females with STDs are often not symptomatic, gonococcal and chlamydial cultures and screening tests for syphilis and trichomoniasis are appropriate at the time of each pelvic examination.

ANTICIPATORY GUIDANCE

An essential part of the health supervision visit is anticipatory guidance. During this counseling, the clinician directs the

parent's or the older child's attention to issues that may arise in the future. Guidance must be appropriate to age, focus on concerns expressed by the parent and patient, and address issues in depth rather than run through a number of issues superficially. Both oral and printed materials are used. Handouts can be an important supplement to anticipatory guidance. When selecting written materials, providers should be sensitive to issues of literacy and primary language spoken by the family members. A routine schedule for preventive handouts is shown in Table 8–4. Areas of concern include diet, injury prevention, developmental and behavioral issues, and health promotion. Injury prevention is discussed in the next section; other topics are found in other chapters of this book.

Injury Prevention

Injuries are the leading cause of death in children and adolescents after the first year of life (Figure 8–3). For young people aged 15–19 years, injuries are responsible for more than half of all deaths. Each year, 16 million visits to emergency departments are occasioned by injuries to children and adolescents, and more than 500,000 of these patients are hospitalized. In the case of physical injury to a young child, the physician must recognize that some injuries may be intentional or the result of parental neglect (see Chapter 7).

Injury prevention counseling is an important component of each health supervision visit and can be reinforced during all visits. Counseling should focus on problems that are frequent and age appropriate. Passive strategies of prevention should be emphasized, because these are more effective than active strategies; for example, placing chemicals out of reach in high, locked cupboards to prevent poisoning will be more effective than instructing parents to watch their children closely.

Informational handouts about home safety, such as The Injury Prevention Program (TIPP; available from the AAP), can be provided in the waiting room. Advice can then be tailored to the specific needs of each family, with reinforcement from age-specific TIPP handouts.

The pediatrician's influence can extend beyond the office to advocate for safer communities. For example, a community program in Seattle, Washington, to promote the use of bicycle helmets has increased helmet use from 2% to more than 60% through a combination of office education, low-cost helmets, and legislative advocacy. The primary care provider is in an ideal position to identify high-risk situations and intervene before injury occurs. For example, if a teenager has emotional problems (eg, depression) and a history of driving violations, the clinician should recommend a mental health referral; this, in turn, could prevent a motor vehicle accident.

A. Motor Vehicle Injuries

The primary cause of death of children in the United States is motor vehicle injuries. In 1998, about 57% of children aged 15 years or younger who were killed in motor vehicle accidents were unrestrained. Car safety seats for children are

Table 8–4. Preventive handouts for health supervision visits.

Age	Suggested Topics
2 wk	Breast feeding
2 mo	Attachment
4 mo	Language and motor development
6 mo	Nutrition
12 mo	Safe and constructive family relationships
18 mo	Toilet training basics
2 y	Time-out technique
3 y	Chores and social competence
4 y	Sexuality education across the ages
5 y	Media and child health
6 y	School work: Encouraging success
8 y	Sibling rivalry
10 y	Social competence
12 y	Adolescents: Promoting responsibility

required in all U.S. states, and their proper use could reduce vehicle-associated fatalities and hospitalizations by at least 50%. The type of safety seat to be used depends on the child's weight and age: rear-facing infant seat for a child under 20 lb and 1 year of age; forward-facing car seat for a child 20–40 lb and older than 1 year; and belt-positioning booster seat for a child who has outgrown the safety seat but is under 60 lb. When children have grown enough to properly fit the vehicle seat belts (usually when 4 feet tall), they should use a combination lap and shoulder belt. A rear-facing car seat should never be used in a seat with a passenger air bag. A car seat should never be used if the child has outgrown the seat—for example, ears above the back of the seat or shoulders above the seat strap slots.

Up-to-date information on car seats is available through the AAP (at <http://www.aap.org/family/carseatguide.htm>).

When a child is a passenger in a car crash, the case fatality rate is 1%; for children hit by cars, the risk of fatality increases threefold. Pedestrian safety skills should be taught to children early in childhood; however, parental supervision of children near roadways continues to be required for many years. A final motor vehicle risk for health involves the use of portable electronic devices. Using a cellular telephone while driving is associated with a fourfold increase in motor vehicle accidents. Parents and teenage drivers should avoid this risk.

B. Bicycle Injuries

In 2001, over 400,000 Americans sustained a bicycle-related injury, and two thirds of these injuries involved children or adolescents. Head trauma accounts for three fourths of all

Children 1 – 4 years

Children 5 – 9 years

Older children 10 – 14 years

Young adults 15 – 19 years

▲ **Figure 8-3.** Leading causes of death in children at 1–4 years, 5–9 years, 10–14 years, and 15–19 years (the 2004 rate per 100,000 population). (National Center for Health Statistics, 2007.)

bicycle-related fatalities. More than 85% of brain injuries can be prevented through the use of bicycle helmets, and due to a recent increase in use of helmets, the rate of fatality to bicyclists is dropping. Bike riders—parents and children alike—should wear a helmet every time they ride. Unfortunately, low bicycle helmet use rates are still common in some communities.

C. Injuries and Violence Prevention

The United States has a higher rate of firearm-related death than any other industrialized country. Injuries from firearms are more frequent among young people aged 15–24 years than among any other age group, and black males are especially vulnerable. Some gun deaths may be accidental, but most are the result of homicide or suicide. A gun in the home doubles the likelihood of a lethal suicide attempt. Although handguns are often kept in homes for protection, a gun is more likely to kill a family member or a friend than an intruder. The most effective way to prevent firearm injuries is to remove guns from the home and community. Families who keep firearms at home should lock them in a cabinet or drawer and store ammunition in a separate locked location.

A nonviolent environment should be provided to all children. Secure parent–infant attachments, social and conflict-resolution skills, and the avoidance of violence (on television or actual) all have a role in promoting nonviolence.

D. Drowning and Near Drowning

Drowning is the second leading cause of injury-related death in children, and those aged 1–3 years have the highest rate of drowning. For every death by drowning, six children are hospitalized for near drowning, and up to 10% of survivors experience severe brain damage. Children younger than 1 year of age are most likely to drown in the bathtub. Buckets filled with water also present a risk of drowning to the older infant or toddler. For children aged 1–4 years, drowning or near drowning occurs most often in home swimming pools; and for school-aged children and teens, drowning occurs most often in large bodies of water (eg, swimming pools or open water). After the age of 5 years, the risk of drowning in a swimming pool is much greater for black males than white males. School-aged children should be taught to swim, and recreational swimming should always be supervised. Home pools must be fenced securely, and parents should know how to perform cardiopulmonary resuscitation.

E. Fire and Burn Injuries

Fires and burns are the leading cause of injury-related deaths in the home. Categories of burn injury include smoke inhalation; flame contact; scalding; and electrical, chemical, and ultraviolet burns. Scalding is the most common type of burn in children. Most scalds involve foods and beverages, but nearly one fourth of scalds are with tap water, and for that reason it is recommended that hot water heaters be set to less than 54°C (130°F). Most fire-related deaths result

from smoke inhalation. Smoke detectors can prevent 85% of the injuries and deaths caused by fires in the home. Families should discuss a fire plan with children and practice emergency evacuation from the home.

Sunburn is a common thermal injury, perhaps because symptoms of excessive sun exposure do not begin until after the skin has been damaged. Sunburn and excessive sun exposure are associated with skin cancers. Prevention of sunburn is best achieved by sun avoidance, particularly during the midday hours of 10 AM to 3 PM. Sunscreen using a sun protection factor (SPF) of 15–30 extends the duration of time that a child can spend in the sun without sunburn. It should be applied liberally (15 mL for a 7-year-old) and reapplied every 2 hours even if designated as waterproof. Hats, sunglasses, and special precautions for fair-skinned individuals and infants are also important aspects of safe sun exposure. The safety of sunscreen is not established for infants younger than 6 months; thus sun avoidance, appropriate clothing, and hats are recommended for this age group. Lightweight fabric wetsuits with long sleeves are now made for children and offer more protection from the sun than a traditional swimsuit.

NUTRITION COUNSELING

Screening for nutritional problems and guidance for age-appropriate dietary choices should be part of every health supervision visit. Overnutrition, undernutrition, and eating disorders can be detected by a careful analysis of dietary and activity patterns interpreted in the context of a child's growth pattern. When obtaining a dietary history, it is helpful to assess the following: who purchases and prepares food; who feeds the child; whether meals and snacks occur at consistent times and in a consistent setting; whether children are allowed to snack or "graze" between meals; the types and portion sizes of food and drinks provided; the frequency of eating meals in restaurants or eating take-out food; and whether the child eats while watching television.

Iron-fortified formula or breast milk should be used for the first year of life, after which whole cow's milk can be given. Because of continued rapid growth and high energy needs, children should continue to drink whole milk until age 2 years. Baby foods are generally introduced at about 4–6 months of age.

For children 2 years of age and older, a prudent diet consists of diverse food sources, encourages high-fiber foods (eg, fruits, vegetables, grain products), and limits sodium and fat intake. Foods to be avoided or limited include processed foods, soft drinks, and candy. Parents should be gently reminded that they are modeling for a lifetime of eating behaviors in their children, both in terms of the types of foods they provide, and the structure of meals (eg, the importance of the family eating together). For additional information on nutritional guidelines, undernutrition, and obesity, see Chapter 10; for eating disorders, see Chapter 5; for adolescent obesity, see Chapter 3.

American Academy of Pediatrics, Committee on Nutrition: Prevention of pediatric overweight and obesity. *Pediatrics* 2003;112:424 [PMID: 12897303].

COUNSELING ABOUT TELEVISION & OTHER MEDIA

The average child in the United States watches approximately 3 hours of television per day, and this does not include time spent watching videotapes or DVDs, playing video games, or playing on computers. Having a television set in the bedroom is associated with watching more television, and 32% of 2- to 7-year-olds and 65% of 8- to 18-year-olds have a bedroom television set.

The excessive watching of television has a negative and potentially long-lasting impact on the health and well-being of children. Television viewing has been shown to have negative effects with respect to violence, sexuality, substance abuse, nutrition, and body self-image. More recent data suggest that excessive television viewing in childhood may have a long-lasting negative effect on cognitive development and academic achievement.

Some educational television programs would not be expected to adversely affect children and may in fact have some benefit. Regardless, it is important that clinicians assess media exposure in their patients, and offer parents concrete advice. The AAP recommends that children younger than 2 years of age should not watch any television, and that children 2 years and older be limited to 2 hours total time each day for all media. Additionally, parents should monitor what their children watch, remove television sets from their children's bedrooms, and encourage alternative activities.

IMMUNIZATIONS

A child's immunization status should be assessed at every clinic visit and every opportunity should be taken to vaccinate. Even though parents may keep an immunization record, it is critical that providers also keep an accurate record of a child's immunizations. This information should be written in a prominent location in the paper or electronic chart or kept in an immunization registry.

Despite high overall national immunization coverage levels, areas of underimmunization continue to exist in the United States. An understanding of true contraindications (versus "false contraindications") and a "no missed opportunities" approach to immunization delivery has been shown to successfully increase immunization levels. Therefore, it is important that clinicians screen records and administer required immunizations at all types of visits, and administer all needed vaccinations simultaneously. Additionally, clinicians should operate reminder/recall systems, in which parents of underimmunized children are prompted by mail or telephone to visit the clinic for immunization. The assessment of clinic-wide immunization levels and feedback of these data to providers have also been shown to increase immunization rates.

Immunization schedules and other details of specific vaccines are presented in Chapter 9. A wealth of information for parents and providers about immunizations is also available at the National Immunization Program's web site (<http://www.cdc.gov/vaccines>).

OTHER TYPES OF GENERAL PEDIATRIC SERVICES

ACUTE-CARE VISITS

Acute-care visits account for 30% or more of the general pediatrician's office visits. These visits are conducted in an efficient, structured way. Office personnel should determine the reason for the visit and whether it is an emergent situation, obtain a brief synopsis of the child's symptoms, carefully document vital signs, and list known drug allergies. The pediatric clinician should document the events related to the presenting problem and carefully describe them in the medical record. The record should include supporting laboratory data and a diagnosis. Treatments and follow-up instructions must be recorded, including when to return to the office if the problem is not ameliorated. Immunization status should be screened, as previously discussed. Depend-

ing on the severity of illness, this may also be an opportunity for age-appropriate health maintenance screenings and anticipatory guidance. This may be particularly true with older school-aged children or adolescents who may be seen more rarely for routine health maintenance visits.

PRENATAL VISITS

Ideally, a couple's first trip to a physician's office should take place before the birth of their baby. A prenatal visit goes a long way toward establishing trust and enables a pediatric provider to learn about a family's expectations, concerns, and fears regarding the anticipated birth. If the infant develops a problem during the newborn period, a provider who has already met the family is in a better position to maintain rapport and communication with the new parents.

In addition to helping establish a relationship between parents and pediatric providers, the prenatal visit can be used to gather information about the parents and the pregnancy, provide information and advice, and identify high-risk situations. A range of information can be provided to parents regarding feeding choices and the benefits of breast feeding; injury prevention, including sleeping position and the appropriate use of car seats; and techniques for managing colic. Potential high-risk situations that may be identified include mental health issues in the parents, a history of domestic violence, or maternal medical problems that may affect the infant.

Serwint JR: The prenatal pediatric visit. *Pediatr Rev* 2003;24:31 [PMID: 12509543].

SPORTS PHYSICALS

The purpose of the preparticipation health evaluation is to determine whether a child can safely participate in organized sports activity. Attention should be directed toward those parts of the body that are most vulnerable to the stresses of sports. The history and physical examination should focus on the following systems: cardiovascular (stenotic lesions, hypertension, surgery), respiratory (asthma), vision, genitourinary (absence or loss of function of one testicle), gastrointestinal (hepatosplenomegaly, hernia), skin (infection), musculoskeletal (inflammation, dysfunction), and neurologic (concussions, uncontrolled seizures). The sports physical should include counseling about medication usage, protective equipment, proper supervision and instruction, injury management, and the emotional aspects of competition and teamwork. Information about certain sports should be included. For example, protective eyewear, mouth guards, padded goalposts, and efforts to minimize heading the ball should be discussed with a soccer player and his or her parent. The physician should suggest sports that will be compatible with the child's size, strength, endurance, agility, and history of chronic illness. The potential for mild menstrual irregularities should be explained to the adolescent female athlete. The athlete with moderate to

severe menstrual irregularities should be referred for endocrinologic evaluation. Anticipatory guidance should address nutritional needs to maintain growth, cessation of activity when pain occurs, and fluid and electrolyte availability to avoid dehydration. (See Chapter 25 for a more detailed discussion of sports medicine.)

Injuries in youth soccer: A subject review. American Academy of Pediatrics. Committee on Sports Medicine and Fitness. *Pediatrics* 2000;105:659 [PMID: 10699129].

CHRONIC DISEASE MANAGEMENT

Chronic disease in pediatrics is defined as illness that has been present for more than 3 months. Twenty-five percent of children and 35% of adolescents have illnesses that meet the definition of a chronic illness. The most common chronic illnesses in pediatric practice include asthma, otitis media with effusion, skin disorders, attention-deficit/hyperactivity disorder, and allergic diseases.

The goal of chronic disease management is to optimize quality of life while minimizing the side effects of treatment interventions. The child and family's emotional responses to chronic illness should be addressed, and referrals to counselors should be offered if needed. Pediatric subspecialty referrals need to be arranged and monitored and results recorded in the chart in an organized manner. Chronic problems often mean chronic use of medications and the need to monitor their use. Documentation should be made in the medical record whenever a prescription is refilled. A medication summary page in the chart allows easy access to the drug history and is a convenient place to make notes (Figure 8–4).

Nutrition and the management of medical devices (eg catheters, gastrostomy tubes) may need to be addressed.

Ludder-Jackson P, Vessey JA: *Primary Care of the Child with a Chronic Condition*, 3rd ed. Mosby-Year Book, 2000.

COUNSELING

Topics amenable to office counseling include behavioral issues such as negativism and noncompliance, temper tantrums, oppositional behavior, and biting; childhood fears and feeding disorders; school problems; family upheavals such as separation, divorce, or remarriage; attention-deficit/hyperactivity disorder; and deaths of family members or close friends. Forty-five minutes is usually enough time for the therapeutic process to evolve, and this time should be protected from interruption. The young child is usually interviewed with the parent; school-aged children and adolescents benefit from time alone with the physician. After assessing the situation in one or two sessions, the primary care physician must decide whether the child's and family's needs are within his or her area of expertise or whether referral to another professional such as a psychologist or an education specialist would be appropriate. The pediatrician should know the warning signs of childhood depression and bipolar disorder and have a low threshold for referral of these concerns to the appropriate mental health professional.

CONSULTATIONS

Physicians, other professionals, and parents may initiate consultations with a general pediatrician. Parents, subspecialists,

Medication: _____

Date: Visit (V) or Phone Call (PC)	Tablet Size or Liquid Concentration	Sig.	Disp.	Number of Refills	Approved by	Called by	Pharmacy and Phone No.

Notes (eg, levels): _____

▲ **Figure 8–4.** Medication summary sheet.

family physicians, or professionals such as school officials, psychologists, or social workers may all seek medical consultation. Finally, an insurance company representative may want a second opinion before authorizing a set of services.

Consultations usually require one or two 45- to 60-minute appointments. When the patient is referred to a pediatric consultant, the number of visits and the extent of service should be specified. A screening questionnaire, completed in advance by a parent, should delineate the patient's physical, behavioral, and developmental (or school) problems and serve as an initial database.

The types of consultations the general pediatrician may be asked to do include an evaluation only, an evaluation and interpretation, or an evaluation and treatment of an isolated problem. The type of consultation being requested should be clearly determined at the time of referral of the patient. This understanding should be clarified with the patient's insurance company so that appropriate authorization and reimbursement for the visit can occur.

Communication with the Referring Source

Communication is the key to a satisfactory referral process. The pediatric consultant frequently sends the referral source a brief letter acknowledging the referral and requesting additional information. The final consultation report should be sent promptly, with content appropriate for the referring source. School officials will want to know whether the patient is physically healthy or, if not, to receive a summary of their health care responsibilities. A referring physician expects a full report, and a copy is usually sent to the patient's parents. Recommendations should be specific (eg, drugs, dosages, other forms of therapy, duration of therapy, specific laboratory tests). A copy of or reference to a recent review article on the subject will also be appreciated.

A medical evaluation should contain a factual summary of the history, physical examination, and laboratory and radiologic findings. Families are grateful if a copy is sent to them for their information and records. At the end of the consultation, the parents should be told when the patient should see the primary physician—usually in 1–2 weeks. Positive comments about the referring physician's competence and judgment serve to support the primary physician–patient relationship. The parents must feel confident that the primary physician can provide the necessary follow-up care. If the referring physician had tentatively made the correct diagnosis prior to referral, the consultant's corroboration should be made clear to the parents and included in the consultation report.

TELEPHONE MANAGEMENT & WEB-BASED INFORMATION

Providing appropriate, efficient, and timely clinical advice over the telephone is a critical element of pediatric primary care in the office setting. An estimated 20–30% of all clinical

care delivered by general pediatric offices is provided by telephone. Telephone calls to and from patients occur both during regular office hours and after the office has closed (termed after-hours), and the personnel and systems in place to handle office-hours versus before- and after-hours calls may differ. In either circumstance, several principles are important: (1) advice is given only by clinicians or other staff with formal medical education (eg, nurse, medical assistant), (2) staff is given additional training in providing telephone care, (3) documentation is made of all pertinent information from calls, (4) standardized protocols covering the most common pediatric symptoms are used, and (5) a physician is always available to handle urgent or difficult calls.

During routine office hours, approximately 20–25% of all telephone calls to pediatric offices involve clinical matters. Many of these calls, however, are routine in nature, and an experienced nurse within the office can screen calls and provide appropriate advice by telephone. Calls from inexperienced or anxious parents about simple concerns should be answered with understanding and respect. Certain types of calls received during office hours should be promptly transferred to a physician: (1) true emergencies, (2) calls regarding hospitalized patients, (3) calls from other medical professionals, and (4) calls from parents who demand to speak with a physician. Nurses should also seek help from a clinician whenever they are uncertain about how to handle a particular call. When in doubt about the diagnosis or necessary treatment, nurses giving telephone advice should err on the side of having the patient seen in the office.

Several different options are available for handling after-hours pediatric telephone care. Clinicians may choose to take all calls from their patients, may rely on “advice” nurses without specific pediatric protocols or training, or may use a system specifically designed for pediatric telephone care, called a pediatric after-hours call center. Pediatric call centers, although not available in all communities, have certain benefits. Calls are managed using standardized protocols, the call centers are typically staffed by nurses with abundant pediatric experience, the calls are well-documented, and call centers often perform ongoing quality assurance. Extensive research on pediatric call centers has revealed a high degree of appropriate referrals to emergency departments, safety in terms of outcomes, parent satisfaction with the process, and savings to the health care system.

In general, after-hours pediatric telephone calls tend to be more serious than calls made during regular office hours. Deciding which patients need to be seen, and how urgently, are the most important aspects of these after-hours telephone “encounters.” Several factors influence this final patient disposition: (1) the age of the patient, (2) the duration and type of symptom, (3) the presence of any underlying chronic condition, (4) whether the child appears “very sick” to the caller, and (5) the anxiety level of the caller. Once all the pertinent medical information is gathered, a decision is made about whether the child should be seen immediately (by ambulance

versus car), seen in the office later (today versus tomorrow), or whether the illness can be safely cared for at home. At the end of the call, it should be confirmed that parents understand and feel comfortable with the plan for their child.

The use of the World Wide Web (Internet) has become common in the pediatric office setting. Many practices routinely use the Internet to give information about the practice, the care of common minor problems, scheduling of appointments, insurance issues, and so on. With time, the Internet is sure to become a larger part of the ambulatory pediatric practice.

COMMUNITY PEDIATRICS

According to the AAP, community pediatrics is “a perspective that enlarges the pediatrician’s focus from one child to all children in the community.” Pediatricians have historically been very involved in supporting and developing services for vulnerable children in their communities. As a group, pediatricians recognize that communities are integral determinants of a child’s health and that the synthesis of public health and personal health principles and practices is important in the practice of community pediatrics. As well, pediatricians have long been committed to working with other professionals in the community and advocating for the needs of all children. For example, pediatricians have been instrumental in the passage of laws requiring protective fencing around swimming pools.

Pediatricians in practice are frequently instrumental in referring children and families to valuable services and resources. For example, uninsured children can be enrolled in either their state Medicaid program or State Children’s Health Insurance Program (SCHIP). Children with special health care needs may be eligible for services typically funded through state health departments and through programs such as those provided based on the Individuals with Disabilities Education Act (IDEA). A variety of community-based immunization programs can provide access to needed immunizations for eligible children. Food and nutrition programs such as the federally funded Women, Infants, and Children (WIC) program provide sources of food at no cost to eligible fami-

lies. Finally, subsidized preschool and child care services such as the federally funded Head Start program provide needed preschool programs. Pediatricians are in a unique position to make referrals to these important services.

COMMON GENERAL PEDIATRIC ISSUES

FEVER

▶ General Considerations

Fever is one of the most common reasons for pediatric office visits, emergency department encounters, and after-hours telephone calls. Several different definitions of fever exist, but most experts define fever as a rectal temperature of 38°C or above. Temperature in pediatric patients can be measured in a variety of manners: rectal (using a mercury or digital thermometer), oral (mercury or digital), axillary (mercury, digital, or liquid crystal strip), forehead (liquid crystal strip), or tympanic (using a device that measures thermal infrared energy from the tympanic membrane). Tympanic measurement of temperature is quick and requires little patient cooperation. Several cautions apply to the use of this technique: tympanic temperatures have been shown to be less accurate in infants younger than 3 months of age and are subject to false readings if the instrument is not positioned properly or the external ear canal is occluded by wax.

▶ Causes

Fever occurs when there is a rise in the hypothalamic set-point in response to endogenously produced pyrogens. Among the broad range of conditions that cause fever are infections, malignancies, autoimmune diseases, metabolic diseases, chronic inflammatory conditions, medications (including immunizations), central nervous system abnormalities, and exposure to excessive environmental heat. In most settings, the majority of fevers in pediatric patients are caused by self-limiting viral infections. Teething does not cause fever over 38.4°C.

▶ Clinical Findings

A. Initial Evaluation

When evaluating a child with fever, one should elicit from the parents information about the duration of fever, how the temperature was taken, the maximum height of fever docu-

mented at home, all associated symptoms, any chronic medical conditions, any medications taken, medication allergies, fluid intake, urine output, exposures and travel, and any additional features of the illness that concern the parents (Table 8–5). In the office, temperature, heart rate, respiratory rate, and blood pressure should be documented, as well as an oxygen saturation if the child has any increased work of breathing. A complete physical examination, including a neurologic examination, should then be performed, with particular attention paid to the child's degree of toxicity and hydration status. A well-appearing, well-hydrated child with evidence of a routine viral infection can be safely sent home with symptomatic treatment and careful return precautions.

Depending on patient age, presence of underlying conditions, type of infection, and the provider's assessment of toxicity and hydration, many children with focal bacterial infections can also be treated as outpatients, with appropriate oral antibiotics as discussed in Chapter 40.

B. Fever without a Focus of Infection

Children who present with fever but without any symptoms or signs of a focal infection are often a diagnostic and management challenge. When assessing a child with fever but no apparent source of infection on examination, the provider needs to carefully consider the likelihood of a serious but “hidden” or occult bacterial infection. With the widespread use of effective vaccines against *Haemophilus influenzae* type b and *Streptococcus pneumoniae*, two of the most common causes of invasive bacterial infections in unimmunized children, the incidence of occult bacterial infections has declined. However, vaccines are not 100% effective, and other organisms cause serious occult infections in children; therefore, febrile children will always demand careful evaluation and observation. Appropriate choices for empiric antibiotic therapy of children with fever without focus are discussed in Chapter 37.

Febrile infants 28 days old or younger, because of their likelihood of serious disease including sepsis, should always be treated conservatively. Hospitalization and parenteral antibiotics should be strongly considered in all circumstances. An initial diagnostic evaluation should include complete blood count; blood culture; urinalysis; urine culture; and Gram stain, protein and glucose tests, and culture of cerebrospinal fluid. Consideration should also be given to the possibility of a perinatal herpes simplex virus infection (neonatal herpes is described in more detail in Chapter 38). A chest radiograph should be obtained for any infant with increased work of breathing.

Infants aged 29–90 days are at risk of developing a variety of invasive bacterial infections, including perinatally acquired organisms (eg, group B streptococci) or infections acquired in the household (eg, pneumococci or meningococci). Febrile infants without a focus of infection can be divided into those who appear toxic versus nontoxic, and those at low risk versus higher risk of invasive bacterial disease. As with febrile

Table 8–5. Guidelines for evaluating children with fever.

A. See immediately if:

1. Child is younger than age 3 months.
2. Fever is $>40.6^{\circ}\text{C}$.
3. Child is crying inconsolably or whimpering.
4. Child is crying when moved or even touched.
5. Child is difficult to awaken.
6. Child's neck is stiff.
7. Purple spots or dots are present on the skin.
8. Child's breathing is difficult, and not better after nasal passages are cleared.
9. Child is drooling saliva and is unable to swallow anything.
10. A convulsion has occurred.
11. Child acts or looks “very sick.”

B. See within 24 hours if:

1. Child is 3–6 months old (unless fever occurs within 48 h after a diphtheria-tetanus-pertussis vaccination and infant has no other serious symptoms).
2. Fever exceeds 40°C (especially if child is younger than age 3 years).
3. Burning or pain occurs with urination.
4. Fever has been present for more than 24 h without an obvious cause or identified site of infection.
5. Fever has subsided for more than 24 h and then returned.
6. Fever has been present > 72 h.

neonates, toxic children in this age group should be admitted to the hospital for parenteral antibiotics and close observation. In nontoxic infants, low risk has been defined as previously healthy; no focal infection on examination; white blood cell (WBC) count between 5000 and $15,000/\text{mm}^3$; band cells less than $1500/\text{mm}^3$; normal urinalysis; and, when diarrhea is present, less than 5 WBCs per high-power field. Nontoxic low-risk infants in this age group are typically treated as outpatients with close follow-up. Clinicians should be confident that lumbar puncture is unnecessary if they decide not to perform this procedure.

In an era of increasing immunization coverage against the most commonly invasive pneumococcal serotypes, it is difficult to estimate the risk of occult bacteremia in febrile 3–36-month-olds with no focus of infection. Nevertheless, when assessing children aged 3–36 months with temperatures of 39°C or higher, urine cultures should be considered in all male children younger than 6 months of age and in all females younger than 2 years of age. Chest radiographs should be performed in any child with increased work of breathing and should also be considered in children with high ($20,000/\text{mm}^3$) WBC counts but no respiratory symptoms. Depending on the child's appearance, underlying medical condition, and height of fever, blood cultures should also be obtained. Empiric antibiotic therapy may be considered, particularly for children with temperature of 39°C and WBC count of $15,000/\text{mm}^3$. However, in previously healthy, well-appearing, fully immunized children with reassuring laboratory studies, observation without antibiotics is appropriate.

► Treatment

Fever phobia is a term that describes parents' anxious response to the fevers that all children experience. In a recent study, 91% of caregivers thought that a fever could cause harmful effects. Seven percent of parents thought that if they did not treat the fever, it would keep going higher. Parents need to be reassured that fevers lower than 41.7°C do not cause brain damage. They should be counseled that, although fevers can occasionally cause seizures—in which case their child needs to be seen—febrile seizures are generally harmless and likewise do not cause brain damage.

Several safe and effective medications are available for the treatment of fever. Acetaminophen is indicated in children older than 2 months of age who have fever of 39°C or are uncomfortable. Acetaminophen is given in a dosage of 15 mg/kg of body weight per dose and can be given every 4–6 hours. The other widely used antipyretic is ibuprofen. Ibuprofen is given in a dosage of 10 mg/kg of body weight per dose and can be given every 6–8 hours. Ibuprofen and acetaminophen are similar in safety and their ability to reduce fever; however, ibuprofen is longer lasting. Aspirin should not be used for treating fever in any child or adolescent, because of its association with the development of Reye syndrome (particularly during infections with varicella and influenza). With all antipyretics, parents should be counseled to be very careful with dosing and frequency of administration as poisoning can be dangerous.

Rehm KP: Fever in infants and children. *Curr Opin Pediatr* 2001;13:83 [PMID: 11216593].

GROWTH DEFICIENCY

Growth deficiency—formerly termed failure to thrive—is deceleration of growth velocity resulting in crossing two major percentile lines on the growth chart. The diagnosis also is warranted if a child younger than age 6 months has not grown for 2 consecutive months or if a child older than age 6 months has not grown for 3 consecutive months. Growth deficiency occurs in about 8% of children.

Patterns of growth deficiency suggest, but are not specific for, different causes. In type I growth deficiency, the head circumference is preserved and the weight is depressed more than the height. This most common type results from inadequate caloric intake, excessive loss of calories, excessive intake of calories, or inability to use calories peripherally. Most such cases result from inadequate delivery of calories. This may be the result of poverty, lack of caregiver under-

standing, poor caregiver-child interaction, abnormal feeding patterns, or a combination of factors. Type II growth deficiency, which is associated with genetically determined short stature, endocrinopathies, constitutional growth delay, heart or renal disease, or various forms of skeletal dysplasias, is characterized by normal head circumference and proportionate diminution of height and weight. In type III growth deficiency, all three parameters of growth—head circumference, weight, and height—are lower than normal. This pattern is associated with central nervous system abnormalities, chromosomal defects, and in utero or perinatal insults.

► Clinical Findings

A. Initial Evaluation

The history and physical examination will identify the cause of growth reduction in the vast majority of cases (Table 8–6). The physical examination should focus on signs of organic disease or evidence of abuse or neglect: dysmorphic features, skin lesions, neck masses, adventitious breath sounds, heart murmurs, abdominal masses, and neuromuscular tone and strength. Throughout the evaluation, the physician should observe the caregiver-child interaction and the level of family functioning. Developmental screening and laboratory screening tests (complete blood count, blood urea nitrogen, creatinine, electrolytes, urinalysis, and urine culture) complete the initial office evaluation.

B. Further Evaluation

A prospective 3-day diet record should be a standard part of the evaluation. Occasionally an infant or child may need to be hospitalized to obtain an accurate assessment of intake. This is useful in assessing undernutrition even when organic disease is present. The diet history is evaluated by a pediatric dietitian for calories, protein, and micronutrients as well as for the pattern of eating. Additional laboratory

Table 8–6. Components of initial evaluation for growth deficiency.

Birth history: newborn screening result; rule out intrauterine growth retardation, anoxia, congenital infections
Feeding and nutrition: difficulty sucking, chewing, swallowing
Feeding patterns: intake of formula, milk, juice, solids
Stooling and voiding of urine: diarrhea, constipation, vomiting, poor urine stream
Growth pattern: several points on the growth chart are crucial
Recurrent infections
Hospitalizations
HIV risk factors
Developmental history
Social and family factors: family composition, financial status, supports, stresses; heritable diseases, heights and weights of relatives
Review of systems

tests should be ordered based on the history and physical examination. For example, stool collection for fat determination is indicated if a history of diarrhea suggests malabsorption. Moderate or high amounts of proteinuria should prompt workup for nephrotic syndrome. Vomiting should suggest a gastrointestinal, metabolic, neurologic, infectious, or renal cause. The tempo of evaluation should be based on the severity of symptoms and the magnitude of growth failure.

▶ Treatment

A successful treatment plan addresses the child's diet and eating patterns, the child's development, caregiver skills, and any organic disease. High-calorie diets in the form of higher calorie formula or liquid supplement and frequent monitoring (every 1 or 2 weeks initially) are essential. Acceptable weight gain varies by age (Table 8–7).

The child with growth deficiency may also be developmentally delayed because of living in an environment that fails to promote development or from the effect on the brain of nutrient deprivation. Restoring nutrition does not fully reverse the deficit but does reduce the long-term consequences.

Education in nutrition, child development, and behavioral management as well as psychosocial support of the primary caregiver is essential. If family dysfunction is mild, behavior modification and counseling will be useful. Day care may benefit the child by providing a structured environment for all activities, including eating. If family dysfunction is severe, the local department of social services can help provide structure and assistance to the family. Rarely, the child may need to be temporarily or permanently removed from the home. Hospitalization is reserved for management of dehydration, for cases in which home therapy has failed to

Table 8–7. Acceptable weight gain by age.

Age (months)	Weight Gain (g/d)
Birth to 3	20-30
3-6	15-20
6-9	10-15
9-12	6-11
12-18	5-8
18-24	3-7

result in expected growth, for children who show evidence of abuse or willful neglect, for management of an illness that compromises a child's ability to eat, or for care pending foster home placement.

Immunization

Matthew F. Daley, MD
Eric A. F. Simoes, MB, BS, DCH, MD
Ann-Christine Nyquist, MD, MSPH

Immunization has been widely recognized as one of the greatest public health achievements of the past century. Largely as a consequence of immunization, the annual incidences of diphtheria, paralytic polio, measles, mumps, rubella, and *Haemophilus influenzae* type b (Hib) in the United States have fallen by more than 99% compared with the average annual incidences of these diseases in the 20th century. Through routine vaccination, children and adolescents can now receive protection against at least 16 different diseases, and many new vaccines are under development.

Every year, roughly 4 million children are born in the United States, and successful immunization of each birth cohort requires the concerted effort of health care providers, public health officials, vaccine manufacturers, and the public. Public perceptions about immunizations, particularly routine childhood immunizations, are generally positive. However, parent concerns about the safety of vaccines have risen in recent years, in part fueled by unfounded speculation about an association between various vaccines or vaccine components and autism. Modern vaccines have a high degree of safety, and serious adverse events following vaccination are rare. Nonetheless, health care providers need to be prepared to discuss the benefits and risks of vaccination with uncertain parents, providing factual information in a clear and empathic fashion.

This chapter starts with general principles regarding immunizations and the recommended pediatric and adolescent vaccination schedules, followed by a discussion of vaccine safety. Descriptions of each routinely recommended vaccine are then presented, in roughly the chronologic order in which they are given. Vaccines that are only given in special circumstances are presented at the end of the chapter. Several abbreviations that are commonly used in this and other vaccine-related publications are summarized in the accompanying box.

Because the field of immunizations is rapidly changing, it is important for health care providers to seek the most up-to-date information available. The immunization recommendations outlined in this chapter are current but will change as technology evolves and our understanding of the epidemiology of vaccine-

preventable diseases changes. The most useful sources for regularly updated information about immunization are the following:

1. National Center for Immunization and Respiratory Diseases at the Centers for Disease Control and Prevention (CDC). Maintains a web site with extensive vaccine-related resources, including the immunization recommendations of the Advisory Committee on Immunization Practices (ACIP), vaccination schedules, Vaccine Information Statements, information for the public and providers, and links to other vaccine materials. Available at: <http://www.cdc.gov/vaccines>.

STANDARDS FOR PEDIATRIC IMMUNIZATION PRACTICES

In the United States, every infant requires between 25 and 26 doses of vaccine by age 18 months to be protected against 14 childhood diseases. In 2006, the immunization rate for

VACCINE-RELATED ABBREVIATIONS

ACIP	Advisory Committee on Immunization Practices
BCG	Bacillus Calmette-Guérin vaccine against tuberculosis
DT	Pediatric diphtheria-tetanus toxoid
DTaP	Pediatric diphtheria and tetanus toxoids and acellular pertussis vaccine
DTP	Pediatric diphtheria and tetanus toxoids and whole-cell pertussis vaccine
HBIG	Hepatitis B immune globulin
HBSAg	Hepatitis B surface antigen
HepA	Hepatitis A vaccine
HepB	Hepatitis B vaccine
Hib	<i>Haemophilus influenzae</i> type b

VAR	Varicella virus vaccine
VIS	Vaccine Information Statement
VSD	Vaccine Safety Datalink
VZig	Varicella-zoster immune globulin
VZV	Varicella-zoster virus

children aged 19–35 months for the routine childhood immunization series was 77%, below the targeted rate of 80% set in the Healthy People 2010 national health goals. Additionally, data from the Vaccine Safety Datalink (VSD) project shows that only 36% of children younger than age 2

years were completely compliant with vaccination recommendations: 30% had a missed opportunity for immunization; 20% had an invalid immunization; and 12% received unnecessary immunization (costing an estimated \$26.5 million). The AAP recommends the following specific proven practices to improve these defects: (1) sending caretakers reminder and recall notices, (2) using prompts during all visits, (3) periodic measurement of immunization rates, and (4) having standing orders for vaccines.

The National Childhood Vaccine Injury Act of 1986 requires that for each vaccine covered under the Vaccine Injury Compensation Program, caretakers should be advised about the risks and benefits of vaccination in a standard manner, using Vaccine Information Statements (VIS) produced by the CDC. Each time a Vaccine Injury Compensation Program–covered vaccine is administered, the current version of the VIS must be provided to the nonminor patient or legal caretaker. Documentation is required in the medical record, including the vaccine manufacturer, lot number, and date of administration and expiration. The name and address of the person administering the vaccine, VIS version and date, and site and route of administration should also be recorded.

Needles used for vaccination should be sterile and disposable to minimize the opportunity for contamination. A 70% solution of alcohol is appropriate for disinfection of the stopper of the vaccine container and of the skin at the injection site. A 5% topical emulsion of lidocaine-prilocaine applied to the site of vaccination for 30–60 minutes prior to the injection minimizes the pain, especially when multiple vaccines are administered.

Compliance with the manufacturer's recommendations for route and site of administration of injectable vaccines are critical for safety and efficacy. All vaccines containing an adjuvant must be administered intramuscularly to avoid granuloma formation or necrosis. With the exception of Bacillus Calmette-Guérin (BCG) vaccine, which is used rarely in the United States, all vaccines are given either intramuscularly or subcutaneously. Intramuscular injections are given at a 90-degree angle to the skin, using a needle that is sufficiently long to reach the muscle tissue, but not so long as to injure underlying nerves, blood vessels, or bones. The anterolateral thigh is the preferred site of vaccination in newborns and children up to 2 years of age, and the deltoid muscle of the arm is the preferred site for children aged 3–18 years. Needle length and location should be as follows: $\frac{5}{8}$ inch in newborn infants in the thigh; 1 inch in infants 1–12 months old (thigh), 1 inch to $1\frac{1}{4}$ inches in 1–18 year olds (thigh), and $\frac{5}{8}$ inch to 1 inch in 1–18 year olds (deltoid). Subcutaneous injections should be administered at a 45-degree angle into the anterolateral aspect of the thigh (for infants younger than 12 months) or the upper outer triceps area (for children 12 months and older) using a 23- or 25-gauge $\frac{5}{8}$ -inch needle. Pulling back on the syringe prior to vaccine injection (aspiration) is not required in CDC recommendations. A separate syringe and needle should be used for each vaccine.

Many combinations of vaccines can be administered simultaneously without increasing the risk of adverse effects or compromising response. Inactivated vaccines (with the exception of cholera and yellow fever) can be given simultaneously with, or at any time after, a different vaccine. Injectable or nasally given live-virus vaccines, if not administered on the same day, should be given at least 4 weeks apart (eg, measles-mumps-rubella [MMR] and varicella [VAR]). Lapses in the immunization schedule do not call for reinstatement of the series. Extra doses of hepatitis B (HepB), Hib, MMR, and VAR are not harmful, but repetitive exposure to tetanus vaccine beyond the recommended intervals can result in hypersensitivity reactions and should be avoided. If an immunoglobulin (Ig) or blood product has been administered, live-virus vaccination should be delayed 3–11 months, depending on the product, to avoid interference with the immune response (eg, 3 months for tetanus Ig, hepatitis A Ig, and hepatitis B Ig; 5–6 months for measles Ig or cytomegalovirus Ig; and 11 months for intravenous Ig for Kawasaki disease).

With the large number of vaccine preparations available, interchangeability of vaccines is an issue. All brands of Hib conjugate, HepB, and hepatitis A (HepA) vaccines are interchangeable. For vaccines containing acellular pertussis antigens, it is recommended that the same brand be used, but when the brand is unknown or the same brand is unavailable, any vaccine with diphtheria and tetanus toxoids and acellular pertussis should be used to continue vaccination. A longer than recommended interval between vaccinations does not reduce final antibody titers, and lapsed schedules do not require restarting the series.

Vaccines very rarely cause acute anaphylactic-type reactions. Nonetheless, all vaccine providers should have the equipment, medications, staff, and training to manage emergencies that may occur following vaccination.

ROUTINE CHILDHOOD & ADOLESCENT IMMUNIZATIONS

Each year, the CDC issues recommended immunization schedules for children and adolescents. While variation from these schedules may be necessitated by epidemiologic or individual clinical circumstances, these schedules serve as an important guide for vaccination providers. In the schedules, vaccines are roughly ordered by the age at which the vaccines

are first given. For example, HepB is given to newborn infants at birth, followed by rotavirus, diphtheria-tetanus-acellular pertussis (DTaP), Hib, pneumococcal conjugate 7-valent (PCV7) and inactivated poliovirus (IPV) vaccines beginning at 2 months of age. Table 9–1 sets forth a schedule of routine immunizations for normal infants and children from birth to 6 years. Table 9–2 presents a schedule of routine immunization for persons aged 7–18 years. Table 9–3 presents recommended schedules for children who did not start vaccination at the recommended time during the first year of life.

Combination vaccines help solve the problem of large numbers of injections during any single clinic visit. Currently available combination vaccines include MMR, measles-mumps-rubella-varicella (MMRV), and various combinations of Hib, HepB, IPV, and DTaP, including a DTaP-HepB-IPV combination vaccine. Additional combination vaccines, including some vaccines specifically for older children and adolescents, are in development. Separate vaccines should not be combined into one syringe by the provider unless approved by the Food and Drug Administration (FDA), because this could decrease the efficacy of each component vaccine.

SAFE HANDLING OF VACCINES

The numerous vaccines and other immunologic substances used by the practitioner vary in the storage temperatures required. The majority of vaccines should never be subjected to freezing temperatures. Vaccines that require routine freezing are MMRV, VAR, and herpes zoster vaccines. Yellow fever vaccine may also be stored frozen. Product package inserts should be consulted for detailed information on vaccine storage conditions and shelf life.

CDC: Recommended childhood and adolescent immunization schedule—United States, 2008. *MMWR Morb Mortal Wkly Rep* 2007;56:Q1–Q4.

SAFETY OF IMMUNIZATION

Although no vaccine is 100% safe and effective, after decades of experience and many millions of doses administered, vaccines have proven to be among the safest of medical interventions. However, as diseases such as measles and polio become exceedingly rare in the United States, the apparent risks of vaccination have taken a more prominent role in the public discourse. When vaccine-preventable diseases are perceived to be treatable or rare, the risks of vaccination may appear to outweigh the benefits, particularly to persons who misunderstand the actual risks from vaccines and the potential for resurgence of some diseases when the public is not adequately immunized. Decisions about vaccination, both at the individual and societal level, need to be made based on accurate and timely information. Parents with questions about vaccine safety should be directed to trusted web sites, such as those of the AAP, the American Academy of Family Physicians

Table 9-1. Recommended immunization schedule for children aged 0–6 years, United States, 2008.

Recommended Immunization Schedule for Persons Aged 0–6 Years — UNITED STATES • 2008

For those who fall behind or start late, see the catch-up schedule

Vaccine	Age	Birth	1 month	2 months	4 months	6 months	12 months	15 months	18 months	19–23 months	2–3 years	4–6 years

Meningococcal ¹⁰											MCV4	

Range of recommended ages
Certain high-risk groups

This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines, as of December 1, 2007, for children aged 7–18 years. Additional information is available at www.cdc.gov/vaccines/recs/schedules. Any dose not administered at the recommended age should be administered at any subsequent visit, when indicated and feasible. Additional vaccines may be licensed and recommended during the year. Licensed combination vaccines may be used whenever any components of the combination are indicated and other components of the vaccine are not contraindicated and

if approved by the Food and Drug Administration for that dose of the series. Providers should consult the respective Advisory Committee on Immunization Practices statement for detailed recommendations, including for high risk conditions: <http://www.cdc.gov/vaccines/pubs/ACIP-list.htm>. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at www.vaers.hhs.gov or by telephone, 800-822-7967.

1. Hepatitis B vaccine (HepB). (Minimum age: birth)

At birth:

- Administer monovalent HepB to all newborns prior to hospital discharge.
- If mother is hepatitis B surface antigen (HBsAg) positive, administer HepB and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth.
- If mother's HBsAg status is unknown, administer HepB within 12 hours of birth. Determine the HBsAg status as soon as possible and if HBsAg positive, administer HBIG (no later than age 1 week).
- If mother is HBsAg negative, the birth dose can be delayed, in rare cases, with a provider's order and a copy of the mother's negative HBsAg laboratory report in the infant's medical record.

After the birth dose:

- The HepB series should be completed with either monovalent HepB or a combination vaccine containing HepB. The second dose should be administered at age 1–2 months. The final dose should be administered no earlier than age 24 weeks. Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg after completion of at least 3 doses of a licensed HepB series, at age 9–18 months (generally at the next well-child visit).

4-month dose:

- It is permissible to administer 4 doses of HepB when combination vaccines are administered after the birth dose. If monovalent HepB is used for doses after the birth dose, a dose at age 4 months is not needed.

2. Rotavirus vaccine (Rota). (Minimum age: 6 weeks)

- Administer the first dose at age 6–12 weeks.
- Do not start the series later than age 12 weeks.
- Administer the final dose in the series by age 32 weeks. Do not administer any dose later than age 32 weeks.
- Data on safety and efficacy outside of these age ranges are insufficient.

3. Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP). (Minimum age: 6 weeks)

- The fourth dose of DTaP may be administered as early as age 12 months, provided 6 months have elapsed since the third dose.
- Administer the final dose in the series at age 4–6 years.

4. Haemophilus influenzae type b conjugate vaccine (Hib). (Minimum age: 6 weeks)

- If PRP-OMP (PedvaxHIB[®] or ComVax[®] [Merck]) is administered at ages 2 and 4 months, a dose at age 6 months is not required.
- TriHIBit[®] (DTaP/Hib) combination products should not be used for primary immunization but can be used as boosters following any Hib vaccine in children age 12 months or older.

5. Pneumococcal vaccine. (Minimum age: 6 weeks for pneumococcal conjugate vaccine [PCV]; 2 years for pneumococcal polysaccharide vaccine [PPV])

- Administer one dose of PCV to all healthy children aged 24–59 months having any incomplete schedule.
- Administer PPV to children aged 2 years and older with underlying medical conditions.

6. Influenza vaccine. (Minimum age: 6 months for trivalent inactivated influenza vaccine [TIV]; 2 years for live, attenuated influenza vaccine [LAIV])

- Administer annually to children aged 6–59 months and to all eligible close contacts of children aged 0–59 months.
- Administer annually to children 5 years of age and older with certain risk factors, to other persons (including household members) in close contact with persons in groups at higher risk, and to any child whose parents request vaccination.
- For healthy persons (those who do not have underlying medical conditions that predispose them to influenza complications) ages 2–49 years, either LAIV or TIV may be used.
- Children receiving TIV should receive 0.25 mL if age 6–35 months or 0.5 mL if age 3 years or older.
- Administer 2 doses (separated by 4 weeks or longer) to children younger than 9 years who are receiving influenza vaccine for the first time or who were vaccinated for the first time last season but only received one dose.

7. Measles, mumps, and rubella vaccine (MMR). (Minimum age: 12 months)

- Administer the second dose of MMR at age 4–6 years. MMR may be administered before age 4–6 years, provided 4 weeks or more have elapsed since the first dose.

8. Varicella vaccine. (Minimum age: 12 months)

- Administer second dose at age 4–6 years; may be administered 3 months or more after first dose.
- Do not repeat second dose if administered 28 days or more after first dose.

9. Hepatitis A vaccine (HepA). (Minimum age: 12 months)

- Administer to all children aged 1 year (i.e., aged 12–23 months). Administer the 2 doses in the series at least 6 months apart.
- Children not fully vaccinated by age 2 years can be vaccinated at subsequent visits.
- HepA is recommended for certain other groups of children, including in areas where vaccination programs target older children.

10. Meningococcal vaccine. (Minimum age: 2 years for meningococcal conjugate vaccine [MCV4] and for meningococcal polysaccharide vaccine [MPSV4])

- Administer MCV4 to children aged 2–10 years with terminal complement deficiencies or anatomic or functional asplenia and certain other high-risk groups. MPSV4 is also acceptable.
- Administer MCV4 to persons who received MPSV4 3 or more years previously and remain at increased risk for meningococcal disease.

The Recommended Immunizations Schedules for Persons Aged 0–18 Years are approved by the Advisory Committee on Immunization Practices (www.cdc.gov/vaccines/recs/acip), The American Academy of Pediatrics (<http://www.aap.org>), and the American Academy of Family Physicians (<http://www.aafp.org>).

Catch-up immunization

Certain high-risk groups

This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines, as of December 1, 2007, for children aged 7–18 years. Additional information is available at www.cdc.gov/vaccines/recs/schedules. Any dose not administered at the recommended age should be administered at any subsequent visit, when indicated and feasible. Additional vaccines may be licensed and recommended during the year. Licensed combination vaccines may be used whenever any components of the combination are indicated and other components of the vaccine are not contraindicated and

if approved by the Food and Drug Administration for that dose of the series. **Providers should consult the respective Advisory Committee on Immunization Practices statement for detailed recommendations, including for high risk conditions:** <http://www.cdc.gov/vaccines/pubs/ACIP-list.htm>. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at www.vaers.hhs.gov or by telephone, 800-822-7967.

1. Tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap). (Minimum age: 10 years for BOOSTRIX[®] and 11 years for ADACEL[™])

- Administer at age 11–12 years for those who have completed the recommended childhood DTP/DTaP vaccination series and have not received a tetanus and diphtheria toxoids (Td) booster dose.
- 13–18-year-olds who missed the 11–12 year Tdap or received Td only are encouraged to receive one dose of Tdap 5 years after the last Td/DTaP dose.

2. Human papillomavirus vaccine (HPV). (Minimum age: 9 years)

- Administer the first dose of the HPV vaccine series to females at age 11–12 years.
- Administer the second dose 2 months after the first dose and the third dose 6 months after the first dose.
- Administer the HPV vaccine series to females at age 13–18 years if not previously vaccinated.

3. Meningococcal vaccine.

- Administer MCV4 at age 11–12 years and at age 13–18 years if not previously vaccinated. MPSV4 is an acceptable alternative.
- Administer MCV4 to previously unvaccinated college freshmen living in dormitories.
- MCV4 is recommended for children aged 2–10 years with terminal complement deficiencies or anatomic or functional asplenia and certain other high-risk groups.
- Persons who received MPSV4 3 or more years previously and remain at increased risk for meningococcal disease should be vaccinated with MCV4.

4. Pneumococcal polysaccharide vaccine (PPV).

- Administer PPV to certain high-risk groups.

5. Influenza vaccine.

- Administer annually to all close contacts of children aged 0–59 months.
- Administer annually to persons with certain risk factors, health-care workers, and other persons (including household members) in close contact with persons in groups at higher risk.

- Administer 2 doses (separated by 4 weeks or longer) to children younger than 9 years who are receiving influenza vaccine for the first time or who were vaccinated for the first time last season but only received one dose.
- For healthy nonpregnant persons (those who do not have underlying medical conditions that predispose them to influenza complications) ages 2–49 years, either LAIV or TIV may be used.

6. Hepatitis A vaccine (HepA).

- Administer the 2 doses in the series at least 6 months apart.
- HepA is recommended for certain other groups of children, including in areas where vaccination programs target older children.

7. Hepatitis B vaccine (HepB).

- Administer the 3-dose series to those who were not previously vaccinated.
- A 2-dose series of Recombivax HB[®] is licensed for children aged 11–15 years.

8. Inactivated poliovirus vaccine (IPV).

- For children who received an all-IPV or all-oral poliovirus (OPV) series, a fourth dose is not necessary if the third dose was administered at age 4 years or older.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.

9. Measles, mumps, and rubella vaccine (MMR).

- If not previously vaccinated, administer 2 doses of MMR during any visit, with 4 or more weeks between the doses.

10. Varicella vaccine.

- Administer 2 doses of varicella vaccine to persons younger than 13 years of age at least 3 months apart. Do not repeat the second dose if administered 28 or more days following the first dose.
- Administer 2 doses of varicella vaccine to persons aged 13 years or older at least 4 weeks apart.

The Recommended Immunizations Schedules for Persons Aged 0–18 Years are approved by the Advisory Committee on Immunization Practices (www.cdc.gov/vaccines/recs/acip), The American Academy of Pediatrics (<http://www.aap.org>), and the American Academy of Family Physicians (<http://www.aafp.org>).

Table 9-3. Recommended immunization schedule for children and adolescents who start late or who are more than 1 month behind: United States, 2008.

Catch-up Immunization Schedule UNITED STATES • 2008
for Persons Aged 4 Months–18 Years Who Start Late or Who Are More Than 1 Month Behind

The table below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age.

Vaccine	Minimum Age for Dose 1	CATCH-UP SCHEDULE FOR PERSONS AGED 4 MONTH S–6 YEARS			
		Minimum Interval Between Doses			
		Dose 1 to Dose 2	Dose 2 to Dose 3	Dose 3 to Dose 4	Dose 4 to Dose 5
Hepatitis B ¹	Birth	4 weeks	8 weeks (and 16 weeks after first dose)		
Rotavirus ²	6 wks	4 weeks	4 weeks		
Diphtheria, Tetanus, Pertussis ³	6 wks	4 weeks	4 weeks	6 months	6 months ³
<i>Haemophilus influenzae</i> type b ⁴	6 wks	4 weeks if first dose administered at younger than 12 months of age 8 weeks (as final dose) if first dose administered at age 12–14 months No further doses needed if first dose administered at 15 months of age or older	4 weeks ⁴ if current age is younger than 12 months 8 weeks (as final dose)⁴ if current age is 12 months or older and second dose administered at younger than 15 months of age No further doses needed if previous dose administered at age 15 months or older	8 weeks (as final dose) This dose only necessary for children aged 12 months–5 years who received 3 doses before age 12 months	
Pneumococcal ⁵	6 wks	4 weeks if first dose administered at younger than 12 months of age 8 weeks (as final dose) if first dose administered at age 12 months or older or current age 24–59 months No further doses needed for healthy children if first dose administered at age 24 months or older	4 weeks if current age is younger than 12 months 8 weeks (as final dose) if current age is 12 months or older No further doses needed for healthy children if previous dose administered at age 24 months or older	8 weeks (as final dose) This dose only necessary for children aged 12 months–5 years who received 3 doses before age 12 months	
Inactivated Poliovirus ⁶	6 wks	4 weeks	4 weeks	4 weeks ⁶	
Measles, Mumps, Rubella ⁷	12 mos	4 weeks	4 weeks		
Varicella ⁸	12 mos	3 months			
Hepatitis A ⁹	12 mos	6 months			
CATCH-UP SCHEDULE FOR PERSONS AGED 7–18 YEARS					
Tetanus, Diphtheria/ Tetanus, Diphtheria, Pertussis ¹⁰	7 yrs ¹⁰	4 weeks	4 weeks if first dose administered at younger than 12 months of age 6 months if first dose administered at age 12 months or older	6 months if first dose administered at younger than 12 months of age	
Human Papillomavirus ¹¹	9 yrs	4 weeks	12 weeks (and 24 weeks after the first dose)		
Hepatitis A ⁹	12 mos	6 months			
Hepatitis B ¹	Birth	4 weeks	8 weeks (and 16 weeks after first dose)		
Inactivated Poliovirus ⁶	6 wks	4 weeks	4 weeks	4 weeks ⁶	
Measles, Mumps, Rubella ⁷	12 mos	4 weeks			
Varicella ⁸	12 mos	4 weeks if first dose administered at age 13 years or older 3 months if first dose administered at younger than 13 years of age			

- Hepatitis B vaccine (HepB).**
 - Administer the 3-dose series to those who were not previously vaccinated.
 - A 2-dose series of Recombivax HB® is licensed for children aged 11–15 years.
- Rotavirus vaccine (Rota).**
 - Do not start the series later than age 12 weeks.
 - Administer the final dose in the series by age 32 weeks.
 - Do not administer a dose later than age 32 weeks.
 - Data on safety and efficacy outside of these age ranges are insufficient.
- Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).**
 - The fifth dose is not necessary if the fourth dose was administered at age 4 years or older.
 - DTaP is not indicated for persons aged 7 years or older.
- Haemophilus influenzae type b conjugate vaccine (Hib).**
 - Vaccine is not generally recommended for children aged 5 years or older.
 - If current age is younger than 12 months and the first 2 doses were PRP-OMP (PedvaxHIB® or ComVax® [Merck]), the third (and final) dose should be administered at age 12–15 months and at least 8 weeks after the second dose.
 - If first dose was administered at age 7–11 months, administer 2 doses separated by 4 weeks plus a booster at age 12–15 months.
- Pneumococcal conjugate vaccine (PCV).**
 - Administer one dose of PCV to all healthy children aged 24–59 months having any incomplete schedule.
 - For children with underlying medical conditions, administer 2 doses of PCV at least 8 weeks apart if previously received less than 3 doses, or 1 dose of PCV if previously received 3 doses.
- Inactivated poliovirus vaccine (IPV).**
 - For children who received an all-IPV or all-oral poliovirus (OPV) series, a fourth dose is not necessary if third dose was administered at age 4 years or older.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.
- IPV is not routinely recommended for persons aged 18 years and older.
- Measles, mumps, and rubella vaccine (MMR).**
 - The second dose of MMR is recommended routinely at age 4–6 years but may be administered earlier if desired.
 - If not previously vaccinated, administer 2 doses of MMR during any visit with 4 or more weeks between the doses.
- Varicella vaccine.**
 - The second dose of varicella vaccine is recommended routinely at age 4–6 years but may be administered earlier if desired.
 - Do not repeat the second dose in persons younger than 13 years of age if administered 28 or more days after the first dose.
- Hepatitis A vaccine (HepA).**
 - HepA is recommended for certain groups of children, including in areas where vaccination programs target older children. See *MMWR* 2006;55(No. RR-7):1–23.
- Tetanus and diphtheria toxoids vaccine (Td) and tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap).**
 - Tdap should be substituted for a single dose of Td in the primary catch-up series or as a booster if age appropriate; use Td for other doses.
 - A 5-year interval from the last Td dose is encouraged when Tdap is used as a booster dose. A booster (fourth) dose is needed if any of the previous doses were administered at younger than 12 months of age. Refer to ACIP recommendations for further information. See *MMWR* 2006;55(No. RR-3).
- Human papillomavirus vaccine (HPV).**
 - Administer the HPV vaccine series to females at age 13–18 years if not previously vaccinated.

Information about reporting reactions after immunization is available online at <http://www.vaers.hhs.gov> or by telephone via the 24-hour national toll-free information line 800-822-7967. Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for immunization, is available from the National Center for Immunization and Respiratory Diseases at <http://www.cdc.gov/vaccines> or telephone, 800-CDC-INFO (800-232-4636).

(AAP), the CDC (<http://www.cdc.gov/vaccines>), and the Immunization Action Coalition (<http://www.immunize.org>).

The safety standards for all vaccines licensed for use in the United States are established by the FDA and involve regular examination of manufacturing techniques as well as production lots of vaccine. No incidents of bacterial or viral contamination of vaccines at the factory level have been reported in the United States for decades.

All vaccines have certain contraindications and precautions that guide their administration. A contraindication indicates that the potential vaccine recipient is at increased risk of a serious adverse event. A vaccine should not be given when a contraindication to that vaccine is present, whereas a precaution indicates a circumstance that might increase the risk of adverse events or diminish the effectiveness of the vaccine. In the setting of precautions, the risks and benefits of vaccination must be carefully weighed prior to a decision regarding vaccination. Precautions are often temporary, in which case vaccination can resume once the precaution no longer applies. Contraindications and precautions are listed below with each vaccine. Additional, more detailed information is available from the CDC, in the AAP *Red Book*, and in vaccine package inserts.

Healthy Children

Minor acute illnesses, with or without low-grade fever, are not contraindications to vaccination, because there is no evidence that vaccination under these conditions increases the rate of adverse effects or decreases efficacy. A moderate to severe febrile illness may be a reason to postpone vaccination. Routine physical examination and temperature assessment are not necessary before vaccinating healthy infants and children.

Children with Chronic Illnesses

Most chronic diseases are not contraindications to vaccination; in fact, children with chronic diseases may be at greater risk of complications from vaccine-preventable diseases, such as influenzal and pneumococcal infections. Premature infants are a good example. They should be immunized according to their chronologic, not gestational, age. Vaccine doses should not be reduced for preterm or low-birth-weight infants. One exception to this rule is children with progressive central nervous system disorders. Vaccination with DTaP should be deferred until the child's neurologic status has been clarified and is more stable.

Immunodeficient Children

Congenitally immunodeficient children should not be immunized with live-virus (oral polio vaccine [OPV], MMR, VAR, MMRV, yellow fever, or live-attenuated influenza vaccine [LAIV]) or live-bacteria vaccines (BCG or live typhoid fever vaccine). Depending on the nature of the immunodeficiency, other vaccines are safe, but may fail to evoke an immune response. Children with cancer and children receiving high-dose corticosteroids or other immunosuppressive agents

should not be vaccinated with live-virus or live-bacteria vaccines. This contraindication does not apply if the malignancy is in remission and chemotherapy has not been administered for at least 90 days. Live-virus vaccines may also be administered to previously healthy children receiving low to moderate doses of corticosteroids (defined as up to 2 mg/kg/d of prednisone or prednisone equivalent, with a 20 mg/d maximum) for less than 14 days; children receiving short-acting alternate-day corticosteroids; children being maintained on physiologic corticosteroid therapy without other immunodeficiency; and children receiving only topical, inhaled, or intraarticular corticosteroids.

Contraindication of live-pathogen vaccines also applies to children with HIV infection who are severely immunosuppressed. In general those who receive MMR should have at least 15% CD4 cells and a CD4 lymphocyte count equivalent to CDC immunologic class 2. MMR for these children is recommended at 12 months of age (after 6 months during an epidemic). The booster dose may be given as early as 1 month later, but doses given before 1 year of age should not be considered part of a complete series. VAR vaccination is also recommended for HIV-infected children with CD4 cells preserved as listed above. OPV, which is contraindicated, is no longer recommended in the United States. The ACIP recommends routine vaccination for all children only with IPV. Thus immunodeficient children should no longer be exposed to OPV through household contacts. MMR and VAR are not contraindicated in household contacts of immunocompromised children.

Allergic or Hypersensitive Children

Hypersensitivity reactions are rare following vaccination (1.53 cases/million doses). They are generally attributable to a trace component of the vaccine other than to the antigen itself; for example, MMR, IPV, and VAR contain microgram quantities of neomycin, and IPV also contains trace amounts of streptomycin and polymyxin B. Children with known anaphylactic responses to these antibiotics should not be given these vaccines. Trace quantities of egg antigens may be present in both inactivated and live influenza and yellow fever vaccines. Children who have had anaphylactic reactions to eggs should not be given these vaccines; children with less serious reactions to eggs can generally be safely immunized. Some vaccines (MMR, MMRV, and VAR) contain gelatin, a substance to which persons with known food allergy may develop an anaphylactic reaction. For any persons with a known history of anaphylactic reaction to any component contained in a vaccine, the vaccine package insert should be reviewed and additional consultation sought, such as from a pediatric allergist.

Special Circumstances

Detailed recommendations for preterm low-birth-weight infants; pediatric transplant recipients; Alaskan Natives/

American Indians; children in residential institutions or military communities; or refugees, new immigrants, or travelers are available from the CDC (at <http://www.cdc.gov/vaccines>) and from the AAP *Red Book*.

Monitoring Vaccine Safety

Physicians administering vaccines are obliged to report serious adverse events following immunization to the Vaccine Adverse Events Reporting System (VAERS). This is a nationwide passive surveillance program for vaccine safety managed cooperatively by the CDC and the FDA. Reports of possible adverse events related to vaccination may be made via the Internet or by mail. VAERS can be reached at <http://vaers.hhs.gov>, or by telephone at 1-800-822-7967. The CDC also undertakes numerous studies using large linked databases of computerized vaccination and medical records. The VSD project, which is a network of health maintenance organizations that share information on immunizations, medical outcomes, and potential confounders, serves as a useful tool to accumulate and analyze data as new vaccine issues arise.

HEPATITIS B VACCINATION

The incidence of reported cases of acute hepatitis B has declined dramatically in the United States, largely attributable to vaccination. Based on surveillance data from 2005, acute hepatitis B incidence has declined by 79% since 1990, to the lowest rate ever measured. The greatest declines have been seen in children younger than 15 years of age, in whom rates have decreased by 98%.

Successes in reducing the burden of hepatitis B are due, in large part, to a comprehensive hepatitis B prevention strategy initiated in 1991. The four central elements of this approach are (1) immunization of all infants beginning at birth; (2) routine screening of all pregnant women for hepatitis B infection, and provision of hepatitis B immune globulin (HBIG) to all infants born to infected mothers; (3) routine vaccination of previously unvaccinated children and adolescents; and (4) vaccination of adults at increased risk of hepatitis B infection.

While high immunization rates have been achieved in young children (more than 93% were fully immunized in 2006), the nation has been less successful at identifying

hepatitis B–infected mothers and at immunizing high-risk adults. Of the estimated 23,000 mothers who deliver each year who are hepatitis B surface antigen (HBsAg) positive, only 9000 are identified through prenatal screening. This circumstance represents a significant missed opportunity for prevention, given that administration of hepatitis B vaccine (HepB) in conjunction with HBIG is 95% effective at preventing mother-to-infant transmission of the virus. Similarly, while HepB alone is 90–95% effective at preventing hepatitis B infection, only 45% of high-risk adults have been vaccinated.

All pregnant women should be routinely screened for HBsAg. Infants born to HBsAg-positive mothers should receive both HepB and HBIG immediately after birth. Infants for whom the maternal HBsAg status is unknown should receive vaccine (but not HBIG) within 12 hours of birth. In such circumstances, the mother's HBsAg status should be determined as soon as possible during her hospitalization, and the infant given HBIG if the mother is found to be HBsAg-positive. For all infants, the hepatitis B immunization series should be started at birth, with the first dose given prior to discharge from the hospital. Given the importance of the birth dose of HepB in preventing perinatal infection, the ACIP has recommended that any decision to defer the birth dose require an explanation in the medical record, accompanied by a copy of the mother's negative HBsAg test during the current pregnancy.

Routine immunization with three doses of HepB is recommended for all infants and all previously unvaccinated children aged 0–18 years. A two-dose schedule is available for adolescents as well. In addition, persons 19 years and older with an increased risk of exposure to hepatitis B virus should be vaccinated. This includes men who have sex with men, persons with multiple sexual partners, intravenous and injection drug users, recipients of clotting factors concentrates, hemodialysis patients, household contacts and sexual contacts of persons with chronic hepatitis B infection, long-term international travelers to endemic areas, and all health care personnel. Screening for markers of past infection before vaccinating is generally not indicated for children and adolescents, but may be considered for high-risk adults. Because HepB vaccines consist of an inactivated subunit of the virus, the vaccines are not infectious and are not contraindicated in immunosuppressed individuals or pregnant women.

► Vaccines Available

1. Hepatitis B vaccine (Recombivax HB, Merck) contains recombinant HepB only.
2. Hepatitis B vaccine (Engerix-B, GlaxoSmithKline) contains recombinant HepB only.
3. Hepatitis B-Hib (Comvax, Merck) contains vaccines against hepatitis B and Hib.
4. DTaP-HepB-IPV (Pediarix, GlaxoSmithKline) contains vaccines against diphtheria, tetanus, pertussis, hepatitis B, and poliovirus.

Only the single-antigen vaccines (Recombivax HB and Engerix-B) can be given between birth and 6 weeks of age. Any single or combination vaccine listed above can be used to complete the hepatitis B vaccination series. Thimerosal has been removed from all pediatric HepB formulations. A combination vaccine against hepatitis A and hepatitis B (Twinrix, GlaxoSmithKline) is available, but is only licensed in the United States for persons 18 years and older.

► Dosage & Schedule of Administration

HepB is recommended for all infants and children in the United States. Table 9-4 presents the vaccination schedule for newborn infants, dependent on maternal HBsAg status. Infants born to mothers with positive or unknown HBsAg status should receive HepB vaccine within 12 hours of birth. Infants born to HBsAg-negative mothers should receive the vaccine prior to hospital discharge.

For children younger than 11 years of age not previously immunized, three intramuscular doses of HepB are needed. Adolescents aged 11–15 years have two options: the standard pediatric three-dose schedule or two doses of adult Recombivax HB (1.0-mL dose), with the second dose administered 4–6 months after the first dose. Simultaneous administration with other vaccines at different sites is safe and effective. The vaccine should be given intramuscularly in either the anterolateral thigh or deltoid, depending on the age and size of the patient.

Certain patients may have reduced immune response to HepB vaccination, including preterm infants weighing less than 2000 g at birth; immunosuppressed patients; and those receiving dialysis. Preterm infants whose mothers are HBsAg-positive or with unknown HBsAg status should receive both HepB and HBIG within 12 hours of birth. For preterm infants whose mothers are known to be HBsAg-negative, initiation of the vaccination series should be delayed until 30 days of chronologic age if the infant is medically stable or prior to

Table 9-4. Hepatitis B vaccine schedules for newborn infants, by maternal hepatitis B surface antigen (HBsAg) status.^a

Maternal HBsAg Status	Single-Antigen Vaccine		Single Antigen + Combination Vaccine	
	Dose	Age	Dose	Age
Positive	1 ^b	Birth (≤ 12 h)	1 ^b	Birth (≤ 12 h)
	HBIG ^c	Birth (≤ 12 h)	HBIG	Birth (≤ 12 h)
	2	1–2 mo	2	2 mo
	3 ^d	6 mo	3	4 mo
Unknown ^e	1 ^b	Birth (≤ 12 h)	1 ^b	Birth (≤ 12 h)
	2	1–2 mo	2	2 mo
	3 ^d	6 mo	3	4 mo
			4 ^d	6 mo (Pediarix) or 12–15 mo (Comvax)
Negative	1 ^{b,f}	Birth (before discharge)	1 ^{b,f}	Birth (before discharge)
	2	1–2 mo	2	2 mo
			3	4 mo
	3 ^d	6–18 mo	4 ^d	6 mo (Pediarix) or 12–15 mo (Comvax)

^aSee text for vaccination of preterm infants weighing < 2000 g.

^bRecombivax HB or Engerix-B should be used for the birth dose. Comvax and Pediarix cannot be administered at birth or before age 6 weeks.

^cHepatitis B immune globulin (HBIG) (0.5 mL) administered intramuscularly in a separate site from vaccine.

^dThe final dose in the vaccine series should not be administered before age 24 weeks (164 days).

^eMothers should have blood drawn and tested for HBsAg as soon as possible after admission for delivery; if the mother is found to be HBsAg-positive, the infant should receive HBIG as soon as possible, but no later than age 7 days.

^fOn a case-by-case basis and only in rare circumstances, the first dose may be delayed until after hospital discharge for an infant who weighs ≥ 2000 g and whose mother is HBsAg-negative, but only if a physician's order to withhold the birth dose and a copy of the mother's original HBsAg-negative laboratory report are documented in the infant's medical record.

Reproduced, with permission, from CDC: A comprehensive immunization strategy to eliminate transmission of hepatitis B virus infection in the United States, part 1: Immunization of infants, children, and adolescents. MMWR Recomm Rep 2005;54(RR-16):1.

hospital discharge if the infant is discharged before 30 days of age. Hemodialysis patients and immunocompromised persons may require larger doses or an increased number of doses, with dose amounts and schedules available in the most recent CDC hepatitis B recommendations (see references).

▶ Contraindications & Precautions

HepB vaccine should not be given to persons with a serious allergic reaction to yeast or to any vaccine components. Individuals with a history of serious adverse events, such as anaphylaxis, after receiving HepB should not receive additional doses. Vaccination is not contraindicated in persons with a history of Guillain-Barré syndrome, multiple sclerosis, autoimmune disease, or other chronic conditions. Pregnancy is also not a contraindication to vaccination.

▶ Adverse Effects

The overall rate of adverse effects is low, with minor effects reported, including fever (1–6%) and pain at the injection site (3–29%). There is no evidence of an association between vaccination and sudden infant death syndrome, multiple sclerosis, autoimmune disease, or chronic fatigue syndrome.

▶ Postexposure Prophylaxis

Postexposure prophylaxis is indicated for unvaccinated persons with perinatal, sexual, household, percutaneous, or mucosal exposure to hepatitis B. When prophylaxis is indicated, unvaccinated individuals should receive HBIg (0.06 mL/kg) and the first dose of HepB at a separate anatomic site. For sexual contact or household blood exposure to an acute case of hepatitis B, HBIg and HepB should be given. Sexual and household contacts of someone with chronic infection should receive HepB (but not HBIg). For individuals with percutaneous or permucosal exposure to blood, HepB should be given, and HBIg considered depending on the HBsAg status of the person who was the source of the blood and on the vaccination response status of the exposed person. All previously vaccinated persons exposed to hepatitis B should be retested for anti-HBs. If antibody levels are adequate (≥ 10 mIU/mL), no treatment is necessary. If levels are inadequate and the exposure was to HBsAg-positive blood, HBIg and vaccination are required.

▶ Antibody Preparations

HBIg is prepared from HIV-negative and hepatitis C virus negative donors with high titers of hepatitis B surface antibody. The process used to prepare this product inactivates or eliminates any undetected HIV and hepatitis C virus. The uses of HBIg are described earlier in this section.

ROTAVIRUS VACCINATION

Rotavirus is the leading cause of hospitalization and death from acute gastroenteritis in young children worldwide. The burden of rotavirus is particularly severe in the developing world, where as many as 500,000 children die each year from rotavirus-associated dehydration and other complications. While deaths from rotavirus are uncommon in the United States (20–60 deaths per year), rotavirus infections cause substantial morbidity: annually, rotavirus causes an estimated 2.7 million diarrheal illnesses, 500,000 office visits, and 55,000–70,000 hospitalizations.

The first licensed rotavirus vaccine (RotaShield), was developed from virus strains isolated from rhesus monkeys. Shortly after its licensure in 1998, the vaccine was found to be associated with intussusception at an estimated rate of 1 case per 10,000 vaccine recipients. Because of this association, the vaccine was withdrawn from the U.S. market in October 1999. Using other parent rotavirus strains, substantial efforts continued to develop safe and effective rotavirus vaccines. In February 2006, a human-bovine reassortant rotavirus vaccine (RotaTeq) was licensed for use in the United States. Soon after licensure, the ACIP recommended the administration of rotavirus vaccine to all infants at 2, 4, and 6 months of age. The vaccine is highly effective, with the three-dose series demonstrating 98% efficacy at preventing severe rotavirus gastroenteritis and 74% at preventing any rotavirus gastroenteritis.

Prior to the licensure of RotaTeq, a large-scale randomized controlled trial of more than 70,000 infants was conducted specifically to evaluate the risk of intussusception following vaccination. The study had adequate statistical power to detect clinical events as uncommon as those seen after RotaShield vaccination. In this study, no increased risk of intussusception or other serious adverse events was seen in vaccine recipients compared with infants who received a placebo.

Concern has been expressed that some health care providers and parents may be reluctant to use the new rotavirus vaccine, either because of the withdrawal of the first rotavirus vaccine or because of the perception that the burden of rotavirus in the United States does not justify vaccination. Several important considerations should alleviate these concerns. Because RotaTeq was developed using fundamentally different techniques than the prior rotavirus vaccine, intus-

susception following vaccination should not be anticipated on theoretical grounds. The large size of prelicensure vaccine trials provides additional reassuring data about vaccine safety. Further, the safety of this vaccine is continuously monitored through a number of mechanisms such as the VSD project and VAERS. Finally, while rotavirus infection is an uncommon cause of death in the United States, thousands of hospitalizations could be prevented through vaccination.

► Vaccine Available

There is currently a single rotavirus vaccine licensed in the United States, a human-bovine reassortant vaccine (RotaTeq, manufactured by Merck). The vaccine contains five reassorted virus types, each with human- and bovine-derived components, suspended in a buffered solution that does not contain thimerosal or other preservatives.

► Dosage & Schedule of Administration

Rotavirus vaccine is a liquid vaccine given by mouth and should never be given by any other route of administration. Each 2-mL dose is dispensed in a squeezable plastic tube with a twist-off cap. Infants readily swallow the vaccine in most circumstances; however, if an infant spits up or vomits after a dose is administered, the dose should not be readministered; the infant can receive the remaining doses at the normal intervals.

Infants should be given rotavirus vaccine at approximately 2, 4, and 6 months of age. The first dose should be given between 6 and 12 weeks of age, subsequent doses should be given between 4 and 10 weeks after the preceding dose, and all three doses should be given by 32 weeks of age. The first dose should not be given to infants older than 12 weeks of age, and no doses should be given to infants older than 32 weeks of age. The vaccination schedule for rotavirus vaccine is more restrictive than for other routinely recommended vaccines for infants because some, although not all, studies of the prior rhesus-based vaccine suggested that the risk of intussusception following vaccination increased with increasing age.

► Contraindications & Precautions

Rotavirus vaccine should not be given to infants with a severe hypersensitivity to any components of the vaccine, or to infants who had a serious allergic reaction to a previous dose of the vaccine. Theoretical concerns exist that giving rotavirus vaccine to infants with acute, moderate to severe gastroenteritis will reduce the immunogenicity of the vaccine. Vaccination should therefore be deferred in this circumstance until the gastroenteritis has improved. Limited data suggest that rotavirus vaccination is safe and effective in premature infants. However, vaccine safety and efficacy in infants with immunocompromising conditions, preexisting chronic gastrointestinal conditions (eg, Hirschsprung disease or short-gut syndrome), or a prior episode of intussus-

ception, has not been established. Clinicians should weigh the risks and benefits of vaccination in such circumstances. Infants living in households with pregnant women or immunocompromised persons can be vaccinated. To minimize the risk of vaccine virus transmission, good hand hygiene should be used when changing the vaccinated infant's diapers.

► Adverse Effects

In several large randomized controlled trials, no serious adverse events were associated with rotavirus vaccination, including no increase in rates of intussusception. Rates of vomiting and diarrhea were 1–3% higher in vaccine recipients than in placebo recipients. Rates of fever, irritability, and hematochezia were similar between vaccine and placebo recipients.

Any unexpected or clinically significant event occurring after rotavirus vaccination should be reported to VAERS (<http://www.vaers.hhs.gov>). There have been cases of intussusception reported to VAERS after rotavirus vaccination, but the rate of such cases was not increased above that expected by chance alone.

DIPHTHERIA-TETANUS-ACELLULAR PERTUSSIS VACCINATION

Diphtheria, tetanus, and pertussis vaccines (DTP vaccines) have been given together in a combined vaccine for many decades, and have led to dramatic reductions in each of these diseases. The efficacy of the combined vaccine is similar to that of individual preparations. For many decades the pertussis component of DTP vaccines contained a whole-cell pertussis vaccine, and this vaccine is still used widely in the world. DTP vaccine has been replaced in the United States entirely with DTaP vaccines, which are acellular pertussis vaccines made with purified, inactivated components of the bacterium.

Diphtheria is caused by a gram-positive bacillus, *Corynebacterium diphtheriae*. It is a toxin-mediated disease, with diphtheria toxin causing local tissue destruction, as in pharyngeal and tonsillar diphtheria, as well as systemic disease, particularly myocarditis and neuritis. The overall case fatality

rate is between 5% and 10%, with higher death rates in persons younger than 5 years or older than 40 years of age. As many as 200,000 cases of diphtheria occurred each year in the 1920s in the United States. Largely because of successful vaccination programs, only 5 cases of diphtheria have been reported in the United States since 2000. In the last several decades, the majority of diphtheria cases in the United States have been in unimmunized or inadequately immunized persons. The clinical efficacy of diphtheria vaccine is not precisely known but has been estimated to be greater than 95%.

The anaerobic gram-positive rod *Clostridium tetani* causes tetanus, usually through infection of a contaminated wound. When *C. tetani* colonizes devitalized tissue, the exotoxin tetanospasmin is disseminated to inhibitory motor neurons, resulting in generalized rigidity and spasms of skeletal muscles. Tetanus-prone wounds include (1) puncture wounds, including those acquired due to body piercing, tattooing, and intravenous drug abuse; (2) animal bites; (3) lacerations and abrasions; and (4) wounds resulting from nonsterile delivery and umbilical cord care (neonatal tetanus). In persons who have completed the primary vaccination series and have received a booster dose within the past 10 years, vaccination is virtually 100% protective. In 2005, the last year for which data are available, 27 cases of tetanus occurred in the United States, with no cases of neonatal tetanus.

Pertussis is also primarily a toxin-mediated disease. Called whooping cough because of the high-pitched inspiratory whoop that can follow intense paroxysms of cough, pertussis is caused by the bacterium *Bordetella pertussis*. Complications from pertussis include death, often from associated pneumonia, seizures, and encephalopathy. Sixty-six deaths from pertussis were reported to the CDC in 2004–2005; 85% were in children 3 months of age or younger. Prior to the widespread use of pertussis vaccines in the 1940s, roughly 1 million pertussis cases were reported over a 6-year period. Pertussis incidence in the United States declined dramatically between the 1940s and 1980s, but beginning in the early 1980s incidence has been slowly increasing, with adolescents and adults accounting for a greater proportion of reported cases. A single booster dose of a different formulation, Tdap, is now recommended for all adolescents and adults, as discussed in more detail later in this chapter. Providing a booster dose of pertussis-containing vaccine should prevent adolescent and adult pertussis cases, but also has the potential to reduce the spread of pertussis to infants, who are most susceptible to complications from the disease.

▶ Vaccines Available

Diphtheria, Tetanus, and Pertussis Combinations

1. DTaP (Daptacel, Sanofi Pasteur) contains tetanus toxoid, diphtheria toxoid, and acellular pertussis vaccine. This DTaP is licensed for ages 6 weeks through 6 years and can be used for doses 1–5.

2. DTaP (Infanrix, GlaxoSmithKline) contains tetanus toxoid, diphtheria toxoid, and acellular pertussis vaccine. This DTaP is licensed for ages 6 weeks through 6 years and can be used for doses 1–5.
3. DTaP (Tripedia, Sanofi Pasteur) contains tetanus toxoid, diphtheria toxoid, and acellular pertussis vaccine. This DTaP is licensed for ages 6 weeks through 6 years and can be used for doses 1–5.
4. Tdap (Boostrix, GlaxoSmithKline) is a tetanus-diphtheria-acellular pertussis vaccine formulated for adolescents aged 10–18 years.
5. Tdap (Adacel, Sanofi Pasteur) is a tetanus-diphtheria-acellular pertussis vaccine for persons aged 11–64 years.

DTaP Combined with Other Vaccines

1. DTaP-Hib (TriHIBit, Sanofi Pasteur) contains a Hib vaccine reconstituted with Tripedia. It is licensed for the fourth dose of the DTaP and Hib vaccination series, but not for doses 1–3.
2. DTaP-IPV-Hepatitis B (Pediatrix, GlaxoSmithKline) contains DTaP combined with polio and HepB. It is approved for doses at 2, 4, and 6 months of age. Although it is approved for use through age 6 years, it is not licensed for booster doses. It cannot be used, for example, as the fourth dose of DTaP (the dose typically given at 15–18 months of age).

Diphtheria and Tetanus Combinations

1. DT (generic, Sanofi Pasteur) contains tetanus toxoid and diphtheria toxoid to be used only in children younger than age 7 years with a contraindication to pertussis vaccination.
2. Td (Decavac, Sanofi Pasteur) contains tetanus toxoid and a reduced quantity of diphtheria toxoid, which is typically used for adults requiring tetanus prophylaxis.
3. Td (generic, Massachusetts Biological Labs) contains tetanus toxoid and a reduced quantity of diphtheria toxoid, which is typically used for adults requiring tetanus prophylaxis.

Tetanus Only

TT (generic, Sanofi Pasteur) contains tetanus toxoid only, and can be used for adults or children.

▶ Dosage & Schedule of Administration

Although several different vaccines are available, a few general considerations can help guide their use in specific circumstances. DTaP (alone or combined with other vaccines) is used for infants and children between 6 weeks and 6 years of age. There is no pertussis-containing vaccine licensed for children aged 7–9 years, so Td is used for this age group when tetanus or diphtheria vaccination is needed. For adolescents and adults, a single dose of Tdap is used, fol-

lowed by booster doses of Td every 10 years; a detailed description of its use is provided later in this chapter.

The primary series of DTaP vaccination should consist of four doses, given at 2, 4, 6, and 15–18 months of age. The fourth dose may be given as early as 12 months of age if 6 months have elapsed since the third dose. Giving the fourth dose between 12 and 15 months of age is indicated if the provider thinks the child is unlikely to return for a clinic visit between 15 and 18 months of age. Children should receive a fifth dose of DTaP at 4–6 years of age. However, a fifth dose of DTaP is not needed if the fourth dose was given after the child's fourth birthday. The same brand of DTaP should be used for all doses if feasible.

▶ Contraindications & Precautions

DTaP vaccines should not be used in individuals who have had an anaphylactic-type reaction to a previous vaccine dose or to a vaccine component. DTaP should not be given to children who developed encephalopathy not attributable to another identified cause within 7 days of a previous dose of DTaP or DTP. DTaP vaccination should also be deferred in individuals with progressive neurologic disorders, such as infantile spasms, uncontrolled epilepsy, or progressive encephalopathy, until their neurologic status is clarified and stabilized.

Precautions to DTaP vaccination include: high fever ($\geq 40.5^{\circ}\text{F}$), persistent inconsolable crying, or shocklike state within 48 hours of a previous dose of DTP or DTaP; seizures within 3 days of a previous dose of DTP or DTaP; Guillain-Barré syndrome less than 6 weeks after a previous tetanus-containing vaccine; or moderate or severe acute illness with or without a fever.

▶ Adverse Effects

Local reactions, fever, and other mild systemic effects occur with one-fourth to two-thirds the frequency noted following whole-cell DTP vaccination. Moderate to severe systemic effects, including fever of 40.5°C , persistent inconsolable crying lasting 3 hours or more, and hypotonic-hypo-responsive episodes, are less frequent than with whole-cell DTP. These are without sequelae. Severe neurologic effects have not been temporally associated with DTaP vaccinations in use in the United States. A recent study from Canada showed no evidence of encephalopathy related to pertussis vaccine (< 1 case per 3 million doses of DTP and < 1 per 3.5 million doses of DTaP). Data are limited regarding differences in reactogenicity among currently licensed acellular pertussis vaccines. With all currently licensed DTaP vaccines, reports of the frequency and magnitude of substantial local reactions at injection sites have increased with increasing dose number (including swelling of the thigh or entire upper arm after receipt of the fourth and fifth doses).

▶ Diphtheria Antibody Preparations

Diphtheria antitoxin, manufactured in horses, is available for the treatment of diphtheria. Dosage depends on the size

and location of the diphtheritic membrane and an estimate of the patient's level of intoxication. Sensitivity to diphtheria antitoxin must be tested before it is given. Consultation on the use of diphtheria antitoxin is available from the CDC's National Center for Immunization and Respiratory Diseases (formerly the National Immunization Program). Diphtheria antitoxin is not commercially available in the United States and must be obtained from the CDC.

▶ Tetanus Antibody Preparations

Human tetanus immune globulin (TIG) is indicated in the management of tetanus-prone wounds in individuals who have had an uncertain number or fewer than three tetanus immunizations. Persons fully immunized with at least three doses do not require TIG, regardless of the nature of their wounds (Table 9–5). The optimal dose of TIG has not been established, but some sources recommend 3000–5000 units as a single dose, with part of the dose infiltrated around the wound.

HAEMOPHILUS INFLUENZAE TYPE B VACCINATION

H influenzae type b (Hib) causes a wide spectrum of serious bacterial illnesses, particularly in young children, including meningitis, epiglottitis, pneumonia, septic arthritis, and cellulitis. Before the introduction of effective vaccines, Hib was the leading cause of invasive bacterial disease in children younger than 5 years of age in the United States. Nearly all Hib disease occurred in this age group, and roughly two thirds of cases occurred in children younger than 18 months of age.

Hib bacteria are surrounded by a polysaccharide capsule (polyribosyl ribitol phosphate [PRP]) that contributes to virulence, and antibodies to this polysaccharide confer immunity to the disease. A polysaccharide-only Hib vaccine was first licensed in the United States in 1985, but the polysaccharide was not strongly immunogenic, did not

Table 9-5. Recommendations for the use of tetanus prophylaxis after a wound.

History of Tetanus Toxoid-containing Vaccine ^a	Clean, Minor Wounds		All Other Wounds	
	DT, Td, or Tdap ^b	Tlg	DT, Td, or Tdap ^b	Tlg
< 3 doses or unknown vaccine status ^a	Yes	No	Yes	Yes
≥ 3 doses and 5-9 y since last tetanus toxoid-containing vaccine ^c	No	No	Yes ^d	No
≥ 3 doses and > 10 y since last tetanus toxoid-containing vaccine ^c	Yes ^c	No	Yes ^c	No

^aFor infants younger than age 6 months who have not received 3 doses of tetanus-containing vaccine, use maternal tetanus immunization history at the time of delivery and apply the guidelines in the table above.

^bAge-appropriate tetanus-containing vaccines should be given. Children younger than age 7 years should receive DTaP or DT. Tdap is preferred (over Td) for adolescents who have never previously received Tdap. Tdap is licensed for 1 dose only. In adolescents who have *previously* received a dose of Tdap and who need additional tetanus toxoid-containing vaccine, Td should be used.

^cPersons who have received at least 3 doses of tetanus toxoid-containing vaccines but have not received a tetanus toxoid-containing vaccine for more than 10 years should receive an age-appropriate tetanus toxoid-containing vaccine regardless of the nature of the wound.

^dPersons who received at least 3 doses of tetanus toxoid-containing vaccines but have not received a tetanus toxoid-containing vaccine for more than 5 years, should receive an age-appropriate tetanus toxoid-containing vaccine unless the wounds are clean and minor.

Recommendations based on American Academy of Pediatrics: Tetanus. In Pickering LK et al (editors): *Red Book, 2006 Report of the Committee on Infectious Diseases*, 27th ed. American Academy of Pediatrics, 2006:650.

induce long-term immune memory, and the vaccine was not effective in children younger than 18 months of age. However, when Hib polysaccharide was chemically bonded (conjugated) to certain protein carriers, the conjugate induced T-cell dependent immune memory and was highly effective in young children. All current Hib vaccines are based on this polysaccharide-protein conjugate technology.

Precisely describing the epidemiology of invasive Hib disease is difficult because bacterial serotyping is required to differentiate Hib-caused infections from those caused by other encapsulated and nonencapsulated *H influenzae* species. However, it has been estimated that roughly 20,000 cases of invasive Hib disease occurred each year in the United States in the early 1980s. Since the introduction of Hib vaccines, disease incidence has declined by more than 99%.

In the United States in 2005, the year from which most recent data are available, 9 cases of invasive Hib disease occurred in children younger than age 5 years. An additional 217 cases were caused by *H influenzae* species in which the serotype was not reported. In recent years, most cases of Hib disease occurred in unvaccinated or partially vaccinated children, including children younger than 6 months of age who were too young to have completed the primary vaccination series.

► Vaccines Available

Four vaccines against Hib disease are available in the United States; two are Hib-only vaccines, and two are combination vaccines. Each vaccine contains Hib polysaccharide conju-

gated to a protein carrier, but different protein carriers are used. The Hib conjugate vaccine that uses a meningococcal outer membrane protein carrier is abbreviated PRP-OMP; and PRP-T vaccine uses a tetanus toxoid carrier.

1. Hib (PedvaxHIB, uses PRP-OMP, Merck).
2. Hib (ActHIB, uses PRP-T, Sanofi Pasteur).
3. DTaP-Hib (TriHIBit, uses PRP-T reconstituted with Tripedia brand of DTaP, Sanofi Pasteur).
4. Hepatitis B-Hib (Comvax, uses PRP-OMP, Merck).

► Dosage & Schedule of Administration

Hib vaccination is routinely recommended for all infants in the United States. The vaccine dose is 0.5 mL given intramuscularly. As shown in Table 9-6, the vaccination schedule depends on which type of Hib vaccine is used. The recommended interval between doses in the primary series is 8 weeks, but a minimal interval of 4 weeks is permitted. For infants who missed the primary vaccination series, a catch-up schedule is used (see Table 9-3). Hib vaccine is not generally recommended for children 5 years of age or older.

► Contraindications & Precautions

Hib vaccine should not be given to anyone who has had a severe allergic reaction to a prior vaccine dose or to any vaccine components. Hib vaccine should not be given to infants before 6 weeks of age, since they appeared to develop immune tolerance and did not mount appropriate immune responses to subsequent doses.

Table 9-6. Schedule for *Haemophilus influenzae* type b (Hib) vaccination depending on type of protein conjugate used.

Conjugate Type	Trade Name	Age			
		2 Months	4 Months	6 Months	12-15 Months
PRP-T ^a	ActHIB, TriHIBit	Dose 1	Dose 2	Dose 3	Booster dose
PRP-OMP ^b	PedvaxHIB, Comvax ^c	Dose 1	Dose 2		Booster dose

^aTetanus toxoid carrier.

^bMeningococcal outer membrane protein.

^cSee Table 9-4 for the use of Comvax in infants born to mothers with positive or unknown hepatitis B surface antigen status.

▶ Adverse Effects

Adverse reactions following Hib vaccination are uncommon. Between 5% and 30% of vaccine recipients experience swelling, redness, or pain at the vaccination site. Systemic reactions such as fever and irritability are rare.

PNEUMOCOCCAL VACCINATION

Streptococcus pneumoniae is the most common cause of invasive bacterial infection in children, with most invasive disease occurring in children younger than age 2 years. Two kinds of vaccines are available in the United States against pneumococci: a 23-valent polysaccharide vaccine (PPV23) and a 7-valent protein-conjugated polysaccharide vaccine (PCV7). Clinical trials with extended spectrum vaccines include a 9-valent vaccine (in South Africa and the Gambia), an 11-valent vaccine (Philippines), and a 13-valent vaccine (Israel). The serotypes represented in available vaccines were chosen for their frequency in disease among adults (PPV23) or children in industrialized countries (PCV7). Additional serotypes needed in developing countries are included in the 9-, 11- and 13-valent vaccines. As in Hib vaccine, the carrier protein may be CRM 197, protein D of *H influenzae*, tetanus and diphtheria toxoids, or meningococcal outer membrane protein. Prior to the year 2000, only PPV23 was available in the United States. The efficacy of this vaccine was 57%; it was not effective in children younger than 2 years; and it was only indicated for certain high-risk children age 2 years or older.

The 7- and 9-valent pneumococcal conjugate vaccines have been evaluated for efficacy against invasive pneumococcal disease in four trials (in the United States, South

Africa, the Gambia, and the Navajo Indian Nation). The pooled efficacy estimate from the first three vaccine trials was 93% (95% confidence interval [CI] 81% and 98%) against invasive disease caused by serotypes in the vaccine. Four studies (in the United States, South Africa, the Gambia, and the Philippines) have evaluated the impact of the vaccine on pneumonia, documenting 20–37% reduction in radiographically confirmed pneumonia. Several trials have evaluated the efficacy of pneumococcal conjugate vaccines against otitis media. Although two trials in Finland using 7-valent vaccines showed significant reduction in culture-confirmed pneumococcal otitis media caused by vaccine serotypes, there was no net reduction of otitis media in the vaccinated children. This was the result of an increase in the rates of otitis media due to nonvaccine types of pneumococci, *H influenzae* and *Moraxella catarrhalis*. However, a trial in Northern California showed that PCV7 had a protective effect against frequent otitis media. There was a 10% reduction in patients with 3 otitis-related visits and a 26% reduction in patients with 10 otitis-related visits within a 6-month period. Furthermore, otitis requiring tympanostomy tube placement was reduced by 24%. A trial of an 11-valent vaccine in the Czech Republic showed a vaccine efficacy of 58% against acute otitis media caused by the vaccine serotypes and a 34% reduction in acute otitis media overall. However, a trial in 383 Dutch children with recurrent acute otitis media showed no efficacy in this population. Finally, in the Gambian vaccine trial, which was conducted in a rural area where access to round-the-clock medical care was difficult, there was a 16% reduction in mortality.

Since the introduction of routine PCV7 immunization in the United States in 2000, dramatic direct and indirect effects have been seen. By 2005, the incidence of invasive disease due to vaccine-related serotypes declined by 90%. Not only has invasive pneumococcal disease due to vaccine serotypes in children declined, but invasive disease in adults and especially the elderly has also declined, with reductions in mortality. There have been reductions in other diseases (eg, otitis media and pneumonia), and a reduced rate of infection and colonization by antibiotic-resistant strains.

An unanticipated effect of the reduction in infection and colonization by vaccine serotypes in both vaccinated children and adults has been an increased prevalence of colonization and disease caused by nonvaccine strains of pneumococci (bacterial replacement). Overall in the United States, despite the changing prevalence of colonizing strains by vaccine serotypes, the slight increase in invasive pneumococcal disease due to nonvaccine strains has been overshadowed by the dramatic decline in disease caused by vaccine serotypes. One of the most common nonvaccine serotypes causing infections is serotype 19A. A recent study from Alaska (not yet replicated in other indigenous populations, such as the Navajo or aboriginal Australians) showed a dramatic decline in overall invasive pneumococcal disease (67% in Alaska Native children younger than 2 years between the prevaccine period and the 3 years after introduction of the vaccine). Subsequent to that, between 2004 and 2006, there has been an 82% increase in invasive pneumococcal disease in this population, caused by nonvaccine serotypes. Serotype 19A accounted for almost one third of the invasive pneumococcal disease in these children.

Universal immunization of all infants with PCV7 is now recommended, with four doses given at 2, 4, 6, and 12–15 months of age. Children aged 24–59 months at high risk of invasive pneumococcal disease should receive both the conjugate and polysaccharide vaccines (PCV7 and PPV23). Although definitive data about using PCV7 and PPV23 in combination are not available for invasive disease, it did reduce acute otitis media in one study. It is also known that immunization with PCV7 induces immunologic memory that is boosted by some of the serotypes in PPV23. Additionally, PPV23 provides coverage against a broader range of serotypes than does PCV7. Recommendations for using PPV23 in children older than 24 months are found in Table 9–7. Children at high risk of invasive pneumococcal disease include those with chronic cardiovascular, pulmonary (including cystic fibrosis but not asthma), and liver diseases; and those with anatomic and functional asplenia (including sickle cell disease), nephrotic syndrome, chronic renal failure, diabetes mellitus, cerebrospinal fluid leak, or immunosuppression (including those with HIV infection, complement deficiencies, malignancies, prolonged use of steroids, and organ transplants). Penicillin prophylaxis of patients with sickle cell disease should be continued regardless of vaccination with PCV7 or PPV23. Insufficient data are available to provide definitive recommendations for pneumococcal vaccination for immunocompromised children 5 years and older, but two doses of PCV7 and one dose of PPV23 was immunogenic and safe in HIV-infected children aged 2–19 years receiving highly active antiretroviral therapy. For children who had received hematopoietic stem cell transplantation, three doses of PCV7 were safe and immunogenic. For children aged 5–9 years at increased risk of invasive pneumococcal disease, providers can consider giving one dose each of PCV7 and PPV23, with PCV7 administered first, followed

Table 9–7. Recommendations for PPV23 immunization in children 2 years and older who have previously received PCV7.

Population	Initial Vaccination with PPV23	Revaccination with PPV23
Healthy children	Not recommended ^a	Not recommended
Children with sickle cell disease or anatomic or functional asplenia; immunocompromised; or HIV-infected	1 dose of PPV23 at 24 months of age or older, given at least 2 months after last dose of PCV7	Recommended ^b
Persons with chronic illness	1 dose of PPV23 at 24 months of age or older, given at least 2 months after last dose of PCV7	Not recommended

^aPPV23 should be considered in Alaskan Native and American Indian children.

^bFor patients 10 years or younger, revaccination with PPV23 should occur 3–5 years after previous dose of PPV23; for patients older than 10 years, revaccination should occur 5 years or more after previous dose of PPV23. Reproduced, with permission, from CDC: Preventing pneumococcal disease among infants and young children. Recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR* 2000;49(RR-9):1.

by PPV23 at least 8 weeks later. An additional PPV23 booster should be given 3–5 years later.

► Vaccines Available

The currently available PCV7 vaccine (Prevnar, Wyeth) is composed of seven purified capsular polysaccharides, each coupled to a nontoxic modified diphtheria toxin. Serotypes included in the vaccine and potentially cross-reacting serotypes accounted for 86% of bacteremia, 83% of meningitis, and 65% of acute otitis media cases caused by pneumococcus in the prevaccine era. The vaccine is licensed for use in children aged 6 weeks to 9 years.

PPV23 (Pneumovax 23, Merck) is only for use in persons 2 years and older. It contains 25 µg of each purified capsular polysaccharide antigen of 23 serotypes of pneumococcus. These 23 types cause 88% of cases of pneumococcal bacteremia and meningitis in adults and nearly 100% of those in children in the United States. Cross-reactive antibody responses may protect against an additional 8% of bacteremic serotypes in adults.

► Dosage & Schedule of Administration

PCV7 is given as a 0.5-mL intramuscular dose. The first dose can be given as early as 6 weeks of life, with a recommended vaccination schedule of 2, 4, 6, and 12–15 months. Children who receive their first dose of PCV7 at 7–11 months of age

should receive two doses separated by at least 8 weeks, followed by a booster dose at 12–15 months. Children who receive their first dose of PCV7 at 12–23 months require two doses total, separated by 8 weeks. PCV7 may be given concurrently with the other routinely recommended childhood immunizations.

Children older than 23 months at high risk of invasive pneumococcal disease should receive both PCV7 and PPV23, as outlined in Table 9–7. PCV7 and PPV23 should not be given simultaneously, and when both are indicated, they should be given 8 weeks apart. The dose of PPV23 is 0.5 mL given intramuscularly. If splenectomy or immunosuppression can be anticipated, vaccination should be done at least 2 weeks beforehand. Revaccination with PPV23 may be considered after 3–5 years in children at high risk of fatal pneumococcal infection.

▶ Contraindications & Precautions

For both PCV7 and PPV23, vaccination is contraindicated in individuals who suffered a severe allergic reaction such as anaphylaxis after a previous vaccine dose or to a vaccine component. PCV7 and PPV23 vaccination should be deferred during moderate or severe acute illness, with or without fever. A history of invasive pneumococcal disease is not a contraindication to vaccination.

▶ Adverse Effects

The most common adverse effects associated with PCV7 administration are fever, induration, and tenderness at the injection site. When it is given simultaneously with DTaP, no increase in febrile seizures has been seen when compared with administration of DTaP alone.

With PPV23, 50% of vaccine recipients develop pain and redness at the injection site. Fewer than 1% develop systemic side effects such as fever and myalgia. Anaphylaxis is rare. Vaccine safety has not been evaluated during pregnancy.

Singleton RJ et al: Invasive pneumococcal disease caused by nonvaccine serotypes among Alaska Native children with high levels of 7-valent pneumococcal conjugate vaccine coverage. *JAMA* 2007;297:1784 [PMID: 17456820].

POLIOMYELITIS VACCINATION

Vaccines directed against poliovirus infections have eliminated the naturally occurring disease in industrialized coun-

tries. In the United States, the number of reported cases of paralytic poliomyelitis has fallen from more than 18,000 in 1954. In September 2005, four infections with a type 1 vaccine-derived poliovirus were recorded in unvaccinated Amish children in Minnesota, the first report in the United States since 2000, when OPV use was discontinued. Vaccine-derived pathogenic polioviruses can emerge from OPV, and be spread because of continuous replication in immunodeficient persons such as the index case in this outbreak, or by circulation in populations with low vaccine coverage. As of November, 2007, 735 confirmed wild-type poliovirus cases and 50 vaccine-derived poliovirus cases had been reported worldwide since the beginning of the year. This was three times the number of cases in 2003. Poliomyelitis is now endemic in India, Pakistan, Afghanistan, and Nigeria. In 2007 outbreaks following importation occurred in Niger, Chad, the Democratic Republic of Congo, Sudan, Angola, Somalia, and Myanmar.

An injectable poliovirus vaccine of enhanced potency, which has a higher content of antigens than the old IPV, is the only vaccine against poliomyelitis available in the United States since 2000. IPV is incapable of causing poliomyelitis by virtue of being inactivated, whereas OPV can do so rarely.

Completely immunized adult visitors to areas of continuing wild-type poliovirus circulation should receive a booster dose of IPV. Unimmunized or incompletely immunized adults and children should have received two (preferably three) doses of the vaccine prior to travel to these and other areas with circulation of wild-type or vaccine-type virus.

▶ Vaccines Available

1. IPV (IPOL, Sanofi Pasteur) contains antigens of types 1, 2, and 3 poliovirus.
2. DTaP-HepB-IPV (Pediarix, GlaxoSmithKline) contains diphtheria and tetanus toxoids and acellular pertussis adsorbed, hepatitis B, and inactivated poliovirus vaccine.

▶ Dosage & Schedule of Administration

IPV is administered in a dose of 0.5 mL subcutaneously. The DTaP-HepB-IPV combination vaccine can be used in the primary series at 2, 4, and 6 months, and can be used to complete the primary series. It can be administered with Hib and PCV7 vaccines at separate sites but is not approved for the fourth dose of IPV or the fourth and fifth doses of DTaP.

▶ Contraindications & Precautions

IPV vaccination is contraindicated in individuals who suffered a severe allergic reaction such as anaphylaxis after a previous vaccine dose or to a vaccine component. IPV vaccination should be deferred during moderate or severe acute illness with or without fever. Pregnancy is also a precaution to IPV vaccination. Receipt of previous doses of OPV is not a contraindication to IPV.

▶ Adverse Effects

IPV has essentially no adverse effects associated with it other than possible rare hypersensitivity reactions to trace quantities of antibiotics. The DTaP-HepB-IPV combination has similar rates of local and systemic adverse responses to three components administered separately except for fever, which is higher in the combination-vaccinated children.

INFLUENZA VACCINATION

Influenza occurs each winter and early spring, often associated with significant morbidity and mortality in certain high-risk persons. Up to 36,000 deaths per year in the United States are attributable to influenza, and global epidemics (pandemics) can occur. The current threat of a global pandemic with the avian influenza virus (H5N1 strain) is very real, with greater than 300 cases by mid-2007 and a case fatality rate of 60%. Currently there is one vaccine available for the H5N1 virus and more vaccines may become available. Each year, recommendations are formulated in the spring and summer regarding the constituents of influenza vaccine for the coming season. These recommendations are based on the results of surveillance in Asia and the southern hemisphere during the spring and summer. The vaccine each year is a trivalent vaccine containing antigens from two strains of influenza A and one strain of influenza B, which are chosen as being likely to circulate in the United States during the upcoming winter. Children at high risk of seasonal influenza-related complications include those with hemoglobinopathies or with chronic cardiac, pulmonary (including asthma), metabolic, renal, and immunosuppressive diseases (including immunosuppression caused by medications or by HIV); and those with any condition (eg, cognitive dysfunction, spinal cord injuries, seizure disorders, or other neuromuscular disorders) that can compromise respiratory function, or the handling of respiratory secretions, or that can increase the risk of aspiration. Children and adolescents receiving long-term aspirin therapy are also at risk of influenza-related Reye syndrome. Healthy children aged 6–23 months are at substantially increased risk of influenza-related hospitalizations, and children aged 24–59 months (ie, 2–4 years) are at increased risk of influenza-related clinic and emergency department visits.

Annual influenza vaccination is indicated for all children older than 6 months of age who have a chronic health condition that increases their risk of complications from influenza infection. Annual vaccination is now routinely

recommended for all children aged 6–59 months. Members (including other children) of households with persons in high-risk groups and with children younger than age 5 years should also be immunized. Physicians should identify high-risk children in their practices and encourage parents to seek influenza vaccination for them as soon as influenza vaccine is available. In pandemic years, it may be important to advocate vaccination of all children regardless of their usual state of health and in particular school-aged children who are often the epicenter of outbreaks within the community. Influenza prevention may also help prevent lower respiratory tract disease or other secondary complications in high-risk groups, thereby decreasing hospitalizations and deaths.

▶ Vaccines Available

The trivalent inactivated influenza vaccine virus (TIV) is grown in eggs, formalin-inactivated, and may contain trace quantities of thimerosal as a preservative. Only split-virus or purified surface antigen preparations are available in the United States. Several manufacturers produce similar vaccines each year. Fluzone split-virus (Sanofi Pasteur) is approved for children 6 months and older; Fluvirin (Chiron) is approved only for children 4 years and older. Additional manufacturers (GlaxoSmithKline, CSL Biotherapies, ID Biomedical Corporation) produce influenza vaccines approved for adults.

To eliminate the need for injections, and potentially to enhance mucosal and systemic immune response to vaccination, a live attenuated intranasal vaccine has been developed. This vaccine is cold-adapted, and temperature-sensitive. These viruses replicate poorly in the lower respiratory tract, but well in the nasal mucosa (thereby producing immunity). The intranasal trivalent live attenuated influenza virus vaccine (LAIV) (FluMist, MedImmune) is also produced in a trivalent formulation using the virus strains present in the inactivated vaccine. It is also made in eggs and comes in a single-use prefilled sprayer that should be stored refrigerated at 2–8°C.

▶ Dosage & Schedule of Administration

A. Inactivated Influenza Virus Vaccine

Because influenza can circulate yearly from November through early March in the United States, the key time to initiate vaccination is as soon as vaccine is available in the early fall. However, providers should continue vaccinating individuals as long as vaccine is available and there is still influenza activity in the community. Children younger than age 6 months should not be immunized. Two doses are recommended for children younger than age 9 years who are receiving influenza vaccine for the first time; subsequent seasons require single doses. Older children receiving vaccine for the first time require only a single dose. The dose for children aged 6–35 months is 0.25 mL given intramuscularly; for older children the dose is 0.5 mL given intramuscularly. The recommended site of vaccination is the anterolateral aspect of the thigh for younger children and the deltoid for

older children. Pregnancy is not a contraindication to use of inactivated vaccine, and vaccine is recommended for all pregnant women and those contemplating pregnancy during the influenza season. Simultaneous administration with other routine vaccinations is acceptable.

B. Live Attenuated Influenza Virus Vaccine

This vaccine is supplied in a prefilled single-use sprayer containing 0.2 mL of the vaccine, approximately half of which is sprayed into each nostril. A dose divider clip is provided to assist in dividing the dose. If the patient sneezes during administration, the dose should not be repeated. It can be administered to children with minor illnesses, but should not be given if significant nasal congestion is present. Because it is a live vaccine it should be administered 48 hours after cessation of therapy in children receiving anti-influenza antiviral drugs, and antivirals should not be given for 2 weeks after vaccination. Unvaccinated children aged 2–8 years should receive two doses of vaccine 4 weeks apart, and one dose is required for previously vaccinated children aged 2–8, or any older individuals 9–49 years of age.

▶ Contraindications & Precautions

A. Inactivated Influenza Virus Vaccine

TIV is contraindicated in individuals with history of hypersensitivity to eggs or egg proteins, or with life-threatening reactions to previous influenza vaccinations. For patients with anaphylactic egg allergies in whom influenza vaccination is indicated, a protocol for influenza vaccination is referenced later in this chapter.

B. Live Attenuated Influenza Virus Vaccine

LAIV is contraindicated in individuals with history of hypersensitivity to eggs, egg proteins, gentamicin, gelatin, or arginine, or with life-threatening reactions to previous influenza vaccinations, and in children and adolescents receiving concomitant aspirin or aspirin-containing therapy. LAIV should not be administered to the following persons: (1) children younger than 24 months of age, because of an increased risk of hospitalization and wheezing that was observed in clinical trials; (2) any individual with asthma or children younger than age 5 years with recurrent wheezing unless the potential benefit outweighs the potential risk; or (3) individuals with severe asthma or active wheezing.

▶ Adverse Effects

A. Inactivated Influenza Virus Vaccine

Injection site reactions are the most common adverse events after TIV administration. A small proportion of children will experience some systemic toxicity, consisting of fever, malaise, and myalgias. These symptoms generally begin 6–12 hours after vaccination and may last 24–48 hours. Cases of

Guillain-Barré syndrome followed the swine influenza vaccination program in 1976–1977, but careful study by the Institute of Medicine showed no association with that vaccine in children and young adults—nor in any age group that received vaccines in subsequent years.

B. Live Attenuated Influenza Virus Vaccine

The most common adverse reactions (occurring at $\geq 10\%$ in individuals receiving LAIV and at least 5% greater than in placebo) are runny nose or nasal congestion in recipients of all ages and fever higher than 37.7°C in children 2–6 years of age. These reactions were reported more frequently with the first dose and were all self-limited. Antiviral therapy should not be administered until 2 weeks after LAIV unless medically necessary and health care providers should wait 48 hours after cessation of antiviral therapy before administering LAIV.

MEASLES, MUMPS, & RUBELLA VACCINATION

In the 20 years after the 1963 introduction of measles vaccination in the United States, the annual number of reported cases decreased from 500,000 to fewer than 1500. However, between 1989 and 1991 there was a resurgence of measles, with 50,000 cases reported. The major reasons for the increase in cases and the resulting deaths were failure to provide vaccine to preschool children aged 15 months or older, the presence in the community of susceptible children younger than age 15 months, and the growing number of appropriately vaccinated, but nonimmune individuals (2–10% primary vaccine failures) in schools and colleges. These reasons led to recommendations for a two-dose vaccination schedule at 12–15 months and at 4–6 years of age.

In the United States, after the introduction of mumps vaccine in 1967 and the recommendation for its use in 1977, there was a 99% decline in mumps from 185,691 cases reported in 1968 to fewer than 300 cases each year between 2001 and 2003. However, between 2005 and 2006, there was a large multistate outbreak of mumps with almost 6000 confirmed or probable mumps cases reported to the CDC. Six states—Iowa, Kansas, Wisconsin, Illinois, Nebraska, and South Dakota—recorded 85% of the cases. This outbreak occurred mostly on college campuses, but also involved high

schools and middle schools. Several factors may have contributed to the outbreaks: conditions on college and high school campuses may be conducive to spread of respiratory infections; two doses of MMR vaccine may not be 100% effective in preventing mumps and even less effective in preventing asymptomatic infection; and waning immunity may have occurred in young adults who had last received mumps-containing vaccine 6–17 years earlier.

Although these outbreaks have not changed the recommendations for two doses of MMR vaccination for all children, in May 2006 the ACIP redefined evidence of immunity to mumps as follows: one dose of a live mumps virus vaccine for preschool children and adults not at high risk; and two doses for children in grades K–12 and adults at high risk (health care workers, international travelers, and students at post–high school level educational facilities). Other evidence of immunity is birth before 1957, documentation of physician-diagnosed mumps, or laboratory evidence of immunity. The ACIP recommended that health care facilities should consider recommending one dose of MMR vaccine to unvaccinated health workers born before 1957 who do not have other evidence of mumps immunity, and two doses of MMR during a mumps outbreak. The Iowa Department of Public Health curtailed the epidemic by successively introducing mumps vaccine into counties with the largest colleges and universities, expanding vaccination to the whole state, and finally vaccinating adults up to age 46 years.

The use of rubella vaccine is not intended to protect individuals from rubella infection, but rather to prevent the serious consequences of rubella infection during pregnancy: miscarriage, fetal demise, and congenital rubella syndrome. Congenital rubella syndrome is a group of birth defects including deafness, cataracts, heart defects, and mental retardation. In the United States and the United Kingdom, the approach has been to vaccinate young children. The intent is to reduce transmission to susceptible women of childbearing age via a herd immunity effect. Immunity lasts for at least 15 years. With the use of rubella vaccines since 1970, rubella incidence rates have declined more than 99%. However, approximately 10% of young adults are now susceptible to rubella. Rubella is rare in the United States. Currently most cases of rubella are seen in foreign-born adults, and outbreaks have occurred in poultry and meat processing plants that employ many foreign-born workers. Similarly, almost all infants with congenital rubella syndrome are born to foreign-born mothers.

Recently, reports in the medical and lay press have suggested a possible association between MMR vaccination, autism, and gastrointestinal inflammation. The initial reports have been refuted because of the limited number of patients studied, methods of case and control selection, the laboratory evaluations employed, and means of determining developmental regression. Several large epidemiologic studies subsequently found no association between MMR vaccination and either autism or bowel inflammation. Also, no evidence has been found to support the need for separate

administration of measles, mumps, and rubella vaccines (as opposed to the MMR combination). However, the influence of the lay press in the United Kingdom may have contributed to low vaccination rates with measles vaccine, which has resulted in a resurgence of measles.

► Vaccines Available

1. Measles-only vaccine (Attenuvax, Merck): The Moraten strain is a live attenuated vaccine derived from the Edmonston B strain after multiple passages in chick embryo tissue culture.
2. Mumps-only vaccine (Mumpsavax, Merck): The Jeryl Lynn Strain is the only mumps vaccine available in the United States. It is prepared from a clinical isolate passaged in embryonated eggs and in chick embryo tissue culture.
3. Rubella-only vaccine (Meruvax II, Merck): The RA 27/3 strain is the only vaccine available in the United States. It is grown in human diploid cells. The RA 27/3 strain is available as a monovalent vaccine, in combined preparations with measles vaccine, or in measles and mumps vaccines. In most circumstances, MMR or MMRV vaccination is the recommended means of immunizing against rubella.
4. Measles-mumps-rubella (MMR II, Merck)
5. MMRV: In September 2005 the FDA licensed a combined live attenuated measles, mumps, rubella, and varicella vaccine (ProQuad, Merck) for use in children 1–12 years of age. It is identical in composition to MMR with the exception that the varicella component is five times more potent than in the varicella-only (VAR) vaccine. Concomitant administration of MMRV, DTaP, Hib, and HepB vaccines showed that the immune responses to all the antigens when administered simultaneously were comparable to sequential administration of MMRV and the other antigens.

► Dosage & Schedule of Administration

A. Routine Vaccination

Measles, mumps and rubella vaccinations should be given as MMRV or MMR at 12–15 months and again at 4–6 years of age. MMRV is the preferred vaccine if available. A dose of 0.5 mL should be given subcutaneously. The second dose of MMRV or MMR is recommended at school entry to help prevent school-based measles and mumps outbreaks. Children not reimmunized at school entry should receive their second dose by age 11–12 years. If an infant receives the vaccine before 12 months of age, two doses are required to complete the series, the first after at least 12 months of age and the second at least 1 month later. Ig interferes with the immune response to the attenuated vaccine strains of MMR. Therefore, MMR immunization after Ig administration should be deferred by 3–11 months, depending on the type of Ig product received. Consult the AAP's 2006 *Red Book* for specific recommendations.

A person can be considered immune to rubella only with documentation of either serologic immunity to rubella or vaccination with at least one dose of rubella vaccine after age 1 year, or if born before 1957. A clinical diagnosis of rubella is unacceptable. Susceptible pubertal girls and postpubertal women identified by premarital or prenatal screening should also be immunized. Whenever rubella vaccination is offered to a woman of childbearing age, pregnancy should be ruled out and the woman advised to prevent conception for 3 months following vaccination. If a pregnant woman is vaccinated or becomes pregnant within 3 weeks of vaccination, she should be counseled regarding the risk to her fetus. No cases of rubella vaccine-related fetal anomalies have been reported, although theoretical risk of this exists. The risk of congenital rubella syndrome after wild-type maternal infection in the first trimester of pregnancy is 20–85%. All susceptible adults in institutional settings (including colleges), day care center personnel, military personnel, and hospital and health care personnel should be immunized.

B. Vaccination of Travelers

People traveling abroad should be immune to measles and mumps. In high-risk areas, age at primary vaccination should be as soon as possible after the first birthday (ie, at 12 months). However, younger infants 6–11 months of age traveling to high-risk areas should receive the monovalent measles vaccine followed by two subsequent doses of MMR or MMRV followed by MMRV at 12–15 months given at least 4 weeks apart. MMR or MMRV at 4–6 years completes the series. Because maternal antibody to mumps is present in most infants, and the disease is not severe in infancy, infants younger than 12 months of age traveling to endemic countries need not routinely be given mumps vaccine.

C. Revaccination Under Other Circumstances

Persons entering college and other institutions for education beyond high school, medical personnel beginning employment, and persons traveling abroad should have documentation of immunity to measles and mumps, defined as receipt of two doses of measles vaccine after their first birthday, birth before 1957, or a documented measles or mumps history or immunity.

D. Outbreak Control of Measles

A community outbreak is defined as a single documented case of measles. Control depends on immediate protection of all susceptible persons (defined as persons who have no documented immunity to measles in the affected community). In the case of unvaccinated individuals, the following recommendations hold: (1) age 6–11 months, monovalent measles vaccine (or MMR) if cases are occurring in children younger than age 1 year, followed by two doses of MMR at age 12–15 months and again at age 4–6 years; and (2) age 12 months or older, MMR followed by revaccination at 4–6 years. A child

with an unclear or unknown vaccination history should be reimmunized with MMR. Anyone with a known exposure who is not certain of receiving two doses of MMR should receive an additional dose. Unimmunized persons who are not immunized within 72 hours of exposure should be excluded from contact with potentially infected persons until at least 2 weeks after the onset of rash of the last case of measles.

► Contraindications & Precautions

MMR vaccination is contraindicated in pregnant women, women intending to become pregnant within the next 28 days, immunocompromised persons (except those with asymptomatic HIV who have age-specific CD4⁺ lymphocytes counts > 15%), and persons with anaphylactic egg or neomycin allergy. It is also contraindicated in children receiving high-dose corticosteroid therapy (≥ 2 mg/kg/d, or 20 mg/d total, for longer than 14 days) with the exception of those receiving physiologic replacement doses. In these patients, an interval of 1 month between cessation of steroid therapy and vaccination is sufficient. Leukemic patients who have been in remission and off chemotherapy for at least 3 months can receive MMR safely. Children with minor acute illnesses (including febrile illnesses), nonanaphylactic egg allergy, or a history of tuberculosis should be immunized. MMR may be safely administered simultaneously with other routine pediatric immunizations.

► Adverse Effects

Between 5% and 15% of vaccinees receiving MMR become febrile to 39.5°C or higher about 6–12 days following vaccination, lasting approximately 1–2 days, and 5% may develop a transient morbilliform rash. Transient thrombocytopenia occurs in 1:25,000–1:100,000 persons. Encephalitis and other central nervous system conditions, such as aseptic meningitis and Guillain-Barré syndrome, are reported to occur at a frequency of 1 case per 3 million doses in the United States. This rate is lower than the rate of these conditions in unvaccinated children, implying that the relationship between them and MMR vaccination is not causal. MMR vaccination is associated with an increased risk of febrile seizures 8–14 days after vaccination, but no subsequent long-term complications have been seen. A recent study found an increase in female mortality in Guinea Bissau after receiving a high-titered measles vaccine (not used in the United States) at less than 6 months of age. Reactions after mumps vaccination are rare and include parotitis, low-grade fever, and orchitis. In 1989, a nationwide surveillance of neurologic complications after a mumps vaccine was conducted in Japan. At least 311 cases of mild aseptic meningitis (96 had vaccine-type mumps virus in the cerebrospinal fluid) occurred among 630,157 recipients. However, this was not the strain used in the U.S. vaccine. There were no sequelae. A high rate of aseptic meningitis was also found in Brazil, but not in Germany, where different vaccine strains were used. In children, adverse effects from

rubella vaccination are very unusual. Between 5% and 15% of vaccinees develop rash, fever, or lymphadenopathy 5–12 days after rubella vaccination. Rash also occurs alone or as a mild rubella illness in 2–4% of adults. Arthralgia and arthritis occur in 10–25% of adult vaccinees, as opposed to only 0–2% of 6- to 16-year-old vaccinees. Chronic arthritis, which may be causally related to rubella vaccination, occurs more often in women aged 45 or older, starting 10–11 days after vaccination and lasting for up to 1 year. Rare complications include peripheral neuritis and neuropathy, transverse myelitis, and diffuse myelitis.

▶ Antibody Preparations Against Measles

If a child is seen within 72 hours after exposure to measles, vaccination is the preferred method of postexposure protection. If vaccine is contraindicated, Ig, given intramuscularly at a dose of 0.25 mL/kg (0.5 mL/kg in immunocompromised patients; maximum dose in either circumstance is 15 mL), is effective in preventing or modifying measles if it is given within 6 days after exposure. MMR vaccine should be given 5 months later to children receiving the 0.25-mL/kg dose and 6 months later for the higher dose. For children receiving regular intravenous immune globulin, a dose of 100–400 mg/kg should be adequate for measles prophylaxis for exposures occurring within 3 weeks of the last dose.

VARICELLA VACCINATION

Prior to the availability of vaccine, about 4 million cases of varicella-zoster virus (VZV) infection occurred annually in the United States, mostly in children younger than 10 years old. This resulted in 11,000 hospitalizations and 100 deaths per year due to severe complications such as secondary bacterial infections, pneumonia, encephalitis, hepatitis, and Reye syndrome.

A live, attenuated varicella vaccine (VAR) has been licensed in the United States since 1995, and routine immu-

nization of children 12 months of age and older has been recommended since then. The vaccine has been shown to be more than 95% effective at preventing severe disease. The morbidity, mortality, and medical costs associated with varicella infection have significantly declined since VAR was first licensed in the United States. While there is no national system of surveillance for varicella disease in place, a variety of data sources have all shown a consistent pattern of more than 85% reduction in varicella-associated disease. Varicella-related deaths have decreased between 75% and 88% in recent years, and this was observed in all ages, races, and ethnic groups. In the decade since the routine use of VAR has been recommended, there have been reports of “break-through” (usually very mild) varicella occurring in immunized patients. Outbreaks of wild-type infectious VZV have been reported in schools with high one-dose VAR vaccination coverage (96–100%). The vaccine efficacy in those outbreaks was similar (72–85%) to that previously observed. Varicella attack rates among these children varied between 11% and 17% and thus, it was concluded that a single VAR dose could not prevent varicella outbreaks completely.

A second dose of VAR vaccine in children, when given 3 months or 4–6 years after the initial dose, greatly increases the anti-VZV antibody response, which is a correlate of vaccine efficacy. A combination MMRV vaccine has also been shown to be immunologically noninferior to the individual components administered compared with MMR and VAR vaccines administered concomitantly, either as primary immunization or as a booster administered to children age 4–6 years. Among persons older than age 13 years, a second dose results in 94–99% seroconversion with detectable antibody levels persisting for at least 5 years in 97% of them. In a randomized clinical trial of one dose of vaccine compared with two doses administered 3 months apart, the vaccine efficacy for two doses over a 10-year observation period was 98%, significantly higher than the vaccine efficacy for one dose (94%). The two-dose regimen was also 100% efficacious against severe varicella. These observations have led to the recent recommendations of the ACIP and the AAP of two doses of VAR vaccine for children older than 12 months of age, and for adolescents and adults without evidence of immunity.

Data from U.S. and Japanese studies suggest that the vaccine is also effective in preventing or modifying VZV severity in susceptible individuals exposed to VZV if used within 3 days of exposure. A study in the United States suggests that the efficacy of postexposure vaccination is 95% for prevention of any disease and 100% for prevention of moderate or severe disease. There is no evidence that postexposure prophylaxis will increase the risk of vaccine-related adverse events or interfere with development of immunity.

▶ Vaccines Available

1. A cell-free preparation of OKA strain VZV is produced and marketed in the United States as Varivax (Merck). Each dose of VAR contains not less than 1350 plaque-

forming units of VZV and trace amounts of neomycin, fetal bovine serum, and gelatin. Storage in a freezer at a temperature of -15°C or colder provides a shelf life of 15 months. VAR may be stored for 72 hours at refrigerator temperature in its lyophilized state, and it must be administered within 30 minutes after thawing and reconstitution.

2. The availability of MMRV (measles-mumps-rubella-varicella; ProQuad, Merck) for use in children 1–12 years of age simplifies the administration of these antigens. MMRV is well tolerated and provides adequate immune response to all of the antigens it contains. Concomitant administration of MMRV with DTaP, Hib, and HepB vaccines is acceptable. MMRV should be stored in a freezer at a temperature of -15°C or colder.

► Dosage & Schedule of Administration

Two doses (0.5 mL) of VAR vaccine are recommended for immunization of all healthy children aged 12 months and older, and for adolescents and adults without evidence of immunity. For children aged 12 months to 12 years the immunization interval is 3 months, and for persons 13 years or older it is 4 weeks. MMRV is approved only for healthy children aged 12 months to 12 years. A second dose of catch-up vaccination is required for children, adolescents, and adults who previously received one dose of VAR vaccine. All children should have received two doses of vaccine before prekindergarten or school. Asymptomatic or mildly symptomatic HIV-infected children ($\geq 15\%$ CD4⁺ cells) should receive two doses of the single-antigen vaccine (with a 3-month interval between doses).

VAR may be given simultaneously with MMR at separate sites. If not given simultaneously, the interval between administration of VAR and MMR must be greater than 28 days. Simultaneous VAR administration does not appear to affect the immune response to other childhood vaccines. VAR should be delayed 5 months after receiving intravenous immune globulin, blood or plasma. In addition persons who received a VAR vaccine should not be administered an antibody-containing product for at least 2 weeks, and if needed in that interval, the individual may need to be tested for immunity or revaccinated.

► Contraindications & Precautions

Contraindications to VAR vaccination include a severe allergic reaction after a previous vaccine dose or to a vaccine component. Because VAR and MMRV are live-virus vaccines, they are also contraindicated in children who have cellular immunodeficiencies, including those with leukemia, lymphoma, other malignancies affecting the bone marrow or lymphatic systems, and congenital T-cell abnormalities (although VAR vaccine administration to children with acute lymphocytic leukemia is under investigation). The exception to this rule is the recommendation that VAR be administered to HIV-infected children who are not severely

immunosuppressed. Children receiving immunosuppressive therapy, including high-dose steroids, should not receive VAR or MMRV. Household contacts of immunodeficient patients should be immunized. VAR should not be given to pregnant women; however, the presence of a pregnant mother in the household is not a contraindication to immunization of a child within that household.

► Adverse Events

Since the approval of VAR in 1995, more than 50 million doses have been distributed in the United States. The most commonly recognized adverse reactions, occurring in approximately 20% of vaccinees, are minor injection site reactions. Additionally, 3–5% of patients will develop a rash at the injection site, and an additional 3–5% will develop a sparse varicelliform rash outside of the injection site. These rashes typically consist of two to five lesions and may appear 5–26 days after immunization. The two-dose vaccine regimen is generally well tolerated with a safety profile comparable to that of the one-dose regimen. The incidence of fever and varicelliform rash is lower after the second dose than the first.

Studies comparing MMRV to MMR and VAR administered concomitantly showed more systemic adverse events following MMRV (fever 21.5% vs 14.9% and measles-like rash 3% vs 2.1% respectively). The combination vaccine, when given as a second dose following MMR, showed significantly greater proportions of subjects with local site reactions.

Transmission of vaccine virus from healthy patients to healthy recipients is very rare, has never occurred in the absence of a rash in the index case, and has only resulted in mild disease. One case involved transmission from a vaccinee to a susceptible pregnant female. The pregnancy was terminated, but polymerase chain reaction analysis of the fetus showed no evidence of VZV infection. Based on data from the VAERS, rates of serious adverse events following VAR are not increased compared with rates expected after natural infection or the background rates of similar events in the community. Herpes zoster infection has occurred in recipients of VAR in immunocompetent and immunocompromised persons within 25–722 days after immunization. Many of these cases were due to presumably unappreciated latent wild-type virus. Furthermore, based on preliminary data, the age-specific risk of herpes zoster infection seems to be lower in immunocompetent children following VAR immunization than after natural infection.

► Antibody Preparations

Varicella-zoster immune globulin (VZIG) is prepared from plasma harvested from persons known to have high titers of anti-VZV antibody. It has been reliably used in high-risk susceptible persons who are exposed to VZV, such as immunocompromised individuals without a history of chickenpox, susceptible pregnant women, newborns whose mothers develop varicella 5 days prior to delivery or within 48 hours

after delivery, hospitalized premature infants of 28 weeks' or more gestation (whose mother lacks a history of chickenpox or is seronegative), and hospitalized premature infants less than 28 weeks' gestation (regardless of maternal history or serostatus). Exposure is defined as a household contact or playmate contact (> 1 hour per day), hospital contact (in the same or contiguous room or ward), intimate contact with a person with zoster deemed contagious, or a newborn contact. Susceptibility is defined as the absence of a reliable history of varicella in persons born after 1966. Uncertainty in this diagnosis can be resolved with an appropriate test for anti-VZV antibody. VZIG should be given as soon as possible after exposure, and should be administered within 96 hours. Newborns should be given one vial (125 U) intramuscularly. The dose for all others is 125 U/10 kg body weight intramuscularly (maximum dose, 625 U). VZIG should be readministered following reexposure of susceptible persons if more than 3 weeks has elapsed since a prior dose of VZIG.

The availability of VZIG is limited as the sole U.S. manufacturer has stopped production. A Canadian preparation (Vari Zig, Cangene Corporation) is available under an Investigational New Drug application Expanded Access Protocol and can be obtained from FFF Enterprises, Temecula, CA (1-800-843-7477). If VZIG is not available, it is recommended that intravenous Ig be used in its place. The dose is 400 mg/kg administered once. A subsequent exposure does not require additional prophylaxis if this occurs within 3 weeks of intravenous Ig administration.

HEPATITIS A VACCINATION

The incidence of hepatitis A in the United States has decreased dramatically in recent years. In 2003, annual

reported hepatitis A cases had declined by 76% compared with annual cases during 1990–1997, and the 2003 rate was the lowest recorded in the 40 years since surveillance began. While hepatitis A rates naturally fluctuate in multiyear cycles, a novel vaccination strategy appears to be significantly contributing to declining hepatitis A rates.

HepA vaccines first became available in the United States in 1995. The following year, the ACIP recommended hepatitis A vaccination of certain high-risk groups, such as travelers, users of illegal drugs, and men who have sex with men. However, most hepatitis A infections occur in individuals without known risk factors for the disease. More than 50% of all infections are thought to occur in children. Children are more likely than adults to be asymptomatic while infected, and are often the mechanism by which hepatitis A is spread through households and communities.

In recognition of these epidemiologic features of hepatitis A, the ACIP in 1999 recommended vaccination for all children 24 months and older living in 11 states with more than twice the national average of hepatitis A cases, and vaccination was encouraged in an additional 6 states with disease rates exceeding (but less than twice) the national average. Despite only modest immunization coverage levels among children in targeted states, hepatitis A incidence rates have declined in both children and adults, suggesting that herd immunity had been achieved in many regions. The most recent recommendation to further reduce hepatitis A incidence in the United States is the routine administration of hepatitis A vaccine (HepA) to all children 12–23 months of age.

In addition HepA vaccination is indicated for the following groups: (1) travelers to countries with high rates of hepatitis A, (2) children with chronic hepatitis B or hepatitis C infections or other chronic liver disease, (3) children with clotting factor disorders, (4) adolescent and adult males who have sex with men, (5) persons with an occupational exposure to hepatitis A, and (6) illegal drug users.

HepA vaccines are considered very safe; tens of millions of doses have been administered, and no serious adverse events have definitively been caused by the vaccine. Vaccine efficacy is 94–100% against clinical hepatitis A.

► Vaccines Available

Two inactivated HepA vaccines are currently available for children: Havrix (GlaxoSmithKline) and Vaqta (Merck). Havrix contains a preservative (2-phenoxyethanol), but Vaqta does not. Both vaccines are approved for children 12 months and older. A combination vaccine against hepatitis A and hepatitis B (Twinrix, GlaxoSmithKline) is also available, but is only licensed in the United States for persons 18 years and older.

► Dosage & Schedule of Administration

Havrix is available in two formulations. For individuals between the ages of 1 and 18 years, 720 ELU (enzyme-linked immunosorbent assay [ELISA] units) per dose is administered

intramuscularly in two doses of 0.5 mL, separated by 6–12 months. For persons older than 18 years, a higher dose (1440 ELU per dose) is recommended, also in two doses of 1 mL.

Vaqua also has two formulations. For persons aged 1–18 years, two doses of 25 U per dose (0.5 mL) are given, separated by 6–18 months. Individuals older than 17 years are given 50 U per dose (1.0 mL) in a two-dose schedule.

Both vaccines should be shipped and stored at 2–8°C and should not be frozen. HepA vaccines are given intramuscularly, and may be given simultaneously with other vaccines, including HepB.

▶ Contraindications & Precautions

HepA should not be given to anyone with a prior severe allergic reaction such as anaphylaxis after a previous vaccine dose or to a vaccine component. Precautions to vaccination include pregnancy and moderate or severe acute illness with or without fever. The vaccine should not be administered to children with hypersensitivity to 2-phenoxyethanol (in the case of Havrix) or alum (for both preparations).

▶ Adverse Effects

Adverse reactions are uncommon and mild consisting of pain, swelling, and induration at the injection site (10–15%), headache, and loss of appetite.

▶ Antibody Preparations

For children younger than age 12 months at increased risk of hepatitis A infection (eg, those traveling to endemic areas or those with clotting factor disorders), immunoglobulin (Ig) should be used as preexposure prophylaxis. The recommended dosages are 0.02 mL/kg in a single intramuscular dose if the duration of exposure is likely to be less than 3 months and 0.06 mL/kg if exposure is likely to be more than 3 months. For long-term prophylaxis of persons not eligible for vaccination, prophylactic doses can be repeated every 5 months.

Postexposure prophylaxis of persons who recently have been exposed to hepatitis A and who previously have not received HepA vaccine should be administered a single dose of single-antigen vaccine or Ig (0.02 mL/kg) as soon as possible. If vaccine and Ig are given together they should be given simultaneously with Ig at a different anatomic injection site. When indicated, a single intramuscular dose of Ig (0.02 mL/kg) should be given as soon as possible, but not more than 2 weeks after the last exposure. Postexposure prophylaxis is recommended for household or sexual contacts of persons with serologically confirmed hepatitis A, and for day care staff and attendees in outbreak situations.

MENINGOCOCCAL VACCINATION

Building upon the technology used to develop conjugate *H influenzae* type b (Hib) and *S pneumoniae* vaccines, a tetravalent meningococcal polysaccharide-protein conjugate vaccine (MCV4) was licensed in 2005 and is indicated for use in persons 2–55 years of age. This vaccine, protecting against meningococcal serogroups A, C, Y, and W-135, is currently recommended for routine use in young adolescents (aged 11–12 years), those entering high school (at approximately 15 years of age), and college freshmen living in dormitories, as well as other groups at increased risk of meningococcal disease.

Infections with *Neisseria meningitidis* cause significant morbidity and mortality, with an estimated 1400–2800 cases of meningococcal disease occurring in the United States annually. Even with appropriate treatment, meningococcal disease has an estimated case-fatality rate of 10–14%, and up to 19% of survivors are left with serious disabilities, such as neurologic deficits, loss of limbs or limb function, or hearing loss. Five serogroups of meningococcus (A, B, C, W-135, and Y) cause the vast majority of disease worldwide. Serogroups B, C, and Y are the predominant causes of invasive meningococcal disease in the United States, while serogroups A and C cause most disease in developing countries. Intensive research efforts have been made to develop an effective vaccine against serogroup B, which causes more than 50% of cases among children younger than 1 year of age. However, the bacterial capsule proteins of serogroup B are poorly immunogenic in humans, presenting a significant obstacle to vaccine development.

It is important to highlight the characteristics of the new MCV4 vaccine compared with the only other meningococcal vaccine available in the United States, a tetravalent meningococcal polysaccharide vaccine (MPSV4), which was licensed in 1981. Both MCV4 and MPSV4 protect against the same four strains of meningococcus, and both are safe and immunogenic. MCV4 is licensed for use in persons 2–55 years old, while MPSV4 is licensed for persons 2 years and older. The

bacterial polysaccharides used in MPSV4 produce B-cell immune stimulation but no T-cell response. Therefore, MPSV4 does not produce long-lasting immunity, nor does it produce an anamnestic response after a subsequent exposure to the same bacterial antigens. In the case of MCV4, bacterial polysaccharides are conjugated (linked) to a modified diphtheria toxoid, which leads to the stimulation of a T-cell-dependent immune response. MCV4 immunogenicity data, as well as the experience with Hib and pneumococcal conjugate vaccines, support the premise that MCV4 will produce longer-lasting immunity than MPSV4 and will produce an immune memory response, which does not occur with MPSV4.

Since the introduction of MCV4, 15 cases of Guillain-Barré syndrome have been reported in persons aged 11–19 years with onset within 6 weeks of MCV4 vaccination. Guillain-Barré syndrome is a rare illness, regardless of etiology; expected incidence rates for Guillain-Barré syndrome are not precisely known, and the available data cannot determine with certainty whether MCV4 increases the risk of Guillain-Barré syndrome. The CDC has recommended that the routine use of MCV4 continue, given the known morbidity and mortality caused by meningococcus and the insufficient evidence to date to conclude that MCV4 causes Guillain-Barré syndrome.

A single dose of MCV4 is recommended for young adolescents (aged 11–12 years) and for adolescents entering high school (approximately 15 years of age). Meningococcal vaccination is also recommended for certain groups at increased risk of invasive meningococcal disease, including (1) college freshmen living in dormitories, (2) persons living in or traveling to countries with endemic or hyperendemic meningococcal disease, (3) persons with complement deficiencies, (4) persons with functional or anatomic asplenia, (5) military recruits, and (6) microbiologists who work with *N meningitidis*. Whenever meningococcal vaccination is indicated, MCV4 is preferred for persons 2–55 years old, while MPSV4 should be used for persons older than 55 years. If MCV4 is not available, MPSV4 is an appropriate alternative for persons 2–55 years old.

▶ Vaccines Available

1. MCV4 (Menactra, Sanofi Pasteur). A single 0.5-mL dose contains 4 mcg each of capsular polysaccharide from serogroups A, C, Y, and W-135 conjugated to 48 mcg of diphtheria toxoid. Available in single-dose vials only.
2. MPSV4 (Menomune-A/C/Y/W-135, Sanofi Pasteur). Each dose consists of 50 mcg each of the four bacterial capsular polysaccharides. Available in single-dose and 10-dose vials.

▶ Dosage & Schedule of Administration

1. MCV4 is given as a single intramuscular dose of 0.5 mL.
2. MPSV4 is administered as a single subcutaneous dose of 0.5 mL.

MCV4 and MPSV4 can be given at the same time as other vaccines, at a different anatomic site. Protective antibody levels are typically achieved within 10 days of vaccination. Persons 2–55 years old who received MPSV4 more than 3–5 years previously, and who remain at increased risk of meningococcal disease, should be considered for an additional dose of MCV4 vaccination, although data are limited about the need and effectiveness of revaccination.

▶ Contraindications & Precautions

MCV4 and MPSV4 are contraindicated in anyone with a known severe allergic reaction to any component of the vaccine, including diphtheria toxoid (for MCV4) and rubber latex. MCV4 vaccination is contraindicated in someone with a prior history of Guillain-Barré syndrome. Both MCV4 and MPSV4 can be given to individuals who are immunosuppressed. MPSV4 is thought to be safe during pregnancy; no information is available regarding the safety of MCV4 during pregnancy.

▶ Adverse Effects

Both MCV4 and MPSV4 are generally well tolerated in adolescent patients. Local vaccination reactions (redness, swelling, or induration) occurred in 11–16% of persons 11–18 years old receiving MCV4 and 4–6% of persons the same age receiving MPSV4. The most common solicited complaints among children aged 2–10 years were injection site pain and irritability. More severe systemic reactions (presence of any of the following: fever of 39.5°C or above; headache, fatigue, malaise, chills, or arthralgias requiring bed rest; anorexia; multiple episodes of vomiting or diarrhea; rash; or seizures) occurred in 4.3% of MCV4 recipients and 2.6% of MPSV4 recipients.

▶ Postexposure Prophylaxis

Close contacts of a patient with invasive meningococcal disease should receive antimicrobial prophylaxis to prevent the spread of disease. Because the rate of disease among close contacts is highest immediately after exposure, postexposure prophylaxis should be started as soon as possible, ideally within 24 hours of exposure. Close contacts are defined as (1) household members, (2) day care center contacts, and (3) anyone encountering an infected patient's secretions, such as through kissing, mouth-to-mouth resuscitation, or endotracheal intubation. Rifampin or ceftriaxone are used for chemoprophylaxis in children; rifampin, ceftriaxone, or ciprofloxacin may be used for adults.

TETANUS-DIPHTHERIA-ACELLULAR PERTUSSIS VACCINATION (ADOLESCENTS & ADULTS)

Pertussis is increasingly recognized as a disease affecting older children and adults, including fully vaccinated persons with waning immunity. In the United States, the most dramatic increases in pertussis incidence are among adolescents and young adults, prompting development of booster pertussis vaccines for this population. FDA approval in 2005 of the tetanus-diphtheria-acellular pertussis (Tdap) vaccine was based on comparable seroresponse to pertussis antigens and a safety profile similar to control Td. Adolescent and young adult immunization not only has the capacity to protect adolescents from pertussis, but also should limit spread of pertussis from adults to infants and decrease overall pertussis endemicity.

► Vaccines Available

1. Tdap (Boostrix, GlaxoSmithKline) contains tetanus toxoid, diphtheria toxoid, and three acellular pertussis antigens (detoxified pertussis toxin [PT], filamentous hemagglutinin (FHA), and pertactin) and is licensed for use in adolescents aged 10–18 years.
2. Tdap (Adacel, Sanofi Pasteur) contains tetanus toxoid, diphtheria toxoid, and five acellular pertussis antigens (PT, FHA, pertactin, and fimbriae types 2 and 3) and is licensed for use in persons aged 11–64 years.

► Dosage & Schedule of Administration

Adolescents 11–18 years of age should receive a single 0.5-mL dose of Tdap intramuscularly in the deltoid, instead of the tetanus and diphtheria toxoids (Td) vaccine for booster immunization. The preferred age for Tdap immunization is 11–12 years. An interval of at least 5 years between last Td vaccine and Tdap is suggested in order to reduce the risk of local and systemic reactions. Tdap and MCV4 should be administered during the same visit if both vaccines are indicated. If not administered at the same time, a minimum interval of 1 month between vaccines is suggested.

► Contraindications & Precautions

Contraindications to Tdap include severe allergic reaction to any vaccine component and encephalopathy (eg, coma, pro-

longed seizures) not attributable to an identifiable cause within 7 days of administration of a vaccine with pertussis components. Precautions for Tdap administration include Guillain-Barré syndrome occurring within 6 weeks of a previous dose of a tetanus toxoid-containing vaccine, a progressive neurologic disorder, uncontrolled epilepsy, or progressive encephalopathy until the condition has stabilized. Tdap vaccination should be deferred for at least 10 years if there is a history of a severe Arthus reaction after a tetanus toxoid-containing or diphtheria toxoid-containing vaccine.

► Adverse Effects

Pain at the injection site was the most frequently reported local adverse event among adolescents. Headache and fatigue were the most frequently reported systemic adverse events.

HUMAN PAPILLOMAVIRUS VACCINATION

Genital human papillomavirus (HPV) is the most common sexually transmitted infection in the United States. Most of the estimated 6.2 million persons newly infected every year have no symptoms. Over 40% of the 100 HPV types identified can infect the genital area. Approximately 70% of cervical cancers are caused by the high cancer risk types 16 and 18. Over 90% of genital warts are caused by low cancer risk types 6 and 11.

In June 2006, the quadrivalent HPV vaccine types 6, 11, 16, 18 (Gardasil, Merck) was licensed for use in females aged 9–26 years for the prevention of vaccine HPV-type-related cervical cancer, cervical cancer precursors, vaginal and vulvar cancer precursors, and anogenital warts. Routine vaccination of females aged 11–12 years is recommended, although the vaccine series can be started as young as age 9 years. Catch-up vaccination for females aged 13–26 years who were not previously vaccinated or have not completed

the full vaccine series should ideally be administered before potential exposure to HPV through sexual contact. However, females who might have been exposed to HPV or who have an equivocal or abnormal Pap test, a positive hybrid capture II high-risk test, or genital warts can receive and are likely to benefit from the quadrivalent HPV vaccine.

► Vaccine Available

Quadrivalent HPV vaccine (Gardasil, Merck) inactivated vaccine; a 0.5-mL dose contains 20 mcg HPV-6 L1 protein, 40 mcg HPV-11 L1 protein, 40 mcg HPV-16 L1 protein, and 20 mcg HPV-18 L1 protein. The vaccine does not contain thimerosal or antibiotics, but contains an aluminum-containing adjuvant.

► Dosage & Schedule of Administration

HPV vaccine is administered intramuscularly as three separate 0.5-mL doses. The second dose should be administered 2 months after the first dose and the third dose 6 months after the first dose. The minimum interval between the first and second dose is 4 weeks; the minimum recommended interval between the second and third doses of vaccine is 12 weeks. HPV vaccine may be administered with other vaccines. Each vaccine should be administered using a separate syringe at a different anatomic site. If the vaccine schedule is interrupted the series does not need to be restarted.

► Contraindications & Precautions

Quadrivalent HPV vaccine is contraindicated in persons with a history of anaphylaxis to yeast or to any vaccine component. HPV vaccine is not recommended for use in pregnancy. The vaccine can be administered to persons with minor acute illnesses and to immunocompromised persons.

► Adverse Effects

Injection site pain (83.9%), and mild to moderate swelling and erythema, were the most common adverse events reported by vaccine recipients. Fever (10.3%), nausea (4.2%), and dizziness (2.8%) were reported as systemic adverse events. Postmarketing reports of syncope have been reported after vaccination with quadrivalent HPV vaccine and may follow any vaccination, so vaccine recipients should be observed for 15 minutes after vaccination.

VACCINATIONS FOR SPECIAL SITUATIONS

RABIES VACCINATION

After symptoms of infection develop, rabies is almost invariably fatal in humans. Only six persons are known to have recovered from rabies infection, five of whom had either been vaccinated prior to infection or received some form of postexposure prophylaxis. The incidence of human rabies in the United States is very low, with fewer than three cases per year nationwide. Of the 37 human cases of rabies reported in the United States from 1995–2006, bat exposure was suspected in 28 cases. However, there was a definite history of bite in only one or two of these cases. Although dogs represent the most important vector for human rabies worldwide, in the United States, because of widespread vaccination of dogs and cats, bats are the most important cause of human rabies. Rabies is also common in skunks, raccoons, and foxes; it is uncommon in rodents.

Human rabies is preventable with appropriate and timely postexposure prophylaxis. Postexposure care consists of local wound care, passive immunization, and active immunization. Immediately after an animal bite, all wounds should be flushed and aggressively cleaned with soap and water. If possible, the wound should not be sutured. Passive immunization after high-risk exposure consists of the injection of human rabies immune globulin (RIG) near the wound, as described below. Active immunization is accomplished by completing a schedule of immunization with one of the three rabies vaccines licensed in the United States. Because bites from bats are often unrecognized, prophylaxis should be given if a bat is found indoors even if there is no history of contact, especially if found in the same room with a sleeping or unattended child or with an intoxicated or otherwise incapacitated individual.

Local public health officials should be consulted before postexposure rabies prophylaxis is started to avoid unnecessary vaccination and to assist in the proper handling of the animal (if confinement or testing of the animal is appropriate). To facilitate consultation, the physician should know the species of animal, its availability for testing or confinement, the nature of the attack (provoked or unprovoked), and the nature of the exposure (bite, scratch, lick, or aerosol of saliva). Preexposure prophylaxis is indicated for veterinarians, animal handlers, and any persons whose work or home environment potentially places them in close contact with animal species in which rabies is endemic. Rabies immunization should also be considered for children traveling to countries where rabies is endemic; this is particularly important for travelers who will not have prompt access to medical care should an exposure occur.

► Vaccines Available

Rabies vaccines stimulate immunity after 7–10 days, and the immunity persists for 2 years or more postvaccination. Two preparations are licensed in the United States.

1. Imovax Rabies (Sanofi Pasteur) human diploid cell vaccine (HDCV).
2. RabAvert (Chiron) purified chick embryo cell vaccine (PCEC).

► Dosage & Schedule of Administration

The two rabies vaccines licensed in the United States are equally safe and efficacious for both preexposure and postexposure prophylaxis. For each vaccine, 1 mL is given intramuscularly in the deltoid (for adults and older children) or anterolateral thigh (for infants and young children). The volume of the dose is not reduced for children. Vaccine should not be given in the gluteal region.

A. Primary Preexposure Vaccination

Preexposure rabies immunization should be considered for individuals at high risk of exposure to rabies (eg, veterinarians, animal handlers, spelunkers, and people moving to or extensively traveling in areas with endemic rabies). Three intramuscular injections in the deltoid area of 1 mL of any vaccine are given on days 0, 7, and 21 or 28.

B. Postexposure Prophylaxis

After an individual has possibly been exposed to rabies, decisions about whether to initiate postexposure prophylaxis need to be made urgently, in consultation with local public health officials.

1. In previously unvaccinated individuals—After proper wound care has been provided, an individual exposed to rabies should receive rabies vaccination and RIg. Vaccination is given on the day of exposure and on days 3, 7, 14, and 28 following exposure. RIg should also be given as soon as possible after exposure, ideally on the day of exposure, in a recommended dose of 20 IU/kg. If anatomically possible, the entire dose of RIg should be infiltrated into and around the wound. Any remaining RIg should be administered intramuscularly at an anatomic site distant from the location used for rabies vaccination. If RIg was not administered when vaccination was begun, it can be administered up to 7 days after the first dose of vaccine. Postexposure failures have occurred only when some deviation from the approved protocol occurred (eg, no cleansing of the wound, less than usual amount of RIg, no RIg at the wound site, or vaccination in the gluteal area).

2. In previously vaccinated individuals—RIg should not be administered, and only two doses of vaccine on days 0 and 3 after exposure are needed.

C. Booster Vaccination

Previously vaccinated individuals with potential continued exposure to rabies should have a serum sample tested for rabies antibody every 2 years. If the titer is less than 1:5 for virus neutralization, a booster dose of rabies vaccine should be administered.

► Adverse Effects

The rabies vaccines are relatively free of serious reactions. Approximately 30–74% of adults experience pain, swelling, induration, or erythema at the injection site; 5–25% may have mild systemic reactions such as headache, nausea, muscle aches, and dizziness. An immune complex–like reaction occurs in about 6% of persons 2–21 days after receiving booster doses of the rabies vaccine.

Travelers to countries where rabies is endemic may need immediate postexposure prophylaxis and may have to use locally available vaccines and RIg. In many developing countries, the only vaccines readily available may be nerve tissue vaccines derived from the brains of adult animals or suckling mice, and the RIg may be of equine origin. Although adverse reactions to RIg are uncommon and typically mild, the nervous tissue vaccines may induce neuroparalytic reactions in 1:200–1:8000 vaccinees; this is a significant risk and may justify preexposure vaccination prior to travel in circumstances in which exposure to potentially rabid animals is likely.

► Antibody Preparations

In the United States, RIg is prepared from the plasma of human volunteers hyperimmunized with rabies vaccine. The recommended dose is 20 IU/kg body weight. The rabies-neutralizing antibody content is 150 IU/mL, supplied in 2-mL or 10-mL vials. It is very safe.

Dobardzic A et al: Safety review of the purified chick embryo cell rabies vaccine: Data from the Vaccine Adverse Event Reporting System (VAERS), 1997–2005. *Vaccine* 2007;25:4244 [PMID: 17382435].

CDC: Rabies information page: <http://www.cdc.gov/rabies/>.

TYPHOID FEVER VACCINATION

Globally, the burden of typhoid fever is substantial, causing an estimated 22 million illnesses and 200,000 deaths each year. In the United States, typhoid fever is relatively uncommon, with approximately 150–300 laboratory-confirmed cases each year, the majority acquired abroad. In a review of typhoid fever cases reported to the CDC, 74% of patients reported recent travel outside the United States, only 4% of whom had received typhoid vaccination in the preceding 5 years. Approximately 40% of cases were seen in patients younger than 18 years, and both short-term and long-term travel was associated with infection.

Two vaccines against *Salmonella enterica typhi*, the bacterium that causes typhoid fever, are currently available in the United States: a live attenuated vaccine given orally (Ty21a), and an inactivated vaccine composed of purified capsular polysaccharide (ViCPS) given parenterally. Both vaccines

protect 50–80% of vaccine recipients. The oral vaccine is most commonly used because of its ease of administration. However, noncompliance with the oral vaccine dosing schedule occurs frequently, and correct usage should be stressed or the parenteral ViCPS vaccine used.

Routine typhoid vaccination is recommended only for children who are traveling to typhoid-endemic areas or who reside in households with a documented typhoid carrier. While current CDC recommendations emphasize typhoid vaccination for travelers expected to have long-term exposure to potentially contaminated food and drink, vaccination should also be considered for short-term travel to high-risk countries. Although typhoid fever occurs throughout the world, areas of highest incidence include southern Asia and southern Africa. Travelers should be advised that because the typhoid vaccines are not fully protective, and because of the potential for other food- and water-borne illnesses, careful selection of food and drink and appropriate hygiene remain necessary when traveling internationally.

► Vaccines Available

1. Parenteral ViCPS (Typhim Vi, Sanofi Pasteur) is for intramuscular use.
2. Oral live attenuated Ty21a vaccine (Vivotif Berna Vaccine, Swiss Serum and Vaccine Institute) is supplied as enteric-coated capsules.

► Dosage & Schedule of Administration

ViCPS is administered as a single intramuscular dose (0.5 mL) in the deltoid muscle, with boosters needed every 3 years if exposure continues. It is approved for children aged 2 years and older.

The dose of the oral preparation is one capsule every 2 days for a total of four capsules, taken 1 hour before meals. The capsules should be taken with cool liquids and should be kept refrigerated. All doses should be administered at least 1 week prior to potential exposure. A full course of four capsules is recommended every 5 years if exposure continues. Mefloquine and proguanil may decrease the effect of the live vaccine, and the vaccine should be given at least 1 day or 10 days after a dose of mefloquine or proguanil, respectively. This vaccine is not approved for children younger than age 6 years. As with all live attenuated vaccines, Ty21a should not be given to immunocompromised patients.

► Adverse Reactions

Both the oral and parenteral vaccines are well tolerated, and adverse reactions are uncommon and usually self-limited. The oral vaccine may cause gastroenteritis-like illness, fatigue, and myalgia, whereas the parenteral vaccine may cause local and abdominal pain, dizziness, and pruritus.

Fraser A et al: Vaccines for preventing typhoid fever. *Cochrane Database Syst Rev* 2007;CD001261 [PMID: 17636661].

CHOLERA VACCINATION

Cholera causes significant morbidity and mortality worldwide. It may present only as traveler's diarrhea. For travelers, the risk of developing cholera per month of stay in a developing country is low, ranging from 0.001% to approximately 0.01%. No cholera vaccines are available in the United States. Because the causative bacterium, *Vibrio cholerae*, is not invasive, and because secretory IgA is crucial, newer vaccines available in other countries are administered orally. An oral vaccine (consisting of live attenuated bacteria combined with the B subunit of cholera toxin *wc/vBS*, Dukoral, SBL Vaccine AB, Stockholm, Sweden) is safe and immunogenic. It is given as two doses 1 week apart, has an 85% vaccine efficacy against *V cholerae* in the first 6 months and greater than 50% cross-protection against enterotoxigenic *Escherichia coli* diarrhea. Cholera vaccination is no longer required for international travel or for entry into any country.

Hill DR et al: Oral cholera vaccines: Use in clinical practice. *Lancet Infect Dis* 2006;361 [PMID: 16728322].

Zuckerman JN et al: The true burden and risk of cholera: Implications for prevention and control. *Lancet Infect Dis* 2007;7:521 [PMID: 1758453].

TUBERCULOSIS VACCINATION

During 1993–2003 the incidence of tuberculosis (TB) in the United States decreased by 44%, setting the stage for possible elimination of the disease. However, nearly 40% of new cases of TB occur in persons born in other countries. Bacille Calmette-Guérin vaccine (BCG) consists of live attenuated *Mycobacterium bovis*. BCG is not currently indicated for mass use in the United States, chiefly because of doubts about its efficacy. BCG is the most widely used vaccine in the world and has been administered to over 3 billion people (71% of infants worldwide are vaccinated) with a low incidence of serious complications. It is inexpensive, can be given any time after birth, sensitizes the vaccinated individual for 5–50 years, and stimulates both B-cell and T-cell immune responses. BCG is useful in two circumstances in the United States: (1) in tuberculin-negative infants or older children residing in households with untreated or poorly treated individuals with active infection with isoniazid- and rifampin-resistant *Mycobacterium tuberculosis*, and (2) in infants or children found to live under constant exposure without the possibility of removal from continuous exposure or access to prophylaxis and treatment. BCG reduces the risk of tuberculous meningitis and disseminated TB in pediatric populations by 50–100% when administered in the first month of life. BCG appears to have had little epidemiologic effect on TB, despite a reported efficacy of 50% in a meta-analysis of 26 vaccine trials, with the greatest protection against pulmonary disease.

The two currently licensed BCG vaccines in the United States are produced by Organon Teknika Corporation (Tice BCG) and Eli Lilly (BCG Vaccine). They are given intradermally in a dose of 0.05 mL for newborns and 0.1 mL for all other children. Mantoux testing is advised 2–3 months later, and revaccination is advised if the Mantoux test is negative. Adverse effects occur in 1–10% of healthy individuals, including local ulceration, regional lymph node enlargement, and lupus vulgaris. The vaccine is contraindicated in pregnant women and in immunocompromised individuals, including those with HIV infection, because it has caused disseminated or fatal infection.

Factors associated with increased probability that a positive TB skin test is due to *M tuberculosis* infection include (1) larger reactions, (2) contact with an individual known to be infected, (3) family history of TB, (4) longer interval between BCG administration and skin testing, and (5) country of origin with increased incidence of endemic TB. The details and cutoff observations for TB skin testing are described in Chapter 40. To ensure that those infected with TB are evaluated, a 5-mm or greater cutoff for a positive Mantoux test is used in immunocompromised children. In immunocompetent persons, the cutoff is 10 mm or above, whereas it is 15 mm or above when no risk factors are present in the absence of clinical disease (eg, screening). In 2001 a new test (Quantiferon TB) that measures the release of interferon- γ in whole blood in response to stimulation with purified protein derivative was approved by the FDA. This test is not recommended for persons with symptoms of active TB who are at increased risk of progression to active TB, but may be used instead of a TB skin test in those at increased or low risk of latent TB infection, including as screening for recent immigrants.

BCG almost invariably causes its recipients to be tuberculin-positive (5–7 mm), but the reaction often becomes negative after 3–5 years. Thus, a positive Mantoux test in a child with a history of BCG vaccination who is being investigated for TB as a case contact should be interpreted as indicating infection with *M tuberculosis*.

YELLOW FEVER VACCINATION

Immunization against yellow fever is indicated for children as young as age 6 months traveling to endemic areas or to countries that require it for entry, but otherwise immunization should be delayed until age 9 months or older. Public health authorities maintain updated information on these requirements and must be consulted. Yellow fever vaccine is a live vaccine made from the 17D yellow fever attenuated virus strain grown in chick embryos. It is contraindicated in infants younger than age 6 months due to an increased susceptibility to vaccine-associated encephalitis, in persons with anaphylactic egg allergy, and in immunocompromised individuals or individuals with a history of thymus disease. It can only be administered at licensed yellow fever vaccination locations (usually public health departments). A single subcutaneous injection of 0.5 mL of reconstituted vaccine is administered. The International Health Regulations require revaccination at 10-year intervals, but immunity may be lifelong. Adverse reactions are generally mild—consisting of low-grade fever, mild headache, and myalgia 5–10 days after vaccination occurring in fewer than 25% of vaccinees. The risk of vaccine-associated neurotropic disease within 30 days following vaccination has been estimated to be 4–6 cases per 1 million doses. A serious adverse reaction syndrome, vaccine-associated viscerotropic disease, consists of severe multiple organ system failure and death within 1–2 weeks post-vaccination, especially in adults older than 60 years of age. The estimated incidence of this complication among vaccine recipients in the United States is 1 case per 200,000–300,000 doses distributed. Health care providers should be careful to administer yellow fever vaccine only to persons truly at risk of exposure to yellow fever. There is no contraindication to giving other live-virus vaccines simultaneously with yellow fever vaccine or at intervals of a few days to a month.

PASSIVE PROPHYLAXIS

1. Intramuscular Immune Globulin

Ig may prevent or modify infection with hepatitis A virus if administered in a dose of 0.02 mL/kg within 14 days after exposure. Measles infection may be prevented or modified in a susceptible person if Ig is given in a dose of 0.25 mL/kg within 6 days after exposure. Special forms of Ig include tetanus Ig (TIg), hepatitis B Ig (HBIG), rabies Ig (RIg), vaccinia Ig, and

varicella-zoster Ig (VZIg). These are obtained from donors known to have high titers of antibody against the organism in question. Ig must be given intramuscularly. The dose varies depending on the clinical indication. Adverse reactions include pain at the injection site, headache, chills, dyspnea, nausea, and anaphylaxis, although all but the first are rare.

Prophylaxis to prevent respiratory syncytial virus (RSV) in infants and children at increased risk of severe disease is available as an intramuscular immune globulin. Palivizumab (Synagis, MedImmune) is a humanized monoclonal antibody against RSV and is used to prevent RSV infection in high-risk populations with monthly doses during RSV season. Palivizumab should be considered for (1) infants and children younger than age 2 years with chronic lung disease who have required medical therapy (supplemental oxygen, bronchodilator, diuretic, or corticosteroid therapy) for their disease within 6 months before the anticipated RSV season; (2) infants born between 33 and 35 weeks' (32 weeks 1 day and 35 weeks 0 days) gestation or earlier without chronic lung disease with two or more risk factors (child care attendance, school-aged siblings, exposure to environmental air pollution, congenital airway abnormalities, or severe neuromuscular disease) up to age 6 months; (3) infants born at 29–32 weeks' gestation up to 6 months of age; (4) infants up to age 12 months born at 28 weeks' gestation or earlier; and (5) infants and children who are 24 months old or younger with hemodynamically significant cyanotic or acyanotic congenital heart disease. Those most likely to benefit from prophylaxis are infants (< 1 year of age) who are receiving medication to control congestive heart disease, with moderate to severe pulmonary hypertension and cy-

notic heart disease. RSV prophylaxis should be initiated at the onset of the RSV season and continued until the end of the season, regardless of breakthrough RSV illness during that RSV season.

Palivizumab is administered in a dose of 15 mg/kg once a month and is packaged in 50- and 100-mg vials. Palivizumab does not interfere with response to routine childhood vaccinations.

2. Intravenous Immune Globulin

The primary indications for IVIg are for replacement therapy in antibody-deficient individuals; for the treatment of Kawasaki disease, idiopathic thrombocytopenic purpura, Guillain-Barré syndrome, and other autoimmune diseases; and replacement therapy in chronic B-cell lymphocytic leukemia. IVIg may be beneficial in some children with HIV infection, toxic shock syndrome, and for anemia caused by parvovirus B19.

NUTRITIONAL REQUIREMENTS

NUTRITION & GROWTH

The nutrient requirements of children are influenced by (1) growth rate, (2) body composition, and (3) composition of new growth. These factors vary with age and are especially important during early postnatal life. Growth rates are higher in early infancy than at any other time, including the adolescent growth spurt (Table 10–1). Growth rates decline rapidly starting in the second month of postnatal life (proportionately later in the premature infant). Nutrient requirements also depend on body composition. In the adult, the brain, which accounts for only 2% of body weight, contributes 19% to the total basal energy expenditure. In contrast, in a full-term neonate, the brain accounts for 10% of body weight and for 44% of total energy needs under basal conditions. Thus, in the young infant, total basal energy expenditure and the energy requirement of the brain are relatively high.

Composition of new tissue is another factor influencing nutrient requirements. For example, fat accounts for about 40% of weight gain between birth and 4 months but for only 3% between 24 and 36 months. The corresponding figures for protein are 11% and 21%; for water, 45% and 68%. The high rate of fat deposition in early infancy has implications not only for energy requirements but also for the optimal composition of infant feedings. The high percentage of fat in human milk results in efficient fuel storage for the infant.

Because of the high nutrient requirements for growth and the body composition, the young infant is especially vulnerable to undernutrition. Slowed physical growth rate is an early and prominent sign of undernutrition in the young infant. The limited fat stores of the very young infant mean that energy reserves are unusually modest. The relatively large size and continued growth of the brain render the central nervous system especially vulnerable to the effects of malnutrition in early postnatal life.

ENERGY

The major determinants of energy expenditure are (1) basal metabolism, (2) metabolic response to food, (3) physical activity, and (4) growth. The efficiency of energy use may be a significant factor, and thermoregulation may contribute in extremes of ambient temperature if the body is inadequately clothed. Because adequate data on requirements for physical activity in infants and children are unavailable and because individual growth requirements vary, recommendations have been based on calculations of actual intakes by healthy subjects. Suggested guidelines for energy intake of infants and young children are given in Table 10–2. Also included in this table are calculated energy intakes of infants who are exclusively breast fed, which have been verified in a number of centers. Growth velocity of breast-fed infants during the first 3 months equals and may exceed that of formula-fed infants, but from 6–12 months breast-fed infants typically weigh less than formula-fed infants and may show a decrease in growth velocity. The World Health Organization (WHO) has developed growth standards derived from an international sample of healthy breast-fed infants and young children raised in environments that do not constrain growth.

After the first 4 years, energy requirements expressed on a body weight basis decline progressively. The estimated daily energy requirement is about 40 kcal/kg/d at the end of adolescence. Approximate daily energy requirements can be calculated by adding 100 kcal per year to the base of 1000 kcal per day at age 1 year. Appetite and growth are reliable indices of caloric needs in most healthy children, but intake also depends to some extent on the energy density of the food offered. Individual energy requirements of healthy infants and children vary considerably, and malnutrition and disease increase the variability. Premature infant energy requirements can exceed 120 kcal/kg/d, especially during illness or when catch-up growth is desired.

One method of calculating requirements for malnourished patients is to base the calculations on the “ideal body weight” (ie, 50th percentile weight for the patient’s length-

Table 10-1. Changes in growth rate, energy required for growth, and body composition in infants and young children.

Age (months)	Growth Rate (g/d)			Energy Requirements for Growth (kcal/kg/d)	Body Composition

PROTEIN

Only amino acids and ammonium compounds are usable as sources of nitrogen in humans. Amino acids are provided through the digestion of dietary protein. Nitrogen is absorbed from the intestine as amino acids and short peptides. Absorption of nitrogen is more efficient from synthetic diets that contain peptides in addition to amino acids. Some intact proteins are absorbed in early postnatal life, a process that may be important in the development of protein tolerance or allergy.

Because there are no major stores of body protein, a regular dietary supply of protein is essential. In infants and children, optimal growth depends on an adequate dietary protein supply. Relatively subtle effects of protein deficiency are now recognized, especially those affecting tissues with rapid protein turnover rates, such as the immune system and the gastrointestinal (GI) mucosa.

Relative to body weight, rates of protein synthesis and turnover and accretion of body protein are exceptionally high in the infant, especially the premature infant. Eighty percent of the dietary protein requirement of a premature infant is used for growth, compared with only 20% in a 1-year-old child. Protein requirements per unit of body weight decline rapidly during infancy as growth velocity decreases. The recommendations in

Table 10-2 are derived chiefly from the Joint FAO/WHO/UNO Expert Committee and are similar to the Recommended Dietary Allowances. They recommend a protein intake above the quantity provided in breast milk. The protein intake required to achieve protein deposition equivalent to the in utero rate in very low birth weight infants is 3.5-4.0 g/kg/d simultaneously with adequate energy intake. Protein requirements increase in the presence of skin or gut losses, burns, trauma, and infection. Requirements also increase during times of catch-up growth accompanying recovery from malnutrition (approximately 0.2 g of protein per gram of new tissue deposited). Young infants experiencing rapid recovery may need as much as 1-2 g/kg/d of extra protein. By age 1 year, the extra protein requirement is unlikely to be more than 0.5 g/kg/d. Inadequate protein intake may occur in breast-fed infants fed low-protein supplements (eg, fruit juices), in infants with malabsorption (cystic fibrosis), or in infants fed low-protein weaning food (eg, cassava or dilute cereal gruels) as the dietary staple.

The quality of protein depends on its amino acid composition. Infants require 43% of protein as essential amino acids, and children require 36%. Adults cannot synthesize eight essential amino acids: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. Histidine may be added to this list. Cysteine and tyrosine are considered partially essential because their rates of synthesis are limited and may be inadequate in certain circumstances. In young infants, synthetic rates for cysteine, tyrosine, and perhaps taurine are insufficient for needs. Taurine, an amino acid used to conjugate bile acids, may also be conditionally essential in infancy. Lack of an essential amino acid leads to weight loss within 1-2 weeks. Wheat and rice are deficient in lysine, and legumes are deficient in methionine. Appropriate mixtures of vegetable protein are therefore necessary to achieve high protein quality.

Table 10-2. Recommendations for energy and protein intake.

Age	Energy (kcal/kg/d)			Protein (g/kg/d)	
	Based on Measurements of Energy Expenditure	Intake from Human Milk	Guidelines for Average Requirements	Intake from Human Milk	Guidelines for Average Requirements
10 d to 1 mo	—	105	120	2.05	2.5
1-2 mo	110	110	115	1.75	2.25
2-3 mo	95	105	105	1.36	2.25
3-4 mo	95	75-85	95	1.20	2.0
4-6 mo	95	75-85	95	1.05	1.7
6-12 mo	85	70	90	—	1.5
1-2 y	85	—	90	—	1.2
2-3 y	85	—	90	—	1.1
3-5 y	—	—	90	—	1.1

Data reprinted, with permission, from Krebs NF et al: Growth and intakes of energy and zinc in infants fed human milk. *J Pediatr* 1994;124:32; and Garza C, Butte NF: Energy intakes of human milk-fed infants during the first year. *J Pediatr* 1990;117:(S)124.

Because the mechanisms for removal of excess nitrogen are efficient, moderate excesses of protein are not harmful and may help to ensure an adequate supply of certain micronutrients. Adverse effects of excessive protein intake may include increased calcium losses in urine and, over a life span, increased loss of renal mass. Excessive protein intake may also cause elevated blood urea nitrogen, acidosis, hyperammonemia, and, in the premature infant, failure to thrive, lethargy, and fever.

Thureen P, Heird WC: Protein and energy requirements of the preterm/low birth weight (LBW) infant. *Pediatr Res* 2005;57(5 Pt 2):95R [PMID: 15817496].

LIPIDS

Fats are the main dietary energy source for infants and account for up to 50% of the energy in human milk. Over 98% of breast milk fat is triglyceride, which has an energy density of 9 kcal/g. Fats can be stored efficiently in adipose tissue with a minimal energy cost of storage. This is especially important in the young infant. Fats are required for the absorption of fat-soluble vitamins and for myelination of the central nervous system. Fat also provides essential fatty acids (EFAs) necessary for brain development, for phospholipids in cell membranes, and for the synthesis of prostaglandins and leukotrienes. The EFAs are polyunsaturated fatty acids, linoleic acid (18:2 ω 6) and linolenic acid (18:3 ω 3). Arachidonic acid (ARA, 20:4 ω 6) is derived from dietary linoleic acid and is present primarily in membrane phospholipids. Important derivatives of linolenic acid are eicosapentaenoic acid (20:6 ω 3) and docosahexaenoic acid (DHA, 22:6 ω 3) found in human milk and brain lipids. Visual acuity and possibly psychomotor development of formula-fed premature infants is improved with use of formulas supplemented with DHA (22:6 ω 3) and ARA (20:4 ω 6). The benefits of supplementing long-chain fatty acids in healthy

formula-fed term infants remain unclear (although safety has been established).

Clinical features of EFA ω 6 deficiency include growth failure, erythematous and scaly dermatitis, capillary fragility, increased fragility of erythrocytes, thrombocytopenia, poor wound healing, and susceptibility to infection. The clinical features of deficiency of ω 3 fatty acids are less well defined, but dermatitis and neurologic abnormalities, including blurred vision, peripheral neuropathy, and weakness, have been reported. Fatty fish are the best dietary source of ω 3 fatty acids. A high intake of fatty fish is associated with decreased platelet adhesiveness and decreased inflammatory response.

Up to 5–10% of fatty acids in human milk are polyunsaturated, with the specific fatty acid profile reflective of maternal dietary intake. Most of these are 6 series with smaller amounts of long-chain ω 3 fatty acids. About 40% of breast milk fatty acids are monounsaturates, primarily oleic acid (18:1), and up to 10% of total fatty acids are medium-chain triglycerides (MCTs) (C_8 and C_{10}) with a calorie density of 7.6 kcal/g. In general, the percentage of calories derived from fat is a little lower in infant formulas than in human milk. Infant formulas have traditionally contained a relatively high percentage of linoleic acid but minimal long-chain ω 3 fatty acid.

The American Academy of Pediatrics (AAP) recommends that infants receive at least 30% of calories from fat, with at least 2.7% of total fat as linoleic acid, and 1.75% of total fatty acids as linolenic. It is appropriate that 40–50% of energy requirements be provided as fat during at least the first year of life. Children older than 2 years should be switched gradually to a diet containing approximately 30% of total calories from fat, with no more than 10% of calories either from saturated fats or polyunsaturated fats.

β -Oxidation of fatty acids occurs in the mitochondria of muscle and liver. Carnitine is necessary for oxidation of the

fatty acids, which must cross the mitochondrial membranes as acylcarnitine. Carnitine is synthesized in the human liver and kidney from lysine and methionine. Carnitine needs of infants are met by breast milk or infant formulas. In the liver, substantial quantities of fatty acids are converted to ketone bodies, which are then released into the circulation as an important fuel for the brain of the young infant.

MCTs are sufficiently soluble that micelle formation is not required for transport across the intestinal mucosa. They are transported directly to the liver via the portal circulation. MCTs are rapidly metabolized in the liver, undergoing β -oxidation or ketogenesis. They do not require carnitine to enter the mitochondria. Ketones are formed from MCTs even when provided orally. MCTs are useful for patients with luminal phase defects, absorptive defects, and chronic inflammatory bowel disease. The potential side effects of MCT administration include diarrhea when given in large quantities; high octanoic acid levels in patients with cirrhosis; and, if they are the only source of lipids, deficiency of EFA.

CARBOHYDRATES

The energy density of carbohydrate is 4 kcal/g. Approximately 40% of caloric intake in human milk is in the form of lactose, or milk sugar. Lactose supplies 20% of the total energy in cow's milk. The percent of total energy in infant formulas from carbohydrate is similar to that of human milk.

After the first 2 years of life, 50–60% of energy requirements should be derived from carbohydrates, with no more than 10% from simple sugars. These dietary guidelines are, unfortunately, not reflected in the diets of North American children, who typically derive 25% of their energy intake from sucrose and less than 20% from complex carbohydrates.

The rate at which lactase hydrolyzes lactose to glucose and galactose in the intestinal brush border determines how quickly milk carbohydrates are absorbed. Lactase levels are highest in young infants, and decline with age depending on genetic factors. About 20% of nonwhite Hispanic and black children younger than 5 years of age have lactase deficiency. White children typically do not develop symptoms of lactose intolerance until they are at least 4 or 5 years of age, whereas nonwhite Hispanic, Asian-American, and black children may develop these symptoms by 2 or 3 years of age. Lactose-intolerant children have varying symptoms depending on the specific activity of their intestinal lactase and the amount of lactose consumed. Galactose is preferentially converted to glycogen in the liver prior to conversion to glucose for subsequent oxidation. Infants with galactosemia, an inborn meta-

bolic disease caused by deficient galactose-1-phosphate uridylyl-transferase, require a lactose-free diet starting in the neonatal period.

Children and adolescents in North America consume large quantities of sucrose and high-fructose corn syrup in soft drinks and other sweetened beverages, candy, syrups, and sweetened breakfast cereals. Added sugar intake has been reported to average approximately 15% of total energy intake in adolescents, far exceeding recommended intakes. A high intake of these sugars, especially in the form of sweetened beverages, may predispose to obesity and insulin resistance, and is a major risk factor for dental caries. Sucrase hydrolyzes sucrose to glucose and fructose in the brush border of the small intestine. Fructose is absorbed more slowly than and independent of glucose by facilitated diffusion. Fructose does not stimulate insulin secretion or enhance leptin production. Since both insulin and leptin play a role in regulation of food intake, consumption of fructose (eg, as high-fructose corn syrup) may contribute to increased energy intake and weight gain. Fructose is also easily converted to hepatic triglycerides, which may be undesirable in malnourished patients or in patients with insulin resistance or metabolic syndrome and cardiovascular disease risk.

Dietary fiber can be classified as two major types: nondigested carbohydrate (β 1–4 linkages) and noncarbohydrate (lignin). Insoluble fibers (cellulose, hemicellulose, and lignin) increase stool bulk and water content and decrease gut transit time. They may impair mineral absorption. Soluble fibers (pectins, mucilages, oat bran) bind bile acids and reduce lipid and cholesterol absorption. Pectins also slow gastric emptying and the rate of nutrient absorption. Few data regarding the fiber needs of children are available. The Dietary Reference Intakes recommend 14 g of fiber per 1000 kcal consumed. The AAP recommends that children older than 2 years consume in grams per day an amount of fiber equal to 5 plus the age in years. Fiber intakes are often low in North America. Children who have higher dietary fiber intakes have been found to consume more nutrient-dense diets than children with low fiber intakes. In general, higher fiber diets are associated with lower risk of chronic diseases such as obesity, cardiovascular disease, and diabetes.

MAJOR MINERALS

Calcium, phosphorus, magnesium, sodium, and potassium are essential components of human nutrition. Dietary sources, absorption, metabolism, and deficiency of these minerals are summarized in Table 10-3. Recommended dietary intakes are provided in Table 10-4.

Table 10-3. Summary of major minerals.

Mineral	Absorption/Metabolism	Deficiency	
		Causes	Clinical Features
Calcium <i>Dietary sources:</i> dairy products, legumes, broccoli, green leafy vegetables.	20–30% from diet; 60% from human milk (HM). Enhanced by lactose, glucose, protein; impaired by phytate, fiber, oxalate, unabsorbed fat. Absorption is regulated by serum calcitriol, which increases when PTH is secreted in response to low plasma-ionized calcium. PTH also promotes release of calcium from bone. Renal excretion.	Can occur in premature infants without adequate supplementation and in lactating adolescents with limited calcium intake or in patients with steatorrhea.	Osteopenia or osteoporosis, tetany.
Phosphorus <i>Dietary sources:</i> meats, eggs, dairy products, grains, legumes, and nuts; high in processed foods and sodas.	80% from diet. PTH decreases tubular resorption of phosphorus in kidney; homeostasis is maintained by GI tract and kidneys.	Rare, but can occur in premature infants fed unfortified HM (results in osteoporosis and rickets, sometimes hypercalcemia). Also seen in patients with protein-energy malnutrition.	Muscle weakness, bone pain, rhabdomyolysis, osteomalacia, and respiratory insufficiency.
Magnesium <i>Dietary sources:</i> vegetables, cereals, nuts.	Kidney regulates homeostasis by decreasing excretion when intake is low.	Occurs as part of refeeding syndrome with protein-energy malnutrition. Renal disease, malabsorption, or magnesium wasting medications may lead to depletion. May cause secondary hypocalcemia.	Neuromuscular excitability, muscle fasciculation, neurologic abnormalities, ECG changes.
Sodium <i>Dietary sources:</i> processed foods, table salt.	Hyponatremic and hypernatremic dehydration are discussed in Chapter 43. Kidney is primary site of homeostatic regulation.	Results from excess losses associated with diarrhea and vomiting.	Anorexia, vomiting, hypotension and mental apathy. Severe malnutrition, stress, and hypermetabolism may lead to excess intracellular sodium, affecting cellular metabolism.
Chloride <i>Dietary sources:</i> table salt or sea salt, seaweed, many vegetables.	Homeostasis is closely linked to sodium. Plays an important role in physiologic mechanisms of kidney and gut.	Can occur in infants fed low chloride-containing diets, or in children with cystic fibrosis, vomiting, diarrhea, chronic diuretic therapy, or Bartter syndrome.	Associated with failure to thrive and especially poor head growth; anorexia, lethargy, muscle weakness, vomiting, dehydration, hypovolemia. <i>Laboratory findings:</i> may include hypochloremia, hypokalemia, metabolic alkalosis, hyperreninemia.
Potassium <i>Dietary sources:</i> nuts, whole grains, meats, fish, beans, fruits and vegetables, especially bananas, orange juice.	Kidneys control potassium homeostasis via the aldosterone-renin-angiotensin endocrine system. Amount of total body potassium depends on lean body mass.	Occurs in protein-energy malnutrition (eg, refeeding syndrome) and can cause cardiac failure and sudden death if not treated aggressively. With loss of lean body mass, excessive potassium is excreted in urine in any catabolic state. Can also occur during acidosis, from diarrhea, and from diuretic use. Hyperkalemia may result from renal insufficiency.	Muscle weakness, mental confusion, arrhythmias.

ECG, electrocardiogram; GI, gastrointestinal; PTH, parathyroid hormone.

Table 10-4. Recommended daily intake of select minerals.

Age	Calcium	Chloride	Copper	Iron	Magnesium	Potassium	Phosphorus	Selenium	Sodium	Zinc
0-6 mos	210 mg	180 mg*	200 mcg*	0.27 mg*	30 mg*	400 mg	100 mg	15 mcg*	120 mg	2 mg

*Adequate intakes.

TRACE ELEMENTS

Trace elements with recognized roles in human nutrition are iron, iodine, zinc, copper, selenium, manganese, molybdenum, chromium, cobalt (as a component of vitamin B₁₂), and fluoride. Information on food sources, functions, and deficiencies of selected trace elements with the most clinical relevance is summarized in Table 10-5. Dietary requirements are summarized in Table 10-4. Iron deficiency is discussed in detail in Chapter 28.

Fluoride is usually provided as an additive in drinking water or in supplemental vitamin preparations for infants and children. Recommendations for supplemental fluoride appear in Table 10-6.

VITAMINS

1. Fat-Soluble Vitamins

Because they are insoluble in water, the fat-soluble vitamins require digestion and absorption of dietary fat and a carrier system for transport in the blood. Deficiencies in these

vitamins develop more slowly than deficiencies in water-soluble vitamins because the body accumulates stores of fat-soluble vitamins, but prematurity and some childhood conditions can place infants and children at risk (Table 10-7). For the same reason, excessive intakes carry a considerable potential for toxicity (Table 10-8). Recommended intakes are listed in Table 10-9.

Information about the dietary sources of fat-soluble vitamins, absorption and metabolism, and causes and clinical features of deficiency is summarized in Table 10-10. Table 10-11 outlines the clinical evaluation and treatment of these deficiencies.

2. Water-Soluble Vitamins

Deficiencies of water-soluble vitamins are uncommon in the United States because of the abundant food supply and fortification of prepared foods. Cases of deficiencies (eg, scurvy) in children with special needs have been reported in the context of sharply restricted diets. Most bread and wheat products are fortified with B vitamins, including the manda-

Table 10-5. Summary of trace elements.

Mineral	Deficiency		Treatment
	Causes	Clinical Features	
<p>Zinc</p> <p><i>Dietary sources:</i> human milk, meats, shellfish, legumes, nuts, and whole grain cereals.</p> <p><i>Functions:</i> component of many enzymes and gene transcription factors; plays critical roles in nucleic acid metabolism, protein synthesis, and gene expression; supports membrane structure and function.</p>	<p>Diets low in available zinc (high phytate), unfortified synthetic diets; malabsorptive diseases (enteritis, celiac disease, cystic fibrosis); excessive losses (chronic diarrhea); inborn errors of zinc metabolism (acrodermatitis enteropathica, mammary gland zinc secretion defect).</p> <p>Inadequate intake in breast-fed infants after age 6 mo.</p> <p>Prematurity and low birth weight are risk factors.</p>	<p>Mild: impaired growth, poor appetite, impaired immunity.</p> <p>Moderate-severe: mood changes, irritability, lethargy, impaired immune function, increased susceptibility to infection; acro-orificial skin rash, diarrhea, alopecia.</p> <p>Response to zinc supplement is gold standard for diagnosis of deficiency; plasma zinc levels are lowered by acute phase response.</p>	<p>1 mg/kg/d of elemental zinc for 3 mo (eg, 4.5 mg of ZnSO₄ + 7 H₂O/kg/d), given separately from meals and iron supplements.</p> <p>With acrodermatitis enteropathica, 30-50 mg Zn²⁺ per day (or more) sustains remission.</p>
<p>Copper</p> <p><i>Dietary sources:</i> human milk, meats, shellfish, legumes, nuts, and whole grain cereals.</p> <p><i>Functions:</i> vital component of several oxidative enzymes: cytochrome c oxidase (electron transport chain), cytosolic and mitochondrial superoxide dismutase (free radical defense), lysyl oxidase, (cross-linking of elastin and collagen), ferroxidase, (oxidation of ferrous storage iron prior to transport to bone marrow).</p>	<p>Generalized malnutrition, prolonged PN without supplemental copper, malabsorption, or prolonged diarrhea.</p> <p>Prematurity is a risk factor.</p>	<p>Osteoporosis, enlargement of costochondral cartilages, cupping and flaring of long bone metaphyses, spontaneous rib fractures.</p> <p>Neutropenia and hypochromic anemia resistant to iron therapy.</p> <p>Defect of copper metabolism (Menkes kinky hair syndrome) results in severe CNS disease.</p> <p>Low plasma levels help to confirm deficiency; levels are normally very low in young infants. Age-matched normal data are necessary for comparison. Plasma levels are raised by acute phase response.</p>	<p>1% copper sulfate solution (2 mg of salt) or 500 mcg/d elemental copper for infants.</p>
<p>Selenium</p> <p><i>Dietary sources:</i> seafood, meats, garlic (geochemical distribution affects levels in foods).</p> <p><i>Function:</i> essential component of glutathione peroxidase (reduction of hydrogen peroxide to water in the cell cytosol).</p>	<p>Inadequate dietary intake; can occur with selenium-deficient PN.</p> <p>Renal disease.</p>	<p>Skeletal muscle pain and tenderness, macrocytosis, loss of hair pigment.</p> <p>Keshan disease, an often fatal cardiomyopathy in infants and children.</p>	<p>Minimum recommended selenium content for full-term infant formulas is 1.5 mcg/100 kcal, and for pre-term formulas, 1.8 mcg/100 kcal. PN should be supplemented.</p>
<p>Iodine</p> <p><i>Dietary source:</i> iodized salt.</p> <p><i>Functions:</i> essential component of thyroid hormones; regulates metabolism, growth, and neural development.</p>	<p>Inadequate dietary intake.</p> <p>Maternal iodine deficiency causes endemic neonatal hypothyroidism in 5-16% of neonates who may have goiter at birth.</p>	<p>Neurologic endemic cretinism (severe mental retardation, deaf-mutism, spastic diplegia, and strabismus) occurs with severe deficiency.</p> <p>Myxedematous endemic cretinism occurs in some central African countries where signs of congenital hypothyroidism are present.</p>	<p>Use of iodized salt is effective in preventing goiter. Injections of iodized oil can also be used for prevention.</p>
<p>Fluoride</p> <p><i>Function:</i> incorporated into the hydroxyapatite matrix of dentin.</p>	<p>Inadequate intake (unfluoridated water supply).</p>	<p>Low intake increases incidence of dental caries.</p>	<p>See Table 10-6 for supplementation guidelines. Excess fluoride intake results in fluorosis.</p>

CNS, central nervous system; PN, parenteral nutrition.

Table 10-6. Supplemental fluoride recommendations (mg/d).

Age	Concentration of Fluoride in Drinking Water		
	< 0.3 ppm	0.3-0.6 ppm	> 0.6 ppm
6 mo to 3 y	0.25	0	0
3-6 y	0.5	0.25	0
6-16 y	1	0.5	0

tory addition of folic acid to enriched grain products since January 1998. There is conclusive evidence that folic acid supplements (400 mcg/d) during the periconceptional period protect against neural tube defects. Dietary intakes of folic acid from natural foods and enriched products also are protective. Biologic roles of water-soluble vitamins are listed in Table 10-12.

The risk of toxicity from water-soluble vitamins is not as great as that associated with fat-soluble vitamins because excesses are excreted in the urine (see Table 10-8). However, deficiencies of these vitamins develop more quickly than deficiencies in fat-soluble vitamins because of limited stores (see Table 10-7). Additional salient details are summarized in Table 10-13. Although dietary intake of the water-soluble vitamins on a daily basis is not necessary, these vitamins, with

Table 10-7. Circumstances associated with risk of vitamin deficiencies.

Circumstance	Possible Deficiency
Prematurity	All vitamins
Protein-energy malnutrition	B ₁ , B ₂ , folate, A
Synthetic diets without adequate fortification (including total parenteral nutrition)	All vitamins
Vitamin-drug interactions	Folate, B ₁₂ , D, B ₆
Fat malabsorption syndromes	Fat-soluble vitamins
Breast feeding	B ₁ , ^a folate, ^b B ₁₂ , ^c D, ^d K ^e
Periconceptional	Folate
Bariatric surgery (all types)	B vitamins

^aAlcoholic or malnourished mother.

^bFolate-deficient mother.

^cVegan mother or maternal pernicious anemia.

^dInfant not exposed to sunlight and mother's vitamin D status suboptimal.

^eMaternal status poor; neonatal prophylaxis omitted.

Table 10-8. Effects of vitamin toxicity.

Vitamin	Clinical Features of Toxicity
Pyridoxine	Sensory neuropathy at doses > 500 mg/d
Niacin	Histamine release → cutaneous vasodilation; cardiac arrhythmias; cholestatic jaundice; gastrointestinal disturbance; hyperuricemia; glucose intolerance
Folic acid	May mask B ₁₂ deficiency, hypersensitivity
Vitamin C	Diarrhea; increased oxalic acid excretion; renal stones
Vitamin A	(> 20,000 IU/d): vomiting, increased intracranial pressure (pseudotumor cerebri); irritability; headaches; insomnia; emotional lability; dry, desquamating skin; myalgia and arthralgia; abdominal pain; hepatosplenomegaly; cortical thickening of bones of hands and feet
Vitamin D	(> 50,000 IU/d): hypercalcemia; vomiting; constipation; nephrocalcinosis
Vitamin E	(> 25-100 mg/kg/d IV): necrotizing enterocolitis and liver toxicity (but probably due to polysorbate 80 used as a solubilizer)
Vitamin K	<i>Lipid-soluble vitamin K</i> : very low order of toxicity. <i>Water-soluble, synthetic vitamin K</i> : vomiting, porphyria; albuminuria; hemolytic anemia; hemoglobinuria; hyperbilirubinemia (do not give to neonates)

the exception of vitamin B₁₂, are not stored in the body to significant levels. Recommended intakes appear in Table 10-9.

Carnitine is synthesized in the liver and kidneys from lysine and methionine. In certain circumstances (see Table 10-12) synthesis is inadequate, and carnitine can then be considered a vitamin. A dietary supply of other organic compounds, such as inositol, may also be required in certain circumstances.

INFANT FEEDING

BREAST FEEDING

Breast feeding provides optimal nutrition for the normal infant during the early months of life. WHO recommends exclusive breast feeding for approximately the first 6 months of life, with continued breast feeding along with appropriate complementary foods through the first 2 years of life. Numerous immunologic factors in breast milk (including secretory IgA, lysozyme, lactoferrin, bifidus factor, and macrophages) provide protection against GI and upper respiratory infections. In developing countries, lack of refrigeration and contaminated water supplies make formula feeding hazardous. Although formulas have improved progressively and are made to resemble breast milk as closely as possible, it is

impossible to replicate the nutritional or immune composition of human milk. Additional differences of physiologic importance between human milk and formula continue to be identified. Furthermore, the relationship developed through breast feeding can be an important part of early maternal interactions with the infant and provides a source of security and comfort to the infant.

Breast feeding has been reestablished as the predominant initial mode of feeding young infants in the United States. Unfortunately, breast-feeding rates remain low among several subpopulations, including low-income, minority, and young mothers. Many mothers face obstacles in maintaining lactation once they return to work, and rates of breast feeding at 6 months are considerably less than the goal of 50%. Skilled use of a breast pump, particularly an electric one, can help to maintain lactation in these circumstances.

Absolute contraindications to breast feeding are rare. They include tuberculosis (in the mother) and galactosemia (in the infant). Breast feeding is associated with maternal-to-child transmission of HIV, but the risk is influenced by duration and pattern of breast feeding and maternal factors, including immunologic status and presence of mastitis. Complete avoidance of breast feeding by HIV-infected women is presently the only mechanism to ensure prevention of maternal-infant transmission. Current recommendations are that HIV-infected mothers in developed countries refrain from breast feeding if safe alternatives are available. In developing countries, the benefits of breast feeding, especially the protection of the child against diarrheal illness and malnutrition, outweigh the risk of HIV infection via breast

milk. In such circumstances, mixed feeding should be avoided because of the apparent increased risk of HIV transmission with mixed feeds.

In newborns weighing less than 1500 g, human milk should be fortified to increase protein, calcium, phosphorus, and micronutrient content as well as caloric density. Infants with cystic fibrosis can be breast-fed successfully if exogenous pancreatic enzymes are provided. If normal growth rates are not achieved in breast-fed infants with cystic fibrosis, energy or specific macronutrient supplements may be necessary. All infants with cystic fibrosis should receive supplemental vitamins A, D, E, and K, and sodium chloride.

Gartner LM et al: Breastfeeding and the use of human milk. *Pediatrics* 2005;115:496 [PMID: 15687461].

Management of Breast Feeding

In developed countries, health professionals are now playing roles of greater importance in supporting and promoting breast feeding. Organizations such as the AAP and La Leche League have initiated programs to promote breast feeding and provide education for health professionals and mothers.

Perinatal hospital routines and early pediatric care have a great influence on the successful initiation of breast feeding by promoting prenatal and postpartum education, frequent mother-infant contact after delivery, one-on-one advice about breast-feeding technique, demand feeding,

Table 10–10. Summary of fat-soluble vitamins.

Vitamin	Absorption/Metabolism	Deficiency	
		Causes	Clinical Features
<p>Vitamin A</p> <p><i>Dietary sources:</i> dairy products, eggs, liver, meats, fish oils. Precursor β-carotene is abundant in yellow and green vegetables.</p> <p><i>Functions:</i> has critical role in vision, helping to form photosensitive pigment rhodopsin; modifies differentiation and proliferation of epithelial cells in respiratory tract; and is needed for glycoprotein synthesis.</p>	<p>Retinol is stored in liver and from there is exported, attached to retinol-binding protein (RBP) and prealbumin. RBP may be decreased in liver disease or in protein energy malnutrition. Circulating RBP may be increased in renal failure.</p>	<p>Occurs in premature infants, in association with inadequately supplemented PN; protein-energy malnutrition (deficiency worsened by measles); dietary insufficiency and fat malabsorption.</p>	<p>Night blindness, xerosis, xerophthalmia, Bitot spots, keratomalacia, ulceration and perforation of cornea, prolapse of lens and iris, and blindness; follicular hyperkeratosis; pruritus; growth retardation; increased susceptibility to infection.</p>
<p>Vitamin K</p> <p><i>Dietary sources:</i> leafy vegetables, fruits, seeds; synthesized by intestinal bacteria.</p> <p><i>Functions:</i> necessary for the maintenance of normal plasma levels of coagulation factors II, VII, IX, and X; essential for maintenance of normal levels of the anticoagulation protein C; essential for osteoblastic activity.</p>	<p>Absorbed in proximal small intestine in micelles with bile salts; circulates with very low density lipoproteins (VLDL).</p>	<p>Occurs in newborns, especially those who are breast fed and who have not received vitamin K prophylaxis at delivery; in fat malabsorption syndromes; and with use of unabsorbed antibiotics and anticoagulant drugs (warfarin).</p>	<p>Bruising or bleeding in GI tract, genitourinary tract, gingiva, lungs, joints, and brain.</p>
<p>Vitamin E</p> <p><i>Dietary sources:</i> vegetable oils, some cereals, dairy, wheat germ, eggs.</p> <p><i>Functions:</i> α-tocopherol has highest biologic activity; as a free-radical scavenger, stops oxidation reactions. Located at specific sites in cell membrane to protect polyunsaturated fatty acids in membrane from peroxidation and to protect thiol groups and nucleic acids; also acts as cell membrane stabilizer; may function in electron transport chain; may modulate chromosomal expression.</p>	<p>Emulsified in intestinal lumen with bile salts; absorbed via passive diffusion; transported by chylomicrons and VLDL.</p>	<p>May occur with prematurity, cholestatic liver disease, pancreatic insufficiency, abetalipoproteinemia, and short bowel syndrome.</p> <p>Isolated inborn error of vitamin E metabolism.</p> <p>May result from increased consumption during oxidant stress.</p>	<p>Hemolytic anemia; progressive neurologic disorder with loss of deep tendon reflexes, loss of coordination, vibratory and position sensation, nystagmus, weakness, scoliosis, and retinal degeneration.</p>
<p>Vitamin D</p> <p><i>Dietary sources:</i> fortified milk and formulas, egg yolk, fatty fish.</p> <p><i>Functions:</i> calcitriol, the biologically active form of vitamin D, stimulates intestinal absorption of calcium and phosphate, renal reabsorption of filtered calcium, and mobilization of calcium and phosphorus from bone.</p>	<p>Normally obtained primarily from cholecalciferol (D_3) produced by UV radiation of dehydrocholesterol in skin. Ergocalciferol (D_2) is derived from UV irradiation of ergosterol in skin. Vitamin D is transported from skin to liver, attached to a specific carrier protein.</p>	<p>Results from a combination of inadequate sunlight exposure, dark skin pigmentation, and low dietary intake.</p> <p>Breast-fed infants are at risk because of low vitamin D content of human milk. Cow's milk and infant formulas are routinely supplemented with vitamin D.</p> <p>Deficiency also occurs in fat malabsorption syndromes.</p> <p>Hydroxylated vitamin D may be decreased by CYP-450-stimulating drugs, hepatic or renal disease, and inborn errors of metabolism.</p>	<p>Osteomalacia (adults) or rickets (children), in which osteoid with reduced calcification accumulates in bone.</p> <p><i>Clinical findings:</i> craniotabes, rachitic rosary, pigeon breast, bowed legs, delayed eruption of teeth and enamel defects, Harrison groove, scoliosis, kyphosis, dwarfism, painful bones, fractures, anorexia, and weakness.</p> <p><i>Radiographic findings:</i> cupping, fraying, flaring of metaphyses.</p>

CYP, cytochrome P; GI, gastrointestinal; PN, parenteral nutrition; PTH, parathyroid hormone; UV, ultraviolet.

Table 10-11. Evaluation and treatment of deficiencies of fat-soluble vitamins.

Vitamin Deficiency	Diagnostic Laboratory Findings and Treatment
Vitamin A	<p><i>Laboratory findings:</i> serum retinol < 20 mcg/dL; molar ratio of retinol:RBP < 0.7 is also diagnostic.</p> <p><i>Treatment:</i> xerophthalmia requires 5000–10000 IU/kg/d for 5 days PO or IM; with fat malabsorption, standard dose is 2500–5000 IU.</p> <p>Toxicity effects are listed in Table 10-8.</p>
Vitamin K	<p><i>Laboratory findings:</i> assess plasma levels of protein-induced vitamin K absence (PIVKA) or PT.</p> <p><i>Treatment:</i> Oral: 2.5–5.0 mg/d or IM/IV: 1–2 mg/dose as single dose.</p>
Vitamin E	<p><i>Laboratory findings:</i> normal serum level is 3–15 mg/mL for children. Ratio of serum vitamin E to total serum lipid is normally ≥ 0.8 mg/g.</p> <p><i>Treatment:</i> large oral doses (up to 100 IU/kg/d) correct deficiency from malabsorption; for abetalipoproteinemia, 100–200 IU/kg/d are needed.</p>
Vitamin D	<p><i>Laboratory findings:</i> low serum phosphorus and calcium, high alkaline phosphatase, high serum PTH, low 25-OH-cholecalciferol.</p> <p>American Academy of Pediatrics recommends supplementation, as follows: 200 IU/d for all breast-fed infants, beginning in first 2 months of life and continuing until infant is receiving ≥ 500 mL/d of vitamin D-fortified formula or cow's milk.</p> <p><i>Treatment:</i> 1600–5000 IU/d of vitamin D₃ for rickets. If poorly absorbed, give 0.05–0.2 mcg/kg/d of calcitriol.</p>

IM, intramuscular; IV, intravenous; PO, by mouth; PT, prothrombin time; RBP, retinol-binding protein.

rooming-in, avoidance of bottle supplements, early follow-up after delivery, maternal confidence, family support, adequate maternity leave, and advice about common problems such as sore nipples. Breast feeding is undermined by mother-infant separations, bottle-feeding of infants in the nursery at night, routine supplemental bottle feedings, conflicting advice from staff, incorrect infant positioning and latch-on, scheduled feedings, lack of maternal support, delayed follow-up, early return to employment, and inaccurate advice for common breast-feeding difficulties.

Very few women are physiologically unable to nurse their infants. The newborn is generally fed ad libitum every 2–3 hours, with longer intervals (4–5 hours) at night. Thus a newborn infant nurses at least 8–10 times a day, so that a generous milk supply is stimulated. This frequency is not an indication of inadequate lactation. In neonates, a loose stool is often passed with each feeding; later (at age 3–4 months),

Table 10-12. Biologic roles of water-soluble vitamins.

Vitamin	Role
B vitamins involved in production of energy	
Thiamin (B ₁)	Thiamin pyrophosphate is a coenzyme in oxidative decarboxylation (pyruvate dehydrogenase, α -ketoglutarate dehydrogenase, and transketolase).
Riboflavin (B ₂)	Coenzyme of several flavoproteins (eg, flavin mononucleotide [FMN] and flavin adenine dinucleotide [FAD]) involved in oxidative/electron transfer enzyme systems.
Niacin	Hydrogen-carrying coenzymes: nicotinamide-adenine dinucleotide (NAD), nicotinamide-adenine dinucleotide phosphate (NADP); decisive role in intermediary metabolism.
Pantothenic acid	Major component of coenzyme A.
Biotin	Component of several carboxylase enzymes involved in fat and carbohydrate metabolism.
Hematopoietic B vitamins	
Folic acid	Tetrahydrofolate has essential role in one-carbon transfers. Essential role in purine and pyrimidine synthesis; deficiency \rightarrow arrest of cell division (especially bone marrow and intestine).
Cobalamin (B ₁₂)	Methyl cobalamin (cytoplasm): synthesis of methionine with simultaneous synthesis of tetrahydrofolate (reason for megaloblastic anemia in B ₁₂ deficiency). Adenosyl cobalamin (mitochondria) is coenzyme for mutases and dehydratases.
Other B vitamins	
Pyridoxine (B ₆)	Prosthetic group of transaminases, etc, involved in amino acid interconversions; prostaglandin and heme synthesis; central nervous system function; carbohydrate metabolism; immune development.
Other water-soluble vitamins	
L-Ascorbic acid (C)	Strong reducing agent—probably involved in all hydroxylations. Roles include collagen synthesis; phenylalanine \rightarrow tyrosine; tryptophan \rightarrow 5-hydroxytryptophan; dopamine \rightarrow norepinephrine; Fe ³⁺ ; folic acid \rightarrow folinic acid; cholesterol \rightarrow bile acids; leukocyte function; interferon production; carnitine synthesis. Copper metabolism; reduces oxidized vitamin E.

there may be an interval of several days between stools. Failure to pass several stools a day in the early weeks of breast feeding suggests inadequate milk intake and supply.

Expressing milk may be indicated if the mother returns to work or if the infant is premature, cannot suck adequately, or is hospitalized. Electric breast pumps are very effective and can be borrowed or rented.

Table 10-13. Summary of water-soluble vitamins.

Vitamin	Deficiency	
	Causes	Clinical Features
Thiamin (B₁) <i>Dietary sources:</i> whole and enriched grains, lean pork, legumes.	Beriberi in infants breast fed by mothers with history of alcoholism or poor diet; has been described as a complication of PN; protein-energy malnutrition; following bariatric surgery of all types (reported in adults and adolescents).	“Dry” Beriberi (paralytic or nervous): peripheral neuropathy, with impairment of sensory, motor, and reflex functions. “Wet” Beriberi: high output congestive ± signs of dry beriberi. Cerebral Beriberi: triad of ophthalmoplegia, ataxia, and mental confusion.
Riboflavin (B₂) <i>Dietary sources:</i> dairy products, meat, poultry, wheat germ, leafy vegetables.	General undernutrition; inactivation in PN solutions exposed to light.	Cheilosis; angular stomatitis; glossitis; soreness and burning of lips and mouth; dermatitis of nasolabial fold and genitals; ± ocular signs (photophobia → indistinct vision).
Niacin (B₃) <i>Dietary sources:</i> meats, poultry, fish, legumes, wheat, all foods except fats; synthesized in body from tryptophan.	Maize- or millet-based diets (high leucine and low tryptophan intakes); carcinoid tumors.	Pellagra (dermatitis, especially on sun-exposed areas; diarrhea; dementia).
Pyridoxine (B₆) <i>Dietary sources:</i> animal products, vegetables, whole grains.	Prematurity (these infants may not convert pyridoxine to pyridoxal-5-P); B ₆ dependency syndromes; drugs (isoniazid).	Listlessness; irritability; seizures; anemia; cheilosis; glossitis.
Biotin <i>Dietary sources:</i> yeast, liver, kidneys, legumes, nuts, egg yolks (synthesized by intestinal bacteria).	Suppressed intestinal flora and impaired intestinal absorption; regular intake of raw egg whites.	Scaly dermatitis; alopecia; irritability; lethargy.
Folic acid <i>Dietary sources:</i> leafy vegetables (easily destroyed in cooking), fruits, whole grains, wheat germ, beans, nuts.	Breast-fed infants whose mothers are folate-deficient; term infants fed unsupplemented processed cow’s milk or goat’s milk; kwashiorkor; chronic overcooking of food sources; malabsorption of folate because of a congenital defect; celiac disease; drugs (phenytoin). Increased requirements in chronic hemolytic anemias, diarrhea, malignancies, extensive skin disease, cirrhosis, pregnancy.	Megaloblastic anemia; neutropenia; growth retardation; delayed maturation of central nervous system in infants; diarrhea (mucosal ulcerations); glossitis; neural tube defects.
Cobalamin (B₁₂) <i>Dietary sources:</i> eggs, dairy products, liver, meats; <i>none in plants.</i>	Breast-fed infants of mothers with latent pernicious anemia or who are on an unsupplemented vegan diet; absence of luminal proteases; short gut syndrome (absence of stomach or ileum); congenital malabsorption of B ₁₂ .	Megaloblastic anemia; hypersegmented neutrophils; neurologic degeneration: paresthesias, gait problems, depression.
Vitamin C <i>Dietary sources:</i> fruits and vegetables.	Maternal megadoses during pregnancy → deficiency in infants (rebound); diet without fruits or vegetables; seen in infants fed formula based on pasteurized cow’s milk (historical).	Irritability, apathy, pallor; increased susceptibility to infections; hemorrhages under skin, petechiae, in mucous membranes, in joints and under periosteum; long-bone tenderness; costochondral beading.
Carnitine <i>Dietary sources:</i> meats, dairy products; <i>none in plants.</i>	Premature infants fed unsupplemented formula or fed intravenously; dialysis; inherited deficits in carnitine synthesis; organic acidemias; valproic acid.	Increased serum triglycerides and free fatty acids; decreased ketones; fatty liver; hypoglycemia; progressive muscle weakness, cardiomyopathy, hypoglycemia.

PN, parenteral nutrition.

Technique of Breast Feeding

Breast feeding can be started after delivery as soon as both mother and infant are stable. Correct positioning and breast-feeding technique are necessary to ensure effective nipple stimulation and optimal breast emptying with minimal nipple discomfort.

If the mother wishes to nurse while sitting, the infant should be elevated to the height of the breast and turned completely to face the mother, so that their abdomens touch. The mother's arms supporting the infant should be held tightly at her side, bringing the infant's head in line with her breast. The breast should be supported by the lower fingers of her free hand, with the nipple compressed between the thumb and index fingers to make it more protractile. The infant's initial licking and mouthing of the nipple helps make it more erect. When the infant opens its mouth, the mother should rapidly insert as much nipple and areola as possible.

The most common early cause of poor weight gain in breast-fed infants is poorly managed mammary engorgement, which rapidly decreases milk supply. Unrelieved engorgement can result from inappropriately long intervals between feeding, improper infant suckling, an undemanding infant, sore nipples, maternal or infant illness, nursing from only one breast, and latching difficulties. Poor maternal feeding technique, inappropriate feeding routines, and inadequate amounts of fluid and rest all can be factors. Some infants are too sleepy to do well on an *ad libitum* regimen and may need waking to feed at night. Primary lactation failure occurs in fewer than 5% of women.

A sensible guideline for duration of feeding is 5 minutes per breast at each feeding the first day, 10 minutes on each side at each feeding the second day, and 10–15 minutes per side thereafter. A vigorous infant can obtain most of the available milk in 5–7 minutes, but additional sucking time ensures breast emptying, promotes milk production, and satisfies the infant's sucking urge. The side on which feeding is commenced should be alternated. The mother may break suction gently after nursing by inserting her finger between the infant's gums.

Follow-Up

Individualized assessment before discharge should identify mothers and infants needing additional support. All mother-infant pairs require early follow-up. The onset of copious milk secretion between the second and fourth postpartum days is a critical time in the establishment of lactation. Failure to empty the breasts during this time can cause engorgement, which quickly leads to diminished milk production.

Common Problems

Nipple tenderness requires attention to proper positioning of the infant and correct latch-on. Ancillary measures include nursing for shorter periods, beginning feedings on

the less sore side, air drying the nipples well after nursing, and use of lanolin cream. Severe nipple pain and cracking usually indicate improper infant attachment. Temporary pumping may be needed.

Breast-feeding jaundice is exaggerated physiologic jaundice associated with inadequate intake of breast milk, infrequent stooling, and unsatisfactory weight gain. (See Chapter 1.) If possible, the jaundice should be managed by increasing the frequency of nursing and, if necessary, augmenting the infant's sucking with regular breast pumping. Supplemental feedings may be necessary, but care should be taken not to decrease breast milk production further.

In a small percentage of breast-fed infants, breast milk jaundice is caused by an unidentified property of the milk that inhibits conjugation of bilirubin. In severe cases, interruption of breast feeding for 24–36 hours may be necessary. The mother's breast should be emptied with an electric breast pump during this period.

The symptoms of mastitis include flulike symptoms with breast tenderness, firmness, and erythema. Antibiotic therapy covering β -lactamase-producing organisms should be given for 10 days. Analgesics may be necessary, but breast feeding should be continued. Breast pumping may be helpful adjunctive therapy.

Dann MH: The lactation consult: Problem solving, teaching, and support for the breastfeeding family. *J Pediatr Health Care* 2005;19:12 [PMID: 15662357].

Maternal Drug Use

Factors playing a role in the transmission of drugs in breast milk include the route of administration, dosage, molecular weight, pH, and protein binding. Generally, any drug prescribed to a newborn can be consumed by the breast-feeding mother without ill effect. Very few drugs are absolutely contraindicated in breast-feeding mothers; these include radioactive compounds, antimetabolites, lithium, diazepam, chloramphenicol, antithyroid drugs, and tetracycline. For up-to-date information, a regional drug center should be consulted.

Maternal use of illicit or recreational drugs is a contraindication to breast feeding. Expression of milk for a feeding or two after use of a drug is not an acceptable compromise. The breast-fed infants of mothers taking methadone (but not alcohol or other drugs) as part of a treatment program have generally not experienced ill effects when the daily maternal methadone dose is less than 40 mg.

Nutrient Composition

The nutrient composition of human milk is summarized and compared with that of cow’s milk and formulas in Table 10–14. Outstanding characteristics include (1) relatively low but highly

bioavailable protein content, which is adequate for the normal infant; (2) generous but not excessive quantity of essential fatty acids; (3) long-chain unsaturated ω3 fatty acids, of which DHA is thought to be especially important; (4) relatively low sodium and solute load; and (5) lower concentration of highly bioavailable minerals, which are adequate for the needs of normal breast-fed infants for approximately 6 months.

Table 10–14. Composition of human and cow’s milk and typical infant formula (per 100 kcal).

Nutrient (unit)	Minimal Level Recommended ^a	Mature Human Milk	Typical Commercial Formula	Cow’s Milk (mean)

^bProtein of nutritional quality equal to casein.

^cIncludes 300 mg of essential fatty acids.

Complementary Feeding

The AAP and WHO recommend the introduction of solid foods in normal infants at about 6 months of age. Gradual introduction of a variety of foods, including fortified cereals, fruits, vegetables, and meats, should complement the breast milk diet. Meats provide an important dietary source of iron and zinc, both of which are low in human milk by 6 months, and pureed meats may be introduced as an early complementary food. Single-ingredient complementary foods are introduced one at a time at weekly intervals before a new food is given. Fruit juice is not an essential part of an infant diet. Juice should not be introduced until after 6 months; should only be offered in a cup; and the amount should be limited to 4 oz/d. Breast feeding should ideally continue for at least 12 months, and thereafter for as long as mutually desired. Infants who are not breast fed should receive standard iron-fortified infant formula. Whole cow's milk can be introduced after the first year of life.

SPECIAL DIETARY PRODUCTS FOR INFANTS

Soy Protein Formulas

Historically, a common rationale for the use of soy protein formulas was the transient lactose intolerance after acute gastroenteritis. Lactose-free cow's milk protein-based formulas are also now available. These formulas are also useful for infants with galactosemia and hereditary lactase deficiency. Soy protein formulas are often used in cases of suspected intolerance to cow's milk protein. Although infants with true cow's milk protein intolerance may also be intolerant of soy protein, those with documented IgE-mediated allergy to cow's milk protein usually do well on soy formula.

Semi-Elemental & Elemental Formulas

Semi-elemental formulas include protein hydrolysate formulas. The major nitrogen source of most of these products is casein hydrolysate, supplemented with selected amino acids, but partial hydrolysates of whey are also available. These formulas contain an abundance of EFA from vegetable oil; certain brands also provide substantial amounts of MCTs. Elemental formulas are available with free amino acids and varying levels and types of fat components.

Semi-elemental and elemental formulas are invaluable for infants with a wide variety of malabsorption syndromes. They are also effective in infants who cannot tolerate cow's milk and soy protein. Controlled trials suggest that for infants with a family history of atopic disease, partial hydrolysate formulas

may delay or prevent atopic disease. For specific product information, consult standard pediatric reference texts, formula manufacturers, or a pediatric dietitian.

Hays T, Wood RA: A systematic review of the role of hydrolyzed infant formulas in allergy prevention. *Arch Pediatr Adolesc Med* 2005;159:810 [PMID: 15143739].

Hernell O, Lonnerdal B: Nutritional evaluation of protein hydrolysate formulas in healthy term infants: Plasma amino acids, hematology, and trace elements. *Am J Clin Nutr* 2003;78:296 [PMID: 12885712].

Formula Additives

Occasionally it may be necessary to increase the caloric density of an infant feeding to provide more calories or restrict fluid intake. Concentrating formula to 24–26 kcal/oz is usually well tolerated, delivers an acceptable renal solute load, and increases the density of all the nutrients. Beyond this, individual macronutrient additives (Table 10–15) are usually employed to achieve the desired caloric density (up to 30 kcal/oz) based on the infant's needs and underlying condition(s). A pediatric nutrition specialist can be helpful in formulating calorically dense infant formula feedings. The caloric density of breast milk can be increased by adding infant formula powder or any of the additives used with infant formula. Human milk fortifiers are generally used only for premature infants because of their specialized nutrient composition.

Special Formulas

Special formulas are those in which one component, often an amino acid, is reduced in concentration or removed for the dietary management of a specific inborn metabolic disease. Also included under this heading are formulas designed for the management of specific disease states, such as hepatic failure, pulmonary failure with chronic carbon dioxide retention, and renal failure. These condition-specific formulas were formulated primarily for critically ill adults and are even used sparingly in those populations; thus their use in pediatrics should only be undertaken with clear indication and caution.

Complete information regarding the composition of these special formulas, the standard infant formulas, specific metabolic disease formulas, and premature infant formulas can be found in standard reference texts and in the manufacturers' literature.

NUTRITION FOR THE OLDER CHILD

Because of the association of diet with the development of such chronic diseases as diabetes, obesity, and cardiovascular disease, learning a healthy eating behavior at a young age is an important preventative measure.

Salient features of the diet for children older than 2 years include the following:

Table 10-15. Common infant formula additives.

Additive	kcal/g	kcal/Tbsp	kcal/mL	Comments
Dry rice cereal	3.75	15	—	Thickens formula but not breast milk
Polycose (Abbott Nutrition)	3.8	23	2	Glucose polymers
Moducal (Mead Johnson)	3.75	30	—	Maltodextrin
MCT oil (Novartis)	8.3	116	7.7	Not a source of essential fatty acids
Microlipid (Novartis)	9	68.5	4.5	Safflower oil emulsion with 0.4 g linoleic acid/mL
Vegetable oil	9	124	8.3	Does not mix well
Promod (Abbott Nutrition)	4.3	16.8 (3 g protein)	—	Whey protein concentrate
Casec (Mead Johnson)	3.8	16.7 (4 g protein)	—	Calcium caseinate
Duocal (SHS)	4.9	42	—	Protein-free mix of hydrolyzed corn starch (60% kcal) and fat (35% MCT)

MCT, medium-chain triglyceride.

- Consumption of three regular meals per day, and two or three healthful snacks according to appetite, activity, and growth needs.
- Inclusion of a variety of foods. Diet should be nutritionally complete and promote optimal growth and activity.
- Fat should comprise less than 35% of total calories (Severe fat restriction may result in an energy deficit and growth failure). Saturated fats should provide less than 10% of total calories. Monounsaturated fats should provide 10% or more of caloric intake. Consumption of trans-fatty acids, found in stick margarine and shortening, and in many processed foods, should be kept as low as possible.
- Cholesterol intake less than 100 mg/1000 kcal/d, to a maximum of 300 mg/d.
- Carbohydrates should provide 45–65% of daily caloric intake, with no more than 10% in the form of simple sugars. A high-fiber, whole-grain-based diet is recommended.
- Limitation of grazing behavior, eating while watching television, and the consumption of soft drinks and other sweetened beverages.
- Limitation of sodium intake by choosing fresh over processed foods.

The consumption of lean cuts of meats, poultry, and fish should be encouraged. Skim or low-fat milk, soft margarine, and vegetable oils (especially canola or olive oil) should be used. Whole-grain bread and cereals and plentiful amounts of fruits and vegetables are recommended. The consumption of processed foods, soft drinks, desserts, and candy should be limited.

A prudent diet should be only one component of counseling on lifestyles for children. Other aspects are the maintenance of a desirable body weight; promotion of regular physical activity and limiting sedentary behaviors; avoidance of smok-

ing; and screening for hypertension. Universal screening for total cholesterol is controversial. Current recommendations are to routinely screen those children who have a positive family history of premature cardiovascular disease, although this approach will identify only about 50% of those with significantly elevated cholesterol levels. If the result is high (≥ 200 mg/dL), a fasting lipoprotein analysis should be obtained.

PEDIATRIC UNDER- & OVERNUTRITION

PEDIATRIC UNDERNUTRITION

ESSENTIALS OF DIAGNOSIS AND TYPICAL FEATURES

- ▶ Poor weight gain or weight loss.
- ▶ Loss of subcutaneous fat, temporal wasting.
- ▶ Most commonly related to inadequate caloric intake.
- ▶ Often associated with marginal or low iron and zinc status.

▶ General Considerations

Pediatric undernutrition is usually multifactorial in origin, and successful treatment depends on accurate identification and management of those factors. The terms “organic” and “non-

organic” failure to thrive, though still used by many medical professionals, are not helpful because any systemic illness or chronic condition can cause growth impairment and yet may also be compounded by psychosocial or behavioral problems.

► Clinical Findings

Failure to thrive is a term used to describe infants and young children whose weight curve has fallen by two major percentile channels from a previously established rate of growth. (See Chapter 2.) The acute loss of weight, or failure to gain weight at the expected rate, produces a condition of reduced weight for height known as *wasting*. The reduction in height for age, as is seen with more chronic malnutrition, is termed *stunting*.

The typical pattern for mild pediatric undernutrition is decreased weight, with normal height and head circumference. In more chronic malnutrition, height and eventually head circumference growth slow relative to the standard for age. Significant calorie deprivation produces severe wasting, called *marasmus*. Significant protein deprivation in the face of adequate energy intake, possibly with additional insults such as infection, may produce edematous malnutrition called *kwashiorkor*.

A discussion of the multiple medical conditions that can cause pediatric undernutrition is beyond the scope of this chapter. However, the most common cause is inadequate dietary intake. In young but otherwise healthy breast-fed or bottle-fed infants, a weak suck is often the causative factor. Inappropriate formula mixing or a family’s dietary beliefs may lead to hypocaloric or unbalanced dietary intakes. Diets restricted because of suspected food allergies or intolerances may result in inadequate intake of calories, protein, or specific micronutrients. Iron and zinc are micronutrients that are often marginal in many young children with undernutrition. Cases of severe malnutrition and kwashiorkor have occurred in infants of well-intentioned parents who substitute “health food” milk alternatives (eg, rice milk or unfortified soy milk) for infant formula.

► Treatment

Poor eating is often a learned behavior. Families should be counseled regarding choices of foods that are appropriate for the age and developmental level of the child. Children should have structured meal times (eg, three meals and two to three snacks during the day), ideally at the same time other family members eat. Consultation with a pediatric dietitian can be helpful for educating families. Poor feeding may be related to family dysfunction. Children whose households are chaotic and children who are abused, neglected, or exposed to poorly controlled mental illness may be described as poor eaters, and may fail to gain. Careful assessment of the social environment of such children is critical, and disposition options may include support services, close medical follow-up visits, family counseling, and even foster placement while a parent receives therapy.

PEDIATRIC OVERWEIGHT/OBESITY (SEE ALSO CHAPTER 3 FOR SPECIFICS OF ADOLESCENT OBESITY)

ESSENTIALS OF DIAGNOSIS AND TYPICAL FEATURES

- Excessive rate of weight gain; upward change in BMI percentiles.
- BMI between the 85th and 95th percentiles indicates overweight.
- BMI > 95th percentile indicates obesity and is associated with increased risk of secondary complications.

► General Considerations

The prevalence of childhood and adolescent obesity has increased rapidly in the United States and many other parts of the world. Currently in the United States, approximately 17% of 6- to 19-year-olds are obese, with even higher rates among subpopulations of minority and economically disadvantaged children. The increasing incidence of childhood obesity is related to a complex combination of genetic, environmental, psychosocial, biologic, and socioeconomic factors.

Overweight status in the pediatric population is associated with significant comorbidities which, if untreated, are likely to persist into adulthood. The probability of obesity persisting into adulthood has been estimated to increase from 20% at 4 years to 80% by adolescence. Obesity is associated with cardiovascular and endocrine abnormalities (eg, dyslipidemia, insulin resistance, and type 2 diabetes), orthopedic problems, pulmonary complications (eg, obstructive sleep apnea), and mental health problems.

► Clinical Findings

A. Definitions

BMI is the standard measure of obesity in adults. Its use in children provides a consistent measure across age groups. BMI is correlated with more accurate measures of body fatness and is calculated with readily available information: weight and height ($\text{kg} \div \text{m}^2$). Routine plotting of the BMI on age- and gender-appropriate charts (available at <http://www.cdc.gov/growthcharts>; see also Chapter 2) can identify those with excess weight gain relative to linear growth. New definitions were proposed in 2007 by an Expert Committee (http://www.ama-assn.org/ped_obesity_rec.pdf). BMI between

the 85th and 95th percentile for age and sex identifies those who are overweight. Obesity is defined as BMI at or above 95% and is associated with increased risk of secondary complications. Severe obesity is characterized by BMI for age and sex at or above the 99th percentile. An upward change in BMI percentiles in any range should prompt an evaluation and possible treatment. Although the degree of change that indicates risk has not been defined, an annual increase of 3–4 BMI units is almost always an indicator of a rapid increase in body fat. For children younger than 2 years, weight for length greater than the 95th percentile indicates overweight and warrants further assessment, especially of energy intake and feeding behaviors.

B. Risk Factors

There are multiple risk factors for developing obesity, reflecting the complex relationships between genetic and environmental factors. Family history is a strong risk factor. If one parent is obese, the odds ratio is approximately 3 for obesity in adulthood, but if both parents are obese, the odds ratio increases to greater than 10.

Environmental risk factors offer potential areas to target for intervention. Excessive consumption of sugar-sweetened beverages, large portion sizes, frequent consumption of foods prepared outside the home, excessive television viewing, and sedentary lifestyle are all associated with a greater risk of excessive weight gain.

C. Assessment

Early recognition of high-risk patterns of weight gain or high-risk behaviors is essential, as it is likely that anticipatory guidance or intervention before weight gain becomes severe will be more successful. Routine evaluation at well-child visits should include:

1. Measurement of weight and height, calculation of BMI, and plotting all three parameters on age- and sex-appropriate growth charts. Evaluate for upward crossing of BMI percentile channels.
2. History regarding diet and activity patterns (Table 10–16); family history, and review of systems. Physical examination should include careful blood pressure measurement, distribution of adiposity (central vs generalized); markers of comorbidities, such as acanthosis nigricans, hirsutism, hepatomegaly, orthopedic abnormalities; physical stigmata of genetic syndrome (eg, Prader-Willi syndrome).
3. Laboratory studies are generally reserved for children with BMI in the obesity category (> 95th percentile) or those in the overweight category who have risk factors. Suggested laboratory tests include fasting lipid profile and glucose; and liver function tests (aspartate transaminase [AST] and alanine transaminase [ALT]). Other studies should be guided by historical and physical findings.

Table 10–16. Suggested areas for assessment of diet and activity patterns.

Diet

Portion sizes: adult portions for young children
 Frequency of meals away from home (restaurants or take out)
 Frequency/amounts of sugar-sweetened beverages (soda, juice drinks)
 Meal and snack pattern: structured vs grazing, skipping meals
 Frequency of eating fruits and vegetables
 Frequency of family meals

Activity

Time spent in sedentary activity: television, video games
 Time spent in vigorous activity: organized sports, physical education, free play
 Activities of daily living: walking to school, chores, yard work

► Treatment

Therapy should be based on risk factors, including age, severity of obesity, and comorbidities, as well as family history and support. For all children with uncomplicated obesity, the primary goal is to achieve healthy eating and activity patterns, not necessarily to achieve ideal body weight. For children with a secondary complication, improvement of the complication is an important goal. For children 2–7 years old with BMI at the 95th percentile or modestly above and without complications, the goal should generally be maintenance of baseline weight, allowing the child to “grow into” his or her height, with a gradual normalization of BMI. For children 2–7 years old with BMI at the 95th percentile or above and secondary complications, weight loss is indicated. For children older than 7 years with BMI between the 85th and 95th percentile, without complications, weight maintenance is an appropriate goal. If secondary complications are present, weight loss is recommended; an appropriate goal is 1 pound weight loss per month until a BMI less than 85% is achieved. Excessive acute weight loss should be avoided, as this may contribute to nutrient deficiencies and linear growth stunting.

There are few studies of the long-term effects of weight control programs for children. Treatment focused on behavior changes in the context of family involvement has been associated with sustained weight loss and decreases in BMI. Clinicians should assess the family’s readiness to take action (transtheoretical model and motivational interviewing). Concurrent changes in dietary patterns and increasing physical activity are most likely to provide success. The whole family should be encouraged to adopt healthy eating patterns, with parents modeling healthy food choices, controlling foods brought into the home, and guiding appropriate portion sizes. Limiting sedentary activity has been found to be more effective than specifically promoting increased physical activity. The AAP recommends no television for children younger than 2 years old, and a maximum of 2 h/d of television and video games for older children.

A “staged approach” for treatment has been proposed, with different levels depending on the severity of overweight, the age of the child, the ability of the family to implement changes, the preferences of the parents and child, and the skills of the health care provider.

1. *Prevention plus*: Counseling regarding problem areas identified by screening questions (see Table 10–16); emphasis on lifestyle changes, including healthy eating and physical activity patterns. This is especially appropriate for preventing further weight gain or for mildly overweight children.
2. *Structured weight management*: Provision of a more specific and structured dietary pattern, such as meal planning, exercise prescription, and behavior change goals. This may be done in the primary care setting but generally requires ancillary health professionals, including a dietitian, behavior specialist, and physical therapist. Monitoring is monthly or tailored to the needs of the patient and family.
3. *Comprehensive multidisciplinary approach*: This level further increases the structure of therapeutic interventions and support, uses a multidisciplinary team, and may involve weekly group meetings.
4. *Tertiary care intervention*: This level is for patients who have not been successful at the other intervention levels or who are severely obese. Interventions are prescribed by a multidisciplinary team, and may include intensive behavior therapy, specialized diets, medications, and surgery.

No single prescription is effective for all patients. The physician’s focus should be on assessing the severity of the problem, identifying treatment needs in the context of the family’s preferences and abilities, and utilizing local resources, including availability of registered dietitians with expertise in pediatric weight management and behaviorists or family therapists.

Pharmacotherapy can be an adjunct to dietary, activity, and behavioral treatment, but by itself it is unlikely to result in significant or sustained weight loss. Two medications are approved for obesity treatment in adolescents: sibutramine, a selective serotonin reuptake inhibitor, is approved for patients older than 16 years; orlistat, a lipase inhibitor, is approved for patients older than 12 years. Bariatric surgery is being performed in some centers for severe obesity in adolescents, particularly those with comorbidities. Evidence is emerging that in carefully selected and closely monitored patients, surgery can result in significant weight loss with a reduction in comorbidities for those who are severely afflicted.

NUTRITION SUPPORT

ENTERAL NUTRITION

Indications

Enteral nutrition support is indicated when a patient cannot adequately meet nutritional needs by oral intake alone and has a functioning GI tract. This method of support can be used for short- and long-term delivery of nutrition. Even when the gut cannot absorb 100% of nutritional needs, some enteral feedings should be attempted. Enteral nutrition, full or partial, has many benefits, including:

1. Maintaining gut mucosal integrity
2. Preserving gut-associated lymphoid tissue
3. Stimulating gut hormones and bile flow

The nutritional needs of most patients requiring enteral nutrition can be met with standard enteral formulations. Specialized formulas are available for patients of all ages with severe milk protein allergy, single- or multiple-nutrient malabsorption, renal failure, and hepatic failure. The decision to use such specialized formulas must be made in the context of the patient’s condition and nutritional needs.

Access Devices

Nasogastric feeding tubes can be used for supplemental enteral feedings, but generally are not used for more than 6 months because of the complications of otitis media and sinusitis. Initiation of nasogastric feeding usually requires a brief hospital stay, especially for infants younger than age 6 months, to ensure tolerance to feedings and to allow for parental instruction in tube placement and feeding administration.

If long-term feeding support is anticipated, a more permanent feeding device, such as a gastrostomy tube, may be considered. Unfortunately, many insurance carriers do not cover the cost of formula for tube feedings. Referral to a home care company is necessary for equipment and other services such as nursing visits and dietitian follow-up.

Table 10–17 suggests appropriate timing for initiation and advancement of drip and bolus feedings, according to a child’s age. Clinical status and tolerance to feedings should ultimately guide their advancement.

Monitoring

Monitoring the adequacy of enteral feeding depends on nutritional goals. Growth should be frequently assessed,

Table 10-17. Guidelines for the initiation and advancement of tube feedings.

Age	Drip Feeds		Bolus Feeds	
	Initiation	Advancement	Initiation	Advancement
Preterm	1-2 mL/kg	1 mL as tolerated	5-20 mL	5-10 mL as tolerated
Birth-12 mo	5-10 mL/h	5-10 mL q 2-8 h	10-60 mL	20-40 mL q 3-4 h
1-6 y	10-15 mL/h	10-15 mL q 2-8 h	30-90 mL	30-60 mL q feed
6-14 y	15-20 mL/h	10-20 mL q 2-8 h	60-120 mL	60-90 mL q feed
> 14 y	20-30 mL/h	20-30 mL q 2-8 h	60-120 mL	60-120 mL q feed

especially for young infants and malnourished children. Hydration status should be monitored carefully at the initiation of enteral feeding. Either constipation or diarrhea can be problems, and attention to stool frequency, volume, and consistency can help guide management. When diarrhea occurs, factors such as infection, hypertonic enteral medications, antibiotic use, and alteration in normal gut flora should be addressed before making formula changes.

It is important to determine whether the feeding schedule is developmentally appropriate. This will not be possible for all patients, especially those who are critically ill. However, for children who are more stable, tube-feeding schedules should mimic as closely as possible an age-appropriate feeding schedule (eg, six small feedings per day for a toddler). When night drip feedings are used in conjunction with daytime feeds, it is suggested that less than 50% of goal calories be delivered at night so as to maintain a daytime sense of hunger and satiety. This is especially important once a transition to oral intake begins. Children who are satiated by tube feedings are less likely to take significant amounts of food by mouth, thus possibly delaying the transition from tube to oral nutrition.

PARENTERAL NUTRITION

Indications

A. Peripheral Parenteral Nutrition

Peripheral parenteral nutrition (PN) is indicated when complete enteral feeding is temporarily impossible or undesirable. Short-term partial intravenous (IV) nutrition via a peripheral vein is a preferred alternative to administration of dextrose and electrolyte solutions alone. Because of the osmolality of the solutions required, it is usually impossible to achieve total calorie and protein needs with PN via a peripheral vein.

B. Central Parenteral Nutrition

Provision of total nutritional needs by the parenteral route will require a centrally placed venous catheter. Total PN should be provided only when clearly indicated. Apart from the expense, numerous risks are associated with this method of feeding (see section on Complications, later). Even when

PN is indicated, every effort should be made to provide at least a minimum of nutrients enterally to help preserve the integrity of the GI mucosa and of GI function.

The primary indication for PN is the loss of function of the GI tract that prohibits the provision of more than a small proportion of required nutrients by the enteral route. Important examples include short bowel syndrome, some congenital defects of the GI tract, and prematurity.

Catheter Selection & Position

An indwelling central venous catheter is preferred for long-term PN. For periods of up to 3–4 weeks, a percutaneous central venous catheter threaded into the superior vena cava from a peripheral vein can be used. For the infusion of dextrose concentrations higher than 12.5%, the tip of the catheter should be located in the superior vena cava. Catheter positioning in the right atrium has been associated with complications, including arrhythmias and right atrial thrombus. After placement, a chest radiograph must be obtained to check catheter position. If the catheter is to be used for nutrition and medications, a double-lumen catheter is preferred.

Complications

A. Mechanical Complications

1. Related to catheter insertion or to erosion of catheter through a major blood vessel—Complications include trauma to adjacent tissues and organs, damage to the brachial plexus, hydrothorax, pneumothorax, hemothorax, and cerebrospinal fluid penetration. The catheter may slip during dressing or tubing changes, or the patient may manipulate the line.

Chaturvedi A et al: Catheter malplacement during central venous cannulation through arm veins in pediatric patients. *J Neurosurg Anesthes* 2003;15:170 [PMID: 12826963].

2. Clotting of the catheter—Addition of heparin (1000 U/L) to the solution is an effective means of preventing this complication. If an occluded catheter does not respond to heparin

flushing, filling the catheter with recombinant tissue plasminogen activator or sterile 95% ethanol may be effective.

3. Related to composition of infusate—Calcium phosphate precipitation may occur if excess amounts of calcium or phosphorus are administered. Factors that increase the risk of calcium phosphate precipitation include increased pH and decreased concentrations of amino acids. Precipitation of medications incompatible with PN or lipids can also cause clotting.

Freytes CO: Thromboembolic complications related to indwelling central venous catheters in children. *Curr Opin Oncol* 2003;15:289 [PMID: 12874506].

B. Septic Complications

Septic complications are the most common cause of non-elective catheter removal, but strict use of aseptic technique and limiting entry into the catheter can reduce the rates of line sepsis.

Fever above 38–38.5°C in a patient with a central catheter should be considered a line infection until proved otherwise. Cultures should be obtained and IV antibiotics empirically initiated. Removing the catheter may be necessary with certain infections (eg, fungal), and catheter replacement may be deferred until infection is treated.

C. Metabolic Complications

Many of the metabolic complications of IV nutrition are related to deficiencies or excesses of nutrients in administered fluids. These complications are less common as a result of experience and improvements in nutrient solutions. However, specific deficiencies still occur, especially in premature infants. Avoidance of deficiencies and excesses and of metabolic disorders requires attention to the nutrient balance, electrolyte composition, and delivery rate of the infusate and careful monitoring, especially when the composition or delivery rate is changed.

Currently the most challenging metabolic complication is cholestasis, which is particularly common in premature infants of very low birth weight. The cause of cholestasis associated with TPN is unknown. Patient and medical risk factors include prematurity, sepsis, hypoxia, major surgery (especially GI surgery), absence of enteral feedings, and small bowel bacterial overgrowth. Risk factors related to IV nutrition include amino acid excess or imbalance and prolonged duration of administration. Amino acid solutions with added cysteine decrease cholestasis. Practices that may minimize cholestasis include initiating even minimal enteral feedings as soon as feasible, avoiding sepsis by meticulous line care, avoiding overfeeding, using cysteine- and taurine-containing amino acid formulations designed for infants, preventing or treating small bowel bacterial overgrowth, protecting TPN solutions from light, and avoiding hepatotoxic medications.

Forchielli ML, Walker WA: Nutritional factors contributing to the development of cholestasis during parenteral nutrition. *Adv Pediatr* 2003;50:245 [PMID: 14626490].

NUTRIENT REQUIREMENTS & DELIVERY

Energy

When patients are fed intravenously, no fat and carbohydrate intakes are unabsorbed, and no energy is used in nutrient absorption. These factors account for at least 7% of energy in the diet of the enterally fed patient. The intravenously fed patient usually expends less energy in physical activity because of the impediment to mobility. Average energy requirements may therefore be lower in children fed intravenously, and the decrease in activity probably increases this figure to a total reduction of 10–15%. Caloric guidelines for the IV feeding of infants and young children are outlined below.

Age	Requirements (kcal/kg/d)
0-1 mo	100-110
2-4 mo	90-100
5-60 mo	70-90
> 5 y	1500 kcal for first 20 kg + 25 kcal for each additional kg/d

The guidelines are averages, and individuals vary considerably. Factors significantly increasing the energy requirement estimates include exposure to cold environment, fever, sepsis, burns, trauma, cardiac or pulmonary disease, and catch-up growth after malnutrition.

With few exceptions, such as some cases of respiratory insufficiency, at least 50–60% of energy requirements are provided as glucose. Up to 40% of calories may be provided by IV fat emulsions.

Dextrose

The energy density of IV dextrose (monohydrate) is 3.4 kcal/g. Dextrose is the main exogenous energy source provided by total IV feeding. IV dextrose suppresses gluconeogenesis and provides a substrate that can be oxidized directly, especially by the brain, red and white blood cells, and wounds. Because of the high osmolality of dextrose solutions (D₁₀W yields 505 mOsm/kg H₂O), concentrations greater than 10–12.5% cannot be delivered via a peripheral vein or improperly positioned central line.

Dosing guidelines: The standard initial quantity of dextrose administered will vary by age (Table 10–18). Tolerance to IV dextrose normally increases rapidly, due primarily to suppression of hepatic production of endogenous glucose. Dextrose can be increased by 2.5 g/kg/d; by 2.5–5% per day; or by 2–3 mg/kg/min per day if there is no glucosuria or hyperglycemia. Standard final infusate for infants via a

Table 10-18. Pediatric macronutrient guidelines for parenteral nutrition.

Age	Dextrose		Amino Acids	Lipid
	mg/kg/min	g/kg/d	g/kg/d	g/kg/d
	50-60% kcal		10-20% kcal	30-40% kcal
Preterm	Initial 5-8 Max 11-12.5	Initial 7-11 Max 16-18	Initial 1.5-2 Max 3-4	Initial 0.5-1 Max 2.5-3.5
Birth-12 mo	Initial 6-8 Max 11-15	Initial 9-11 Max 16-21.5	Initial 1.5-2 Max 3	Initial 1 Max 2.5-3.5
1-6 y	Initial 6-7 Max 10-12	Initial 8-10 Max 14-17	Initial 1-1.5 Max 2-2.5	Initial 1 Max 2.5-3.5
> 6 y	Initial 5-7 Max 9	Initial 8-10 Max 13	Initial 1 Max 1.5-2	Initial 1 Max 3
> 10 y	Initial 4-5 Max 6-7	Initial 5-7 Max 8-10	Initial 1 Max 1.5-2	Initial 1 Max 2-3
Adolescents	Initial 2-3 Max 5-6	Initial 3-4 Max 7-8	Initial 1 Max 1.5-2	Initial 0.5-1 Max 2

properly positioned central venous line usually ranges from 15–25% dextrose, although concentrations of up to 30% dextrose may be used at low flow rates. Tolerance to IV dextrose loads is markedly diminished in premature neonates and in hypermetabolic states.

Problems associated with IV dextrose administration include hyperglycemia, hyperosmolality, and glucosuria (with osmotic diuresis and dehydration). Possible causes of unexpected hyperglycemia include the following: (1) inadvertent infusion of higher glucose concentrations than ordered, (2) uneven flow rate, (3) sepsis, (4) a stress situation, and (5) pancreatitis. IV insulin reduces hyperglycemia but does not increase glucose oxidation rates; it may also decrease the oxidation of fatty acids, resulting in less energy for metabolism. Hence, insulin should be used very cautiously. A standard IV dose is 1 U/4 g of carbohydrate, but much smaller quantities may be adequate and, usually, one starts with 0.2–0.3 U/4 g of carbohydrate.

Hypoglycemia may occur after an abrupt decrease in or cessation of IV glucose. When cyclic IV nutrition is provided, the IV glucose load should be decreased steadily for 1–2 hours prior to discontinuing the infusate. If the central line must be removed, the IV dextrose should be tapered gradually over several hours.

Maximum oxidation rates for infused dextrose decrease with age. It is important to note that the ranges for dextrose administration provided in Table 10–18 are guidelines and that individual patient tolerance and clinical circumstances may warrant administration of either less or more dextrose. Quantities of exogenous dextrose in excess of maximal glucose oxidation rates are used initially to replace depleted

glycogen stores; hepatic lipogenesis occurs thereafter. Excess hepatic lipogenesis may lead to a fatty liver. Lipogenesis results in release of carbon dioxide, which when added to the amount of carbon dioxide produced by glucose oxidation (which is 40% greater than that produced by lipid oxidation) may elevate the PaCO₂ and aggravate respiratory insufficiency or impede weaning from a respirator.

Lipids

The energy density of lipid emulsions (20%) is 10 kcal/g of lipid or 2 kcal/mL of infusate. The lipids are derived from either soybean or safflower oil. All consist of more than 50% linoleic acid and 4–9% linolenic acid. It is recognized that this high level of linoleic acid is not ideal, except when small quantities of lipid are being given to prevent an EFA deficiency. Ultimately, improved emulsions are anticipated. Because 10% and 20% lipid emulsions contain the same concentrations of phospholipids, a 10% solution delivers more phospholipid per gram of lipid than a 20% solution. Twenty percent lipid emulsions are preferred.

The level of lipoprotein lipase (LPL) activity is the rate-limiting factor in the metabolism and clearance of fat emulsions from the circulation. LPL activity is inhibited or decreased by malnutrition, leukotrienes, immaturity, growth hormone, hypercholesterolemia, hyperphospholipidemia, and theophylline. LPL activity is enhanced by glucose, insulin, lipid, catecholamines, and exercise. Heparin releases LPL from the endothelium into the circulation and enhances the rate of hydrolysis and clearance of triglycerides. In small premature infants, low-dose heparin infusions may increase tolerance to IV lipid emulsion.

The advantages of using fat emulsions to provide up to 40% of caloric intake include the following:

1. The high energy density allows more energy to be provided when fluid volume is restricted.
2. The low osmolality (280 mOsm/kg H₂O) is of special value when using a peripheral line.
3. EFA deficiencies can be prevented.
4. The production of CO₂ is 40% lower per unit of energy, an important consideration in cases of pulmonary insufficiency.
5. The energy cost of fat storage is negligible.
6. The risk of fatty liver is decreased because of decreased hepatic lipogenesis from dextrose.

Potential disadvantages of fat emulsions include the following:

1. Impairment of function of neutrophils, macrophages, and the reticuloendothelial system.
2. Coagulation defects, including thrombocytopenia, elevated prothrombin time, and partial thromboplastin time.
3. Decrease in pulmonary oxygen diffusion.
4. Competition by free fatty acids with bilirubin and drugs for albumin-binding sites.
5. Increase in low-density lipoprotein cholesterol.

In general, these adverse effects can be avoided by starting with modest quantities and advancing cautiously in light of results of triglyceride monitoring and clinical circumstances. In cases of severe sepsis, special caution is required to ensure that the lipid is metabolized effectively. Monitoring with long-term use is also essential.

Dosing guidelines: Check serum triglycerides before starting and after increasing the dose. Commence with 1 g/kg/d, given over 12–20 hours or 24 hours in small preterm infants. Advance by 0.5–1.0 g/kg/d, every 1–2 days, up to goal (see Table 10–18).

As a general rule, do not increase the dose if the serum triglyceride level is above 250 mg/dL during infusion (150 mg/dL in neonates) or if the level is greater than 150 mg/dL 6–12 hours after cessation of the lipid infusion.

Serum triglyceride levels above 400–600 mg/dL may precipitate pancreatitis. In patients for whom normal amounts of IV lipid are contraindicated, 4–8% of calories as IV lipid should be provided (300 mg linoleic acid/100 kcal) to prevent essential fatty acid deficiency. Neonates and malnourished pediatric patients receiving lipid-free PN are at high risk for EFA deficiency because of limited adipose stores.

Nitrogen

One gram of nitrogen is yielded by 6.25 g of protein (1 g of protein contains 16% nitrogen). Caloric density of protein is equal to 4 kcal/g.

A. Protein Requirement

Protein requirements for IV feeding are the same as those for normal oral feeding (see Table 10–2).

B. Protein-Energy Interactions

There are important interactions between protein and energy requirements. A positive nitrogen balance cannot be achieved on a hypocaloric diet, because protein will be catabolized for energy. When energy intake is low, the administration of some amino acid does, however, lessen the severity of the negative nitrogen balance. Conversely, when nitrogen intake is low, the provision of calories improves nitrogen balance to some extent. In infants, the energy necessary to minimize nitrogen loss associated with an amino acid-free diet is approximately 70 kcal/kg/d. At this level of energy intake, positive nitrogen balance depends on the level of nitrogen intake and is independent of further increase in energy intake.

In infants receiving about 50 kcal/kg/d, increasing protein intake up to 3 g/kg/d improves the nitrogen balance. In these circumstances, therefore, a ratio of grams of nitrogen per kilocalorie as low as 1:100 can be advantageous. However, at higher levels of energy intake, ratios of 1:250 to 1:150 or more are optimal. Although these ratios provide a useful crude check, they are not usually the best means of determining protein requirements.

C. Intravenous Amino Acid Solutions

Nitrogen requirements can be met by one of the commercially available amino acid solutions. For older children and adults, none of the standard preparations has a clear advantage over the others as a source of amino acids. For infants, however, including premature infants, accumulating evidence suggests that the use of TrophAmine (B. Braun Medical) is associated with a normal plasma amino acid profile, superior nitrogen retention, and a lower incidence of cholestasis. TrophAmine contains 60% essential amino acids, is relatively high in branched-chain amino acids, contains taurine, and is compatible with the addition of cysteine within 24–48 hours after administration. The dose of added cysteine is 40 mg/g of TrophAmine. The relatively low pH of TrophAmine is also advantageous for solubility of calcium and phosphorus.

D. Dosing Guidelines

Amino acids can be started at 1–2 g/kg/d in most patients (see Table 10–18). In severely malnourished infants, the initial amount should be 1 g/kg/d. Even in infants of very low birth weight, there is evidence that higher initial amounts of amino acids are tolerated with little indication of protein “toxicity.” Larger quantities of amino acids in relation to calories can minimize the degree of negative nitrogen balance when the infusate is hypocaloric. Amino acid intake can be advanced by 0.5–1.0 g/kg/d toward the goal. Normally the

final infusate will contain 2–3% amino acids, depending on the rate of infusion. Concentration should not be advanced beyond 2% in peripheral vein infusate due to osmolality.

E. Monitoring

Monitoring for tolerance of the IV amino acid solutions should include routine blood urea nitrogen. Serum alkaline phosphatase, γ -glutamyltransferase, and bilirubin should be monitored to detect the onset of cholestatic liver disease.

Minerals & Electrolytes

A. Calcium, Phosphorus, and Magnesium

Intravenously fed premature and full-term infants should be given relatively high amounts of calcium and phosphorus. Current recommendations are as follows: calcium, 500–600 mg/L; phosphorus, 400–450 mg/L; and magnesium, 50–70 mg/L. After 1 year of age, the recommendations are as follows: calcium, 200–400 mg/L; phosphorus, 150–300 mg/L; and magnesium, 20–40 mg/L. The ratio of calcium to phosphorus should be 1.3:1.0 by weight or 1:1 by molar ratio. These recommendations are deliberately presented as milligrams per liter of infusate to avoid inadvertent administration of concentrations of calcium and phosphorus that are high enough to precipitate in the tubing. During periods of fluid restriction, care must be taken not to inadvertently increase the concentration of calcium and phosphorus in the infusate. These recommendations assume an average fluid intake of 120–150 mL/kg/d and an infusate of 25 g of amino acid per liter. With lower amino acid concentrations, the concentrations of calcium and phosphorus should be decreased.

B. Electrolytes

Standard recommendations are given in Table 10–19. After chloride requirements are met, the remainder of the anion required to balance the cation should be given as acetate to avoid the possibility of acidosis resulting from excessive chloride. The required concentrations of electrolytes depend to some extent on the flow rate of the infusate and must be modified if flow rates are unusually low or high and if there

are specific indications in individual patients. IV sodium should be administered sparingly in severely malnourished patients because of impaired membrane function and high intracellular sodium levels. Conversely, generous quantities of potassium are indicated. Replacement electrolytes and fluids should be delivered via a separate infusate.

C. Trace Elements

Recommended IV intakes of trace elements are as follows: zinc, 100 mcg/kg; copper, 20 mcg/kg; manganese, 1 mcg/kg; chromium, 0.2 mcg/kg; selenium, 2 mcg/kg; and iodide, 1 mcg/kg. Of note, IV zinc requirements may be as high as 400 mcg/kg for premature infants and can be up to 250 mcg/kg for infants with short bowel syndrome and significant GI losses of zinc. When IV nutrition is supplemental or limited to fewer than 2 weeks, and preexisting nutritional deficiencies are absent, only zinc need routinely be added.

IV copper requirements are relatively low in the young infant because of the presence of hepatic copper stores. These are significant even in the 28-week fetus. Circulating levels of copper and manganese should be monitored in the presence of cholestatic liver disease. If monitoring is not feasible, temporary withdrawal of added copper and manganese is advisable. Copper and manganese are excreted primarily in the bile, but selenium, chromium, and molybdenum are excreted primarily in the urine. These trace elements, therefore, should be administered with caution in the presence of renal failure.

Although low doses of iron are routinely added in some centers to the IV infusate for infants and children, no official recommendation has been made because of the lack of adequate published data regarding compatibility. Iron added to the infusate should be in a diluted form of iron dextran in a concentration of 1 mg/L. After age 2 months, maintenance IV iron requirements for the full-term infant are approximately 100 mcg/kg/d. After the first month, the premature infant requires up to 200 mcg/kg/d intravenously. Although overload is unlikely to occur during short-term PN, surreptitious accumulation of extra iron could occur if PN is prolonged. This risk is enhanced if the patient has received blood transfusions. A second concern is that the potential for free iron is increased in malnourished infants with low transferrin levels. Excess iron is thought to enhance the risk of gram-negative septicemia. Iron has powerful oxidant properties and can enhance the demand for antioxidants, especially vitamin E. None of these concerns appears to preclude the routine use of iron supplements during IV nutrition, but they do emphasize the need for a conservative approach in determining dosage schedules.

Vitamins

Two vitamin formulations are available for use in pediatric PN: MVI Pediatric and MVI-12 (Astra-Zeneca). MVI Pediatric contains the following: vitamin A, 0.7 mg; vitamin D, 400 IU; vitamin E, 7 mg; vitamin K, 200 mcg; ascorbic acid, 80

Table 10–19. Electrolyte requirements for parenteral nutrition.

Electrolyte	Preterm Infant	Full-Term Infant	Child	Adolescent
Sodium	2-5 mEq/kg	2-3 mEq/kg	2-3 mEq/kg	60-150 mEq/d
Chloride	2-5 mEq/kg	2-3 mEq/kg	2-3 mEq/kg	60-150 mEq/d
Potassium	2-3 mEq/kg	2-3 mEq/kg	2-3 mEq/kg	70-180 mEq/d

mg; thiamin, 1.2 mg; riboflavin, 1.4 mg; niacinamide, 17 mg; pyridoxine, 1 mg; vitamin B₁₂, 1 mcg; folic acid, 140 mcg; pantothenate, 5 mg; and biotin, 20 mcg. This formulation is suboptimal, with too little vitamin A and excessive amounts of water-soluble vitamins, but it is the best one available. Recommended dosing is as follows: 5 mL for children weighing more than 3 kg, 3.25 mL for infants 1–3 kg, and 1.5 mL for infants weighing less than 1 kg. Children older than 11 years can receive 10 mL of the adult formulation, MVI-12, which contains the following: vitamin A, 1 mg; vitamin D, 200 IU; vitamin E, 10 mg; ascorbic acid, 100 mg; thiamin, 3 mg; riboflavin, 3.6 mg; niacinamide, 40 mg; pyridoxine, 4 mg; vitamin B₁₂, 5 mcg; folic acid, 400 mcg; pantothenate, 15 mg; and biotin, 60 mcg. MVI-12 contains no vitamin K.

IV lipid preparations contain enough tocopherol to affect total blood tocopherol levels. The majority of tocopherol in soybean oil emulsion is α -tocopherol, which has substantially less biologic activity than the α -tocopherol present in safflower oil emulsions.

A dose of 40 IU/kg/d of vitamin D (maximum 400 IU/d) is adequate for both full-term and preterm infants.

Fluid Requirements

The initial fluid volume and subsequent increments in flow rate are determined by basic fluid requirements, the patient's

clinical status, and the extent to which additional fluid administration can be tolerated and may be required to achieve adequate nutrient intake. Calculation of initial fluid volumes to be administered should be based on standard pediatric practice. Tolerance of higher flow rates must be determined on an individual basis. If replacement fluids are required for ongoing abnormal losses, these should be administered via a separate line.

Monitoring

Vital signs should be checked on each shift. In a patient with a central catheter in situ, a fever of more than 38.5°C requires that peripheral and central-line blood cultures, urine culture, complete physical examination, and examination of the IV entry point be made. Instability of vital signs, elevated white blood cell count with left shift, and glycosuria suggest sepsis. Removal of the central venous catheter should be considered if the patient is toxic or unresponsive to antibiotics.

A. Physical Examination

Monitor especially for hepatomegaly (differential diagnoses include fluid overload, congestive heart failure, steatosis, and hepatitis) and edema (differential diagnoses include fluid overload, congestive heart failure, hypoalbuminemia, and thrombosis of superior vena cava).

Table 10-20. Routine parenteral nutrition monitoring summary.

Variables	Acute Stage	Long-Term ^a
Growth		
Weight	Daily	Weekly
Length	Weekly	
Head circumference	Weekly	
Urine		
Glucose (dipstick)	With each void	With changes in intake or status
Specific gravity	Void	
Volume	Daily	
Blood		
Glucose	4 hours after changes, ^b then daily × 2 days	Weekly
Na ⁺ , K ⁺ , Cl ⁻ , CO ₂ , blood urea nitrogen	Daily for 2 days after changes, ^b then twice weekly	Weekly
Ca ²⁺ , Mg ²⁺ , P	Initially, then twice weekly	Weekly
Total protein, albumin, bilirubin, aspartate transaminase, and alkaline phosphatase	Initially, then weekly	Every other week
Zinc and copper	Initially according to clinical indications	Monthly
Triglycerides	Initially, 1 day after changes, ^b then weekly	Weekly
Complete blood count	Initially, then twice weekly; according to clinical indications (see text)	Twice weekly

^aLong-term monitoring can be tapered to monthly or less often, depending on age, diagnosis, and clinical status of patient.

^bChanges include alterations in concentration or flow rate.

B. Intake and Output Record

Calories and volume delivered should be calculated from the previous day's intake and output records (that which was delivered rather than that which was ordered). The following entries should be noted on flow sheets: IV, enteral, and total fluid (mL/kg/d); dextrose (g/kg/d or mg/kg/min); protein (g/kg/d); lipids (g/kg/d); energy (kcal/kg/d); and percent of energy from enteral nutrition.

C. Growth, Urine, and Blood

Routine monitoring guidelines are given in Table 10–20. These are minimum requirements, except in the very long-term stable patient. Individual variables should be moni-

tored more frequently as indicated, as should additional variables or clinical indications. For example, a blood ammonia analysis should be ordered for an infant with lethargy, pallor, poor growth, acidosis, azotemia, or abnormal liver test results.

Emergencies & Injuries

Maria J. Mandt, MD
Glenn Faries, MD

ADVANCED LIFE SUPPORT FOR INFANTS & CHILDREN

When faced with a seriously ill or injured child, a systematic approach and rapid determination of the child's physiologic status with concurrent initiation of resuscitative measures is imperative. Initial management must be directed at correcting any physiologic derangement. Specifically, one must evaluate the airway for any obstruction, assess ventilatory status, and evaluate for shock. Intervention to correct any abnormalities in these three parameters must be undertaken immediately. Following this initial intervention the provider must then carefully consider the underlying cause, focusing on those that are treatable or reversible. Specific diagnoses can then be made, and targeted therapy (eg, intravenous [IV] glucose for hypoglycemia) can be initiated.

Pediatric cardiac arrest more frequently represents progressive respiratory deterioration or shock rather than primary cardiac etiologies. Unrecognized deterioration may lead to bradycardia, agonal breathing, and ultimately asystole. Resulting hypoxic and ischemic insult to the brain and other vital organs make neurologic recovery extremely unlikely, even in the doubtful event that the child survives the arrest. Children who respond to rapid intervention with ventilation and oxygenation alone or to less than 5 minutes of advanced life support are much more likely to survive neurologically intact. Therefore, it is essential to recognize the child who is at risk for progressing to cardiopulmonary arrest and to provide aggressive intervention before asystole occurs.

Note: Standard precautions (personal protective equipment) must be maintained during resuscitation efforts.

THE ABCS OF RESUSCITATION

Any severely ill child should be rapidly evaluated in a deliberate sequence of *airway* patency, *breathing* adequacy, and *circulation* integrity. Derangement at each point must be

corrected before proceeding. Thus, if a child's airway is obstructed, the airway must be opened (eg, by head positioning and the chin lift maneuver) before breathing and circulation are assessed.

Airway

Look, listen, and feel for upper airway patency: *Look* for chest or abdominal wall movement suggestive of breathing effort. *Listen* for adventitious breath sounds such as stridor, stertor, or gurgling. Placing a stethoscope at the mouth or over the trachea improves the ability to hear air entry. *Feel* for air movement with your face near the child's mouth and nose. Evidence of spontaneous breathing effort and increased work of breathing without air movement is suggestive of airway obstruction. Significant airway obstruction often is associated with altered level of consciousness, including agitation or lethargy.

The airway is managed initially by noninvasive means such as oxygen administration, chin lift, jaw thrust, suctioning, or bag–valve–mask ventilation. Invasive maneuvers such as endotracheal intubation, laryngeal mask insertion, or rarely, cricothyroidotomy are required if the aforementioned maneuvers are unsuccessful. If neck injury is suspected, the cervical spine must be immobilized and kept from extension or flexion. (See section on Approach to the Pediatric Trauma Patient, later.) The following discussion assumes that basic life support has been instituted.

Knowledge of pediatric anatomy is important for airway management. Children's tongues are large relative to their oral cavities, and the larynx is high and anteriorly located. Infants are obligate nasal breathers; therefore, secretions or blood in the nasopharynx can cause significant distress.

A. Place the head in the sniffing position. The neck should be slightly flexed and the head gently extended so as to bring the face forward. This position aligns the oral, pharyngeal, and tracheal planes. Reposition the head if airway obstruction persists after head tilt and jaw thrust. In infants and children younger than about 8 years of age, the

▲ **Figure 11-1.** Correct positioning of the child younger than age 8 years for optimal airway alignment: a folded sheet or towel is placed beneath the shoulders to accommodate the occiput and align the oral, pharyngeal, and tracheal airways.

relatively large occiput causes significant neck flexion and poor airway positioning. This is relieved by placing a towel roll under the shoulders, thus returning the child to a neutral position (Figure 11-1). In an older child, slightly more head extension is necessary. Avoid hyperextension of the neck, especially in infants.

B. Perform the chin lift or jaw thrust maneuver (Figure 11-2). Lift the chin upward while avoiding pressure on the submental triangle, or lift the jaw by traction upward on the

angle of the jaw. **Head tilt must not be done if cervical spine injury is possible.**

C. Suction the mouth of any foreign material.

D. Remove visible foreign bodies, using fingers or a Magill forceps. Visualize by means of a laryngoscope if necessary. Blind finger sweeps should not be done.

E. Insert an oropharyngeal airway or a nasopharyngeal airway in the conscious patient (Figure 11-3) to relieve upper airway obstruction due to prolapse of the tongue into the posterior pharynx. This is the most common cause of airway obstruction in unconscious children. The correct size for an oropharyngeal airway is obtained by measuring from the upper central gumline to the angle of the jaw (Figure 11-4). Nasopharyngeal airways should fit snugly within the nares and should be equal in length to the distance from the nares to the tragus (Figure 11-5).

Breathing

Assessment of respiratory status is largely accomplished by inspection. *Look* for adequate and symmetrical chest rise and fall, rate and work of breathing (eg, retractions, flaring, and grunting), accessory muscle use, skin color, and tracheal deviation. Note the mental status. Pulse oximetry measurement and end-tidal CO₂ determination, if available, are highly desirable. *Listen* for adventitious breath sounds such as wheezing. Auscultate for air entry, symmetry of breath sounds, and rales. *Feel* for subcutaneous crepitus.

If spontaneous breathing is inadequate, initiate positive-pressure ventilation with bag-mask ventilation and 100% oxygen and coordinate bagging with the patient's efforts, if present. Ensure a proper seal by choosing a mask that encompasses the area from the bridge of the nose to the cleft

A

of the chin. Form an E–C clamp around the mask to seal the mask tightly to the child’s face. The thumb and index finger form the “C” surrounding the mask, while the middle, ring, and little fingers lift the jaw into the mask (Figure 11–6). Two-person ventilation using the technique is optimal. Adequacy of ventilation is reflected in adequate chest movement and auscultation of good air entry bilaterally. If the chest does not rise and fall easily with bagging, reposition the

airway as previously described. Perform airway foreign body extraction maneuvers if the airway remains obstructed, including visualizing the airway with a laryngoscope and using Magill forceps. The presence of asymmetrical breath sounds in a child in shock or in severe distress suggests pneumothorax and is an indication for needle thoracostomy. In small children, the transmission of breath sounds throughout the chest may impair the ability to auscultate the

presence of a pneumothorax. Bag-mask ventilation is effective in the *vast* majority of cases.

Note: Effective oxygenation and ventilation are the keys to successful resuscitation.

Using cricoid pressure (Sellick maneuver) during all positive-pressure ventilation, intubate the trachea in patients who are unresponsive to bag-mask ventilation, those in coma, those who require airway protection, or those who will require prolonged ventilation. Cricothyroidotomy is rarely necessary. Advanced airway management techniques are described in the references accompanying this section. (See also section on Approach to the Pediatric Trauma Patient, later.)

Circulation

The diagnosis of shock can and should be made by clinical examination, and must be done rapidly. Clinical assessments A–F aid in assessing perfusion.

A. Pulses

Check adequacy of peripheral pulses. Pulses become weak and thready only with severe hypovolemia. Compare peripheral pulses with central pulses.

B. Heart Rate

Compare with age-specific norms. Tachycardia can be a nonspecific sign of distress; bradycardia for age is a prearrest sign and necessitates aggressive resuscitation.

C. Extremities

As shock progresses, extremities become cooler, from distal to proximal. A child whose extremities are cool distal to the elbows and knees is in severe shock.

D. Capillary Refill Time

This is an important indicator of perfusion; longer than 2 seconds is abnormal unless the child is cold.

E. Mental Status

Hypoxia, hypercapnia, or ischemia will result in altered mental status. Other important treatable conditions may also result in altered mental status, such as intracranial hemorrhage, meningitis, and hypoglycemia.

F. Skin Color

Pallor, gray, mottled, or ashen skin colors all indicate compromised circulatory status.

G. Blood Pressure

It is important to remember that shock (inadequate perfusion of vital organs) may be present before the blood pressure falls below the normal limits for age. As intravascular volume falls, peripheral vascular resistance increases. Blood pressure is maintained until there is 35–40% depletion of blood volume, followed by precipitous and often irreversible deterioration. Shock that occurs with any signs of decreased perfusion but normal blood pressure is **compensated** shock. When blood pressure also falls, **decompensated** shock is present. Blood pressure determination should be done manually, using an appropriately sized cuff, because automated machines can give erroneous readings in children.

MANAGEMENT OF SHOCK

IV access is essential but can be difficult to establish in children with shock. Peripheral access, especially via the antecubital veins, should be attempted first, but central cannulation should follow quickly if peripheral access is unsuccessful. Alternatives are percutaneous cannulation of femoral, subclavian, or internal or external jugular veins; cutdown at antecubital, femoral, or saphenous sites; or intraosseous (IO) lines (Figure 11–7). Consider IO needle placement in any severely ill child when venous access cannot be established rapidly. Decisions on more invasive access should be based on individual expertise as well as urgency of obtaining access. Use short, wide-bore catheters to allow maximal flow rates. Two IV lines should be started in severely ill children. In newborns, the umbilical veins may be cannulated. Consider arterial access if beat-to-beat monitoring or frequent laboratory tests will be needed.

Differentiation of Shock States & Initial Therapy

Therapy for inadequate circulation is determined by the cause of circulatory failure.

A. Hypovolemic Shock

The most common type of shock in the pediatric population is hypovolemia. Frequent causes include dehydration, diabetes, heat illness, hemorrhage, and burns. Normal saline or lactated Ringer solution (isotonic crystalloid) is given as initial therapy. Give 20 mL/kg body weight, repeated as necessary, with frequent reassessments, until perfusion normalizes. Children tolerate large volumes of fluid replacement. Typically, in hypovolemic shock, no more than 50 mL/kg is needed, but more may be required if ongoing losses are severe. Appropriate monitoring and reassessment will guide your therapy. Packed red blood cell transfusion is indicated in trauma patients not responding to two boluses of crystalloid solution. Pressors are not required in simple hypovolemic states.

▲ **Figure 11–7.** Interosseous (IO) cannulation technique. The IO line is inserted by grasping the needle hub firmly with the palm of the hand and angling the needle tip perpendicular to the anterior tibial surface approximately two fingerbreadths distal to the tibial plateau. With a firm, twisting motion, advance the needle until a sudden lessening of resistance is felt as the needle enters the marrow space. Aspiration of blood and marrow confirms IO placement.

B. Distributive Shock

Distributive shock results from increased vascular capacitance with normal circulating volume. Examples are sepsis, anaphylaxis, and spinal cord injury. Initial therapy is again isotonic volume replacement with crystalloid, but pressors may be required if perfusion does not normalize after delivery of two 20-mL/kg boluses of crystalloid. Children in distributive shock must be admitted to a pediatric intensive care unit.

C. Cardiogenic Shock

Cardiogenic shock can occur as a complication of congenital heart disease, myocarditis, dysrhythmias, ingestions (eg, clonidine, cyclic antidepressants), or as a complication of prolonged shock due to any cause. The diagnosis is suggested by any of the following signs: abnormal cardiac rhythm,

distended neck veins, rales, abnormal heart sounds such as an S_3 or S_4 , friction rub, narrow pulse pressure, or hepatomegaly. Chest radiographs may show cardiomegaly and pulmonary edema. An initial bolus of crystalloid may be given, but pressors, and possibly afterload reducers, are necessary to improve perfusion. Giving multiple boluses of fluid is deleterious. Comprehensive cardiopulmonary monitoring is essential. Children in cardiogenic shock must be admitted to a pediatric intensive care unit.

► Observation & Further Management

Clinically reassess physiologic response to each fluid bolus to determine additional needs. Serial central venous pressure determinations or a chest radiograph may help determine volume status. Place an indwelling urinary catheter to monitor urine output.

Caution must be exercised with volume replacement if intracranial pressure is potentially elevated, as in severe head injury, diabetic ketoacidosis, or meningitis. Even in such situations, however, normal intravascular volume must be restored in order to achieve adequate mean arterial pressure and, thus, cerebral perfusion pressure.

SUMMARY OF CARDIOPULMONARY RESUSCITATION

Assess the ABCs in sequential fashion and, before assessing the next system, immediately intervene if physiologic derangement is detected. It is essential that each system be reassessed after each intervention to ensure improvement and prevent failure to recognize clinical deterioration.

EMERGENCY PEDIATRIC DRUGS

Although careful attention to airway and breathing remains the mainstay of pediatric resuscitation, medications are often needed. Rapid delivery to the central circulation, which can be via peripheral IV catheter, is essential. Infuse medications close to the catheter's hub and flush in with saline to achieve the most rapid systemic effects. If no IV or IO access is achievable, some drugs may be given by endotracheal tube (Table 11–1). The use of length-based emergency measuring tapes that contain preprinted drug dos-

Lidocaine
Epinephrine
Atropine
Naloxone

ages, equipment sizes, and IV fluid amounts (Broselow tapes) or preprinted resuscitation drug charts is much more accurate than estimation formulas and helps minimize dosing errors. Selected emergency drugs used in pediatrics are summarized in Table 11–2.

APPROACH TO THE SERIOUSLY ILL CHILD

An unstable patient may present with a known diagnosis (asthma with status asthmaticus and respiratory failure; complications of known congenital heart disease) or in cardiorespiratory failure of unknown cause. The initial approach must rapidly identify and reverse life-threatening conditions. Children with chronic disease may present with an acute exacerbation or secondary to a new, unrelated problem.

PREPARATION FOR EMERGENCY MANAGEMENT

Resuscitation occurs simultaneously at two levels: rapid cardiopulmonary assessment, with indicated stabilizing measures, while venous access is gained and cardiopulmonary monitoring initiated. The technique of accomplishing these concurrent goals is outlined as follows:

A. If advance notice of the patient's arrival has been received, prepare a resuscitation room and summon appropriate personnel as needed, such as a neurosurgeon for an unresponsive child after severe head injury or a radiology technician for imaging studies.

B. Assign team responsibilities, including a team leader plus others designated to manage the airway, perform chest compressions, achieve access, draw blood for laboratory studies, place monitors, gather additional historical data, and provide family support. The team approach is invaluable.

C. Age-appropriate equipment (including laryngoscope blade, endotracheal tubes, nasogastric or orogastric tubes, IV lines, and an indwelling urinary catheter) and monitors (cardiorespiratory monitor, pulse oximeter, and appropriate blood pressure cuff) should be assembled and readily available. Use a length-based emergency tape if available. See Table 11–3 for endotracheal tube sizes. Cuffed endotracheal tubes are acceptable during the inpatient setting for children and infants beyond the newborn period. Cuff inflation pressures must be carefully

Table 11-2. Emergency pediatric drugs.

Drug	Indications	Dosage and Route	Comment
Atropine	<ol style="list-style-type: none"> 1. Bradycardia, especially cardiac in origin 2. Vagally mediated bradycardia, eg, during laryngoscopy and intubation 3. Anticholinesterase poisoning 	0.01–0.02 mg/kg (minimum, 0.1 mg; maximum, 2 mg) IV, IO, ET. May repeat every 5 min.	Atropine may be useful in hemodynamically significant primary cardiac-based bradycardias. Because of paradoxical bradycardia sometimes seen in infants, a minimum dose of 0.1 mg is recommended by the American Heart Association. Epinephrine is the first-line drug in pediatrics for bradycardia caused by hypoxia or ischemia.
Bicarbonate	<ol style="list-style-type: none"> 1. Documented metabolic acidosis 2. Hyperkalemia 	1 mEq/kg IV or IO; by arterial blood gas: $0.3 \times \text{kg} \times \text{base deficit}$. May repeat every 5 min.	Infuse slowly. Sodium bicarbonate will be effective only if the patient is adequately oxygenated, ventilated, and perfused. Some adverse side effects.
Calcium chloride 10%	<ol style="list-style-type: none"> 1. Documented hypocalcemia 2. Calcium channel blocker overdose 3. Hyperkalemia, hypermagnesemia 	10–30 mg/kg slowly IV, preferably centrally, or IO with caution.	Calcium is no longer indicated for asystole. Potent tissue necrosis results if infiltration occurs. Use with caution.
Epinephrine	<ol style="list-style-type: none"> 1. Bradycardia, especially hypoxic-ischemic 2. Hypotension (by infusion) 3. Asystole 4. Fine ventricular fibrillation refractory to initial defibrillation 5. Pulseless electrical activity 6. Anaphylaxis 	<p><i>Bradycardia and cardiac arrest:</i> IV/IO: 0.01 mg/kg of 1:10,000 solution. ET: 0.1 mg/kg of 1:1,000 solution.</p> <p><i>Anaphylaxis:</i> SC/IM: 0.01 mg/kg of 1:1000 solution. Maximum dose: 0.3 mg. May repeat every 5–15 min. Constant infusion by IV drip: 0.1–1 mcg/kg/min</p>	Epinephrine is the single most important drug in pediatric resuscitation. Recent pediatric studies have shown no added advantage to high-dose epinephrine in terms of survival to discharge or neurologic outcome. Because other studies have indicated adverse effects, including increased myocardial oxygen consumption during resuscitation and worsened postarrest myocardial dysfunction, high-dose epinephrine is no longer recommended.
Glucose	<ol style="list-style-type: none"> 1. Hypoglycemia 2. Altered mental status (empirical) 3. With insulin, for hyperkalemia 	0.25–0.5g/kg IV or IO. Continuous infusion may be necessary.	2–4 mL/kg D ₁₀ W, 1–2 mL/kg D ₂₅ W.
Naloxone	<ol style="list-style-type: none"> 1. Opioid overdose 2. Altered mental status (empirical) 	0.1 mg/kg IV, IO, or ET; maximum dose, 2 mg. May repeat as necessary.	Side effects are few. A dose of 2 mg may be given in young children. Repeat as necessary, or give as constant infusion in opioid overdoses.

D₅W, 5% glucose in water; ET, endotracheally; IO, intraosseously; IV, intravenously; SC, subcutaneously.

monitored and maintained below 20 cm H₂O. In certain circumstances, such as poor lung compliance or high airway resistance, the use of cuffed tubes may be preferable in controlled settings.

RECEPTION & ASSESSMENT

Upon patient arrival, the team leader begins a rapid assessment as team members perform their preassigned tasks. If the patient is received from prehospital care providers, careful attention must be paid to their report, which contains information that they alone have observed. Interventions and medications should be ordered only by the team leader to avoid confusion. The leader should refrain from personally performing procedures, which may distract him or her

from optimal direction of the resuscitation. A complete timed record should be kept of events, including medications, interventions, and response to intervention.

All Cases

In addition to cardiac compressions and ventilation, ensure that the following are instituted:

1. 100% high-flow oxygen.
2. Cardiorespiratory monitoring, pulse oximetry, and end-tidal CO₂ if the patient is intubated.
3. Vascular (peripheral, IO, or central) access; two lines preferred.
4. Blood drawn and sent. Bedside blood glucose determination is essential.

APPROACH TO THE PEDIATRIC TRAUMA PATIENT

Injuries, including motor vehicle crashes, falls, burns, and immersions, account for the greatest number of deaths among children older than age 1 year. All providers of pediatric care must be cognizant of this sobering statistic. Cooperative efforts between injury prevention specialists, prehospital providers, and emergency, critical care, and rehabilitation physicians and nurses will help reduce these terrible losses.

A team approach to the severely injured child, using assigned roles as outlined in the preceding section, will optimize outcomes. A calm atmosphere in the receiving area will contribute to thoughtful care. Conscious children are terribly frightened by serious injury; reassurance can help alleviate anxiety. Analgesia and sedation must be given to stable patients. It is unconscionable to let children suffer pain needlessly. Treat pain expeditiously using oral or parenteral analgesics with ongoing monitoring. Parents are often anxious, angry, or guilty, requiring ongoing support from staff, social workers, or child life workers (therapists knowledgeable about child development). To provide optimal multidisciplinary care, regional pediatric trauma centers provide dedicated teams of pediatric specialists in emergency pediatrics, trauma surgery, orthopedics, neurosurgery, and critical care. Most children with severe injuries are not seen

in these centers. Primary care providers must be able to provide initial assessment and stabilization of the child with life-threatening injuries before transport to a verified pediatric trauma center.

MECHANISM OF INJURY

Document the time of occurrence, the type of energy transfer (eg, hit by a car, rapid deceleration), secondary impacts (if the child was thrown by the initial impact), appearance of the child at the scene, interventions performed, and clinical condition during transport. The report of emergency service personnel is invaluable. Forward all of this information with the patient to the referral facility if secondary transport occurs.

Trauma in children is predominantly blunt, with penetrating trauma occurring in 10% of cases. Head and abdominal injuries are particularly common and important.

INITIAL ASSESSMENT & MANAGEMENT

The vast majority of children who reach a hospital alive survive to discharge. As most deaths from trauma in children are due to head injuries, cerebral resuscitation must be the foremost consideration when treating children with serious injuries. The ultimate measure of outcome is the child's eventual level of functioning. Strict attention to the ABCs ensures optimal oxygenation, ventilation, and perfusion, and ultimately, cerebral perfusion.

The primary and secondary survey is a method for evaluating and treating injured patients in a systematic way that provides a rapid assessment and stabilization phase, followed by a head-to-toe examination and definitive care phase.

PRIMARY SURVEY

The primary survey is designed to immediately identify and treat all physiologic derangements resulting from trauma. It is the resuscitation phase. Priorities are still airway, breathing, and circulation, but with important further considerations in the trauma setting:

- Airway, with cervical spine control
- Breathing
- Circulation, with hemorrhage control
- Disability (neurologic deficit)
- Exposure (maintain a warm Environment, undress the patient completely, and Examine)

Evaluation and treatment of the ABCs are discussed earlier in this chapter. Modifications in the trauma setting are added in the sections that follow.

Airway

Failure to manage the airway appropriately is the most common cause of **preventable** morbidity and death. Administer

100% high-flow oxygen to all patients. During assessment and management of the airway, provide cervical spine protection, initially by manual inline immobilization, not traction. A hard cervical spine collar is then applied. The head and body are secured to a backboard, surrounded by a lightweight means of cushioning (eg, rolled blankets) to further immobilize the head and body and allow log-rolling of the child in case of vomiting. Assess the airway for patency. Use jaw thrust rather than chin lift during intubation to avoid flexion or extension of the neck. Suction the mouth and pharynx free of blood, foreign material, or secretions, and remove loose teeth. Insert an oropharyngeal airway if upper airway noises are heard or obstruction from posterior prolapse of the tongue occurs. A child with a depressed level of consciousness (Glasgow Coma Scale score < 9), a need for prolonged ventilation or hyperventilation, severe head trauma, or an impending operative intervention requires endotracheal intubation after bag-mask preoxygenation. Orotracheal intubation is the route of choice and is possible without cervical spine manipulation. Nasotracheal intubation may be possible in children 12 years of age or older who have spontaneous respirations—if not contraindicated by midfacial injury with the possibility of cribriform plate disruption. Laryngeal mask airway (LMA) devices are being used with increasing frequency, in both the prehospital and hospital settings. The device consists of a flexible tube attached to an inflatable rubber mask (Figure 11–8). The LMA is inserted blindly into the hypopharynx and is seated over the larynx, occluding the esophagus. Advantages to its use include ease of insertion, lower potential for airway trauma, and higher success rates. Patients remain at higher risk for aspiration with LMA use compared with orotracheal intubation; therefore, the LMA should not be used for prolonged, definitive airway management. Rarely, if tracheal intubation cannot be accomplished—particularly in the setting of massive facial trauma—cricothyroidotomy may be necessary. Needle cricothyroidotomy using a large-bore catheter through the cricothyroid membrane is the procedure of choice in patients younger than age 12 years. Operative revision will be needed for formal controlled tracheostomy.

Breathing

Most ventilatory problems are resolved adequately by the airway maneuvers described earlier in this chapter and by positive-pressure ventilation. Breathing assessment is as described previously: Assess for an adequate rate and for symmetrical chest rise, work of breathing, color, tracheal deviation, crepitus, flail segments, deformity, or penetrating wounds. Sources of traumatic pulmonary compromise include pneumothorax, hemothorax, pulmonary contusion, flail chest, and central nervous system (CNS) depression. Asymmetrical breath sounds, particularly with concurrent tracheal deviation, cyanosis, or bradycardia, suggest pneumothorax, possibly under tension. To evacuate a tension pneumothorax, insert a large-bore catheter-over-needle assembly attached to a syringe through the second intercostal

▲ **Figure 11-8.** Laryngeal mask airways of various sizes.

space in the midclavicular line into the pleural cavity and withdraw air. If a pneumothorax or hemothorax is present, place a chest tube in the fourth intercostal space in the anterior axillary line. Connect to water seal. Insertion should be over the rib to avoid the neurovascular bundle that runs below the rib margin. Open pneumothoraces can be treated temporarily by taping petrolatum-impregnated gauze on three sides over the wound, creating a flap valve.

Circulation

After airway and breathing interventions have begun, hemodynamic status should be addressed. In addition to the circulatory assessment previously discussed, evaluation for ongoing external or internal hemorrhage is also important in the trauma evaluation. Large-bore IV access should be obtained early during the assessment, preferably at two sites. If peripheral access is not readily available, a central line, cutdown, or IO line is established. A cardiorespiratory monitor and oximeter is applied, usually at patient arrival. Peripheral perfusion and blood pressure should be assessed and recorded at frequent intervals. Determine hematocrit

and urinalysis in all patients. Blood type and cross-match should be obtained in the hypotensive child unresponsive to isotonic fluid boluses or with known hemorrhage. Consider coagulation studies, chemistry panel, liver transaminases, amylase, and toxicologic screening as clinically indicated.

External hemorrhage can be controlled by direct pressure. To avoid damage to adjacent neurovascular structures, avoid placing hemostats on vessels, except in the scalp. Determination of the site of internal hemorrhage can be challenging. Sites include the chest, abdomen, retroperitoneum, pelvis, and thighs. Bleeding into the intracranial vault rarely causes shock in children except in infants. Evaluation by an experienced clinician with adjunctive computed tomography (CT) or ultrasound will localize the site of internal bleeding.

Suspect cardiac tamponade after penetrating or blunt injuries to the chest if shock, pulseless electrical activity, narrowed pulse pressure, distended neck veins, hepatomegaly, or muffled heart sounds are present. Ultrasound may be diagnostic if readily available. Diagnose and treat with pericardiocentesis and rapid volume infusion.

Trauma ultrasonography, or the focused assessment with sonography for trauma (FAST), is routinely used in the adult trauma population. The purpose of the four-view examination (Morison pouch, splenorenal pouch, pelvic retrovesical space, and subcostal view of the heart) is to detect free fluid or blood in dependent spaces. In adults, such detection indicates clinically significant injury likely to require surgery. Accuracy and indications in children are much less clear. Solid organ injuries are more frequently missed and much of the pediatric trauma management is nonoperative. As a result, detection of free fluid by ultrasound in children is less likely to lead to surgery or result in a change in management.

Treat signs of poor perfusion vigorously: A tachycardic child with a capillary refill time of 3 seconds, or other evidence of diminished perfusion, is in *shock* and is sustaining vital organ insults. Remember that hypotension is a late finding. Volume replacement is initially accomplished by rapid infusion of normal saline or lactated Ringer solution at 20 mL/kg of body weight, followed by 10 mL/kg of packed red blood cells if perfusion does not normalize after two crystalloid bolus infusions.

Rapid reassessment must follow each bolus. If clinical signs of perfusion have not normalized, repeat the bolus. Lack of response or later or recurring signs of hypovolemia suggest the need for blood transfusion and possible surgical exploration. For every milliliter of external blood loss, 3 mL of crystalloid solution should be administered.

A common problem is the brain-injured child who is at risk for intracranial hypertension and who is also hypovolemic. In such cases, circulating volume must be restored to ensure adequate cerebral perfusion; therefore, fluid replacement is required until perfusion normalizes. Thereafter provide maintenance fluids with careful serial reassessments. **Do not restrict fluids** for children with head injuries.

Table 11-4. AVPU system for evaluation of level of consciousness.

A Alert
V Responsive to Voice
P Responsive to Pain
U Unresponsive

Disability–Neurologic Deficit

Assess pupillary size and reaction to light and the level of consciousness. The level of consciousness can be reproducibly characterized by the AVPU system (Table 11-4). Pediatric Glasgow Coma Scale assessments can be done as part of the secondary survey (Table 11-5).

Exposure & Environment

Significant injuries can be missed unless the child is completely undressed and examined fully, front and back. Cutting away clothing can minimize movement. Because of their high ratio of surface area to body mass, infants and children cool rapidly. Hypothermia compromises outcome except with iso-

lated head injuries; therefore, continuously monitor the body temperature and use warming techniques as necessary. Hyperthermia can adversely affect outcomes in children with acute brain injuries, so maintain normal body temperatures.

Monitoring

Cardiopulmonary monitors, pulse oximetry, and end-tidal CO₂ monitors should be put in place immediately. At the completion of the primary survey, additional “tubes” should be placed.

A. Nasogastric or Orogastric Tube

Children’s stomachs should be assumed to be full. Gastric distention from positive-pressure ventilation increases the chance of vomiting and aspiration. The nasogastric route should be avoided in patients with significant midface injuries, as its use increases the risk of intracranial placement.

B. Urinary Catheter

An indwelling urinary bladder catheter should be placed to monitor urine output. Contraindications are based on the risk of urethral transection; signs include blood at the meatus or in the scrotum or a displaced prostate detected on rectal examination. Urine should be tested for blood. After the initial flow of urine with catheter placement, the urine output should exceed 1 mL/kg/h.

Table 11-5. Glasgow Coma Scale.^a

^aThe appropriate number from each section is added to total between 3 and 15. A score < 8 usually indicates central nervous system depression requiring positive-pressure ventilation.

^bIf no modification is listed, the same response applies for both infants and children.

SECONDARY SURVEY

After the resuscitation phase, a head-to-toe examination should be performed to reveal all injuries and determine priorities for definitive care.

Skin

Search for lacerations, hematomas, swelling, and abrasions. Remove foreign material, and cleanse as necessary. Cutaneous findings may indicate underlying pathology (eg, a flank hematoma overlying a renal contusion), although surface signs may be absent even with significant internal injury. Make certain the child’s tetanus immunization status is current. Consider tetanus immune globulin for incompletely immunized children.

Head

Check for hemotympanum and for clear or bloody cerebrospinal fluid leak from the nares. Battle sign (hematoma over the mastoid) and raccoon eyes are late signs of basilar skull fracture. Explore wounds, evaluating for foreign bodies and defects in galea or skull. CT scan of the head is an integral part of evaluation for altered level of consciousness, post-traumatic seizure, or focal neurologic findings (see section on Head Injury, later). Pneumococcal vaccine is indicated for basilar skull fractures.

Spine

Cervical spine injury must be excluded in all children. This can be done clinically in children older than 4 or 5 years of age with normal neurologic findings on examination (including voluntary movement of all extremities) who are able to deny midline neck pain or midline tenderness on palpation of the neck and who have no other painful injuries that might obscure the pain of a cervical spine injury. If radiographs are indicated, a cross-table lateral neck view is obtained initially, followed by anteroposterior, odontoid, and in some cases oblique views. Normal studies do not exclude significant injury, either bony or ligamentous, or involving the spinal cord itself. Therefore, an obtunded child should be maintained in cervical spine immobilization until the child has awakened and an appropriate neurologic examination can be performed. The entire thoracolumbar spine must be palpated and areas of pain or tenderness examined by radiography.

Chest

Pneumothoraces are detected and decompressed during the primary survey. Hemothoraces can occur with rib fractures or with injury to intercostal vessels, large pulmonary vessels, or lung parenchyma. Tracheobronchial disruption is suggested by large continued air leak despite chest tube decompression. Pulmonary contusions may require ventilatory support. Myocardial contusions and aortic injuries are unusual in children.

Abdomen

Blunt abdominal injury is common in multisystem injuries. Significant injury may exist without cutaneous signs or instability of vital signs. Tenderness, guarding, distention, diminished or absent bowel sounds, or poor perfusion mandates immediate evaluation by a pediatric trauma surgeon. Injury to solid viscera frequently can be managed nonoperatively in stable patients; however, intestinal perforation or hypotension necessitates operative treatment. Serial examinations, ultrasound, and CT scan provide diagnostic help. Elevated liver function tests have good specificity but only fair sensitivity for hepatic injury. Coagulation studies are rarely beneficial if no concomitant closed head injury is present. Obtaining a serum amylase immediately postinjury is controversial, as recent studies have shown variable correlation between elevated levels and pancreatic injury.

Pelvis

Pelvic fractures are classically manifested by pain, crepitus, and abnormal motion. Pelvic fracture is a relative contraindication to urethral catheter insertion. Perform a rectal examination, noting tone, tenderness, and in boys, prostate position. Stool should be tested for blood.

Genitourinary System

If urethral transection is suspected (see earlier discussion), perform a urethrogram before catheter placement. Diagnostic imaging of the child with hematuria often includes CT scan or occasionally, IV urograms. Management of kidney injury is largely nonoperative except for renal pedicle injuries.

Extremities

Long bone fractures are common but rarely life-threatening. Test for pulses, perfusion, and sensation. Neurovascular compromise requires immediate orthopedic consultation. Delayed diagnosis of fracture may occur when children are comatose; reexamination is necessary to avoid overlooking previously missed fractures. Treatment of open fractures includes antibiotics, tetanus prophylaxis, and orthopedic consultation.

Central Nervous System

Most deaths in children with multisystem trauma are from head injuries, so optimal neurointensive care is important. Significant injuries include diffuse axonal injury; cerebral edema; subdural, subarachnoid, and epidural hematomas; and parenchymal hemorrhages. Spinal cord injury occurs less commonly. Level of consciousness by the AVPU system (see Table 11–4) or Glasgow Coma Scale (see Table 11–5) should be assessed serially. A full sensorimotor examination should be performed. Deficits require immediate neurosurgical consultation. Extensor or flexor posturing represents intracranial hypertension, not seizure activity, until proven otherwise. If accompanied by a fixed, dilated pupil, such posturing indicates that a herniation syndrome is present, and mannitol or 3% hypertonic saline should be given if perfusion is normal. Treatment goals include aggressively treating hypotension to optimize cerebral perfusion, providing supplemental oxygen to keep saturations above 90%, achieving eucapnia (end-tidal CO₂ 35–40 mm Hg), avoiding hyperthermia, and minimizing painful stimuli. Early rapid sequence intubation, sedation, and paralysis should be considered. Mild prophylactic hyperventilation is no longer recommended, although brief periods of hyperventilation are still indicated in the setting of acute herniation. Seizure activity warrants exclusion of significant intracranial injury. In the trauma setting, seizures are frequently treated with fosphenytoin. Acute spinal cord injury may benefit from high-dose methylprednisolone therapy. Corticosteroids are not indicated for head trauma.

HEAD INJURY

Closed head injuries range in severity from minor asymptomatic trauma without sequelae, to those leading to death. Head injury, including the shaken-baby syndrome, is common in cases of child abuse. Even following minor closed head injury, neuropsychiatric sequelae can occur.

ASSESSMENT

The considerations discussed earlier in the Approach to the Pediatric Trauma Patient section apply here as well. The history should include the time, mechanism, and details of the injury. Distance of the fall, landing surface, level of consciousness at event, subsequent mental status and activity, amnesia, and vomiting are important details to obtain.

The physical examination, including a detailed neurologic examination, should be complete and mindful of the mechanism of injury. Look for associated injuries such as mandibular fracture, scalp or skull injury, or cervical spine injury. Cerebrospinal fluid leak from the ears or nose or the later appearance of periorbital hematomas (raccoon eyes) or Battle sign imply basilar skull fracture and indicate the need for pneumococcal vaccine. Obtain vital signs and assess the child's level of consciousness by the AVPU system (see Table 11–4) or Glasgow Coma Scale (see Table 11–5), noting irritability or lethargy; pupillary equality, size, and reaction to light; funduscopic examination; reflexes; body posture; and rectal tone. Always consider child abuse; the injuries observed should be consistent with the history and the child's developmental level.

Radiographic studies may be indicated. Plain films are useful only in cases of penetrating head trauma or for ruling out foreign bodies. Major morbidity does not result directly from skull fractures, but rather from the associated intracranial injury. CT scans should be performed based on clinical findings in the child with persistent vomiting or an abnormal or lateralizing neurologic examination, including an abnormal mental status that does not quickly return to normal. In infants, a normal neurologic examination does not exclude significant intracranial hemorrhage; in the setting of an appropriate mechanism, and if scalp findings such as large hematomas are found, consider performing CT.

CONCUSSION

A concussion injury is defined as a brief loss or alteration of consciousness followed by a return to normal. Brain tissue is not damaged, and there are no focal findings on detailed neurologic examination. There may be pallor, amnesia, or several episodes of vomiting. Disposition is based on the clinical course and suitability of follow-up. The patient may be discharged when neurologically normal after a period of observation. Parents should closely observe the child at home and return if the child exhibits altered level of consciousness, persistent vomiting, gait disturbances, unequal pupils, seizures, or increasing headache, or if the parents have any concerns.

CONTUSION

A bruise of the brain matter is a contusion. The child's level of consciousness decreases, and focal findings, if any, correspond to the area of the brain that is injured. These patients require CT scan, a period of observation, and consideration of neurorehabilitation follow-up for post-traumatic brain injury sequelae.

DIFFUSE AXONAL INJURY

Diffuse axonal injury is a potentially severe form of traumatic brain injury characterized by coma without focal signs on neurologic examination. No external signs of trauma may be apparent. The initial CT scan is normal or may demonstrate only scattered small areas of cerebral contusion and areas of low density. Prolonged disability may follow diffuse axonal injury.

ACUTE INTRACRANIAL HYPERTENSION

Close observation will detect early signs and symptoms of intracranial pressure elevation. Early recognition is essential to avoid disastrous outcomes. In addition to traumatic causes, intracranial pressure elevation with or without herniation syndromes may be seen in spontaneous intracranial hemorrhage, CNS infection, hydrocephalus, ruptured arteriovenous malformation, metabolic derangement (eg, diabetic ketoacidosis), ventriculoperitoneal shunt obstruction, or tumor. Symptoms include headache, vision changes, vomiting, gait difficulties, and a progressively decreasing level of consciousness. Other signs may include stiff neck, cranial nerve palsies, and progressive hemiparesis. Cushing triad (bradycardia, hypertension, and irregular respirations) is a late and ominous finding. Papilledema is also a late finding. Consider CT scan before lumbar puncture if there is concern about intracranial pressure elevation because of the risk of precipitating herniation. Lumbar puncture should be deferred if the patient is unstable.

▶ Treatment

Therapy for intracranial pressure elevation must be swift and aggressive. Strict attention to adequate oxygenation, ventila-

tion, and perfusion is paramount. Controlled rapid sequence intubation with appropriate sedation, muscle relaxation, agents to reduce the intracranial pressure elevation that accompanies intubation, and avoidance of hypoperfusion and hypoxemia are all important aspects of treatment. Brief periods of hyperventilation are reserved for acute herniation. Mannitol (0.5 g/kg IV), an osmotic diuretic, will reduce brain water, as will furosemide (0.1–0.2 mg/kg IV). Hypertonic saline (3%) is also used for this purpose. These measures may acutely lower intracranial pressure. Fluid infusion and, ultimately, pressors should be used to maintain normal arterial blood pressure and peripheral perfusion, if necessary. Adjunctive measures include elevating the head of the bed 30 degrees, treating hyperpyrexia and pain, and maintaining the head in a midline position. Obtain immediate neurosurgical evaluation. Further details about management of intracranial hypertension (cerebral edema) are presented in Chapter 13.

DISPOSITION FOR CHILDREN WITH CLOSED HEAD INJURY

Patients with mild head injury may be discharged with detailed written instructions, if the examination remains normal after a period of observation and parental supervision and follow-up are appropriate. Children with persistent deficits require admission or prolonged observation. In patients whose mental status improves over time, observation may be done without further radiographic studies. If mental status deteriorates, however, CT scan and neurosurgical consultation are indicated. If the CT scan is normal and the neurologic findings normalize, these children may be discharged after a period of observation. Patients with severe head injury require cerebral resuscitation, evaluation by a neurosurgeon, and admission to hospital.

BURNS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Burn classification depends on location and extent of injury.
- ▶ Burns of the hands, feet, face, eyes, ears, and perineum are always considered to be major burns.

Thermal injury is a major cause of accidental death and disfigurement in children. Pain, morbidity, the association

with child abuse, and the preventable nature of burns constitute an area of major concern in pediatrics. Common causes include hot water or food, appliances, flames, grills, vehicle-related burns, and curling irons. Burns occur commonly in toddlers—in boys more frequently than in girls.

EVALUATION OF THE BURNED PATIENT

Classification

Burns are classified clinically according to the nature of the burn and the extent and thickness; associated injuries are ascertained in the initial evaluation.

Superficial burns are easily recognized and treated. They are painful, dry, red, and hypersensitive. Sunburn is a common example. Healing occurs with minimal damage to epidermis. Partial-thickness burns are subgrouped as superficial or deep, depending on appearance and healing time. Each subgroup is treated differently. Superficial partial-thickness burns are red and often blister. Deep partial-thickness burns are white and dry, blanch with pressure, and the involved skin has decreased sensitivity to pain. Full-thickness burns affect all epidermal and dermal elements, leaving devascularized skin. The wound is white or black, dry, depressed, leathery in appearance, and without sensation. Unless skin grafting is provided, the scar will be hard, uneven, and fibrotic. Deep full-thickness, or subdermal, burns are the most severe, extending through all layers of skin as well as into the underlying fascia, muscle, and possibly bone.

Management

Management also depends on the depth and extent of injury. Burn extent can be classified as major or minor. Minor burns are less than 10% of the body surface area for superficial and partial-thickness burns, or less than 2% for full-thickness burns. Partial- or full-thickness burns of the hands, feet, face, eyes, ears, and perineum are considered major.

A. Superficial and Partial-Thickness Burns

These injuries can generally be treated in the outpatient setting. It is *mandatory* that effective analgesia be rapidly provided, and redosed as indicated by the child. Oral codeine or parenteral narcotics are indicated. Superficial burns are treated with cool compresses and analgesia. Treatment of partial-thickness burns with blisters consists of antiseptic cleansing, topical antimicrobial coverage, and observation for infection. Blisters appear early in deeper partial-thickness burns and, if open, may be debrided. Alternatively, the blister may be used as a protective flap after cleaning and dressing. After debridement, the wound should be cleansed with dilute (1–5%) povidone-iodine solution, thoroughly washed with normal saline, and covered with topical antibiotic. The wound should be protected with a bulky dressing and reexamined within 24 hours and serially thereafter. Wounds with a potential to cause disfigurement or functional impairment—especially wounds of the hand or digits—should

be referred promptly to a burn surgeon. Outpatient analgesia should be provided on discharge.

B. Full-Thickness, Deep or Extensive Partial-Thickness, and Subdermal Burns

Major burns require particular attention to the ABCs of trauma management. Early establishment of an artificial airway is critical with oral or nasal burns because of their association with inhalation injuries and critical airway narrowing.

The protocol for the primary survey should be followed (see earlier discussion). There may be inhalation injury from carbon monoxide, cyanide, or other toxic products. A nasogastric tube and bladder catheter should be placed. The secondary survey should ascertain whether any other injuries are present, including those suggestive of abuse.

Fluid administration is based on several principles. Capillary permeability is markedly increased. Fluid needs are based on examination findings, percentage of body surface area burned, depth, and age. Maintaining normal intravascular pressure and replacing fluid losses are essential. Figure 11-9 shows percentages of body surface area by body part in infants and children. The Parkland formula for fluid therapy is 4 mL/kg/% body surface area burned for the first 24 hours, with half in the first 8 hours, **in addition to maintenance rates**. Acutely, however, fluid resuscitation should be based on clinical assessment of volume status.

Indications for admission include major burns as previously defined, uncertainty of follow-up, suspicion of abuse, presence of upper airway injury, explosion, inhalation, electrical or chemical burns, burns associated with fractures, or the need for parenteral pain control. Children with chronic metabolic or connective tissue diseases and infants deserve hospitalization. Children with subdermal burns require immediate hospitalization at a burn center under the care of a burn specialist, fluid resuscitation, debridement of the wound, and placement of temporary wound coverage.

ELECTRICAL BURNS

Even brief contact with a high-voltage source will result in a contact burn. When an infant or toddler bites an electric cord, burns to the commissure of the lips occur that appear gray and necrotic, with surrounding erythema. If an arc is created with passage of current through the body, the pattern of the thermal injury will depend on the path of the current; therefore, search for an exit wound and internal injuries. Extensive damage to deep tissues may occur. Current traversing the heart may cause nonperfusing arrhythmias. Neurologic effects of electrical burns can be immediate (eg, confusion, disorientation, peripheral nerve injury), delayed (eg, nerve damage in the thrombosed limb after compartment syndrome), or late (eg, impaired concentration or memory).

DISORDERS DUE TO ALTERED ENVIRONMENTAL TEMPERATURE

HEAT-RELATED ILLNESSES & HEAT STROKE

Compared with adults, children are at an increased risk of heat-related illnesses because of their unique response to heat stress. Related illnesses range from miliaria rubra (prickly heat) to heat cramps and exhaustion, to life-threatening heat stroke.

Miliaria rubra commonly occurs in infants and young children during hot weather and manifests as an erythematous, papular rash concentrated on the face, upper neck, and extremities. Superinfection may result in a pustular appearance to the rash. The condition results from the obstruction of immature sweat glands. Treatment includes dressing the child in loose-fitting clothing and avoiding oil-based topical lubricants.

Heat cramps are characterized by brief, severe cramping (not rigidity) of skeletal or abdominal muscles following exertion. Core body temperature is normal or slightly elevated. There may be associated hyponatremia, hypochloremia, and rarely, hypokalemia. Mild cases can be treated with oral salt-containing solutions; more severe cases require IV infusion of normal saline solution.

Heat exhaustion includes multiple and often vague constitutional symptoms manifesting after heat exposure. Patients continue to sweat and have varying proportions of salt and water depletion. Core temperatures should be monitored frequently and are often normal or slightly increased. Presenting symptoms and signs include weakness, fatigue, headache, disorientation, pallor, thirst, nausea and vomiting, and occasionally muscle cramps without CNS dysfunction. Shock may be present. Treat with IV fluids, guided by serum electrolyte levels. Both heat cramps and heat exhaustion can be prevented by acclimatization and liberal water and salt intake during exercise.

Heat stroke represents failure of thermoregulation and is life-threatening. Diagnosis is based on a rectal temperature above 40.6°C with associated neurologic signs in a patient with an exposure history. Lack of sweating is **not** a necessary criterion. Symptoms are similar to those of heat exhaustion, but CNS dysfunction is more prominent. Patients with heat stroke are often incoherent and combative. In more severe cases, vomiting, shivering, coma, seizures, nuchal rigidity, and posturing may be present. Cardiac output may be high, low, or normal. Cellular hypoxia, enzyme dysfunction, and disrupted cell membranes lead to global end-organ derangements: rhabdomyolysis, myocardial necrosis, electrolyte abnormalities, acute tubular necrosis and renal failure, hepatic degeneration, acute respiratory distress syndrome, and disseminated intravascular coagulation. Consider sepsis, malignant hyperthermia, and neuroleptic malignant syndrome in the differential diagnosis.

Heat Stroke Management

1. Address the ABCs (airway, breathing, circulation), and administer 100% oxygen.
2. Administer IV fluids: isotonic crystalloid for hypotension, 5% dextrose normal saline for maintenance. Consider central venous pressure monitoring.
3. Once resuscitative efforts have begun, cool the patient by removing clothing; misting with cool water; applying ice

at neck, groin, and axilla; fanning; and other cooling devices.

4. Place monitors, check rectal temperatures continuously, and place a Foley catheter and nasogastric tube.
5. Order laboratory tests: complete blood count; electrolytes; glucose; creatinine; prothrombin time and partial thromboplastin time; creatine kinase; liver function tests; arterial blood gases; urinalysis; and serum calcium, magnesium, and phosphate.
6. Admit to the pediatric intensive care unit.

HYPOTHERMIA

Seriously ill children should have core temperature quickly determined. Hypothermia in children, defined as core body temperature less than 35°C, is frequently associated with cold water submersion incidents. Other disorders cause incidental hypothermia, including sepsis, metabolic derangements, ingestions, CNS disorders, and endocrinopathies. Neonates, trauma victims, intoxicated patients, and the chronically disabled are particularly at risk. Mortality rates are high and are related to the underlying disorder. Conversely, moderate therapeutic hypothermia (32–34°C) following hypoxic-ischemic CNS insult and isolated traumatic brain injury is now recommended as potentially beneficial for CNS recovery.

As core temperature falls, a variety of mechanisms begin to conserve and produce heat. Peripheral vasoconstriction allows optimal maintenance of core temperature. Heat production can be increased by a hypothalamic-mediated increase in muscle tone and metabolism. Shivering increases heat production to two to four times basal levels.

► Clinical Findings

Clinical manifestations of hypothermia vary with severity of body temperature depression. Severe cases (< 28°C) mimic death: patients are pale or cyanotic, pupils may be fixed and dilated, muscles are rigid, and there may be no palpable pulses. Heart rates as low as 4–6 beats/min may provide adequate perfusion, because of lowered metabolic needs in severe hypothermia. Because findings resulting from primary hypothermia may be easily confused with those of postmortem changes, death is not pronounced until the patient has been rewarmed and remains unresponsive to resuscitative efforts. Children with a core temperature as low as 19°C have survived neurologically intact.

► Treatment

A. General Supportive Measures

Management of hypothermia is largely supportive. Core body temperature must be continuously documented; monitor with a low-reading indwelling rectal thermometer. Patients must be handled gently, because the hypothermic

myocardium is exquisitely sensitive and prone to arrhythmias. Ventricular fibrillation may occur spontaneously or as a result of minor handling or invasive procedures. If asystole or ventricular fibrillation is present on the cardiac monitor, perform chest compressions and use standard pediatric advanced life support techniques as indicated. Defibrillation and pharmacologic therapy should be initiated as appropriate but may not be successful until core rewarming has occurred. Spontaneous reversion to sinus rhythm at 28–30°C may take place as rewarming proceeds.

B. Rewarming

Remove wet clothing from all patients. Rewarming techniques are categorized as passive external, active external, or active core rewarming. The method chosen is based on the degree of hypothermia. Passive rewarming, such as covering with blankets, is appropriate only for mild cases (> 33°C). Active external rewarming methods include warming lights, thermal mattresses or electric warming blankets, immersion in warm baths, and hot water bottles or warmed bags of IV solutions. One must be aware of the potential for core temperature depression after rewarming has begun, as vasodilation allows cooler peripheral blood to be distributed to the core circulation.

Active core rewarming techniques are used alone or in combination with active external warming for moderate to severe hypothermia. The techniques include the delivery of warmed, humidified oxygen and the use of warmed (to 40°C) fluids for IV replacement, peritoneal dialysis, and mediastinal lavage. Bladder and bowel irrigation are not generally effective because of low surface areas for temperature exchange. Extracorporeal blood rewarming achieves controlled core rewarming, can stabilize volume and electrolyte disturbances, and is maximally effective (Table 11–6).

SUBMERSION INJURIES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ CNS and pulmonary injuries account for major morbidity.
- ▶ Child may appear well at presentation, but late CNS and pulmonary changes can occur hours later.
- ▶ Minimum observation period is 8–12 hours.

Drowning is the second most common cause of death by unintentional injury among children. Water hazards are ubiquitous and include lakes and streams, swimming pools,

Table 11–6. Management of hypothermia.

General measures

- Remove wet clothing.
- Administer warmed and humidified 100% oxygen.
- Monitor core temperature, heart and respiratory rates, and blood pressure continuously.
- Consider central venous pressure determination for severe hypothermia.

Laboratory studies

- Complete blood count and platelets
- Serum electrolytes, glucose, creatinine, amylase
- Prothrombin time, partial thromboplastin time
- Arterial blood gases
- Consider toxicology screen

Treatment

- Correct hypoxemia, hypercapnia, pH < 7.2, clotting abnormalities, and glucose and electrolyte disturbances.
- Start rewarming techniques: passive, active (core and external), depending on degree of hypothermia.
- Replace intravascular volume with warmed intravenous crystalloid infusion at 42°C.
- Treat asystole and ventricular fibrillation per PALS protocols.
- Continue cardiac massage at least until core temperature reaches 30°C, when defibrillation is more likely to be effective.

PALS, pediatric advanced life support.

bathtubs, and even toilets, buckets, and washing machines. Risk factors include epilepsy, alcohol, and lack of supervision. Males predominate in submersion deaths, as in most other nonintentional deaths. Prevention is paramount.

Major morbidity stems from CNS and pulmonary insult. Laryngospasm or breath-holding may lead to loss of consciousness and cardiovascular collapse before aspiration can occur (dry drowning). Anoxia from laryngospasm or aspiration leads to irreversible CNS damage after only 4–6 minutes. A child must fall through ice or directly into icy water for cerebral metabolism to be slowed sufficiently by hypothermia to provide protection from anoxic damage. Cardiovascular changes include myocardial depression and arrhythmias. Electrolyte alterations are generally slight. Unless hemolysis occurs, hemoglobin concentrations also change only slightly.

▶ Clinical Findings & Treatment

Depending on the duration of submersion and any protective hypothermia effects, children may appear clinically dead or completely normal. Observation over time assists with prognosis. The child who has been rewarmed to at least 33°C and is still apneic and pulseless will probably not survive to discharge or will be left with severe neurologic deficits. Until a determination of brain death can be made, however, aggressive resuscitation should be continued in a patient with return of circulation.

One should keep in mind possible associated injuries, including head or neck trauma. For children who appear well initially, observation for 8–12 hours will detect late pulmonary

compromise or changes in neurologic status. Respiratory distress, an abnormal chest radiograph, abnormal arterial blood gases, or hypoxemia by pulse oximetry indicates the need for treatment with supplemental oxygen, cardiopulmonary monitoring, and frequent reassessment. Serially assess respiratory distress and mental status. Signs of pulmonary infection may appear many hours after the submersion event.

Patients who are in coma and who require mechanical ventilation have a high risk of anoxic encephalopathy. The value of therapy with hyperventilation, corticosteroids, intentional hypothermia, and barbiturates remains unproved.

Zuckerbraun NS, Saladino RA: Pediatric drowning: Current management strategies for immediate care. *Clin Ped Emerg Med* 2005;6:49.

ANIMAL & HUMAN BITES

Bites account for a large number of visits to the emergency department. Most fatalities are due to dog bites. However, human and cat bites cause the majority of infected bite wounds.

DOG BITES

Boys are bitten more frequently than girls, and the dog is known by the victim in most cases. Younger children have a higher incidence of head and neck wounds, whereas school-age children are bitten most often on the upper extremities.

Dog bites are treated similarly to other wounds: high-pressure, high-volume irrigation with normal saline, debridement of any devitalized tissue, removal of foreign matter, and tetanus prophylaxis. The risk of rabies from dogs is low in developed countries, but rabies prophylaxis should be considered when appropriate. Wounds should be sutured only if necessary for cosmetic reasons because wound closure increases the risk of infection. Prophylactic antibiotics have not been proven to decrease rates of infection in low-risk dog bite wounds not involving the hands or feet. If a bite involves a joint, periosteum, or neurovascular bundle, prompt orthopedic surgery consultation should be obtained.

Pathogens that infect dog bites include *Pasteurella canis* and *P multocida*, streptococci, staphylococci, and anaerobes. Infected dog bites can be treated with penicillin for *P multocida*, and broad-spectrum coverage can be provided by amoxicillin and clavulanic acid or cephalexin (see dose for cat bites in the next section). Complications of dog bites include scarring, CNS infections, septic arthritis, osteomyelitis, endocarditis, and sepsis.

CAT BITES

Cat-inflicted wounds occur more frequently in girls, and their principal complication is infection. The infection risk is higher in cat bites than dog bites because cat bites produce a puncture

wound. Management is similar to that for dog bites. Cat wounds should *not* be sutured except when absolutely necessary for cosmetic reasons. *P multocida* is the most common pathogen. Cat bites create a puncture-wound inoculum, and prophylactic antibiotics (penicillin plus cephalexin, or amoxicillin and clavulanic acid) are recommended. The dose of amoxicillin trihydrate and clavulanic acid should be on the high side of recommended dosage in order to ensure adequate tissue penetration both in dog and cat bites. The dosage of the amoxicillin component should be 80 mg/kg/24 h in three divided doses. The maximum dosage is 2 g/24 h. Scratches or bites from cats may also result in cat scratch fever.

HUMAN BITES

Most human bites occur during fights. *P multocida* is not a known pathogen in human bites; cultures most commonly grow streptococci, staphylococci, anaerobes, and *Eikenella corrodens*. Hand wounds and deep wounds should be treated with antibiotic coverage against *E corrodens* and gram-positive pathogens by a penicillinase-resistant antibiotic. Wound management is the same as for dog bites. Only severe lacerations involving the face should be sutured. Other wounds can be managed by delayed primary closure or healing by secondary intention. A major complication of human bite wounds is infection of the metacarpophalangeal joints. A hand surgeon should evaluate clenched-fist injuries from human bites. Operative debridement is followed in many cases by IV antibiotics.

Younggren BN: Emergency management of difficulty wounds: Part I. *Emerg Med Clin North Am* 2007;25:101 [PMID: 17400075].

PROCEDURAL SEDATION & ANALGESIA (PSA)

Relief of pain and anxiety are paramount concepts in the provision of acute care pediatrics, and should be considered at all times. Many agents also have amnestic properties. Parenteral agents can be effective and safe and produce few side effects if used judiciously.

Conditions such as fracture reduction, laceration repair, burn care, sexual assault examinations, lumbar puncture, and diagnostic procedures such as CT and magnetic resonance imaging may all be performed more effectively and compassionately if effective sedation or analgesia is used. The clinician should decide whether procedures will require sedation, analgesia, or both, and then choose agents accordingly.

Safe and effective sedation requires thorough knowledge of the selected agent and its side effects, as well as suitable monitoring devices, resuscitative medications, equipment, and personnel. The decision to perform PSA must be patient-oriented and tailored to specific procedural needs, while ensuring the child's safety throughout the procedure.

In order to successfully complete this task, a thorough preprocedural assessment should be completed, including a directed history and physical examination. Risks, benefits, and limitations of the procedure should be discussed with the parent or guardian and informed, verbal consent must be obtained. PSA then proceeds as follows:

1. Choose the appropriate medication(s).
2. Ensure appropriate NPO (nothing-by-mouth) status for 2–6 hours, depending on age and type of intake. For certain emergency procedures, suboptimal NPO status may be allowed, with attendant risks identified.
3. Establish vascular access as required.
4. Ensure that resuscitative equipment and personnel are readily available. Attach appropriate monitoring devices, as indicated.
5. Give the agent selected, with continuous monitoring for side effects. A dedicated observer, usually a nurse, should monitor the patient at all times. Respiratory effort, perfusion, and mental status should be assessed and documented serially.
6. Titrate the medication to achieve the desired sedation level. The ideal level depends on sedation goals and procedure type. PSA goals in the emergency department setting usually involve minimal or moderate sedation. Minimal sedation is a state in which the patient's sensorium is dulled, but he is still responsive to verbal stimuli. Moderate sedation is a depression of consciousness in which the child responds to tactile stimuli. In both cases, airway reflexes are preserved. It is important to remember that sedation is a continuum and the child may drift to deeper, unintended levels of sedation.
7. Continue monitoring the patient after the procedure has finished and the child has returned to baseline mental status. Once a painful stimulus has been corrected, mental status can decrease.
8. Criteria for discharge include the child's ability to sit unassisted, take oral fluids, and answer verbal commands. A PSA discharge handout should be given, with precautions for close observation and avoidance of potentially dangerous activities.

The following are some commonly used sedatives and analgesics:

1. Midazolam—This agent has particular usefulness in pediatrics due to its safety, rapid onset, and short half-life. Administration may be oral, rectal, intranasal, intramuscular, or IV. When given slowly intranasally, the drug's kinetics are similar as when given intravenously, although many patients report a burning sensation with administration. Oral or rectal administration results in relatively delayed onset, and titration is difficult. Intramuscular injections can be combined with opioid analgesics if systemic analgesia is desired. IV administration allows optimal ability to titrate dosing to the desired sedation level. It is best to place an IV

for complicated or prolonged procedures to facilitate redosing, which also provides IV access if resuscitation becomes necessary. Potential side effects of midazolam include cardiorespiratory depression.

2. Barbiturates—This class of agents (eg, pentobarbital) has the benefit of minimizing movement during procedures, which makes them advantageous for diagnostic studies such as CT or magnetic resonance imaging. Rectal administration of thio-pental is safe and effective. Onset of action with IV administration is rapid. Potential side effects, although uncommon, include cardiorespiratory depression and laryngospasm.

3. Narcotics—Agents such as fentanyl and morphine have powerful analgesic and sedative effects and can be combined with anxiolytics such as benzodiazepines. Desired and adverse effects, such as respiratory depression, are potentiated when benzodiazepines and narcotics or barbiturates are given together. Therefore, sedative doses should be reduced when sedatives and analgesics are given together.

4. Ketamine—A commonly used drug in the emergency department, ketamine provides analgesia, anxiolysis and amnesia while allowing the child to retain protective airway reflexes and cardiovascular stability. In addition to providing “dissociative sedation,” this sympathomimetic drug also increases heart rate and blood pressure. Side effects include salivation (therefore, it is usually given with glycopyrrolate as an antisialivation agent), laryngospasm (rarely), nystagmus, emergence reactions, and vomiting. With comprehensive knowledge of this medication, its use can be a significant advantage to children.

5. Propofol—Propofol is a nonopioid, nonbarbiturate sedative that is highly effective. It is finding increased use as an adjunct to analgesia for painful procedures in the emergency department. Onset of action and recovery are rapid. Side effects include transient hypotension and dose-dependent respiratory depression or apnea. Careful monitoring is essential.

Poisoning

Barry H. Rumack, MD
Richard C. Dart, MD, PhD

12

Accidental and intentional exposures to toxic substances occur in children of all ages. Children younger than age 6 years are primarily involved in accidental exposures, with the peak incidence in 2-year-olds. Of the more than 2.5 million exposures reported by the American Association of Poison Control Centers' National Poison Data System in 2006, 51% occurred in children aged 5 years and under, 6% in those aged 6–12 years, and 7% in those aged 13–19 years. Young children are occasionally exposed to intentional poisoning through the actions of parents or caregivers. Administration of agents such as diphenhydramine to induce sleep in a day-care setting, Münchhausen syndrome by proxy to obtain parental secondary gain, or deliberate harm should be suspected when the history is not consistent. Involvement of child abuse specialists is very helpful in these cases. (See Chapter 7.) Adolescents are involved in intentional episodes when attempting suicide or experimenting with various drugs and agents. In some locales, small-scale industrial or manufacturing processes may be associated with homes and farms, and exposures to hazardous substances should be considered in the history.

Bronstein AC et al: 2006 Annual Report of the American Association of Poison Control Centers' National Poison Data System (NPDS). *Clin Toxicol (Phila)* 2007;45:815 [PMID: 18163234].

PHARMACOLOGIC PRINCIPLES OF TOXICOLOGY

In the evaluation of the poisoned patient, it is important to compare the anticipated pharmacologic or toxic effects with the patient's clinical presentation. If the history is that the patient ingested a tranquilizer 30 minutes ago, but the clinical examination reveals dilated pupils, tachycardia, dry mouth, absent bowel sounds, and active hallucinations—clearly anticholinergic toxicity—diagnosis and therapy should proceed accordingly.

LD₅₀

Estimates of the LD₅₀ (the amount per kilogram of body weight of a drug required to kill 50% of a group of experimental animals) or median lethal dose are of little clinical value in humans. It is usually impossible to determine with accuracy the amount swallowed or absorbed, the metabolic status of the patient, or in which patients the response to the agent will be atypical. Furthermore, these values are often not valid in humans even if the history is accurate.

Half-Life ($t_{1/2}$)

The $t_{1/2}$ of an agent must be interpreted carefully. Most published $t_{1/2}$ values are for therapeutic dosages. The $t_{1/2}$ may increase as the quantity of the ingested substance increases for many common intoxicants such as salicylates. One cannot rely on the published $t_{1/2}$ for salicylate (2 hours) to assume rapid elimination of the drug. In an acute salicylate overdose (150 mg/kg), the apparent $t_{1/2}$ is prolonged to 24–30 hours.

Volume of Distribution

The volume of distribution (Vd) of a drug is determined by dividing the amount of drug absorbed by the blood level. With theophylline, for example, the Vd is 0.46 L/kg body weight, or 32 L in an average adult. In contrast, digoxin distributes well beyond total body water. Because the calculation produces a volume above body weight this figure is referred to as an “apparent volume of distribution” (Table 12–1).

The Vd can be useful in predicting which drugs will be removed by dialysis or exchange transfusion. When a drug is differentially concentrated in body lipids or is heavily tissue or protein bound and has a high Vd, only a small proportion of the drug will be in the free form and thus accessible to diuresis, dialysis, or exchange transfusion. A drug that is water soluble, can be ionized, and has a low Vd may cross

Table 12-1. Some examples of pK_a and V_d .^a

Drug	pK_a	Diuresis	Dialysis	Apparent V_d
Amobarbital	7.9	No	No	200-300% body weight
Amphetamine	9.8	No	Yes	60% body weight
Aspirin	3.5	Alkaline	Yes	15-40% body weight
Chlorpromazine	9.3	No	No	40-50 L/kg (2800-3500% body weight)
Codeine	8.2	No	No	5-10 L/kg (350-700% body weight)
Desipramine	10.2	No	No	30-40 L/kg (2100-2800% body weight)
Ethchlorvynol	8.7	No	No	5-10 L/kg (350-700% body weight)
Glutethimide	4.5	No	No	10-20 L/kg (700-1400% body weight)
Isoniazid	3.5	Alkaline	Yes	61% body weight
Methadone	8.3	No	No	5-10 L/kg (350-700% body weight)
Methicillin	2.8	No	Yes	60% body weight
Phenobarbital	7.4	Alkaline	Yes	75% body weight
Phenytoin	8.3	No	No	60-80% body weight
Tetracycline	7.7	No	No	200-300% body weight

^aComprehensive listings of pharmacokinetic data for a large number of drugs are included just prior to the index in each edition of *Goodman & Gilman's The Pharmacological Basis of Therapeutics* (see reference list).

the dialysis membrane well and also respond to diuresis. In general, methods of extracorporeal elimination are not effective for toxic agents with a V_d greater than 1 L/kg.

Metabolism & Excretion

The route of excretion or detoxification is important for planning treatment. Methanol, for example, is metabolized to the toxic product, formic acid. This metabolic step may be blocked by the antidote fomepizole or ethanol.

Blood Levels

Care of the poisoned patient should never be guided solely by laboratory measurements. Treatment should be directed first by the clinical signs and symptoms, followed by more specific therapy based on laboratory determinations. Clinical information may speed the identification of a toxic agent by the laboratory.

PREVENTING CHILDHOOD POISONINGS

Inclusion of poison prevention as part of routine well child care should begin at the 6-month well baby visit. The poison prevention handout included as Table 12-2 may be copied and distributed to parents. It contains poison prevention information as well as first-aid actions that should be taken in the event of an exposure. All poison control centers in the United States can be reached by

dialing 1-800-222-1222; the call will be automatically routed to the correct regional center.

GENERAL TREATMENT OF POISONING

The telephone is often the first contact in pediatric poisoning. Some patients may contact their pediatrician's office first. Proper telephone management can reduce morbidity and prevent unwarranted or excessive treatment. The decision to refer the patient is based on the identity and dose of the ingested agent, the age of the child, the time of day, the reliability of the parent, and whether child neglect or endangerment is suspected. Poison control centers are the source of expert telephone advice and have excellent follow-up programs to manage patients in the home as well as provide further poison prevention information.

INITIAL TELEPHONE CONTACT

Basic information obtained at the first telephone contact includes the patient's name, age, weight, address, and telephone number; the agent and amount of agent ingested; the patient's present condition; and the time elapsed since ingestion or other exposure. Use the history to evaluate the urgency of the situation and decide whether immediate emergency transportation to a health facility is indicated. An emergency exists if the ingestant is high risk (caustic solutions, hydrogen fluoride, drugs of abuse, or medications

such as a calcium channel blocker, opioid, hypoglycemic agent, or antidepressant) or if the self-poisoning was intentional. If immediate danger does not exist, obtain more details about the suspected toxic agent. If the child requires transport to a health facility, instruct parents that everything in the vicinity of the child that may be a cause of poisoning should be brought to the health care facility.

It may be difficult to obtain an accurate history. Obtain names of drugs or ingredients, manufacturers, prescription numbers, names and phone numbers of prescribing physician and pharmacy and any other pertinent information. Find out whether the substance was shared among several children, whether it had been recently purchased, who had last used it, how full the bottle was, and how much was spilled. Determine if this occurred in the home, school or elsewhere. If unsure of the significance of an exposure, consult with a poison control center.

Each year, children are accidentally poisoned by medicines, polishes, insecticides, drain cleaners, bleaches, household chemicals, and materials commonly stored in the garage. It is the responsibility of adults to make sure that children are not exposed to potentially toxic substances.

Obtaining Information About Poisons

Current data on ingredients of commercial products and medications can be obtained from a certified regional poison center. It is important to have the actual container at hand when calling. **Caution:** Antidote information on labels of commercial products or in the *Physicians' Desk Reference* may be incorrect or inappropriate.

Follow-Up

In over 95% of cases of ingestion of potentially toxic substances by children, a trip to the hospital is not required. In these cases, it is important to call the parent at 1 and 4 hours after ingestion. If the child has ingested an additional unknown agent and develops symptoms, a change in management may be needed, including transportation to the hospital. An additional call should be made 24 hours after the ingestion to begin the process of poison prevention.

INITIAL EMERGENCY DEPARTMENT CONTACT

Make Certain the Patient Is Breathing

As in all emergencies, the principles of treatment are attention to airway, breathing, and circulation. These are sometimes overlooked under the stressful conditions of a pediatric poisoning.

Treat Shock

Initial therapy of the hypotensive patient should consist of laying the patient flat and administering intravenous (IV) isotonic solutions. Vasopressors should be reserved for poisoned patients in shock who do not respond to these standard measures.

Treat Burns & Skin Exposures

Burns may occur following exposure to strongly acidic or strongly alkaline agents or petroleum distillates. Burned areas should be decontaminated by flooding with sterile saline solution or water. A burn unit should be consulted if more than minimal burn damage has been sustained. Skin decontamination should be performed in a patient with cutaneous exposure. Emergency department personnel in contact with a patient who has been contaminated (with an organophosphate insecticide, for example) should themselves be decontaminated if their skin or clothing becomes contaminated.

Take a Pertinent History

The history should be taken from the parents and all individuals present at the scene. It may be crucial to determine all of the kinds of poisons in the home. These may include drugs used by family members, chemicals associated with the hobbies or occupations of family members, or the purity of the water supply. Unusual dietary or medication habits or other clues to the possible cause of poisoning should also be investigated.

DEFINITIVE THERAPY OF POISONING

Treatment of poisoning or potential poisoning has evolved over time, and general measures such as prevention of absorption and enhancement of excretion are only instituted when specifically indicated. Specific therapy is directed at each drug, chemical, or toxin as described in the management section that follows.

Prevention of Absorption

A. Emesis and Lavage

These measures are rarely used in pediatric patients and should be performed only in consultation with a poison center.

B. Charcoal

The dose of charcoal is 1–2 g/kg (maximum, 100 g) per dose. Repeating the dose of activated charcoal may be useful for those agents that slow passage through the gastrointestinal (GI) tract. When multiple doses of activated charcoal are given, repeated doses of sorbitol or saline cathartics must not be given. Repeated doses of cathartics may cause electrolyte imbalances and fluid loss. Charcoal dosing is repeated every 2–6 hours until charcoal is passed through the rectum.

C. Catharsis

Despite their widespread use, cathartics do not improve outcome. The use of cathartics should therefore be avoided.

Table 12-2. Poison prevention and emergency treatment handout.

POISON SAFETY TIPS	
If you or your child has come in contact with poison, call the Poison Control Center (1-800-222-1222) . Nurses and poison experts will answer your call. In most cases, they can help you take care of the problem right at home. When you need to get to the hospital, they will call ahead with detailed information to help doctors treat you or your child quickly and correctly.	
How people get poisoned	
People can breathe poison, eat or drink it, or get it on the skin or in the eyes. You probably know that antifreeze, bleach, and bug spray are poisonous. But did you know that vitamins, perfume, and makeup can be dangerous? Eating some plants can be toxic. Some spider bites can be dangerous. Taking medicine that is too old or not prescribed for you can make you sick. Also, mixing different kinds of medicine can be dangerous.	
Poison safety “do’s” and “don’ts”	
DO:	DON’T:
1. Ask for “safety-lock” tops on all prescription drugs.	1. Don’t store food and household cleaners together.
2. Keep cleaners, bug sprays, medicines, and other harmful products out of the reach and sight of children. If possible, keep the products locked up.	2. Don’t take medicine in front of children; children love to imitate “mommy” and “daddy.”
3. Store medicine in original containers.	3. Don’t call medicine candy.
4. Read the label before taking medicine; don’t take medicine that doesn’t have a label.	4. Don’t take medicine that is not for you. Never take medicine in the dark.
5. Follow the directions for all products.	5. Don’t put gasoline, bug spray, antifreeze or cleaning supplies in soft-drink bottles, cups or bowls. Always keep them in their original containers.
Kids can get into things at any age!	
Children aged 0-6 months	Children aged 1-3 years
Learn to roll over and reach for things.	Have the highest accident rate of any group.
Learn about their environment by putting things in their mouths.	Begin to imitate parents and other adults.
Children aged 7-12 months	Put things in their mouths.
Start to get curious and explore.	Start to climb on things.
Learn to crawl, pull up to stand, and walk holding on.	
Put everything in their mouths.	
Pull things down.	
Different dangers at different times of the year	
Spring and summer dangers	Fall and winter dangers
Pesticides	Antifreeze
Fertilizers	Carbon monoxide
Outdoor plants and mushrooms	Black widow spider bites
Snake, spider, and other insect bites	Plants and autumn berries
Bee stings	Holly, mistletoe, and other holiday decorations
Ticks	
Charcoal lighter fluid	
Follow this checklist to make sure your home is safe	
Kitchen	
__ Remove products like detergent, drain cleaner, and dishwashing liquid from under the sink.	
__ Remove medicines from counters, tables, refrigerator top, or window sills.	
__ Put child safety latches on all drawers and cabinets that contain harmful products.	
__ Store harmful products away from food.	

(continued)

Table 12-2. Poison prevention and emergency treatment handout. (*Continued*)

Bathroom
__ Regularly clean out your medicine chest. Flush old medicine down the toilet.
__ Keep all medicine in original safety-top containers.
__ Keep medicine, hair spray, powder, makeup, fingernail polish, hair-care products, and mouthwash out of reach.
Bedroom
__ Don't keep medicine in or on dresser or bedside table.
__ Keep perfume, makeup, aftershave, and other products out of reach.
Laundry Area
__ Keep bleach, soap, fabric softener, starch, and other supplies out of reach.
__ Keep all products in their original containers.
Garage/Basement
__ Keep bug spray, weed killers, gasoline, oil, paint, and other supplies in locked area.
__ Keep all products in their original containers.
General Household
__ Keep beer, wine, and liquor out of reach.
__ Keep ashtrays clean and out of reach.
__ Keep plants out of reach.
__ Keep paint in good repair.
Emergency action in case your child...
Breathes Poison:
Get child to fresh air right away. Open doors and windows.
Gets Poison on the Skin:
Remove clothes that have poison on them. Rinse skin with lukewarm water for 10 minutes. Wash gently with soap and water and rinse.
Gets Poison in the Eye:
Gently pour lukewarm water over the eye from a large glass 2 or 3 inches from the eye. Repeat for 15 minutes. Have child blink as much as possible while pouring water in the eye. Do not force the eyelid open.
Swallows Poison:
<i>Medicines:</i> Do not give child anything until you talk with the poison center or your doctor.
<i>Chemicals or household products:</i> Unless your child has passed out or cannot swallow, give milk or water right away. Call the Poison Control Center .
Pediatrician: _____ (Tel): _____
National Toll Free Number which connects with your local Poison Center: 1-800-222-1222

Information adapted from, and used, courtesy of the Rocky Mountain Poison Center, Denver, CO.

D. Whole Gut Lavage

Whole bowel lavage uses an orally administered, nonabsorbable hypertonic solution such as CoLyte or GoLYTELY. The use of this procedure in poisoned patients remains controversial. Preliminary recommendations for use of whole bowel irrigation include poisoning with sustained-release preparations, mechanical movement of items through the bowel (eg, cocaine packets, iron tablets), and poisoning with substances that are poorly absorbed by charcoal (eg, lithium, iron). Underlying bowel pathology and intestinal obstruction

are relative contraindications to its use. Consultation with a certified regional poison center is recommended.

Enhancement of Excretion

Excretion of certain substances can be hastened by urinary alkalinization or dialysis. It is important to make certain that the patient is not volume depleted. Volume-depleted patients should receive a normal saline bolus of 10–20 mL/kg, followed by sufficient IV fluid administration to maintain urine output at 2–3 mL/kg/h.

A. Urinary Alkalinization

1. Alkaline diuresis—Urinary alkalinization should be chosen on the basis of the substance's pK_a , so that ionized drug will be trapped in the tubular lumen and not reabsorbed (see Table 12–1). Thus, if the pK_a is less than 7.5, urinary alkalinization is appropriate; if it is over 8.0, this technique is not usually beneficial. The pK_a is sometimes included along with general drug information. Urinary alkalinization is achieved with sodium bicarbonate. It is important to observe for hypokalemia, caused by the shift of potassium intracellularly. Follow serum K^+ and observe for electrocardiogram (ECG) evidence of hypokalemia. If complications such as renal failure or pulmonary edema are present, hemodialysis or hemoperfusion may be required.

B. Dialysis

Hemodialysis (or peritoneal dialysis if hemodialysis is unavailable) is useful in the poisonings listed below and in the general management of a critically ill patient. Dialysis should be considered part of supportive care if the patient satisfies any of the following criteria:

1. Clinical criteria

- Potentially life-threatening toxicity that is caused by a dialyzable drug and cannot be treated by conservative means.
- Hypotension threatening renal or hepatic function that cannot be corrected by adjusting circulating volume.
- Marked hyperosmolality or severe acid–base or electrolyte disturbances not responding to therapy.
- Marked hypothermia or hyperthermia not responding to therapy.

2. Immediate dialysis—Immediate dialysis should be considered in ethylene glycol and methanol poisoning only if acidosis is refractory, the patient does not respond to fomepizole treatment, or blood levels of ethanol of 100 mg/dL are consistently maintained. Refractory salicylate intoxication may benefit from dialysis.

MANAGEMENT OF SPECIFIC COMMON POISONINGS

ACETAMINOPHEN (PARACETAMOL)

Overdosage of acetaminophen is the most common pediatric poisoning and can produce severe hepatotoxicity. The incidence of hepatotoxicity in adults and adolescents has been reported to be 10 times higher than in children younger than age 5 years. In the latter group, fewer than 0.1% develop hepatotoxicity after acetaminophen overdose. In children, toxicity most commonly results from repeated overdosage arising from confusion about the age-appropriate dose, use of multiple products that contain acetaminophen, or use of adult suppositories.

Acetaminophen is normally metabolized in the liver. A small percentage of the drug goes through a pathway leading to a toxic metabolite. Normally, this electrophilic reactant is removed harmlessly by conjugation with glutathione. In overdosage, the supply of glutathione becomes exhausted, and the metabolite may bind covalently to components of liver cells to produce necrosis. Some authors have proposed that therapeutic doses of acetaminophen may be toxic to children with depleted glutathione stores. However, there is no evidence that administration of therapeutic doses can cause toxicity, and only a few inadequate case reports have been made in this regard.

► Treatment

Treatment is to administer acetylcysteine. It may be administered either orally or intravenously. Consultation on difficult cases may be obtained from your regional poison control center or the Rocky Mountain Poison and Drug Center (1-800-525-6115). Blood levels should be obtained 4 hours after ingestion or as soon as possible thereafter and plotted on Figure 12–1. The nomogram is used only for acute ingestion, not repeated supratherapeutic ingestions. If the patient has ingested acetaminophen in a liquid preparation, blood levels obtained 2 hours after ingestion will accurately reflect the toxicity to be expected relative to the standard nomogram (see Figure 12–1). Acetylcysteine is administered to patients whose acetaminophen levels plot in the toxic range on the nomogram. Acetylcysteine is effective even when given more than 24 hours after ingestion, although it is most effective when given within 8 hours postingestion.

The oral (PO) dose of acetylcysteine is 140 mg/kg, diluted to a 5% solution in sweet fruit juice or carbonated soft drink. The primary problems associated with administration are nausea and vomiting. After this loading dose, 70 mg/kg should be administered orally every 4 hours for 72 hours.

For children weighing 40 kg or more, IV acetylcysteine (Acetadote) should be administered as a loading dose of 150 mg/kg administered over 15–60 minutes; followed by a second infusion of 50 mg/kg over 4 hours, and then a third infusion of 100 mg/kg over 16 hours (a dosage calculator is available at <http://www.acetadote.com>) (Table 12–3).

▲ **Figure 12-1.** Semi-logarithmic plot of plasma acetaminophen levels versus time. (Modified and reproduced, with permission, from Rumack BH, Matthew H: Acetaminophen poisoning and toxicity. *Pediatrics* 1975;55:871.)

For patients weighing less than 40 kg, IV acetylcysteine must have less dilution to avoid hyponatremia (Table 12-4).

Aspartate aminotransferase (AST-SGOT), alanine aminotransferase (ALT-SGPT), serum bilirubin, and plasma prothrombin time should be followed daily. Significant abnormalities of liver function may not peak until 72-96 hours after ingestion.

Repeated miscalculated overdoses given by parents to treat fever are the major source of toxicity in children younger than age 10 years, and parents are often unaware of the significance of symptoms of toxicity, thus delaying its prompt recognition and therapy.

 Rumack BH: Acetaminophen hepatotoxicity: The first 35 years. *J Toxicol Clin Toxicol* 2002;40:3 [PMID: 11990202].

ALCOHOL, ETHYL (ETHANOL)

Alcoholic beverages, tinctures, cosmetics, mouthwashes, and rubbing alcohol are common sources of poisoning in children. Concomitant exposure to other depressant drugs increases the seriousness of the intoxication. In most states, alcohol levels of 50-80 mg/dL are considered compatible with impaired faculties, and levels of 80-100 mg/dL are considered evidence of intoxication. (Blood levels cited here are for adults; comparable figures for children are not available.)

Recent erroneous information regarding hand sanitizers has indicated that a "lick" following application on the hand could cause toxicity in children. In fact this is not the case, but because these hand sanitizers contain 62% ethanol, toxicity following ingestion is very possible. Potential blood ethanol concentration following consumption of a 62% solution in a 10-kg child is calculated as follows:

$$1 \text{ oz} = 30 \text{ mL} \times 62\% = 18.6 \text{ mL of pure ethanol}$$

$$18.6 \text{ mL} \times 0.79 \text{ (the specific gravity)} = 14.7 \text{ g of ethanol, or } 14,700 \text{ mg}$$

Table 12-3. Intravenous acetylcysteine administration for children weighing 40 kg or more.

Body Weight		FIRST 150 mg/kg in 200 mL 5% Dextrose in 15 min	SECOND 50 mg/kg in 500 mL 5% Dextrose in 4 h	THIRD 100 mg/kg in 1000 mL 5% Dextrose in 16 h
(kg)	(lb)	Acetadote (mL)	Acetadote (mL)	Acetadote (mL)
100	220	75	25	50
90	198	67.5	22.5	45
80	176	60	20	40
70	154	52.5	17.5	35
60	132	45	15	30
50	110	37.5	12.5	25
40	88	30	10	20

In a patient weighing 10 kg, the distribution into total body water (V_d) will be 6 L—this is the amount of the body water into which the ethanol will be distributed.

$$14,700 \text{ mg} \div 6 \text{ L} = 2450 \text{ mg/L}$$

$$2450 \text{ mg/L} \div 10 = 245 \text{ mg/dL}$$

Based on these calculations, a 10-kg child consuming 0.5 oz would have a concentration of 122.5 mg/dL; a 20-kg child consuming 1 oz would have a concentration of 122.5 mg/dL; a 30-kg child consuming 1 oz would have a concentration of 81.7 mg/dL; and a 70-kg adult consuming 1 oz would have a concentration of 35 mg/dL.

One “pump” from a hand sanitizer bottle dispenses approximately 2.5 mL of the product. If ingested, this amount (containing 62% ethanol) would create a blood ethanol concentration as follows:

1. In a 10-kg child: 23.1 mg/dL.
2. In a 20-kg child: 11.6 mg/dL.
3. In a 30-kg child: 7.7 mg/dL.

Children show a change in sensorium with blood levels as low as 10–20 mg/dL and any child displaying such changes should be seen immediately. Although a “lick” or a “drop” is unlikely to produce toxicity, the accuracy of the history should be considered when determining whether or not to see a child.

Complete absorption of alcohol requires 30 minutes to 6 hours, depending on the volume, the presence of food, and the time spent in consuming the alcohol. The rate of metabolic degradation is constant (about 20 mg/h in an adult). Absolute ethanol, 1 mL/kg, results in a peak blood level of about 100 mg/dL in 1 hour after ingestion. Acute intoxication and chronic alcoholism increase the risk of subarachnoid hemorrhage.

► Treatment

Management of hypoglycemia and acidosis is usually the only measure required. Start an IV drip of D_5W or $D_{10}W$ if blood glucose is less than 60 mg/dL. Fructose and glucagon have been suggested but are no longer used. Death is usually caused by respiratory failure. In severe cases, cerebral edema may occur and should be appropriately treated.

Table 12-4. Intravenous acetylcysteine administration for children weighing less than 40 kg.

Body Weight		Loading Infusion (15 min)—150 mg/kg		
(kg)	(lb)	NAC 20% (mL)	Diluent Volume D_5W (mL)	Final Volume (mL)
30	66	22.5	90	112.5
25	55	18.75	75	93.75
20	44	15	60	75
15	33	11.25	45	56.25

AMPHETAMINES & RELATED DRUGS (METHAMPHETAMINE)

Clinical Presentation

A. Acute Poisoning

Amphetamine and methamphetamine poisoning is common because of the widespread availability of “diet pills” and the use of “speed,” “crank,” “crystal,” and “ice” by adolescents. (Care must be taken in the interpretation of slang terms because they have multiple meanings.) A new cause of amphetamine poisoning is drugs for treating attention-deficit/hyperactivity disorder, such as methylphenidate. Symptoms include central nervous system (CNS) stimulation, anxiety, hyperactivity, hyperpyrexia, hypertension, abdominal cramps, nausea and vomiting, and inability to void urine. Severe cases often include rhabdomyolysis. A toxic psychosis indistinguishable from paranoid schizophrenia may occur. Methamphetamine laboratories in homes are a potential cause of childhood exposure to a variety of hazardous and toxic substances.

B. Chronic Poisoning

Chronic amphetamine users develop tolerance; more than 1500 mg of IV methamphetamine can be used daily. Hyperactivity, disorganization, and euphoria are followed by exhaustion, depression, and coma lasting 2–3 days. Heavy users, taking more than 100 mg/d, have restlessness, incoordination of thought, insomnia, nervousness, irritability, and visual hallucinations. Psychosis may be precipitated by the chronic administration of high doses. Depression, weakness, tremors, GI complaints, and suicidal thoughts occur frequently.

Treatment

The treatment of choice is diazepam, titrated in small increments to effect. Very large total doses may be needed. In cases of extreme agitation or hallucinations, droperidol (0.1 mg/kg per dose) or haloperidol (up to 0.1 mg/kg) parenterally has been used. When combinations of amphetamines and barbiturates (diet pills) are used, the action of the amphetamines begins first, followed by a depression caused by the barbiturates. In these cases, treatment with additional barbiturates is contraindicated because of the risk of respiratory failure.

Chronic users may be withdrawn rapidly from amphetamines. If amphetamine–barbiturate combination tablets have been used, the barbiturates must be withdrawn gradually to prevent withdrawal seizures. Psychiatric treatment should be provided.

Schwartz RH, Miller NS: MDMA (ecstasy) and the rave: A review. *Pediatrics* 1997;100:705 [PMID: 9310529].

ANESTHETICS, LOCAL

Intoxication from local anesthetics may be associated with CNS stimulation, acidosis, delirium, ataxia, shock, convul-

sions, and death. Methemoglobinuria has been reported following local dental analgesia. The maximum recommended dose for subcutaneous (SQ) infiltration is 4.5 mg/kg. The temptation to exceed this dose in procedures lasting a long time is great and may result in inadvertent overdosage. PO application of viscous lidocaine may produce toxicity. Hypercapnia may lower the seizure threshold to locally injected anesthetics.

Local anesthetics used in obstetrics cross the placental barrier and are not efficiently metabolized by the fetal liver. Mepivacaine, lidocaine, and bupivacaine can cause fetal bradycardia, neonatal depression, and death. Prilocaine causes methemoglobinemia, which should be treated if levels in the blood exceed 40% or if the patient is symptomatic.

Accidental injection of mepivacaine into the head of the fetus during paracervical anesthesia has caused neonatal asphyxia, cyanosis, acidosis, bradycardia, convulsions, and death.

Treatment

If the anesthetic has been ingested, mucous membranes should be cleansed carefully and activated charcoal may be administered. Oxygen administration is indicated, with assisted ventilation if necessary. Methemoglobinemia is treated with methylene blue, 1%, 0.2 mL/kg (1–2 mg/kg per dose, IV) over 5–10 minutes; this should promptly relieve the cyanosis. Acidosis may be treated with sodium bicarbonate, seizures with diazepam, and bradycardia with atropine. Therapeutic levels of mepivacaine, lidocaine, and procaine are less than 5 mg/mL.

Spiller HA et al: Multi-center retrospective evaluation of oral benzocaine exposure in children. *Vet Hum Toxicol* 2000;42:228 [PMID: 10928690].

ANTI-HISTAMINES

Although antihistamines typically cause CNS depression, children often react paradoxically with excitement, hallucinations, delirium, ataxia, tremors, and convulsions followed by CNS depression, respiratory failure, or cardiovascular collapse. Anticholinergic effects such as dry mouth, fixed dilated pupils, flushed face, fever, and hallucinations may be prominent.

Antihistamines are widely available in allergy, sleep, cold, and antiemetic preparations, and many are supplied in sustained-release forms, which increase the likelihood of dangerous overdoses. They are absorbed rapidly and metabolized by the liver, lungs, and kidneys. A potentially toxic dose is 10–50 mg/kg of the most commonly used antihistamines, but toxic reactions have occurred at much lower doses.

Treatment

Activated charcoal should be used to reduce drug absorption. Whole bowel irrigation may be useful for sustained-release preparations. Physostigmine (0.5–2.0 mg IV, slowly administered) dramatically reverses the central and peripheral anti-

cholinergic effects of antihistamines, but it should be used only for diagnostic purposes. Diazepam (0.1–0.2 mg/kg IV) can be used to control seizures. Forced diuresis is not helpful. Exchange transfusion was reported to be effective in one case.

Ten Eick AP et al: Safety of antihistamines in children. *Drug Saf* 2001;24:119 [PMID: 11235817].

ARSENIC

Arsenic is used in some insecticides (fruit tree or tobacco sprays), rodenticides, weed killers, and wood preservatives. It is well absorbed primarily through the GI and respiratory tracts, but skin absorption may occur. Arsenic can be found in the urine, hair, and nails by laboratory testing.

Highly toxic soluble derivatives of this compound, such as sodium arsenite, are frequently found in liquid preparations and can cause death in as many as 65% of victims. The organic arsenates found in persistent or preemergence weed killers are relatively less soluble and less toxic. Poisonings with a liquid arsenical preparation that does not contain alkyl methanearsonate compounds should be considered potentially lethal. Patients exhibiting clinical signs other than gastroenteritis should receive treatment until laboratory tests indicate that treatment is no longer necessary.

► Clinical Findings

A. Acute Poisoning

Abdominal pain, vomiting, watery and bloody diarrhea, cardiovascular collapse, paresthesias, neck pain, and garlic odor on the breath occur as the first signs of acute poisoning. Convulsions, coma, anuria, and exfoliative dermatitis are later signs. Inhalation may cause pulmonary edema. Death is the result of cardiovascular collapse.

B. Chronic Poisoning

Anorexia, generalized weakness, giddiness, colic, abdominal pain, polyneuritis, dermatitis, nail changes, alopecia, and anemia often develop.

► Treatment

In acute poisoning administer activated charcoal. Then immediately give dimercaprol (commonly known as BAL), 3–5 mg/kg intramuscularly (IM), and follow with 2 mg/kg IM every 4 hours. The dimercaprol–arsenic complex is dialyzable. A second choice is succimer. The initial dose is 10 mg/kg every 8 hours for 5 days. A third choice is penicillamine, 100 mg/kg PO to a maximum of 1 g/d in four divided doses.

Chronic arsenic intoxication should be treated with succimer or penicillamine. Collect a 24-hour baseline urine specimen and then begin chelation. If the 24-hour urine arsenic level is greater than 50 mg, continue chelation for 5 days. After 10 days, repeat the 5-day cycle once or twice, depending on how soon the urine arsenic level falls below 50 mg/24 h.

Abernathy CO et al: Arsenic: Health effects, mechanisms of actions, and research issues. *Environ Health Perspect* 1999;107:593 [PMID: 10379007].

BARBITURATES

The toxic effects of barbiturates include confusion, poor coordination, coma, miotic or fixed dilated pupils, and respiratory depression. Respiratory acidosis is commonly associated with pulmonary atelectasis, and hypotension occurs frequently in severely poisoned patients. Ingestion of more than 6 mg/kg of long-acting or 3 mg/kg of short-acting barbiturates is usually toxic.

► Treatment

Activated charcoal should be administered. Careful, conservative management with emphasis on maintaining a clear airway, adequate ventilation, and control of hypotension is critical. Urinary alkalization and the use of multiple-dose charcoal may decrease the elimination half-life of phenobarbital but have not been shown to alter the clinical course. Hemodialysis is not useful in the treatment of poisoning with short-acting barbiturates. Analeptics are contraindicated.

Cote CJ et al: Adverse sedation events in pediatrics: Analysis of medications used for sedation. *Pediatrics* 2000;4:633 [PMID: 11015502].

BELLADONNA ALKALOIDS (ATROPINE, JIMSONWEED, POTATO LEAVES, SCOPOLAMINE, STRAMONIUM)

The effects of anticholinergic compounds include dry mouth; thirst; decreased sweating with hot, dry, red skin; high fever; and tachycardia that may be preceded by bradycardia. The pupils are dilated, and vision is blurred. Speech and swallowing may be impaired. Hallucinations, delirium, and coma are common. Leukocytosis may occur, confusing the diagnosis.

Atropinism has been caused by normal doses of atropine or homatropine eye drops, especially in children with Down syndrome. Many common plants and over-the-counter medications contain belladonna alkaloids.

► Treatment

If the patient is awake and showing no signs or symptoms, administer activated charcoal. Gastric emptying is slowed by anticholinergics, so that gastric decontamination may be useful even if delayed. Physostigmine (0.5–2.0 mg IV, administered slowly) dramatically reverses the central and peripheral signs of atropinism but should be used only as a diagnostic agent. High fever must be controlled. Catheterization may be needed if the patient cannot void.

Burns MJ et al: A comparison of physostigmine and benzodiazepines for the treatment of anticholinergic poisoning. *Ann Emerg Med* 2000;35:374 [PMID: 10736125].

CARBON MONOXIDE

The degree of toxicity correlates well with the carboxyhemoglobin level taken soon after acute exposure but not after oxygen has been given or when there has been some time since exposure. Onset of symptoms may be more rapid and more severe if the patient lives at a high altitude, has a high respiratory rate (ie, infants), is pregnant, or has myocardial insufficiency or lung disease. Normal blood may contain up to 5% carboxyhemoglobin (10% in smokers).

The most prominent early symptom is headache. Other effects include confusion, unsteadiness, and coma. Proteinuria, glycosuria, elevated serum aminotransferase levels, or ECG changes may be present in the acute phase. Permanent cardiac, liver, renal, or CNS damage occurs occasionally. The outcome of severe poisoning may be complete recovery, vegetative state, or any degree of mental injury between these extremes. The primary mental deficits are neuropsychiatric.

► Treatment

The biologic half-life of carbon monoxide on room air is approximately 200–300 minutes; on 100% oxygen, it is 60–90 minutes. Hyperbaric oxygen therapy at 2.0–2.5 atm of oxygen shortens the half-life to 30 minutes. After the level has been reduced to near zero, therapy is aimed at the nonspecific sequelae of anoxia. Dexamethasone (0.1 mg/kg IV or IM every 4–6 hours) should be added if cerebral edema develops.

Chou KJ: Characteristics and outcome of children with carbon monoxide poisoning with and without smoke exposure referred for hyperbaric oxygen therapy. *Pediatr Emerg Care* 2000;3:151 [PMID: 10888449].

CAUSTICS

1. Acids (Hydrochloric, Hydrofluoric, Nitric, & Sulfuric Acids; Sodium Bisulfate)

Strong acids are commonly found in metal and toilet bowl cleaners, batteries, and other products. Hydrofluoric acid is the most toxic and hydrochloric acid the least toxic of these household substances. However, even a few drops can be fatal if aspirated into the trachea.

Painful swallowing, mucous membrane burns, bloody emesis, abdominal pain, respiratory distress due to edema of the epiglottis, thirst, shock, and renal failure can occur. Coma and convulsions sometimes are seen terminally. Residual lesions include esophageal, gastric, and pyloric strictures as well as scars of the cornea, skin, and oropharynx.

Hydrofluoric acid is a particularly dangerous poison. Dermal exposure creates a penetrating burn that can progress for hours or days. Large dermal exposure or ingestion may produce life-threatening hypocalcemia abruptly as well as burn reactions.

► Treatment

Emetics and lavage are contraindicated. Water or milk (< 15 mL/kg) is used to dilute the acid, because a heat-producing chemical reaction does not occur. Take care not to induce emesis by excessive fluid administration. Alkalies should not be used. Burned areas of the skin, mucous membranes, or eyes should be washed with copious amounts of warm water. Opioids for pain may be needed. An endotracheal tube may be required to alleviate laryngeal edema. Esophagoscopy should be performed if the patient has significant burns or difficulty in swallowing. Acids are likely to produce gastric burns or esophageal burns. Evidence is not conclusive, but corticosteroids have not proved to be of use.

Hydrofluoric acid burns on skin are treated with 10% calcium gluconate gel or calcium gluconate infusion. Severe exposure may require large doses of IV calcium. Therapy should be guided by calcium levels, the ECG, and clinical signs.

2. Bases (Clinitest Tablets, Clorox, Drano, Liquid-Plumr, Purex, Sani-Clor—Examine the Label or Call a Poison Center to Determine Contents)

Alkalies produce more severe injuries than acids. Some substances, such as Clinitest tablets or Drano, are quite toxic, whereas the chlorinated bleaches (3–6% solutions of sodium hypochlorite) are usually not toxic. When sodium hypochlorite comes in contact with acid in the stomach, hypochlorous acid, which is very irritating to the mucous membranes and skin, is formed. Rapid inactivation of this substance prevents systemic toxicity. Chlorinated bleaches, when mixed with a strong acid (toilet bowl cleaners) or ammonia, may produce irritating chlorine or chloramine gas, which can cause serious lung injury if inhaled in a closed space (eg, bathroom).

Alkalies can burn the skin, mucous membranes, and eyes. Respiratory distress may be due to edema of the epiglottis, pulmonary edema resulting from inhalation of fumes, or pneumonia. Mediastinitis or other intercurrent infections or shock can occur. Perforation of the esophagus or stomach is rare.

► Treatment

The skin and mucous membranes should be cleansed with copious amounts of water. A local anesthetic can be instilled in the eye if necessary to alleviate blepharospasm. The eye should be irrigated for at least 20–30 minutes. Ophthalmologic consultation should be obtained for all alkaline eye burns.

Ingestions should be treated with water as a diluent. Routine esophagoscopy is no longer indicated to rule out burns of the esophagus due to chlorinated bleaches unless an unusually large amount has been ingested or the patient is symptomatic. The absence of oral lesions does not rule out the possibility of laryngeal or esophageal burns following granular alkali ingestion. The use of corticosteroids is controversial, but has not been shown to improve long-term

outcome except possibly in partial-thickness esophageal burns. Antibiotics may be needed if mediastinitis is likely, but they should not be used prophylactically. (See Caustic Burns of the Esophagus section in Chapter 20.)

COCAINE

Cocaine is absorbed intranasally or via inhalation or ingestion. Effects are noted almost immediately when the drug is taken intravenously or smoked. Peak effects are delayed for about an hour when the drug is taken orally or nasally. Cocaine prevents the reuptake of endogenous catecholamines, thereby causing an initial sympathetic discharge, followed by catechol depletion after chronic abuse.

Clinical Findings

A local anesthetic and vasoconstrictor, cocaine is also a potent stimulant to both the CNS and the cardiovascular system. The initial tachycardia, hyperpnea, hypertension, and stimulation of the CNS are often followed by coma, seizures, hypotension, and respiratory depression. In severe cases of overdose, various dysrhythmias may be seen, including sinus tachycardia, atrial arrhythmias, premature ventricular contractions, bigeminy, and ventricular fibrillation. If large doses are taken intravenously, cardiac failure, dysrhythmias, rhabdomyolysis, or hyperthermia may result in death.

In addition to those poisoned through recreational use of cocaine, others are at risk of overdose. A “body stuffer” is one who quickly ingests the drug, usually poorly wrapped, to avoid discovery. A “body packer” wraps the drug carefully for prolonged transport. A stuffer typically manifests toxicity within hours of ingestion; a packer is asymptomatic unless the package ruptures, usually days later.

Treatment

Except in cases of body stuffers or body packers, decontamination is seldom possible. Activated charcoal should be administered, and whole bowel irrigation may be useful in selected cases. Testing for cocaine in blood or plasma is generally not clinically useful, but a qualitative analysis of the urine may aid in confirming the diagnosis. For severe cases, an ECG is indicated. In suspected cases of body packing, radiographs of the GI tract may show multiple packets. Radiographic films are usually not helpful for identifying stuffers. Seizures are treated with IV diazepam titrated to response. Hypotension is treated with standard agents.

Because cocaine abuse may deplete norepinephrine, an indirect agent such as dopamine may be less effective than a direct agent such as norepinephrine. Agitation is best treated with a benzodiazepine.

Qureshi AI et al: Cocaine use and the likelihood of nonfatal myocardial infarction and stroke: Data from the Third National Health and Nutrition Examination Survey. *Circulation* 2001;103:502 [PMID: 11157713].

CONTRACEPTIVE PILLS

The only known toxic effects following acute ingestion of oral contraceptive agents are nausea, vomiting, and vaginal bleeding in girls.

COSMETICS & RELATED PRODUCTS

The relative toxicities of commonly ingested products in this group are listed in Table 12–5. Permanent wave neutralizers may contain bromates, peroxides, or perborates. Bromates have been removed from most products because they can cause nausea, vomiting, abdominal pain, shock, hemolysis, renal failure, and convulsions.

Perborates can cause boric acid poisoning. Four grams of bromate salts is potentially lethal.

Poisoning is treated by gastric lavage with 1% sodium thiosulfate. Sodium bicarbonate, 2%, in the lavage fluid may reduce hydrobromic acid formation. Sodium thiosulfate, 25%, 1.65 mL/kg, can be given intravenously, but methylene blue should not be used to treat methemoglobinemia in this situation because it increases the toxicity of bromates. Dialysis is indicated in renal failure but does not enhance excretion of bromate.

Table 12–5. Relative toxicities of cosmetics and similar products.

High toxicity	Low toxicity
Permanent wave neutralizers	Perfume
Moderate toxicity	Hair removers
Fingernail polish	Deodorants
Fingernail polish remover	Bath salts
Metallic hair dyes	No toxicity
Home permanent wave lotion	Liquid makeup
Bath oil	Vegetable hair dye
Shaving lotion	Cleansing cream
Hair tonic (alcoholic)	Hair dressing (nonalcoholic)
Cologne, toilet water	Hand lotion or cream
	Lipstick

Fingernail polish removers used to contain toluene but now usually have an acetone base, which does not require specific treatment other than monitoring CNS status.

Cobalt, copper, cadmium, iron, lead, nickel, silver, bismuth, and tin are sometimes found in metallic hair dyes. In large amounts they can cause skin sensitization, urticaria, dermatitis, eye damage, vertigo, hypertension, asthma, methemoglobinemia, tremors, convulsions, and coma. Treatment for ingestions is to administer demulcents and, only with large amounts, the appropriate antidote for the heavy metal involved.

Home permanent wave lotions, hair straighteners, and hair removers usually contain thioglycolic acid salts, which cause alkaline irritation and perhaps CNS depression.

Shaving lotion, hair tonic, hair straighteners, cologne, and toilet water contain denatured alcohol, which can cause CNS depression and hypoglycemia.

Deodorants usually consist of an antibacterial agent in a cream base. Antiperspirants are aluminum salts, which frequently cause skin sensitization. Zirconium oxide can cause granulomas in the axilla with chronic use.

CYCLIC ANTIDEPRESSANTS

Cyclic antidepressants (eg, amitriptyline, imipramine) have a very low ratio of toxic to therapeutic doses, and even a moderate overdose can have serious effects.

Cyclic antidepressant overdose causes dysrhythmias, coma, convulsions, hypertension followed by hypotension, and hallucinations. These effects may be life-threatening and require rapid intervention. One agent, amoxapine, differs in that it causes fewer cardiovascular complications, but it is associated with a higher incidence of seizures.

► Treatment

Decontamination should include administration of activated charcoal unless the patient is symptomatic.

An ECG should be obtained in all patients. A QRS interval greater than 100 ms specifically identifies patients at risk to develop dysrhythmias. If dysrhythmias are demonstrated, the patient should be admitted and monitored until free of irregularity for 24 hours. Another indication for monitoring is persistent tachycardia of more than 110 beats/min. The onset of dysrhythmias is rare beyond 24 hours after ingestion.

Alkalinization with sodium bicarbonate (0.5–1.0 mEq/kg IV) or hyperventilation may dramatically reverse ventricular dysrhythmias and narrow the QRS interval. Lidocaine may be added for treatment of arrhythmias. Bolus administration of sodium bicarbonate is recommended for all patients with QRS widening to above 120 ms and for those with significant dysrhythmias, to achieve a pH of 7.5–7.6. Forced diuresis is contraindicated. A benzodiazepine should be given for convulsions.

Hypotension is a major problem. Cyclic antidepressants block the reuptake of catecholamines, thereby producing

initial hypertension followed by hypotension. Treatment with physostigmine is contraindicated. Vasopressors are generally effective. Dopamine is the agent of choice because it is readily available. If dopamine is ineffective, norepinephrine (0.1–1 µg/kg/min, titrated to response) should be added. Diuresis and hemodialysis are not effective.

Kerr GW et al: Tricyclic antidepressant overdose: A review. *Emerg Med J* 2001;18:236 [PMID: 11435353].

DIGITALIS & OTHER CARDIAC GLYCOSIDES

Toxicity is typically the result of incorrect dosing or unrecognized renal insufficiency. Clinical features include nausea, vomiting, diarrhea, headache, delirium, confusion, and, occasionally, coma. Cardiac dysrhythmias typically involve bradydysrhythmias, but every type of dysrhythmia has been reported in digitalis intoxication, including atrial fibrillation, paroxysmal atrial tachycardia, and atrial flutter. Death usually is the result of ventricular fibrillation. Transplacental intoxication by digitalis has been reported.

► Treatment

Administer activated charcoal. Potassium is contraindicated in acute overdose unless there is laboratory evidence of hypokalemia. In acute overdose, hyperkalemia is more common. Hypokalemia is common in chronic toxicity.

The patient must be monitored carefully for ECG changes. The correction of acidosis better demonstrates the degree of potassium deficiency present. Bradycardias have been treated with atropine. Phenytoin, lidocaine, magnesium salts (not in renal failure), amiodarone, and bretylium have been used to correct arrhythmias.

Definitive treatment is with digoxin immune Fab (ovine) (Digibind). Indications for its use include hypotension or any dysrhythmia, typically ventricular dysrhythmias and progressive bradydysrhythmias that produce clinical concern. Elevated T waves indicate high potassium and may be an indication for digoxin immune Fab (Digibind, DigiFab) use. Techniques of determining dosage and indications related to levels, when available are described in product literature.

Woolf AD et al: The use of digoxin-specific Fab fragments for severe digitalis intoxication in children. *N Engl J Med* 1992;326:1739 [PMID: 1997016].

DIPHENOXYLATE WITH ATROPINE (LOMOTIL) & LOPERAMIDE (IMODIUM)

Loperamide (Imodium) has largely replaced Lomotil and does not produce significant toxicity. Ingestions of up to 0.4 mg/kg can safely be managed at home.

Lomotil contains diphenoxylate hydrochloride, a synthetic narcotic, and atropine sulfate. Small amounts are potentially lethal in children; it is contraindicated in chil-

dren younger than age 2 years. Early signs of intoxication with this preparation result from its anticholinergic effect and consist of fever, facial flushing, tachypnea, and lethargy. However, the miotic effect of the narcotic predominates. Later, hypothermia, increasing CNS depression, and loss of the facial flush occur. Seizures are probably secondary to hypoxia.

► Treatment

Prolonged monitoring (24 hours) with pulse oximetry and careful attention to airway is sufficient in most cases.

Naloxone hydrochloride (0.4–2.0 mg IV in children and adults) should be given. Repeated doses may be required because the duration of action of diphenoxylate is considerably longer than that of naloxone.

McCarron MM et al: Diphenoxylate-atropine (Lomotil) overdose in children: An update. *Pediatrics* 1991;87:694 [PMID: 2020516].

DISINFECTANTS & DEODORIZERS

1. Naphthalene

Naphthalene is commonly found in mothballs, disinfectants, and deodorizers. Naphthalene's toxicity is often not fully appreciated. It is absorbed not only when ingested but also through the skin and lungs. It is potentially hazardous to store baby clothes in naphthalene, because baby oil is an excellent solvent that may increase dermal absorption. **Note:** Most mothballs contain *para*-dichlorobenzene and not naphthalene (see next section). Metabolic products of naphthalene may cause severe hemolytic anemia, similar to that due to primaquine toxicity, 2–7 days after ingestion. Other physical findings include vomiting, diarrhea, jaundice, oliguria, anuria, coma, and convulsions. The urine may contain hemoglobin, protein, and casts.

► Treatment

Administer activated charcoal. Urinary alkalization may prevent blocking of the renal tubules by acid hematin crystals. Anuria may persist for 1–2 weeks and still be completely reversible.

Siegel E, Wason S: Mothball toxicity. *Pediatr Clin North Am* 1986;33:369 [PMID: 3515301].

2. *P*-Dichlorobenzene, Phenolic Acids, & Others

Disinfectants and deodorizers containing *p*-dichlorobenzene or sodium sulfate are much less toxic than those containing naphthalene. Disinfectants containing phenolic acids are highly toxic, especially if they contain a borate ion. Phenol precipitates tissue proteins and causes respiratory alkalosis followed by metabolic acidosis. Some phenols cause methemoglobinemia.

Local gangrene occurs after prolonged contact with tissue. Phenol is readily absorbed from the GI tract, causing diffuse capillary damage and, in some cases, methemoglobinemia. Pentachlorophenol, which has been used in terminal rinsing of diapers, has caused infant fatalities.

The toxicity of alkalis, quaternary ammonium compounds, pine oil, and halogenated disinfectants varies with the concentration of active ingredients. Wick deodorizers are usually of moderate toxicity. Iodophor disinfectants are the safest. Spray deodorizers are not usually toxic, because a child is not likely to swallow a very large dose.

Signs and symptoms of acute quaternary ammonium compound ingestion include diaphoresis, strong irritation, thirst, vomiting, diarrhea, cyanosis, hyperactivity, coma, convulsions, hypotension, abdominal pain, and pulmonary edema. Acute liver or renal failure may develop later.

► Treatment

Activated charcoal may be used. Castor oil dissolves phenol and may retard its absorption. This property of castor oil, however, has not been proved clinically. Mineral oil and alcohol are contraindicated because they increase the gastric absorption of phenol. The metabolic acidosis must be managed carefully. Anticonvulsants or measures to treat shock may be needed.

Because phenols are absorbed through the skin, exposed areas should be irrigated copiously with water. Undiluted polyethylene glycol may be a useful solvent as well.

Van Berkel M, de Wolff FA: Survival after acute benzalkonium chloride poisoning. *Hum Toxicol* 1988;7:191 [PMID: 3378808].

DISK-SHAPED BATTERIES

Small, flat, smooth disk-shaped batteries measure between 10 and 25 mm in diameter. About 69% of them pass through the GI tract in 48 hours and 85% in 72 hours. Some may become entrapped. These batteries contain caustic materials and heavy metals.

Batteries impacted in the esophagus may cause symptoms of refusal to take food, increased salivation, vomiting with or without blood, and pain or discomfort. Aspiration into the trachea may also occur. Fatalities have been reported in association with esophageal perforation.

When a history of disk battery ingestion is obtained, radiographs of the entire respiratory tract and GI tract should be taken so that the battery can be located and the proper therapy determined.

► Treatment

If the disk battery is located in the esophagus, it must be removed immediately. If the battery has been in the esophagus for more than 24 hours, the risk of caustic burn is greater.

Location of the disk battery below the esophagus has been associated with tissue damage, but the course is benign in most cases. Perforated Meckel diverticulum has been the major complication. It may take as long as 7 days for spontaneous passage to occur, and lack of movement in the GI tract may not require removal in an asymptomatic patient.

Some researchers have suggested repeated radiographs and surgical intervention if passage of the battery pauses, but this approach may be excessive. Batteries that have opened in the GI tract have been associated with some toxicity due to mercury, but the patients have recovered.

Emesis is ineffective. Asymptomatic patients may simply be observed and stools examined for passage of the battery. If the battery has not passed within 7 days or if the patient becomes symptomatic, radiographs should be repeated. If the battery has come apart or appears not to be moving, a purgative, enema, or nonabsorbable intestinal lavage solution should be administered. If these methods are unsuccessful, surgical intervention may be required. Levels of heavy metals (mainly mercury) should be measured in patients in whom the battery has opened or symptoms have developed.

Litovitz TL, Schmitz BF: Ingestion of cylindrical and button batteries: An analysis of 2382 cases. *Pediatrics* 1992;89:747 [PMID: 2304794].

ETHYLENE GLYCOL & METHANOL

Ethylene glycol and methanol are the toxic alcohols. The primary source of ethylene glycol is antifreeze, whereas methanol is present in windshield wiper fluid and also as an ethanol denaturant. Ethylene glycol causes severe metabolic acidosis and renal failure. Methanol causes metabolic acidosis and blindness. Onset of symptoms with both agents occurs within several hours after ingestion, longer if ethanol was ingested simultaneously.

► Treatment

The primary treatment is to block the enzyme alcohol dehydrogenase, which converts both agents to their toxic metabolites. This is accomplished with fomepizole (loading dose of 15 mg/kg) or ethanol. Fomepizole is preferred for children, due to its reduced side effects in this age group.

Barceloux DG et al: American Academy of Clinical Toxicology Practice Guidelines on the Treatment of Methanol Poisoning. *J Toxicol Clin Toxicol* 2002;40:415 [PMID: 12216995].

Brent J et al: Fomepizole for the treatment of ethylene glycol poisoning: Methylpyrazole for toxic alcohols study group. *N Engl J Med* 1999;40:832 [PMID: 10080845].

GAMMA-HYDROXYBUTYRATE, GAMMA-BUTYROLACTONE, & BUTANEDIOL

Gamma-hydroxybutyrate (GHB), γ -butyrolactone (GBL), and butanediol have become popular drugs of abuse in adoles-

cents and adults. GHB is a CNS depressant that is structurally similar to the inhibitory neurotransmitter γ -aminobutyric acid. GBL and butanediol are converted in the body to GHB. These drugs cause deep but short-lived coma; the coma often lasts only 1–4 hours. Treatment consists of supportive care with close attention to airway and endotracheal intubation if respiratory depression or decreased gag reflex complicates the poisoning. Atropine has been used successfully for symptomatic bradycardia.

Withdrawal from GHB, GBL, or butanediol can cause several days of extreme agitation, hallucination, or tachycardia. Treatment with high doses of benzodiazepines or with butyrophenones (eg, haloperidol or droperidol) or secobarbital may be needed for several days.

Dyer JE et al: Gamma-hydroxybutyrate withdrawal syndrome. *Ann Emerg Med* 2001;37:147 [PMID: 11174231].

Sporer KA et al: Gamma-hydroxybutyrate serum levels and clinical syndrome after severe overdose. *Ann Emerg Med* 2003;42:3 [PMID: 12827115].

HYDROCARBONS (BENZENE, CHARCOAL LIGHTER FLUID, GASOLINE, KEROSENE, PETROLEUM DISTILLATES, TURPENTINE)

Ingestion of hydrocarbons may cause irritation of mucous membranes, vomiting, blood-tinged diarrhea, respiratory distress, cyanosis, tachycardia, and fever. Although a small amount (10 mL) of certain hydrocarbons is potentially fatal, patients have survived ingestion of several ounces of other petroleum distillates. The more aromatic a hydrocarbon is and the lower its viscosity rating, the more potentially toxic it is. Benzene, gasoline, kerosene, and red seal oil furniture polish are the most dangerous. A dose exceeding 1 mL/kg is likely to cause CNS depression. A history of coughing or choking, as well as vomiting, suggests aspiration with resulting hydrocarbon pneumonia. This is an acute hemorrhagic necrotizing disease that usually develops within 24 hours of the ingestion and resolves without sequelae in 3–5 days. However, several weeks may be required for full resolution of hydrocarbon pneumonia. Pneumonia may be caused by the aspiration of a few drops of petroleum distillate into the lung or by absorption from the circulatory system. Pulmonary edema and hemorrhage, cardiac dilation and dysrhythmias, hepatosplenomegaly, proteinuria, and hematuria can occur following large overdoses. Hypoglycemia is occasionally present. A chest radiograph may reveal pneumonia within hours after the ingestion. An abnormal urinalysis in a child with a previously normal urinary tract suggests a large overdose.

► Treatment

Both emetics and lavage should be avoided. Mineral oil should not be given, because it can cause a low-grade lipid pneumonia.

Epinephrine should not be used with halogenated hydrocarbons because it may affect an already sensitized myocardium. The usefulness of corticosteroids is debated, and antibiotics should be reserved for patients with infections. Oxygen and mist are helpful. Extracorporeal membrane oxygenation has been successful in at least two cases of failure with standard therapy.

Lorenc JD: Inhalant abuse in the pediatric populations: A persistent challenge. *Curr Opin Pediatr* 2003;15:204 [PMID: 12640280].

IBUPROFEN

Most exposures in children do not produce symptoms. In one study, for example, children ingesting up to 2.4 g remained asymptomatic. When symptoms occur, the most common are abdominal pain, vomiting, drowsiness, and lethargy. In rare cases, apnea (especially in young children), seizures, metabolic acidosis, and CNS depression leading to coma have occurred.

► Treatment

If a child has ingested less than 100 mg/kg, dilution with water or milk may be all that is necessary to minimize the GI upset. In children, the volume of liquid used for dilution should be less than 4 oz. When the ingested amount is more than 400 mg/kg, seizures or CNS depression may occur; therefore, gastric lavage may be preferred to emesis. Activated charcoal may also be of value. There is no specific antidote. Neither alkalinization of the urine nor hemodialysis is helpful.

Cuzzolin L et al: NSAID-induced nephrotoxicity from the fetus to the child. *Drug Safety* 2001;24:2:9 [PMID: 11219488].

Oker EE et al: Serious toxicity in a young child due to ibuprofen. *Acad Emerg Med* 2000;7:821 [PMID: 10917334].

INSECT STINGS (BEE, WASP, & HORNET)

Insect stings are painful but not usually dangerous; however, death from anaphylaxis may occur. Bee venom has hemolytic, neurotoxic, and histamine-like activities that can on rare occasion cause hemoglobinuria and severe anaphylactoid reactions. Massive envenomation from numerous stings may cause hemolysis, rhabdomyolysis, and shock leading to multiple organ failure.

► Treatment

The physician should remove the stinger, taking care not to squeeze the attached venom sac. For allergic reactions, epinephrine 1:1000 solution, 0.01 mL/kg, should be administered IV or SQ above the site of the sting. Three to four

whiffs from an isoproterenol aerosol inhaler may be given at 3- to 4-minute intervals as needed. Corticosteroids (hydrocortisone; 100 mg IV) and diphenhydramine (1.5 mg/kg IV) are useful ancillary drugs but have no immediate effect. Ephedrine or antihistamines may be used for 2 or 3 days to prevent recurrence of symptoms.

A patient who has had a potentially life-threatening insect sting should be desensitized against the Hymenoptera group, because the honey bee, wasp, hornet, and yellow jacket have common antigens in their venom. For the more usual stings, cold compresses, aspirin, and diphenhydramine (1 mg/kg PO) are sufficient.

Ross RN et al: Effectiveness of specific immunotherapy in the treatment of hymenoptera venom hypersensitivity: A meta-analysis. *Clin Ther* 2000;22:351 [PMID: 10963289].

Vetter RS et al: Mass envenomations by honey bees and wasps. *West J Med* 1999;170:223 [PMID: 10344177].

INSECTICIDES

The petroleum distillates or other organic solvents used in these products are often as toxic as the insecticide itself. Decontamination may be performed by aspirating the stomach with a nasogastric tube.

1. Chlorinated Hydrocarbons (eg, Aldrin, Carbinol, Chlordane, DDT, Dieldrin, Endrin, Heptachlor, Lindane, Toxaphene)

Signs of intoxication include salivation, GI irritability, abdominal pain, vomiting, diarrhea, CNS depression, and convulsions. Inhalation exposure causes irritation of the eyes, nose, and throat; blurred vision; cough; and pulmonary edema.

Chlorinated hydrocarbons are absorbed through the skin, respiratory tract, and GI tract. Decontamination of skin with soap and evacuation of the stomach contents are critical. All contaminated clothing should be removed. Castor oil, milk, and other substances containing fats or oils should not be left in the stomach because they increase absorption of the chlorinated hydrocarbons. Convulsions should be treated with diazepam (0.1–0.3 mg/kg IV). Epinephrine should not be used because it may cause cardiac arrhythmias.

2. Organophosphate (Cholinesterase-Inhibiting) Insecticides (eg, Chlorothion, Co-Ral, DFP, Diazinon, Malathion, Paraoxon, Parathion, Phosdrin, TEPP, Thio-TEPP)

Dizziness, headache, blurred vision, miosis, tearing, salivation, nausea, vomiting, diarrhea, hyperglycemia, cyanosis, sense of constriction of the chest, dyspnea, sweating, weakness, muscular twitching, convulsions, loss of reflexes and sphincter control, and coma can occur.

The clinical findings are the result of cholinesterase inhibition, which causes an accumulation of acetylcholine.

The onset of symptoms occurs within 12 hours of the exposure. Red cell cholinesterase levels should be measured as soon as possible. (Some normal individuals have a low serum cholinesterase level.) Normal values vary in different laboratories. In general, a decrease of red cell cholinesterase to below 25% of normal indicates significant exposure.

Repeated low-grade exposure may result in sudden, acute toxic reactions. This syndrome usually occurs after repeated household spraying rather than agricultural exposure.

Although all organophosphates act by inhibiting cholinesterase activity, they vary greatly in their toxicity. Parathion, for example, is 100 times more toxic than Malathion. Toxicity is influenced by the specific compound, type of formulation (liquid or solid), vehicle, and route of absorption (lungs, skin, or GI tract).

► Treatment

Decontamination of skin, nails, hair, and clothing with soapy water is extremely important. Atropine plus a cholinesterase reactivator, pralidoxime, is an antidote for organophosphate insecticide poisoning. After assessment and management of the ABCs, atropine should be given and repeated every few minutes until airway secretions diminish. An appropriate starting dose of atropine is 2–4 mg IV in an adult and 0.05 mg/kg in a child. The patient should receive enough atropine to stop secretions (mydriasis is not an appropriate stopping point). Severe poisoning may require gram quantities of atropine administered over 24 hours.

Because atropine antagonizes the muscarinic parasympathetic effects of the organophosphates but does not affect the nicotinic receptor, it does not improve muscular weakness. Pralidoxime should also be given immediately in more severe cases and repeated every 6–12 hours as needed (25–50 mg/kg diluted to 5% and infused over 5–30 minutes at a rate of no more than 500 mg/min). Pralidoxime should be used in addition to—not in place of—atropine if red cell cholinesterase is less than 25% of normal. Pralidoxime is most useful within 48 hours after the exposure but has shown some effects 2–6 days later. Morphine, theophylline, aminophylline, succinylcholine, and tranquilizers of the reserpine and phenothiazine types are contraindicated. Hyperglycemia is common in severe poisonings.

Eisenstein EM, Amitai Y: Index of suspicion: Case 1. Organophosphate intoxication. *Pediatr Rev* 2000;21:205 [PMID: 10854316].

3. Carbamates (eg, Carbaryl, Sevin, Zectran)

Carbamate insecticides are reversible inhibitors of cholinesterase. The signs and symptoms of intoxication are similar to those associated with organophosphate poisoning but are generally less severe. Atropine titrated to effect is sufficient treatment. Pralidoxime should not be used with carbaryl poisoning but is of value with other carbamates. In combined exposures to organophosphates, give atropine but

reserve pralidoxime for cases in which the red cell cholinesterase is depressed below 25% of normal or marked effects of nicotinic receptor stimulation are present.

4. Botanical Insecticides (eg, Black Flag Bug Killer, Black Leaf CPR Insect Killer, Flit Aerosol House & Garden Insect Killer, French's Flea Powder, Raid)

Allergic reactions, asthma-like symptoms, coma, and convulsions have been reported. Pyrethrins, allethrin, and rotenone do not commonly cause signs of toxicity. Antihistamines, short-acting barbiturates, and atropine are helpful as symptomatic treatment.

IRON

Five stages of intoxication may occur in iron poisoning: (1) Hemorrhagic gastroenteritis, which occurs 30–60 minutes after ingestion and may be associated with shock, acidosis, coagulation defects, and coma. This phase usually lasts 4–6 hours. (2) Phase of improvement, lasting 2–12 hours, during which patient looks better. (3) Delayed shock, which may occur 12–48 hours after ingestion. Metabolic acidosis, fever, leukocytosis, and coma may also be present. (4) Liver damage with hepatic failure. (5) Residual pyloric stenosis, which may develop about 4 weeks after the ingestion.

Once iron is absorbed from the GI tract, it is not normally eliminated in feces but may be partially excreted in the urine, giving it a red color prior to chelation. A reddish discoloration of the urine suggests a serum iron level greater than 350 mg/dL.

► Treatment

GI decontamination is based on clinical assessment. The patient should be referred to a health care facility if symptomatic or if the history indicates toxic amounts. Gastric lavage and whole bowel irrigation should be considered in these patients.

Shock is treated in the usual manner. Sodium bicarbonate and Fleet Phospho-Soda left in the stomach to form the insoluble phosphate or carbonate have not shown clinical benefit and have caused lethal hypernatremia or hyperphosphatemia. Deferoxamine, a specific chelating agent for iron, is a useful adjunct in the treatment of severe iron poisoning. It forms a soluble complex that is excreted in the urine. It is contraindicated in patients with renal failure unless dialysis can be used. IV deferoxamine chelation therapy should be instituted if the patient is symptomatic and a serum iron determination cannot be obtained readily, or if the peak serum iron exceeds 400 mcg/dL (62.6 $\mu\text{mol/L}$) at 4–5 hours after ingestion.

Deferoxamine should not be delayed until serum iron levels are available in serious cases of poisoning. IV administration is indicated if the patient is in shock, in which case it

should be given at a dosage of 15 mg/kg/h. Infusion rates up to 35 mg/kg/h have been used in life-threatening poisonings. Rapid IV administration can cause hypotension, facial flushing, urticaria, tachycardia, and shock. Deferoxamine, 90 mg/kg IM every 8 hours (maximum, 1 g), may be given if IV access cannot be established, but the procedure is painful. The indications for discontinuation of deferoxamine have not been clearly delineated. Generally, it can be stopped after 12–24 hours if the acidosis has resolved and the patient is improving.

Hemodialysis, peritoneal dialysis, or exchange transfusion can be used to increase the excretion of the dialyzable complex. Urine output should be monitored and urine sediment examined for evidence of renal tubular damage. Initial laboratory studies should include blood typing and cross-matching; total protein; serum iron, sodium, potassium, and chloride; PCO_2 ; pH; and liver function tests. Serum iron levels fall rapidly even if deferoxamine is not given.

After the acute episode, liver function studies and an upper GI series are indicated to rule out residual damage.

Juurink DN et al: Iron poisoning in young children: Association with the birth of a sibling. *CMAJ* 2003;165:1539 [PMID: 12796332].

LEAD

Lead poisoning (plumbism) causes vague symptoms, including weakness, irritability, weight loss, vomiting, personality changes, ataxia, constipation, headache, and colicky abdominal pain. Late manifestations consist of retarded development, convulsions, and coma associated with increased intracranial pressure, which is a medical emergency.

Plumbism usually occurs insidiously in children younger than age 5 years. The most likely sources of lead include flaking leaded paint, artist's paints, fruit tree sprays, solder, brass alloys, home-glazed pottery, and fumes from burning batteries. Only paint containing less than 1% lead is safe for interior use (eg, furniture, toys). Repetitive ingestions of small amounts of lead are far more serious than a single massive exposure. Toxic effects are likely to occur if more than 0.5 mg of lead per day is absorbed.

Blood lead levels are used to assess the severity of exposure. A complete blood count and serum ferritin concentration should be obtained; iron-deficiency increases absorption of lead. Glycosuria, proteinuria, hematuria, and aminoaciduria occur frequently. Blood lead levels usually exceed 80 mcg/dL in symptomatic patients. Abnormal blood lead levels should be repeated in asymptomatic patients to rule out laboratory error. Specimens must be meticulously obtained in acid-washed containers. A normocytic, slightly hypochromic anemia with basophilic stippling of the red cells and reticulocytosis may be present in plumbism. Stippling of red blood cells is absent in cases involving only recent ingestion.

The cerebrospinal fluid (CSF) protein is elevated, and the white cell count usually is less than 100 cells/mL. CSF pressure may be elevated in patients with encephalopathy; lumbar punctures must be performed cautiously to prevent herniation.

► Treatment

Succimer is an orally administered chelator approved for use in children and reported to be as efficacious as calcium edetate. Treatment for blood lead levels of 20–45 mcg/dL in children has not been determined. Succimer should be initiated at blood lead levels over 45 mcg/dL. The initial dose is 10 mg/kg (350 mg/m²) every 8 hours for 5 days. The same dose is then given every 12 hours for 14 days. At least 2 weeks should elapse between courses. Blood lead levels increase somewhat (ie, rebound) after discontinuation of therapy. Courses of dimercaprol (4 mg/kg per dose) and calcium edetate may still be used but are no longer the preferred method, except in cases of lead encephalopathy.

Anticonvulsants may be needed. Mannitol or corticosteroids and volume restriction are indicated in patients with encephalopathy. A high-calcium, high-phosphorus diet and large doses of vitamin D may remove lead from the blood by depositing it in the bones. A public health team should evaluate the source of the lead. Necessary corrections should be completed before the child is returned home.

Rogan WJ et al: Treatment of Lead-Exposed Children Trial Group: The effect of chelation therapy with succimer on neuropsychological development in children exposed to lead. *N Engl J Med* 2001;344:1421 [PMID: 11346806].

MAGNETS

Although not strictly toxic, small magnets have been found to cause bowel obstructions in children. Recent cases have resulted in warnings and a recall by the Consumer Product Safety Commission following intestinal perforation and death in a 20-month-old child. Obstruction may occur following ingestion of as few as two magnets.

Alzahem AM et al: Ingested magnets and gastrointestinal complications. *J Paediatr Child Health* 2007;43:497 [PMID:17535185].
Consumer Product Safety Commission: <http://www.cpsc.gov/CPSC/PUB/PREREL/prhtml07/07163.html> 2007

MUSHROOMS

Toxic mushrooms are often difficult to distinguish from edible varieties. Contact a poison control center to obtain identification assistance. Symptoms vary with the species ingested, time of year, stage of maturity, quantity eaten, method of preparation, and interval since ingestion. A mushroom that is toxic to one individual may not be toxic to

another. Drinking alcohol and eating certain mushrooms may cause a reaction similar to that seen with disulfiram and alcohol. Cooking destroys some toxins but not the deadly one produced by *Amanita phalloides*, which is responsible for 90% of deaths due to mushroom poisoning. Mushroom toxins are absorbed relatively slowly. Onset of symptoms within 2 hours of ingestion suggests muscarinic toxin, whereas a delay of symptoms for 6–48 hours after ingestion strongly suggests *Amanita* (amanitin) poisoning. Patients who have ingested *A phalloides* may relapse and die of hepatic or renal failure following initial improvement.

Mushroom poisoning may produce muscarinic symptoms (salivation, vomiting, diarrhea, cramping abdominal pain, tenesmus, miosis, and dyspnea), coma, convulsions, hallucinations, hemolysis, and delayed hepatic and renal failure.

► Treatment

Administer activated charcoal. If the patient has muscarinic signs, give atropine, 0.05 mg/kg IM (0.02 mg/kg in toddlers), and repeat as needed (usually every 30 minutes) to keep the patient atropinized. Atropine, however, is used only when cholinergic effects are present and not for all mushrooms. Hypoglycemia is most likely to occur in patients with delayed onset of symptoms. Try to identify the mushroom if the patient is symptomatic. Consultation with a certified poison center is recommended. Local botanical gardens, university departments of botany, and societies of mycologists may be able to help. Supportive care is usually all that is needed; however, in the case of *A phalloides*, penicillin, silibinin, or hemodialysis may be indicated.

Lampe KF, McCann MA: Differential diagnosis of poisoning by North American mushrooms, with particular emphasis on *Amanita phalloides*-like intoxication. *Ann Emerg Med* 1987;16:956 [PMID: 3631682].

Pawlowska J et al: Liver transplantation in three family members after *Amanita phalloides* mushroom poisoning. *Transplant Proc* 2002;34:3313 [PMID: 12493457].

NITRITES, NITRATES, ANILINE, PENTACHLOROPHENOL, & DINITROPHENOL

Nausea, vertigo, vomiting, cyanosis (methemoglobinemia), cramping abdominal pain, tachycardia, cardiovascular collapse, tachypnea, coma, shock, convulsions, and death are possible manifestations of nitrite or nitrate poisoning.

Nitrite and nitrate compounds found in the home include amyl nitrite, butyl nitrates, isobutyl nitrates, nitroglycerin, pentaerythritol tetranitrate, sodium nitrite, nitrobenzene, and phenazopyridine. Pentachlorophenol and dinitrophenol, which are found in wood preservatives, produce methemoglobinemia and high fever because of uncoupling of oxidative phosphorylation. Headache, dizziness, and bradycardia have been reported. High concentrations of nitrites in well water or spinach have been the most common cause of nitrite-induced methemoglobinemia. Symptoms do not usually

occur until 15–50% of the hemoglobin has been converted to methemoglobin. A rapid test is to compare a drop of normal blood with the patient's blood on a dry filter paper. Brown discoloration of the patient's blood indicates a methemoglobin level of more than 15%.

► Treatment

Administer activated charcoal. Decontaminate affected skin with soap and water. Oxygen and artificial respiration may be needed. If the blood methemoglobin level exceeds 30%, or if levels cannot be obtained and the patient is symptomatic, give a 1% solution of methylene blue (0.2 mL/kg IV) over 5–10 minutes. Avoid perivascular infiltration, because it causes necrosis of the skin and subcutaneous tissues. A dramatic change in the degree of cyanosis should occur. Transfusion is occasionally necessary. Epinephrine and other vasoconstrictors are contraindicated. If reflex bradycardia occurs, atropine should be used.

Kennedy N et al: Faulty sausage production causing methemoglobinemia. *Arch Dis Child* 1997;76:367 [PMID: 9166036].

OPIOIDS (CODEINE, HEROIN, METHADONE, MORPHINE, PROPOXYPHENE)

Opioid-related medical problems may include drug addiction, withdrawal in a newborn infant, and accidental overdoses. Unlike other narcotics, methadone is absorbed readily from the GI tract. Most opioids, including heroin, methadone, meperidine, morphine, and codeine, are excreted in the urine within 24 hours and can be detected readily.

Narcotic-addicted adolescents often have other medical problems, including cellulitis, abscesses, thrombophlebitis, tetanus, infective endocarditis, HIV infection, tuberculosis, hepatitis, malaria, foreign body emboli, thrombosis of pulmonary arterioles, diabetes mellitus, obstetric complications, nephropathy, and peptic ulcer.

► Treatment

A. Overdose

Opioids can cause respiratory depression, stridor, coma, increased oropharyngeal secretions, sinus bradycardia, and urinary retention. Pulmonary edema rarely occurs in children; deaths usually result from aspiration of gastric contents, respiratory arrest, and cerebral edema. Convulsions may occur with propoxyphene overdosage.

Although suggested doses for naloxone hydrochloride range from 0.01–0.1 mg/kg, it is generally unnecessary to calculate the dosage on this basis. This extremely safe antidote should be given in sufficient quantity to reverse opioid binding sites. For children younger than age 1 year, 1 ampoule (0.4 mg) should be given initially; if there is no response, five more ampoules (2 mg) should be given rapidly. Older children should be given 0.4–0.8 mg, followed by 2–4 mg if there is no

response. An improvement in respiratory status may be followed by respiratory depression, because the antagonist's duration of action is less than 1 hour. Neonates poisoned in utero may require 10–30 mg/kg to reverse the effect.

B. Withdrawal in the Addict

Diazepam (10 mg every 6 hours PO) has been recommended for the treatment of mild narcotic withdrawal in ambulatory adolescents. Management of withdrawal in the confirmed addict may be accomplished with the administration of clonidine, by substitution with methadone, or with reintroduction of the original addicting agent, if available through a supervised drug withdrawal program. A tapered course over 3 weeks will accomplish this goal. Death rarely, if ever, occurs. The abrupt discontinuation of narcotics (cold turkey method) is not recommended and may cause severe physical withdrawal signs.

C. Withdrawal in the Newborn

A newborn infant in opioid withdrawal is usually small for gestational age and demonstrates yawning, sneezing, decreased Moro reflex, hunger but uncoordinated sucking action, jitteriness, tremor, constant movement, a shrill protracted cry, increased tendon reflexes, convulsions, vomiting, fever, watery diarrhea, cyanosis, dehydration, vasomotor instability, seizure, and collapse.

The onset of symptoms commonly begins in the first 48 hours but may be delayed as long as 8 days, depending on the timing of the mother's last fix and her predelivery medication. The diagnosis can be confirmed easily by identifying the narcotic in the urine of the mother and the newborn.

Several treatment methods have been suggested for narcotic withdrawal in the newborn. Phenobarbital (8 mg/kg/d IM or PO in 4 doses for 4 days and then reduced by one third every 2 days as signs decrease) may be continued for as long as 3 weeks. Methadone may be necessary in those infants with congenital methadone addiction who are not controlled in their withdrawal by large doses of phenobarbital. Dosage should be 0.5 mg/kg/d in two divided doses but can be increased gradually as needed. After control of the symptoms is achieved, the dose may be tapered over 4 weeks.

It is unclear whether prophylactic treatment with these drugs decreases the complication rate. The mortality rate of untreated narcotic withdrawal in the newborn may be as high as 45%.

Traub SJ et al: Pediatric "body packing". *Arch Pediatr Adolesc Med* 2003;157:174 [PMID: 12580688].

PHENOTHIAZINES (CHLORPROMAZINE, PROCHLORPERAZINE, TRIFLUOPERAZINE)

► Clinical Findings

A. Extrapyramidal Crisis

Episodes characterized by torticollis, stiffening of the body, spasticity, poor speech, catatonia, and inability to communi-

cate although conscious are typical manifestations. These episodes usually last a few seconds to a few minutes but have rarely caused death. Extrapyramidal crises may represent idiosyncratic reactions and are aggravated by dehydration. The signs and symptoms occur most often in children who have received prochlorperazine. They are commonly mistaken for psychotic episodes.

B. Overdose

Lethargy and deep prolonged coma commonly occur. Promazine, chlorpromazine, and prochlorperazine are the drugs most likely to cause respiratory depression and precipitous drops in blood pressure. Occasionally, paradoxical hyperactivity and extrapyramidal signs as well as hyperglycemia and acetonemia are present. Seizures are uncommon.

C. Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome is a rare idiosyncratic complication of phenothiazine use that may be lethal. It is a syndrome involving mental status change (confusion, coma), motor abnormalities (lead pipe rigidity, clonus), and autonomic dysfunction (tachycardia, hyperpyrexia).

► Treatment

Extrapyramidal signs are alleviated within minutes by the slow IV administration of diphenhydramine, 1–2 mg/kg (maximum, 50 mg), or benztropine mesylate, 1–2 mg IV (1 mg/min). No other treatment is usually indicated.

Patients with overdoses should receive conservative supportive care. Activated charcoal should be administered. Hypotension may be treated with standard agents, starting with isotonic saline administration. Agitation is best treated with diazepam. Neuroleptic malignant syndrome is treated by discontinuing the drug, giving aggressive supportive care, and administering dantrolene or bromocriptine.

O'Malley GF et al: Olanzapine overdose mimicking opioid intoxication. *Ann Emerg Med* 1999;34:279 [PMID: 10424936].

PLANTS

Many common ornamental, garden, and wild plants are potentially toxic. Only in a few cases will small amounts of a plant cause severe illness or death. Table 12–6 lists the **most toxic plants, symptoms and signs of poisoning, and treatment**. Contact your poison control center for assistance with identification.

PSYCHOTROPIC DRUGS

Psychotropic drugs consist of four general classes: stimulants (amphetamines, cocaine), depressants (eg, narcotics, barbiturates), antidepressants and tranquilizers, and hallucinogens (eg, LSD, PCP).

Table 12-6. Poisoning due to plants.^a

	Symptoms and Signs	Treatment
Arum family: <i>Caladium</i> , <i>Dieffenbachia</i> , calla lily, dumbcane (oxalic acid)	Burning of mucous membranes and airway obstruction secondary to edema caused by calcium oxalate crystals.	Accessible areas should be thoroughly washed. Corticosteroids relieve airway obstruction. Apply cold packs to affected mucous membranes.
Castor bean plant (ricin—a toxalbumin) Jequinty bean (abrin—a toxalbumin)	Mucous membrane irritation, nausea, vomiting, bloody diarrhea, blurred vision, circulatory collapse, acute hemolytic anemia, convulsions, uremia.	Fluid and electrolyte monitoring. Saline cathartic. Forced alkaline diuresis will prevent complications due to hemagglutination and hemolysis.
Foxglove, lily of the valley, and oleander ^b	Nausea, diarrhea, visual disturbances, and cardiac irregularities (eg, heart block).	See treatment for digitalis drugs in text.
Jimsonweed: See Belladonna Alkaloids section in text	Mydriasis, dry mouth, tachycardia, and hallucinations.	Activated charcoal.
Larkspur (ajacine, <i>Delphinium</i> , delphinine)	Nausea and vomiting, irritability, muscular paralysis, and central nervous system depression.	Symptomatic. Atropine may be helpful.
Monkshood (aconite)	Numbness of mucous membranes, visual disturbances, tingling, dizziness, tinnitus, hypotension, bradycardia, and convulsions.	Activated charcoal, oxygen. Atropine is probably helpful.
Poison hemlock (coniine)	Mydriasis, trembling, dizziness, bradycardia. Central nervous system depression, muscular paralysis, and convulsions. Death is due to respiratory paralysis.	Symptomatic. Oxygen and cardiac monitoring equipment are desirable. Assisted respiration is often necessary. Give anticonvulsants if needed.
<i>Rhododendron</i> (grayanotoxin)	Abdominal cramps, vomiting, severe diarrhea, muscular paralysis. Central nervous system and circulatory depression. Hypertension with very large doses.	Atropine can prevent bradycardia. Epinephrine is contraindicated. Antihypertensives may be needed.
Yellow jessamine (active ingredient, geisemine, is related to strychnine)	Restlessness, convulsions, muscular paralysis, and respiratory depression.	Symptomatic. Because of the relation to strychnine, activated charcoal and diazepam for seizures are worth trying.

^aMany other plants cause minor irritation but are not likely to cause serious problems unless large amounts are ingested. See Lampe KF, McCann MA: *AMA Handbook of Poisonous and Injurious Plants*. American Medical Association, 1985.

^bDone AK: Ornamental and deadly. *Emerg Med* 1973;5:255.

► Clinical Findings

The following clinical findings are commonly seen in patients abusing drugs. See also other entries discussed in alphabetic order in this chapter.

A. Stimulants

Agitation, euphoria, grandiose feelings, tachycardia, fever, abdominal cramps, visual and auditory hallucinations, mydriasis, coma, convulsions, and respiratory depression.

B. Depressants

Emotional lability, ataxia, diplopia, nystagmus, vertigo, poor accommodation, respiratory depression, coma, apnea, and convulsions. Dilation of conjunctival blood vessels suggests marijuana ingestion. Narcotics cause miotic pupils and, occasionally, pulmonary edema.

C. Antidepressants and Tranquilizers

Hypotension, lethargy, respiratory depression, coma, and extrapyramidal reactions.

D. Hallucinogens and Psychoactive Drugs

Belladonna alkaloids cause mydriasis, dry mouth, nausea, vomiting, urinary retention, confusion, disorientation, paranoid delusions, hallucinations, fever, hypotension, aggressive behavior, convulsions, and coma. Psychoactive drugs such as LSD cause mydriasis, unexplained bizarre behavior, hallucinations, and generalized undifferentiated psychotic behavior.

► Treatment

Only a small percentage of the persons using drugs come to the attention of physicians; those who do are usually

experiencing adverse reactions such as panic states, drug psychoses, homicidal or suicidal thoughts, or respiratory depression.

Even with cooperative patients, an accurate history is difficult to obtain. A drug history is most easily obtained in a quiet spot by a gentle, nonthreatening, honest examiner, and without the parents present. The user often does not really know what drug has been taken or how much. Street drugs are almost always adulterated with one or more other compounds. Multiple drugs are often taken together. Friends may be a useful source of information.

The patient's general appearance, skin, lymphatics, cardiorespiratory status, GI tract, and CNS should be focused on during the physical examination, because they often provide clues suggesting drug abuse.

Hallucinogens are not life-threatening unless the patient is frankly homicidal or suicidal. A specific diagnosis is usually not necessary for management; instead, the presenting signs and symptoms are treated. Does the patient appear intoxicated? In withdrawal? "Flashing back?" Is some illness or injury (eg, head trauma) being masked by a drug effect? (Remember that a known drug user may still have hallucinations from meningoencephalitis.)

The signs and symptoms in a given patient are a function not only of the drug and the dose but also of the level of acquired tolerance, the "setting," the patient's physical condition and personality traits, the potentiating effects of other drugs, and many other factors.

A common drug problem is the "bad trip," which is usually a panic reaction. This is best managed by "talking the patient down" and minimizing auditory and visual stimuli. Allowing the patient to sit with a friend while the drug effect dissipates may be the best treatment. This may take several hours. The physician's job is not to terminate the drug effect but to help the patient through the bad experience.

Drug therapy is often unnecessary and may complicate the clinical course of a drug-related panic reaction.

Although phenothiazines have been commonly used to treat bad trips, they should be avoided if the specific drug is unknown, because they may enhance toxicity or produce unwanted side effects. Diazepam is the drug of choice if a sedative effect is required. Physical restraints are rarely indicated and usually increase the patient's panic reaction.

For treatment of life-threatening drug abuse, consult the section on the specific drug elsewhere in this chapter and the section on general management at the beginning of the chapter.

After the acute episode, the physician must decide whether psychiatric referral is indicated; in general, patients who have made suicidal gestures or attempts and adolescents who are not communicating with their families should be referred.

SALICYLATES

The use of childproof containers and publicity regarding accidental poisoning have reduced the incidence of acute salicylate poisoning. Nevertheless, serious intoxication still occurs and must be regarded as an emergency. In recent years, the frequency of poisoning has begun to rise again.

Salicylates uncouple oxidative phosphorylation, leading to increased heat production, excessive sweating, and dehydration. They also interfere with glucose metabolism and may cause hypoglycemia or hyperglycemia. Respiratory center stimulation occurs early.

Patients usually have signs of hyperventilation, sweating, dehydration, and fever. Vomiting and diarrhea sometimes occur. In severe cases, disorientation, convulsions, and coma may develop.

The severity of acute intoxication can, in some measure, be judged by serum salicylate levels. High levels are always dangerous irrespective of clinical signs, and low levels may be misleading in chronic cases. Other laboratory values usually indicate metabolic acidosis despite hyperventilation, low serum K^+ values, and often abnormal serum glucose levels.

In mild and moderate poisoning, stimulation of the respiratory center produces respiratory alkalosis. In severe intoxication (occurring in severe acute ingestion with high salicylate levels and in chronic toxicity with lower levels), respiratory response is unable to overcome the metabolic overdose.

Once the urine becomes acidic, progressively smaller amounts of salicylate are excreted. Until this process is reversed, the half-life will remain prolonged, because metabolism contributes little to the removal of salicylate.

Chronic severe poisoning may occur as early as 3 days after a regimen of salicylate is begun. Findings usually include vomiting, diarrhea, and dehydration.

▶ Treatment

Charcoal binds salicylates well and should be given for acute ingestions. Mild poisoning may require only the administration of oral fluids and confirmation that the salicylate level is falling. Moderate poisoning involves moderate dehydration and depletion of potassium. Fluids must be administered at a rate of 2–3 mL/kg/h to correct dehydration and produce urine with a pH of greater than 7.0. Initial IV solutions should be isotonic, with sodium bicarbonate constituting half the electrolyte content. Once the patient is rehydrated, the solution can contain more free water and approximately 40 mEq/L of K^+ .

Severe toxicity is marked by major dehydration. Symptoms may be confused with those of Reye syndrome, encephalopathy, and metabolic acidosis. Salicylate levels may even be in the therapeutic range. Major fluid correction of dehydration is required. Once this has been accomplished, hypokalemia must be corrected and sodium bicarbonate given. Usual requirements are sodium bicarbonate, 1–2 mEq/kg/h

over the first 6–8 hours, and K^+ , 20–40 mEq/L. A urine flow of 2–3 mL/kg/h should be established. Despite this treatment some patients will develop the paradoxical aciduria of salicylism. This is due to hypokalemia and the saving of K^+ and excretion of H^+ in the renal tubule. Correction of K^+ will allow the urine to become alkaline and ionize the salicylate, resulting in excretion rather than reabsorption of nonionized salicylate in acid urine.

Renal failure or pulmonary edema is an indication for dialysis. Hemodialysis is most effective and peritoneal dialysis is relatively ineffective. Hemodialysis should be used in all patients with altered mental status or deteriorating clinical status. Acetazolamide should not be used.

Yip L et al: Concepts and controversies in salicylate toxicity. *Emerg Med Clin North Am* 1994;12:351 [PMID: 8187688].

SCORPION STINGS

Scorpion stings are common in arid areas of the southwestern United States. Scorpion venom is more toxic than most snake venoms, but only minute amounts are injected. Although neurologic manifestations may last a week, most clinical signs subside within 24–48 hours.

The most common scorpions in the United States are *Vejovis*, *Hadrurus*, *Androctonus*, and *Centruroides* species. Stings by the first three produce edema and pain. Stings by *Centruroides* (the Bark scorpion) cause tingling or burning paresthesias that begin at the site of the sting; other findings include hypersalivation, restlessness, muscular fasciculation, abdominal cramps, opisthotonos, convulsions, urinary incontinence, and respiratory failure.

► Treatment

Sedation is the primary therapy. Antivenom is reserved for severe poisoning. In severe cases, the airway may become compromised by secretions and weakness of respiratory muscles. Endotracheal intubation may be required. Patients may require treatment for seizures, hypertension, or tachycardia.

The prognosis is good as long as the patient's airway is managed appropriately.

LoVecchio F et al: Incidence of immediate and delayed hypersensitivity to *Centruroides* antivenom. *Ann Emerg Med* 1999;34:615 [PMID: 10533009].

SEROTONIN REUPTAKE INHIBITORS

Fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft) and many other agents comprise this class of drugs. Adverse effects in therapeutic dosing include suicidal thoughts, aggressive behavior, extrapyramidal effects, and cardiac dysrhythmias, and in overdose may include vomiting, lethargy, seizures, hypertension, tachycardia, hyperthermia, and abdominal pain. The findings in overdose are included in the

serotonin syndrome due to the action of these drugs, which results in an increase of serotonin (5-hydroxytryptamine [5-HT]). Despite the degree of toxicity these agents generally are not life-threatening and intervention usually is not necessary.

Emptying the stomach is not helpful, but activated charcoal may be useful. Laboratory measurements of the drugs are not of benefit other than to establish their presence.

Treatment with benzodiazepines is the most beneficial. Hypotension may be treated with fluids or norepinephrine. Cyproheptadine is an antagonist of serotonin, but its use has been limited. A dose of 0.25 mg/kg/d divided every 6 hours to a maximum of 12 mg/d may be useful in treating the serotonin syndrome. Adults and older adolescents have been treated with 12 mg initially followed by 2 mg every 2 hours to a maximum of 32 mg/d.

Boyer EW, Shannon M: The serotonin syndrome. *N Engl J Med* 2005;352:1112 [PMID: 15784664].

SNAKEBITE

Despite the lethal potential of venomous snakes, human morbidity and mortality rates are surprisingly low. The outcome depends on the size of the child, the site of the bite, the degree of envenomation, the type of snake, and the effectiveness of treatment.

Nearly all poisonous snakebites in the United States are caused by pit vipers (rattlesnakes, water moccasins, and copperheads). A few are caused by elapids (coral snakes), and occasional bites occur from cobras and other nonindigenous exotic snakes kept as pets. Snake venom is a complex mixture of enzymes, peptides, and proteins that may have predominantly cytotoxic, neurotoxic, hemotoxic, or cardiotoxic effects but other effects as well. Up to 25% of bites by pit vipers do not result in venom injection. Pit viper venom causes predominantly local injury with pain, discoloration, edema, and hemorrhage.

Swelling and pain occur soon after rattlesnake bite and are a certain indication that envenomation has occurred. During the first few hours, swelling and ecchymosis extend proximally from the bite. The bite is often obvious as a double puncture mark surrounded by ecchymosis. Hematemesis, melena, hemoptysis, and other manifestations of coagulopathy develop in severe cases. Respiratory difficulty and shock are the ultimate causes of death. Even in fatal rattlesnake bites, a period of 6–8 hours usually elapses between the bite and death; as a result, there is usually enough time to start effective treatment.

Coral snake envenomation causes little local pain, swelling, or necrosis; and systemic reactions are often delayed. The signs of coral snake envenomation include bulbar paralysis, dysphagia, and dysphoria; these signs may appear in 5–10 hours and may be followed by total peripheral paralysis and death in 24 hours.

Treatment

Children in snake-infested areas should wear boots and long trousers, should not walk barefoot, and should be cautioned not to explore under ledges or in holes.

A. Emergency (First-Aid) Treatment

The most important first-aid measure is transportation to a medical facility. Splint the affected extremity and minimize the patient's motion. Tourniquets and ice packs are contraindicated. Incision and suction are not useful for either crotalid or elapid snake bite.

B. Definitive Medical Management

Blood should be drawn for hematocrit, clotting time and platelet function, and serum electrolyte determinations. Establish two secure IV sites for the administration of antivenom and other medications.

Specific antivenom is indicated when signs of progressive envenomation are present. Two antivenoms are available for treating pit viper envenomation: polyvalent pit viper antivenom and polyvalent Crotalidae Fab (CroFab). Both are effective, but their indications differ. For coral snake bites, an eastern coral snake antivenom (Wyeth Laboratories) is available. Patients with pit viper bites should receive antivenom if progressive local injury, coagulopathy, or systemic signs (eg, hypotension, confusion) are present. (Antivenom should not be given IM or SQ.) See package labeling or call your certified poison center for details of use. Hemorrhage, pain, and shock diminish rapidly with adequate amounts of antivenom. For coral snake bites, give three to five vials of antivenom in 250–500 mL of isotonic saline solution. An additional three to five vials may be required.

To control pain, administer a narcotic analgesic, such as meperidine (0.6–1.5 mg/kg per dose, given PO or IM). Cryotherapy is contraindicated because it commonly causes additional tissue damage. Early physiotherapy minimizes contractures. In rare cases, fasciotomy to relieve pressure within muscular compartments is required. The evaluation of function and of pulses will better predict the need for fasciotomy. Antihistamines and corticosteroids (hydrocortisone, 1 mg/kg, given PO for a week) are useful in the treatment of serum sickness or anaphylactic shock. Antibiotics are not needed unless clinical signs of infection occur. Tetanus status should be evaluated and the patient immunized, if needed.

SOAPS & DETERGENTS

1. Soaps

Soap is made from salts of fatty acids. Some toilet soap bars contain both soap and detergent. Ingestion of soap bars may cause vomiting and diarrhea, but they have a low toxicity. Induced emesis is unnecessary.

2. Detergents

Detergents are nonsoap synthetic products used for cleaning purposes because of their surfactant properties. Commercial products include granules, powders, and liquids. Dishwasher detergents are very alkaline and can cause caustic burns. Low concentrations of bleaching and antibacterial agents as well as enzymes are found in many preparations. The pure compounds are moderately toxic, but the concentration used is too small to alter the product's toxicity significantly, although occasional primary or allergic irritative phenomena have been noted in persons who frequently use such products and in employees manufacturing these products.

A. Cationic Detergents (Ceepryn, Diaparene Cream, Phemerol, Zephiran)

Cationic detergents in dilute solutions (0.5%) cause mucosal irritation, but higher concentrations (10–15%) may cause caustic burns to mucosa. Clinical effects include nausea, vomiting, collapse, coma, and convulsions. As little as 2.25 g of some cationic agents have caused death in an adult. In four cases, 100–400 mg/kg of benzalkonium chloride caused death. Cationic detergents are rapidly inactivated by tissues and ordinary soap.

Because of the caustic potential and rapid onset of seizures, emesis is not recommended. Activated charcoal should be administered. Anticonvulsants may be needed.

B. Anionic Detergents

Most common household detergents are anionic. Laundry compounds have water softener (sodium phosphate) added, which is a strong irritant and may reduce ionized calcium. Anionic detergents irritate the skin by removing natural oils. Although ingestion causes diarrhea, intestinal distention, and vomiting, no fatalities have been reported.

The only treatment usually required is to discontinue use if skin irritation occurs and replace fluids and electrolytes. Induced vomiting is not indicated following ingestion of automatic dishwasher detergent, because of its alkalinity. Dilute with water or milk.

C. Nonionic Detergents (Brij Products; Tritons X-45, X-100, X-102, and X-144)

These compounds include lauryl, stearyl, and oleyl alcohols and octyl phenol. They have a minimal irritating

effect on the skin and are almost always nontoxic when swallowed.

SPIDER BITES

Most medically important bites in the United States are caused by the black widow spider (*Latrodectus mactans*) and the North American brown recluse (violin) spider (*Loxosceles reclusa*). Positive identification of the spider is helpful, because many spider bites may mimic those of the brown recluse spider.

1. Black Widow Spider

The black widow spider is endemic to nearly all areas of the United States. The initial bite causes sharp fleeting pain. Local and systemic muscular cramping, abdominal pain, nausea and vomiting, and shock can occur. Convulsions occur more commonly in small children than in older children. Systemic signs of black widow spider bite may be confused with other causes of acute abdomen. Although paresthesias, nervousness, and transient muscle spasms may persist for weeks in survivors, recovery from the acute phase is generally complete within 3 days. In contrast to popular opinion, death is extremely rare.

Most authors recommend calcium gluconate as initial therapy (50 mg/kg IV per dose, up to 250 mg/kg/24 h), although it is often not effective and the effects are of short duration. Methocarbamol (15 mg/kg PO) or diazepam titrated to effect is useful. Morphine or barbiturates may occasionally be needed for control of pain or restlessness, but they increase the possibility of respiratory depression. Antivenom is available but should be reserved for severe cases in which the previously mentioned therapies have failed. Local treatment of the bite is not helpful.

2. Brown Recluse Spider (Violin Spider)

The North American brown recluse spider is most commonly seen in the central and Midwestern areas of the United States. Its bite characteristically produces a localized reaction with progressively severe pain within 24 hours. The initial bleb on an erythematous ischemic base is replaced by a black eschar within 1 week. This eschar separates in 2–5 weeks, leaving an ulcer that heals slowly. Systemic signs include cyanosis, morbilliform rash, fever, chills, malaise, weakness, nausea and vomiting, joint pains, hemolytic reactions with hemoglobinuria, jaundice, and delirium. Fatalities are rare. Fatal disseminated intravascular coagulation has been reported.

Although of unproved efficacy, the following therapies have been used: dexamethasone, 4 mg IV four times a day, during the acute phase; polymorphonuclear leukocyte inhibitors, such as dapsone or colchicine, and oxygen applied to the bite site; and total excision of the lesion to the fascial level.

Sams HH et al: Nineteen documented cases of *Loxosceles reclusa* envenomation. *J Am Acad Dermatol* 2001;44:603 [PMID: 11260528].

THYROID PREPARATIONS (THYROID DESICCATED, SODIUM LEVOTHYROXINE)

Ingestion of the equivalent of 50–150 g of desiccated thyroid can cause signs of hyperthyroidism, including irritability, mydriasis, hyperpyrexia, tachycardia, and diarrhea. Maximal clinical effect occurs about 9 days after ingestion—several days after the protein-bound iodine level has fallen dramatically.

Administer activated charcoal. If the patient develops clinical signs of toxicity, propranolol, 0.01–0.1 mg/kg (maximum, 1 mg), is useful because of its antiadrenergic activity.

Brown RS et al: Successful treatment of massive acute thyroid hormone poisoning with iopanoic acid. *J Pediatr* 1998;132:903 [PMID: 9602214].

VITAMINS

Accidental ingestion of excessive amounts of vitamins rarely causes significant problems. Occasional cases of hypervitaminosis A and D do occur, however, particularly in patients with poor hepatic or renal function. The fluoride contained in many multivitamin preparations is not a realistic hazard, because a 2- or 3-year-old child could eat 100 tablets, containing 1 mg of sodium fluoride per tablet, without experiencing serious symptoms. Iron poisoning has been reported with multivitamin tablets containing iron. Pyridoxine abuse has caused neuropathies; nicotinic acid has resulted in myopathy.

Fraser DR: Vitamin D. *Lancet* 1995;345:104 [PMID: 7815853].

WARFARIN

Warfarin is used as a rodenticide. It causes hypoprothrombinemia and capillary injury. It is absorbed readily from the GI tract but is absorbed poorly through the skin. A dose of 0.5 mg/kg of warfarin may be toxic in a child. A prothrombin time is helpful in establishing the severity of the poisoning.

If bleeding occurs or the prothrombin time is prolonged, give 1–5 mg of vitamin K₁ (phytonadione) IM or SQ. For large ingestions with established toxicity, 0.6 mg/kg may be given.

Another group of long-acting anticoagulant rodenticides (brodifacoum, difenacoum, bromadoline, diphacinone, pinene, valone, and coumatetralyl) have been a more serious toxicologic problem than warfarin. They also cause hypo-

prothrombinemia and a bleeding diathesis that responds to phytonadione, although the anticoagulant activity may persist for periods ranging from 6 weeks to several months. Treatment with vitamin K₁ may be needed for weeks.

Isbister GK, Whyte IM: Management of anticoagulant poisoning. *Vet Hum Toxicol* 2001;43:117 [PMID: 11308119].

Critical Care

Todd C. Carpenter, MD
 Emily L. Dobyns, MD
 Eva N. Grayck, MD
 Peter M. Mourani, MD
 Kurt R. Stenmark, MD

13

Caring for critically ill children remains one of the most demanding and challenging aspects of pediatrics. The care of patients with life-threatening conditions, from serious medical illness to traumatic injuries and recovery from major surgery, requires a detailed understanding of human physiology and the pathophysiology of major illnesses, as well as an understanding of and experience with the rapidly changing technologies available in a modern intensive care unit (ICU). In addition, the science of caring for the critically ill patient has evolved rapidly over the past decade, as the molecular mediators of illness have become better defined and new therapies have been devised based on those advances. As a result, critical care is more than ever a multidisciplinary field that requires a team-oriented approach, including critical care physicians and nursing staff, pharmacists, referring physicians, consulting specialists, and social services specialists.

The intensivist plays an essential role in coordinating and directing the care provided by the ICU team, and stands at the crossroads of the various participating disciplines. There are two primary models of ICU organization: “open” units, where primary responsibility for the patient remains with the referring physician and secondary responsibility lies with the intensivist as consultant; and “closed” units, where only the on-site intensivist is allowed to write orders directing the patient’s care. Although the merits of these organizational approaches are debated, a substantial and growing body of evidence from studies conducted in adult medical, surgical, and pediatric ICUs suggests that the closed ICU model leads to significant reductions in ICU length of stay and resource use, and to reductions in mortality of as much as 15%.

An additional factor to consider in the provision of critical care services for children is the cost of those services in relation to the outcomes achieved. Critical care services in the United States are estimated to account for 30% of all acute-care hospital costs; some estimates run as high as 1% of the gross national product. One study examining the cost-

effectiveness of pediatric ICU care, compared with adult ICU care, found that the short- and long-term mortality among pediatric patients was three times lower than it was among adult ICU patients, despite similar ICU costs and length of stay. These findings suggest that pediatric critical care services are relatively cost-effective.

ACUTE RESPIRATORY FAILURE

Acute respiratory failure, defined as the inability of the respiratory system to adequately deliver oxygen or remove carbon dioxide, contributes significantly to the morbidity and mortality of critically ill children. This condition accounts for approximately 50% of deaths in children younger than age 1 year. Anatomic and developmental differences place infants at higher risk than adults for respiratory failure. An infant’s thoracic cage is more compliant than that of the adult or older child. The intercostal muscles are poorly developed and unable to achieve the “bucket-handle” motion characteristic of adult breathing. Furthermore, the diaphragm is shorter and relatively flat with fewer type I muscle fibers, and therefore less effective and more easily fatigued. The infant’s airways are smaller in caliber than those in older children and adults, resulting in greater resistance to inspiratory and expiratory airflow and greater

Table 13–1. Types of respiratory failure.

Findings	Causes	Examples
Type I Hypoxia Decreased PaO ₂ Normal PaCO ₂	Ventilation-perfusion defect	Positional (supine in bed), acute respiratory distress syndrome (ARDS), atelectasis, pneumonia, pulmonary embolus, bronchopulmonary dysplasia
	Diffusion impairment	Pulmonary edema, ARDS, interstitial pneumonia
	Shunt	Pulmonary arteriovenous malformation, congenital adenomatoid malformation
Type II Hypoxia Hypercapnia Decreased PaO ₂ Increased PaCO ₂	Hypoventilation	Neuromuscular disease (polio, Guillain-Barré syndrome), head trauma, sedation, chest wall dysfunction (burns), kyphosis, severe reactive airways

susceptibility to occlusion by mucus plugging and mucosal edema. Compared with adults, the alveoli of children are smaller and have less collateral ventilation, resulting in a greater tendency to collapse and develop atelectasis. Finally, young infants may have an especially reactive pulmonary vascular bed, impaired immune system, or residual effects from prematurity, all of which increase the risk of respiratory failure.

Respiratory failure can be classified into two types, which usually coexist in variable proportion. The partial arterial oxygen pressure (PaO₂) is low in both, whereas the partial arterial carbon dioxide pressure (PaCO₂) is high only in patients with type II respiratory failure (Table 13–1). Type I respiratory failure is a failure of oxygenation and occurs in three situations: (1) **ventilation-perfusion mismatch**, or V/Q mismatch, which occurs when blood flows to parts of the lung that are inadequately ventilated, or when ventilated areas of the lung are inadequately perfused; (2) **diffusion defects**, caused by thickened alveolar membranes or excessive interstitial fluid at the alveolar-capillary junction; and (3) **intrapulmonary shunt**, which occurs when structural anomalies in the lung allow blood to flow through the lung without participating in gas exchange. Type II respiratory failure generally results from alveolar hypoventilation and is usually secondary to situations such as central nervous system (CNS) dysfunction, oversedation, or neuromuscular disorders (see Table 13–1).

► Clinical Findings

A. Symptoms and Signs

The clinical findings in respiratory failure are caused by the low PaO₂, high PaCO₂, and pH changes affecting the lungs, heart, kidneys, and brain. The clinical features of progressive

respiratory failure are summarized in Table 13–2. Hypercapnia depresses the CNS, and also results in acidemia that depresses myocardial function. Patients in respiratory failure can exhibit significant changes in CNS and cardiac function. Features of respiratory failure are not always clinically evident, however, and some signs or symptoms may have nonrespiratory causes. Furthermore, a strictly clinical assessment of arterial hypoxemia or hypercapnia is not reliable. As a result, the precise assessment of the adequacy of oxygenation and ventilation must be based on both clinical and laboratory data.

B. Laboratory Findings

Laboratory findings are helpful in assessing the severity and acuity of respiratory failure and in determining specific treatment. Arterial oxygen saturation can be measured continuously and noninvasively by **pulse oximetry**, a technique that should be used in the assessment and treatment of all patients with suspected respiratory failure. **End-tidal CO₂ (ETCO₂) monitoring** provides a continuous noninvasive means of assessing arterial PCO₂. Because carbon dioxide diffuses freely across the alveolar-capillary barrier, the ETCO₂ level approximates the alveolar PCO₂, which should equal the arterial PCO₂. Though useful for following trends in ventilation, this technique is susceptible to significant error, particularly with patients who have rapid, shallow breathing or increased dead space ventilation. **Arterial blood gas (ABG) analysis** remains the gold standard for assessment of acute respiratory failure. ABGs give information on the patient's acid-base status (with a measured pH and calculated bicarbonate level) as well as PaO₂ and PaCO₂ levels. The PaO₂ is a

▲ **Figure 13-1.** Relationship between alveolar ventilation, arterial oxygen saturation (Sao₂), and partial pressures of oxygen and CO₂ in the arterial blood (Pao₂ and Paco₂, respectively). (Reproduced, with permission, from Pagtakhan RD, Chernick V: Respiratory failure in the pediatric patient. *Pediatr Rev* 1982;3:244.)

critical determinant of oxygen delivery to the tissues, and the Paco₂ is a sensitive measure of ventilation related inversely to the minute ventilation (Figure 13-1). Although measurement of capillary or venous blood gases may provide some reassurance regarding ventilatory function when results are normal, they yield virtually no useful information regarding oxygenation and may generate highly misleading information about the ventilatory status of patients who have poor perfusion or who had difficult blood draws. As a result, ABG analysis is important for all patients with suspected respiratory failure, particularly those with abnormal venous or capillary gases.

Knowing the ABG values and the inspired oxygen concentration also enables one to calculate the difference between alveolar oxygen concentration and the arterial oxygen value, known as the **alveolar-arterial oxygen difference** (A-aDO₂, or A-a gradient). The A-a gradient is less than 15 mm Hg under normal conditions, though it widens with increasing inspired oxygen concentrations to about 100 mm Hg in normal patients breathing 100% oxygen. This number has prognostic value in severe hypoxemic respiratory failure, with A-a gradients over 400 mm Hg being strongly associated with mortality. Diffusion impairment, shunts, and V/Q mismatch all increase the A-aDO₂ (Table 13-3).

In addition to the calculation of the A-aDO₂, assessment of intrapulmonary shunting (the percentage of pulmonary blood flow that passes through nonventilated areas of the lung) may be helpful. Normal individuals have less than a 5% physiologic shunt from bronchial, thebesian, and coronary circulations. Shunt fractions greater than 15% usually

Table 13-3. Key equations describing pulmonary function and oxygen delivery.

PiO ₂	= (barometric pressure - 47) × % inspired oxygen concentration
A-aDO ₂	= PiO ₂ - (Paco ₂ /R) - Pao ₂ (normal = 5 - 15 mm Hg)

Ve	= Expiratory minute volume (L/min)
V _{O₂}	= Oxygen consumption per minute

indicate the need for aggressive respiratory support. When intrapulmonary shunt reaches 50% of pulmonary blood flow, Pao₂ does not increase regardless of the amount of supplemental oxygen used.

► Treatment

A. Oxygen Supplementation

Patients with hypoxemia induced by respiratory failure may respond to **supplemental oxygen** administration alone (Table 13–4). Those with hypoventilation and diffusion defects respond better than do patients with shunts or V/Q mismatch. Severe V/Q mismatch generally responds only to aggressive airway management and mechanical ventilation. Patients with severe hypoxemia, hypoventilation, or apnea require assistance with bag and mask ventilation until the airway is successfully intubated and controlled artificial ventilation can be provided. Ventilation may be maintained for some time with a mask of the proper size, but gastric distention, emesis, and inadequate tidal volumes are possible complications. An artificial airway may be lifesaving for patients who fail to respond to simple oxygen supplements.

B. Intubation

Intubation of the trachea in infants and children requires experienced personnel and the right equipment. A patient in respiratory failure whose airway must be stabilized should first be positioned properly to facilitate air exchange while supplemental oxygen is given. The sniffing position is used in infants. Head extension with jaw thrust is used in older children without neck injuries. If obstructed by secretions or vomitus, the airway must be cleared by suction. When not obstructed, the airway should open easily with proper positioning and placement of an oral or nasopharyngeal airway of the correct size. Patients with a normal airway may be intubated under intravenous (IV) anesthesia by experienced personnel (Table 13–5). Patients with obstructed upper airways (eg, patients with croup, epiglottitis, foreign bodies, or subglottic stenosis) should be awake when intubated unless trained airway specialists decide otherwise.

The size of the endotracheal tube is of critical importance in pediatrics (see Table 11–3 for sizes). An inappropriately large endotracheal tube can cause pressure necrosis of the tissues in the subglottic region, and can lead to scarring and stenosis of the subglottic region that requires surgical repair. An inappropriately small endotracheal tube can result in inadequate pulmonary toilet and excessive air leak around the endotracheal tube, making optimal ventilation and oxygenation difficult. Two useful methods for calculating the correct size of endotracheal tube for a child are (1) measuring the child's height with a Broselow tape and then reading the corresponding endotracheal tube size on the tape, or (2) in children older than age 2 years, choosing a tube size equal to the computation $(16 + \text{age in years}) \div 4$.

Correct placement of the endotracheal tube should be confirmed by auscultation for the presence of equal bilateral breath sounds and the use of a colorimetric filter (pH-sensitive indicator that changes from purple to yellow when exposed to carbon dioxide) by the detection of carbon dioxide. An assessment of air leakage around the endotracheal tube is also important. To do this, connect an anesthesia bag and pressure manometer to the endotracheal tube and allow it to inflate, creating positive pressure. Check for the leak by auscultating over the throat, noting the pressure at which air escapes around the endotracheal tube. Leaks at pressures of 15–20 cm H₂O are acceptable. Leaks at higher pressures are acceptable only in patients who have severe lung disease and poor compliance and thus require high pressures to ventilate and oxygenate. Leaks at lower pressures may lead to ineffective ventilation. The endotracheal tube should be up-sized or a cuffed endotracheal tube should be used if continued mechanical ventilation is needed. Special attention to the inflation pressure of the cuff endotracheal tube is required to avoid pressure necrosis of the airway. A chest radiograph is necessary for final assessment of endotracheal tube placement.

Table 13–4. Supplemental oxygen therapy.

Source	Maximum % O ₂	Range of Rates	Advantages	Disadvantages
Nasal cannula	35–40%	0.125–4 L/min	Easily applied, relatively comfortable	Uncomfortable at higher flow rates, requires open nasal airways, easily dislodged, lower % O ₂ , nosebleeds
Simple mask	50–60%	5–10 L/min	Higher % O ₂ , good for mouth breathers	Uncomfortable, dangerous for patients with poor airway control and at risk for emesis, hard to give airway care, unsure of % O ₂
Face tent	40–60%	8–10 L/min	Higher % O ₂ , good for mouth breathers, less restrictive	Uncomfortable, dangerous for patients with poor airway control and at risk for emesis, hard to give airway care, unsure of % O ₂
Rebreathing mask	80–90%	5–10 L/min	Higher % O ₂ , good for mouth breathers, highest O ₂ concentration	Uncomfortable, dangerous for patients with poor airway control and at risk for emesis, hard to give airway care, unsure of % O ₂
Oxyhood	90–100%	5–10 L/min (mixed at wall)	Stable and accurate O ₂ concentration	Difficult to maintain temperature, hard to give airway care

Table 13-5. Drugs commonly used for controlled intubation.

Drug	Class of Agent	Dose	Advantages	Disadvantages
Atropine	Anticholinergic	0.02 mg/kg, minimum of 0.1 mg	Prevents bradycardia, dries secretions	Tachycardia, fever; seizures and coma with high doses
Fentanyl	Narcotic (sedative)	1-3 mcg/kg IV	Rapid onset, hemodynamic stability	Respiratory depression, chest wall rigidity with rapid administration in neonates
Midazolam	Benzodiazepine (sedative)	0.1-0.2 mg/kg IV	Rapid onset, amnestic	Respiratory depression, hypotension
Thiopental	Barbiturate (anesthetic)	3-5 mg/kg IV	Rapid onset, lowers intracranial pressure (ICP)	Hypotension, decreased cardiac output, no analgesia provided
Ketamine	Dissociative anesthetic	1-2 mg/kg IV 2-4 mg/kg IM	Rapid onset, bronchodilator, hemodynamic stability	Increases oral and airway secretions, may increase ICP and pulmonary artery pressure
Rocuronium	Nondepolarizing muscle relaxant	1 mg/kg	Rapid onset, suitable for rapid sequence intubation, lasts 30 min	Requires refrigeration
Pancuronium	Nondepolarizing muscle relaxant	0.1 mg/kg	Longer duration of action (40-60 min)	Tachycardia, slow onset (2-3 min)

IV, intravenously, IM, intramuscularly.

MECHANICAL VENTILATION

The increased compliance of an infant's chest wall, the relative alveolar hypoplasia in early childhood, the small caliber of the airways, and the small tidal volumes of young children make mechanical ventilation of the pediatric patient challenging. The goals of mechanical ventilation are to facilitate the movement of gas into and out of the lungs (ventilation) and to improve oxygen uptake into the bloodstream (oxygenation). Modern mechanical ventilators can accom-

plish these objectives in a variety of ways. Depending on the mode of ventilation selected, the ventilator can deliver a machine-controlled breath (control ventilation), or can assist the patient's own spontaneous respiratory efforts (support ventilation), or can do both (mixed mode ventilation). Additionally, ventilator breaths can be delivered as a targeted tidal volume (volume ventilation) or as a targeted airway pressure (pressure ventilation). This section describes the modes of mechanical ventilation most commonly used in pediatric intensive care units (PICUs).

Pressure Ventilation

In pressure-controlled modes of ventilation, air flow begins at the start of the inspiratory cycle and continues until a preset airway pressure is reached. That airway pressure is then maintained until, at the end of the set inspiratory time, the exhalation valve on the ventilator opens and gas exits into the machine. Because airway pressure is the controlling variable with this mode of ventilation, changes in the compliance of the respiratory system will lead to fluctuations in the actual tidal volume delivered to the patient. The advantage of pressure-controlled ventilation lies primarily in the avoidance of high airway pressures that might cause lung injury or barotrauma, particularly in patients with fragile lung parenchyma, such as premature infants. The main disadvantage of pressure-controlled ventilation is the possibility of delivering either inadequate or excessive tidal volumes during periods of changing lung compliance, as described earlier.

Volume Ventilation

Volume-controlled ventilation is the most commonly used mode of mechanical ventilation in most PICUs. Volume ventilation delivers a preset tidal volume. Changes in lung

compliance will lead to fluctuations in the airway pressure generated by the tidal volume. The main advantage of volume ventilation is more reliable delivery of the desired tidal volume and thus better control of ventilation. More reliable tidal volume delivery may also help prevent atelectasis due to hypoventilation. Disadvantages of volume ventilation include the risk of barotrauma from excessive airway pressures and difficulties overcoming leaks in the ventilator circuit. Older volume ventilators also suffered from a lack of continuous gas flow through the circuit, thus increasing the patient's work of breathing on spontaneous breaths. Most modern machines provide a continuous flow through the circuit and have improved triggering mechanisms to deliver the breaths in synchrony with the patient's demands.

Modes of Ventilation

Most modern ventilators can deliver either a pressure-controlled or a volume-controlled breath in several manners. **Control** modes deliver breaths at a selected rate and duration (inspiratory time) and can be targeted for either volume or pressure set by the clinician (as opposed to the patient). Spontaneous breaths are not assisted, and the patient's own respiratory efforts are not considered. **Synchronized intermittent mandatory ventilation** is a mode in which the rate, inspiratory time, and volume or pressure settings are set by the clinician. But the ventilator allows a window of time around each breath in which it waits for the patient to make an inspiratory effort. The machine breath is then synchronized with the patient's effort, to improve the comfort for patients who are breathing spontaneously. In **pressure-support ventilation**, the patient's own efforts are assisted by the delivery of gas flow to achieve a certain airway pressure. This mode of ventilation allows the patient to determine the rate and inspiratory time of breaths, thus improving patient comfort and decreasing the work of breathing. Perhaps the most common mode of ventilation in PICUs is **synchronized intermittent mandatory ventilation with pressure support**, a mixed mode allowing pressure-supported breaths between the synchronized machine breaths. Whether such mixed modes of ventilation provide any measurable advantage over single modes remains unclear.

Setting the Ventilator

When initiating mechanical ventilation, the clinician will vary the parameters according to the mode of ventilation selected. Volume-controlled modes of ventilation generally require a set tidal volume, inspiratory time, rate, and level of positive end-expiratory pressure (PEEP). A typical initial tidal volume is 8–10 mL/kg, as long as that volume does not cause excessive airway pressures. The inspiratory time is typically set at 1 second or 33% of the respiratory cycle, whichever is shorter. Rate can be adjusted to patient comfort and blood gas measurements, but generally patients starting on mechanical ventilation require full support at least initially with a rate of 20–30 breaths/min.

Pressure-controlled ventilation is set up in a similar fashion, although the sufficiency of the inspiratory pressure to provide an adequate tidal volume is assessed by observing the patient's chest rise and by measuring the returned tidal volume. Typically, patients without lung disease require pressures of 15–20 cm H₂O, and patients with respiratory illnesses initially require 20–30 cm H₂O pressure to provide adequate ventilation.

Positive End-Expiratory Pressure

The PEEP level is the final major setting required to initiate mechanical ventilation. All mechanical ventilators open their expiratory limbs at the end of inspiration until a preset pressure is achieved; this is the PEEP value. During ventilation of normal lungs, physiologic PEEP is in the range of 2–4 cm H₂O pressure. This pressure helps to prevent the end-expiratory collapse of open lung units, thus preventing atelectasis and shunting. In disease states such as pulmonary edema, pneumonia, or acute respiratory distress syndrome (ARDS), a higher PEEP may increase the patient's functional residual capacity, help to keep open previously collapsed alveoli, increase mean airway pressure, and improve oxygenation. Conceptually, it is important to remember that PEEP is an expiratory pressure. As a result, high PEEP levels do not open lung units in and of themselves, but rather prevent the collapse of units opened during lung inflation. Indeed, some evidence suggests that elevated levels of PEEP are most effective at improving oxygenation when used together with specific lung recruiting maneuvers. High levels of PEEP, although often valuable in improving oxygenation, may also cause CO₂ retention, barotrauma with resultant air leaks, decreased central venous return and resulting decline in cardiac output, and increased intracranial pressure (ICP). In general, PEEP should be set at 3–5 cm H₂O initially and titrated up to maintain adequate oxygenation at an acceptable fractional inspiratory oxygen (FIO₂), while watching carefully for the adverse effects listed earlier.

Monitoring the Ventilated Patient

Ventilated patients must be monitored carefully for respiratory rate and activity, chest wall movement, and quality of breath sounds. Oxygenation should be measured either by ABGs or by continuous pulse oximetry. Ventilation should be assessed by blood gas analysis or by noninvasive means, such as transcutaneous monitoring or end-tidal sampling. Transcutaneous PO₂ or PCO₂ measurements are most useful with younger patients who have good skin perfusion, but they become problematic with poorly perfused or obese patients. ET-CO₂ monitoring is done by placing a gas-sampling port on the endotracheal tube and analyzing expired gas for CO₂. This technique is more valuable for patients with large tidal volumes, lower respiratory rates, and without leaks around the endotracheal tube. In practice, ET-CO₂ values may differ significantly from measured PaCO₂ values and thus are

most useful for following relative fluctuations in ventilation. Frequent, preferably continuous, blood pressure monitoring is also necessary for patients receiving oxygen at a high PEEP, given the risk of adverse cardiovascular effects.

Adjusting the Ventilator

Mechanical ventilation can assist with both ventilation (PCO_2) and oxygenation (PO_2). Ventilation is most closely associated with the delivered minute volume, or the tidal volume multiplied by the respiratory rate. Abnormal PCO_2 values can be most effectively addressed by changes in the respiratory rate or the tidal volume. Increased rate or tidal volume should increase minute volume and thus decrease PCO_2 levels; decreases in rate or tidal volume should act in the opposite fashion. In some circumstances, additional adjustments may also be necessary. For example, for patients with disease characterized by extensive alveolar collapse, increasing PEEP may improve ventilation by helping to keep open previously collapsed lung units. Also, for patients with disease characterized by significant airway obstruction, decreases in respiratory rate may allow more time for exhalation and improve ventilation despite an apparent decrease in the minute volume provided.

The variables most closely associated with oxygenation are the inspired oxygen concentration and the mean airway pressure during the respiratory cycle. Increases in inspired oxygen concentration will generally increase arterial oxygenation, unless right-to-left intracardiac or intrapulmonary shunting is a significant component of the patient's illness. Concentrations of inspired oxygen above 60–65%, however, may lead to hyperoxic lung injury. Patients with hypoxemic respiratory failure requiring those levels of oxygen or higher to maintain adequate arterial saturations should have their hypoxemia addressed by increases in mean airway pressure.

Mean airway pressure is affected by PEEP, peak inspiratory pressure, and inspiratory time. Increases in any one of those factors will increase mean airway pressure and should improve arterial oxygenation. It is important to bear in mind, however, that increases in mean airway pressure may also lead to decreases in cardiac output. In this circumstance, raising mean airway pressure may increase arterial oxygenation but actually compromise oxygen delivery to the tissues. For patients with severe hypoxemic respiratory failure, these tradeoffs highlight the need for careful monitoring by experienced personnel.

High-frequency oscillatory ventilation (HFOV) is an alternate mode of mechanical ventilation in which the ventilator provides very small, very rapid tidal volumes. Respiratory rates used during oscillatory ventilation typically range from 5–10 Hz (rates of 300–600 breaths/min) in most PICU patients. This mode of ventilation has been used successfully for neonates, older pediatric patients, and adults; and for diseases as diverse as pneumonia, pulmonary contusion, ARDS, and asthma. HFOV is increasingly used as initial therapy in severe, diffuse lung diseases, such as ARDS, which

require high mean airway pressures to maintain oxygenation. The advantage of HFOV is that these high levels of mean airway pressure can be achieved without high peak inspiratory pressures or large tidal volumes, thus theoretically protecting the lung from ventilator-induced lung injury. Disadvantages of HFOV include general poor tolerance by patients who are not heavily sedated or paralyzed, the risk of cardiovascular compromise due to high mean airway pressures, and the risk of barotrauma in patients with heterogeneous lung disease. Although HFOV clearly may be useful for selected patients, it remains unclear whether HFOV provides a benefit compared with carefully managed conventional modes of ventilation.

Managing the Ventilated Patient

Patients undergoing mechanical ventilation require the same meticulous supportive care given to all PICU patients. Since mechanical ventilation is often frightening and uncomfortable for patients, leading to dyssynchrony with the ventilator and impaired ventilation and oxygenation, careful attention must be directed toward optimizing comfort and decreasing anxiety. Sedative-anxiolytics are typically provided as intermittent doses of benzodiazepines, with or without opioids. Some patients respond better to the steady state of sedation provided by continuous infusion of these agents, although oversedation of the ventilated patient may lead to longer durations of ventilation and difficulties with weaning from the ventilator.

For a patient with severe respiratory illness, even small movements by the patient may compromise ventilation and oxygenation. In such cases, muscle paralysis may facilitate oxygenation and ventilation. Nondepolarizing neuromuscular blocking agents are most commonly used for this purpose, given as intermittent doses or as continuous infusions. When muscle relaxants are given, extra care must be taken to ensure that levels of sedation are adequate, as many of the usual signs of patient discomfort are masked by the paralytics.

ACUTE RESPIRATORY DISTRESS SYNDROME

ARDS is a syndrome of acute respiratory failure characterized by increased pulmonary capillary permeability and pulmonary edema that results in refractory hypoxemia, decreased

lung compliance, and bilateral diffuse alveolar infiltrates on chest radiography. Statistics of ARDS reflect one of the true successes of current ICU management, as mortality has decreased over the past decade from approximately 50–60% to less than 40%.

An international consensus conference was convened in 1997 to establish the current guidelines defining four diagnostic criteria for ARDS: (1) an underlying illness or injury that predisposes to ARDS; (2) bilateral infiltrates on chest radiograph; (3) an absence of evidence of heart failure, and in particular left ventricular (LV) failure; and, most importantly, (4) severe hypoxemic respiratory failure. Hypoxemia is assessed using the ratio of the arterial oxygen level (PaO_2) to the inspired oxygen concentration (FiO_2). When the $\text{PaO}_2:\text{FiO}_2$ ratio is less than 200, and the other criteria are met, the case is defined as ARDS. When the $\text{PaO}_2:\text{FiO}_2$ ratio is between 200 and 300, and the other criteria are met, the case is defined as acute lung injury. This definition is debated, however, particularly since the current criteria do not include any assessment of the airway pressure needed to oxygenate the patient. Numerous other diagnostic systems have been proposed.

In addition, because the clinical disorder or disorders that led to the development of acute lung injury clearly influence the patient's prognosis for recovery, precise definition of the underlying problem is important. Although the average mortality in this population is 40%, the rate is dependent on the associated clinical disorder. Mortality can be as high as 90% among adult ARDS patients with underlying liver failure, and less than 10% among pediatric ARDS associated with respiratory syncytial virus infection. The development of multisystem organ failure is a frequent complicating factor in the care of the patient with ARDS, and the failure of organs outside the lung has a large role in determining the prognosis. In fact, nonpulmonary organ failure is the leading cause of death in the most recent studies of adult or pediatric ARDS patients.

► Clinical Presentation & Pathophysiology

ARDS may be precipitated by a variety of insults (Table 13–6), of which infection is the most common. Despite the diversity of causes, the clinical presentation is remarkably similar in most cases. ARDS can be divided roughly into four clinical phases (Table 13–7). In the earliest phase, the patient may have dyspnea and tachypnea with a relatively normal PO_2 and hyperventilation-induced respiratory alkalosis. No significant abnormalities are noted on physical or radiologic examination of the chest. Experimental studies suggest that neutrophils accumulate in the lungs at this stage and that their products damage lung endothelium.

Over the next few hours, hypoxemia increases and respiratory distress becomes clinically apparent, with cyanosis, tachycardia, irritability, and dyspnea. Radiographic evidence of early parenchymal change is the appearance of “fluffy” alveolar infiltrates initially appearing in dependent lung fields, indicative of pulmonary edema. The edema fluid typically has

Table 13–6. Acute respiratory distress syndrome risk factors.

Direct Lung Injury	Indirect Lung Injury
Aspiration of gastric contents	Sepsis
Hydrocarbon ingestion or aspiration	Shock
Inhalation injury (heat or toxin)	Pancreatitis
Pulmonary contusion	Burns
Pneumonia	Trauma
Near-drowning	Fat embolism
	Drug overdoses (including aspirin, opioids, barbiturates, tricyclic antidepressants)
	Transfusion of blood products

a high concentration of protein (75–95% of plasma protein concentration), which is characteristic of an increased permeability-type edema and differentiates it from cardiogenic or hydrostatic pulmonary edema. Protein in the air spaces inactivates surfactant, which, combined with damage to type 2 alveolar pneumocytes, leads to a marked deficiency in surfactant content in the lung. As a result, the lung is particularly prone to collapse and to shearing injuries due to the high surface tension required to open collapsed alveoli.

Alveolar epithelial injury in ARDS lowers the threshold for alveolar edema formation and impairs gas exchange. The functional integrity of the alveolar epithelium, as measured by the ability of the alveoli to clear liquid out of the air spaces, has prognostic importance in ARDS. Those patients who still show evidence of functional alveolar liquid clearance mechanisms during the first day of their illness have a much higher survival rate than those with evidence of severe epithelial impairment.

Pulmonary hypertension, decrease in lung compliance, and increase in airway resistance are also commonly noted. Clinical studies suggest that airway resistance may be increased in 50% of patients with ARDS.

Computed tomography studies of adult patients in the acute phases of ARDS demonstrate heterogeneous collapse of the lung, with typical areas of dependent consolidation, overinflation in the upper zones, and relatively small areas of normally expanded lung. These findings suggest that the lung in ARDS is best viewed as “small” rather than stiff, prompting a shift toward ventilating these patients with smaller tidal volumes and a tolerance for the relative hypercarbia that may ensue. In addition, a large body of research has shown that ventilation with large tidal volumes and low PEEP levels allows a pattern of cyclic alveolar overdistention and collapse, which causes a lung injury histologically similar to ARDS, even in normal lungs. This phenomenon is now called ventilator-induced lung injury. Taken together, these findings have given rise to the view that the acute phase of ARDS can best be treated by rerecruiting those areas of dependent collapse and

Table 13-7. Pathophysiologic changes of modern acute respiratory distress syndrome (low-pressure pulmonary edema).

	Symptoms	Laboratory Findings	Pathophysiology
Phase 1 (early changes)			
Normal radiograph	Dyspnea, tachypnea, normal chest examination	Mild pulmonary hypertension, normoxic or mild hypoxemia, hypercapnia.	Neutrophil sequestration, no clear tissue damage
Phase 2 (onset of parenchymal changes)^a			
Patchy alveolar infiltrates beginning in dependent lung No perivascular cuffs (unless a component of high pressure edema is present) Normal heart size	Dyspnea, tachypnea, cyanosis, tachycardia, coarse rales	Pulmonary hypertension, normal wedge pressure, increased lung permeability, increased lung water, increasing shunt, progressive decrease in compliance, moderate to severe hypoxemia.	Neutrophil infiltration, vascular congestion, fibrin strands, platelet clumps, alveolar septal edema, intra-alveolar protein, white cells, type I epithelial damage
Phase 3 (acute respiratory failure with progression, 2–10 d)			
Diffuse alveolar infiltrates Air bronchograms Decreased lung volume No bronchovascular cuffs Normal heart	Tachypnea, tachycardia, hyperdynamic state, sepsis syndrome, signs of consolidation, diffuse rhonchi	Phase 2 changes persist. Progression of abnormalities, increasing shunt fraction, further decrease in compliance, increased minute ventilation, impaired oxygen extraction of hemoglobin.	Increased interstitial and alveolar inflammatory exudate with neutrophil and mononuclear cells, type II cell proliferation, beginning fibroblast proliferation, thromboembolic occlusion
Phase 4 (pulmonary fibrosis, pneumonia with progression, > 10 d)^b			
Persistent diffuse infiltrates Superimposed new pneumonic infiltrates Recurrent pneumothorax Normal heart size Enlargement with cor pulmonale	Symptoms as above, recurrent sepsis, evidence of multiple organ system failure	Phase 3 changes persist. Recurrent pneumonia, progressive lung restriction, impaired tissue oxygenation, impaired oxygen extraction. Multiple organ system failure.	Type II cell hyperplasia, interstitial thickening; infiltration of lymphocytes, macrophages, fibroblasts; loculated pneumonia or interstitial fibrosis; medial thickening and remodeling of arterioles

^aThe process is readily reversible at this stage if the initiating factor is controlled.

^bMultiple organ system failure is common. The mortality rate is greater than 80% at this stage, since resolution is more difficult.

Modified slightly and reproduced, with permission, from Demling RH: Adult respiratory distress syndrome: Current concepts. *New Horizons* 1993;1:388.

minimizing the stretch-induced injury, or volutrauma, in the nondependent areas of the lung. This approach has been termed the open-lung strategy and has been the subject of intense scrutiny in recent years (see below).

The subacute phase of ARDS (5–10 days after lung injury) is characterized by type 2 pneumocyte and fibroblast proliferation in the interstitium of the lung. This results in decreased lung volumes and signs of consolidation that are noted clinically and radiographically. Worsening of the hypoxemia with an increasing shunt fraction, as well as a further decrease in lung compliance, are noted. Some patients develop an accelerated fibrosing alveolitis in which fibroblasts and collagen formation in the interstitium are markedly increased. The mechanisms responsible for these changes are unclear. Current investigation centers on the role of growth and differentiation factors, such as transforming growth factor- β and platelet-derived growth factor released by resident and

nonresident lung cells such as alveolar macrophages, mast cells, neutrophils, alveolar type 2 cells, and fibroblasts.

During the chronic phase of ARDS (10–14 days after lung injury), fibrosis, emphysema, and pulmonary vascular obliteration occur. During this phase of the illness, oxygenation defects generally improve, and the lung becomes more fragile and susceptible to barotrauma. Air leak is common among patients still ventilated with high levels of airway pressure at this late stage in their illness. Also, patients have increased amounts of dead space, and difficulties with ventilation are common. Airway compliance remains low, perhaps because of ongoing pulmonary fibrosis and insufficient surfactant production.

Secondary infections are common in the subacute and chronic phases of ARDS and significantly influence the outcome. The mechanisms responsible for increased host susceptibility to infection during this phase are not well understood.

Mortality in the late phase of ARDS exceeds 80%. Death is usually caused by multiorgan failure and systemic hemodynamic instability rather than by hypoxemia.

▶ Treatment

A. Monitoring

Multiorgan system monitoring is mandatory for patients with ARDS. ABG analysis is required for accurate assessment of oxygenation and ventilation and for the rational titration of ventilator strategies that may have profound adverse effects. Hemodynamic monitoring should include, at a minimum, central venous pressure (CVP) measurements to help determine the level of cardiac preload, and an indwelling arterial catheter for continuous blood pressure measurements and ABG sampling. For patients with severe disease or concurrent cardiac dysfunction, consideration can be given to pulmonary artery catheterization to help with fluid management and to allow assessment of mixed venous blood saturation as an index of overall tissue oxygenation. Obtaining chest films daily is important for patients receiving vigorous support because severe ARDS is associated with a 40–60% incidence of air leaks. Since secondary infections are common and increase mortality rates strikingly, surveillance for infection is important, requiring appropriate cultures and following the temperature curve and white blood cell count. Renal, liver, and gastrointestinal (GI) function should be watched closely because of the great likelihood of multiorgan dysfunction.

B. Fluid Management

Given the increases in pulmonary capillary permeability in ARDS, pulmonary edema accumulation is likely with any elevation in pulmonary hydrostatic pressures. In this setting, most clinicians reduce intravascular volume to the lowest level that is still compatible with an adequate cardiac output and adequate oxygen delivery to the tissues.

C. Hemodynamic Support

Hemodynamic support is directed toward increasing perfusion and oxygen delivery. In those circumstances when volume expansion is necessary to improve oxygen delivery, this can best be achieved by giving packed red blood cells to maintain the hematocrit between 35% and 40%, and by giving colloid or crystalloid solutions to nonanemic volume-depleted patients. Inotropes should be used as needed to optimize oxygen delivery to the tissues.

D. Ventilatory Support

In addition to the basic principles of ventilator management described earlier (see section on Adjusting the Ventilator), current ventilatory management of ARDS is directed at the rerecruitment of areas of dependent alveolar collapse and the protection of noncollapsed areas from overdistention. Since

an FiO_2 greater than 60% over 24 hours can cause additional injury to the lung, mean airway pressure should be increased to provide an adequate PaO_2 (> 55 mm Hg) at an FiO_2 of 60% or less. In general, this can be accomplished by incremental increases in PEEP every 15–30 minutes until adequate oxygenation is achieved or until a limiting side effect of the PEEP is reached. Ventilation with high levels of PEEP acts by helping to prevent dependent collapse of edematous lung units. PEEP levels of 12–14 cm H_2O are not unusual, and levels as high as 20–25 cm H_2O have been used successfully in these patients. Before increasing PEEP significantly, the physician should optimize conditions by making sure that the patient's intravascular volume is appropriate, the endotracheal tube does not leak, and the patient is heavily sedated and paralyzed.

The actual mode of ventilation employed (volume or pressure) with an ARDS patient is probably unimportant. However, recent work from a large multicenter trial sponsored by the National Institutes of Health suggests that the tidal volumes used may be important. Using a PEEP strategy similar to that described in the preceding paragraph, the investigators compared the effects of a low (6 mL/kg) tidal volume versus a normal (12 mL/kg) tidal volume in 861 adult ARDS patients. Those patients ventilated with the lower tidal volume demonstrated fewer extrapulmonary organ failures and an overall 25% decrease in mortality. In keeping with these findings and with experimental data demonstrating ventilator-induced lung injury at alveolar pressures greater than 30 cm H_2O , we suggest that current practice for pediatric ARDS patients should consist of ventilation with tidal volumes in the 6- to 8-mL/kg range, or at least with tidal volumes small enough to keep alveolar pressures below 30–35 cm H_2O .

E. Other Therapies

As previously described, HFOV is an increasingly popular technique that has been used successfully in pediatric patients with ARDS. When used as part of a strategy of aggressive increases in mean airway pressure to rerecruit deflated areas of the lung and to prevent cyclic overdistention and collapse, HFOV is a physiologically rational approach to this illness. It has not yet been determined whether HFOV provides additional benefits compared with open-lung strategy ventilation using conventional ventilator modes.

Prone positioning is a technique of changing the patient's position in bed from supine to prone, with the goal of allowing postural drainage and improving ventilation of collapsed dependent lung units. This technique often dramatically improves oxygenation, particularly for patients early in the course of ARDS. The oxygenation improvements are often not sustained, however, necessitating repeated position changes to maintain the effect. Whether prone positioning contributes to improved outcomes for patients with ARDS remains uncertain.

Based on the ability of inhaled **nitric oxide** (iNO) to reduce pulmonary artery pressure and to improve the matching of ventilation with perfusion without producing systemic vasodilation, iNO has been proposed as a beneficial therapy for ARDS. Several recent multicenter trials of iNO in the treatment of ARDS, both in adults and in children, have shown acute improvements in oxygenation in subsets of patients but no significant improvement in overall survival. As a result, the current role of iNO in the treatment of ARDS remains unclear. Additional studies are now focusing on the anti-inflammatory role (by reducing neutrophil adhesion and activation) iNO may play in ARDS. Studies to evaluate the combined effects of several of these alternative therapies are also being planned.

Surfactant replacement therapy has been tried with some success in patients with ARDS. In some instances surfactant replacement improves lung compliance and oxygenation, and hastens weaning from mechanical ventilation. In randomized trials of surfactant replacement, there were no differences in outcome (death, length of ventilation, or hospitalization), but there was some evidence of decreased inflammation. A multicenter trial of surfactant treatment for pediatric ARDS is currently in progress.

The use of **corticosteroids** to modulate the inflammatory component of ARDS remains controversial, with many conflicting studies. Early trials demonstrated that, when administered at high dose to cure or to prevent ARDS, glucocorticoids provided no survival benefit and even may have favored life-threatening infections. More recent clinical data on low-dose, prolonged glucocorticoid treatment of ARDS have shown significant improvement in inflammation and lung physiology with a favorable benefit-risk profile. A large multicenter trial of methylprednisolone in the late phase of ARDS (> 7 days after onset) in adults showed no difference in mortality rates compared with placebo, but an increased number of ventilator-free and shock-free days during the first 28 days, in association with improved oxygenation, respiratory-system compliance, and blood pressure with fewer days of vasopressor therapy. As compared with placebo, methylprednisolone did not increase the rate of infectious complications but was associated with a higher rate of neuromuscular weakness. In addition, starting steroids more than 2 weeks after the onset of ARDS was associated with an increased risk of death. A more recent multicenter trial of early and prolonged (2 weeks at full dose; then tapered off > 2 weeks) treatment with low-dose methylprednisolone (1 mg/kg/d) revealed that steroid treatment down-regulated systemic inflammation and was associated with significant improvement in pulmonary and extrapulmonary organ dysfunction, and with reduction in duration of mechanical ventilation and ICU length of stay. These recent studies suggest, with some exceptions, that early steroid treatment could be beneficial for ARDS patients; however, no definitive studies have been performed in the pediatric population.

Extracorporeal membrane oxygenation (ECMO) has been used in pediatric patients with severe ARDS. In older studies, patients who received ECMO had better survival

rates than did control subjects. ECMO has not been studied in comparison with current conventional ventilation strategies. In addition, recent improvements in outcome for pediatric ARDS patients receiving conventional therapies have made the role of ECMO less clear and have made further prospective randomized studies of ECMO difficult to complete. For now, ECMO remains a rescue therapy for patients with severe ARDS unresponsive to other modalities.

F. Follow-Up

Information regarding the long-term outcome of pediatric patients with ARDS remains limited. One report of 10 children followed 1–4 years after severe ARDS showed three still symptomatic and seven with hypoxemia at rest. Until further information is available, all patients with a history of ARDS need close follow-up of pulmonary function.

INDICATIONS FOR CENTRAL VENOUS & ARTERIAL CANNULATION

Placement of catheters into the central venous or arterial circulation may be justified for continuous assessment of intravascular volume or cardiac function; blood drawing for lab work; or administration of volume, drugs, or hyperalimentation. One should always weigh the risks of bleeding, infection, and clotting against the expected benefits before placing any indwelling catheter.

General Rules for Cannulation of the Venous System

1. Perform a “time-out” before beginning. Confirm out loud with the bedside nurse, the identity of the patient, the procedure needed, and the intended site for line placement.
2. Set up and examine all equipment needed before getting started. Use of a limited number of kits and equipment will provide greater consistency and success.
3. Properly position the patient.
4. Apply EMLA cream (eutectic mixture of local anesthetics, lidocaine 2.5% and prilocaine 2.5%) to the area of puncture (45 minutes before the procedure) or infiltrate with local anesthetic before prepping the skin. Sedation is often necessary but should be performed by a qualified person.
5. The remainder of the procedure should occur under aseptic technique (including gown, mask, and hair cover for operator and assistant).
6. Sterilize and drape the area around the point of entry.
7. When searching for the vessel, make straight passes while maintaining slight negative pressure. Advance and withdraw the needle at the same speed. Frequently, the blood return will occur during withdrawal.
8. Once there is free flow of venous blood into the syringe, remove the syringe without moving the needle, and if using the Seldinger technique, pass the J wire through the needle. When appropriate (subclavian and internal jugular vein cannulations), watch the electrocardiogram for arrhythmias, because they frequently occur when the J wire touches the right side of the heart.
9. Withdraw the needle over the J wire and clean the wire of blood.
10. If using a 5F or larger catheter, make a small nick with a No. 11 blade at the point where the J wire enters the skin. Dilate central veins by passing the dilator over the J wire into the vein. Remove the dilator (skip this step for arterial cannulation) and pass the intravascular catheter over the J wire. As you advance the catheter toward the entry site into the skin be sure the wire is always visible, or protrudes out the end of the catheter, to prevent the wire becoming lodged within the vessel.
11. With the catheters in place, remove the wire.

12. Check to make sure that blood can be drawn and flushed easily through each port of the new line. Withdraw blood through a syringe containing saline before flushing to prevent introduction of air bubbles.
13. Suture the line in place.
14. Verify the position of the line on radiograph.

Points of Entry for Venous Line Placement

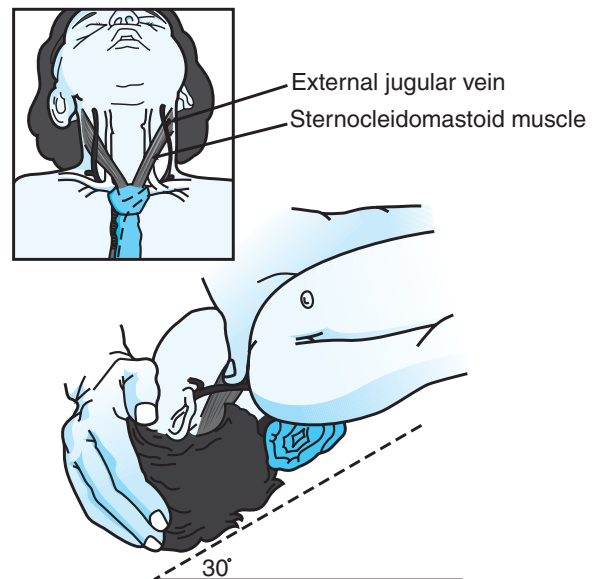

A. External Jugular Vein

Place a soft cloth roll beneath the patient’s shoulder and turn the head to the contralateral side (Figure 13–2). The Valsalva maneuver, Trendelenburg position, and occlusion of the vessel at the clavicular level are ways of temporarily increasing jugular distention and visibility.

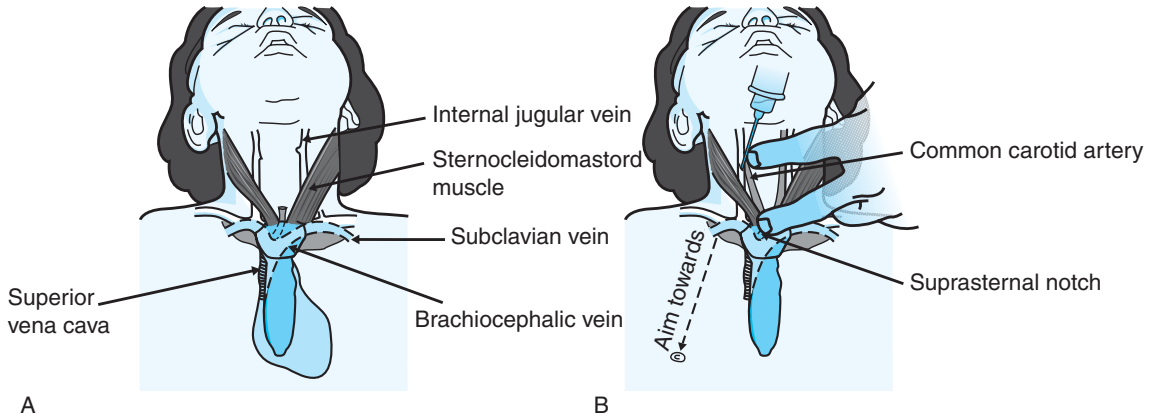

To overcome the problems of this vessel’s mobility and thick wall, apply cephalic retraction of the skin over the vessel superior to the point of needle entry. Maintain gentle negative pressure in the syringe attached to the needle as it is advanced toward the vessel. Needle entry into the vessel lumen is usually signaled by a change in resistance followed by appearance of venous blood in the hub of the needle. Remove the syringe without moving the needle and pass a soft J wire into the vessel lumen. Remove the needle and pass the central line over the J wire.

B. Internal Jugular Vein

Once the patient has been prepped, draped, and positioned as shown in Figure 13–3, feel for the trachea halfway between

▲ Figure 13-2. External jugular vein technique.

▲ Figure 13-3. **A:** The internal jugular vein and its relationship to the surrounding anatomy. **B:** Technique of anterior internal jugular cannulation.

the angle of the jaw and the suprasternal notch and then feel lateral to the trachea for the carotid pulse. Just lateral to the carotid pulse, at a 30-degree angle from horizontal, insert a finder needle (25-gauge), aiming between the ipsilateral nipple and shoulder. Once venous return is established, remove the finder needle and repeat the procedure with the appropriate-size larger needle.

C. Subclavian Vein

After the patient has been prepped, draped, and positioned (Figure 13-4), move the needle flat along the chest, enter-

ing along the inferior edge of the clavicle just lateral to the midclavicular line and aiming for the suprasternal notch. Once venous return is established, use the Seldinger technique.

D. Femoral Vein

With the patient’s leg slightly abducted (Figure 13-5), find the femoral artery 3–4 cm below the inguinal ligament. The femoral vein is just medial and parallel to the femoral artery. Insert the needle at a 30- to 45-degree angle. Once venous return is established, use the Seldinger technique.

▲ Figure 13-4. Subclavian artery. **A:** Anatomy. **B:** Technique.

▲ **Figure 13-5.** Femoral vein. **A:** Anatomy. **B:** Technique.

E. Antecubital Vein

Peripherally inserted catheter lines (2.8–4 F) are long, soft, Silastic, styletted catheters most commonly threaded from an antecubital vessel to the right atrium. These lines are not difficult to insert and are easy to dress and keep clean. They are suited for long-term use because they are tolerable for the patient, good for infusion of hyperalimentation and drugs, and less thrombogenic. In general, they are not suitable for obtaining blood for laboratory analysis.

General Rules for Cannulation of the Arterial System

The Seldinger technique can be applied for arterial tree cannulation as well. Most arteries can be cannulated percutaneously.

1. Puncture the skin at the insertion site to eliminate any drag or resistance on the catheter advancement.
2. Insert the cannula at a 30-degree angle to the skin surface, advancing at a slow rate toward the arterial pulse. Watch the hub of the cannula for a flash of arterial blood.

3. When arterial flash is seen, lower the catheter to a 10-degree angle with the surface of the skin and advance the catheter into the lumen of the artery. If successful, pulsatile arterial flow will continue into the catheter.
4. Hold the catheter while removing the needle stylet. Arterial blood will pulse out of the catheter if the tip is in the arterial lumen.
5. Advance the catheter into the lumen; attach a syringe containing normal saline with 1 U/mL of heparin; aspirate to make certain that there are no bubbles; and then gently flush the catheter.
6. If arterial flow into the needle stylet stops during catheter advancement, advance this unit an additional centimeter. Remove the needle stylet and place it on a sterile surface. Pull the catheter out slowly. When the tip of the catheter flips into the arterial lumen, the pulsatile arterial blood flow is seen. Rotate the catheter to ensure that the catheter is free within the vessel lumen, then advance the remainder of the catheter length into the vessel.
7. Suture the catheter in place while ensuring that the arterial trace is not damped.
8. Dress the insertion site with sterile gauze, and tape it to the skin.

Points of Entry for Arterial Line Placement

Always consider whether collateral arterial blood is flowing to the structures distal to the insertion point. The Allen test must be done prior to radial or ulnar artery cannulation.

Arterial sites, listed in order of preference, include:

1. Radial artery (nondominant arm first)
2. Femoral artery (morbidity is the same as for the radial artery beyond the newborn period)
3. Posterior tibial artery
4. Dorsalis pedis artery
5. Ulnar artery (if distal radial filling is present in that hand)
6. Axillary artery
7. Brachial artery (poor collateral flow, used only during cardiac surgery in newborn-sized patients with arterial access limitations)

Final Considerations

1. Patient benefit should outweigh any risks from central venous or arterial cannulation.
2. Coagulation status of the patient at the time of placement and throughout the time of use must be considered, because deep venous and arterial thrombus formation is partially related to the patient's coagulation status.
3. The incidence of catheter colonization and infection increases if central venous and arterial lines are left in for more than 6 days.

BRAIN INJURY & CEREBRAL EDEMA

Intracranial hypertension is a common feature of many illnesses treated in the PICU (Table 13–8). The early signs and symptoms of intracranial hypertension (Table 13–9) tend to be nonspecific. The classic Cushing triad of bradycardia, hypertension, and apnea occurs late and is often incomplete in children.

Accurate assessment and treatment of elevations in ICP requires an understanding of the basic pathophysiology of intracranial hypertension and of the current evidence supporting the various treatment options. Most of our understanding and approach to treatment is based on studies of patients with traumatic brain injuries. Whether those concepts are directly relevant to the pathophysiologic processes involved in more global CNS injuries, such as hypoxia and metabolic disorders, remains a matter of debate.

Within the constraints of a closed skull, an enlargement of brain tissue, an increased volume of cerebrospinal fluid (CSF), or an increased volume of blood (or the presence of a space-occupying lesion such as a tumor or an abscess) will reduce the size of the other compartments or increase pressure. The factors contributing to intracranial hypertension can be understood by considering each of these three primary compartments.

The brain occupies about 80% of the volume of the skull. Apart from solid tumors, increases in the brain compartment are generally a result of cerebral edema. Cerebral edema can be divided into three forms: vasogenic, hydrostatic, and cytotoxic. **Vasogenic** edema occurs in areas of inflamed tissue characterized by increased capillary permeability, and is most typical around CNS tumors, abscesses, and infarcts. This form of edema is thought to be at least partially responsive to corticosteroid therapy. **Hydrostatic**, or interstitial, edema is a result of elevated CSF hydrostatic pressures. It occurs primarily in lesions associated with obstruction to CSF flow, and in a typical periventricular distribution. This form of edema is best treated by CSF drainage. The third form of cerebral edema, **cytotoxic** edema, is the most common of the three forms seen in the PICU and is, unfortunately, the least easily treated. Cytotoxic edema occurs as a result of direct injury to brain cells, often leading to irreversible cell swelling and death. This form of cerebral edema is typical of traumatic brain injuries as well as hypoxic-ischemic injuries and metabolic disease.

CSF occupies an estimated 10% of the intracranial space. Intracranial hypertension due primarily to increases in CSF volume (eg, hydrocephalus, primary or secondary) is generally easily diagnosed by computed tomography scan and easily treated with appropriate drainage and shunting.

Cerebral blood volume comprises the final 10% of the intracranial space. Changes in cerebral blood volume generally result from alterations in vascular diameter in response to local metabolic demands or to local vascular pressures—

so-called metabolic and pressure autoregulation. These physiologic responses are the means by which the CNS circulation regulates and maintains adequate blood flow to the brain. Given the difficulty in effectively treating cytotoxic brain swelling and the relative rarity of uncomplicated CSF obstructive lesions in the PICU, most of the current therapies aimed at controlling intracranial hypertension rely on altering cerebral blood volume.

Several factors interact to control cerebral blood volume via the autoregulatory responses of the cerebral vasculature. The rate of cerebral metabolism is an important determinant of cerebral blood volume. High metabolic rates lead to vasodilation and increased blood volume, whereas low metabolic rates allow the vessels to constrict and reduce blood flow and blood volume. Partial pressure of carbon dioxide is another important determinant of cerebral blood volume, as elevations in blood PCO_2 lead to cerebral vasodilation and decreases in PCO_2 lead to vasoconstriction. Finally, cerebral blood volume is linked to cerebral blood flow through the phenomenon of pressure autoregulation. As shown in Figure 13-6, at low systolic blood pressures the cerebral vessels are maximally dilated and blood flow is only increased by increasing blood pressure. Within the range of autoregulation, the cerebral vessels attempt to maintain a constant flow rate over a range of pressures; increased blood pressure results in vasoconstriction, in turn reducing cerebral blood volume. Once the cerebral vessels are maximally constricted, continued increases in pressure may further increase cerebral blood flow and volume.

Treatments for intracranial hypertension are largely derived from experience with traumatic brain injury. An important concept in this regard is that of a “primary” as opposed to a “secondary” brain injury. In this context, primary injury refers to direct damage to brain tissue resulting

▲ **Figure 13-6.** Pressure autoregulation in the cerebral vasculature.

from the original insult to the CNS, such as physical damage from trauma. This injury is complete before the patient reaches the health care system. As the injured brain swells due to cytotoxic edema, intracranial hypertension develops, potentially limiting cerebral blood flow to portions of the brain and leading to extension of the initial injury (ie, secondary injury). Medical treatment of the patient with intracranial hypertension aims to prevent or reduce secondary injuries.

The primary goal of treatment is to optimize perfusion of areas of the brain that are salvageable. This can be accomplished by reducing ICP and by ensuring adequate perfusion. Rational guidance of treatment requires invasive monitoring so that it can be effectively titrated. Although a complete discussion of the indications for ICP monitoring is beyond the scope of this chapter, the topic can be briefly summarized with the suggestion that an ICP monitor be used for patients at significant risk for intracranial hypertension, in whom the treatment of elevated CNS pressures is planned. Monitoring other parameters of CNS oxygen delivery (ie, blood pressure, ABGs, and intravascular volume) generally mandates the placement of arterial and central venous catheters. Little evidence exists to support the utility of ICP-directed therapies in conditions associated with global CNS injuries (eg, anoxic brain injuries).

Maintenance of adequate cardiac output and oxygen delivery to the CNS is critical in treating patients with intracranial hypertension. Studies in both adult and pediatric head injury patients show that even a single episode of hypotension or arterial hypoxemia is associated with a marked increase in mortality rates. Although studies have not delineated clear age-appropriate thresholds for blood pressure and PaO_2 in this setting, a rational starting point for therapy would seem to be maintenance of an adequate circulating blood volume, a blood pressure at least well within the normal range for age, and a PaO_2 of at least 60 mm Hg. Hypotension and hypoxemia should be treated urgently and aggressively.

In general, the threshold at which treatment for intracranial hypertension should be started is in the range of 15–20 cm H_2O pressure. Above this pressure, very minor increases in the volume of the intracranial contents lead to large increases in ICP (Figure 13-7). Initial therapy for intracranial hypertension should always consist of securing the airway and providing adequate sedation. Additional measures would include the removal of any mass lesions (eg, tumors, abscesses, and hematomas) and adequate ventricular drainage. Further efforts are then largely directed at reducing cerebral blood volume.

Osmotic diuretics such as mannitol or 3% normal saline are often used to treat intracranial hypertension. They are thought to act first by decreasing blood viscosity, allowing for increased flow and subsequent autoregulatory vasoconstriction. The osmotic effects on the cells and interstitium of the brain prolong the reduction in ICP. Although mannitol therapy has never been subjected to a placebo-controlled trial, it

▲ **Figure 13-7.** Compliance curve of the skull with changing volume of intracranial contents.

leads to better outcomes than barbiturate therapy in patients with refractory ICP elevations. Current guidelines suggest the use of mannitol in doses of 0.25–0.5 g/kg for intracranial hypertension unresponsive to sedation. Renal failure due to acute tubular necrosis can be a treatment-limiting side effect, particularly if serum osmolarity is allowed to rise above 320 mmol and intravascular volume depletion occurs. Continuous infusion of 3% saline at 0.1–1 ml/kg/h can alternatively be used to increase osmolarity, using the minimum dose to achieve ICP of less than 20 mm Hg. Serum sodium and osmolarity should be followed and should generally not exceed sodium of 160 mEq/L or serum osmolarity of 360 mOsm/L.

Controlled ventilation is recommended for mild to moderate intracranial hypertension, maintaining PCO_2 of 30–35 mm Hg. Hyperventilation—long a mainstay in the treatment of intracranial hypertension—is controversial and only used in emergent situations involving patients with acute ICP elevations unresponsive to other measures, including sedation, paralysis, ventricular drainage, and osmotic diuretics. Although acutely effective in causing cerebral vasoconstriction, hyperventilation leads to much larger decreases in blood flow than in blood volume, such that hyperventilation to the point necessary to control ICP may actually compromise CNS perfusion and lead to worsened secondary injury. This concept has been confirmed by studies showing worse outcomes in head-injured patients consistently hyperventilated to a PCO_2 of 25 mm Hg or less. Due to the risks of worsened CNS ischemia, monitoring cerebral perfusion by blood flow studies or jugular bulb saturation is recommended for patients undergoing extreme hyperventilation.

The use of barbiturates in this setting is based on their suppression of cerebral metabolism and the subsequent metabolic autoregulatory effects on cerebral blood volume. Although effective in many instances for ICP elevations, these agents are potent cardiac depressants, and their use

often leads to hypotension, necessitating the use of a pressor to maintain perfusion. In addition, plasma barbiturate levels correlate poorly with effect on ICP, suggesting that monitoring of CNS electrical activity by electroencephalography is necessary to accurately titrate their use. Current guidelines suggest the use of barbiturates for treating intracranial hypertension refractory to sedation, paralysis, ventricular drainage, and osmotic diuretics.

Another important concept in the management of intracranial hypertension is that of the cerebral perfusion pressure. The cerebral perfusion pressure is the driving pressure across the cerebral circulation and is defined as mean arterial pressure minus CVP (or ICP, whichever is higher). Some authors have suggested that careful attention to maintenance of a supranormal cerebral perfusion pressure may lead to better outcomes for head-injured patients. Although there are no well-controlled trials to draw from (particularly for pediatric patients), current guidelines suggest that maintenance of a “normal” cerebral perfusion pressure for age (50–70 mm Hg) is a valid secondary goal of treatment, as long as it is included in a plan to use the other ICP-directed therapies discussed earlier.

A suggested treatment algorithm for patients with documented intracranial hypertension is presented in Figure 13–8. As mentioned earlier, this algorithm represents the current best evidence for the management of intracranial hypertension. The information is largely drawn from experience with traumatic brain injuries, and the direct applicability of these concepts to other illnesses associated with intracranial hypertension remains unclear.

ETHICAL DELIBERATION & END-OF-LIFE CARE IN THE PICU

Bioethics Consultation in the PICU

Advances in critical care medicine give PICU practitioners the ability to prolong life without being able to ensure a reasonable quality of life. Health care professionals in this setting are often called on to help patients and families wrestle with questions of medical futility. As conflict surrounding care and

▲ **Figure 13–8.** Proposed treatment algorithm for intracranial hypertension in head injury. CSF, cerebrospinal fluid; ICP, intracranial pressure; P_{CO_2} , partial pressure of arterial CO_2 .

decision making has arisen, the introduction of ethics consultation in the ICU setting has served to improve the process by helping to identify, analyze, and resolve ethical problems. Ethics consultation can independently clarify views and allow the health care team, patient, and family to make decisions that respect patient autonomy and promote maximum benefit and minimal harm to the patient.

Managed Withdrawal of Treatment

With increasing frequency, PICU deaths are predictable and result from the withholding or withdrawing of life-sustaining medical therapy (LSMT). Discussions with patients and families regarding the decision to limit resuscitation or to withdraw LSMT should respect the following basic principles:

- Deliberations begin with a clear statement that the patient's good is the goal.
- With the assistance of the health care team, the patient and family can make reasonable decisions about limitation or withdrawal of LSMT based on goals of care for the patient.
- The burden of continued life (pain and suffering) should outweigh any potential benefit from continued therapy.
- Discussions with the patient and family are conducted by experienced personnel with the ability to communicate in a clear and compassionate manner at an appropriate time and place.
- It should be emphasized that decisions are not irrevocable; if at any time the family or health care providers wish to reconsider the decision, full medical therapy should be reinstated until the situation is clarified.

Palliative Care

Helping a patient experience a dignified and pain-free death is one of the many unique challenges facing caregivers in the PICU. Pediatric death is characterized by its relative infrequency, by the prognostic uncertainties of many pediatric illnesses, and by the fine line between congenital disorder and incurable disease. When a predictable early death is likely, intensivists are often called on to care for the patient and family during the final days and hours of the patient's life.

In the past several years, palliative medicine has developed as a specialized field of practice to address the needs of dying children. The practice of providing supportive care at end of life in pediatrics is fundamentally different from that in adult medicine. In-hospital deaths in pediatrics encompass a more heterogeneous patient population with developmental issues and family dynamics that complicate the process.

Once the inclusive decision is made to limit or withdraw LSMT, a palliative care plan should be agreed on and instituted. The plan should address the following basic principles:

- Adequate pain control and sedation
- Provision of warmth and cleanliness
- Nutrition
- Ongoing patient and family support

The decision to withhold or withdraw LSMT from a pediatric patient does not suggest a plan to hasten the death. The goal of palliative care remains optimization of the patient's and family's experience prior to and following the death. (See also Chapter 30.)

Tissue & Organ Donation

Organ transplantation has become standard therapy. Although the demand for tissue and solid organs has increased, donations have not. The prospect of organ or tissue donation should be considered with all patients dying in the PICU. To be a solid organ donor, the patient must be clinically brain dead and have no conditions contraindicating donation. With patients from whom life-support must be withdrawn, tissue (heart valves, corneas, skin, and bone) can be obtained after cardiac death. The need for new donor organs has led to the reemergence of procuring organs from nonheartbeating (asystolic) donors. In these cases the family or patient has refused life-sustaining therapy and has chosen to have life-support withdrawn, and to donate organs after death.

Death is determined using “traditional” or “cardiopulmonary” criteria of (1) unresponsiveness, (2) apnea, and (3) absent circulation. A high level of scrutiny exists regarding nonheartbeating donors in pediatric patients, and before it has wide acceptance standards of practice need to be developed further. The Required Request Law mandates that health care professionals approach all donor-eligible families to inquire about organ procurement. The decision to donate must be made free of coercion, with informed consent, and without financial incentive.

Brain Death (See Chapter 23)

The development of criteria and expertise in the clinical brain death exam arose out of the demand for solid organs from patients still receiving LSMT. Currently, the diagnosis of brain death is based on national guidelines that render some clarity and standardization to this critical task.

Clinical Brain Death Examination

Establish the cause of the disease or injury and exclude potentially reversible syndromes that may produce signs similar to brain death. Also establish the following:

- Coexistence of coma and apnea¹ (“apnea test” ~3 minutes with $\text{PCO}_2 > 60$ mm Hg)
- Absence of brainstem function
- Normal blood pressure and temperature
- Flaccid muscle tone, no spontaneous movements
- Examination consistent throughout observation period

Recommended observation periods for children of the following ages:

- Seven days to 2 months old—Two examinations over 48 hours; with electroencephalography

- Two months to 1 year—Two examinations over 24 hours; with electroencephalography
- Over 1 year—Two examinations over 12–24 hours

Ethics Committee, American College of Critical Care Medicine; Society of Critical Care Medicine: Recommendations for non-heartbeating organ donation. NUTRITIONAL SUPPORT OF THE CRITICALLY ILL CHILD

Metabolic & Physiologic Responses

When severely ill pediatric patients are admitted to the PICU, the initial therapy is directed at the primary or underlying problem and at providing cardiorespiratory and hemodynamic support. Although this management is critical to sustaining life in these patients, provision of adequate nutritional support is often overlooked early in the course of therapy. As increasing evidence demonstrates that nutritional status and support affect the morbidity and mortality of critically ill patients, it is vital that this aspect of care be addressed early in the hospital course.

Trauma, surgery, burns, and sepsis impose metabolic and physiologic disturbances that vary in degree, but have many similarities. The insult triggers the afferent limb of the neuro-physiologic reflex, which is composed of pain and neurosensory pathways. In response, the efferent limb consisting of neurologic and endocrine pathways, increases autonomic sympathetic activity with norepinephrine and epinephrine secretions and increases pituitary release of many hormones, including adrenocorticotropic hormone (ACTH), growth hormone, and antidiuretic hormone. Release of catecholamines inhibits insulin secretion and activity, and stimulates glucagon and ACTH production. ACTH and antidiuretic hormone increase corticosteroid release, inhibit insulin activity, and increase aldosterone. The overall effect is to direct an end-organ increase in metabolic rate and to provide increased substrate availability for energy use (Table 13–10). In addition, the body has a cellular response to tissue injury. Cells

¹Cerebral angiography, radionuclide scanning, or transcranial Doppler ultrasonography can be used to assess brain function if apnea testing cannot be performed or if there is need for corroborative studies.

Table 13–10. Metabolic and physiologic responses to severe illness.

Physiologic	
Cardiovascular	
Increased cardiac output	
Peripheral vasodilatation and capillary leak	
Expansion of vascular compartment	
Pulmonary	
Increased minute ventilation	
Ventilation-perfusion mismatch	
Inefficient gas exchange	
Increased CO ₂ responsiveness	
Skeletal muscle	
Easier fatigability	
Slower relaxation	
Altered force-frequency pattern	
Renal	
Salt and water retention	
Impaired concentrating ability	
Metabolic	
Hormone and hormone-like levels	
Increased insulin	
Increased glucocorticoids	
Increased catecholamines	
Increased interleukin-1	
Increased tumor necrosis factor	
Carbohydrate metabolism	
Increased blood glucose	
Increased gluconeogenesis	
Increased glucose turnover	
Glucose intolerance	
Fat metabolism	
Increased lipid turnover and utilization	
Insuppressible lipolysis	
Decreased ketogenesis	
Protein metabolism	
Increased muscle protein catabolism	
Increased muscle branched-chain amino acid oxidation	
Increased serum amino acids	
Increased nitrogen losses	

migrate to the damaged area to facilitate wound healing and aid in infection control with the release of inflammatory mediators. These cells are mainly dependent on glucose for their energy source, which is an important reason the hypermetabolic state is necessary. These events initiate a hypermetabolic response that influences the mobilization and use of nutrients as substrates. Although all substrates are increasingly used, the fraction of calories derived from glucose is reduced, and the fraction derived from protein and lipid breakdown is increased.

Hyperglycemia and glucose intolerance are characteristic traits of the hypermetabolic state. Although glucose use is increased, serum glucose levels are elevated, reflecting neuroendocrine stimulation of glycogenolysis and gluconeogenesis. Gluconeogenesis occurs primarily from lactate, alanine, glutamine, and other amino acids derived from muscle breakdown and from glycerol derived from lipolysis. The

hepatic production of glucose is increased, and fails to respond to increased plasma concentrations of glucose or insulin when these substances are infused intravenously. Hyperglycemia and secondary hyperinsulinemia also inhibit ketosis despite the increased rate of lipolysis. The hyperglycemia does, however, maintain glucose supply to the brain. An elevated glucagon-insulin ratio and increased secretion and plasma concentrations of catecholamines produce relative peripheral insulin resistance. Inefficient glucose and fatty acid uptakes are inadequate to meet increased energy needs, leading to increased oxidation of branched-chain amino acids. Because branched-chain amino acids are essential amino acids, their oxidation depletes a valuable pool of precursors for protein synthesis. Administration of excess glucose can lead to hyperosmolar complications, excess energy expenditure, increased CO₂ production, cholestasis, and fatty infiltration of the liver.

Lipids are the major source of energy used during periods of stress starvation. Thus, lipolysis is increased and lipogenesis is decreased despite high levels of glucose and insulin. During stress starvation, peripheral tissues, such as skeletal muscle, myocardium, and respiratory muscles are able to use lipids as their primary energy source. Turnover of medium- and long-chain fatty acids is increased, although the clearance rate of long-chain fatty acids and triglycerides is reduced, primarily through a reduction in peripheral lipoprotein lipase activity that is inhibited by tumor necrosis factor- α (TNF α). If excess lipids are administered, complications such as hyperlipidemia, bacteremia, and suppression of *in vitro* tests of polymorphonuclear and lymphocyte function may occur.

Protein catabolism is the hallmark of the metabolic stress response. Although the rate of protein synthesis is actually increased in the hypermetabolic state, it is significantly inadequate compared with the rate of protein breakdown. Protein is broken down mainly to provide carbon skeletons for use in gluconeogenesis, but amino acids are also used to support the cellular inflammatory response, the hepatic synthesis of acute-phase reactant proteins, and wound healing. Thus, the contribution of protein to total caloric expenditure increases from 10% in normal children to 15–20% in critically ill children. The discrepancy between protein catabolism and synthesis leads to a negative nitrogen balance and loss of lean body mass. This condition can be reduced or even reversed with increased nonprotein calorie and protein nutrition. Increased nutrient intake appears to make a difference in the ability of the patient to tolerate stress.

Nutritional Assessment

The pediatric patient is at a marked disadvantage compared with adults during periods of stress starvation. The child is a growing organism with little metabolic reserve to compensate for the metabolic stresses created by surgery, trauma, and sepsis. Preexisting nutritional status and the degree of stress imposed by the disease process are important factors in

Table 13-11. Estimating needs for critically ill pediatric patients.^a

	Age	Resting Energy Expenditure (REE) (kcal/kg)	Average Range of Energy Needs (kcal/kg)	Average Range of Protein Needs (g/kg)
Infants	0-6 mo	55	90-120	2-3.5
	6-12 mo	55	90-120	1.5-2.5
Children	1-3 y	55	75-100	1.5-2.5
	4-6 y	45	65-90	1.5-2.0
	7-10 y	40	55-70	1.0-2.0
Males	11-14 y	30	40-55	1.0-2.0
	15-18 y	30	40-45	1.0-1.5
	19-24 y	25	30-40	1.0-1.5
Females	11-14 y	30	40-55	1.0-2.0
	15-18 y	25	30-40	1.0-1.5
	19-24 y	25	30-40	1.0-1.5

^aBased on World Health Organization formulas for protein and energy requirements.

estimating nutritional requirements of the critically ill patient. Accurate assessment of nutritional requirements is important as both overfeeding and underfeeding can increase morbidity. One way to estimate nutritional requirements is to apply U.S. recommended dietary allowances. However, because these recommendations are based on populations of normal healthy subjects, applying recommended dietary allowances to critically ill patients significantly overestimates their caloric requirements. Therefore, several equations have been formulated in an attempt to predict basal energy needs of the critically ill patient. Some of these formulas estimate the basal metabolic rate, which is the energy requirement for a fasting (10–12 hours) person who recently awoke from sleep and is at rest with a normal body temperature in the absence of any stress. Other formulas estimate the resting energy expenditure (REE), which is the energy expenditure of a person at rest with a normal body and ambient temperature, but not necessarily fasting. The basal metabolic rate and REE are similar, usually differing by less than 10%. Harris-Benedict and the World Health Organization have recommended formulas that are among the most commonly used (Table 13-11). Once the basal metabolic demand has been estimated, it is then multiplied by a stress factor correlated to the underlying disease process to determine the ultimate energy requirements for the patient (Table 13-12). Compared with recommended dietary allowances, these formulas better estimate energy requirements in sick patients. However, recent evidence suggests that even they may not be accurate enough to use in critically ill children.

Indirect calorimetry has been used to measure patients' REE and appears to reflect a more accurate method of determining nutritional requirements. Indeed, indirect calo-

rimetry measurements were used to derive the stress factors used with prediction formulas. Though this method was once used strictly for research, portable, accurate devices are available that can be used anywhere in the hospital. Indirect calorimetry measures the amount of oxygen absorbed across the lung. This value is assumed to be equal to the amount of oxygen consumed in metabolic processes. The metabolic rate determined in milliliters of oxygen consumed per minute can be converted to calories per hour, thereby providing a measure of REE. Carbon dioxide production is also meas-

Table 13-12. Activity and stress factors (\times REE).

Condition	Factor
ICU on ventilation	Activity 1.0-1.15
Confined to bed	Activity 1.1-1.2
Light activity	Activity 1.2-1.3
Fever, per 1°C	Stress 1.12-1.13
Major surgery	Stress 1.2-1.3
Multiple fractures	Stress 1.2-1.35
Peritonitis	Stress 1.2-1.5
Cardiac failure	Stress 1.25-1.5
Head injury	Stress 1.3-1.4
Liver failure	Stress 1.4-1.5
Sepsis	Stress 1.4-1.5
Burns	Stress 1.5-2.0

ICU, intensive care unit; REE, resting energy expenditure.

ured. The ratio of CO₂ production to O₂ consumption yields the respiratory quotient, which is a measure of substrate use. Inefficiencies in substrate use can be discovered and corrected by modification of the respiratory quotient through alteration of energy substrates that are provided to the patient. A recent study compared the use of two well-known prediction formulas with indirect calorimetry in 55 critically ill children. The data suggest that prediction methods are unreliable for clinical use, and that indirect calorimetry is the only useful way of determining REE in sick children.

Provision of Nutrition

Once energy requirements are determined, the practitioner must decide whether to deliver nutritional support through the enteral or the parenteral route. Enteral feeding is preferred because it is more physiologic, associated with fewer complications, and in some cases the only way to safely deliver some nutrients. More knowledge exists about enteral feeding in relation to both energy requirements and utilization; and practically, it is less expensive than parenteral nutrition.

Patients should be screened shortly after admission for nutritional requirements and preferred route of administration. Over the years, many practice patterns have been developed that list specific conditions or therapies in which enteral feeding may not be well tolerated by patients. Recent studies are proving that these may not be based on true physiologic differences and that a majority of patients who are critically ill can tolerate enteral feedings. The list of absolute contraindications for enteral feeding is shrinking and now may be limited to diseases of the GI tract.

Because it provides for a more physiologic digestive process, direct gastric feeding is preferable to the intestinal route. Patients supported with gastric feeds can usually tolerate higher osmotic loads and larger volumes, and have a lower frequency of diarrhea. Gastric acid also has a bactericidal effect that may decrease a patient's susceptibility to infection. However, for severely ill patients who are sedated and on mechanical ventilation, the high risk of reflux and aspiration becomes an increasing concern with this manner of feeding. Therefore, transpyloric feeding has been instituted in these patients and in any patient at high risk for aspiration. Although transpyloric feeding may limit reflux and aspiration, it does not entirely eliminate it. A suggested enteral feeding algorithm for critically ill children is presented in Figure 13–9.

The choice of formulas must be based on age, GI function, history of feeding tolerance, nutrient requirements, and route of feeding. Osmolality, nutrient complexity, caloric density, and cost are all factors that should be taken into consideration. An increasing number of commercially made formulas and additives are now available to meet the nutritional needs of the critically ill patient (Table 13–13).

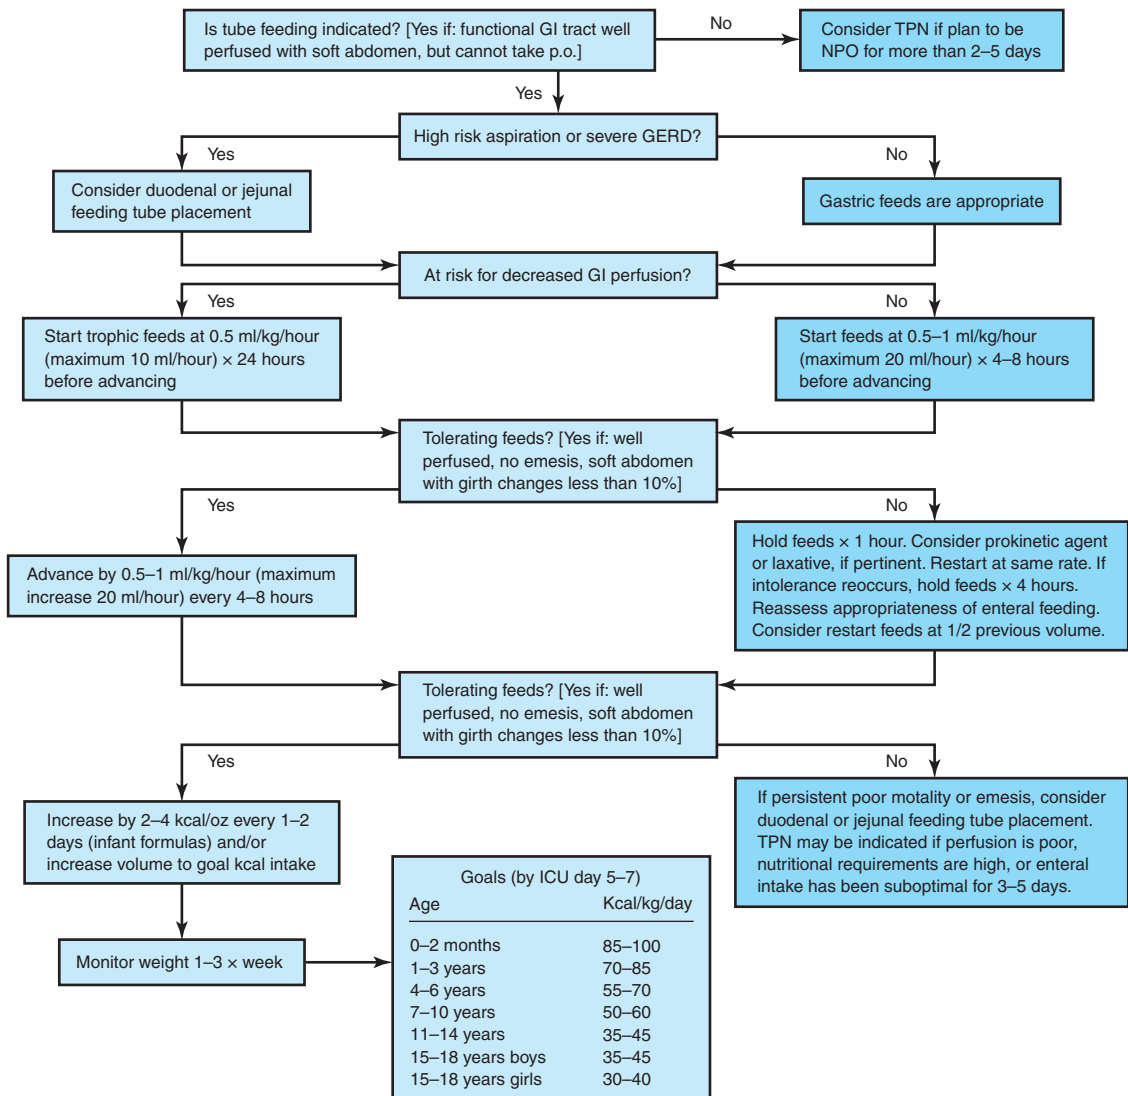

Parenteral nutrition is indicated for patients who are unable to meet nutritional needs with enteral feeds. It consists of the IV delivery of nutrients, fluid, carbohydrates, protein,

fat, electrolytes, vitamins, minerals, and trace elements. The proportions of these elements are individualized to suit the patient's specific nutritional needs. Parenteral nutrition often requires central venous access, and thus this method also carries the risks associated with central venous catheters (infection, clots, and insertion-related complications).

Parenteral nutrition can be ordered in many ways, as nutrients can be ordered based on a child's weight or per liter, or a combination of both. Standard ranges and guidelines are usually provided on order forms. Parenteral energy needs can be approximately 10–15% lower than estimated enteral needs due to reduced energy required for digestion, absorption, and fecal losses. The percentage of protein, carbohydrate, and fat that contributes to ideal total energy intake varies with the individual and the disease condition. General guidelines for energy distribution are 8–15% protein, 45–60% carbohydrate, and 25–40% fat. Solutions should be instituted slowly and advanced gradually over several days as tolerated by the patient. Guidelines for the administration of a balanced parenteral diet are provided in Chapter 10. A constant flow rate is important to maintaining steady glucose delivery. If parenteral nutrition must be stopped abruptly, a 10% glucose solution should be started to prevent hypoglycemia. Administration of high glucose and amino acid concentrations in total parenteral nutrition requires central venous access.

Immunonutrition is an area of growing interest and research. The term describes a point of view that dietary factors can confer an advantage to the immune system or other adaptive functions in infants and children. The claims of health benefits ascribed to foods or dietary supplements are not new, but until recently these claims have not been supported by scientific review. Breast milk, the model for infant formula manufacturers, has long been recognized for its immunonutritive properties, containing such nutrients as secretory immunoglobulins, lysozymes, interferon, and growth factors. However, the contribution of specific components to a positive outcome has yet to be elucidated. Growing evidence supports the immunomodulatory effects of minerals (eg, iron, zinc, selenium, and vitamin A), amino acids (arginine and glutamine), and nucleotides. Evidence also points to the emergence of prebiotics, nondigestible food components that favor the colonization and growth of bacteria normally resident in the colon; and probiotics, live microbial feed supplements with beneficial effects to the host. Although some of these concepts hold promise, it is still too early to advocate any specific guidelines, because some of these nutrients used in high doses have been reported to produce possible harmful effects.

ASTHMA (LIFE-THREATENING)

Status asthmaticus may be defined as reversible small airway obstruction that is refractory to sympathomimetic and anti-inflammatory agents and that may progress to respiratory failure without prompt and aggressive intervention. Life-threatening asthma is caused by severe bronchospasm, excessive mucus secretion, inflammation, and edema of the airways (see Chapter 18). Reversal of these mechanisms is the key to successful treatment. Status asthmaticus remains a common diagnosis among children admitted to the PICU, and asthma is associated with surprisingly high mortality rates.

Table 13-13. Pediatric enteral formulas.

Formula Category	Formula Examples	Typical Uses
Standard, milk protein-based	PediaSure PediaSure with Fiber Kindercal (with/without fiber) Nutren Junior	Nutritionally complete for ages 1-10 years. Can be used for tube feeds or oral supplements.
Food based	Compleat Pediatric	Made with beef protein, fruits, and vegetables—does contain lactose. Fortified with vitamins and minerals.
Semielemental	Peptamen Jr.	Indicated for impaired gut function with peptides as protein source, and high MCT content with lower total fat % than standard pediatric formulas.
Elemental	Pediatric Vivonex (24 kcal/oz) Elecare Neocate One Plus	Indicated for impaired gut function or protein allergy, and contains free amino acids and lower fat with majority as MCT.

MCT, medium-chain triglycerides.

The physical examination helps determine the severity of illness. Accessory muscle use (sternocleidomastoid) correlates well with a forced expiratory volume in 1 second and peak expiratory flow rates less than 50% of normal predicted values. A pulsus paradoxus of over 22 mm Hg has been correlated with elevated PaCO₂ levels. The absence of wheezing may be misleading because, in order to produce a wheezing sound, the patient must take in a certain amount of air. The ABG analysis remains the single most important laboratory determination in the evaluation of a child in severe status asthmaticus. Patients with severe respiratory distress, signs of exhaustion, alterations in consciousness, elevated PaCO₂, or acidosis should be admitted to the PICU.

► Treatment

Much of the morbidity associated with the treatment of severe asthma is related to the complications of mechanical ventilation that occur in patients with severe airflow obstruction. As a result, the goal of initial treatment of the patient with life-threatening status asthmaticus is to improve the patient's ability to ventilate without resorting to intubation and mechanical ventilation. The medical therapies described in the following discussion should be undertaken swiftly and aggressively with the goal of reversing the

bronchospasm before respiratory failure necessitates invasive ventilation.

Due to inadequate minute ventilation and V/Q mismatching, patients with severe asthma are almost always hypoxemic and should receive supplemental **humidified oxygen** immediately.

Inhaled β_2 -agonist therapy with agents such as albuterol remains first-line therapy to reverse acute bronchoconstriction. If the patient is in severe distress and has poor inspiratory flow rates, thus preventing adequate delivery of nebulized medication, subcutaneous injection of epinephrine or terbutaline may be considered. The frequency of β_2 -agonist administration varies according to the severity of the patient's symptoms and the occurrence of adverse side effects. Nebulized albuterol may be given intermittently at a dose of 0.1 mg/kg per nebulization up to 5.0 mg, or it can be administered continuously at a dose of 0.5 mg/kg/h to a maximum of 20 mg/h, usually without serious side effects. The heart rate and blood pressure should be monitored closely, because excessive tachycardia and ventricular ectopy may occur.

Systemic **corticosteroids** are the mainstay of therapy for the inflammatory component of asthma. Corticosteroids act by decreasing inflammation, stabilizing mast cells, and increasing β_2 -receptor expression. These agents speed the resolution of asthma exacerbations and should be given to all patients admitted to the hospital with severe asthma. The anti-inflammatory effect is generally observed 6–12 hours after administration. It is preferable to administer the corticosteroid by the intravenous route due to the risk of vomiting or difficulty swallowing. A typical pediatric dose is 1 mg/kg of IV methylprednisolone every 6 hours, with the adult dose between 40 and 250 mg. The acute complications of corticosteroid use include GI bleeding, hyperglycemia, and hypertension.

Inhaled **anticholinergic bronchodilators** may also improve lung function when administered to patients with severe asthma along with albuterol. Nebulized ipratropium bromide is the drug of choice, and is given at a dose of 250–500 mcg per dose. Although it has variable effectiveness, ipratropium has fewer side effects and should be considered along with albuterol in patients with severe asthma, especially when they have chronic high use of β -agonists.

Intravenous β -agonists should be considered in patients with severe bronchospasm unresponsive to inhaled bronchodilators. The agent most commonly used in the United States is terbutaline, a relatively specific β_2 -agonist, which can be given as a bolus dose or as a continuous infusion. Owing to its relative specificity for β_2 -receptors, terbutaline has fewer cardiac side effects than previously available IV β -agonists such as isoproterenol. Terbutaline is given as a bolus or loading dose of 10 mcg/kg followed by a continuous infusion of 0.5–5 mcg/kg/min. In general, patients receiving IV β_2 -agonist therapy should have indwelling arterial lines for continuous blood pressure and blood gas monitoring.

Theophylline is a methylxanthine that remains a controversial agent in the management of severe asthma. Clinical

studies yield mixed results on its benefit when given with steroids and β_2 -agonists for children with asthma. The theoretical advantage of this medication is that it relaxes airway smooth muscle by a separate mechanism from β_2 -agonists by preventing degradation of cyclic guanosine monophosphate. Besides causing bronchodilation, this agent decreases mucociliary inflammatory mediators and reduces microvascular permeability. However, the pharmacokinetics of theophylline are erratic and therapeutic levels can be difficult to manage, and serious side effects, such as seizures and cardiac arrhythmias, can occur with high drug levels. Theophylline is given IV as aminophylline. Each 1 mg/kg of aminophylline given as a loading dose will increase the serum level by approximately 2 mg/dL. For a patient who has not previously received aminophylline or oral theophylline preparations, load with 7–8 mg/kg of aminophylline in an attempt to achieve a level of 10–15 mg/dL; then start a continuous infusion of aminophylline at a dosage of 0.8–1 mg/kg/h. A postbolus level and steady-state level should be drawn with the initiation of the medication. Watch closely for toxicity (gastric upset, tachycardia, and seizures) and continue to monitor steady-state serum levels closely, trying to maintain steady-state levels of 12–16 mg/dL.

Magnesium sulfate has been reported to be an effective bronchodilator in adult patients with severe status asthmaticus when given in conjunction with steroids and β_2 -agonists, and may be considered for patients in danger of worsening respiratory failure. The mechanism of action of magnesium is unclear, but its smooth muscle relaxation properties are probably caused by interference with calcium flux in the bronchial smooth muscle cell. Magnesium sulfate is given IV at a dose of 25–50 mg/kg per dose. Although it is usually well tolerated, hypotension and flushing are side effects.

Heliox is a mixture of helium and oxygen that is less viscous than ambient air and can improve airway delivery of albuterol. A 2003 meta-analysis of heliox did not report a benefit in the initial treatment of acute asthma, although it may be considered in refractory asthma. The caveat for use of heliox is that it requires at least 60–70% helium to decrease airway resistance, limiting its use in patients requiring higher concentrations of supplemental oxygen.

While **leukotriene antagonists** are used for maintenance asthma therapy, their use in the intensive care setting has not been yet demonstrated.

If the previously described aggressive management fails to result in significant improvement, **mechanical ventilation** may be necessary. In general, if there is steady deterioration (increased acidosis and rising PaCO_2) despite intensive therapy for asthma, the patient should be intubated and ventilated mechanically. Mechanical ventilation for patients with asthma is difficult because the severe airflow obstruction often leads to very high airway pressures, air trapping, and resultant barotrauma. The goal of mechanical ventilation with an intubated asthmatic patient is to maintain adequate oxygenation and ventilation with the least amount

of barotrauma until other therapies become effective. Worsening hypercarbia after intubation should be anticipated and aggressive efforts to normalize blood gases should be moderated, as such efforts may only lead to complications. Due to the severe airflow obstruction, these patients will require long inspiratory times to deliver a breath and long expiratory times to avoid air trapping. In general, the ventilator rate should be decreased until the expiratory time is long enough to allow emptying prior to the next machine breath. Ventilator rates of 8–12 breaths/min are typical initially. Either volume- or pressure-targeted modes of ventilation can be used effectively in these patients, although tidal volumes and pressure limits should be closely monitored. As a patient moves towards extubation, a support mode of ventilation is useful, as the patient can set his or her own inspiratory time and flow rate. Due to air trapping, patients can have significant auto-PEEP. The level of PEEP on the ventilator is usually set relatively low (3–5 cm H_2O) to minimize high peak pressures. Isolated reports have noted patients who respond to greater PEEP, but these cases are the exception. The acute ventilator strategies and the resulting hypercarbia typically are uncomfortable, requiring that patients be heavily sedated and often medically paralyzed. Fentanyl and midazolam are good choices for sedation. Ketamine, a dissociative anesthetic, should be considered for its sedative properties, although it also increases bronchial secretions, which can complicate management. Barbiturates should be avoided as well as morphine, which increases histamine release. Most patients, at least initially, will also require neuromuscular blockade to optimize ventilation and minimize airway pressures. In intubated patients who are not responding to the preceding strategies, **inhaled anesthetics**, such as isoflurane, can be considered. These agents can cause significant hypotension due to vasodilation.

► Monitoring

Severely asthmatic patients should be monitored for heart rate, blood pressure, O_2 saturation, and arterial pH and PaCO_2 . Continuous blood pressure monitoring is necessary because air trapping can lead to increased levels of occult PEEP (auto-PEEP), an effect that can impair venous return and decrease cardiac output. Close ventilator monitoring is necessary because increases in inspiratory pressure or decreases in pulmonary compliance may signal worsening bronchoconstriction, mucus plugging, or an extrapleural air leak. Chest films of ventilated asthmatic patients should be obtained daily and immediately with sudden changes in patient condition, due to the risk of pneumothorax and pneumomediastinum. In addition, if the patient is receiving neuromuscular blocking agents, the degree of nerve block should be monitored closely because nondepolarizing agents such as pancuronium, when given with corticosteroids, can cause prolonged paralysis and muscle weakness.

SHOCK

Shock may be defined as failure of the cardiovascular system to deliver critical substrates (eg, oxygen) and remove toxic metabolites. This failure leads to anaerobic metabolism in cells and ultimately to irreversible cellular damage. Shock has been categorized into a series of recognizable stages: compensated, uncompensated, and irreversible.

Patients in compensated shock have relatively normal cardiac output and normal blood pressures, but have alterations in the microcirculation that increase flow to some organs and reduce flow to others. In infants, compensatory increase in cardiac output is achieved primarily by tachycardia rather than by increase in stroke volume. Heart rates of 190–210 beats/min are common in infants with compensated shock, but heart rates over 220 beats/min raise the possibility of supraventricular tachycardia. In older patients, cardiac contractility (stroke volume) and heart rate increase to improve cardiac output. Blood pressure remains normal initially because of peripheral vasoconstriction and increased systemic vascular resistance. Thus hypotension occurs late and is more characteristic of the uncompensated stage of shock. In the uncompensated stage, the oxygen and nutrient supply to the cells deteriorates further with subsequent cellular breakdown and release of toxic substances, causing further redistribution of flow. At this point, the patient is hypotensive, with poor cardiac output.

► Classification

Shock can be classified by mechanism into hypovolemic (including distributive), cardiogenic, and septic. Often, two or three of these occur together.

A. Hypovolemic Shock

Hypovolemic shock is caused by decreased circulating blood volume or preload. This may result from loss of whole blood or plasma or from fluid loss from the kidney or gut. These patients usually have intact compensatory mechanisms that maintain normal blood pressure by increasing cardiac out-

put and shunting blood away from certain organs. These responses protect blood flow to the heart and brain. Untreated, hypovolemic shock can progress to an irreversible stage. Additionally, a relative hypovolemia occurs when arterial and capillary shunting past tissue beds occurs with an increase in venous capacitance, causing blood to pool—so-called distributive shock. This results from anaphylaxis or vasodilating drugs.

B. Cardiogenic Shock/Failure

Age-dependent differences occur in myocardial physiology that are relevant to therapy. Neonatal myocardium has reduced systolic performance and contractility. The sarcolemma, sarcoplasmic reticulum, and T-tubules are less well developed, resulting in a greater dependency on trans-sarcolemma Ca^{2+} flux (ie, extracellular serum Ca^{2+}) for contraction. A high resting state of myocardial contractility occurs that limits the response to inotropic agents. Relatively minor increases in afterload can result in diminished stroke volume. Diastolic compliance is diminished, and small changes in volume result in large changes in ventricular wall tension. Consequently preload reserve is limited, and maximization of the Frank-Starling curve occurs relatively quickly (10–15 mm Hg in animal models). Aggressive volume resuscitation beyond this is often ineffective and not tolerated. Stroke volume is relatively fixed, and greater increases in cardiac output are seen through increased heart rate.

Central to the understanding of cardiogenic failure are the progressive nature of ventricular dysfunction and the compensatory mechanisms that occur in the presence of excessive hemodynamic demands. Inadequate cardiac output activates the renin-angiotensin system. The consequent sodium and water retention augments intravascular volume and increases cardiac output through increased preload. With progression, cardiac compliance is decreased and preload augmentation via the Frank-Starling mechanism is maximized. Subsequently, small changes in ventricular volume can lead to large increases in ventricular pressure, and therefore pulmonary venous pressure, with resultant pulmonary edema. Thus fluids should be cautiously administered in this setting and should possibly be guided by central venous pressure or left atrial/pulmonary artery capillary wedge pressure monitoring. The atrial distention that occurs in the failing heart leads to increased production and release of atrial natriuretic peptide, a vasodilator that augments sodium and water excretion.

Heart failure also induces autonomic nervous system changes, including increased activation of the adrenergic sympathetic system and decreased parasympathetic stimulation. Increased adrenergic tone is associated with elevated circulating norepinephrine levels and increased vasoconstriction and afterload. These combined factors in turn lead to a cycle of increased afterload, increased energy expenditure, decreased cardiac output, myocyte death, and progressive ventricular dysfunction. The cardiomyocyte effects of pro-

longed adrenergic stimulation include down-regulation of β -receptors, decreased norepinephrine stores, and therefore potentially decreased responses to sympathetic stimulation. Increased cellular concentrations of cyclic adenosine monophosphate and inositol triphosphate lead to increased inward Ca^{2+} flux and at least transient increases in contractility. Subsequently, sustained intracellular calcium impairs ventricular relaxation (lusitropy) and augments the propensity for arrhythmias. Blood flow is redistributed away from the splanchnic system, skin, and muscles and toward the heart, brain, adrenal glands, and diaphragm. Endothelial dysfunction is common and contributes to the abnormal vascular tone. Endothelin-1 production is elevated in the lung and increases pulmonary vascular resistance and systemic vascular resistance (SVR). The release of endothelial-derived nitric oxide is also impaired. Circulating arginine vasopressin and $\text{TNF}\alpha$ levels are elevated. In the later stages of heart failure, cardiomyocyte hypertrophy, fibroblast hyperplasia, and increased production and accumulation of extracellular matrix proteins lead to impaired myocardial function.

Signs and symptoms of cardiac failure are produced by the body's attempts to compensate for the decreased pump function, including activating the sympathetic nervous and renin-angiotensin-aldosterone systems. The child in acute heart failure will present with hypotension and evidence of poor perfusion, such as metabolic acidosis and organ dysfunction. In response to the poor output, tachycardia and vasoconstriction will be manifest as cool and mottled extremities. Although the extremities are cool, the child's core temperature will be elevated. To improve cardiac output, the body will retain fluid and sodium, resulting in generalized edema. Pulmonary edema will cause tachypnea, and rales can be heard on auscultation. The pulmonary edema may be severe enough to compromise respiration and lead to hypoxemia and respiratory failure.

The workup can be performed at the same time treatment is initiated, and should include an echocardiogram to evaluate cardiac anatomy and function. Serial echocardiograms may also be helpful to specifically assess the improvement in function with treatment. A chest radiograph can reveal the amount of cardiomegaly, pulmonary edema, and the presence of any effusions. Laboratory tests should include electrolyte measurements and renal and liver function tests.

Management of cardiogenic failure in the pediatric patient is complicated by the varied underlying causes that often require disparate therapies. Cardiac output is a product of stroke volume and heart rate. The factors that influence cardiac output are preload, afterload, contractility, and cardiac rhythm. An analysis of a low cardiac output state should consider the specific cardiac lesion and should use these factors as a framework for therapy.

Cardiogenic failure results from an imbalance of systemic oxygen delivery and demand. Therapy is aimed at restoring oxygen delivery and reducing demand. Sedation, reduced environmental stress, temperature regulation, supplemental

O_2 , red cell transfusion, and augmentation of cardiac output all have roles. The overall goal of increasing cardiac output should include restoring an appropriate sinus rate and rhythm, optimizing preload, augmenting myocardial contractility with minimal increases in myocardial O_2 consumption, and maximizing afterload reduction. If bradycardia is excessive, temporary pacing with transthoracic, transesophageal, or intracardiac methods should be considered. Excessive tachycardia is to be avoided, as it shortens ventricular diastole, leading to a reduction in diastolic filling, shortened diastolic coronary perfusion, and increased myocardial O_2 consumption.

Cardiogenic failure is associated with elevated ventricular filling pressures (> 20 mm Hg). Thus, although increasing preload can result in augmented cardiac output (to a degree), volume should be administered cautiously—the Frank-Starling curve may remain flat with little further improvement possible, occurring at the expense of elevating pulmonary venous pressure with resultant pulmonary edema. Diuretics can be administered to reduce pulmonary edema and to improve pulmonary compliance, the work of breathing, and oxygenation. Contractility can be augmented through inotropic stimulation of myocardial β_1 -receptors (Table 13–14). Dopamine is an α - and β -agonist that, at moderate doses (3–10 mcg/kg/min), improves myocontractility. Low doses (< 3 mcg/kg/min) may increase blood flow to the renal, coronary, and splanchnic beds, via D_1 receptors. Newer agents (eg, fenoldopam) are selective for the dopaminergic receptors and are being used to selectively improve renal blood flow and urine output. At higher doses (generally > 10 mcg/kg/min) the α -receptor effects predominate, with vasoconstriction increasing SVR and pulmonary vascular resistance. As a first-line pharmacotherapy single agent, low-dose dopamine is often beneficial by improving contractility without increasing afterload and by limiting chronotropic effect. Dobutamine is predominantly a β -agonist that additionally causes a dose-dependent vasodilation (β_2 -receptor) and shifts the ventricular pressure-volume loop toward normal, reducing LV filling pressure and hence pulmonary venous pressure. Its use in infants may be limited by its chronotropic effects leading to impaired ventricular filling. Many institutes use dobutamine as an alternative first-line agent. Isoproterenol is a pure β -agonist that causes significant tachycardia, increased myocardial O_2 consumption, and systemic and pulmonary arterial vasodilation. Though limited by its tachycardic effects as an inotrope, it is useful in instances of associated bradycardia, such as occur in heart transplantation and heart block. Epinephrine is an α - and β -agonist that causes the greatest increase in myocardial O_2 consumption of all inotropes. At a low dose (< 0.05 mcg/kg/min) it increases heart rate and contractility and decreases SVR (β -receptor). At higher doses the α -receptor effects predominate, increasing SVR. Despite these drawbacks, epinephrine can be useful as a second-line agent in cases unresponsive to low-dose dopamine. A vasodilator is often

Table 13-14. Pharmacologic support of the shock patient.

Drug	Dose	Alpha-Adrenergic Effect ^a	Beta-Adrenergic Effect ^a	Vasodilator Effect	Actions and Advantages	Disadvantages
Dopamine	1-20 mcg/kg/min	+ to +++ (dose-related)	+ to +++ (dose-related)	At low doses, renal vasodilation occurs (dopaminergic receptors)	Moderate inotrope, wide and safe dosage range, short half-life.	May cause worsening of pulmonary vasoconstriction
Dobutamine	1-10 mcg/kg/min	0	+++		Moderate inotrope, less chronotropic, fewer dysrhythmias than with isoproterenol or epinephrine.	Marked variation among patients
Epinephrine	0.05-1 mcg/kg/min	++ to +++ (dose-related)	+++		Significant increases in inotropy, chronotropy, and SVR.	Tachycardia, dysrhythmias, renal ischemia, systemic and PVR
Isoproterenol	0.05-1 mcg/kg/min	0	+++	Peripheral vasodilation	Significant increase in inotropy and chronotropy. SVR can drop, and PVR should not increase and may decrease.	Significant myocardial oxygen consumption increases, tachycardia, dysrhythmias
Norepinephrine	0.05-1 mcg/kg/min	+++	+++		Powerful vasoconstrictor (systemic and pulmonary); rarely used except possibly in patients with very low SVR or in conjunction with vasodilator.	Reduced cardiac output if afterload is too high, renal ischemia
Nitroprusside	0.05-8 mcg/kg/min	0	0	Arterial and venous dilation (smooth muscle relaxation)	Decreases SVR and PVR, very short-acting. Blood pressure returns to previous levels within 1-10 min after infusion is stopped.	Toxicities (thiocyanates and cyanide), increased intracranial pressure and ventilation-perfusion mismatch, methemoglobinemia, increased intracranial pressure
Milrinone	0.25-0.75 mcg/kg/min	0	0		Phosphodiesterase III inhibition. Decreases SVR and PVR, increases myocardial contractility with only mild increase in myocardial O ₂ consumption. Usually used with low-dose dopamine or dobutamine.	

^a0, no effect; +, small effect; ++, moderate effect; +++, potent effect. PVR, pulmonary vascular resistance; SVR, systemic vascular resistance.

administered in combination with epinephrine to offset the drug's α -receptor effects. Milrinone (0.25–0.75 mcg/kg/min) is a useful phosphodiesterase inhibitor, preventing degradation of both cyclic guanosine monophosphate and cyclic adenosine monophosphate. Its beneficial effects include a

limited increase in myocardial O₂ consumption, decreased SVR and pulmonary vascular resistance, increased contractility, and improved lusitropy. It is frequently used as a first-line drug, often in combination with low-dose dopamine or epinephrine.

Afterload reduction is an important additional therapy that increases stroke volume and decreases myocardial O_2 consumption. Agents commonly used are nitroprusside, hydralazine, and the angiotensin-converting enzyme inhibitors. Nitroprusside is a rapid-acting IV agent that is readily titratable and causes venodilation and arteriolar dilation, resulting in decreased SVR and pulmonary vascular resistance. Venodilation can decrease preload, and volume may therefore need to be coadministered to restore an appropriate preload. It is limited by its toxic metabolite, cyanide, which will accumulate over days of treatment and inhibit mitochondrial function, leading to metabolic acidosis. Angiotensin-converting enzyme inhibitors are the agents of choice for oral afterload reduction and have been shown to improve survival and functional status in adults. Patients should be switched to angiotensin-converting enzyme inhibitors as soon as indicated. LV afterload is a function of systolic transmural pressure (aortic pressure/intrapleural pressure), and mechanical afterload reduction can be attained by delivering positive airway pressure through mechanical ventilation or through continuous or bilevel positive airway pressure. This must be taken into account when weaning a patient with significant LV dysfunction from mechanical ventilation. If cardiac output cannot be augmented sufficiently despite aggressive medical therapy, consideration should be given to mechanical circulatory support as a bridge to cardiac transplantation. Such support is provided by ECMO, a ventricular access device, or intra-aortic balloon pump counterpulsation.

Congenital heart defects pose special concerns. **Aortic stenosis**, for instance, obstructs flow across the LV outflow tract, elevates intraventricular pressure, and increases systolic workload and LV hypertrophy. Due to the outflow tract gradient and hypertrophy, diastolic flow in the coronaries is decreased, which can result in subendocardial ischemia. Dopamine is indicated for inotropic support. Afterload reduction is relatively contraindicated, as it may further compromise coronary flow.

Hypertrophic cardiomyopathy is associated with a hypertrophied nondilated left ventricle, often with dynamic left or biventricular outflow tract obstruction. Coronary abnormalities with luminal compromise are frequent. Systolic function is elevated, ejection fraction is increased, and diastolic dysfunction is evident. Inotropes are avoided due to increased dynamic gradient, coronary compromise, and subendocardial ischemia. Cardiac output is optimized by providing sufficient preload and pharmacotherapy with β -blockers and calcium channel antagonists.

Aortic insufficiency is associated with retrograde flow into the left ventricle during diastole. The amount of regurgitation depends in part on the pressure gradient across the aortic valve and on the heart rate. With increasing heart rates, diastole is shortened and regurgitation limited. Therapy should include inotropic support to improve overall cardiac output and aggressive afterload reduction to reduce

the regurgitant fraction. Heart rate can be increased with isoproterenol or transesophageal pacing.

In **mitral regurgitation**, blood is forced back into the low-pressure left atrium during systole. The regurgitant fraction depends partly on the relative resistance to flow across the mitral and aortic valves during systole. Therapy includes inotropic support to improve total cardiac output, and aggressive afterload reduction to improve antegrade aortic flow.

Patients with **anomalous left coronary artery** exhibit myocardial dysfunction secondary to myocardial ischemia. The anomalous coronary artery typically arises from the pulmonary artery. In this scenario, blood flow to the right coronary artery is diverted to the left coronary artery and into the pulmonary artery, resulting in a “steal” phenomenon in the left coronary distribution and ischemia. Medical therapy is futile, though dopamine and milrinone may be used to temporize the situation while awaiting urgent surgical correction. Prior to surgery, care must be exercised not to reduce pulmonary arterial pressure (and increase steal) or excessively increase myocardial O_2 consumption.

Cardiopulmonary bypass (high or low flow) and deep hypothermic circulatory arrest are frequently required to facilitate surgical correction of congenital defects. These techniques are associated with widespread organ system effects, including increased total body water, transient myocardial dysfunction, gas exchange abnormalities, coagulation abnormalities, and hormonal and stress responses. Impairment in myocardial contractility is predictable 6–12 hours following surgery. The myocardium can be supported with increased preload, inotropes, and afterload reduction. The use of perioperative steroids and modified ultrafiltration are tools that appear to limit post-bypass–induced myocardial and vascular dysfunction.

C. Septic Shock

Septic shock has components of both cardiogenic and hypovolemic shock. Septic shock is only indirectly caused by microorganisms. Rather, septic shock is the direct result of the production and secretion of inflammatory mediators. Proinflammatory mediators (TNF α , interleukin-1, interleukin-6, interleukin-8, and platelet-activating factor) are produced and released in excess of the anti-inflammatory mediators (interleukin-10, glucocorticoids, and catecholamines), resulting in a proinflammatory cascade that initiates a number of pathophysiologic responses.

Septic shock caused by gram-negative organisms appears to be mediated by endotoxins (lipopolysaccharides) and the subsequent release of cytokines (TNF α , interleukin-1, and interleukin-10), eicosanoid products, bradykinin, and endorphins. These agents can directly mediate many of the manifestations of septic shock and act to amplify the injury by attracting granulocytes and macrophages—cells that cause further cellular injury. Vasodilators (prostaglandin I_2 and endorphins) predominate early, causing a drop in systemic

vascular resistance. Cardiac output generally is increased to compensate for the decreased systemic vascular resistance. This phase has been described as warm shock, because the skin remains well perfused and warm. As septic shock progresses, the heart is no longer able to maintain such a high output, and vasoconstrictors (thromboxane, leukotrienes, and endothelin) predominate, with resultant decreased peripheral perfusion. Extremities become cool, urine output decreases, and oxygen delivery falls.

Shock caused by gram-positive organisms is becoming more common in the PICU. This may be due to use of broad-spectrum empiric antibiotics, the increasing use of long-term intravascular catheters and other surgically implanted foreign bodies, the changing epidemiology of gram-positive pathogens, and antibiotic resistance among gram-positive organisms. The pathogenesis of gram-positive septic shock is different from that of gram-negative sepsis. Gram-positive infections most often arise from skin wounds, soft tissues, and catheter sites, rather than the GI and genitourinary sources associated with gram-negative infections. Gram-negative bacteria have an outer membrane composed of endotoxin that plays a key role in the pathogenesis of gram-negative infection, while the cell wall of gram-positive bacteria is embedded with molecules of lipoteichoic acid that are able to mimic some properties of endotoxin. Additionally, gram-positive bacteria make a range of soluble extracellular toxins, including the pyrogenic toxin superantigens of staphylococci and streptococci.

These superantigens are unusual because they do not require previous processing and specific presentation by antigen-presenting cells, and are able to bind and activate more lymphocytes than conventionally processed antigens. It is hypothesized that toxins are released in gram-positive septic shock, resulting in a massive lymphocyte activation with a release of T-cell cytokines, which are the proximate cause of cellular injury and organ failure.

The host response to gram-positive sepsis is also different from that to gram-negative sepsis. Gram-negative endotoxin induces a rapid (1–5 hours) release of proinflammatory cytokines. Gram-positive toxins induce a more delayed response (50–75 hours) dominated by TNF α and interferon- α .

D. Other Organ Involvement

Organ dysfunction is common during and after an episode of shock. Dysfunction most often affects the kidney, blood coagulation, the lungs, the CNS, the liver, and the GI tract. The kidney responds to hypotension by increasing plasma renin and angiotensin concentrations, thereby decreasing glomerular filtration rate and urine output. This can progress to damage of the energy-consuming renal parenchyma, causing acute tubular necrosis. Coagulopathies may exist in any type of shock, but are especially common in septic shock. They result from the release of mediators that activate the clotting cascade, leading ultimately to a consumptive coagulopathy (ie, disseminated intravascular coagulation). The

CNS dysfunction is related to decreased cerebral perfusion pressure and thus to decreased substrate delivery to the brain. Liver dysfunction commonly occurs after shock and may be manifested by increases in liver enzymes and decreased production of clotting factors leading to a bleeding diathesis. GI problems include ileus, bleeding (eg, gastritis and ulcers), and necrosis with sloughing of intestinal mucosa. Evaluation of multiorgan system dysfunction is mandatory in the workup of shock. Multiorgan system failure secondary to shock greatly increases the mortality of the disease.

▶ Monitoring

Both noninvasive and invasive monitoring of the patient in shock provides information on the severity, progression, and response to treatment. Extremely valuable information can be derived from examination of the cardiovascular, mucocutaneous, musculoskeletal, renal, and central nervous systems.

A. Clinical Findings

1. Cardiovascular system—Tachycardia is not always present, even when hypotension is profound. Hypotension occurs late in pediatric shock (median systolic blood pressure for a child older than age 2 years can be estimated by adding 90 mm Hg to twice the age in years). An important part of the cardiovascular examination is simultaneous palpation of distal and proximal pulses. An increase in the amplitude difference of pulses between proximal arteries (carotid, brachial, and femoral) and distal arteries (radial, posterior tibial, and dorsalis pedis) can be palpated in early shock and reflects increased systemic vascular resistance. Distal pulses may be thready or absent even in the presence of normal blood pressure because of poor stroke volume compensated by tachycardia and increased systemic vascular resistance. In uncompensated shock, hypotension is present and proximal pulses are also diminished. Early shock causes peripheral cutaneous vasoconstriction, which preserves flow to vital organs.

2. Skin—Because of peripheral vasoconstriction, the skin is gray or ashen in newborns and pale and cold in older patients. Capillary refilling after blanching is slow (> 3 seconds). Mottling of the skin may also be observed.

3. Musculoskeletal system—Decreased oxygen delivery to the musculoskeletal system produces hypotonia. Decreased spontaneous motor activity, flaccidity, and prostration are observed.

4. Urinary output—Urine output is directly proportionate to renal blood flow and the glomerular filtration rate and therefore is a good reflection of cardiac output. Catheterization of the bladder is necessary to give accurate and continuous information. (Normal urine output is > 1 mL/kg/h; output < 0.5 mL/kg/h is considered significantly decreased.)

5. Central nervous system—The level of consciousness reflects the adequacy of cortical perfusion. When cortical

perfusion is severely impaired, the infant or child fails to respond first to verbal stimuli, then to light touch, and finally to pain. Lack of motor response and failure to cry in response to venipuncture or lumbar puncture should alert the clinician to the severity of the situation. In uncompensated shock in the presence of hypotension, brainstem perfusion may be decreased. Poor thalamic perfusion can result in loss of sympathetic tone. Finally, poor medullary flow produces irregular respirations followed by gasping, apnea, and respiratory arrest.

B. Invasive Monitoring

Patients with poor cardiac output who are hypovolemic often need invasive monitoring for diagnostic and therapeutic reasons. Arterial catheters give constant blood pressure readings, and to an experienced interpreter, the shape of the waveform is helpful in evaluating cardiac output. CVP monitoring gives useful information about relative changes in volume status as therapy is given. CVP monitoring does not provide information about absolute volume status, as decreased right ventricular compliance will produce a higher CVP for the same volume status as a normally compliant ventricle. Intravascular volume can be assessed more accurately by monitoring pulmonary capillary wedge pressure or left atrial pressure using a pulmonary artery catheter. The pulmonary artery catheter also provides valuable information on cardiac status and vascular resistance and enables calculations of oxygen delivery and consumption (Table 13–15), but is associated with a higher complication rate than CVP lines. Most patients can be managed using alternative strategies to monitor clinical status. Measurements of arterial and mixed venous oxygen saturations and arterial and central venous pressures, along with echocardiography, are useful in assessing cardiac function and oxygen consumption. Newer technologies are under investigation to monitor cardiac output via a peripheral artery.

▶ Treatment

Early stabilization of hemodynamics with fluid and inotropes is similar in either gram-positive or gram-negative sepsis.

A. Fluid Resuscitation

Fluid infusion should start with 20 mL/kg boluses titrated to clinical monitors of cardiac output, heart rate, urine output, capillary refill, and level of consciousness. Patients who do not respond rapidly to a 30- to 60 mL/kg fluid bolus should be monitored in an intensive care setting and considered for invasive hemodynamic monitoring (placement of a CVP monitor, arterial line, and occasionally pulmonary artery catheter).

Initially, most patients tolerate crystalloid (salt solution), which is readily available and inexpensive. However, 4 hours after a crystalloid infusion, only 20% of the solution remains in the intravascular space. Patients with serious capillary leaks and ongoing plasma losses (eg, burn cases) should initially receive crystalloid, because in these cases colloid (protein and salt solution) leaks into the interstitium. The protein draws intravascular fluid into the interstitium, thus increasing ongoing losses. Patients with hypoalbuminemia or those with intact capillaries who need to retain volume in the intravascular space (eg, patients at risk for cerebral edema) probably benefit from colloid infusions. Experience with dextran (a starch compound dissolved in salt solution) is limited. Patients with normal heart function tolerate increased volume better than those with poor function. Additionally, large volumes of fluid for acute stabilization in children with shock do not increase the incidence of ARDS or cerebral edema. Increased fluid requirements may persist for several days.

B. Pharmacotherapy

Empiric antibiotics are chosen according to the most likely cause of infection. Inotropic support should be considered

Table 13–15. Hemodynamic parameters.^a

Parameter	Formula	Normal Values	Units
Cardiac output	$CO = HR \times SV$	Wide age-dependent range	L/min
Cardiac index	$CI = CO/BSA$	3.5–5.5	L/min/m ²
Stroke index	$SI = SV/BSA$	30–60	mL/m ²
Systemic vascular resistance	$SVR = 79.9 \frac{(MAP - CVP)}{CI}$	800–1600	dyne s/cm ⁵ /m ²
Pulmonary vascular resistance	$PVR = 79.9 \frac{(MPAP - PCWP)}{CI}$	80–240	dyne s/cm ⁵ /m ²

^aFormulas and normal values from Katz RW, Pollack M, Weibley R: Pulmonary artery catheterization in pediatric intensive care. *Adv Pediatr* 1983;30:169. for patients who continue to have clinical evidence of decreased cardiac output after receiving 60 mL/kg of fluid resuscitation. Dopamine remains the first-line vasopressor although there is ongoing interest in early use of norepinephrine in patients with low SVR and hypotension. Dopamine causes vasoconstriction by stimulating the release of norepinephrine from sympathetic nerves. Infants younger than 6 months of age may not have fully developed sympathetic vesicles and may therefore be resistant to dopamine and more responsive to norepinephrine. As discussed earlier with cardiogenic shock, dopamine can increase myocardial contractility and renal, coronary, and cerebral blood flow by its action on β -receptors and dopaminergic receptors. At higher doses (10–15 mg/kg/min), α -vasoconstrictor actions predominate. Dobutamine may be added to dopamine; however, children younger than 12 months of age may be less responsive. For septic patients with hypotension and low-output states, epinephrine is another front-line agent that can be used alone or in conjunction with dopamine (see Table 13–14). Hypocalcemia is often a contributor to cardiac dysfunction in shock. Calcium replacement should be given to normalize ionized calcium levels.

The role of inflammatory mediators in the pathogenesis of septic shock continues to be defined. Drugs that block some of these mediators appear to be beneficial when given early to animals. Human studies of these same blockers have failed to demonstrate a clear benefit. The differences in pathogenesis and host response to gram-positive or gram-negative sepsis may explain some of the differential responsiveness to anti-inflammatory agents seen in past clinical trials. Additionally, the discrepancies may result from low-affinity binding by these antibodies. The molecular mechanisms by which lipopolysaccharide activates cells are becoming better understood, which may assist in the development of more effective therapies. Modulation of T cells (with glucocorticoids, cyclosporine, and antibodies directed at cytokines) in models of superantigen-induced injury have proven beneficial, but remain experimental. Ibuprofen, because of its ability to block cyclooxygenase (cyclooxygenase metabolites are potent modulators of cell function), was also extensively studied in patients with septic shock, although the evidence does not support the use of ibuprofen for septic shock. Excess production of nitric oxide by the inducible isoform of nitric oxide synthase in inflammatory cells contributes to the hypotension and poor perfusion occurring in shock. Analogs of *N*-methyl-L-arginine, however, while useful in animal models of septic shock, worsened outcome in studies of adults with severe septic shock, presumably due to broad deleterious effects of total blockade of nitric oxide production.

Protein C is a primary regulator of coagulation, fibrinolysis, and coagulation-induced inflammation. Deficits in protein C activation correlate with morbidity and mortality in septic shock. Deficiencies of protein C have been found in children and adults with sepsis. Recombinant activated pro-

tein C reduced mortality rates in an animal model of sepsis. A large randomized, double-blind, placebo-controlled trial of recombinant activated protein C in adults with severe sepsis showed a significant reduction in mortality rates in treated patients. A similarly designed clinical trial of activated protein C in pediatric patients with severe sepsis was halted due to concern over hemorrhagic complications without an observed clear benefit.

Corticosteroids, by virtue of their action on many mediators, are thought to play a role in shock, and based on positive results in animal models of septic shock, have been advocated for treatment of shock in humans. Children with meningococcal meningitis and patients with AIDS who have *Pneumocystis carinii* pneumonia have shown improvement in oxygenation and a trend toward improved survival when treated with corticosteroids. The use of hydrocortisone in adults with relative adrenal insufficiency and septic shock improved short-term outcome. Importantly, a low aldosterone state may be more common in children with septic shock than was previously thought. Hydrocortisone (50 mg/kg) should be considered for children at risk for adrenal insufficiency—those with purpura fulminans or pituitary or adrenal abnormalities, those receiving steroids for chronic illness, and those with septic shock and multiorgan system dysfunction not responding well to traditional inotropic therapy. The studies do not currently support a definitive need for an adrenal stimulation test prior to initiating corticosteroid therapy due to the difficulty in interpreting the results.

Vasopressin is under investigation as an additional agent to treat refractory septic shock. Early studies indicate that it can improve organ perfusion and decrease the doses of epinephrine required to maintain organ perfusion.

ECMO has been considered in the treatment of shock in patients with recoverable cardiac and pulmonary function who require both pulmonary and cardiac support.

PAIN & ANXIETY CONTROL

Anxiety control and pain relief are important responsibilities of the critical care physician. It is well recognized that infants and children experience pain and require pain relief. Indeed, outcomes are improved in children receiving appropriate pain control. A child's anxiety in the PICU may heighten perception of pain to a level that causes deterioration of his or her condition. It is important to distinguish between anxiety and pain, because pharmacologic therapy may be directed at one or both of these symptoms (Table 13–16). Furthermore, before initiating or increasing sedative drugs, it is important to exclude or address physiologic causes of agitation, such as hypoxemia, hypercapnia, and cerebral hypoperfusion caused by low cardiac output.

Sedation

Sedative (anxiolytic) drugs are used to induce calmness without producing sleep—although at high doses, all anxiolytics will cause drowsiness and sleep. The five indications for the use of sedative drugs are (1) to allay fear and anxiety, (2) to

manage acute confusional states, (3) to facilitate treatment or diagnostic procedures, (4) to facilitate mechanical ventilation, and (5) to obtund physiologic responses to stress—that is, reduce tachycardia, hypertension, or increased ICP. Parenteral administration (bolus or infusion) allows titration of response in the critically ill child. Sedatives fall into several classes, with the opioid and benzodiazepine classes serving as the mainstay of anxiety treatment in the ICU.

A. Benzodiazepines

Benzodiazepines possess anxiolytic, hypnotic, anticonvulsant, and skeletal muscle relaxant properties. Although their exact mode of action is unknown, it appears to be located within the limbic system of the CNS and to involve the neuroinhibitory transmitter γ -aminobutyric acid. Most benzodiazepines are metabolized in the liver, with their metabolites subsequently excreted in the urine; thus, patients in liver failure are likely to have long elimination times.

Benzodiazepines can cause respiratory depression if given rapidly in high doses, and they potentiate the analgesic and respiratory depressive effects of opioids and barbiturates. Therefore, it is important to monitor cardiorespiratory status and have resuscitation equipment available. Three benzodiazepines with differing half-lives are presently used in the ICU setting:

1. Midazolam—Midazolam has the shortest half-life (1.5–3.5 hours) of the benzodiazepines and is the only benzodiazepine that should be administered as a continuous IV infusion. It produces excellent retrograde amnesia lasting for 20–40 minutes after a single IV dose. Therefore, it can be used either for short-term sedation or for “awake” proce-

Table 13–16. Pain and anxiety control.

Drug	Dose and Method of Administration ^a	Advantages	Disadvantages	Usual Duration of Effect
Morphine	IV, 0.1 mg/kg; continuous infusion, 0.01–0.05 mg/kg/h	Excellent pain relief, reversible	Respiratory depression, hypotension, nausea, suppression of intestinal motility, histamine release	2–4 h
Meperidine	IV, 1 mg/kg	Good pain relief, reversible	Respiratory depression, histamine release, nausea, suppression of intestinal motility	2–4 h
Fentanyl	IV, 1–2 mcg/kg; continuous infusion, 0.5–2 mcg/kg/h	Excellent pain relief, reversible, short half-life	Respiratory depression, chest wall rigidity, severe nausea and vomiting	30 min
Diazepam	IV, 0.1 mg/kg	Sedation and seizure control	Respiratory depression, jaundice, phlebitis	1–3 h
Lorazepam	IV, 0.1 mg/kg	Longer half-life, sedation and seizure control	Nausea and vomiting, respiratory depression, phlebitis	2–4 h
Midazolam	IV, 0.1 mg/kg	Short half-life, only benzodiazepine given as continuous infusion	Respiratory depression	20–40 min

^aIntravenous (IV) administration is most common in the ICU. The effects of morphine, meperidine, and fentanyl are reversible by administration of naloxone (opioid antagonist).

dures such as endoscopy or as a continuous infusion in the anxious, restless patient. The single IV dose is 0.05–0.1 mg/kg, whereas a continuous infusion should be started at a rate of 0.1 mg/kg/h after an initial loading dose of 0.1 mg/kg. The midazolam infusion dosage must be titrated upward to achieve the desired effect. Midazolam is not an analgesic; therefore, small doses of an analgesic such as morphine or fentanyl may be needed.

2. Diazepam—Diazepam has a longer half-life than midazolam and can be given orally (PO) as well as by the IV route. Its disadvantage in the ICU is its intermediary metabolite, nordazepam, which has a very long half-life and may accumulate, prolonging sedation. It produces excellent anxiolysis and amnesia. Additionally, it is used to treat acute status epilepticus. The IV dose is 0.1 mg/kg, which can be repeated every 15 minutes to achieve the desired effect or until undesirable side effects (somnia and respiratory depression) occur.

3. Lorazepam—Lorazepam possesses the longest half-life of the three benzodiazepines discussed here and can be used to achieve sedation for as long as 6–8 hours. It has less effect on the cardiovascular and respiratory systems than other benzodiazepines and can be given PO, IV, or intramuscularly (IM). The IV route is most commonly used. The IV dosage is 0.1 mg/kg. Lorazepam can also be used to treat acute status epilepticus.

B. Other Drugs

1. Chloral hydrate—Chloral hydrate is an enteral sedative and hypnotic agent frequently used in children. After administration, it is rapidly metabolized by the liver to its active form trichloroethanol, which has an 8-hour half-life. A sedative dose is 6–20 mg/kg per dose, usually given every 6–8 hours, whereas the hypnotic dose is up to 50 mg/kg with a maximum dose of 1 g. The hypnotic dose is frequently used to sedate young children for outpatient radiologic procedures such as computed tomographic scanning and magnetic resonance imaging. There is little effect on respiration or blood pressure with therapeutic doses of chloral hydrate. The drug is irritating to mucous membranes, however, and may cause gastric upset if administered on an empty stomach.

2. Ketamine—Ketamine is a phencyclidine derivative that produces a trancelike state of immobility and amnesia known as dissociative anesthesia. After IM or IV administration, it causes central sympathetic nervous system stimulation with resultant increases in heart rate, blood pressure, and cardiac output. Respiration is not depressed at therapeutic doses. Because salivary and tracheobronchial mucous gland secretions are increased, atropine should be administered 20 minutes prior to the ketamine. A disadvantage of ketamine use is the occurrence of unpleasant dreams or hallucinations. This effect occurs less often in children than in adults, and can be reduced even further by the concurrent

administration of a benzodiazepine. Because of its inotropic properties, ketamine is useful for the sedation of certain critically ill patients whose conditions are unstable. Additionally, its bronchodilator effects make it the induction agent of choice for patients with status asthmaticus requiring intubation. It is given as an IV injection of 1–2 mg/kg over 60 seconds, with supplementary doses of 0.5 mg/kg being required every 10–30 minutes to maintain an adequate level of anesthesia. Alternatively, it can be administered as an IM injection of 3–7 mg/kg, which usually produces the desired level of anesthesia within 3–4 minutes. If prolonged anesthesia is required, ketamine can be administered by IV infusion at doses of 3–20 mg/kg/h.

3. Antihistamines—The antihistamines diphenhydramine and hydroxyzine can be used as sedatives, but are not as effective as the benzodiazepines. Diphenhydramine produces sedation in only 50% of those patients. It can be given IV, IM, or PO at a dose of 1 mg/kg. Hydroxyzine can be given either IM or PO. It is frequently used concurrently with morphine or meperidine, adding anxiolysis and potentiating their effects. The sedative effects of both drugs can last from 4–6 hours following a single dose.

4. Propofol—Propofol is an anesthetic induction agent whose main advantages are a rapid recovery time and no cumulative effects resulting from its rapid hepatic metabolism. It has no analgesic properties and frequently causes pain on injection. Dose-related hypotension and metabolic acidosis have been reported in pediatric patients, and the FDA recommends against the use of propofol in pediatric patients outside the controlled environment of the operating room.

5. Barbiturates—Barbiturates (phenobarbital and thiopental) can cause direct myocardial and respiratory depression and are, in general, poor choices for sedation of seriously ill patients. Phenobarbital has a very long half-life (up to 4 days), and recovery from thiopental, although it is a short-acting barbiturate, can be prolonged because remobilization from tissue stores occurs.

6. Dexmedetomidine—Dexmedetomidine is an α_2 -adrenoceptor agonist with sedative, analgesic, and anxiolytic effects. It produces rapid sedation while maintaining a high degree of patient rousability. Dexmedetomidine has few side effects but can produce a dose-dependent hemodynamic decline. Pediatric studies are ongoing to determine its role in the pediatric ICU.

Analgesia

A. Opioid Analgesics

Opioid analgesics (morphine, fentanyl, codeine, and meperidine) are the mainstays of therapy for most forms of acute severe pain as well as chronic cancer pain management. They possess both analgesic and dose-related sedative effects,

although a range of plasma concentrations produce analgesia without sedation. In addition, opioids can cause respiratory depression, nausea, pruritus, slowed intestinal motility, miosis, urinary retention, cough suppression, biliary spasm, and vasodilation. The dose of opioid required to produce adequate analgesia varies greatly from one individual to the next. Therefore, in the intensive care setting, a continuous infusion of morphine or fentanyl allows dosages to be easily titrated to achieve the desired effect.

In general, infants younger than age 3 months are more susceptible than older children to the respiratory depressant effects of opioids. Starting dosages for these patients should be about one-third to one-half the usual pediatric dose. Most opioids (except meperidine) have minimal cardiac depressive effects, and critically ill patients generally tolerate them well. Fentanyl does not cause the histamine release that morphine does and thus produces less vasodilation and a less-pronounced drop in systemic blood pressure. Opioids are metabolized in the liver, with metabolites excreted in the urine. Thus patients with hepatic or renal impairment may have a prolonged response to their administration. Long-term (> 7 days) administration and high doses (> 1.5–2.5 mg/kg cumulative fentanyl dose) of continuous infusions of opioids or benzodiazepines can lead to tolerance and physical dependence with the development of withdrawal symptoms (agitation, tachypnea, tachycardia, sweating, and diarrhea) upon acute termination of these drugs. In these patients, gradual tapering of the opioid dosage over a 5- to 10-day period will prevent withdrawal symptoms. The mechanism of opioid tolerance is related to conformational changes in the drug-receptor interaction. The use of continuous infusions and synthetic opioids is associated with the faster development of tolerance. As with any potent sedative or analgesic used in the ICU setting, appropriate patient monitoring (pulse oximetry, cardiorespiratory monitoring, and blood pressure monitoring) should be used during the period of opioid administration, and equipment should be available to support prompt intervention if undesired side effects occur.

The ICU regimen for sedation and analgesia must be carefully modified when the patient is transferred to the ward or a lower vigilance area. Patients with baseline respiratory, hepatic, or renal insufficiencies are most predisposed to respiratory insufficiency from sedatives or opioid analgesics.

Advantages of continuous infusions of sedatives are (1) a more constant level of sedation and increased patient comfort, and (2) better tolerance of newer approaches to mechanical ventilation. Prolongation of mechanical ventilation, hospitalization, and inability to assess neurologic function and mental status are recognized as disadvantages of continuous infusions. Daily interruption of continuous sedation, allowing adult patients to “wake up,” is associated with a decrease in duration of mechanical ventilation and length of stay in the ICU. Currently, similar data are not available for pediatric patients.

Frequently pediatric patients will require relatively deep levels of sedation while undergoing a procedure (eg, vascular

line placement or radiographic studies). Often these patients are not intubated and are not expected to require intubation and ventilatory support—termed “moderate sedation/analgesia.” A systematic approach should include the following:

1. Pertinent history to elicit underlying illnesses
2. Physical examination focusing on the anatomy and adequacy of the child’s airway (ie, large tonsils or facial deformity)
3. Informed consent
4. Appropriate patient fasting from solids (6 hours) and liquids (2 hours)
5. Age- and size-appropriate equipment
6. Drug dosages calculated on a milligram per kilogram basis
7. Monitoring and documentation of vital signs (including continuous pulse oximetry, respiratory rate and pattern, and level of arousability)
8. Separate observer to monitor deeply sedated patients
9. Practitioner capable of intubating and treating patients who enter a deeper state of sedation than initially anticipated
10. Discharge criteria ensuring that the patient has recovered to his or her baseline level of consciousness

Short-acting agents are preferred. Agents typically used include an opioid (usually fentanyl or morphine) and a benzodiazepine (most often midazolam). Another option is ketamine and midazolam. It is important to select and become comfortable with a specific combination, and to learn its indications and potential complications. Using a familiar agent and following the systematic approach outlined earlier have reduced anesthetic complications in this population of patients.

Patient-controlled analgesia is done via a computer-governed infusion pump for constant infusion or patient-regulated bolus infusion of opioid analgesics. The basal infusion mode is intended to provide a constant serum level of analgesic. The bolus mode allows the patient, by pushing a button, to self-administer additional doses for breakthrough pain. The patient is usually permitted six boluses an hour, with 10-minute lockouts. If the patient is using allotted hourly boluses, this usually means that the basal infusion rate is too low. The patient must understand the concept of patient-controlled analgesia in order to be a candidate for its use. In some circumstances in pediatrics it is more appropriate for the nurse or parent to administer the bolus dose.

Naloxone reverses the analgesic, sedative, and respiratory depressive effects of opioid agonists. Its administration should be titrated to achieve the desired effect (eg, reversal of respiratory depression) because full reversal using 1–10 mcg/kg may cause acute anxiety, dysphoria, nausea, and vomiting. Furthermore, because the duration of effect of naloxone is shorter (30 minutes) than that of most opioids, the patient must be observed carefully for reappearance of the undesired effect.

B. Nonopioid Analgesics

Nonopioid analgesics used in the treatment of mild to moderate pain include acetaminophen, aspirin, and other nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen and naproxen.

1. Acetaminophen—Acetaminophen is the most commonly used analgesic in pediatrics in the United States and is the drug of choice for mild to moderate pain because of its low toxicity and lack of effect on bleeding time. It is metabolized by the liver. Suggested doses are 10–15 mg/kg PO to approximately 10–20 mg/kg per rectum every 4 hours.

2. Aspirin—Aspirin is also an effective analgesic for mild to moderate pain at doses of 10–15 mg/kg PO every 4 hours. However, its prolongation of bleeding time, association with Reye syndrome, and propensity to cause gastric irritation limit its usefulness in pediatric practice. Aspirin and other NSAIDs are still useful, especially for pain of inflammatory origin, bone pain, and pain associated with rheumatic conditions.

3. Other NSAIDs—Ibuprofen and naproxen use has been limited in pediatrics to date. Naproxen is FDA-approved for children aged 2–12 years (5–7 mg/kg PO every 8–12 hours), whereas ibuprofen requires more frequent dosing intervals (4–10 mg/kg PO every 6–8 hours).

All of the NSAIDs have a therapeutic ceiling after which no increase occurs in analgesic potency. They all can cause gastritis and should be given with antacids or with meals, and they should be used with caution in people at risk for renal compromise. In addition, the analgesic effects of acetaminophen, aspirin, and other NSAIDs are additive to those of opioids. Thus, if additional analgesia is required, their use should be continued and an appropriate oral opioid (codeine or morphine) or parenteral opioid (morphine or fentanyl) begun.

Skin

14

Joseph G. Morelli, MD
Joanna M. Burch, MD

GENERAL PRINCIPLES

DIAGNOSIS OF SKIN DISORDERS

Examination of the skin requires that the entire surface of the body be palpated and inspected in good light. The onset and duration of each symptom should be recorded, together with a description of the primary lesion and any secondary changes, using the terminology set forth in Table 14–1. In practice, the characteristics of skin lesions are described in an order opposite that shown in the table. Begin with distribution, then configuration, color, secondary changes, and primary changes. For example, guttate psoriasis could be described as generalized, discrete, red, scaly papules.

TREATMENT OF SKIN DISORDERS

Topical Therapy

Treatment should be simple and aimed at preserving normal skin physiology. Topical therapy is often preferred because medication can be delivered in optimal concentrations to the desired site.

Water is an important therapeutic agent, and optimally hydrated skin is soft and smooth. This occurs at approximately 60% environmental humidity. Because water evaporates readily from the cutaneous surface, skin hydration (stratum corneum of the epidermis) is dependent on the water concentration in the air, and sweating contributes little. However, if sweat is prevented from evaporating (eg, in the axilla, groin), local humidity and hydration of the skin are increased. As humidity falls below 15–20%, the stratum corneum shrinks and cracks; the epidermal barrier is lost and allows irritants to enter the skin and induce an inflammatory response. Replacement of water will correct this condition if evaporation is prevented. Therefore, dry and scaly skin is treated by soaking the skin in water for 5 minutes and then adding a barrier to evaporation (Table 14–2). Oils and ointments prevent evaporation for 8–12 hours, so they must

be applied once or twice a day. In areas already occluded (axilla, diaper area), creams or lotions are preferred, but more frequent application may be necessary.

Overhydration (maceration) can also occur. As environmental humidity increases to 90–100%, the number of water molecules absorbed by the stratum corneum increases and the tight lipid junctions between the cells of the stratum corneum are gradually replaced by weak hydrogen bonds; the cells eventually become widely separated, and the epidermal barrier falls apart. This occurs in immersion foot, diaper areas, axillae, and the like. It is desirable to enhance evaporation of water in these areas by air drying.

Wet Dressings

By placing the skin in an environment where the humidity is 100% and allowing the moisture to evaporate to 60%, pruritus is relieved. Evaporation of water stimulates cold-dependent nerve fibers in the skin, and this may prevent the transmission of the itching sensation via pain fibers to the central nervous system. It also is vasoconstrictive, thereby helping to reduce the erythema and also decreasing the inflammatory cellular response.

The simplest form of wet dressing consists of one set of wet underwear (eg, long johns) worn under dry pajamas. The underwear should be soaked in warm (not hot) water and wrung out until no more drops come out. This should be done overnight for a few days up to 1 week. When the condition has improved, the wet dressings are discontinued.

Topical Glucocorticoids

Twice-daily application of topical corticosteroids is the mainstay of treatment for all forms of dermatitis (Table 14–3). Topical steroids can also be used under wet dressings. After wet dressings are discontinued, topical steroids should be applied only to areas of active disease. They should never be applied to normal skin to prevent recurrence. Only low-

Table 14-1. Examination of the skin.

Clinical Appearance	Description and Examples
Primary lesions (first to appear)	
Macule	Any circumscribed color change in the skin that is flat. Examples: white (vitiligo), brown (café-au-lait spot), purple (petechia).
Papule	A solid, elevated area < 1 cm in diameter whose top may be pointed, rounded, or flat. Examples: acne, warts, small lesions of psoriasis.
Plaque	A solid, circumscribed area > 1 cm in diameter, usually flat-topped. Example: psoriasis.
Vesicle	A circumscribed, elevated lesion < 1 cm in diameter and containing clear serous fluid. Example: blisters of herpes simplex.
Bulla	A circumscribed, elevated lesion > 1 cm in diameter and containing clear serous fluid. Example: bullous impetigo.
Pustule	A vesicle containing a purulent exudate. Examples: acne, folliculitis.
Nodule	A deep-seated mass with indistinct borders that elevates the overlying epidermis. Examples: tumors, granuloma annulare. If it moves with the skin on palpation, it is intradermal; if the skin moves over the nodule, it is subcutaneous.
Wheal	A circumscribed, flat-topped, firm elevation of skin resulting from tense edema of the papillary dermis. Example: urticaria.
Secondary changes	
Scales	Dry, thin plates of keratinized epidermal cells (stratum corneum). Examples: psoriasis, ichthyosis.
Lichenification	Induration of skin with exaggerated skin lines and a shiny surface resulting from chronic rubbing of the skin. Example: atopic dermatitis.
Erosion and oozing	A moist, circumscribed, slightly depressed area representing a blister base with the roof of the blister removed. Examples: burns, impetigo. Most oral blisters present as erosions.
Crusts	Dried exudate of plasma on the surface of the skin following acute dermatitis. Examples: impetigo, contact dermatitis.
Fissures	A linear split in the skin extending through the epidermis into the dermis. Example: angular cheilitis.
Scars	A flat, raised, or depressed area of fibrotic replacement of dermis or subcutaneous tissue. Examples: acne scar, burn scar.
Atrophy	Depression of the skin surface caused by thinning of one or more layers of skin. Example: lichen sclerosis.
Color	
	The lesion should be described as red, yellow, brown, tan, or blue. Particular attention should be given to the blanching of red lesions. Failure to blanch suggests bleeding into the dermis (petechiae).
Configuration of lesions	
Annular (circular)	Annular nodules represent granuloma annulare; annular scaly papules are more apt to be caused by dermatophyte infections.
Linear (straight lines)	Linear papules represent lichen striatus; linear vesicles, incontinentia pigmenti; linear papules with burrows, scabies.
Grouped	Grouped vesicles occur in herpes simplex or zoster.
Discrete	Discrete lesions are independent of each other.
Distribution	
	Note whether the eruption is generalized, acral (hands, feet, buttocks, face), or localized to a specific skin region.

potency steroids (see Table 14-3) are applied to the face or intertriginous areas.

DISORDERS OF THE SKIN IN NEWBORNS

TRANSIENT DISEASES IN NEWBORNS

1. Milia

Milia are tiny epidermal cysts filled with keratinous material. These 1- to 2-mm white papules occur predominantly on the face in 40% of newborns. Their intraoral counterparts are called Epstein pearls and occur in up to 60–85% of neonates. These cystic structures spontaneously rupture and exfoliate their contents.

Table 14-2. Bases used for topical preparations.

Base	Combined With	Uses
Foam		Cosmetically eloquent; increasing number of products available.
Liquids		Wet dressings: relieve pruritus, vasoconstrict
	Powder	Shake lotions, drying pastes: relieve pruritus, vasoconstrict
	Grease and emulsifier; oil in water	Cream: penetrates quickly (10–15 min) and thus allows evaporation
	Excess grease and emulsifier; water in oil	Emollient cream: penetrates more slowly and thus retains moisture on skin
Grease		Ointments: occlusive (hold material on skin for prolonged time) and prevent evaporation of water
Gel		Transparent, colorless, semisolid emulsion: nongreasy, more drying and irritating than cream
Powder		Enhances evaporation

Characteristics of bases for topical preparations:

1. Thermolabile, low-residue foam vehicle is more cosmetically acceptable and uses novel permeability pathway for delivery.
2. Most greases are triglycerides (eg, Aquaphor, petrolatum, Eucerin).
3. Oils are fluid fats (eg, Alpha Keri, olive oil, mineral oil).
4. True fats (eg, lard, animal fats) contain free fatty acids that cause irritation.
5. Ointments (eg, Aquaphor, petrolatum) should not be used in intertriginous areas such as the axillae, between the toes, and in the perineum, because they increase maceration. Lotions or creams are preferred in these areas.
6. Oils and ointments hold medication on the skin for long periods and are therefore ideal for barriers or prophylaxis and for dried areas of skin. Medication gets into the skin more slowly from ointments.
7. Creams carry medication into skin and are preferable for intertriginous dermatitis.
8. Foams, solutions, gels, or lotions should be used for scalp treatments.

2. Sebaceous Gland Hyperplasia

Prominent white to yellow papules at the opening of pilosebaceous follicles without surrounding erythema—especially over the nose—represent overgrowth of sebaceous glands in response to maternal androgens. They occur in more than half of newborns and spontaneously regress in the first few months of life.

3. Neonatal Acne

Inflammatory papules and pustules with occasional comedones predominantly on the face occur in as many as 20% of newborns. Although neonatal acne can be present at birth, it most often occurs between 2 and 4 weeks of age. Spontaneous resolution occurs over a period of 6 months to 1 year. A rare entity that is often confused with neonatal acne is

neonatal cephalic pustulosis. This is a more monomorphic eruption with red papules and pustules on the head and neck that appears in the first month of life. There is associated neutrophilic inflammation and yeasts of the genus *Malassezia*. This eruption will resolve spontaneously, but responds to topical antiyeast preparations.

4. Harlequin Color Change

A cutaneous vascular phenomenon unique to neonates in the first week of life occurs when the infant (particularly one of low birth weight) is placed on one side. The dependent half develops an erythematous flush with a sharp demarcation at the midline, and the upper half of the body becomes pale. The color changes usually subside within a few seconds after the infant is placed supine but may persist for as long as 20 minutes.

5. Mottling

A lacelike pattern of bluish, reticular discoloration representing dilated cutaneous vessels appears over the extremities and often the trunk of neonates exposed to lowered room temperature. This feature is transient and usually disappears completely on rewarming.

6. Erythema Toxicum

Up to 50% of full-term infants develop erythema toxicum. Usually at 24–48 hours of age, blotchy erythematous macules

Table 14-3. Topical glucocorticoids.

Glucocorticoid	Concentrations
Low potency^a = 1–9	
Hydrocortisone	0.5%, 1%, 2.5%
Desonide	0.05%
Moderate potency = 10–99	
Mometasone furoate	0.1%
Hydrocortisone valerate	0.2%
Fluocinolone acetonide	0.025%
Triamcinolone acetonide	0.01%
Amcinonide	0.1%
High potency = 100–499	
Desoximetasone	0.25%
Fluocinonide	0.05%
Halcinonide	0.1%
Super potency = 500–7500	
Betamethasone dipropionate	0.05%
Clobetasol propionate	0.05%

^a1% hydrocortisone is defined as having a potency of 1.

2–3 cm in diameter appear, most prominently on the chest but also on the back, face, and extremities. These are occasionally present at birth. Onset after 4–5 days of life is rare. The lesions vary in number from a few up to as many as 100. Incidence is much higher in full-term versus premature infants. The macular erythema may fade within 24–48 hours or may progress to formation of urticarial wheals in the center of the macules or, in 10% of cases, pustules. Examination of a Wright-stained smear of the lesion reveals numerous eosinophils. No organisms are seen on Gram stain. These findings may be accompanied by peripheral blood eosinophilia of up to 20%. All of the lesions fade and disappear within 5–7 days. Transient neonatal pustular melanosis is a pustular eruption in newborns of African-American descent. The pustules rupture leaving a collarette of scale surrounding a macular hyperpigmentation. Unlike erythema toxicum, the pustules contain mostly neutrophils and often involve the palms and soles.

7. Sucking Blisters

Bullae, either intact or as erosions (the blister base) without inflammatory borders, may occur over the forearms, wrists, thumbs, or upper lip. These presumably result from vigorous sucking in utero. They resolve without complications.

8. Miliaria

Obstruction of the eccrine sweat ducts occurs often in neonates and produces one of two clinical pictures. Superficial obstruction in the stratum corneum causes miliaria crystallina, characterized by tiny (1- to 2-mm), superficial grouped vesicles without erythema over intertriginous areas and adjacent skin (eg, neck, upper chest). More commonly, obstruction of the eccrine duct deeper in the epidermis results in erythematous grouped papules in the same areas and is called miliaria rubra. Rarely, these may progress to pustules. Heat and high humidity predispose the patient to eccrine duct pore closure. Removal to a cooler environment is the treatment of choice.

9. Subcutaneous Fat Necrosis

This entity presents in the first 7 days of life as reddish or purple, sharply circumscribed, firm nodules occurring over the cheeks, buttocks, arms, and thighs. Cold injury is thought to play an important role. These lesions resolve spontaneously over a period of weeks, although in some instances they may calcify.

Conlon J, Drolet B: Skin lesions in the neonate. *Pediatr Clin North Am* 2004;51:863 [PMID: 15275979].

PIGMENT CELL BIRTHMARKS, NEVI, & MELANOMA

Birthmarks may involve an overgrowth of one or more of any of the normal components of skin (eg, pigment cells,

blood vessels, lymph vessels). A nevus is a hamartoma of highly differentiated cells that retain their normal function.

1. Mongolian Spot

A blue-black macule found over the lumbosacral area in 90% of infants of Native-American, African-American, and Asian descent is called a mongolian spot. These spots are occasionally noted over the shoulders and back and may extend over the buttocks. Histologically, they consist of spindle-shaped pigment cells located deep in the dermis. The lesions fade somewhat with time as a result of darkening of the overlying skin, but some traces may persist into adult life.

2. Café-au-Lait Macule

A café-au-lait macule is a light brown, oval macule (dark brown on brown or black skin) that may be found anywhere on the body. Café-au-lait spots over 1.5 cm in greatest diameter are found in 10% of white and 22% of black children. These lesions persist throughout life and may increase in number with age. The presence of six or more such lesions over 1.5 cm in greatest diameter may be a clue to neurofibromatosis type 1 (NF-1). Patients with McCune-Albright syndrome (see Chapter 32) have a large, unilateral café-au-lait macule.

3. Spitz Nevus

A reddish-brown solitary nodule appearing on the face or upper arm of a child represents a Spitz nevus. Histologically, it consists of pigment-producing cells of bizarre shape with numerous mitoses. Although these lesions can look concerning histologically, they have a benign clinical course.

ACQUIRED MELANOCYTIC NEVI

1. Common Moles

Well-demarcated, brown to brown-black macules represent junctional nevi. They can begin to appear in the first years of life and increase with age. Histologically, these lesions are clones of melanocytes at the junction of the epidermis and dermis. Approximately 20% may progress to compound nevi—papular lesions with melanocytes both in junctional and intradermal locations. Intradermal nevi are often lighter in color and can be fleshy and pedunculated. Melanocytes in these lesions are located purely within the dermis. Nevi look dark blue (blue nevi) when they contain more deeply situated melanocytes in the dermis.

2. Melanoma

Melanoma in prepubertal children is very rare. Pigmented lesions with variegated colors (red, white, blue), notched borders, asymmetrical shape, and very irregular or ulcerated surfaces should arouse a suspicion of melanoma. Ulceration and bleeding are advanced signs of melanoma. If melanoma is suspected, wide local excision sent for pathologic examination should be done as the treatment of choice.

3. Congenital Melanocytic Nevi

One in 100 infants is born with a congenital nevus. Congenital nevi tend to be larger and darker brown than acquired nevi and may have many terminal hairs. If the pigmented plaque covers more than 5% of the body surface area, it is considered a giant or large congenital nevus; these large nevi occur in 1 in 20,000 infants. Often the lesions are so large they cover the entire trunk (bathing trunk nevi). Histologically, they are compound nevi with melanocytes often tracking around hair follicles and other adnexal structures deep in the dermis. The risk of malignant melanoma in small congenital nevi is controversial in the literature, but most likely very low. Transformation to malignant melanoma in giant congenital nevi has been estimated in the best studies to be between 1% and 5%. Two thirds of melanomas in children with giant congenital nevi develop in areas other than the skin.

Kregel S et al: Melanoma risk in congenital melanocytic naevi: A systematic review. *Br J Dermatol* 2006;155:1 [PMID: 16792745].

 Turchin I et al: Myths and misconceptions: The risk of melanoma in small congenital nevi. *Skinmed* 2004;3:228 [PMID: 15249787].

VASCULAR BIRTHMARKS

1. Capillary Malformations

► Clinical Findings

Capillary malformations are an excess of capillaries in localized areas of skin. The degree of excess is variable. The color of the lesions ranges from light red-pink to dark red. Light red macules are found over the nape of the neck, upper eyelids, and glabella of newborns. Fifty percent of infants have such lesions over their necks. Eyelid and glabellar lesions usually fade completely within the first year of life. Lesions that occupy the total central forehead area usually do not fade. Those on the neck persist into adult life.

Port-wine stains are dark red macules appearing anywhere on the body. A bilateral facial port-wine stain or one covering the entire half of the face may be a clue to Sturge-Weber syndrome, which is characterized by seizures, mental retardation, glaucoma, and hemiplegia. (See Chapter 23.) Most infants with smaller, unilateral facial port-wine stains do not have Sturge-Weber syndrome. Similarly, a port-wine stain over an extremity may be associated with hypertrophy of the soft tissue and bone of that extremity (Klippel-Trénaunay syndrome).

► Treatment

The pulsed dye laser is the treatment of choice for infants and children with port-wine stains.

Rallan D et al: Laser treatment of vascular lesions. *Clin Dermatol* 2006;24:8 [PMID: 16427501].

2. Hemangioma

► Clinical Findings

A red, rubbery nodule is a hemangioma. The lesion is often not present at birth but is represented by a permanent blanched area on the skin that is supplanted at age 2–4 weeks by red nodules. Histologically, these are benign tumors of capillary endothelial cells. Hemangiomas may be superficial, deep, or mixed. The terms *strawberry* and *cavernous* are misleading and should not be used. The biologic behavior of a hemangioma is the same despite its location. Fifty percent reach maximal regression by age 5 years, 70% by age 7 years, and 90% by age 9 years, leaving redundant skin, hypopigmentation, and telangiectasia. Local complications include superficial ulceration and secondary pyoderma.

► Treatment

Complications that require immediate treatment are (1) visual obstruction (with resulting amblyopia), (2) airway obstruction (hemangiomas of the head and neck [“beard hemangiomas”] may be associated with subglottic hemangiomas), and (3) cardiac decompensation (high-output failure). In these instances, the treatment of choice is with prednisolone, 2–3 mg/kg orally daily for 6–12 weeks. Interferon alfa-2a has been used to treat serious hemangiomas unresponsive to prednisone. Ten percent of patients with hemangiomas treated with interferon alfa-2a have developed spastic diplegia. Therefore, interferon alfa-2a therapy should be reserved for truly life-threatening hemangiomas, unresponsive to prednisolone therapy. If the lesion is ulcerated or bleeding, pulsed dye laser treatment may be helpful. The Kasabach-Merritt syndrome, characterized by platelet trapping with consumption coagulopathy, does not occur with solitary cutaneous hemangiomas. It is seen only with internal hemangiomas or the very rare vascular tumors called kaposiform hemangioendotheliomas and tufted angiomas.

Smolinski KN, Yan AC: Hemangiomas of infancy: Clinical and biological characteristics. *Clin Pediatr (Phila)* 2005;44:747 [PMID: 16327961].

3. Lymphatic Malformations

Lymphatic malformations may be superficial or deep. Superficial lymphatic malformations present as fluid-filled vesicles often described as looking like frog spawn. Deep lymphatic malformations are rubbery, skin-colored nodules occurring most commonly in the parotid area (cystic hygromas) or on the tongue. They often result in grotesque enlargement of soft tissues. Histologically, they can be either macrocystic or microcystic.

► Treatment

Therapy includes injection of picibanil, doxycycline, or surgery.

Lee BB et al: Current concepts in lymphatic malformations. *Vasc Endovascular Surg* 2005;39:67 [PMID: 15696250].

EPIDERMAL BIRTHMARKS

1. Epidermal Nevus

▶ Clinical Findings

The majority of these birthmarks present in the first year of life; however, they can first appear in adulthood. They are hamartomas of the epidermis that are warty to papillomatous plaques, often in a linear array. They range in color from skin-colored to dirty yellow to brown. Histologically they have a thickened epidermis with hyperkeratosis. The condition of widespread epidermal nevi associated with other developmental anomalies (central nervous system, eye, and skeletal), is called the epidermal nevus syndrome.

▶ Treatment

Treatment once or twice daily with topical calcipotriene may flatten some lesions. The only definitive cure is surgical excision.

Vujevich J, Mancini A: The epidermal nevus syndromes: Multisystem disorders. *J Am Acad Dermatol* 2004;50:957 [PMID: 15153903].

2. Nevus Sebaceus

▶ Clinical Findings

This is a hamartoma of sebaceous glands and underlying apocrine glands that is diagnosed by the appearance at birth of a yellowish, hairless plaque in the scalp or on the face. The lesions can be contiguous with an epidermal nevus on the face, and widespread lesions can constitute part of the epidermal nevus syndrome.

Histologically, nevus sebaceus represents an overabundance of sebaceous glands without hair follicles. At puberty, with androgenic stimulation, the sebaceous cells in the nevus

divide, expand their cellular volume, and synthesize sebum, resulting in a warty mass.

▶ Treatment

Because 15% of these lesions become basal cell carcinomas after puberty, excision is recommended before puberty.

Terenzi V et al: Nevus sebaceous of Jadassohn. *Craniofac Surg* 2006;17:1234 [PMID: 17119437].

CONNECTIVE TISSUE BIRTHMARKS (JUVENILE ELASTOMA, COLLAGENOMA)

▶ Clinical Findings

Connective tissue nevi are smooth, skin-colored papules 1–10 mm in diameter that are grouped on the trunk. A solitary, larger (5–10 cm) nodule is called a shagreen patch and is histologically indistinguishable from other connective tissue nevi that show thickened, abundant collagen bundles with or without associated increases of elastic tissue. Although the shagreen patch is a cutaneous clue to tuberous sclerosis (see Chapter 23), the other connective tissue nevi occur as isolated events.

▶ Treatment

These nevi remain throughout life and need no treatment.

HEREDITARY SKIN DISORDERS

1. Ichthyosis

Ichthyosis is a term applied to several heritable diseases characterized by the presence of excessive scales on the skin. Major categories are listed in Table 14–4.

Table 14–4. Four major types of ichthyosis.

Name	Age at Onset	Clinical Features	Genetic Defect	Inheritance
Ichthyosis with normal epidermal turnover				
Ichthyosis vulgaris	Childhood	Fine scales, deep palmar and plantar markings	Filaggrin	Autosomal dominant
X-linked ichthyosis	Birth	Palms and soles spared; thick scales that darken with age; corneal opacities in patients and carrier mothers	Cholesterol sulfatase	X-linked
Ichthyosis with increased epidermal turnover				
Epidermolytic hyperkeratosis	Birth	Verrucous, yellow scales in flexural areas and palms and soles	Keratins 1 and 10	Autosomal dominant
Lamellar ichthyosis	Birth; collodion baby	Erythroderma, ectropion, large coarse scales; thickened palms and soles	Transglutaminase 1, ATP-binding cassette A12	Autosomal recessive

ATP, adenosine triphosphate.

Table 14-5. Types of epidermolysis bullosa.

Name	Age at Onset	Clinical Features	Genetic Defect	Inheritance
Nonscarring types				
Epidermolysis bullosa simplex	Birth to first few years of life	Hemorrhagic blisters over lower legs; cooling prevents blisters; blisters brought out by walking	Keratins 5 and 14, plectin	Autosomal dominant
Junctional bullous dermolysis	Birth	Erosions on legs, oral mucosa; severe perioral involvement	Laminin 5, α -6- β -4 integrin, type XVII collagen	Autosomal recessive
Scarring types				
Epidermolysis bullosa dystrophica, dominant	Infancy	Numerous blisters on hands and feet; milia formation	Type VII collagen	Autosomal dominant
Epidermolysis bullosa dystrophica, recessive	Birth	Repeated episodes of blistering, secondary infection and scarring—“miten hands and feet”	Type VII collagen	Autosomal recessive

► Treatment

Treatment consists of controlling scaling with lactic acid with ammonium hydroxide (Lac-Hydrin or AmLactin) 12% or urea cream 10–40% applied once daily. Daily lubrication and a good dry skin care regimen are important for these patients.

Oji V, Traupe H: Ichthyoses: Differential diagnosis and molecular genetics. *Eur J Dermatol* 2006;16:349 [PMID: 16935789].

2. Epidermolysis Bullosa

This is a group of heritable disorders characterized by skin fragility with blistering. Depending on the genetic defect, and therefore where the blister occurs, these disorders can be divided into scarring and nonscarring types (Table 14-5).

For the severely affected, a good deal of the surface area of the skin may have blisters and erosions, requiring daily wound care and dressings. These children are prone to frequent skin infections, have anemia, growth problems, mouth erosions and esophageal strictures, and chronic pain issues, among many others.

► Treatment

Treatment consists of protection of the skin with topical emollients as well as nonstick dressings. The other medical needs and potential complications of the severe forms of epidermolysis bullosa require a multidisciplinary approach. For the less severe types, protecting areas of greatest trauma with padding and dressings as well as intermittent topical or oral antibiotics for superinfection are appropriate treatments. If hands and feet are involved, reducing skin friction with 5% glutaraldehyde every 3 days is helpful.

Lucky AW: Update on epidermolysis bullosa. Yale University/Astellas Pharma Lectureship Series in Dermatology. Lecture 18, 2007.

COMMON SKIN DISEASES IN INFANTS, CHILDREN, & ADOLESCENTS

ACNE

Acne affects 85% of adolescents. The onset of adolescent acne is between ages 8 and 10 years in 40% of children. The early lesions are usually limited to the face and are primarily closed comedones (whiteheads; see following discussion).

► Pathogenesis

The primary event in acne formation is obstruction of the sebaceous follicle and subsequent formation of the micro-comedo (not evident clinically). This is the precursor to all future acne lesions. This phenomenon is androgen-dependent in adolescent acne. The keratinocytes of the sebaceous follicles contain an enzyme, 5 α -reductase, which converts plasma testosterone to dihydrotestosterone (DHT). This androgen is a potent stimulus for cell proliferation. The four primary factors in the pathogenesis of acne are (1) plugging of the sebaceous follicle; (2) increased sebum production; (3) proliferation of *Propionibacterium acnes* in the obstructed follicle, and (4) inflammation. Many of these factors are influenced by androgens.

Drug-induced acne should be suspected in teenagers if all lesions are in the same stage at the same time and if involvement extends to the lower abdomen, lower back, arms, and legs. Drugs responsible for acne include corticotropin (ACTH), glucocorticoids, androgens, hydantoin, and isoniazid, each of which increases plasma testosterone.

► Clinical Findings

Open comedones are the predominant clinical lesion in early adolescent acne. The black color is caused not by dirt but by oxidized melanin within the stratum corneum cellular plug.

Open comedones do not often progress to inflammatory lesions. Closed comedones, or whiteheads, are caused by obstruction just beneath the follicular opening in the neck of the sebaceous follicle, which produces a cystic swelling of the follicular duct directly beneath the epidermis. Most authorities believe that closed comedones are precursors of inflammatory acne lesions (red papules, pustules, nodules and cysts). If open or closed comedones are the predominant lesions on the skin in adolescent acne, the condition is called comedonal acne.

In typical adolescent acne, several different types of lesions are present simultaneously. Severe, chronic, inflammatory lesions may rarely occur as interconnecting, draining sinus tracts. Adolescents with cystic acne require prompt medical attention, because ruptured cysts and sinus tracts result in severe scar formation. New acne scars are highly vascular and have a reddish or purplish hue. Such scars return to normal skin color after several years. Acne scars may be depressed beneath the skin level, raised, or flat to the skin. In adolescents with a tendency toward keloid formation, keloidal scars can occur following acne lesions, particularly on the chest and upper back.

► Differential Diagnosis

Consider rosacea, nevus comedonicus, flat warts, miliaria, molluscum contagiosum, and the angiofibromas of tuberous sclerosis.

► Treatment

Different treatment options are listed in Table 14–6. Recent data have indicated that combination therapy that targets multiple pathogenic factors increases the efficacy of treatment.

A. Topical Keratolytic Agents

Topical keratolytic agents address the plugging of the follicular opening with keratinocytes and include retinoids, benzoyl peroxide, and azelaic acid. The first-line treatment for both comedonal and inflammatory acne is a topical retinoid (tretinoin [retinoic acid], adapalene, and tazarotene). These are the most effective keratolytic agents. These topical agents may be used once daily, or the combination of a retinoid applied to acne-bearing areas of the skin in the evening and a benzoyl peroxide gel or azelaic acid applied in the morning may be used. This regimen will control 80–85% of cases of adolescent acne.

B. Topical Antibiotics

Topical antibiotics are less effective than systemic antibiotics and at best are equivalent in potency to 250 mg of tetracycline orally once a day. One percent clindamycin phosphate solution is the most efficacious topical antibiotic. Most *P. acnes* strains are now resistant to topical erythromycin solutions. Topical antibiotic therapy alone should never be used.

Table 14–6. Acne treatment.

Type of Lesion	Treatment
Comedonal acne	One of the following: Retinoic acid, 0.025, 0.05, or 0.1% cream; 0.01 or 0.025% gel; or 0.1% microgel Adapalene, 0.1% gel or solution; 0.05% cream
Papular inflammatory acne	One from first grouping, plus one of the following: Benzoyl peroxide, 2.5, 4, 5, 8, or 10% gel or lotion; 4 or 8% wash Azelaic acid, 15% cream Clindamycin, 1% lotion, solution, or gel
Pustular inflammatory acne	One from first grouping, plus one of the following: Oral antibiotics Tetracycline, 250–500 mg, bid Minocycline or doxycycline, 50–100 mg, bid
Nodulocystic acne	Accutane, 1 mg/kg/d

Multiple studies have shown a combination of benzoyl peroxide or a retinoid and a topical antibiotic are more effective than the antibiotic alone.

C. Systemic Antibiotics

Antibiotics that are concentrated in sebum, such as tetracycline, minocycline, and doxycycline should be reserved for moderate to severe inflammatory acne. The usual dose of tetracycline is 0.5–1.0 g divided twice a day on an empty stomach; minocycline and doxycycline 50–100 mg taken once or twice daily can be taken with food. Monotherapy with oral antibiotics should never be used. Recent recommendations are that oral antibiotics should be used for a finite time period, and then discontinued as soon as possible. The tetracycline antibiotics should not be given to children younger than 8 years of age due to the effect on dentition (staining of teeth). These antibiotics have anti-inflammatory effects in addition to decreasing *P. acnes* in the follicle.

D. Oral Retinoids

An oral retinoid, 13-*cis*-retinoic acid (isotretinoin; Accutane), is the most effective treatment for severe cystic acne. The precise mechanism of its action is unknown, but decreased sebum production, decreased follicular obstruction, decreased skin bacteria, and general anti-inflammatory activities have been described. The initial dosage is 40 mg once or twice daily. This therapy is reserved for severe nodulocystic acne, or acne recalcitrant to aggressive standard therapy. Side effects include dryness and scaling of the skin, dry lips, and, occasionally, dry eyes and dry nose. Fifteen percent of patients may experience some mild

achiness with athletic activities. Up to 10% of patients experience mild, reversible hair loss. Elevated liver enzymes and blood lipids have rarely been described. Acute depression may occur. Isotretinoin is teratogenic in young women of childbearing age. Because of this and the other side effects, it is not recommended unless strict adherence to the Food and Drug Administration (FDA) guidelines is ensured. The FDA has implemented a strict registration program (iPLEDGE) that must be used to obtain isotretinoin.

E. Other Acne Treatments

Hormonal therapy (oral contraceptives) is often an effective option for girls who have perimenstrual flares of acne or have not responded adequately to conventional therapy. Adolescents with endocrine disorders such as polycystic ovary syndrome also see improvement of their acne with hormonal therapy. Oral contraceptives can be added to a conventional therapeutic regimen and should always be used in female patients who are prescribed oral isotretinoin unless absolute contraindications exist.

F. Avoidance of Cosmetics and Hair Spray

Acne can be aggravated by a variety of external factors that result in further obstruction of partially occluded sebaceous follicles. Discontinuing the use of oil-based cosmetics, face creams, and hair sprays may alleviate the comedonal component of acne within 4–6 weeks.

G. Patient Education and Follow-Up Visits

The multifactorial pathogenesis of acne and its role in the treatment plan must be explained to adolescent patients. Time should be set aside at the first visit to answer questions. Acne therapy is aimed at preventing the microcomedone, so therapy takes 8–12 weeks to produce improvement. This delay should be stressed to the patient. Realistic expectations should be encouraged in the adolescent patient because no therapy will prevent an adolescent from ever having another acne lesion. A written education sheet is useful.

Follow-up visits should be made every 8–12 weeks. An objective method to chart improvement should be documented by the provider, because patients' assessment of improvement tends to be inaccurate. Explain again what medications are being used and why, what the treatment is intended to achieve, and that 8–12 weeks of consistent therapy is required for improvement in most cases. Ensure on follow-up that the patient is applying the medication properly (eg, topical keratolytics are to be applied to the entire area of skin that tends to be affected, not to individual lesions already present).

Strauss JS et al: Guidelines of care for acne vulgaris management. *J Am Acad Dermatol* 2007;56:651 [PMID: 17276540].

BACTERIAL INFECTIONS OF THE SKIN

1. Impetigo

Erosions covered by honey-colored crusts are diagnostic of impetigo. Staphylococci and group A streptococci are important pathogens in this disease, which histologically consists of superficial invasion of bacteria into the upper epidermis, forming a subcorneal pustule.

▶ Treatment

Impetigo should be treated with an antimicrobial agent effective against *Staphylococcus aureus* (β -lactamase-resistant penicillins or cephalosporins, clindamycin, amoxicillin-clavulanate) for 7–10 days. Topical mupirocin and fusidic acid (three times daily) are also effective.

2. Bullous Impetigo

All impetigo is bullous, with the blister forming just beneath the stratum corneum, but in bullous impetigo there is, in addition to the usual erosion covered by a honey-colored crust, a border filled with clear fluid. Staphylococci may be isolated from these lesions, and systemic signs of circulating exfoliatin are absent. Bullous varicella is a disorder that represents bullous impetigo as a superinfection in varicella lesions.

▶ Treatment

Treatment with oral antistaphylococcal drugs for 7–10 days is effective. Application of cool compresses to debride crusts is a helpful symptomatic measure.

3. Ecthyma

Ecthyma is a firm, dry crust, surrounded by erythema that exudes purulent material. It represents invasion by group A β -hemolytic streptococci through the epidermis to the superficial dermis. This should not be confused with ecthyma gangrenosum. Lesions of ecthyma gangrenosum may be similar in appearance, but they are seen in a severely ill or immunocompromised patient and are due to systemic dissemination of bacteria, usually *Pseudomonas aeruginosa*, through the bloodstream.

▶ Treatment

Treatment is with systemic penicillin.

4. Cellulitis

Cellulitis is characterized by erythematous, hot, tender, ill-defined, edematous plaques accompanied by regional lymphadenopathy. Histologically, this disorder represents invasion of microorganisms into the lower dermis and sometimes beyond, with obstruction of local lymphatics. Group A β -hemolytic streptococci and coagulase-positive staphylo-

cocci are the most common causes; pneumococci and *Haemophilus influenzae* are rare causes. Staphylococcal infections are usually more localized and more likely to have a purulent center; streptococcal infections spread more rapidly, but these characteristics cannot be used to specify the infecting agent. An entry site of prior trauma or infection (eg, varicella) is often present. Septicemia is a potential complication.

► Treatment

Treatment is with an appropriate systemic antibiotic.

5. Folliculitis

A pustule at a follicular opening represents folliculitis. If the pustule occurs at eccrine sweat orifices, it is correctly called poritis. Staphylococci and streptococci are the most frequent pathogens.

► Treatment

Treatment consists of measures to remove follicular obstruction—either cool, wet compresses for 24 hours or keratolytics such as those used for acne.

6. Abscess

An abscess occurs deep in the skin, at the bottom of a follicle or an apocrine gland, and is diagnosed as an erythematous, firm, acutely tender nodule with ill-defined borders. Staphylococci are the most common organisms.

► Treatment

Treatment consists of incision and drainage and systemic antibiotics.

7. Scalded Skin Syndrome

This entity consists of the sudden onset of bright red, acutely painful skin, most obvious periorally, periorbitally, and in the flexural areas of the neck, the axillae, the popliteal and antecubital areas, and the groin. The slightest pressure on the skin results in severe pain and separation of the epidermis, leaving a glistening layer (the stratum granulosum of the epidermis) beneath. The disease is caused by a circulating toxin (exfoliatin) elaborated by phage group II staphylococci. Exfoliatin binds to desmoglein-1 resulting in a separation of cells in the granular layer. The causative staphylococci may be isolated not from the skin but rather from the nasopharynx, an abscess, sinus, blood culture, and so on.

► Treatment

Treatment is with systemic antistaphylococcal drugs.

Patel GK: Treatment of staphylococcal scalded skin syndrome. Expert Rev Anit Infect 2004;2:575 [PMID: 15482221].

Schachner LA: Treatment of uncomplicated skin infections in the pediatric and adolescent patient populations. J Drugs Dermatol 2005;4:s30 [PMID: 16300228].

FUNGAL INFECTIONS OF THE SKIN

1. Dermatophyte Infections

Dermatophytes become attached to the superficial layer of the epidermis, nails, and hair, where they proliferate. They grow mainly within the stratum corneum and do not invade the lower epidermis or dermis. Release of toxins from dermatophytes—especially those whose natural hosts are animals or soil, for example, *Microsporum canis* and *Trichophyton verrucosum*—results in dermatitis. Fungal infection should be suspected with any red and scaly lesion.

► Classification & Clinical Findings

A. Tinea Capitis

Thickened, broken-off hairs with erythema and scaling of underlying scalp are the distinguishing features (Table 14–7). In endemic ringworm, hairs are broken off at the surface of the scalp, leaving a “black dot” appearance. Pustule formation and a boggy, fluctuant mass on the scalp occur in *M canis* and *T tonsurans* infections. This mass, called a kerion, represents an exaggerated host response to the organism. Diffuse scaling of the scalp may also be seen. Fungal culture should be performed in all cases of suspected tinea capitis.

B. Tinea Corporis

Tinea corporis presents either as annular marginated plaques with a thin scale and clear center or as an annular confluent dermatitis. The most common organisms are *Trichophyton mentagrophytes* and *M canis*. The diagnosis is made by scraping thin scales from the border of the lesion, dissolving them in 20% KOH, and examining for hyphae.

Table 14–7. Clinical features of tinea capitis.

Most Common Organisms	Clinical Appearance	Microscopic Appearance in KOH
<i>Trichophyton tonsurans</i> (90%)	Hairs broken off 2–3 mm from follicle; “black dot”; diffuse pustule; seborrheic dermatitis-like; no fluorescence	Hyphae and spores within hair
<i>Microsporum canis</i> (10%)	Thickened broken-off hairs that fluoresce yellow-green with Wood’s lamp	Small spores outside of hair; hyphae within hair

C. Tinea Cruris

Symmetrical, sharply marginated lesions in inguinal areas occur with tinea cruris. The most common organisms are *Trichophyton rubrum*, *T mentagrophytes*, and *Epidermophyton floccosum*.

D. Tinea Pedis

The diagnosis of tinea pedis is becoming more common in the prepubertal child, although it is still most commonly seen in postpubertal males. Presentation is with red scaly soles, blisters on the instep of the foot, or fissuring between the toes.

E. Tinea Unguium (Onychomycosis)

Loosening of the nail plate from the nail bed (onycholysis), giving a yellow discoloration, is the first sign of fungal invasion of the nails. Thickening of the distal nail plate then occurs, followed by scaling and a crumbly appearance of the entire nail plate surface. *T rubrum* and *T mentagrophytes* are the most common causes. The diagnosis is confirmed by KOH examination and fungal culture. Usually only one or two nails are involved. If every nail is involved, psoriasis, lichen planus, or idiopathic trachyonychia is a more likely diagnosis than fungal infection.

▶ Treatment

The treatment of dermatophytosis is quite simple: If hair is involved, griseofulvin is the treatment of choice. Topical antifungal agents do not enter hair or nails in sufficient concentration to clear the infection. The absorption of griseofulvin from the gastrointestinal tract is enhanced by a fatty meal; thus, whole milk or ice cream taken with the medication increases absorption. The dosage of griseofulvin is 20 mg/kg/d. With hair infections, cultures should be done every 4 weeks, and treatment should be continued for 4 weeks following a negative culture result. The side effects are few, and the drug has been used successfully in the newborn period. Itraconazole and terbinafine have been used when response to griseofulvin is unsatisfactory. For nails, daily administration of topical ciclopirox 8% (Penlac nail lacquer) can be considered, as can pulsed-dose itraconazole given in three 1-week pulses separated by 3 weeks.

Tinea corporis, tinea pedis, and tinea cruris can be treated effectively with topical medication after careful inspection to make certain that the hair and nails are not involved. Treatment with any of the imidazoles, allylamines, benzylamines, or ciclopirox applied twice daily for 3–4 weeks is recommended.

Gupta AK et al: Dermatophytosis: The management of fungal infections. *Skinmed* 2005;4:305 [PMID: 16282753].

2. Tinea Versicolor

Tinea versicolor is a superficial infection caused by *Pityrosporum orbiculare* (also called *Malassezia furfur*), a yeastlike fungus. It characteristically causes polycyclic connected hypopigmented

macules and very fine scales in areas of sun-induced pigmentation. In winter, the polycyclic macules appear reddish brown.

▶ Treatment

Treatment consists of application of selenium sulfide (Selsun), 2.5% suspension, or topical antifungals. Selenium sulfide should be applied to the whole body and left on overnight. Treatment can be repeated again in 1 week and then monthly thereafter. It tends to be somewhat irritating, and the patient should be warned about this difficulty.

3. *Candida albicans* Infections (See also Chapter 39)

▶ Clinical Findings

In addition to being a frequent invader in diaper dermatitis, *Candida albicans* also infects the oral mucosa, where it appears as thick white patches with an erythematous base (thrush); the angles of the mouth, where it causes fissures and white exudate (perlèche); and the cuticular region of the fingers, where thickening of the cuticle, dull red erythema, and distortion of growth of the nail plate suggest the diagnosis of candidal paronychia. *Candida* dermatitis is characterized by sharply defined erythematous patches, sometimes with eroded areas. Pustules, vesicles, or papules may be present as satellite lesions. Similar infections may be found in other moist areas, such as the axillae and neck folds. This infection is more common in children who have recently received antibiotics.

▶ Treatment

A topical imidazole cream is the drug of first choice for *C albicans* infections. In diaper dermatitis, the cream form can be applied every 8–12 hours. In oral thrush, nystatin suspension should be applied directly to the mucosa with the parent's finger or a cotton-tipped applicator, because it is not absorbed and acts topically. In candidal paronychia, the antifungal agent is applied over the area, covered with occlusive plastic wrapping, and left on overnight after the application is made airtight. Refractory candidiasis will respond to a brief course of oral fluconazole.

Kyle AA, Dahl MV: Topical therapy for fungal infections. *Am J Clin Dermatol* 2004;5:443 [PMID: 15663341].

VIRAL INFECTIONS OF THE SKIN (SEE ALSO CHAPTER 38)

1. Herpes Simplex Infection

▶ Clinical Findings

Painful, grouped vesicles or erosions on a red base suggest herpes simplex. Rapid immunofluorescent tests for herpes simplex virus (HSV) and varicella-zoster virus (VZV) are available. A Tzanck smear is done by scraping a vesicle base with a No. 15

blade, smearing on a glass slide, and staining the epithelial cells with Wright stain. The smear is positive if epidermal multinucleated giant cells are visualized. A positive Tzanck smear indicates herpesvirus infection (HSV or VZV). In infants and children, lesions resulting from herpes simplex type 1 are seen most commonly on the gingiva, lips, and face. Involvement of a digit (herpes whitlow) will occur if the child sucks the thumb or fingers. Herpes simplex type 2 lesions are seen on the genitalia and in the mouth in adolescents. Cutaneous dissemination of herpes simplex occurs in patients with atopic dermatitis (eczema herpeticum) and appears clinically as very tender, punched out erosions among the eczematous skin changes.

► Treatment

The treatment of HSV infections is discussed in Chapter 38.

Waggoner-Fountain LA, Grossman LB: Herpes simplex virus. *Pediatr Rev* 2004;25:86 [PMID: 14993516].
Whitley RJ: Herpes simplex virus in children. *Curr Treat Options Neurol* 2004;4:231 [PMID: 11931730].

2. Varicella-Zoster Infection

► Clinical Findings

Grouped vesicles in a dermatome, usually on the trunk or face, suggest varicella-zoster reactivation. Zoster in children may not be painful and usually has a mild course. In patients with compromised host resistance, the appearance of an erythematous border around the vesicles is a good prognostic sign. Conversely, large bullae without a tendency to crusting and systemic illness imply a poor host response to the virus. Varicella-zoster and herpes simplex lesions undergo the same series of changes: papule, vesicle, pustule, crust, slightly depressed scar. Lesions of primary varicella appear in crops, and many different stages of lesions are present at the same time (eg, papules), eccentrically placed vesicles on an erythematous base (“dew drop” on a rose petal), erosions, and crusts.

► Treatment

Antihistamines may be used for pruritus; cool baths or drying lotions such as calamine lotion are usually sufficient to relieve symptoms. In immunosuppressed children, intravenous or oral acyclovir should be used.

Heininger U, Seward JF: Varicella. *Lancet* 2006;368:1365 [PMID: 17046469].
Leung AK et al: Herpes zoster in childhood. *Pediatr Health Care* 2006;20:300 [PMID: 16962434].

3. Human Immunodeficiency Virus Infection (See also Chapter 39)

► Clinical Findings

The average time of onset of skin lesions after perinatally acquired HIV infection is 4 months; after transfusion-

acquired infection, it is 11 months. Persistent oral candidiasis and recalcitrant candidal diaper rash are the most frequent cutaneous features of infantile HIV infection. Severe or recurrent herpetic gingivostomatitis, varicella-zoster infection, and molluscum contagiosum infection occur. Recurrent staphylococcal pyodermas, tinea of the face, and onychomycosis are also observed. A generalized dermatitis with features of seborrhea (severe cradle cap) is extremely common. In general, persistent, recurrent, or extensive skin infections should make one suspicious of HIV infection.

► Treatment

The treatment of HIV infections is discussed in Chapter 39.

Wananukul S et al: Mucocutaneous findings in pediatric AIDS related to degree of immunosuppression. *Pediatr Dermatol* 2004;20:289 [PMID: 1286945].

VIRUS-INDUCED TUMORS

1. Molluscum Contagiosum

Molluscum contagiosum is a poxvirus that induces the epidermis to proliferate, forming a pale papule. Molluscum contagiosum consists of umbilicated, flesh-colored papules in groups on the genitalia or trunk. They are common in infants and preschool children, as well as sexually active adolescents.

► Treatment

Treatment for molluscum includes topical imiquimod, topical cantharidin, oral cimetidine, cryotherapy with liquid nitrogen, and curettage. Left untreated, the lesions resolve over months to years.

Dohil MA et al: The epidemiology of molluscum contagiosum in children. *J Am Acad Dermatol* 2006;54:47 [PMID: 16384754].

2. Warts

Warts are skin-colored papules with irregular (verruccous) surfaces. They are intraepidermal tumors caused by infection with human papillomavirus (HPV). There are over 100 types of this DNA virus, which induces the epidermal cells to proliferate, thus resulting in the warty growth. Flat warts are smoother and smaller than common warts and are often seen on the face. Certain types of HPV are associated with certain types of warts (eg, flat warts) or location of warts (eg, genital warts).

► Treatment

No therapy for warts is ideal, and 30% of warts will clear in 6 months irrespective of the therapy chosen. Liquid nitrogen is often used to treat common (vulgaris) warts. The treated lesion should stay white for 20 seconds. Aggressive treatment

with prolonged freeze times and too much pressure applied with a cotton applicator can lead to blistering and scarring. The patient should be seen at treatment intervals of 2–3 weeks. Longer times between treatments result in lower efficacy. Topical salicylic acid, topical imiquimod, and oral cimetidine may also be used. Large mosaic plantar warts are treated most effectively by applying 40% salicylic acid plaster cut with a scissors to fit the lesion. The adhesive side of the plaster is placed against the lesion and taped securely in place with duct or athletic tape. The plaster and tape should be placed on Monday and removed on Friday. Over the weekend, the patient should soak the skin in warm water for 30 minutes to soften it. Then the white, macerated tissue should be pared with a pumice stone, cuticle scissors, or a nail file. This procedure is repeated every week, and the patient is seen every 4 weeks. Most plantar warts resolve in 6–8 weeks when treated in this way. Vascular pulsed dye lasers are a useful adjunct therapy for the treatment of plantar warts.

For flat warts, a good response to 0.05% tretinoin cream or topical imiquimod (Aldara) cream, applied once daily for 3–4 weeks, has been reported.

Surgical excision, electrosurgery, and nonspecific burning laser surgery should be avoided; these modalities do not have higher cure rates and result in scarring.

Venereal warts (*condylomata acuminata*) (see Chapter 42) may be treated with imiquimod, 25% podophyllin resin (podophyllin) in alcohol, or podofilox, a lower concentration of purified podophyllin, which is applied at home. Podophyllin should be painted on the lesions in the practitioner's office and then washed off after 4 hours. Re-treatment in 2–3 weeks may be necessary. Podofilox is applied by the patient once daily, Monday through Thursday, whereas imiquimod is used 3 times a week on alternating days. Lesions not on the vulvar mucous membrane but on the adjacent skin should be treated as a common wart and frozen.

No wart therapy is immediately and definitively successful. Realistic expectations should be set and appropriate follow-up treatments scheduled.

Keogh-Brown MR et al: To freeze or not to freeze: A cost-effectiveness analysis of wart treatment. *Br J Dermatol* 2007;156:687 [PMID: 17326748].

INSECT INFESTATIONS

1. Scabies

► Clinical Findings

Scabies is suggested by linear burrows about the wrists, ankles, finger webs, areolas, anterior axillary folds, genitalia, or face (in infants). Often there are excoriations, honey-colored crusts, and pustules from secondary infection. Identification of the female mite or her eggs and feces is necessary to confirm the diagnosis. Scrape an unscratched papule or burrow with a No. 15 blade and examine microscopically in

immersion oil to confirm the diagnosis. In a child who is often scratching, scrape under the fingernails. Examine the parents for unscratched burrows.

► Treatment

Permethrin 5% is now the treatment of choice for scabies. It should be applied as a single overnight application. The need for re-treatment is rare.

Karthikeyan K: Scabies in children. *Arch Dis Child Educ Pract Ed* 2007;92:ep65 [PMID: 17517973].

2. Pediculoses (Louse Infestations)

► Clinical Findings

The presence of excoriated papules and pustules and a history of severe itching at night suggest infestation with the human body louse. This louse may be discovered in the seams of underwear but not on the body. In the scalp hair, the gelatinous nits of the head louse adhere tightly to the hair shaft. The pubic louse may be found crawling among pubic hairs, or blue-black macules may be found dispersed through the pubic region (maculae cerulea). The pubic louse is often seen on the eyelashes of newborns.

► Treatment

Initial treatment of head lice is often instituted by parents with an over-the-counter pyrethrin or permethrin product. If head lice are not eradicated after two applications 7 days apart with these products, 5% permethrin should be used. Malathion 0.5% is highly effective but is toxic if ingested, and flammable.

Lebwohl M et al: Therapy for head lice based on life cycle, resistance, and safety. *Pediatrics* 2007;119:965 [PMID: 17473098].

3. Papular Urticaria

► Clinical Findings

Papular urticaria is characterized by grouped erythematous papules surrounded by an urticarial flare and distributed over the shoulders, upper arms, and buttocks in infants. Although not a true infestation, these lesions represent delayed hypersensitivity reactions to stinging or biting insects and can be reproduced by patch testing with the offending insect. Fleas from dogs and cats are the usual offenders. Less commonly, mosquitoes, lice, scabies, and bird and grass mites are involved. The sensitivity is transient, lasting 4–6 months. Usually no other family members are affected. It is often difficult for the parents to understand why no one else is affected.

► Treatment

The logical therapy is to remove the offending insect, although in most cases it is very difficult to identify the exact

cause. Topical corticosteroids and oral antihistamines will control symptoms.

Hernandez RG, Cohen BA: Insect bite-induced hypersensitivity and the SCRATCH principles: A new approach to papular urticaria. *Pediatrics* 2006;118:e189 [PMID: 16751615].

DERMATITIS (ECZEMA)

The terms *dermatitis* and *eczema* are currently used interchangeably in dermatology, although the term *eczema* truly denotes an acute weeping dermatosis. All forms of dermatitis, regardless of cause, may present with acute edema, erythema, and oozing with crusting, mild erythema alone, or lichenification. Lichenification is diagnosed by thickening of the skin with a shiny surface and exaggerated, deepened skin markings. It is the response of the skin to chronic rubbing or scratching.

Although the lesions of the various dermatoses are histologically indistinguishable, clinicians have nonetheless divided the disease group called dermatitis into several categories based on known causes in some cases and differing natural histories in others.

1. Atopic Dermatitis

▶ Pathogenesis & Clinical Findings

Atopic dermatitis is a general term for chronic superficial inflammation of the skin that can be applied to a heterogeneous group of patients. Many (not all) patients go through three clinical phases. In the first, infantile eczema, the dermatitis begins on the cheeks and scalp and frequently expresses itself as oval patches on the trunk, later involving the extensor surfaces of the extremities. The usual age at onset is 2–3 months, and this phase ends at age 18 months to 2 years. Only one third of all infants with infantile eczema progress to phase 2 childhood or flexural eczema in which the predominant involvement is in the antecubital and popliteal fossae, the neck, the wrists, and sometimes the hands or feet. This phase lasts from age 2 years to adolescence. Some children have involvement only of the soles of the feet, with cracking, redness, and pain, so-called atopic feet. Only one third of children with typical flexural eczema progress to adolescent eczema, which is usually manifested by the continuation of chronic flexural eczema alone with hand dermatitis. Atopic dermatitis is quite unusual after age 30 years.

Atopic dermatitis results from an interaction among susceptibility genes, the host environment, skin barrier defects, pharmacologic abnormalities, and immunologic response. The case for food and inhalant allergens as specific causes of atopic dermatitis is not strong. There is significant new evidence that the primary defect in atopic dermatitis is an abnormality in the skin barrier formation due to defects in the filaggrin gene.

A few patients with atopic dermatitis have immunodeficiency with recurrent pyodermas, unusual susceptibility to herpes simplex viruses, hyperimmunoglobulinemia E, defective neutrophil and monocyte chemotaxis, and impaired T-lymphocyte function. (See Chapter 31.)

A faulty epidermal barrier predisposes the patient with atopic dermatitis to dry, itchy skin. Inability to hold water within the stratum corneum results in rapid evaporation of water, shrinking of the stratum corneum, and cracks in the epidermal barrier. Such skin forms an ineffective barrier to the entry of various irritants—and, indeed, it may be clinically useful to regard atopic dermatitis as a primary-irritant contact dermatitis and simply tell the patient, “you have sensitive skin.” Chronic atopic dermatitis is frequently infected secondarily with *S aureus* or *Streptococcus pyogenes*. Patients with atopic dermatitis have a deficiency of antimicrobial peptides in their skin, which may account for the susceptibility to recurrent skin infection.

▶ Treatment

A. Acute Stages

Application of wet dressings and topical corticosteroids is the treatment of choice for acute, weeping atopic eczema. A topical steroid preparation is applied two times daily and covered with wet dressings as outlined at the beginning of this chapter. Superinfection or colonization with *S aureus* is common, and appropriate systemic antibiotics may be necessary. If the expected improvement is not seen, bacterial cultures should be obtained to identify the possibility of an organism resistant to standard therapy.

B. Chronic Stages

Treatment is aimed at avoiding irritants and restoring water to the skin. No soaps or harsh shampoos should be used, and the patient should avoid woolen or any rough clothing. Bathing is minimized to every second or third day. Twice-daily lubrication of the skin is very important.

Nonperfumed lotions or creams are suitable lubricants. Plain petrolatum is an acceptable lubricant, but some people find it too greasy and during hot weather it may also cause considerable sweat retention. Liberal use of Cetaphil lotion four or five times daily as a substitute for soap is also satisfactory as a means of lubrication. A bedroom humidifier is often helpful. Topical corticosteroids should be limited to medium strength (see Table 14–3). There is never any reason to use super- or high-potency corticosteroids in atopic dermatitis. In superinfected atopic dermatitis, systemic antibiotics for 10–14 days are necessary.

Tacrolimus and pimecrolimus ointments are topical immunosuppressive agents that are effective in atopic dermatitis. Due to concerns about the development of malignancies, tacrolimus and pimecrolimus should be reserved for children older than 2 years of age with atopic dermatitis unresponsive to medium-potency topical steroids. It has been

argued that an increased risk of malignancy has not been seen in immunologically normal individuals using these products. Recommendations for usage likely will change with time. Treatment failures in chronic atopic dermatitis are most often the result of patient noncompliance. This is a frustrating disease for parent and child. Return to a normal lifestyle for the parent and child is the ultimate goal of therapy.

 Sandilands A et al: Filaggrin's fuller figure: A glimpse into the genetic architecture of atopic dermatitis. *J Invest Dermatol* 2007;127:1282 [PMID: 17502856].

2. Nummular Eczema

Nummular eczema is characterized by numerous symmetrically distributed coin-shaped patches of dermatitis, principally on the extremities. These may be acute, oozing, and crusted or dry and scaling. The differential diagnosis should include tinea corporis, impetigo, and atopic dermatitis.

▶ Treatment

The same topical measures should be used as for atopic dermatitis, although treatment is often more difficult.

3. Primary Irritant Contact Dermatitis (Diaper Dermatitis)

Contact dermatitis is of two types: primary irritant and allergic eczematous. Primary irritant dermatitis develops within a few hours, reaches peak severity at 24 hours, and then disappears. Allergic eczematous contact dermatitis (described in the next section) has a delayed onset of 18 hours, peaks at 48–72 hours, and often lasts as long as 2–3 weeks even if exposure to the offending antigen is discontinued.

Diaper dermatitis, the most common form of primary irritant contact dermatitis seen in pediatric practice, is caused by prolonged contact of the skin with urine and feces, which contain irritating chemicals such as urea and intestinal enzymes.

▶ Clinical Findings

The diagnosis of diaper dermatitis is based on the picture of erythema and scaling of the skin in the perineal area and the history of prolonged skin contact with urine or feces. This is frequently seen in the “good baby” who sleeps many hours through the night without waking. In 80% of cases of diaper dermatitis lasting more than 3 days, the affected area is colonized with *C albicans* even before appearance of the classic signs of a beefy red, sharply marginated dermatitis with satel-

lite lesions. Streptococcal perianal cellulitis and infantile psoriasis should be included in the differential diagnosis.

▶ Treatment

Treatment consists of changing diapers frequently. The area should only be washed following a bowel movement. Washing should be done with a wash cloth and warm water only. Because rubber or plastic pants prevent evaporation of the contactant and enhance its penetration into the skin, they should be avoided as much as possible. Air drying is useful. Treatment of long-standing diaper dermatitis should include application of nystatin or an imidazole cream with each diaper change.

Humphrey S et al: Practical management strategies for diaper dermatitis. *Skin Therapy Lett* 2006;11:1 [PMID: 17021645].

4. Allergic Eczematous Contact Dermatitis (Poison Ivy Dermatitis)

▶ Clinical Findings

Plants such as poison ivy, poison sumac, and poison oak cause most cases of allergic contact dermatitis in children. Allergic contact dermatitis has all the features of delayed-type (T-lymphocyte-mediated) hypersensitivity. Many substances may cause such a reaction; nickel sulfate, potassium dichromate, and neomycin are the most common causes. Nickel is found to some degree in all metals. Nickel allergy is commonly seen on the ears secondary to the wearing of earrings, and near the umbilicus from pants snaps and belt buckles. The true incidence of allergic contact dermatitis in children is unknown. Children often present with acute dermatitis with blister formation, oozing, and crusting. Blisters are often linear and of acute onset.

▶ Treatment

Treatment of contact dermatitis in localized areas is with topical corticosteroids. In severe generalized involvement, prednisone, 1–2 mg/kg/d orally for 10–14 days, can be used.

Militello G et al: Allergic contact dermatitis in children. *Curr Opin Pediatr* 2006;18:385 [PMID: 16914992].

5. Seborrheic Dermatitis

▶ Clinical Findings

Seborrheic dermatitis is an erythematous scaly dermatitis accompanied by overproduction of sebum occurring in areas rich in sebaceous glands (ie, the face, scalp, and perineum). This common condition occurs predominantly in the newborn and at puberty, the ages at which hormonal stimulation of sebum production is maximal. Although it is tempting to speculate that overproduction of sebum causes the dermatitis, the exact relationship is unclear.

Seborrheic dermatitis on the scalp in infancy is clinically similar to atopic dermatitis, and the distinction may become clear only after other areas are involved. Psoriasis also occurs in seborrheic areas in older children and should be considered in the differential diagnosis.

▶ Treatment

Seborrheic dermatitis responds well to low-potency topical corticosteroids.

Schwartz RA et al: Seborrheic dermatitis: An overview. *Am Fam Physician* 2006;74:125 [PMID: 16848386].

6. Dandruff

Dandruff is physiologic scaling or mild seborrhea, in the form of greasy scalp scales. The cause is unknown. Treatment is with medicated dandruff shampoos.

7. Dry Skin Dermatitis (Asteatotic Eczema, Xerosis)

Newborns and older children who live in arid climates are susceptible to dry skin, characterized by large cracked scales with erythematous borders. The stratum corneum is dependent on environmental humidity for its water, and below 30% environmental humidity the stratum corneum loses water, shrinks, and cracks. These cracks in the epidermal barrier allow irritating substances to enter the skin, predisposing the patient to dermatitis.

▶ Treatment

Treatment consists of increasing the water content of the skin in the immediate external environment. House humidifiers are very useful. Minimize bathing to every second or third day.

Frequent soaping of the skin impairs its water-holding capacity and serves as an irritating alkali, and all soaps should therefore be avoided. Frequent use of emollients (eg, Cetaphil, Eucerin, Lubriderm) should be a major part of therapy.

8. Keratosis Pilaris

Follicular papules containing a white inspissated scale characterize keratosis pilaris. Individual lesions are discrete and may be red. They are prominent on the extensor surfaces of the upper arms and thighs and on the buttocks and cheeks. In severe cases, the lesions may be generalized. Such lesions are seen frequently in children with dry skin and have also been associated with atopic dermatitis and ichthyosis vulgaris.

▶ Treatment

Treatment is with keratolytics such as urea cream or lactic acid, followed by skin hydration.

9. Pityriasis Alba

White, scaly macular areas with indistinct borders are seen over extensor surfaces of extremities and on the cheeks in children with pityriasis alba. Suntanning exaggerates these lesions. Histologic examination reveals a mild dermatitis. These lesions may be confused with tinea versicolor.

▶ Treatment

Low-potency topical corticosteroids may help decrease any inflammatory component and may lead to faster return of normal pigmentation.

Lin RL, Janninger CK: Pityriasis alba. *Cutis* 2005;76:21 [PMID: 16144284].

COMMON SKIN TUMORS

If the skin moves with the nodule on lateral palpation, the tumor is located within the dermis; if the skin moves over the nodule, it is subcutaneous. Seventy-five percent of lumps in childhood will be either epidermoid cysts (60%) or pilomatrichomas (15%).

1. Epidermoid Cysts

▶ Clinical Findings

Epidermoid cysts are the most common type of cutaneous cyst. Other names for epidermoid cysts are epidermal cysts, epidermal inclusion cysts, and “sebaceous” cysts. This last term is a misnomer since they contain neither sebum nor sebaceous glands. Epidermoid cysts can occur anywhere, but are most common on the face and upper trunk. They usually arise from and are lined by the stratified squamous epithelium of the follicular infundibulum. Clinically, epidermoid cysts are dermal nodules with a central punctum, representing the follicle associated with the cyst. They can reach several centimeters in diameter. **Dermoid cysts** are areas of sequestration of skin along embryonic fusion lines. They are present at birth and occur most commonly on the lateral eyebrow.

▶ Treatment

Epidermoid cysts can rupture, causing a foreign-body inflammatory reaction, or become infected. Infectious complications should be treated with antibiotics and drainage. Definitive treatment is surgical excision. Treatment of dermoid cysts, if desired, is surgical excision.

2. Pilomatrichomas

These are benign tumors of the hair matrix. They are most commonly seen on the face and upper trunk. They are firm and may be irregular. Their color varies from flesh-colored to pink or blue. The firmness is secondary to calcification of the tumor.

▶ Treatment

Treatment is by surgical excision.

3. Granuloma Annulare

Circles or semicircles of nontender intradermal nodules found over the lower legs and ankles, the dorsum of the hands and wrists, and the trunk, in that order of frequency, suggest granuloma annulare. Histologically, the disease appears as a central area of tissue death (necrobiosis) surrounded by macrophages and lymphocytes.

▶ Treatment

No treatment is necessary. Lesions resolve spontaneously within 1–2 years in most children.

4. Pyogenic Granuloma

These lesions appear over 1–2 weeks following skin trauma as a dark red papule with an ulcerated and crusted surface that may bleed easily even with minor trauma. Histologically, this represents excessive new vessel formation with or without inflammation (granulation tissue). It should be regarded as an abnormal healing response.

▶ Treatment

Pulsed dye laser for very small lesions or curettage followed by electrocautery are the treatments of choice.

5. Keloids

Keloids are scars of delayed onset that continue for up to several years to progress beyond the initial wound margins. The tendency to develop keloids is inherited. They are often found on the face, earlobes, neck, chest, and back.

▶ Treatment

Treatment includes intralesional injection with triamcinolone acetonide, 20 mg/mL, or excision and injection with corticosteroids.

Luba MC et al: Common benign skin tumors. *Am Fam Physician* 2003;67:729 [PMID: 12613727].

PAPULOSQUAMOUS ERUPTIONS

Papulosquamous eruptions (Table 14–8) comprise papules or plaques with varying degrees of scale.

1. Pityriasis Rosea

▶ Pathogenesis & Clinical Findings

Pink to red, oval plaques with fine scales that tend to align with their long axis parallel to skin tension lines (eg, “Christmas tree pattern” on the back) are characteristic lesions of

Table 14–8. Papulosquamous eruptions in children.

Psoriasis
Pityriasis rosea
Tinea corporis
Lichen planus
Pityriasis lichenoides (acute or chronic)
Dermatomyositis
Lupus erythematosus
Pityriasis rubra pilaris
Secondary syphilis

pityriasis rosea. In 20–80% of cases the generalized eruption is preceded for up to 30 days by a solitary, larger, scaling plaque with central clearing and a scaly border (the herald patch). The herald patch is clinically similar to ringworm and can be confused. In whites, the lesions are primarily on the trunk; in blacks, lesions are primarily on the extremities and may be accentuated in the axillary and inguinal areas.

This disease is common in school-aged children and adolescents and is presumed to be viral in origin. The role of human herpesvirus 7 in the pathogenesis of pityriasis rosea is debated. The condition lasts 6 weeks and may be pruritic.

▶ Differential Diagnosis

The major differential diagnosis is secondary syphilis, and a VDRL (Venereal Disease Research Laboratories) test should be done if syphilis is suspected, especially in high-risk patients with palm or sole involvement.

▶ Treatment

Exposure to natural sunlight may help hasten the resolution of lesions. Oral antihistamines can be used for pruritus. Often, no treatment is necessary. Pityriasis rosea that lasts more than 12 weeks should be referred to a dermatologist for evaluation.

Chuh AA et al: Interventions for pityriasis rosea. *Cochrane Database Syst Rev* 2007;(18):CD005068 [PMID:17443568].

2. Psoriasis

▶ Pathogenesis & Clinical Findings

Psoriasis is characterized by erythematous papules covered by thick white scales. Guttate (droplike) psoriasis is a common form in children that often follows an episode of streptococcal pharyngitis by 2–3 weeks. The sudden onset of small papules (3–8 mm), seen predominantly over the trunk and quickly covered with thick white scales, is characteristic of guttate psoriasis. Chronic psoriasis is marked by thick, large scaly plaques (5–10 cm) over the elbows, knees, scalp, and other sites of trauma. Pinpoint pits in the nail plate are seen, as well as yellow discoloration of the nail plate resulting from ony-

cholysis. Psoriasis occurs frequently on the scalp, elbows, knees, periumbilical area, ears, sacral area, and genitalia. It should always be included in the differential diagnosis of “dermatitis” on the scalp or genitalia of children.

The pathogenesis of psoriasis is complex and incompletely understood. It is a familial condition, and multiple psoriasis susceptibility genes have been identified. There is increased epidermal turnover; psoriatic epidermis has a turnover time of 3–4 days versus 28 days for normal skin. These rapidly proliferating epidermal cells produce excessive stratum corneum, giving rise to thick, opaque scales.

► Differential Diagnosis

Papulosquamous eruptions that present problems of differential diagnosis are listed in Table 14–8.

► Treatment

Topical corticosteroids are the initial treatment of choice. Penetration of topical steroids through the enlarged epidermal barrier in psoriasis requires that more potent preparations be used, for example, fluocinonide 0.05% (Lidex) or clobetasol 0.05% (Temovate) ointment twice daily.

The second line of therapy is topical calcipotriene (Dovonex) applied twice daily or the combination of a superpotent topical steroid twice daily on weekends and calcipotriene twice daily on weekdays for 8 weeks.

Topical retinoids such as tazarotene (0.1%, 0.5% cream, gel) can be used in combination with topical corticosteroids to help restore normal epidermal differentiation and turnover time. However, these treatments can cause skin to become dry.

Anthralin therapy is also useful. Anthralin is applied to the skin for a short contact time (eg, 20 minutes once daily) and then washed off with a neutral soap (eg, Dove). A 6-week course of treatment is recommended. This can be used in combination with topical corticosteroids.

Crude coal tar therapy is messy and stains bedclothes. The newer tar gels (Estar, PsoriGel) cause less staining and are most efficacious. They are applied twice daily for 6–8 weeks. These preparations are sold over the counter and are not usually covered by insurance plans.

Scalp care using a tar shampoo requires leaving the shampoo on for 5 minutes, washing it off, and then shampooing with commercial shampoo to remove scales. It may be necessary to shampoo daily until scaling is reduced. More severe cases of psoriasis are best treated by a dermatologist.

Hair loss with hair shaft defects (hair fails to grow out enough to require haircuts)

- Monilethrix—alternating bands of thin and thick areas
- Pili annulati—alternating bands of light and dark pigmentation
- Pili torti—hair twisted 180 degrees, brittle
- Trichorrhexis invaginata (bamboo hair)—intussusception of one hair into another
- Trichorrhexis nodosa—nodules with fragmented hair

single area is necessary before hair loss can be detected clinically. Examination should begin with the scalp to determine whether inflammation, scale, or infiltrative changes are present. Hairs should be examined microscopically for breaking and structural defects and to see whether growing or resting hairs are being shed. Placing removed hairs in mounting fluid (Permount) on a glass microscope slide makes them easy to examine. Three diseases account for most cases of hair loss in children: alopecia areata, tinea capitis (described earlier in this chapter), and hair pulling.

Silverberg NB: Helping children cope with hair loss. *Cutis* 2006;78:333 [PMID: 17186792].

1. Alopecia Areata

► Clinical Findings

Loss of every hair in a localized area is called alopecia areata. This is the most common cause of hair loss in children. An immunologic pathogenic mechanism is suspected because dense infiltration of lymphocytes precedes hair loss. Ninety-five percent of children with alopecia areata completely regrow their hair within 12 months, although as many as 40% may have a relapse in 5–6 years.

A rare and unusual form of alopecia areata begins at the occiput and proceeds along the hair margins to the frontal scalp. This variety, called ophiasis, often eventuates in total scalp hair loss (alopecia totalis). The prognosis for regrowth in ophiasis is poor.

► Treatment

Treatment of alopecia areata is difficult. Systemic corticosteroids given to suppress the inflammatory response will result in hair growth, but the hair may fall out again when the drug is discontinued. Systemic corticosteroids should never be used

for a prolonged time period. Superpotent topical steroids, minoxidil (Rogaine), and anthralin are treatment options. In children with alopecia totalis, a wig is most helpful.

Tan E et al: A clinical study of childhood alopecia areata in Singapore. *Pediatr Dermatol* 2002;19:298 [PMID: 12220271].

2. Hair Pulling

► Clinical Findings

Traumatic hair pulling causes the hair shafts to be broken off at different lengths, with an ill-defined area of hair loss, petechiae around follicular openings, and a wrinkled hair shaft on microscopic examination. This behavior may be merely habit, an acute reaction to severe stress, trichotillomania, or a sign of another psychiatric disorder. Eyelashes and eyebrows rather than scalp hair may be pulled out.

► Treatment

If the behavior has a long history, psychiatric evaluation may be helpful. Oiling the hair to make it slippery is an aid to behavior modification.

Tay YK et al: Trichotillomania in childhood: Case series and review. *Pediatrics* 2004;113:e494 [PMID: 15121993].

REACTIVE ERYTHEMAS

1. Erythema Multiforme

► Clinical Findings

Erythema multiforme begins with papules that later develop a dark center and then evolve into lesions with central bluish discoloration or blisters and the characteristic target lesions (iris lesions) that have three concentric circles of color change. Primary injury is to endothelial cells, with later destruction of epidermal basal cells. Erythema multiforme has sometimes been diagnosed in patients with severe mucous membrane involvement, but Stevens-Johnson syndrome is the usual diagnosis when severe involvement of conjunctiva, oral cavity, and genital mucosa also occur.

Many causes are suspected, particularly concomitant herpes simplex virus; drugs, especially sulfonamides; and *Mycoplasma* infections. Recurrent erythema multiforme is usually associated with reactivation of herpes simplex virus. In the mild form, spontaneous healing occurs in 10–14 days, but Stevens-Johnson syndrome may last 6–8 weeks.

► Treatment

Treatment is symptomatic in uncomplicated erythema multiforme. Removal of offending drugs is an obvious measure. Oral antihistamines such as hydroxyzine, 2 mg/kg/d orally, are useful. Cool compresses and wet dressings will relieve pruritus. Steroids have not been demonstrated to be effective. Chronic acyclovir therapy has been successful in

Lamoreaux MR et al: Erythema multiforme. *Am Fam Physician* 2006;74:1883 [PMID: 17168345].

2. Drug Eruptions

Drugs may produce urticarial, morbilliform, scarlatiniform, pustular, bullous, or fixed skin eruptions. Urticaria may appear within minutes after drug administration, but most reactions begin 7–14 days after the drug is first administered. These eruptions may occur in patients who have received these drugs for long periods, and eruptions continue for days after the drug has been discontinued. Drug eruptions with fever, eosinophilia, and systemic symptoms (DRESS syndrome) is most commonly seen with anticonvulsants, but may be seen with other drugs. Drugs commonly implicated in skin reactions are listed in Table 14–10.

Greenberger PA: Drug allergy. *J Allergy Clin Immunol* 2006;117:s464 [PMID: 16455348].

MISCELLANEOUS SKIN DISORDERS SEEN IN PEDIATRIC PRACTICE

1. Aphthous Stomatitis

Recurrent erosions on the gums, lips, tongue, palate, and buccal mucosa are often confused with herpes simplex. A

smear of the base of such a lesion stained with Wright stain will aid in ruling out herpes simplex by the absence of epithelial multinucleate giant cells. A culture for herpes simplex is also useful in differential diagnostics. The cause remains unknown, but T-cell-mediated cytotoxicity to various viral antigens has been postulated.

▶ Treatment

There is no specific therapy for this condition. Rinsing the mouth with liquid antacids provides relief in most patients. Topical corticosteroids in a gel base may provide some relief. In severe cases that interfere with eating, prednisone, 1 mg/kg/d orally for 3–5 days, will suffice to abort an episode. Colchicine, 0.2–0.5 mg/d, sometimes reduces the frequency of attacks.

Scully C: Clinical practice. Aphthous ulceration. *N Engl J Med* 2005;355:165 [PMID: 16837680].

2. Vitiligo

Vitiligo is characterized clinically by the development of areas of depigmentation. These are often symmetrical and occur mainly on extensor surfaces. The depigmentation results from a destruction of melanocytes. The basis for this destruction is unknown, but immunologically mediated damage is likely and vitiligo sometimes occurs in individuals with autoimmune endocrinopathies, selective IgA deficiency, or graft-versus-host disease.

▶ Treatment

Treatment is not very effective. Potent topical steroids, tacrolimus, or both for 4 months are the initial treatment. Topical calcipotriene has also been used. Narrow-band ultraviolet B waves (UVB 311 nm) may be used in severe cases.

Huggins RH et al: Childhood vitiligo. *Cutis* 2007;79:277 [PMID: 17500374].

Eye

15

Rebecca Sands Braverman, MD

Normal vision is a sense that develops during infancy and childhood. The child must experience equally good visual inputs from well-aligned eyes during this period while the visual nervous system is still exhibiting plasticity. Thus, pediatric ophthalmology emphasizes early diagnosis and treatment of pediatric eye diseases in order to obtain the best possible visual outcome. But eye disease in children does not always originate in the ocular system. Abnormal eye findings in a child may be a sign of systemic disease.

COMMON NONSPECIFIC SIGNS & SYMPTOMS

Nonspecific signs and symptoms commonly occur as the chief complaint or as an element of the history of a child with eye disease. Five of these findings are described here, along with a sixth—leukocoria—which is less common, but often has serious implications. Do not hesitate to seek the help of a pediatric ophthalmologist when you believe the diagnosis and treatment of these signs and symptoms requires in-depth clinical experience.

REDNESS

Redness (injection) of the bulbar conjunctiva or deeper vessels is a common presenting complaint. It may be mild and localized or diffuse and bilateral. Causes include superficial or penetrating foreign bodies, infection, allergy, and conjunctivitis associated with systemic entities such as Stevens-Johnson syndrome or Kawasaki disease. Irritating noxious agents also cause injection. Subconjunctival hemorrhage may be traumatic or spontaneous or may be associated with hematopoietic disease, vascular anomalies, or inflammatory processes. Uncommonly, an injected eye can be due to an intraocular or orbital tumor.

TEARING

Tearing in infants is usually due to nasolacrimal obstruction but may also be associated with congenital glaucoma, in which case photophobia and blepharospasm may also be present. Inflammation, allergic and viral diseases, or conjunctival and corneal irritation can also cause tearing.

DISCHARGE

Purulent discharge is usually associated with bacterial conjunctivitis. In infants and toddlers with nasolacrimal obstruction, a mucopurulent discharge may be present with low-grade, chronic dacryocystitis. Watery discharge occurs with viral infection, iritis, superficial foreign bodies, and nasolacrimal obstruction. Mucoïd discharge may be a sign of allergic conjunctivitis or nasolacrimal obstruction. A mucoïd discharge due to allergy typically contains eosinophils; a purulent bacterial discharge contains polymorphonuclear leukocytes.

PAIN & FOREIGN BODY SENSATION

Pain in or around the eye may be due to foreign bodies, corneal abrasions, lacerations, acute infections of the globe or ocular adnexa, iritis, and angle-closure glaucoma. Large refractive errors, poor accommodative ability, and sinus disease may manifest as headaches. Trichiasis (inturned lashes) and contact lens problems also cause ocular discomfort.

PHOTOPHOBIA

Acute aversion to light may occur with corneal abrasions, foreign bodies, and iritis. Squinting of one eye in bright light is a common sign of intermittent exotropia. Photophobia is present in infants with glaucoma, albinism, aniridia, and retinal dystrophies such as achromatopsia. Photophobia is common after ocular surgery and after dilation of the pupil with mydriatic and cycloplegic agents. Photophobia in indi-

▲ **Figure 15-1.** Leukocoria of the left eye caused by retrolental membrane (persistent hyperplastic primary vitreous or persistent fetal vasculature).

Individuals with no ocular pathology may be due to migraine headache, meningitis, and retrobulbar optic neuritis.

LEUKOCORIA

Although not a common sign or complaint, leukocoria (a white pupil) is associated with serious diseases and requires prompt ophthalmologic consultation. Causes of leukocoria include retinoblastoma, retinopathy of prematurity, pupillary membrane, cataract, vitreous opacities, retinal detachment, *Toxocara* infection, and retinal dysplasia (Figure 15-1).

REFRACTIVE ERRORS

Refractive error refers to the optical state of the eye (Figure 15-2). It is a physical characteristic like height or weight and can be quantitated. Not all refractive errors require correction, but severe errors can cause amblyopia (reduced vision with or without an organic lesion). Those that do can usually be corrected with glasses. Less often, contact lenses are required, usually for very high or asymmetrical refractive errors, or for adolescents who do not want to wear spectacles. Laser refractive surgery is not currently indicated for most children. There are three common refractive errors: myopia, hyperopia, and astigmatism. Inequality of the refractive state between the two eyes (anisometropia) can cause amblyopia. Children at particular risk for refractive errors requiring correction with spectacles include those who were born prematurely, those with Down syndrome, those who are offspring of parents with refractive errors, and those who have certain systemic conditions such as Stickler, Marfan, or Ehlers-Danlos syndrome.

MYOPIA (NEARSIGHTEDNESS)

For the myopic or nearsighted individual, objects nearby are in focus; those at a distance are blurred. This is because the

▲ **Figure 15-2.** Different refractive states of the eye. **A:** Emmetropia. Image plane from parallel rays of light falls on retina. **B:** Myopia. Image plane focuses anterior to retina. **C:** Hyperopia. Image plane focuses posterior to retina. **D:** Astigmatism, myopic type. Images in horizontal and vertical planes focus anterior to retina. **E:** Astigmatism, hyperopic type. Images in horizontal and vertical planes focus posterior to retina. **F:** Astigmatism, mixed type. Images in horizontal and vertical planes focus on either side of retina.

plane of focus is anterior to the retina. The onset is typically at about age 8 years and may progress throughout adolescence and young adulthood. A myopic person may squint to produce a pinhole effect, which improves distance vision. Divergent lenses provide clear distance vision. Many studies have been done attempting to slow or stop myopic progression. Atropine eye drops have shown some effect, but produce many side effects. A newer drug, pirenzepine, has shown promise in animal studies, and human studies are underway.

Tan DT et al, and Asian Pirenzepine Study Group: One-year multicenter, double-masked, placebo-controlled, parallel safety and efficacy study of 2% pirenzepine ophthalmic gel in children with myopia. *Ophthalmology* 2005;112:84 [PMID: 15629825].

HYPEROPIA (FARSIGHTEDNESS)

Saying that the hyperopic child is sighted for far (not near) vision is somewhat misleading, because the child can focus on near objects if the hyperopia is not excessive. Large amounts of uncorrected hyperopia can cause esotropia (inward deviation, or crossing, of the eyes) and amblyopia (see later section on Amblyopia & Strabismus). Most infants have a hyperopic refraction that begins to diminish during the toddler years and does not require correction.

ASTIGMATISM

When either the cornea or the crystalline lens is not perfectly spherical, an image will not be sharply focused in one plane. Schematically, there will be two planes of focus. Both of the planes can be either in front of or behind the retina, or one of the planes can be in front of the retina and the other behind it. This refractive state is described as astigmatism. Large amounts of astigmatism not corrected at an early age can cause decreased vision from amblyopia, but proper refractive correction can prevent this.

Harvey EM et al: Prescribing eyeglass correction for astigmatism in infancy and early childhood: A survey of AAPOS members. *J AAPOS* 2005;9:189 [PMID: 15838450].

OPHTHALMIC EXAMINATION

Ophthalmic examination of the pediatric patient begins with a calm demeanor and reassuring voice. Having a parent present is invaluable. The examination includes a history, assessment of visual acuity, external examination, observation of ocular alignment and motility, and ophthalmoscopic examination. Intraocular pressure is less frequently measured. Testing of binocular status and near point is desirable when age and cooperation permit.

Circumstances will dictate the use of ancillary procedures such as instilling fluorescein dye and radiologic tests (magnetic resonance imaging [MRI] and computed tomography [CT] scan). Electroretinography and electrooculography test retinal function. Visual evoked response testing assesses the function of the cortical visual pathways. Visual field testing demonstrates the presence or absence of scotomas and visual field defects occurring anywhere along the visual pathway. In the office setting, visual field testing may be done in a gross manner (confrontation) by bringing an object from the periphery of the child's field of vision into each of four quadrants or by having an older child count the examiner's fingers as they are presented in two quadrants simultaneously, but accurate results can be difficult to achieve in young children.

HISTORY

Evaluation begins by ascertaining the chief complaint and taking a history of the present illness. Elements of the history include onset of the complaint, its duration, whether it is monocular or binocular, treatment received thus far, and associated systemic symptoms. If an infectious disease is suspected, ask about possible contact with others having similar findings. The ocular history is obtained, as is the perinatal and developmental history and any history of allergy. The family history should be explored for ocular disorders that may be familial.

VISUAL ACUITY

Visual acuity testing is the single most important test of visual function and should be part of every general physical examination. This is the nonophthalmologist's most definitive test for amblyopia, refractive errors, and lesions along the optic pathways. Acuity should be tested in each eye individually, using an adhesive eye patch to prevent peeking. Glasses should be worn during vision screening if they have been prescribed in the past. In older children who can cooperate, use of a pinhole will improve vision in children not wearing the appropriate spectacle prescription.

Vision Screening

Vision screening in the pediatric age group is a challenge, especially in younger and developmentally delayed children. Accuracy of the screening test being administered to a particular population and expense in terms of time, equipment, and personnel are some factors that must be considered. Vision screening is consistent with the recommendations of the American Academy of Pediatrics (<http://www.aap.org>). Risk factors that should be screened for because they interfere with normal visual development and are amblyogenic include media opacities, strabismus, and refractive errors that are different in the two eyes (anisometropia) or of large magnitude in both eyes.

The type of test used to determine visual acuity is dictated by the child's age. In the sleeping newborn, the presence of a blepharospastic response to bright light is an adequate response. At age 6 weeks, eye-to-eye contact with slow following movements is becoming established and can be detected. By age 3 months, the infant should demonstrate fixing and following ocular movements for objects at a distance of 2–3 feet. At age 6 months, interest in movement across the room is the norm. Vision can be recorded for the presence or absence of fixing and following behavior and whether vision is steady (unsteady when nystagmus is present) and maintained. Vision should be tested and recorded for each eye. Visual acuity can be quantified in infants using other techniques, such as the 15-diopter prism test, preferential looking technique, or the pattern visual evoked response.

In the verbal child, the use of familiar icons will allow for a quantitative test. Allen or Lea symbols with familiar pictures can be used to test children younger than 2–3 years of age. When it is not possible to measure visual acuity or assess alignment in the preschool-aged group, random dot stereopsis testing (for depth perception) is effective in screening for manifest strabismus and amblyopia, but this test may miss some cases of anisometropic (unequal refractive error) amblyopia and small-angle strabismus. This test is not designed to detect refractive errors.

Four-year-old children are often ready to play the tumbling E game (in which the child identifies the orientation of the letter E, which is turned in one of four directions) or the

HOTV letters game (in which these four letters are shown individually at a distance and matched on a board that the child is holding). Literate children are tested with letters. Typical acuity levels in developmentally appropriate children are approximately 20/60 or better in children younger than 2–3 years, 20/40–20/30 in 3-year-old children, 20/30–20/25 in 4-year-old children, and 20/20 in literate children 5–6 years old. Perhaps more important than the absolute visual acuity is the presence of a difference of acuity between the two eyes, which might be a sign of amblyopia, uncorrected refractive error, or disease. As little as one line difference in acuity should be considered significant.

The practitioner should be aware of two situations in which vision screening is complicated by nystagmus. Children who require a face turn or torticollis (in which the head is tilted to the right or left) to quiet the nystagmus will have poor visual acuity results when tested in the absence of the compensatory head posture. When latent nystagmus is present, acuity testing is particularly challenging (see later section on Nystagmus). Nystagmus appears or worsens when an eye is occluded, degrading central vision. To minimize the nystagmus, the occluder should be held about 12 inches in front of the eye not being tested. Testing both eyes simultaneously without occlusion often gives a better visual acuity measurement than when either eye is tested individually.

Photoscreening

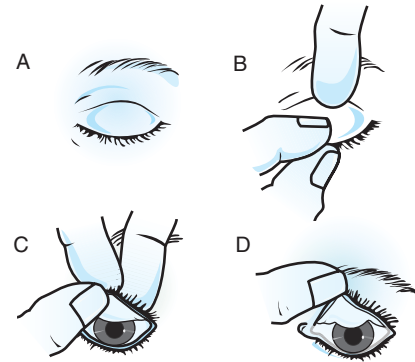

Traditional vision screening methods using eye charts in children aged 3–5 years require the child's cooperation as well as proficiency in testing by the examiner. Photoscreening has been developed to address the difficulties in screening young children. It requires a special camera that takes two photographs of each eye, a trained examiner to take the photographs, and a site for interpretation of the photographs. Photoscreening does not screen directly for amblyopia but for amblyogenic factors, which include strabismus, media opacities, and refractive errors. If the photographs suggest an amblyogenic factor, children are referred to an eye care professional for a complete eye examination. Problems exist with sensitivity and specificity of the instruments and poor follow-up for referrals made to eye care professionals. The cost-effectiveness of photoscreening remains an area of continued research.

EXTERNAL EXAMINATION

Inspection of the anterior segment of the globe and its adnexa requires adequate illumination and often magnifica-

▲ **Figure 15-3.** Eversion of the upper lid. **A:** The patient looks downward. **B:** The fingers pull the lid down, and an index finger or cotton tip is placed on the upper tarsal border. **C:** The lid is pulled up over the finger. **D:** The lid is everted.

tion. A penlight provides good illumination and should be used in both straight-ahead and oblique illumination. A Wood's lamp or a blue filter cap placed over a penlight is needed for evaluation after applying a fluorescent stain. Immobilization of the child may be necessary. A drop of topical anesthetic may facilitate the examination.

In cases of suspected foreign body, pulling down on the lower lid provides excellent visualization of the inferior cul-de-sac (palpebral conjunctiva). Visualizing the upper cul-de-sac and superior bulbar conjunctiva is possible by having the patient look inferiorly while the upper lid is pulled away from the globe and the examiner peers into the upper recess. Illumination with a penlight is necessary. The upper lid should be everted to evaluate the superior tarsal conjunctiva (Figure 15-3).

When indicated for further evaluation of the cornea, a small amount of fluorescein solution should be instilled into the lower cul-de-sac. Blue light will stain defects yellow-green. Disease-specific staining patterns may be observed. For example, herpes simplex lesions of the corneal epithelium produce a dendrite or branchlike pattern. A foreign body lodged beneath the upper lid shows one or more vertical lines of stain on the cornea due to the constant movement of the foreign body over the cornea. Contact lens overwear produces a central staining pattern. A fine, scattered punctate pattern may be a sign of viral keratitis or medication toxicity. Punctate erosions of the inferior third of the cornea can be seen with staphylococcal blepharitis or exposure keratitis secondary to incomplete lid closure.

PUPILS

The child's pupils should be evaluated for reaction to light, regularity of shape, and equality of size as well as for the presence of afferent pupillary defect. This defect, occurring

in optic nerve disease, is evaluated by the swinging flashlight test (see later section on Diseases of the Optic Nerve). Irregular pupils are associated with iritis, trauma, pupillary membranes, and structural defects such as iris coloboma (see later section on Iris Coloboma).

Pupils vary in size due to lighting conditions and also age. In general, infants have miotic (constricted) pupils. Children have larger pupils than either infants or adults, whereas the elderly have miotic pupils.

Anisocoria, a size difference between the two pupils, may be physiologic if the size difference is within 1 mm and is the same in light and dark. Anisocoria occurs with Horner syndrome, third nerve palsy, Adie tonic pupil, iritis, and trauma. Medication could also cause abnormal pupil size or reactivity. For example, contact with atropine-like substances (belladonna alkaloids) will cause pupillary dilation with little or no pupillary reaction. Systemic antihistamines and scopolamine patches, among other medicines, can dilate the pupils and interfere with accommodation (focusing).

ALIGNMENT & MOTILITY EVALUATION

Alignment and motility should be tested because amblyopia is associated with strabismus, a misalignment of the visual axes of the eyes. Besides alignment, ocular rotations should be evaluated in the six cardinal positions of gaze (Table 15-1; Figure 15-4). A small toy is an interesting target for testing ocular rotations in infants; a penlight works well in older children.

Alignment can be assessed in several ways. In order of increasing accuracy, these methods are observation, the corneal light reflex test, and cover testing. Observation includes an educated guess about whether the eyes are properly aligned. Corneal light reflex evaluation (Hirschberg test) is performed by shining a light beam at the patient's eyes, observing the reflections off each cornea, and estimating whether these "reflexes" appear to be positioned properly. If the reflection of light is noted temporally on the cornea, esotropia is suspected (Figure 15-5). Nasal reflection of the light suggests exotropia (outward deviation). Accuracy of these tests increases with increasing angles of misalignment.

Table 15-1. Function and innervation of each of the extraocular muscles.

Muscle	Function	Innervation
Medial rectus	Adductor	Oculomotor (third)
Lateral rectus	Abductor	Abducens (sixth)
Inferior rectus	Depressor, adductor, extorter	Oculomotor
Superior rectus	Elevator, adductor, intorter	Oculomotor
Inferior oblique	Elevator, abductor, extorter	Oculomotor
Superior oblique	Depressor, abductor, intorter	Trochlear (fourth)

MR = medial rectus
SR = superior rectus
SO = superior oblique
LR = lateral rectus
IR = inferior rectus
IO = inferior oblique

▲ Figure 15-4. Cardinal positions of gaze and muscles primarily tested in those fields of gaze. Arrow indicates position in which each muscle is tested.

Another way of evaluating alignment is with the cover test, in which the patient fixes on a target while one eye is covered. If an esotropia or an exotropia is present, the deviated eye will make a corrective movement to fixate on the target when the previously fixating eye is occluded. The other eye is tested similarly. When the occluder is removed from the eye just uncovered, a refixation movement of that eye indicates a phoria, or latent deviation, if alignment is reestablished. If the uncovered eye picks up fixation and strabismus is still present, then that eye can be presumed to be dominant and the nonpreferred eye possibly amblyopic. If the eye remains deviated after the occluder is removed, a tropia is noted to be present (Figure 15-6). A deviated eye that is blind or has very poor vision will not fixate on a target. Consequently, spurious results to cover testing may occur, as can happen with disinterest on the part of the patient, small-angle strabismus, and inexperience in administering cover tests.

OPHTHALMOSCOPIC EXAMINATION

A handheld direct ophthalmoscope allows visualization of the ocular fundus. As the patient's pupil becomes more constricted, viewing the fundus becomes more difficult. Although it is taught that pupillary dilation can precipitate

▲ Figure 15-5. Temporal displacement of light reflection showing esotropia (inward deviation) of the right eye. Nasal displacement of the reflection would show exotropia (outward deviation).

Eyes straight (maintained in position by fusion).

Position of eye under cover in orthophoria (fusion-free position). The right eye under cover has not moved.

Position of eye under cover in esophoria (fusion-free position). Under cover, the right eye has deviated inward. Upon removal of cover, the right eye will immediately resume its straight-ahead position.

Position of eye under cover in exophoria (fusion-free position). Under cover, the right eye had deviated outward. Upon removal of the cover, the right eye will immediately resume its straight-ahead position.

▲ **Figure 15-6.** Cover testing. The patient is instructed to look at a target at eye level 20 feet away. Note that in the presence of constant strabismus (ie, a tropia rather than a phoria), the deviation will remain when the cover is removed. (Reprinted, with permission, from Riordan-Eva P, Whitcher J: *Vaughan & Asbury's General Ophthalmology*, 17th ed., McGraw-Hill, 2008.)

an attack of closed-angle glaucoma in the predisposed adult, children are very rarely predisposed to angle closure. Exceptions include those with a dislocated lens, past surgery, or an eye previously compromised by a retrolental membrane, such as in retinopathy of prematurity. Therefore, if an adequate view of the fundus is precluded by a miotic pupil, use of a dilating agent (eg, 1 drop in each eye of 2.5% phenylephrine or 0.5% or 1% tropicamide) should provide adequate mydriasis (dilation). In infants, 1 drop of a combination of 1% phenylephrine with 0.2% cyclopentolate (Cyclomydril) is safer. Structures to be observed during ophthalmoscopy include the optic disk, blood vessels, the macular reflex, and retina, as well as the clarity of the vitreous media. By increasing the amount of plus lens dialed into the instrument, the point of focus moves anteriorly from the retina to the lens and finally to the cornea.

Ophthalmoscopy should include assessment of the clarity of the ocular media, that is, the quality of the red reflex. The practitioner should take the time to become familiar with this reflex. The red reflex test (Brückner test) is useful for identifying disorders such as media opacities (eg, cataracts), large refractive errors, tumors such as retinoblastoma, and strabismus. A difference in quality of the red reflexes between the two eyes constitutes a positive Brückner test and requires referral to an ophthalmologist.

The red reflex of each eye can be compared simultaneously when the observer is approximately 4 feet away from the patient. The largest diameter of light is shown through the ophthalmoscope, and no correction (zero setting) is dialed in the ophthalmoscope unless it is to compensate for the exam-

iner's uncorrected refractive error. A red reflex chart is available through the American Academy of Pediatrics.

OCULAR TRAUMA

A foreign body of the globe or adnexa may be difficult to visualize due to its small size or location. The clinician should always maintain a high index of suspicion for an occult or intraocular foreign body if the history suggests this. In cases such as these, ophthalmologic referral needs to be considered.

OCULAR FOREIGN BODIES

Clinical Findings

Foreign bodies on the globe and palpebral conjunctiva usually cause discomfort and red eye. The history may suggest the origin of the foreign body, such as being around a metal grinder or being outside on a windy day when a sudden foreign body sensation was encountered associated with tearing, redness, and pain. Pain with blinking suggests that the foreign body may be trapped between the eyelid and the eye.

Magnification with a slit lamp may be needed for inspection. Foreign bodies that lodge on the upper palpebral conjunctiva are best viewed by everting the lid on itself and removing the foreign body with a cotton applicator. The conjunctival surface (palpebral conjunctiva) of the lower lid presents no problem with visualization. After simple removal of a foreign body that is thought not to be contam-

inated, no other treatment is needed if no corneal abrasion has occurred.

► Treatment

When foreign bodies are noted on the bulbar conjunctiva or cornea (Figure 15–7), removal is facilitated by using a topical anesthetic. If the foreign body is not too adherent, it can be dislodged with a stream of irrigating solution (Dacriose or saline) or with a cotton applicator after instillation of a topical anesthetic. Otherwise, a foreign body spud or needle is used to undermine the foreign body. This must be done with adequate magnification and illumination. An antibiotic ointment is then instilled. Ferrous corneal bodies often have an associated rust ring, which may be removed under slit-lamp visualization in cooperative children or under anesthesia if necessary.

A

B

▲ **Figure 15–7.** **A:** Corneal foreign body at the nasal edge of the cornea. **B:** Subconjunctival foreign body of graphite.

CORNEAL ABRASION

A corneal abrasion results in loss of the most superficial layer of corneal cells and causes severe ocular pain, tearing, and blepharospasm. An inciting event is usually identifiable as the cause of a corneal abrasion. Children often suffer corneal abrasions accidentally while playing with siblings or pets as well as participating in sports. Contact lens users frequently develop abrasions due to poorly fitting lenses, overnight wear, and use of torn or damaged lenses.

► Clinical Findings

Symptoms of a corneal abrasion are sudden and severe eye pain, usually after an inciting event such as an accidental finger poke to the eye. Decreased vision secondary to pain and tearing are common complaints. Eyelid edema, tearing, injection of the conjunctiva, and poor cooperation with the ocular examination due to pain are common signs of a corneal abrasion. Fluorescein dye is instilled into the eye and a cobalt blue or Wood's lamp is used to illuminate the effected eye. The area with the abrasion will stain bright yellow.

► Treatment

Ophthalmic ointment, such as erythromycin ointment, lubricates the surface of the cornea and also helps prevent infections. Patching the affected eye when a large abrasion is present may provide comfort but is not advised for corneal abrasions caused by contact lens wear or other potentially contaminated sources. Large corneal abrasions result in referred pain to the ipsilateral brow. If a brow ache is present it may be treated by the use of a topical cycloplegic agent such as 1% cyclopentolate. Daily follow-up is required until healing is complete.

INTRAOCULAR FOREIGN BODIES & PERFORATING OCULAR INJURIES

Severe trauma may result in penetration of the eye by foreign bodies or retained foreign bodies, and is an ocular emergency. Intraocular foreign bodies and penetrating injuries are most often caused by being in close proximity to high-velocity projectiles such as windshield glass broken during a motor vehicle accident, metal ground without use of protective safety goggles, and improperly detonated fireworks.

► Clinical Findings

Sudden ocular pain occurs; vision loss, as well as multiple organ trauma, may be present.

Intraocular foreign bodies and corneal and scleral lacerations (ruptured globe) require emergency referral to an ophthalmologist. The diagnosis may be difficult if the obvious signs of corneal perforation (shallow anterior chamber with hyphema, traumatic cataract, and irregular pupil) are

▲ **Figure 15-8.** Corneal laceration with irregular pupil and vitreous loss.

not present (Figure 15-8). Furthermore, nonradiopaque materials such as glass will not be seen on x-ray film.

CT scan may be useful in evaluating ocular trauma, including bony injury and foreign body wound. MRI will not provide bony detail and must be avoided if a magnetic foreign body is suspected.

▶ Treatment

In cases of suspected intraocular foreign body or perforation of the globe, it may be best to keep the child at rest, gently shield the eye with a metal shield or cut-down paper cup, and keep the extent of examination to a necessary minimum to prevent expulsion of intraocular contents. In this setting, the child should be given nothing by mouth in case eye examination under anesthesia or surgical repair is required.

Aldakaf A et al: Intraocular foreign bodies associated with traumatic cataract. *Ophthalmologia* 2006;50:90 [PMID: 17345812].

BLUNT ORBITAL TRAUMA

Blunt orbital and soft tissue trauma may produce so-called black eye or ecchymosis (blue or purplish hemorrhagic areas) of the eyelids.

Trauma to the orbit from a closed fist, collision with another player during team sports, and falls are common etiologies of blunt orbital injuries. Orbital compartment syndrome, which may result from severe orbital trauma, is caused by hemorrhaging within the orbit or severe orbital edema (or both) and may lead to permanent vision loss.

▶ Clinical Findings

Blunt trauma to the orbit may result in orbit fractures. The orbital floor is a common location for a fracture (called a blowout fracture). A specific fracture that occurs mainly in children after blunt orbit trauma is called the white-eyed blowout fracture. This results from a greenstick fracture of

the orbit with entrapment of extraocular muscles. It is called “white-eyed” because the external orbital soft tissue injury may appear to be minimal, but the patient will have severe pain with eye movement, nausea, vomiting, and restriction of eye movements.

A blowout fracture must be suspected in a patient with symptoms of double vision, pain with eye movements, and restriction of extraocular muscle movements after blunt orbital trauma. CT images of an orbital floor fracture often reveal herniation of orbital fat or the inferior rectus muscle into the maxillary sinus. Assessment of ocular motility, globe integrity, and intraocular pressure will determine the extent of the blunt orbital injury. Consultation with an ophthalmologist may be necessary to determine the full spectrum of the patient’s injuries.

Orbital compartment syndrome is an emergency requiring immediate treatment. Patients present with severe edema or ecchymosis of the eyelids (which makes it very difficult to open the eyelids), proptosis, and possibly an acute traumatic optic neuropathy resulting in decreased vision or an afferent papillary defect. Neuroimaging may reveal a retrobulbar hemorrhage and proptosis.

Neuroimaging of a greenstick orbital floor fracture often reveals distortion of the entrapped extraocular muscle within a small orbit fracture.

▶ Treatment

Cold compresses or ice packs for brief periods (eg, 10 minutes at a time) are recommended in older children in the first 24 hours after injury to reduce hemorrhage and swelling.

Patients with clinical signs of muscle entrapment require urgent surgical repair to help prevent permanent ischemic injury to the involved extraocular muscle. Large fractures may need repair to prevent enophthalmos, a sunken appearance to the orbit. This can usually be performed on a nonemergent basis.

Orbital compartment syndrome requires emergent lateral eyelid canthotomy and cantholysis to decompress the orbit. Treatment should not be delayed in order to image the orbits. Prompt treatment can prevent permanent vision loss.

Tse R et al: The white-eyed medial blowout fracture. *Plast Reconstr Surg* 2007;119:277 [PMID: 17255684].

LACERATIONS

The lids and lacrimal apparatus are susceptible to laceration. Inspection of the eyelids reveals the extent and severity of the traumatic laceration. Lacerations of the nasal third of the eyelid and involving the eyelid margin are at risk for lacrimal system injury and subsequent chronic tearing.

▶ Treatment

Except for superficial lacerations away from the globe, repair in children is best performed in the operating room under

▲ **Figure 15-9.** Laceration involving right lower lid and canaliculus.

general anesthesia. Special consideration must be given to lacerations involving the lid margin, full-thickness lacerations, lacerations that may involve the levator muscle in the upper lid, and to those that may involve the canaliculus (Figure 15-9). These injuries are best repaired by an ophthalmologist and may require intubation of the nasolacrimal system with silicone tubes.

BURNS

Severe thermal or chemical burns can cause scars resulting in ectropion or entropion of the lid and scarring of the conjunctiva and cul-de-sac.

► Clinical Findings

Eyelid burns can occur in toddlers from contact with a lighted cigarette. The cornea is often involved as well. Curling irons can cause similar burns. These burns usually heal following application of antibiotic ointment.

Burns of the conjunctiva and cornea may be thermal, radiant, or chemical. Radiant energy causes ultraviolet keratitis. Typical examples are welder's burn and burns associated with skiing without goggles in bright sunlight.

Chemical burns with strong acidic and alkaline agents can be blinding and constitute a true ocular emergency. Examples are burns caused by exploding batteries, spilled drain cleaner, and bleach.

Superficial thermal burns cause pain, tearing, and injection. Corneal epithelial defects can be diagnosed using fluorescein dye, which will stain areas of the cornea where the epithelium is absent. The fluorescein dye pattern will show a uniformly stippled appearance of the corneal epithelium in ultraviolet keratitis.

► Treatment

Management is with topical antibiotics and patching. A cycloplegic agent is added if corneal involvement is present, because pain from ciliary spasm and iritis may accompany the injury.

Alkalis tend to penetrate deeper than acids into ocular tissue. This results in damage to the conjunctival vessels which give the eye a white or blanched appearance. Immediate treatment consists of copious irrigation and removal of precipitates as soon as possible after the injury. The patient should be referred to an ophthalmologist after immediate first aid has been given.

HYPHEMA

Blunt trauma to the globe may cause a hyphema, or bleeding within the anterior chamber from a ruptured vessel located near the root of the iris or in the anterior chamber angle.

► Clinical Findings

A hyphema may be microscopic or may fill the entire anterior chamber (Figure 15-10). Blunt trauma severe enough to cause a hyphema may be associated with additional ocular injury, including iritis, lens subluxation, retinal edema or detachment, and glaucoma. In patients with sickle cell anemia or trait, even moderate elevations of intraocular pressure may quickly lead to optic atrophy and permanent vision loss. Therefore, all African Americans whose sickle cell status is unknown should be tested if hyphema is observed. These patients require extra vigilance in diagnosing and treating hyphema. Nontraumatic causes of hyphema include juvenile xanthogranuloma and blood dyscrasias. Rarely, hyphema is noted in the newborn after a stressful birth.

▲ **Figure 15-10.** Hyphema filling approximately 20% of the anterior chamber.

Slit-lamp examination or even penlight examination may reveal a layer of blood within the anterior chamber. Other injuries to the globe and orbit are often present.

► Treatment

A shield should be placed over the eye, the head elevated, and arrangements made for ophthalmologic referral.

NONACCIDENTAL TRAUMA & SHAKEN BABY SYNDROME

Shaken baby syndrome is a form of nonaccidental trauma characterized by a constellation of examination findings, including traumatic brain injury, retinal hemorrhages, and fractures of long bones or ribs. The history leading to the diagnosis of shaken baby syndrome is often vague and poorly correlated with the extent of injury.

► Clinical Findings

Victims often have multiple organ system involvement that includes, but is not limited to, traumatic brain injury, bone fractures and retinal hemorrhages. The presentation can vary from irritability to emesis, change in mental status, or cardiopulmonary arrest.

Neuroimaging of the brain as well as a skeletal survey are tools used to diagnose shaken baby syndrome. Ophthalmic consultation and a dilated retinal examination are necessary to document retinal hemorrhages. Hemorrhages may be unilateral or bilateral and may be located in the posterior pole or periphery. Whereas retinal hemorrhages tend to resolve fairly quickly, those in the vitreous do not. If a blood clot lies over the macula, deprivation amblyopia may occur and may require intraocular surgery by a retinal specialist. Other ocular findings associated with nonaccidental trauma include lid ecchymosis, subconjunctival hemorrhage, hyphema, retinal folds, retinoschisis, and optic nerve edema. Acute-onset esotropia can also occur.

► Differential Diagnosis

The diagnosis of shaken baby syndrome has obvious legal ramifications and is a subject of debate within the literature. The differential includes but is not limited to retinal hemorrhages secondary to a fall, seizures, chest compressions during cardiopulmonary resuscitation, blood dyscrasias, and Terson syndrome, among others. A team effort between the primary treating physician, neurosurgery, orthopedics, ophthalmology, and social services is often needed to determine the true cause of a patient's injuries.

► Treatment

Management of any systemic injuries is required. Observation by an ophthalmologist of retinal hemorrhages for resolution is the usual course of treatment. Vitreous hemor-

rhages or large preretinal hemorrhages that do not resolve within several weeks may need surgical treatment by a retinal specialist.

PREVENTION OF OCULAR INJURIES

Air rifles, paintballs, and fireworks are responsible for many serious eye injuries in children. Golf injuries can be very severe. Bungee cords have been associated with multiple types of severe ocular trauma, including corneal abrasion, iris tears, hyphema, vitreous hemorrhage, retinal detachment, and blindness. Use of these items and associated activities should be avoided or very closely supervised. Safety goggles should be used in laboratories and industrial arts classes and when operating snow blowers, power lawn mowers, and power tools, or when using hammers and nails. Sports-related eye injuries can be prevented with protective eyewear. Sports goggles and visors of polycarbonate plastic will prevent injuries in games using fast projectiles such as tennis or racquet balls, or where opponents may swing elbows or poke at the eye.

The one-eyed individual should be specifically advised to always wear polycarbonate eyeglasses and goggles for all sports. High-risk activities such as boxing and the martial arts should be avoided by one-eyed children.

DISORDERS OF THE OCULAR STRUCTURES

DISEASES OF THE EYELIDS

The eyelids can be affected by various dermatologic and infectious conditions.

1. Blepharitis

Blepharitis is inflammation of the lid margin characterized by crusty debris at the base of the lashes; varying degrees of erythema at the lid margins; and in severe cases, secondary corneal changes such as punctate erosions, vascularization, and ulcers. When conjunctival injection accompanies blepharitis, the condition is known as blepharoconjunctivitis. *Sta-*

phylococcus is the most common bacterial cause. Treatment includes lid scrubs with a nonburning baby shampoo several times a week and application of a topical antibiotic ointment such as erythromycin or bacitracin at bedtime.

2. Rosacea

Rosacea can also occur in the pediatric age group and cause chronic blepharoconjunctivitis with corneal changes that decrease vision. Systemic antibiotics and local treatment are required.

3. Pediculosis

Pediculosis of the lids (phthiriasis palpebrarum) is caused by *Phthirus pubis*. Nits and adult lice can be seen on the eyelashes when viewed with appropriate magnification. Mechanical removal and application to the lid margins of phospholine iodide or 1% mercuric oxide ointment can be effective. Other bodily areas of involvement must also be treated if involved. Family members and contacts may also be infected (see Chapter 14).

4. Papillomavirus

Papillomavirus may infect the lid and conjunctiva. Warts may be recurrent, multiple, and difficult to treat. Treatment modalities include cryotherapy, cautery, carbon dioxide laser, and surgery.

5. Staphylococcal Infection

Localized staphylococcal infections of the glands of Zeis within the lid cause a sty (hordeolum) (Figure 15–11). When the infection coalesces and points internally or externally, it may discharge itself or require incision. The lesion is tender and red. Warm compresses help to hasten the acute process. Some practitioners prescribe a topical antibiotic ointment. Any coexisting blepharitis should be treated.

▲ **Figure 15-11.** Hordeolum and blepharitis, left upper lid.

A

B

▲ **Figure 15-12.** Chalazion. **A:** Right lower lid, external view. **B:** Right lower lid conjunctival surface.

6. Chalazion

A chalazion is an inflammation of the meibomian glands, which may produce a tender nodule over the tarsus of the upper or lower lid. In addition to localized erythema of the corresponding palpebral conjunctiva, there may be a yellow lipogranuloma (Figure 15–12). Treatment includes warm compresses for 10–15 minutes four times a day for up to 6 weeks. If incision and curettage are needed because the lesion is slow to resolve, the child will require a general anesthetic.

VIRAL LID DISEASE

Viral infections of the eyelids can result in eyelid vesicles or papules.

► Clinical Findings

Herpes simplex virus may involve the lids at the time of primary herpes simplex infection. Vesicular lesions with an erythematous base occur. Herpes zoster causes vesicular disease in association with a skin eruption in the dermatome of the ophthalmic branch of the trigeminal nerve. Molluscum

contagiosum lesions are typically umbilicated papules. If near the lid margin, the lesions may shed and cause conjunctivitis.

A vesicular rash is the most common sign of viral eyelid disease. Fluorescein dye should be administered topically to both eyes followed by examination with a cobalt blue light to determine if corneal or conjunctival involvement is present. Herpes simplex or herpes zoster can be diagnosed by rapid viral culture (24–48 hours) or detection of antigen in skin lesions (3 hours).

► Treatment

Primary herpes simplex blepharoconjunctivitis should be treated with systemic acyclovir (a liquid formulation is available), valacyclovir, or famciclovir. When either the conjunctiva or the cornea is involved, treatment should include topical 1% trifluridine or 3% vidarabine.

Treatment of ophthalmic herpes zoster with nucleoside analogues within 5 days after onset may reduce the morbidity. When vesicles are present on the tip of the nose with herpes zoster (Hutchinson sign), ocular involvement, including iritis, may develop. Impetigo is in the differential diagnosis of vesicular lid disease.

Molluscum contagiosum lesions may be treated with cautery or excision.

LID PTOSIS

Eyelid ptosis results in a droopy eyelid that may be unilateral or bilateral. If the pupil is obstructed, deprivation amblyopia may result.

► Clinical Findings

Ptosis—a droopy upper lid (Figure 15–13)—may be congenital or acquired but is usually congenital in children owing to a defective levator muscle. Other causes of ptosis are myasthenia gravis, lid injuries, third nerve palsy, and Horner syndrome (see next section). Ptosis may be associated with astigmatism and amblyopia.

An association sometimes seen with congenital ptosis is the Marcus Gunn jaw-winking phenomenon. Intermittent reduction of the ptosis occurs during mastication or sucking, due to

▲ **Figure 15–13.** Congenital ptosis of severe degree, left upper lid.

a synkinesis or simultaneous firing of either the external or internal pterygoid muscle (innervated by the trigeminal nerve) and the levator muscle (innervated by the oculomotor nerve).

► Treatment

Surgical correction is indicated for moderate to severe ptosis. Mild cases less often require operative management. Cosmesis may be better if surgery is delayed until most of the facial growth has occurred, usually around age 5 years.

HORNER SYNDROME

Horner syndrome, which may be congenital or acquired, presents with signs of unequal pupils (anisocoria), eyelid ptosis, iris heterochromia, and anhidrosis.

► Clinical Findings

Parents may notice unequal pupils or different colored eyes. Penlight examination of the eyes may reveal unequal pupils (anisocoria), iris heterochromia, and eyelid ptosis of the affected eye.

The ptosis is usually mild with a well-defined upper lid crease. This differentiates it from congenital ptosis, which typically has a poorly defined lid crease. Another key finding of congenital Horner syndrome is heterochromia of the two irides, with the lighter colored iris occurring on the same side as the lesion (Figure 15–14). Anhidrosis can occur in congenital and acquired cases. Of note, not all of the three signs must be present to make the diagnosis. The syndrome is caused by an abnormality or lesion to the sympathetic chain. The congenital variety is most commonly the result of birth trauma. Acquired cases may occur in children who have had cardiothoracic surgery, trauma, or brainstem vascular malformation. Most worrisome is a Horner syndrome caused by neuroblastoma of the sympathetic chain in the apical lung region. An excellent screening test for this is the spot urine vanillylmandelic acid/creatinine ratio.

Pharmacologic assessment of the pupils with topical cocaine and hydroxyamphetamine or epinephrine will help determine whether the Horner syndrome is due to a preganglionic or postganglionic lesion of the sympathetic chain. There are preliminary studies that suggest that topical apraclonidine may also be useful in the diagnosis of Horner syndrome. Physical examination, including palpation of the

▲ **Figure 15–14.** Congenital Horner syndrome. Ptosis, miosis, and heterochromia. Lighter colored iris is on the affected left side.

neck and abdomen for masses, and MRI of structures in the head, neck, chest, and abdomen should be considered.

▶ Treatment

Management of any underlying disease is required. The ptosis and vision should be monitored by an ophthalmologist.

Mahoney NR et al: Pediatric Horner syndrome: Etiologies and roles of imaging and urine studies to detect neuroblastoma and other responsible mass lesions. *Am J Ophthalmol* 2006;142:651 [PMID: 17011859].

EYELID TICS

Eyelid tics may occur as a transient phenomenon lasting several days to months. Although a tic may be an isolated finding in an otherwise healthy child, it may also occur in children with multiple tics, attention-deficit/hyperactivity disorder, or Tourette syndrome. Caffeine consumption may cause or exacerbate eyelid tics. If the disorder is a short-lived annoyance, no treatment is needed.

DISORDERS OF THE NASOLACRIMAL SYSTEM

NASOLACRIMAL DUCT OBSTRUCTION

Nasolacrimal obstruction occurs in up to 6% of infants. Most cases clear spontaneously during the first year. Obstruction in any part of the drainage system may result from incomplete canalization of the duct or membranous obstructions. Nasolacrimal obstruction may also occur in individuals with craniofacial abnormalities or amniotic band syndrome.

▶ Clinical Findings

Nasolacrimal duct obstruction presents with tearing and mucoid discharge from the affected eye. Signs and symptoms include tearing (epiphora), mucoid discharge especially in the morning, erythema of one or both lids, and conjunctivitis (Figure 15–15). Light sensitivity and blepharospasm suggest possible congenital glaucoma and warrant an urgent ophthalmic referral.

▶ Differential Diagnosis

The differential diagnosis of tearing includes nasolacrimal duct obstruction, congenital glaucoma, foreign bodies, nasal disorders, and in older children, allergies.

▶ Treatment

Massage over the nasolacrimal sac may empty debris from the nasolacrimal sac and may clear the obstruction, although the efficacy of massage in clearing nasolacrimal obstruction is debated. Cleansing the lids and medial can-

▲ **Figure 15-15.** Nasolacrimal obstruction, right eye. Mattering on upper and lower lids.

thal area decreases the likelihood of infection and irritation. Superinfection may occur, and treatment with topical antibiotics may help decrease the discharge. The mainstay of surgical treatment is probing, which is successful 80% or more of the time, but the success rate may decrease after the infant reaches 1 year of age. Other surgical procedures, including infraction of the inferior nasal turbinate, balloon dilation, and silicone tube intubation, may be necessary if probing fails. Much less often, dacryocystorhinostomy is required.

Casady DR et al: Stepwise treatment paradigm for congenital nasolacrimal duct obstruction. *Ophthalm Plast Reconstr Surg* 2006;22:243 [PMID: 16855492].

Lee DH et al: Success of simple probing and irrigation in patients with nasolacrimal duct obstruction and otitis media. *J AAPOS* 2005;9:192 [PMID: 15838451].

CONGENITAL DACRYOCYSTOCELE

Congenital dacryocystocele is thought to result from obstructions proximal and distal to the nasolacrimal sac. An intranasal duct cyst may be present beneath the inferior turbinate at the valve of Hasner. These cysts may be associated with respiratory distress. At birth, the nasolacrimal sac is distended and has a bluish hue that often leads to an erroneous diagnosis of hemangioma. The tense and swollen sac displaces the medial canthus superiorly (Figure 15–16). Massage and warm compresses are rarely effective. Repeated probing and endoscopic marsupialization of the intranasal cyst under general anesthesia may be required. Dacryocystitis and sepsis can result from dacryocystocele.

Becker BB: The treatment of congenital dacryocystocele. *Am J Ophthalmol* 2006;142:835 [PMID: 16989760].

▲ **Figure 15-16.** Congenital dacryocystocele on the left side. Raised, bluish discolored mass of enlarged nasolacrimal sac. Note superiorly displaced medial canthus.

DACRYOCYSTITIS

Dacryocystitis is an infection of the nasolacrimal sac and results in erythema and edema over the nasolacrimal sac.

Acute and chronic dacryocystitis are typically caused by bacteria that colonize the upper respiratory tract, such as *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Streptococcus viridans*, *Moraxella catarrhalis*, and *Haemophilus* species.

► Clinical Findings

Acute dacryocystitis presents with inflammation, swelling, tenderness, and pain over the lacrimal sac (located inferior to the medial canthal tendon). Fever may be present. The infection may point externally (Figure 15-17). A purulent discharge and tearing can be expected, because the cause of infection is almost always nasolacrimal obstruction.

Signs of chronic dacryocystitis are mucopurulent debris on the lids and lashes, tearing, injection of the palpebral conjunctiva, and reflux of pus at the puncta when pressure is applied over the sac. Chronic dacryocystitis and recurrent episodes of low-grade dacryocystitis are caused by nasolacrimal obstruction.

► Treatment

Treatment of severe acute dacryocystitis is with intravenous antibiotics after attempts at identifying the offending organism by culture and staining. Oral antibiotics can be tried in milder

▲ **Figure 15-17.** Acute dacryocystitis in an 11-week-old infant.

cases. Topical antibiotic administration is adjunctive and is also used with recurrent chronic infections. Warm compresses are beneficial. After the acute episode subsides—and in chronic cases—the nasolacrimal obstruction must be relieved surgically. If it cannot be drained via the intranasal portion of the nasolacrimal duct, external drainage may be necessary. This should be done as a last resort since a fistula may develop.

DISEASES OF THE CONJUNCTIVA

Conjunctivitis may be infectious, allergic, or associated with systemic disease. Trauma, irritation of the conjunctiva, and intraocular inflammation also can cause injection of conjunctival vessels that can be confused with conjunctivitis (Table 15-2).

OPHTHALMIA NEONATORUM

Ophthalmia neonatorum (conjunctivitis in the newborn) occurs during the first month of life. It may be due to inflammation resulting from silver nitrate prophylaxis given at birth, bacterial infection (gonococcal, staphylococcal, pneumococcal, or chlamydial), or viral infection. In developed countries, *Chlamydia* is the most common cause. Neonatal conjunctivitis may threaten vision if caused by *Neisseria gonorrhoeae*. Herpes simplex is a rare but serious cause of neonatal conjunctivitis, since it may indicate systemic herpes simplex infection.

► Clinical Findings

Ophthalmia neonatorum is characterized by redness and swelling of the lids and conjunctiva and by discharge (Figure 15-18). Gram staining, Giemsa staining for elementary bodies, polymerase chain reaction amplification for *Chlamydia* and herpes simplex virus, and bacterial and viral cultures aid in making an etiologic diagnosis.

► Prevention & Treatment

Although no single prophylactic medication can eliminate all cases of neonatal conjunctivitis, povidone-iodine may provide broader coverage against the organisms causing this disease than silver nitrate or erythromycin ointment. Silver nitrate is not effective against *Chlamydia*. The choice of prophylactic agent is often dictated by local epidemiology and cost considerations.

Treatment of these infections requires specific systemic antibiotics because they can cause serious infections in other organs. Specifically, *Chlamydia* can cause a delayed-onset pneumonitis. Parents should be examined and receive treatment when a sexually associated pathogen is present.

Darville T: Chlamydia trachomatis infections in neonates and young children. *Semin Pediatr Infect Dis* 2005;16:235 [PMID: 16210104].

Woods CR: Gonococcal infections in neonates and young children. *Semin Pediatr Infect Dis* 2005;16:258 [PMID: 16210106].

Table 15-2. Clinical and laboratory features of conjunctivitis.

	Viral	Bacterial	Chlamydial	Allergic
Itching	Minimal	Minimal	Minimal	Severe
Hyperemia	Generalized	Generalized	Generalized	Generalized
Tearing	Profuse	Moderate	Moderate	Moderate
Exudation	Minimal, mucoid	Profuse, purulent	Profuse; mucoid or mucopurulent	Minimal, slight mucus
Preauricular adenopathy	Common	Uncommon	Common in inclusion conjunctivitis	None
Stained conjunctival smears and scrapings	Lymphocytes, plasma cells, multinucleated giant cells, eosinophilic intranuclear inclusions	Neutrophils, bacteria	Neutrophils, plasma cells, basophilic intracytoplasmic inclusions	Eosinophils
Associated systemic signs and symptoms	Rash, sore throat, fever in some patients	Occasional fever, sore throat	Pneumonia in neonates	Variable—may or may not be present

Reprinted, with permission, from Riordan-Eva P, Whitcher J: *Vaughan & Asbury's General Ophthalmology*, 17th ed., McGraw-Hill, 2008.

BACTERIAL CONJUNCTIVITIS

► Clinical Findings & Differential Diagnosis

In general, bacterial conjunctivitis is accompanied by a purulent discharge, whereas viral infection produces a watery discharge. One or both eyes may be involved. Regional lymphadenopathy is not a common finding in bacterial conjunctivitis except in cases of oculoglandular syndrome due to *S aureus*, group A β -hemolytic streptococci, *Mycobacterium tuberculosis* or atypical mycobacteria, *Francisella tularensis* (the agent of tularemia), and *Bartonella henselae* (the agent of cat-scratch disease).

Children with bacterial conjunctivitis usually present with mucopurulent discharge and injection of the conjunctiva of one or both eyes, which may be associated with an upper respiratory infection. The differential diagnosis includes

viral or chlamydial infection, and allergic, chemical, or toxic reactions to agents accidentally instilled into the eyes. Table 15-2 outlines signs and symptoms that may help delineate the cause of conjunctivitis.

Common bacterial causes of conjunctivitis in older children include nontypable *Haemophilus* species, *S pneumoniae*, *M catarrhalis*, and *S aureus*.

► Treatment

If conjunctivitis is not associated with systemic illness, topical antibiotics such as erythromycin, polymyxin-bacitracin, sulfacetamide, tobramycin, and fluoroquinolones are adequate. Systemic therapy is recommended for conjunctivitis associated with *Chlamydia trachomatis*, *N gonorrhoeae*, and *N meningitidis*.

Silver LH et al: Clinical safety of moxifloxacin ophthalmic solution 0.5% (VIGAMOX) in pediatric and nonpediatric patients with bacterial conjunctivitis. *Surv Ophthalmol* 2005;50(Suppl 1):S55 [PMID: 16257311].

VIRAL CONJUNCTIVITIS

Adenovirus infection is often associated with pharyngitis, a follicular reaction and injection of the palpebral conjunctiva, and preauricular adenopathy (pharyngoconjunctival fever). Epidemics of adenoviral keratoconjunctivitis occur. Conjunctivitis can occur as part of an acute measles illness. Herpes simplex virus may cause conjunctivitis or blepharoconjunctivitis.

► Clinical Findings

Children with viral conjunctivitis usually present with injection of the conjunctiva of one or both eyes and watery ocular discharge; an upper respiratory infection is sometimes present. A vesicular rash involving the eyelids suggests herpes simplex virus.

▲ **Figure 15-18.** Ophthalmia neonatorum due to *Chlamydia trachomatis* infection in a 2-week-old infant. Note marked lid and conjunctival inflammation.

▶ Treatment

Treatment of adenovirus conjunctivitis is supportive. Children with presumed adenoviral keratoconjunctivitis are considered contagious 10–14 days from the day of onset. They should stay out of school and group activities as long as their eyes are red and tearing. Strict hand-washing precautions are recommended.

Herpes conjunctivitis can be treated with topical trifluridine 1% drops or 3% vidarabine ointment. Oral acyclovir may be used prophylactically in children to reduce recurrence of herpes simplex ocular disease or during the primary infection to decrease the duration and severity of the infection.

ALLERGIC CONJUNCTIVITIS

▶ Clinical Findings

In allergic conjunctivitis, the child has red and itchy eyes, may have a mucoid discharge, and often has other allergic symptoms such as sneezing and rhinitis. Vernal conjunctivitis is a seasonal form of allergic conjunctivitis occurring mostly in the spring and summer and is associated with tearing, itching, and a stringy discharge. Vernal allergic conjunctivitis is more common in males. Contact lens wear may induce a conjunctivitis that appears similar to the palpebral form of vernal conjunctivitis.

The diagnosis of allergic and vernal conjunctivitis is based predominantly on the history. Ocular itching is the major symptom of both conditions. Redness of the conjunctiva, tearing and discharge may be part of the history but need not be present on examination to make the diagnosis. Vernal conjunctivitis may present with giant cobblestone papillae (Figure 15–19) on the eyelid conjunctiva, nodules around the corneal limbus, and even sterile corneal ulcers.

▲ **Figure 15–19.** Vernal conjunctivitis. Cobblestone papillae in superior tarsal conjunctiva.

▶ Treatment

Topical ophthalmic solutions that combine both an antihistamine and mast cell stabilizers, including olopatadine 0.1%, epinastine HCl 0.05%, and ketotifen fumarate 0.025%, are very effective at treating allergic conjunctivitis. Other agents available include a combination topical vasoconstrictor plus an antihistamine (naphazoline antazoline), a nonsteroidal anti-inflammatory drug such as ketorolac tromethamine 0.5%, a mast cell stabilizer such as lodoxamide tromethamine 0.1%, or a corticosteroid such as prednisolone 0.125% (Table 15–3). Corticosteroids should be used with caution because their extended use causes glaucoma or cataracts in some patients.

Treatment of vernal conjunctivitis includes a mast cell stabilizer such as 4% cromolyn sodium or 0.1% lodoxamide tromethamine and limited use of a topical corticosteroid.

Abelson MB, Granet D: Ocular allergy in pediatric practice. *Curr Allergy Asthma Rep* 2006;6:306 [PMID: 16822383].

MUCOCUTANEOUS DISEASES

Systemic conditions affecting the skin or the oral and genitourinary mucosa often result in ocular involvement. Severe inflammation involving the conjunctiva may result in permanent scarring, eyelid malposition, and dry eye syndrome.

Conjunctivitis and conjunctival changes are associated with systemic syndromes, such as erythema multiforme (Stevens-Johnson syndrome; see Chapter 14), Reiter syndrome, and Kawasaki disease (see Chapter 19). The latter is also associated with iritis.

▶ Clinical Findings

With Stevens-Johnson syndrome, conjunctival changes include erythema, vesicular lesions that frequently rupture, and symblepharon (adhesions) between the raw edges of the bulbar (eye) and palpebral (lid) conjunctivae.

▶ Treatment

Management of conjunctivitis associated with mucocutaneous disease depends on its severity. Artificial tears and ointment provide comfort and a topical corticosteroid may help prevent adhesions and dry eye in severe cases. Lysis of adhesions or use of a scleral ring by an ophthalmologist may be required. Surgical treatment of severe cases of symblepharon with amniotic membrane grafts are under investigation. Topical cyclosporine may help decrease the inflammatory reaction that leads to the destruction of tear-producing glands and subsequent dry eye syndrome. Cycloplegic agents and topical corticosteroids are prescribed for iritis in Kawasaki disease.

Chang YS et al: Erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis: Acute ocular manifestations, causes, and management. *Cornea* 2007;26:123 [PMID: 17251797].

Table 15-3. Common ocular allergy medications.

Generic Name	Brand Name	Mechanism of Action	Side Effects	Dosage	Indications
Lodoxamide tromethamine 0.1%	Alomide	Mast cell stabilizer	Transient burning or stinging	1 drop 4 times daily—taper	Vernal keratoconjunctivitis
Cromolyn Na 4%	Crolom, Opticrom	Mast cell stabilizer	Transient burning or stinging	1 drop 4–6 times daily	Vernal keratoconjunctivitis
Olopatadine	Patanol	Mast cell stabilizer, H ₁ -receptor antagonist	Headache, burning or stinging	Twice daily (interval 6–8 h)	Itching due to allergic conjunctivitis
Ketorolac tromethamine 0.5%	Acular	Nonsteroidal anti-inflammatory drug	Transient burning or stinging	1 drop 4 times daily	Itching due to seasonal allergic conjunctivitis
Levocabastine HCl 0.05%	Livostin	H ₁ -receptor antagonist	Transient burning or stinging, headache	1 drop 4 times daily	Relief of symptoms of seasonal allergic conjunctivitis
Naphazoline HCl 0.1%	AK-Con, Naphcon, Opcon, Vasocon	Ocular decongestant, vasoconstrictor	Mydriasis, increased redness, irritation, discomfort, punctate keratitis, increased intraocular pressure, dizziness, headache, nausea, nervousness, hypertension, weakness, cardiac effects, hyperglycemia	Varies by preparation	Temporary relief of redness due to minor eye irritants
Pheniramine maleate	Component in AKCon A, Opcon-A, Naphcon-A	Antihistamine		1 drop every 3–4 h, as needed	Relief of symptoms of seasonal allergic conjunctivitis

DISORDERS OF THE IRIS

IRIS COLOBOMA

Iris coloboma is a developmental defect due to incomplete closure of the anterior embryonal fissure. The child's pupil has an elongated shape reminiscent of a keyhole or cat's eye (Figure 15–20). The effect on visual acuity is variable. Iris coloboma may occur as an isolated defect or in association

▲ **Figure 15-20.** Iris coloboma located inferiorly.

with various chromosomal abnormalities and syndromes. Variable genetic expression of colobomas can include a broad spectrum, from iris coloboma, to microphthalmia-with-cyst, and clinical anophthalmia.

► Clinical Findings

Penlight examination of the pupils reveals a keyhole shape to the pupil rather than the normal round configuration. A dilated examination by an ophthalmologist is necessary to determine if the coloboma involves additional structures of the eye including the retina. If the retina is involved, vision may be poor. A genetic evaluation is usually recommended due to the high rate of associated genetic syndromes.

► Treatment

Patients with coloboma should be monitored by an ophthalmologist for signs of amblyopia, significant refractive errors, and strabismus. Rarely, if the retina is involved, detachment may occur requiring surgical intervention by a retinal specialist.

ANIRIDIA

Aniridia is a bilateral disorder that results in the absence of almost all of the iris (Figure 15–21). Cataract, corneal changes, macular hypoplasia, and glaucoma are often seen. Aniridia

▲ **Figure 15-21.** Bilateral aniridia. Iris remnants present temporally in each eye.

may occur as an autosomal dominant disease or in a sporadic form associated with Wilms tumor. The aniridia gene is located within the 11p13 chromosome region. Aniridia, genitourinary abnormalities, and mental retardation have been linked to an 11p deletion.

▶ Clinical Findings

Photophobia, nystagmus, and poor vision are present in aniridia. Abdominal ultrasonography is indicated in the sporadic form of aniridia to diagnose Wilms tumor. Genetic evaluation is indicated, as well.

▶ Treatment

An ophthalmologist should determine if cataracts or glaucoma are present in patients with aniridia. Surgical treatment is often indicated. If Wilms tumor is present, treatment by an oncologist is necessary.

ALBINISM

Albinism is caused by defective melanogenesis, usually as an autosomal recessive disease, but an X-linked form does occur. Tyrosinase is an essential enzyme in the production of melanin. Many cases of complete albinism are caused by mutations of the tyrosinase gene. Albinism with some pigment production, especially in people of African descent, is more commonly caused by mutations of the *p* gene.

▶ Clinical Findings

Affected individuals are usually legally blind and have nystagmus (see later section on Nystagmus). Iris, skin, and hair color vary with the type and severity of albinism as well as the individual's race. Iris transillumination is abnormal transmission of light through an iris with decreased pigment. This may be obvious or may require slit-lamp examination with retroillumination to detect focal areas of trans-illumination. Other ocular abnormalities include foveal hypoplasia, abnormal optic pathway projections, strabismus, and poor stereoacuity.

Albinism may be associated with other systemic manifestations. Bleeding problems occur in individuals with Her-

mansky-Pudlak syndrome (chromosome 10q23 or 5q13), in which oculocutaneous albinism is associated with a platelet abnormality. Chédiak-Higashi syndrome (chromosome 1q42–44) is characterized by neutrophil defects, recurrent infections, and oculocutaneous albinism. Other conditions associated with albinism are Waardenburg, Prader-Willi, and Angelman syndromes.

▶ Treatment

Children with albinism should be evaluated by a pediatric ophthalmologist in order to optimize their visual function. Low-vision aids such as telescopes, stand magnifiers, and large-print books are often required. Vision teachers in schools as well as ophthalmic specialists trained in treating low-vision patients can help increase the patient's ability to perform activities of daily living and function within society. Parents and patients must be advised to use sunscreen and wear protective clothing to help prevent skin cancer.

OTHER IRIS CONDITIONS

Heterochromia, or a difference in iris color, can occur in congenital Horner syndrome, after iritis, or with tumors and nevi of the iris and use of topical prostaglandins. Malignant melanoma of the iris may also cause iris heterochromia. Acquired iris nodules (Lisch nodules), which occur in type 1 neurofibromatosis, usually become apparent by age 8 years. When seen on slit-lamp examination, Lisch nodules are 1–2 mm in diameter and often beige in color, although their appearance can vary. Iris xanthogranuloma occurring with juvenile xanthogranuloma can cause hyphema and glaucoma. Patients with juvenile xanthogranuloma should be evaluated by an ophthalmologist for ocular involvement.

Ward et al: Neurofibromatosis 1: From lab bench to clinic. *Pediatr Neurol* 2005;32:221 [PMID: 15797177].

GLAUCOMA

▶ General Considerations

Glaucoma is caused by increased intraocular pressure and results in vision loss due to optic nerve injury, corneal scarring, and amblyopia. Pediatric glaucoma can be congenital or acquired, pupillary block or angle closure, and unilateral or bilateral. Glaucoma can be classified on an anatomic basis into two types: open-angle and closed-angle. In children, precipitation of angle-closure glaucoma by dilating the pupil of an otherwise healthy eye is a very rare occurrence.

Glaucoma also occurs with ocular and systemic syndromes. Aniridia and anterior segment dysgenesis are examples. Systemic syndromes associated with glaucoma include Sturge-Weber syndrome, the oculocerebrorenal syndrome of Lowe, and the Pierre Robin syndrome. Glaucoma can also

occur with hyphema, iritis, lens dislocation, intraocular tumor, and retinopathy of prematurity.

► Clinical Findings

Signs of glaucoma presenting within the first year of life include buphthalmos (enlargement of the globe due to low scleral rigidity in the infant eye) as well as tearing, photophobia, blepharospasm, corneal clouding due to edema, and optic nerve cupping. After age 3 years, usually only optic nerve changes occur. Findings may be unilateral or bilateral. In general, a red, inflamed eye is not typical of congenital or infantile glaucoma.

Sudden eye pain, redness, corneal clouding, and vision loss suggests possible pupillary block or angle-closure glaucoma. Urgent referral to an ophthalmologist is indicated. Genetic evaluation should be completed if other systemic abnormalities are noted.

► Treatment

Treatment depends on the cause, but surgery is often indicated. Topical medications, which are available to help decrease the intraocular pressure, have limited success in pediatric glaucoma.

Tanimoto SA, Brandt JD: Options in pediatric glaucoma after angle surgery has failed. *Curr Opin Ophthalmol* 2006;17:132 [PMID: 16552247].

UVEITIS

Inflammation of the uveal tract can be subdivided according to the uveal tissue primarily involved (iris, choroid, or retina) or by location (anterior, intermediate, or posterior uveitis). Perhaps the most commonly diagnosed form of uveitis in childhood is traumatic iridocyclitis or iritis.

ANTERIOR UVEITIS

Iridocyclitis associated with juvenile rheumatoid arthritis occurs most often in girls with pauciarticular arthritis and a positive antinuclear antibody test. Inflammatory bowel disease is also associated with iritis—perhaps more commonly with Crohn disease than with ulcerative colitis. Other causes of anterior uveitis in children include syphilis, tuberculosis, sarcoidosis, relapsing fever (borreliosis), and Lyme disease, all but the last also causing posterior uveitis. Juvenile spondyloarthropathies, including ankylosing spondylitis, Reiter syndrome, and psoriatic arthritis, are also associated with anterior uveitis. A substantial percentage of cases are of unknown origin.

► Clinical Findings

Injection, photophobia, pain, and blurred vision usually accompany iritis (anterior uveitis or iridocyclitis). An exception to this is iritis associated with juvenile rheumatoid arthritis (see Chapter 27). The eye in such cases is quiet and asymptomatic, but slit-lamp examination reveals anterior chamber inflammation with inflammatory cells and protein flare. Children with juvenile rheumatoid arthritis should be screened according to a schedule recommended by the American Academy of Pediatrics (<http://www.aap.org>). Children with Crohn disease or ulcerative colitis should have routine periodic ophthalmologic examinations to detect ocular inflammation, which may be asymptomatic, and cataracts associated with use of systemic corticosteroids.

Other ocular findings of the anterior segment include conjunctivitis, episcleritis, and sterile corneal infiltrates. Posterior segment findings may include central serous retinopathy, panuveitis (inflammation of all uveal tissue), choroiditis, ischemic optic neuropathy, retinal vasculitis, neuroretinitis, and intermediate uveitis (see later section on Intermediate Uveitis).

Posterior subcapsular cataracts can develop in patients with or without ocular inflammation. Most, if not all, of these patients have been taking corticosteroids as part of the long-term treatment of their autoimmune disease.

► Treatment

Treatment with a topical corticosteroid and a cycloplegic agent is aimed at quieting the inflammation and preventing or delaying the onset of cataract and glaucoma. Methotrexate and other immunosuppressive agents can be used in refractory cases.

Levy-Clarke GA et al: Management of chronic pediatric uveitis.

Curr Opin Ophthalmol 2005;16:281 [PMID: 16175040].

Reiff A: Ocular complications of childhood rheumatic diseases: Uveitis. *Curr Rheumatol Rep* 2006;8:459 [PMID: 17152145].

POSTERIOR UVEITIS

The terms *choroiditis*, *retinitis*, and *retinochoroiditis* denote the tissue layers primarily involved in posterior uveitis. Infectious agents are the most common cause of posterior uveitis in the pediatric population.

► Clinical Findings

Children with posterior uveitis often present with systemic manifestations of a congenital infection. Examples include deafness, developmental delay, cataracts, “salt and pepper” retinopathy, and cardiac disorders seen in congenital rubella.

Serologic analysis and retinal examination by an ophthalmologist are used to identify the cause of posterior uveitis. Active toxoplasmosis (see Chapter 41) produces a white lesion appearing as a “headlight in the fog” owing to the

overlying vitreitis. Inactive lesions have a hyperpigmented border. Contiguous white satellite lesions suggest reactivation of disease.

A granular “salt and pepper” retinopathy is characteristic of congenital rubella. In infants, the TORCH complex (toxoplasmosis, other infections, rubella, cytomegalovirus [CMV], and herpes simplex virus) and syphilis must be suspected in congenital infections that cause chorioretinitis.

Congenital lymphocytic choriomeningitis is diagnosed by immunofluorescent antibody or enzyme-linked immunosorbent assay serologic testing. Congenital lymphocytic choriomeningitis virus may also present with chorioretinitis. The virus is transmitted to humans by consumption of food contaminated with rodent urine or feces. It most closely resembles congenital toxoplasmosis in presentation. If possible, pregnant women should avoid exposure to rodents.

Ocular candidiasis occurs typically in an immunocompromised host or an infant in the intensive care nursery receiving hyperalimentation. Candidal chorioretinitis appears as multifocal, whitish yellow, fluffy retinal lesions that may spread into the vitreous and produce a so-called cotton or fungus ball vitreitis.

Acute retinal necrosis syndrome is caused most often by varicella-zoster virus and occasionally by herpes simplex virus. Patients may present with vision loss and a red and painful eye. Ophthalmoscopy may show unilateral or bilateral patchy white areas of retina, arterial sheathing, vitreous haze, atrophic retinal scars, retinal detachment, and optic nerve involvement.

CMV infection must be considered as a cause of retinitis in immunocompromised and HIV-infected children. CMV retinitis appears as a white retinal lesion, typically but not always associated with hemorrhage, or as a granular, indolent-appearing lesion with hemorrhage and a white periphery. Cotton-wool spots (nerve fiber layer infarcts) also commonly occur in HIV-positive patients.

In toddlers and older youngsters, *Toxocara canis* or *T cati* infections (ocular larva migrans; see Chapter 41) occur from ingesting soil contaminated with parasite eggs. The disease is usually unilateral. Common signs and symptoms include a red injected eye, leukocoria, and decreased vision. Fundoscopic examination may show endophthalmitis (vitreous abscess) or localized granuloma. Diagnosis is based on the appearance of the lesion and serologic testing using enzyme-linked immunosorbent assay for *T canis* and *T cati*.

► Treatment

Congenital toxoplasmosis infections must be treated with a triple drug regimen (see Chapter 41). Studies have shown improved ophthalmic and neurologic outcomes with prolonged treatment. Other infectious agents such as *Candida*, varicella, and CMV may require systemic and intraocular injections of antimicrobial agents as well as retinal surgery. Treatment of toxocariasis includes periocular corticosteroid

injections and vitrectomy. The prognosis for vision depends on the severity of retinal and systemic involvement.

Chung H et al: Retinal complications in patients with solid organ or bone marrow transplantations. *Transplantation* 2007;83:694 [PMID: 17414700].

INTERMEDIATE UVEITIS

Pars planitis, often of uncertain cause, can be associated with vitreous floaters. The inflammation is described as snowbanking because a heaped-up white precipitate is located in the far anterior periphery of the retina and vitreous base.

► Clinical Findings

Patients with pars planitis often complain of decreased vision and floaters. They may also have a history of a red eye and ocular discomfort. Patients with intermediate uveitis often have decreased vision. A prolonged duration of the disease can lead to deprivation amblyopia and strabismus.

A dilated examination is required for observation of inflammation and snowbanking of the pars plana and vitreitis. Slit-lamp and dilated fundoscopic examination by an ophthalmologist often reveal chronic signs of inflammation associated with intermediate uveitis, including macular edema, cataracts, increased intraocular pressure, irregular pupil, iris adhesion to the lens, and band keratopathy.

Intermediate uveitis is often idiopathic although there are several other etiologies worth investigating. *Toxocara* infections with peripheral granuloma can be associated with intermediate uveitis, as can inflammatory bowel disease, multiple sclerosis, and sarcoidosis. Retinoblastoma and other neoplasms can imitate uveitis, causing a so-called masquerade syndrome.

► Treatment

The most common treatment regimen for intermediate uveitis includes subtenon steroid injections, vitrectomy by a retinal surgeon, and systemic immunosuppression. Secondary glaucoma often requires tube shunt surgery. The prognosis depends on the severity of the disease and associated secondary complications such as glaucoma and cataracts.

OCULAR MANIFESTATIONS OF ACQUIRED IMMUNODEFICIENCY SYNDROME

Ocular infections are important manifestations of AIDS (see Chapter 39). As CD4 T-lymphocyte counts fall below 200/ μ L, opportunistic infections increase in these patients. Pathogens commonly causing eye infection include CMV and varicella-zoster virus. Acute retinal necrosis syndrome (see earlier section on Posterior Uveitis) is a severe necrotizing retinitis that often results in blindness in patients with AIDS. Most

cases are thought to be caused by varicella-zoster virus. Other implicated agents are herpes simplex types 1 and 2.

Patients with CD4 counts below 50/ μ L are at high risk for CMV retinitis and should have a complete ocular evaluation by an ophthalmologist. Various retinal abnormalities include cotton-wool spots, retinal hemorrhages, microaneurysms, perivasculitis, and decreased visual acuity from ischemic maculopathy.

► Treatment

Therapy with antiviral agents is required, but the prognosis is poor. Active CMV retinitis must be treated with intravenous antiviral therapy. Ganciclovir is the usual initial therapy; foscarnet may be required if resistance develops. Intravitreal ganciclovir or ganciclovir implants in conjunction with oral valganciclovir may be required in severe cases or in individuals intolerant to intravenous therapy. The incidence of CMV retinitis has fallen dramatically with the use of multidrug antiretroviral therapy.

Thorne JE et al: Studies of Ocular Complications of AIDS Research Group. Effect of cytomegalovirus retinitis on the risk of visual acuity loss among patients with AIDS. *Ophthalmology* 2007;114:591 [PMID: 17123624].

DISORDERS OF THE CORNEA

CONDITIONS CAUSING CORNEAL CLOUDING

Corneal clouding can be caused by developmental abnormalities, metabolic disorders, trauma and infection.

► Clinical Findings

Corneal clouding, tearing, blepharospasm, and photophobia in a newborn are signs of congenital glaucoma until proven otherwise. Direct trauma to the cornea during a forceps delivery can result in corneal haze and significant amblyopia. Systemic abnormalities such as developmental delay and liver or kidney failure suggest metabolic disorders such as mucopolysaccharidoses, Wilson disease, and cystinosis. Corneal infiltrates occur with viral infections, staphylococcal lid disease, corneal dystrophies, and interstitial keratitis due to congenital syphilis.

A complete ocular evaluation by an ophthalmologist is required and should be completed urgently when congenital glaucoma is suspected.

► Treatment

Treatment depends on the underlying condition. Surgical treatment of glaucoma and possible corneal transplantation may be required.

MICROCORNEA & MEGALOCORNEA

Microcornea—a corneal diameter less than 10 mm in a full-term infant or older child—may be associated with other anterior segment malformations or a microphthalmic globe. Megalocornea—diameter of 12.5 mm or greater—should be regarded as due to congenital glaucoma until proved otherwise.

VIRAL KERATITIS

Herpes simplex, herpes zoster, and adenovirus can all infect the cornea. When the epithelium breaks down, a dendritic or amoeboid pattern can be seen with fluorescein staining. Corneal involvement with herpes simplex can be recurrent and lead to blindness.

► Clinical Findings

Patients commonly present with a painful, red eye. Photophobia and decreased vision are also common complaints. Fever, malaise, and symptoms of upper respiratory tract infection may be present.

Fluorescein administration to the involved cornea will reveal areas of staining when viewed with a blue light. Decreased visual acuity, photophobia, and conjunctivitis may also be noted. Slit-lamp examination may reveal white infiltrates beneath the corneal epithelium.

► Treatment

Topical antivirals such as trifluridine and vidarabine are indicated when herpes simplex infection is limited to the corneal epithelium, although additional systemic therapy is required in newborns. Topical corticosteroids may be a useful addition to antiviral therapy when stromal disease is present. The use of corticosteroids in the presence of herpetic disease should be undertaken only by an ophthalmologist because of the danger of worsening the disease. Oral acyclovir started in the early phase (first 5 days) may be helpful in treating herpes zoster eye disease. Acyclovir prophylaxis is helpful in preventing recurrent herpetic epithelial keratitis (see earlier section on Viral Conjunctivitis) and stromal keratitis caused by herpes simplex.

Adenovirus conjunctivitis may progress to keratitis 1–2 weeks after onset. Vision may be decreased. In most cases no treatment is necessary because adenovirus keratitis is most often self-limiting. However, adenovirus is highly contagious and easily spread (see section on Viral Conjunctivitis).

CORNEAL ULCERS

Bacterial corneal ulcers in healthy children who are not contact lens wearers are usually secondary to corneal trauma from corneal abrasion or a penetrating foreign body. Decreased vision, pain, injection, a white corneal infiltrate or ulcer (Figure 15–22), and hypopyon (pus in the anterior

▲ **Figure 15-22.** Corneal ulcer. Note white infiltrate located on inferior cornea.

chamber) may all be present. Prompt referral to an ophthalmologist is necessary for culture and antibiotic treatment.

DISORDERS OF THE LENS

Lens disorders involve abnormality of clarity or position. Lens opacification (cataract) can affect vision depending on its density, size, and position. Visual potential is also influenced by age at onset and the success of amblyopia treatment.

CATARACTS

Cataracts in children may be unilateral or bilateral, may exist as isolated defects, or may be accompanied by other ocular disorders or systemic disease (Figure 15-23).

► Clinical Findings

A. Symptoms and Signs

Leukocoria, poor fixation, and strabismus or nystagmus (or both) may be the presenting complaints. Absence of a red

▲ **Figure 15-23.** Cataract causing leukocoria.

reflex in the newborn should suggest the possibility of cataract, especially if the pupil has been dilated for the examination. This requires an urgent referral to an ophthalmologist.

B. Laboratory Findings

Laboratory investigation for infectious and metabolic causes of congenital cataracts is often indicated. Such investigation would include cultures or serologic tests for toxoplasmosis, rubella, CMV, herpes simplex virus, and syphilis, as well as evaluation for metabolic errors, such as occur with galactosemia or Lowe syndrome.

► Treatment

Early diagnosis and treatment are necessary to prevent deprivation amblyopia in children younger than age 9 years, because they are visually immature. Cataracts that are visually significant require removal. Visually significant cataracts in infants are usually removed prior to 6 weeks of age to prevent deprivation amblyopia. Rehabilitation with an intraocular lens is commonplace, especially with cataracts removed after the age of 2 years. But contact lenses and glasses still play a role, as does occlusion of the better-seeing eye to treat the amblyopia.

Forbes BJ, Guo S: Update on the surgical management of pediatric cataracts. *J Pediatr Ophthalmol Strabismus* 2006;43:143 [PMID: 16761634].

Vasavada AR, Nihalani BR: Pediatric cataract surgery. *Curr Opin Ophthalmol* 2006;17:54 [PMID: 16436925].

DISLOCATED LENSES

Nontraumatic lens dislocation is usually bilateral. Subluxation causes refractive errors of large magnitude that are difficult to correct. Another ophthalmologic concern is pupillary block glaucoma, in which a malpositioned unstable lens interferes with the normal flow of aqueous humor from the ciliary body (posterior to the pupil), where it is produced, into the trabecular meshwork (anterior to the pupillary plane).

► Clinical Findings

Slit-lamp examination reveals malposition of the intraocular lens. Refraction often reveals significant astigmatism. Systemic diseases including Marfan syndrome, homocystinuria, Weill-Marchesani syndrome, sulfite oxidase deficiency, hyperlysinemia, syphilis, and Ehlers-Danlos syndrome are often associated with dislocated lenses. A complete ophthalmic evaluation, as well as genetic and metabolic evaluation, may be necessary.

► Treatment

Surgical lensectomy may be required if the visual acuity is not improved significantly with glasses or contact lenses.

Underlying metabolic and or genetic disorders require a multidisciplinary approach.

DISORDERS OF THE RETINA

RETINAL HEMORRHAGES IN THE NEWBORN

Retinal hemorrhages are commonly seen in the otherwise healthy newborn. Retinal hemorrhages occur most often after vaginal delivery but can also be present after suction delivery or cesarean section.

► Clinical Findings

A dilated retinal examination reveals unilateral or bilateral hemorrhages that can be located anywhere in the retina. They may appear as dot, blot, subretinal, or preretinal hemorrhages. They may also break into the vitreous.

► Treatment

In general, retinal hemorrhages of the newborn disappear quickly, usually within the first month of life, which may help differentiate this condition from retinal hemorrhages that occur in the shaken baby syndrome. Retinal hemorrhages also occur in association with coagulopathy.

RETINOPATHY OF PREMATURITY

Retinopathy of prematurity (ROP) continues to be an important cause of blindness, especially for infants born before 28 weeks' gestation and weighing less than 1250 g. Premature infants with incomplete retinal vascularization are at risk for developing abnormal peripheral retinal vascularization, which may lead to retinal detachment. However, most cases of ROP do not progress to retinal detachment and require no treatment.

► Pathogenesis

The risk of developing visually threatening ROP is inversely proportional to birth weight and gestational age. Infants weighing less than 1500 g at birth or born at less than 33 weeks' gestation may develop visually threatening ROP. The cause of this disorder—including the role of supplemental oxygen in the neonatal period—is still not fully understood. Other risk factors for severe ROP are bronchopulmonary dysplasia, intraventricular hemorrhage, sepsis, apnea and bradycardia, and mutations of the Norrie disease gene. White males, infants with zone 1 disease, and infants with very low birth weight and gestational age have a higher risk of reaching threshold.

Recent studies suggest that vascular endothelial growth factor may play a key role in ROP development, and methods of modulating it are being investigated.

Table 15-4. Stages of retinopathy of prematurity.

Stage I	Demarcation line or border dividing the vascular from the avascular retina.
Stage II	Ridge. Line of stage I acquires volume and rises above the surface retina to become a ridge.
Stage III	Ridge with extraretinal fibrovascular proliferation.
Stage IV	Subtotal retinal detachment.
Stage V	Total retinal detachment.

► Clinical Findings

The Cryotherapy for Retinopathy of Prematurity (CRYO-ROP) study outlined a standard nomenclature to describe the progression and severity of ROP (Table 15-4). Since retinal blood vessels emanate from the optic nerve and do not fully cover the developing retina until term, the optic nerve is used as the central landmark. The most immature zone of retina, zone 1, is the most posterior concentric imaginary circle around the optic nerve. Further out is zone 2, and beyond that is zone 3. Zone 1 disease is by definition more high-risk than disease in more anterior zones. Similarly, the stages of the abnormal vessels are numbered from zero, or simply incomplete vascularization, through stages I–V. When five contiguous or eight noncontiguous clock hours of stage III disease occur, “threshold” has been reached. At this stage in the CRYO-ROP study, 50% of eyes had a bad outcome without treatment, progressing to stage IV or V. This was therefore chosen as the stage for mandatory treatment. “Plus disease” (+) refers to dilation and tortuosity of the vessels around the optic nerve and is an ominous sign of active, worsening ROP. “Rush disease” refers to cases in which the disease skips intervening stages and goes rapidly to retinal detachment.

Screening guidelines recommend the first retinal examination by an ophthalmologist be done at age 4–6 weeks after birth, or 31 weeks' postconception, whichever is earlier. The frequency of follow-up examinations depends on the findings and the risk factors for developing the disease. Most infants are evaluated every 1–2 weeks. ROP often resolves when the infant reaches 40 weeks' estimated gestational age. Examinations can be discontinued when the retinas are fully vascularized, or when the infant is 45 weeks' gestational age and has never had prethreshold disease or worse, or is vascularized out to zone 3 and never had zone 1 or 2 disease.

► Treatment

The treatment of threshold ROP within 72 hours of diagnosis can reduce the occurrence of bad visual outcomes by 50%. Diode laser treatment has largely replaced cryotherapy because it provides better access for treating zone 1 disease and causes less inflammation. However, some patients still

progress to a retinal detachment, which can have a very poor prognosis for vision. Surgical treatment for a retinal detachment involves scleral buckling or a lens-sparing vitrectomy by an ophthalmologist specializing in vitreoretinal surgery.

With smaller, sicker infants surviving, treatment guidelines have been amended to treat earlier than threshold in some infants. The Early Treatment for Retinopathy of Prematurity (ETROP) studies showed that early treatment of high-risk prethreshold ROP significantly reduced unfavorable outcomes. Infants with zone 1 ROP are at the highest risk for complications from ROP. Studies investigating oxygen management and its influence on the progression of ROP are underway.

Children with a history of ROP require lifelong management by an ophthalmologist. They are at a much higher risk of developing strabismus, amblyopia, myopia, and glaucoma than the average child.

Drack A: Retinopathy of prematurity. *Adv Pediatr* 2006;53:211 [PMID: 17089868].

RETINOBLASTOMA

Retinoblastoma is the most common primary intraocular malignancy of childhood, with an incidence estimated between 1:17,000 and 1:34,000 live births (see Chapter 29). Most patients present before age 3 years; children with hereditary or bilateral retinoblastoma usually present earlier than those with unilateral, sporadic disease.

▶ Pathogenesis

Inherited forms of retinoblastoma are autosomal dominant with high penetrance. The disease may consist of a solitary mass or multiple tumors in one or both eyes. All bilateral cases and some unilateral cases are caused by germinal mutations; however, most unilateral cases are caused by a somatic retinal mutation. In both situations, the mutation occurs in the retinoblastoma gene (*Rb*) at chromosome 13q14. This is a tumor suppressor gene. One mutated copy may be inherited in an autosomal dominant fashion (germline mutation). If a second mutation spontaneously occurs in any cell, tumorigenesis is likely. Individuals with a germinal mutation are at risk for the development of tumors other than retinoblastoma (pineal tumors, osteosarcoma, and other soft tissue sarcomas). All children with unilateral or bilateral retinoblastoma must be presumed to have the germline form, and followed expectantly for other tumors in the remaining eye and at extraocular sites. Approximately 15% of patients with unilateral disease have germline mutations.

▶ Clinical Findings

A. Symptoms and Signs

The most common presenting sign in a child with previously undiagnosed retinoblastoma is leukocoria (see Figure 15–1).

Evaluation of the pupillary red reflex is important, although a normal red reflex does not rule out retinoblastoma. Examination requires indirect ophthalmoscopy with scleral depression and pupillary dilation, performed by an ophthalmologist. Other presentations include strabismus, red eye, glaucoma, or pseudo-hypopyon (appearance of puslike material in the anterior chamber).

B. Special Tests

Genetic testing is available for patients with retinoblastoma. Once the causative mutation is found in an affected individual, unaffected members of the family should be tested to determine their personal and reproductive risk. This will avoid many unnecessary examinations under anesthesia for young relatives of patients with retinoblastoma.

▶ Treatment

Treatment of unilateral cases, especially of large tumors, often requires enucleation, because at the time of presentation the eye is filled with tumor. Vision and eyes can be salvaged in some cases. Chemoreduction of intraocular tumors is a newer treatment technique used to reduce initial tumor volume. In conjunction with local treatment such as laser photocoagulation, cryotherapy, plaque radiotherapy, and thermotherapy, combined therapy can often preserve vision and spare the patient enucleation and radiation that may lead to disfigurement and the induction of secondary tumors, especially in eyes classified with less extensive disease. Agents used in chemoreduction include carboplatin, etoposide, and vincristine. Eradication of tumor before infiltration into the optic nerve or choroid carries a good prognosis for survival.

Linn Murphree A: Intraocular retinoblastoma: The case for a new group classification. *Ophthalmol Clin North Am* 2005;18:41 [PMID: 15763190].

Wilson WG: Retinoblastoma. *Pediatr Rev* 2007;28:37 [PMID: 17197460].

RETINAL DETACHMENT

Retinal detachment occurs infrequently in children. Common causes are trauma and high myopia. Other causes are ROP, Marfan syndrome, and Stickler syndrome.

▶ Clinical Findings

Symptoms of detachment are floaters, flashing lights, and loss of visual field; however, children often cannot appreciate or verbalize their symptoms. A detachment may not be discovered until the child is referred after failing a vision screening examination, strabismus supervenes, or leukocoria is noted.

► Treatment

Treatment of retinal detachment is surgical. For children with conditions predisposing to retinal detachment, or a strong family history, examinations under anesthesia by an ophthalmologist, with prophylactic laser treatment, are often recommended.

DIABETIC RETINOPATHY

Diabetic retinopathy is a specific vascular complication of diabetes mellitus. Patients with type 1, or insulin-dependent, diabetes are at higher risk of developing severe proliferative retinopathy leading to visual loss than are those with type 2, or non-insulin-dependent, diabetes.

► Clinical Findings

Acute onset of diabetes may be accompanied by sudden myopia and by cataracts. Sudden decreased vision in a diabetic patient may suggest the presence of severe ocular complications such as vitreous hemorrhage, macular edema, or retinal detachment.

In children older than age 9 years, referral to an ophthalmologist for screening of retinopathy should occur within 3–5 years after the onset of diabetes. Both conditions may be reversible with good glucose control. Young children with type 1 diabetes should be followed for the Wolfram, or DIDMOD, syndrome, in which diabetes mellitus occurs in conjunction with diabetes insipidus, optic atrophy, and deafness.

► Treatment

Severe proliferative diabetic retinopathy requires panretinal laser photocoagulation or vitreoretinal surgery (or both). Cataracts often require surgical removal and intraocular lens placement. Intraocular steroid injections have been used to treat macular edema in adults, but their role in children is not well established.

Huo B et al: Clinical outcomes and cost-effectiveness of retinopathy screening in youth with type 1 diabetes. *Diabetes Care* 2007;30:362 [PMID: 17259509].

DISEASES OF THE OPTIC NERVE

OPTIC NEUROPATHY

Optic nerve function is evaluated by checking visual acuity, color vision, pupillary response, and visual fields.

► Clinical Findings

Poor optic nerve function results in decreased central or peripheral vision, decreased color vision, strabismus, and nystagmus. Optic nerve disorders can be due to congenital malformation, malignancy, inflammation, infection, metabolic disorders, and trauma.

▲ **Figure 15-24.** Myelinization extending from optic nerve superiorly onto the retina.

The swinging flashlight test is used to assess function of each optic nerve. It is performed by shining a light alternately in front of each pupil to check for an afferent pupillary defect or Marcus Gunn pupillary defect. An abnormal response in the affected eye is pupillary dilation when the light is directed into that eye after having been shown in the other eye with its healthy optic nerve. This results from poorer conduction along the optic nerve of the affected eye, which in turn results in less pupillary constriction of both eyes than occurs when the light is shined into the noninvolved eye. Hippus—rhythmic dilating and constricting movements of the pupil—can be confused with an afferent pupillary defect.

The optic nerve is evaluated as to size, shape, color, and vascularity. Occasionally, myelinization past the entrance of the optic nerve head occurs. It appears white, with a feathered edge (Figure 15-24). Myelinization onto the retina can be associated with myopia and amblyopia. Anatomic defects of the optic nerve include colobomatous defects and pits.

► Treatment

Management of the underlying condition resulting in the optic neuropathy is necessary.

OPTIC NERVE HYPOPLASIA

Optic nerve hypoplasia may be associated with absence of the septum pellucidum and hypothalamic-pituitary dysfunction, which is known as septo-optic dysplasia, or de Morsier syndrome. Children with septo-optic dysplasia and hypocortisolism are at risk for sudden death during febrile illness.

from thermoregulatory disturbance and dehydration from diabetes insipidus.

Optic nerve hypoplasia may occur in infants of diabetic mothers and has also been associated with alcohol use or ingestion of quinine or phenytoin during pregnancy. Anatomically, the optic nerve may range from absent (aplasia) to almost full size, with a segmental defect. However, the nerve often appears larger than it is because it is surrounded by a depigmented halo.

► Clinical Findings

Visual function with optic nerve hypoplasia ranges from mildly decreased to absent light perception. If only one eye is involved, the child usually presents with strabismus. If both eyes are affected, nystagmus is usually the presenting sign. Ophthalmoscopy is performed to directly visualize the optic nerves and to determine the severity of the hypoplasia. Neuroimaging of the brain and endocrine consultation should be performed in all patients with bilateral optic nerve hypoplasia.

► Treatment

Sensory amblyopia and significant refractive errors should be treated by an ophthalmologist. Strabismus surgery may be necessary in certain patients. Endocrine abnormalities should be managed as necessary.

PAPILDEMA

Papilledema (optic disk edema or choked disk) is associated with increased intracranial pressure due to any cause, such as tumor or intracranial infection.

► Pathogenesis

Hydrocephalus and intracranial tumors are common causes of papilledema. In pseudotumor cerebri (idiopathic intracranial hypertension), neuroimaging is normal but papilledema, headaches, and pulsating tinnitus may be present. Papilledema occurs almost equally in boys and girls and sometimes is associated with obesity or upper respiratory tract infection. Other associated causes are viral infections, corticosteroid use and withdrawal, sinus infection, trauma, tetracycline use, growth hormone, and venous sinus thrombosis. Early in the course of the disorder, the patient may not notice a change in vision, although the blind spot may be enlarged. Transient obscuration of vision (amaurosis fugax) may occur as the process becomes more long-standing. Further effects on vision will occur as the papilledema becomes chronic and ultimately leads to optic atrophy. Workup and treatment are directed toward finding the underlying systemic or central nervous system (CNS) cause.

► Clinical Findings

Direct visualization of the optic nerve by ophthalmoscopy reveals an elevated disk with indistinct margins, increased

vessel diameter, and hyperemia. Hemorrhages and exudates are present in more severe cases. Observed changes may be subtle to striking. Optic nerve head changes are bilateral and generally symmetrical.

► Treatment

Treatment of idiopathic intracranial hypertension may be pharmacologic—for example, using acetazolamide, a carbonic anhydrase inhibitor, or a corticosteroid. Diagnostic lumbar puncture may also be curative. Optic nerve sheath fenestration and ventriculoperitoneal shunt are surgical interventions used when conservative measures fail.

Thuente DD et al: Pediatric optic nerve sheath decompression. *Ophthalmology* 2005;112:724 [PMID: 15808268].

PAPILLITIS

Papillitis is a form of optic neuritis seen on ophthalmoscopic examination as an inflamed optic nerve head. Optic neuritis in the pediatric age group may be idiopathic or associated with multiple sclerosis, acute disseminated encephalomyelitis, Devic disease, or cat-scratch disease.

► Clinical Findings

Papillitis may have the same appearance as papilledema. However, papillitis may be unilateral, whereas papilledema is almost always bilateral. Papillitis can be differentiated from papilledema by an afferent pupillary defect (Marcus Gunn pupil), by its greater effect in decreasing visual acuity and color vision, and by the presence of a central scotoma. Papilledema that is not yet chronic will not have as dramatic an effect on vision. Because increased intracranial pressure can cause both papilledema and a sixth (abducens) nerve palsy, papilledema can be differentiated from papillitis if esotropia and loss of abduction are also present. However, esotropia may also develop secondarily in an eye that has lost vision from papillitis. In pseudopapilledema (a normal variant of the optic disk), the disk appears elevated, with indistinct margins and a normal vascular pattern. Pseudopapilledema sometimes occurs in hyperopic individuals. Retrobulbar neuritis, an inflamed optic nerve, but with a normal-appearing nerve head, is associated with pain and the other findings of papillitis.

Workup of the patient with papillitis includes lumbar puncture and cerebrospinal fluid analysis. *B henselae* infection can be detected by serology. MRI is the preferred imaging study. An abnormal MRI is associated with a worse visual outcome.

► Treatment

Treatment of the underlying disease and use of systemic corticosteroids is necessary.

OPTIC ATROPHY

Optic atrophy is pallor of the optic nerve noted on ophthalmoscopy. Optic atrophy is found in children most frequently after neurologic compromise during the perinatal period. An example would be a premature infant who develops an intraventricular hemorrhage. Hydrocephalus, glioma of the optic nerve, craniosynostosis, certain neurologic diseases, and toxins such as methyl alcohol can cause optic atrophy, as can certain inborn errors of metabolism, long-standing papilledema, or papillitis.

► Clinical Findings

Direct examination of the optic nerve by ophthalmoscopy reveals an optic nerve head with a cream or white color and possibly cupping. Neuroimaging may be necessary to delineate CNS abnormalities.

► Treatment

Treatment of the underlying condition is indicated.

DISEASES OF THE ORBIT

PERIORBITAL & ORBITAL CELLULITIS

The fascia of the eyelids joins with the fibrous orbital septum to isolate the orbit from the lids. This septum serves as a barrier to the posterior spread of infection from preseptal infection. Infections arising anterior to the orbital septum are termed preseptal. Orbital cellulitis denotes infection posterior to the orbital septum and may cause serious complications, such as an acute ischemic optic neuropathy or cerebral abscess.

► Pathogenesis

Preseptal (periorbital) cellulitis, which indicates infection of the structures of the eyelid, is characterized by lid edema, erythema, swelling, pain, and mild fever. It usually arises from a local exogenous source such as an abrasion of the eyelid, from other infections (hordeolum, dacryocystitis, or chalazion), or from infected varicella or insect bite lesions. *Staphylococcus aureus* and *Streptococcus pyogenes* are the most common pathogens cultured from these sources. Preseptal infections in children younger than age 3 years also occur from bacteremia, although this is much less common since *Haemophilus influenzae* immunization became available. *Streptococcus pneumoniae* bacteremia is still an occasional cause of this infection. Children with periorbital cellulitis from presumed bacteremia must be examined for additional foci of infection.

Orbital cellulitis almost always arises from contiguous sinus infection, because the walls of three sinuses make up portions of the orbital walls and infection can breach these walls or extend by way of a richly anastomosing venous system. The

orbital contents can develop a phlegmon (orbital cellulitis), or frank pus can develop in the orbit (orbital abscess).

► Clinical Findings

Children with preseptal cellulitis often present with erythematous and edematous eyelids. The vision, eye movements and eye itself are normal. Decreased vision, restricted eye movements, and an afferent pupillary defect suggest orbital cellulitis.

Orbital cellulitis presents with signs of periorbital disease as well as proptosis (a protruding eye), restricted eye movement, and pain with eye movement. Fever is usually high. CT scanning or MRI is required to establish the extent of the infection within the orbit and sinuses. The pathogenic agents are those of acute or chronic sinusitis—respiratory flora and anaerobes. *S aureus* is also frequently implicated.

► Treatment

Therapy for preseptal and orbital cellulitis infection is with systemic antibiotics. Treatment of orbital infections may require surgical drainage for subperiosteal abscess in conjunction with intravenous antibiotics. Drainage of infected sinuses is often part of the therapy.

Hennemann S et al: Clinical inquiries. What is the best initial treatment for orbital cellulitis in children? *J Fam Pract* 2007;56:662 [PMID: 17669292].

CRANIOFACIAL ANOMALIES

Craniofacial anomalies can affect the orbit and visual system. Craniofacial anomalies occur with craniosynostoses and midface syndromes such as Treacher Collins and Pierre Robin syndromes. Fetal alcohol syndrome is associated with similar changes of the ocular adnexa.

► Clinical Finding

Ocular abnormalities associated with craniofacial disease involving the orbits include visual impairment, proptosis, corneal exposure, hypertelorism (widely spaced orbits), strabismus, amblyopia, lid coloboma, papilledema, and optic atrophy.

► Treatment

Orbital and ocular abnormalities associated with craniofacial anomalies often require a multispecialty approach. Management may require orbital and strabismus surgery. Ophthalmologists also treat amblyopia and corneal exposure if present.

▲ **Figure 15-25.** Right upper lid hemangioma causing ptosis.

ORBITAL TUMORS

Both benign and malignant orbital lesions occur in children. The most common benign tumor is capillary hemangioma (Figure 15-25). The most common primary malignant tumor of the orbit is rhabdomyosarcoma.

► Clinical Findings

Capillary hemangiomas may be located superficially in the lid or deep in the orbit and can cause ptosis, refractive errors, and amblyopia. Deeper lesions may cause proptosis. Capillary hemangiomas in infants initially increase in size before involuting at about age 2–4 years.

Orbital dermoid cysts vary in size and are usually found temporally at the brow and orbital rim or supranasally. These lesions are firm, well encapsulated, and mobile. Rupture of the cyst causes a severe inflammatory reaction.

Lymphangioma occurring in the orbit is typically poorly encapsulated, increases in size with upper respiratory infection, and is susceptible to hemorrhage. Other benign tumors of the orbit are orbital pseudotumor, neurofibroma, teratoma, and tumors arising from bone, connective tissue, and neural tissue.

Orbital rhabdomyosarcoma (see Chapter 29) grows rapidly and displaces the globe. The average age at onset is 6–7 years. The tumor is often initially mistaken for orbital swelling due to insignificant trauma.

Tumors metastatic to the orbit also occur; neuroblastoma is the most common. The patient may exhibit proptosis, orbital ecchymosis (raccoon eyes), Horner syndrome, or opsoclonus (dancing eyes). Ewing sarcoma, leukemia, Burkitt lymphoma, and the histiocytosis X group of diseases may involve the orbit.

Examination of vision, eye movements, eyelids, and orbits often reveals amblyopia, eyelid malposition, strabismus, and proptosis. Neuroimaging with CT or MRI is required to delineate the location and size of orbital tumors.

► Treatment

Therapy for capillary hemangiomas includes observation and intralesional or systemic corticosteroids. Treatment is indicated if the lesion is large enough to cause amblyopia.

Induced astigmatism or amblyopia (or both) are treated with glasses and patching respectively. Treatment of orbital dermoids is by excision.

Rhabdomyosarcoma is treated with radiation and chemotherapy after biopsy confirms the diagnosis. With expeditious diagnosis and proper treatment, the survival rate of patients with orbital rhabdomyosarcoma confined to the orbit approaches 90%.

Treatment of metastatic disease requires management by an oncologist and may require chemotherapy and radiation therapy.

NYSTAGMUS

Nystagmus is a rhythmic oscillation or jiggling of the eyes. It may be unilateral or bilateral, more pronounced in one eye, or gaze-dependent.

Nystagmus may be associated with esotropia or may occur with ocular lesions that cause deprivation amblyopia (eg, cataract and eyelid ptosis) or conditions in which the visual pathways are hypoplastic, sometimes referred to as “sensory nystagmus.” Nystagmus is seen with optic nerve hypoplasia, macular hypoplasia, aniridia, and albinism. Nystagmus can also occur with normal ocular structures and seemingly normal CNS development, sometimes referred to as “motor nystagmus.” In the latter instance, the nystagmus may be blocked in certain positions of gaze, in which case a face turn or torticollis may develop. Latent nystagmus occurs when one eye is occluded. This type of nystagmus occurs in patients with congenital esotropia. An associated amblyopia may be present.

Most nystagmus occurring in childhood is of ocular origin, but CNS disease and, less frequently, inner ear disease are other causes. A CNS cause is likely when the nystagmus is acquired. Patients should be referred to an ophthalmologist when nystagmus is observed.

► Clinical Findings

Evaluation of nystagmus begins with the pediatric ophthalmologist. Careful evaluation for iris transillumination defects caused by albinism should be performed.

An electroretinogram is usually required to rule out retinal pathology as the cause. Some types of nystagmus, usually motor nystagmus, can be treated, generally with surgery; less frequently, prisms are useful. Spasmus nutans,

in which a rapid, shimmering, dysconjugate nystagmus occurs with head bobbing and torticollis, usually improves with time. Glioma of the hypothalamus can mimic spasmus nutans. Neuroimaging may be necessary to determine if the cause of the nystagmus is due to a CNS disease.

► Treatment

Therapy is directed at managing the underlying ocular or CNS disease. An ophthalmologist can optimize vision by correcting significant refractive errors and strabismus. The range of vision varies depending on the cause of the nystagmus.

AMBLYOPIA & STRABISMUS

Visual development is a learned function. For it to proceed normally, a child must experience a normal visual environment with well-aligned eyes that are free of vision-threatening disease and significant refractive errors. The consequences of not meeting these requirements during the sensitive period of visual development in the first decade of life are strabismus and decreased vision, or amblyopia.

AMBLYOPIA

Amblyopia is a unilateral or bilateral reduction in central visual acuity due to the sensory deprivation of a well-formed retinal image that occurs with or without a visible organic lesion commensurate with the degree of visual loss. Amblyopia can occur only during the critical period of visual development in the first decade of life when the visual nervous system is plastic. Approximately 3% of the population is amblyopic.

Amblyopia is classified according to its cause. Strabismic amblyopia can occur in the nondominant eye of a strabismic child. Refractive amblyopia can occur in both eyes if significant refractive errors are untreated (ametropic or refractive amblyopia). Another type of refractive amblyopia can occur in the eye with the worse refractive error when imbalance is present between the eyes (anisometropic amblyopia). Deprivation amblyopia occurs when dense cataracts or complete ptosis prevents formation of a formed retinal image. Of the three types of amblyopia, the deprivation form of amblyopia results in the worst vision.

► Clinical Findings

Screening for amblyopia should be a component of periodic well-child examinations. The single best screening technique to discover amblyopia is obtaining visual acuity in each eye. In preverbal children unable to respond to visual acuity assessment, amblyogenic factors are sought, including strabismus, media opacities, unequal Brückner reflexes (pupillary red reflexes), and a family history suggestive of strabis-

mus, amblyopia, or ocular disease occurring in childhood (see earlier section on Ophthalmic Examination).

► Treatment

The earlier treatment is begun, the better will be the chance of improving visual acuity. Treatment is usually discontinued after age 9 years. Amblyogenic factors such as refractive errors are addressed. Because of the extreme sensitivity of the visual nervous system in infants, congenital cataracts and media opacities must be diagnosed and treated within the first few weeks of life. Visual rehabilitation and amblyopia treatment must then be started to foster visual development.

After eradicating amblyogenic factors, the mainstay of treatment is patching the sound eye, which causes the visual nervous system to process input from the amblyopic eye and in that way permits the development of useful vision. Other treatment modalities include “fogging” the sound eye with cycloplegic drops (atropine), lenses, and filters.
