Exposure to elemental mercury, as well as to most of its compounds, can best be monitored by the total levels of mercury in blood and urine. A difficulty in relying on the level of blood mercury for quantitatively evaluating an earlier exposure to mercury vapor is posed by the peak in the blood concentration that occurs 2–4 days after exposure; blood analyses after longer periods are therefore generally less informative. Another problem in evaluating mercury exposure especially from blood mercury levels arises from the likelihood of mercury release from tissues. Peaks of mercury concentration in urine after exposure appear and decline more slowly than in blood. Total mercury concentrations in urine following exposure to mercury vapor are of interest especially because of the oxidation of Hg^0 to Hg^{2+}; the latter accumulates primarily in the kidney, from which it may directly enter the urine (see section 2.4). The significance of exhaled Hg^0 following acute exposure may be confounded by the output from dental amalgam and by the possibility of the reduction of Hg^{2+} in the body.

Hair analysis has also proven useful, and reasonably good correlations have been observed between hair and blood mercury contents. Segmental analysis of scalp hair, growing at a rate of around 3 mm/week, can provide some indication of the history of exposure over relatively long periods. Hair analysis is particularly useful in providing evidence of exposure to methylmercury because this compound is incorporated into hair as such (see section 4). The estimation of mercury and its compounds is discussed in greater detail in section 2.3. In environmental or biological samples, as emphasized before, the interchangeability of the various chemical species of Hg makes total mercury levels more significant than those of elemental Hg.

Mercury vapor can pose health problems in occupational settings and also following, for instance, accidental breakage of such instruments as thermometers and barometers in the home or the use of mercury and mercurials for cosmetic, therapeutic, and other purposes. A major contribution of mercury from such sources at present results from the application of Hg amalgams in dental fillings. Urinary levels of mercury, ultimately derived from dental amalgams, have attained or even exceeded occupational health limits. To quote just one of many papers, urine collected from individuals carrying more than 36 dental amalgam restorations contained on the average 30 nmol Hg/L, compared to 6 nmol/L in the urine of control subjects without amalgams (12). According to WHO reports (7), occupational exposure to 50 mg Hg vapor/m^3 air increases the rate of urinary Hg excretion to more than 30 nmol/mmol creatinine. The potential internal Hg exposure due to dental amalgams may also be judged by the report that mean levels of Hg^0 in the breath of subjects who carry amalgam restorations was 8.2 ng/L (or mg/m^3), more than 100 times higher than in the breath of subjects without amalgam fillings (3). Individuals who have many amalgam restorations may absorb 10–12 mg of mercury per day (12). Exposure of dental health professionals also results from present practice, and one report describes an increased frequency of reproductive failures in female dentists and dental assistants (13). Overall, however, no clear-cut health effects of amalgam exposure have been described (14), and its toxicological significance remains under discussion.

1.3.1 Biomonitoring/Biomarkers Blood and urine levels of Hg are commonly assayed and provide at least a qualitative measure for evaluating exposure to mercury. This topic has already been considered earlier in section 1.2 Exposure Assessment. Because elemental mercury is fairly rapidly oxidized to Hg^{2+} in body fluids, exposure to Hg^0 is generally evaluated by blood and urine analysis for elemental plus inorganic mercury. This commonly involves reducing the inorganic mercury to the element and using UV spectroscopy for Hg vapor. Analysis specifically for Hg^0 in the presence of Hg^{2+} omits the reduction step. Further details will be given under the heading of mercuric chloride (section 2.3).

1.4 Toxic Effects

Because the element is relatively inert, it exerts little direct toxic action. On the other hand, it is readily oxidized to mercuric ions. One biological mechanism for this oxidation involves the enzyme catalase in presence of hydrogen peroxide; the reverse reaction, the reduction of Hg^{2+} to Hg^0, has also been observed in animals. In any case, all evidence points to Hg^{2+} as the ultimate toxicant during exposure to mercury vapor, salts of mercurous mercury, and in part also to organic mercurials. Many aspects of the toxicity of elemental mercury will therefore be included in section 2.4 under the heading of Toxic Effects of Hg^{2+}. The fact that Hg^0 to some extent like methylmercury (see section C on Organic Mercury Compounds), but in contrast to Hg^{2+}, acts primarily on the central nervous system can be explained by its lipid solubility and consequent ability to cross cell membranes such as those in the blood–brain barrier. After moving across this barrier, elemental mercury is likely to be extensively oxidized to Hg^{2+} and consequently to become trapped in the central nervous system.

1.4.1 Experimental Studies Liquid (metallic) mercury is very poorly absorbed from the gastrointestinal tract. Release of mercury vapor in the intestine may be retarded by a coating of insoluble HgS formed in the intestine. This may help explain the survival of patients treated in

former centuries for constipation by ingestion of the metal. Inhalation is the most important route of exposure to Hg^0: as much as 80% of inhaled vapor is retained in the lungs (15). As pointed out by Clarkson (5), this high value represents essentially complete absorption across the alveolar membranes. Dermal absorption of elemental mercury has also been described but, though not insignificant, is much smaller. Thus, for every mg of Hg/liter of air, the vapor is taken up by the skin at an average rate of 0.24 $mg/cm^2 \cdot min$. The calculated amount of mercury thus retained amounted only to about 2% of simultaneous pulmonary absorption. Moreover, only half of the Hg^0 taken up in the skin could be recovered as systemic mercury (16); the remaining portion presumably is retained and accumulates in dermal cells and is subsequently lost upon their desquamation.

Mercury vapor is rapidly distributed throughout the body, readily penetrates cellular barriers such as the placenta and the blood–brain barrier, and appears in milk and other secreted body fluids. Once it has crossed the placenta and the blood–brain barrier, elemental mercury is oxidized and becomes largely trapped as Hg^{2+} in the central nervous system. Inhalation of the vapor by rats and mice, leads to mercury accumulation primarily in the gray area of the central nervous system. The highest levels are in certain neurons of the cerebellum, the spinal cord, the medulla, the pons, and the midbrain (17). Such inhalation is, therefore, associated primarily with neurotoxic effects. Similar lesions are produced by methylmercury, also reflecting the trapping of mercury in the brain (see section 4). Toxic effects of Hg^0 on the developing central nervous system have been described in rat fetuses and pups. Limited evidence only has been found for carcinogenic actions of elemental mercury (see the genotoxicity of Hg^{2+} in section 2.4), and it is not classified as carcinogenic by the USEPA. Sarcomas have been reported in rats following intraperitoneal injection (18).

In general, many of the cytotoxic actions of the metal resemble those of its oxidation product, the mercuric ion (see section 2.4). Differences in their overall toxicity are mostly related to their usual portals of entry and to their different distributions in the body. Thus, the first pass of Hg^0 through the lungs during inhalation exposes these organs to much higher concentrations of mercury than the kidneys; the inverse is true for Hg^{2+} following ingestion. Similarly, the ready passage of mercury vapor across the blood–brain barrier, in contrast to the essential impermeability of that barrier to Hg^{2+}, helps to explain the primarily neurotoxic effects of the vapor.

1.4.2 Human Experience Hursh et al. (15) studied the clearance of radioactive mercury vapor inhaled by human subjects. Seven percent of inhaled mercury in their study was exhaled again, with a half-time of 18 h. The half-life of total mercury in the kidney region was as long as 64 days, consonant with oxidation to Hg^{2+} and preferential renal uptake. Acute inhalation of mercury vapor at a concentration in excess of 1 mg/m^3 may cause damage to the lungs; renal malfunction has also been observed. The major functional lesions, however, are found in the central nervous system. They are manifested by behavioral and other deficits. Erethism, a peculiar form of emotional instability, has long been recognized as a symptom of mercury intoxication. Other symptoms include tremor, weight loss, gingivitis, headache, and drowsiness. Acute exposure can also cause pneumonitis and contact dermatitis. Overt toxicity may be expected in populations exposed to time-averaged air concentrations of Hg^0 that exceed 0.1 mg/m^3.

There are conflicting reports in the literature on reproductive effects of human exposure to metallic mercury. The potential problems encountered by workers exposed to dental amalgam have already been discussed in section 1.3 Exposure Assessment. Reproductive toxicity in males was studied by Cordier et al. (19) whose results indicate that paternal exposure prior to conception might increase the subsequent risk of spontaneous abortion.

Elemental mercury does not react with chelators (see section 2.4). Their successful therapeutic use following exposure to Hg^0 therefore indicates, as already mentioned, that the element is oxidized to Hg^{2+} in the body. Indeed, about 80% of Hg^0 taken in by humans is subsequently excreted as

mercuric mercury.

1.5 Standards, Regulations or Guidelines of Exposure

OSHA, NIOSH, and the American Conference of Government Industrial Hygienists (ACGIH) have selected a permissible exposure level (PEL) (time-weighted average) of 50 mg Hg^0/m^3 of air. The USEPA Integrated Risk Information System (see Ref. 52) quotes a reference concentration in air of 0.3 mg/m^3; no NOAEL was determined for chronic inhalation exposure, but a LOAEL, adjusted for occupational inhalation and workweek was calculated as 9 mg/m^3 (2).

1.6 Studies on Environmental Impact

Because of the ready interchangeability of elemental, inorganic, and organic mercury, the problem of general environmental impact of mercury will be considered here under a common heading for the element and its compounds. Additional information is provided in section 4.6 for methylmercury, a frequent and potentially very toxic contaminant of the human food chain. This compound is formed by bacterial methylation of inorganic mercury, a further reason for minimizing levels of total mercury in the environment.

Mercury is added to the environment from two main sources: “natural” mercury, and mercury arising from human activities (anthropogenic mercury). Natural sources include degassing of mercury from the earth's crust and from volcanic eruptions. The presence of mercury in fish (mostly in the form of methylmercury, see section 4.6) such as sword fish, which is at the top of the marine food chain and is harvested far from likely industrial sources of mercury, has thus been attributed ultimately to mercury from volcanic activity. The anthropogenic origin of mercury is associated with mining, coal combustion and incinerators, agricultural and industrial applications, surface waste disposal and other activities; these anthropogenic sources contribute a major fraction of the Hg added to the atmosphere each year (20). Atmospheric Hg^0 becomes oxidized to Hg^{2+}, and as such may be deposited on land or water. Deposited Hg, in turn, tends to be reduced to the volatile metal. Because of this volatility, elemental mercury is continuously cycled through various environmental compartments and becomes widely distributed throughout the environment. However, it is only in proximity to specific point sources that environmental damage is likely to become significant.

The total mercury content of unpolluted waters usually falls below 1 ng/L. The average daily intake of total mercury from air by the general population in the United States has been estimated at 0.04 mg/day; a similar value was found for drinking water (0.05 mg/day). The total intake in non-fish food was calculated as 3.6 mg/day; normal fish consumption raised this value to 6.6 mg/day. Note that intake of Hg^0 from dental amalgams can rise as high as 21 mg/day.

Section 1.2 already referred to the considerable scope for minimizing the anthropogenic input of mercury into the environment, especially by substituting Hg-free processes for those that depend on mercury. It was noted, for instance, that washing of coal reduces its mercury content by an average of 21% (2). Further reductions are probably achievable with the development of new procedures. Of course, washing of coal only transfers the metal to waste slurries and thereby does not automatically reduce the concentration in the environment.

The magnitude of the human contribution to environmental pollution is reflected in the two to fivefold increase in atmospheric Hg since the beginning of the Industrial Revolution. The persistent problem of such contributions is dramatically emphasized by the report that during a period of 33 years, about 213 metric tons of mercury and mercuric nitrate were spilled into creeks at the Oak Ridge National Laboratory (3). Mercury remaining at that site is present now primarily as insoluble HgS; bacterial oxidation to the more soluble sulfate, however, will continue to make the metal slowly available for reactions in the biosphere.

Mercury
Ernest Foulkes, Ph.D.

B. Inorganic Mercury Compounds

Occupational exposure to inorganic mercury compounds occurs during mining for the major mercury ore, cinnabar (mercuric sulfide, HgS), and as a result of their extensive industrial applications. Among these compounds, for instance, is mercuric oxide (HgO), once a common constituent of many types of batteries, including Zn–carbon cells, Zn–silver oxide cells, and others. Mercuric sulfate has also been used in paints and is a catalyst in the chemical industry (see section 4.2). Mercuric nitrate was formerly applied in the felting process for beaver furs in the hat industry (thence the suggested origin of the term "a mad hatter," believed to have been originally applied to an affected victim of occupational exposure in the hatting industry). Mercuric fulminate is a common constituent of percussion caps of firearm ammunitions. Mercuric acetate and bromide are common laboratory reagents. Several mercuric mercury salts have, in the past, also been extensively used as antibacterial compounds.

Among important mercurous salts are mercurous chloride (calomel), employed as the standard calomel electrode, and mercurous sulfate, also found in batteries. Mercurous acetate, iodide, phosphate, and tannate salts have all been used at one time to treat syphilitic lesions. Mercurous chromate has served as green colorant for chinaware.

The various salts of mercurous (Hg^{+}) and mercuric (Hg^{2+}) ions are all more or less toxic; the toxic entity is usually the mercury ion. The actual toxicity of the compounds also depends, of course, on their water solubility and thence their availability for absorption. The actions of mercurous ions in the body have been attributed to their oxidation to the mercuric form; this, in turn, readily reacts with biological molecules. Mercurous mercury $(Hg–Hg)^{++}$ in aqueous solution decomposes into mercuric and elemental mercury according to the equation

$$(Hg–Hg)^{2+} = Hg^{0} + Hg^{2+}$$

Mercuric ions in solution readily form a variety of coordination complexes. For instance, in the presence of high chloride concentrations such as in physiological saline, Hg^{2+} exists mostly as polychloride anions like $HgCl_3^{-}$; such anions are involved in the intestinal absorption of mercuric mercury (21). Iodide complexes such as K_2HgI_4 are freely available. Complexes are also produced with ammonia or amino groups, as in $Hg(NH_3)_2Cl_2$. Mercuric ions also form relatively stable covalent mercury–carbon bonds to produce the organic mercurials; these are used for many purposes and will be discussed further under heading C. Organic Compounds of Mercury. Some organic mercury compounds are relatively nontoxic, whereas others, especially the short-chain alkyl derivatives, are potent neurotoxins.

Although mercury vapor is absorbed primarily through the lungs, uptake of inorganic mercury compounds mostly follows ingestion. Table 30.1, based on Ref. 22, summarizes the daily retention of mercury and mercurials by adults in the general environment.

Table 30.1. Daily Retention of Mercury and Mercurials by Adults in the General Environment[a]

Source	Hg vapor	Inorganic mercury	Methylmercury
Air	0.024	0.001	0.0064
Food: fish	0	0.042	2.3

Non-fish	0	0.250	0
Water	0	0.003	0
Dental amalgams	>3.0	0	0
Total	>3.0	0.3	2.3

[a] Values represent individual retention (in mg/day) of different species of mercury taken in from air, food, and water, or from dental amalgam. Calculations are based on 80% fractional retention of inhaled Hg vapor and 7% and 96% fractional intestinal absorption of ingested inorganic and methylmercury, respectively.

Several points in this table deserve special emphasis. Note in particular that dental amalgam represents the major source of total mercury uptake and retention, significantly higher than that from background levels in food, water, and air. Mercury as mercuric chloride and similar salts is not well absorbed; the same is even truer of essentially insoluble mercurous salts. In contrast, methylmercury, derived mostly from fish in the diet, is strongly retained in the body (see section 4.4.1). It represents the major source of body mercury in populations that consume larger than average amounts of fish in their diet. These observations were made in studies of several isolated populations, and their toxicological significance is further reviewed in section 4.4. In an unpolluted environment, the FDA Total Diet Study (23) on populations not primarily dependent on fish consumption reported for the period 1982–1984 an average daily Hg intake in the general environment of approximately 50 ng/kg body weight; this applied to all age groups except young children. To this daily dose must be added any mercury taken in as a result of cosmetic and therapeutic uses of mercury and its compounds. The percutaneous toxicity of inorganic heavy metal compounds, including those of mercury, is generally relatively low (24).

The two representative inorganic salts selected for more detailed discussion are mercuric and mercurous chloride.

Mercury
Ernest Foulkes, Ph.D.

C. Organic Compounds of Mercury
As mentioned in the introduction to section B, the mercuric ion readily forms covalent bonds with carbon; some organic mercurials contain Hg–N bonds, as in mercuric succinimide. A large number of carbon–mercury compounds have been synthesized, and some are extensively used in agriculture and industry, for instance, for seed dressing and as antifungal compounds in paints and other materials.

Some organic mercurials have also been employed for therapeutic purposes, although especially systemic administration is rare now. Mercurials such as mercurochrome (dibromohydroxymercurifluorescein) and merthiolate (ethylmercurithiosalycilate) have been applied as topical antiseptics. Among widely used systemic mercurial drugs were the diuretic isopropyl alcohol derivatives whose general structure is $R \cdot CH_2 \cdot CH(OY) \cdot CH_2 \cdot HgX$, where X stands for chloride, thioacetate, or other residues, and Y is commonly a methyl group. The $Hg \cdot X$ bond is ionic, leaving one mercury valence free to react with tissue components. The same important property is found in the monoaryl or monoalkyl derivatives of mercuric mercury. Thus, parachloromercuribenzoate is a common sulfhydryl reagent, extensively used in biochemical laboratories, and monomethylmercury forms biologically active complexes with L-cysteine or glutathione (see section 4.1).

Although monosubstituted organic mercurials may react directly in this manner with, and thereby inhibit the function of, critical sulfhydryl groups, much of their toxic potential is associated with the likelihood of degradation to free mercuric ions. The highly neurotoxic dimethylmercury, which is very lipid-soluble and rapidly absorbed through the skin and taken up across the blood–brain barrier into the brain, is presumably demethylated at least to the monomethyl compound before exerting any effects. Risks of exposure to dimethylmercury are exacerbated by the ability of the compound to pass through latex gloves; this apparently permitted the fatal poisoning of a laboratory worker, as reported recently in the news media.

The mercurial diuretics and many of the other organic mercurials are relatively nontoxic and possess little occupational relevance; they will therefore not be discussed in detail here. However, exceptions to the generally low toxicity of many organic mercurials are the extremely toxic short-chain alkylmercurials. Of primary interest from the environmental and toxicological points of view are monomethylmercury salts, as further discussed in section 4.0. The dimethyl compound is a volatile and extremely potent neurotoxin; it is very easily absorbed through the skin or by inhalation, but poses little threat outside the laboratory. As already mentioned in section 1.4, the high neurotoxicity of methylmercury compounds, in contrast to the primarily nephrotoxic action of inorganic mercury, can be explained by their respective abilities rapidly to cross the blood–brain barrier. The alkylmercurial selected here for more detailed discussion is the chloride salt of monomethylmercury (see section 4). Other salts, like the nitrate, are biologically indistinguishable from the chloride. Ethyl mercury, another short-chain monosubstituted alkylmercury compound, has also been used as a biocide and exhibits toxic effects similar to those of the methyl derivative.

A large number of aryl and alkoxyalkyl mercury compounds are known. The aryl compounds especially are used in occupational settings. A well-known example is the application of phenylmercury as a biocide in paints and agricultural products. Parachloromercuribenzoate (PCMB) is an aryl compound frequently employed in biochemical laboratories as a sulfhydryl reagent. The arylmercurial selected here for more detailed consideration is the acetate salt of phenylmercury (see section 5). The nature of the alkyl or aryl residue in organic mercury compounds largely determines their ability to reach especially intracellular target sites in selected organs and the stability of the mercury–carbon bond. Generally, long-chain alkyl mercurials are more readily dealkylated than short-chain compounds.

4.0 Methylmercuric Chloride

4.0.1 CAS Number: [*115-09-3*]

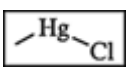
4.0.2 Synonyms: Chloromethylmercury; MMC; methylmercury chloride; monomethyl mercury chloride; caspan; methylmercury (II) chloride

4.0.3 Trade Name: Caspan

4.0.4 Molecular Weight: 251.10

4.0.5 Molecular Formula: $CH_3 \cdot HgCl$

4.0.6 Molecular Structure:



4.1 Chemical and Physical Properties

4.1.1 General Monomethylmercuric mercury is a univalent cation. Despite its ionic nature, however, it is significantly more lipid-soluble than inorganic mercury compounds. The chloride salt is a white crystalline solid at room temperature and has a melting point of 170°C. Its specific gravity is 4.06,

and its vapor pressure at 25°C is 0.0085 mmHg. At higher temperatures, it volatilizes with a disagreeable odor. It is slightly soluble in water (<0.1 mg/mL at 21°C). The free mercury valence bond in monomethylmercury reacts with sulfhydryl groups in biological molecules. Thus, biliary secretion of methylmercury involves a complex with glutathione, the most common endogenous and low molecular weight thiol compound in cells (37). An L-cysteine complex of methylmercury is transported across membranes by the neutral amino acid carrier system (38). The direct binding of methylmercury, for example, to protein sulfhydryl groups through the free valence bond of mercury may, in part, explain the toxicity of methylmercury. At the same time, demethylation to the mercuric ion in the body also contributes to the toxic effects observed.

4.1.2 Odor and Warning Properties In spite of its disagreeable odor, methylmercury is not readily recognized at low concentrations. In biological matrices the compound is set free from sulfhydryl complexes at pH 1 and can then be measured by gas chromatography and other convenient techniques (see section 2.1.2). The procedure of Magos (25) for determining methylmercury in the presence of inorganic mercury was referred to in section 2.1.2. It avoids the need for separating inorganic from organic mercurials before chemical reduction, based on the fact that stannous chloride does not reduce mercury bound covalently to carbon. Another sensitive method (lower detection limit 15 ng/g) for estimating methylmercury takes advantage of its enzymatic conversion to methane (39).

4.2 Production and Use

Alkylmercury compounds, like methylmercury, are generally prepared by a Grignard reaction in ethyl ether:

$$RMgX + HgY_2 = RHgY + MgXY$$

The compounds served in the past for seed dressing, but by 1970 this application was abandoned after a disastrous episode of methylmercury poisoning in Iraq (5). Although no longer widely used, the compound may enter the environment as a by-product of mercury-catalyzed reactions, as in the case of the production of acetaldehyde in the presence of mercuric sulfate: Minamata disease in Japan resulted from the contamination of marine food supplies by methylmercury, produced either in the catalytic reaction or by the microbial methylation of inorganic mercury. Both drained in industrial wastes into Minamata Bay. Methylmercury becomes widely spread through the aquatic food chain, where it accumulates, especially in organisms like swordfish in the ocean or pike in fresh water. Such organisms at the top of the food chain are then likely to be consumed by humans.

Because of its high toxicity, industrial and agricultural use of the compound and therefore its industrial production have generally been abandoned. Methylmercury remains of considerable concern, however, because of its continuous synthesis in nature by bacterial methylation of inorganic mercury. Minimization of environmental mercury contamination therefore remains imperative.

4.3 Exposure Assessment

The odor of methylmercury at low concentrations is not sufficient to detect it. Current assessment of exposures therefore requires chemical determination of the compound in air, food, or water. Detection of past exposures can be based on an analysis of blood or hair. The compound becomes incorporated into hair at a concentration much higher than its level in blood. It remains stable in hair, so that a longitudinal history of its blood levels may be obtained.

In spite of its fairly long half-life in blood (see section 4.4), methylmercury is slowly degraded in the body to inorganic mercury. After longer periods following exposure to methylmercury, total mercury levels in blood and urine may prove informative. Analytical techniques for estimating methylmercury were briefly reviewed in sections 2.1.2 and 4.1.2.

4.4 Toxic Effects

4.4.1 Experimental Studies Methylmercury is one of the most toxic common mercurials. ATSDR has described the NOAEL and LOAEL values for different organ systems in various species (3). Lethal doses vary with the duration and rate of administration, the strain and developmental stage of the animal, the gender, and presumably other factors such as diet. An acute oral dose equivalent to

16 mg Hg/kg resulted in the death of 4 of 6 male mice, but no increased mortality was seen in females that received less than 40 mg Hg/kg.

The compound is readily absorbed into the body by inhalation or ingestion. Pulmonary uptake was measured in rats (40); net intestinal absorption of 95% of the compound present in a fish diet has been seen in human volunteers (41). Some absorption may also occur through the skin.

As described later, methylmercury is readily distributed throughout the body. The central nervous system is not well protected against the toxicant by the blood–brain barrier and is highly sensitive to its actions, especially in immature organisms. Indeed, methylmercury acts primarily as a general neurotoxin that affects cortical function, neuromuscular coordination, and other activities. Such neurotoxic effects characterize the so-called Minamata disease (see section 4.4.2). The mechanism of the neurotoxic action reportedly involves a variety of effects (42). For instance, methylmercury decreases the evoked release of neurotransmitters, perhaps through changes in Ca^{2+} metabolism; it inhibits several mitochondrial enzymes and depolarizes the mitochondrial membrane, thereby decreasing production of ATP; protein synthesis is also inhibited. Like the nonspecific cytotoxicity of Hg^{2+}, the early cellular effects of methylmercury are diverse, and damage can be attributed to more than one mechanism. One such mechanism involves damage to the microtubules involved in intracellular solute distribution and other functions (5).

The toxicant also crosses the placenta, and the fetal LD_{50} in rats was reached at maternal doses of approximately 20 mg/kg body weight. Reproductive effects of methylmercury have frequently been reported following oral exposure of various animal species, including rats, mice, hamsters, and monkeys (3).

The relatively free passage of methylmercury across cell membranes is further illustrated by its secretion into maternal milk; it appears in bile as sulfhydryl complexes (37). Enterohepatic recirculation, as well as renal tubular reabsorption, contribute to the relatively long biological half-life of the mercurial. The compound may also be demethylated in the intestine and excreted in feces as Hg^{2+}.

4.4.2 Human Experience The absorption of methylmercury in humans and its wide distribution in the body are partly explained by the appreciable lipid solubility of the compound; this facilitates its passage across cell membranes. Attention must be drawn, however, to the fact that the lipid solubility of methylmercury is limited by its ionic nature. Transfer across some cellular barriers like the blood–brain barrier is further catalyzed by membrane transporters for neutral L-amino acids; these react with and transport the L-cysteine complex of methylmercury into cells (38).

Large numbers of humans have been accidentally exposed to methylmercury, mostly by ingestion of contaminated fish or grain. In some isolated populations that depend primarily on fish as a source of dietary protein, levels of methylmercury in hair or blood may exceed estimated safe levels (5). Acutely fatal oral doses estimated from tissue concentrations range from 10 to 60 mg/kg (43).

The half-life in human blood reportedly varies from 5 to 23 weeks; such a long residence time may reflect extensive enterohepatic recirculation, as well as renal tubular reabsorption. In blood, the concentration ratio of methylmercury in red cells and plasma is generally elevated; values as high as 20/1 have been observed. This is in strong contrast to the distribution ratio of about 1 for Hg^{2+}, a fact potentially useful in distinguishing between exposures to the two toxicants.

Methylmercury is secreted into maternal milk and may constitute a serious risk to nursing infants. The risk of exposure in utero is enhanced by the ready passage of the compound through the placenta. Methylmercury is one of the most important developmental neurotoxins. The great sensitivity of the developing central nervous system to the compound has been dramatically demonstrated in several major episodes of accidental exposure, as in Minamata Bay in Japan. Unlike

the extensive information on developmental toxicity of methylmercury, there is little documentation of reproductive effects in humans.

Another catastrophic episode was caused in Iraq by consumption of seed grains treated with methylmercury as a fungicide. The estimated exposure in this case ranged from 0.71 to 5.7 mg/kg · day for a period of 43–68 days; there was a high mortality (459 deaths out of 6350 hospital admissions) (44). The symptoms of the so-called Minamata disease, typical of severe nervous system toxicity, have included paresthesia of the extremities and/or the perioral area, ataxia, visual disturbances, speech and hearing difficulties, tremors, and other neuromuscular deficiencies.

The high affinity of methylmercury for—SH groups has encouraged the development of treatments aimed at reducing its absorption from the intestine and at stimulating its excretion. Thus, Clarkson et al. showed that a synthetic polythiol resin (45) inhibits intestinal absorption of the mercurial by 50%. Keratin, in the form of reduced hair powder, had been previously used for this purpose by Takahashi and Hirayama (46).

Evidence for human carcinogenicity is limited. A number of authors have reported carcinogenic effects in rats and mice exposed orally to methylmercury; other investigators observed no increase in tumor incidence. The EPA has classified the compound as a possible human carcinogen (2).

4.5 Standards, Regulations, or Guidelines of Exposure

A benchmark dose was established by the EPA for ingestion of methylmercury (2) not to exceed 1.1 mg/kg body weight per day. It was derived from observations on neurological changes in Iraqi children and represents the intake of the compound associated with the lower limit on a 95% confidence interval for a dose that produces a 10% increase in adverse effects. This dose maintains a blood concentration in adults of about 44 mg/L or a hair concentration of 11 mg Hg/g. As pointed out by the EPA (2), fetuses of mothers whose hair concentrations are less than 1 mg Hg/g, a level associated with the present RfD (Reference Dose, defined as the daily permissible intake over a lifetime) of 0.1 mg/kg body weight per day, are not likely to suffer ill effects. The World Health Organization (22) concluded that exposure leading to hair levels in adults of up to 50 mg Hg/g and a blood concentration not exceeding 200 mg Hg/L has minimal risks.

An action level of 1 mg Hg/g was chosen by the FDA for human consumption of fish, which contain almost all of their body burden of mercury as methylmercury. This compares to an average level in tuna fish, for instance, of 0.2 mg/g. A minimal risk level for neurodevelopmental lesions of 0.5 mg Hg/kg · day was derived for methylmercury uptake for periods of 1 year or longer (47); the same value was proposed by ATSDR. Application of different safety factors to the results of epidemiological studies carried out on the fish-eating population of the Seychelle Islands led the EPA to a maximum permissible methylmercury intake equivalent to 0.1 mg Hg/kg · day (95% of this intake consists of methylmercury). The American Conference of Government Industrial Hygienists (ACGIH) chose a concentration of 10 mg/m^3 for the maximum permissible and time-weighted concentration of methylmercury in air. No standards have been set by the Occupational Health and Safety Administration (OSHA). There is currently no OSHA PEL for this compound.

4.6 Studies on Environmental Impact

Methylmercury may be added to the environment as such or may be formed by biological methylation of soluble inorganic mercury, especially in lake and marine sediments. Therefore, control of methylmercury levels in the environment requires minimizing the concentration of total mercury. Significant bioaccumulation of methylmercury has been observed in both marine and fresh water fish, especially those at the top of the food chain; in albacore tuna, the average body concentration of Hg was reported as 264 ng/g (2). In Minamata, fish-eating animals such as sea gulls and cats exhibited symptoms of neurotoxicity. Generally, wildlife is likely to be strongly affected by methylmercury in their food chain.

5.0 Phenylmercuric Acetate

A number of phenylmercuric salts are commonly available, including the acetate, bromide, chloride, cyanide, and iodide. The acetate salt, $[(C_6H_5) \cdot Hg]^+[OOC \cdot CH_3]^-$, (PMA), has been selected here

for more consideration. It must be emphasized, however, that the toxic properties of water-soluble phenylmercury salts, as of other salts of mercury and of its derivatives, are generally independent of their anion.

5.0.1 CAS Number: [*62-38-4*]

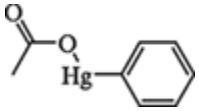
5.0.2 Synonyms: Phenylmercury acetate; PMA; (acetato-O)phenylmercury; (acetato)phenyl mercury; phenylmercury (II) Acetate; acetoxyphenylmercury; (aceto)phenylmercury; PMAC; PMAS; Gallotox; Liquiphene; Phix; Mersolite; Tag HL-331; Nylmerate; Scutl; Riogen; Advacide PMA 18; Cosan PMA; Mergal A25; Metasol 30; Nildew AC 30; Nuodex PMA 18; Agrosan; Cekusil; Celmer; Hong Nien; Pamisan; Seedtox; Shimmer-ex; Unisan; acetic acid, phenylmercury deriv.; (acetoxymercuri)benzene; agrosan gn 5; algimycin; antimucin wdr; benzene, (acetoxymercurio)-; Bufen; ceresan universal; contra creme; dyanacide; Femma; FMA; fungitox or; HL-331; hostaquik; kwiksan; leytosan; mersolite 8; norforms; phenmad; phenomercuric acetate; phenylmercuriacetate; pmacetate; PMAL; purasan-sc-10; puraturf 10; quicksan; quicksan 20; sanitized spg; SC-110; spor-kil; TAG; tag 331; trigosan; ziarnik; Anticon; Fungicide R; Fungitox; Meracen; Mercuron; Neantina

5.0.3 Trade Names: PMA, PMAS, liquiphene, mersolite, and numerous others

5.0.4 Molecular Weight: 336.75

5.0.5 Molecular Formula: $C_8H_8HgO_2$

5.0.6 Molecular Structure:



5.1 Chemical and Physical Properties
5.1.1 General The salt crystallizes in small, white, rhombic crystals, whose melting point is 153°C. It is only slightly soluble in water but dissolves in glacial acetic acid and in various organic solvents. It is readily degraded *in vivo* to mercuric ions.

5.1.2 Odor and Warning Properties The salt possesses no significant odor or other physical properties that would reveal its presence in low concentrations. Therefore, evaluating its presence requires a chemical assay (see section 5.3).
5.2 Production and Use
Phenylmercury compounds are used as catalysts in manufacturing certain polyurethanes. They were also formerly employed for seed dressing (see methylmercury in section 4); as slimicides; as fungicides in paper, pulp and both latex and waterborne paints; and as topical disinfectants and spermicides. The use of PMA in interior latex paints was banned by the EPA in 1992. The compound is synthesized by refluxing a mixture of mercuric acetate and acetic acid in a large excess of benzene; the excess benzene prevents the formation of polymercurated benzene derivatives.
5.3 Exposure Assessment
Assessment of exposure requires chemical analysis. Because of the instability of the Hg–C bond, especially in the body, it is usually most convenient to determine total mercury. The NIOSH Manual of Analytical Methods (4) lists no specific analytical procedure for phenylmercury.
5.4 Toxic Effects
There is relatively little information on the toxic effects of PMA in humans and animals. However, because of the relative ease with which the C–Hg bond can be split, it is not surprising to find a number of adverse effects described in the literature. In general, the toxicity of PMA resembles that of inorganic mercury.

5.4.1 Experimental Studies PMA is absorbed from the intestine in rats, dogs and chicks, and can cause a variety of lesions (48); the compound circulates in the blood. NIOSH lists more recent references to gastrointestinal effects (3). Daily intake of PMA in feed at a level equivalent to 1.7 mg Hg/kg body weight produced no observed gastrointestinal effects in rats over a period of 2 years. Solecki et al. (49) observed nephrosis in rats at a lower chronic dose in drinking water, equivalent to 0.4 mg Hg/kg/day. A daily dose of 4.2 mg led to increased incidence of renal cell adenomas. Takeda et al. (50) compared the distribution and excretion of various mercury compounds injected subcutaneously into rats. Mercury administered as phenylmercury distributed in the body and was excreted in urine similarly to mercury given as $HgCl_2$; this confirms the conclusion that the aryl compound rapidly breaks down to inorganic mercury. Urinary excretion of Hg from both compounds peaked 2 days after injection.

5.4.2 Human Experience There is very little information on the toxicity of PMA in humans. Use of phenylmercury as a disinfectant by a diaper service in Argentina (51) led to acrodynia in infants.

5.5 Standards, Regulations, or Guidelines of Exposure

An oral reference dose for PMA equivalent to 0.08 mg Hg/kg · day was calculated for human consumption by the EPA (52). This was based on a LOAEL in rats equivalent to 50 mg Hg/kg · day. The ACGHI has chosen 100mg as the time-averaged maximum concentration of arylmercury per liter of air. No standards have been set by OSHA.

5.6 Studies on Environmental Impact

No information was located on the possible environmental impact of PMA. In general, as with any other mercurial, contamination of the environment should, of course, be avoided. This is especially desirable because degradation and metabolism of mercurials may lead to formation of more toxic compounds in the human food chain, such as methylmercury in fish.

Aluminum

Bertram D. Dinman, MD, Sc.D

A. Introduction

Because of this element's electrochemical properties, its positvely charged ions form very tight chemical bonds with other anions such that dissociation is minimal in neutral or near-neutral-pH environments. Since most living organizations operate at or about such pH levels, by implication most naturally occurring aluminum compounds would display minimal potentials for cellular or subcellular interactions. Its binding forces, in addition to making this element available only recently (at the time of writing), has also meant that aluminum was relatively unavailable to the milieu intériur. However, since progressively more of the metal and its compounds came into common human use and commerce, ultimately its wide usage could be expected to eventually result in the possibility intimate human contact and finally, human health and hazard concerns.

These events have indeed occurred so that aluminum and its possible association with neurological disorders became a prominent health issue of the late twentieth century. Because of the foregoing electrochemical physical realities, concerns have focused on the *element's* health effects per se, with little or attention directed at effects of aluminum compounds, such as chloride, phosphate, and sulfates. This should also not be unexpected, given their *relative* biological inavailability. Obviously, some aluminum compounds do ionize sufficient to lower pH in aqueous environments (e.g., aluminum chloride or phosphate) and act as simple irritants. However, most other aluminum compounds, as expected have had very little *apparent* biologic availability or effects, and thus are accorded little scientific attention as compounds per se.

These facts are reflected in the content of contemporary biomedical literature. Although multiple aluminum compounds have been studied, few, if any, are studied except as they serve to “transport” aluminum into the body. The overwhelming majority represent interest in aluminum's effects alone rather than an individual compound's possible bioimpact.

For these reasons, this chapter deals mainly with aluminum as an element and the most common prevalent form: the oxides. Since its other compounds as such are the subject of so little current investigation, these other compounds are considered separately later in this chapter.

Aluminum
Bertram D. Dinman, MD, Sc.D

B. Aluminum and its Oxides

Aluminum is the third most common element—after oxygen and silicon—of the lithosphere, representing 8.13%. Paradoxically, despite its ubiquity in the environment, because of its high affinity for oxygen it is never found in its free, elemental state. In the *pH-neutral, aqueous environments* characteristic of most biological systems the common, naturally occurring aluminum oxides, oxy- and hydroxides, silicates, alkali and alkaline-earth metal, and phosphate compounds are extremely insoluble and thus relatively inaccessible to biological interaction. Other compounds of aluminum that *do not commonly occur in nature*, such as aluminum sulfate or aluminum citrate, are more soluble and thus have been used by experimentalists. Unfortunately, information so derived often bears questionable relevance to aluminum's relative biological inactivity resulting from real-world encounters with this element. In addition, its amphotericity and ability to form double salts contributes toward serious analytical problems in defining its various chemical and physical species in natural systems. Inadequate understanding of the physicochemical behavior and chemical species of aluminum occuring in living systems have accentuated inconsistencies in biomedical research outcomes. Confusion among aluminum physicochemical nomenclature (1) has further obscured understanding of inconsistent toxicological research results (2). Thus, although aluminum has been present at microgram levels in most biotic systems over evolutionary timescales, its effect on such

systems remains controversial and poorly defined.

Indeed, relative physicochemical inaccessibility caused it to be the last of the common metals to be commercially produced. The Romans referred to any astringent substance as *alum*, but in the Middle Ages it was recognized as an independent substance manufactured from *alum stone*. A few drops of the metal were chemically isolated in 1825 by Hans C. Oersted, but its importance in commerce dates from the almost simultaneous appearance of patents in 1886. Charles Martin Hall via a backdated, refiling claimed to have discovered the electrolytic reduction process in the United States on February 23; in France Paul-Louis-Toussaint Héroult filed his patent application on April 23. (Ironically, Hall and Héroult subsequently both died at age 51 in 1914 of the same cause: typhoid fever.) After both legal and commercial developmental problems, the inventors finally succeeded in developing the new industry so that the price of the metal dropped from $75 a pound in 1890 to 29–30 ¢ /lb by the end of the nineteenth century.

Regardless of problems regarding the physicochemical behavior of this element and its compounds, toxicologists have paid considerable attention to this element and its compounds. As early as 1897, Doelkin (3) applied aluminum to the cortex of experimental animals with locally damaging results. (Such interest undoubtedly reflects the simultaneous ready availability of the metal and the development of modern toxicology.) However, this and subsequent other experiments should also consider issues such as the biological relevance of those chemical species studied, the dose-dependent effect of the doses employed, or to the appropriateness of portals of entry. The direct application of various chemical species to organs or tissue sites of interest implicitly reflects the particular difficulty of delivering these biologically nonreactive compounds of the element to a target organ or cellular site via the usual natural routes of transfer. Although positive experimental outcomes could be assured by such design strategies, their relevance to biological reality may be tenuous.

Aluminum
Bertram D. Dinman, MD, Sc.D

C. Aluminum Chloride, Sulfate, Phosphide, and Fluoride and Sodium Aluminate
As has been noted in the foregoing, the electrophysical forces strongly binding aluminum to the anion(s) results in compounds possessing little—if any—aqueous solubility, which, in turn, favors neither their absorption nor biological accessibility at physiologic pH ranges. This is clearly the case for essentially all of the oxides that are insoluble in water at normal pH. By contrast, several of the double salts display a range of slight solubilities, whereas, in turn, the simple salts show a higher range. (These statements represent generalizations, since within this classification of salts there is a small range; e.g., the simple salt AlF_3 is relatively insoluble in water). As would be expected, these simpler salts, such as aluminum chloride or the simple sulfate, are capable of evoking irritant effects at biological interfaces. Even here, such effects usually require relatively large dosing or protracted skin contact; when they are inhaled, irritation can also be seen at higher doses, particularly with respirable particulate sizes (see Ref. 148 and Section 3.4.2.2).

Biomedical research periodically focuses on the health effects of aluminum; however, which chemical species is active and significant in biological systems has yet to be defined. Despite this lacuna, biomedical researchers generally have not been reluctant to administer a wide variety of aluminum compounds via variably relevant or pertinent portals of entry. Under these circumstances such research focuses on the effects of *aluminum atom or ion*, rather than on the aluminum *compound* itself. These aluminum compounds are regarded as simply carriers of the element into the milieu intériur; thus, there is very little health and biomedical literature concerned with effect(s) of the compounds per se, beyond any exceptions to be noted. Accordingly, it is such biological

misperceptions that help account for the relative paucity of recent literature on aluminum compounds that follow.

2.0 Aluminum Chloride

2.0.1 CAS Number: [*7446-70-0*]

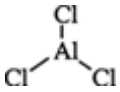
2.0.2 Synonyms: Aluminum trichloride; trichloroaluminum; aluminum chloride, anhydrous

2.0.3 Trade Names: NA

2.0.4 Molecular Weight: 1233.34

2.0.5 Molecular Formula: $AlCl_3$

2.0.6 Molecular Structure:



2.1 Chemical and Physical Properties

2.1.1 General

Melting point	194°C
Density (at 20°C)	2.44 g/L
Boiling point	262°C, decomposes
Appearance	granular crystals, white to colorless; when impure, gray or yellow to greenish
Vapor pressure	1 mm Hg at 100°C
Vapor density	4.5
Solubility	69.9 g/L water; dissolves freely in benzene, ether, many organic solvents
	Very deliquescent, readily forms HCl fumes in atmospheric water or air
	When heated in small quantities, volatilizes without melting

2.1.2 Odor and Warning Properties Strong odor of hydrogen chloride

2.2 Production and Use

This compound can be synthesized by a number of methods, including the heating of aluminum in a current of chlorine, followed by dissolving the product in water and crystalization. The synthesis can also be accomplished by reacting purified gaseous HCl with molten aluminum.

This compound has many uses; the major use is in cosmetics (aluminum chloride hexahydrate antiperspirants) and the pharmaceutical industry. It has wide application in chemical synthesis as a catalyst, especially in Friedel–Crafts reactions, for instance, in cracking of petroleum, for ethylbenzene, dyestuff intermediates, and detergent alkylate and as a chemical intermediate for numerous aluminum compounds. It also finds major uses in manufacture of specialty papers and in photography.

2.3 Exposure Assessment

Either NIOSH method 7300 (10) or NIOSH method 7013 (9), in which the analyte is aluminum, can be used. Although methods for analysis of aluminum in blood or urine are also applicable, the meaning of any findings in terms of aluminum chloride body exposure or body burdens would be only speculative.

2.4 Toxic Effects

2.4.1 Experimental Studies The acute oral LD_{50} (rat) was reported to be relatively high, 370 mg/kg (31); similarly, the LD_{50} for the rabbit was 400 mg/kg rabbit (169).

2.4.2 Human Experience Because of this compound's ready tendency to volatilize hydrochloric acid in the presence of moisture, it may produce an unpleasant, irritant environment. If it is applied as a dry material on the skin or mucous membranes, an astringent as well as inflammatory response may occur. Splashes or other exposures to the eye produce marked irritation and possible conjunctival inflammation and ulceration. Although respiratory tract inflammation might be expected, there are no reliable reports that this has occurred.

2.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV TWA is 2.0 mg/m^3 soluble salts, as aluminum. This TLV is based on the amount of hydrolyzed acid and the corresponding TLV. On the basis that 3 mol of HCl, with a TLV of 5 ppm, hydrolyze from 1 mol of $AlCl_3$, a TLV TWA of 2 mg/m^3, as aluminum, is recommended to yield a comparable degree of freedom from irritation as provided by the TLV for HCl.

The (OSHA) PEL is 2.0 mg/m^3.

3.0 Aluminum Sulfate

3.0.1 CAS Number: [*10043-01-3*]

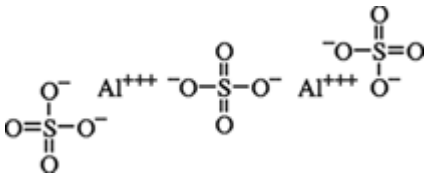
3.0.2 Synonyms Although "alums" were used by the ancient Greeks and Romans as medicinal astringents, knowledge of their exact chemical nature long postdated this use. Currently, it is clear that "alum" consisted of a group of crystalline double salts composed primarily of aluminum and sulfate plus a monovalent cation, namely, potassium, ammonium, or sodium, with the general formula $M^+Al^{3+}(SO_4)_2{}^* 12\ H_2O$. Accordingly, although these three compounds, specifically (*1*) aluminum potassium sulfate ($AlKO_8S_2$), (*2*) aluminum sodium sulfate ($AlNaO_8S_2$), and (*3*) aluminum ammonium sulfate [$AlNH_4\ (SO_4)_2$]—may be referred to and used as an "alum", such usage is imprecise. To further complicate the issue, $Al_2(SO_4)_3 \cdot 18\ H_2O$—most properly referred to as "aluminum sulfate"—in common usage equally inappropriately is called and used as an "alum." Given these common usages, it is not unexpected that a large number of synonyms are in common use, such as aluminum trisulfate alum, kaolinite, cake alum, exsiccated alum, pearl alum, potassium alum, alum flour, alum meal, and filter alum.

3.0.3 Trade Names: NA

3.0.4 Molecular Weight: 342.14

3.0.5 Molecular Formula: $Al_2O_{12}S_3$

3.0.6 Molecular Structure:



3.1 Chemical and Physical Properties

3.1.1 General

Physical appearance	odorless white or colorless powder or crystals
Specific gravity	2.71
Melting point (decomposes)	770°C, becomes anhydrous at 250°C

Solubility	freely in water, glycerine; solution in water is medium strong acid, pH insoluble in alcohol

3.1.2 Odor and Warning Properties Odorless; when heated or burning, produces irritant sulfur oxides fumes.
3.2 Production and Use
Aluminum sulfate is used mostly for clarification as a particulate flocculant in raw water, clarifying sugar and in baking powders. Other major applications are in pulp/papermaking, in fabric dying, in dye manufacture, in lakes, and as a catalyst.
3.3 Exposure Assessment
See Section 2.3.
3.4 Toxic Effects
3.4.1 Experimental Studies Presently there is very scanty modern data; a 1966 study indicated very low acute toxicity in rats at an oral LD_{50} of 6.1 g/kg (170).

3.4.2 Human Experience 3.4.2.1 General Information: NA

3.4.2.2 Clinical Cases 3.4.2.2.1 Acute Toxicity No human experience has been reported. On the basis of its potential irritant behavior, one might expect its mild to moderate irritant capacity to cause skin redness and mild inflammation on moderate to heavy skin contact with particulate dusts or powdered forms, especially if not removed. Similarly, it could be expected to produce mild pulmonary irritation and cough with heavy exposure to dusts. With pyrolysis, sulfur oxide fumes can be generated, and could produce upper and possibly midrespiratory tract lung irritation cough, and other disorders.

3.4.2.2.1.1 The Camelford Episode Acute oral ingestion of aluminum sulfate occurred in a population accidentally exposed for several days to 20 tons distributed through the water distribution system of Camelford, Cornwall in 1988. Acute symptomatology seen in this episode is nondescript, numerous and varied; questionable, involving the digestive, (sore throat, gastric upsets), skin rashes, backache, and musculoskeletal problems; and with general neuropsychological (anxiety, depression, cognitive problems such as partial loss of memory and concentration ability) complaints and generalized fatigue (171). Because of nonuniform distribution, dose estimations of this large, short-term loading could not be determined, although elevated levels of aluminum as well as other metals persisted for the next several days.

Two years after the episode Rowland et al. (172) compared a 480-person cohort from the Camelford area with 532 persons from an uninvolved district. The exposed cohort more readily reported the occurrence of *all* 18 symptoms in a questionnaire than covered the control cohort. The exposed cohort had a statistically significantly higher relative risk of joint pains complaints, although this complaint occurred in less than 25% of all respondents. The minimal 45% overall response rate among the exposed cohort confounded this study's positive findings.

Further complicating this investigation, neuropsychological evaluation of 10 individuals was performed serially between 8 and 26 months after the episode; the adequacy of information processing and memory was assessed. While showing “consistent impairment of these functions,” the investigators qualified these findings, as they were unable to differentiate between acute brain damage and the imposed psychological stress of the episode (173). By contrast, the same investigator led a study of the psychological performance of children from Camelford and outside the area and could find no differences (175).

Seven years after the Camelford episode, public health authorities (176) reported a 5-year retrospective study of two similar-sized cohorts as previously. Over this 5-year period, serial determinations of standardized hospital discharge ratios were compared and analyzed. They reported

standardized discharge ratios for the Camelford cohort higher than those of the control groups but offered no explanation for this phenomenon.

McMillan et al. (173) also reported that 6 and 7 months after the Camelford exposure the aluminum present in the bones of two of those exposed had disappeared. Similarly, no stainable aluminum was present in bone biopsies of eight exposed persons 12–17 months after the episode. Although this might generally be expected, whether this test (i.e., biopsy and bone stain) of the continued presence of Al in bone is sufficiently sensitive to truly indicate its presence in bone could be questioned, given Priest's (49) indications of a more prolonged bone residence time.

3.4.2.2.2 Chronic and Subchronic Toxicity 3.4.2.2.2.1 Occupationally Exposed Populations Simonsson et al. (148) reported on the exposures of workers engaged in the synthesis of the simple aluminum sulfate salt; three other workers in another plant producing aluminum fluoride were reported incidentally. Exposures were poorly controlled as a result of start-up problems, and atmospheric exposure concentrations ranged from 0 to 53 mg/m^3 as dusts with 25–30% in the respirable range. The employees manifested nocturnal wheezing and breathlessness characteristic of occupational asthma. This reversible airway obstruction persisted despite 2–5 years of nonexposure (mean = 41 months) in 11 of the 19 workers initially affected. The similarity of these cases of reversible obstructive airway disease or occupational asthma cases to those seen in aluminum smelters is noteworthy. However, the occupational asthma syndrome is not uncommon, as it has been been reported consequent to other irritant metal salt exposures, such as from chromates, platinum, nickel, and vanadium. The onset of this condition following production upsets has been seen elsewhere, suggesting a similarity to the reactive airway dysfunction syndrome (RADS). In the cases reported here, the potential irritant capacities of large doses of the simple aluminum sulfate salt would not be not unexpected. It is not reasonable to suggest that many of these cases represented RADS.

3.5 Standards, Regulations, or Guidelines of Exposure

ACGIH: TLV TWA as soluble Al salt; ACGIH = 2.0 mg/m^3 (For discussion of rationale, see Section 2.5)

OSHA: PEL = 2.0 mg/m^3

4.0 Aluminum Phosphide

4.0.1 CAS Number: [*20859-73-8*]

4.0.2 Synonyms: Aluminum monophosphide, phostoxin, aluminum phosphide, celphos, celphide, celphine

4.0.3 Trade Names: Alutal, Celphide, Delicia, Gas-Ex-T, Phosfume, Phostek, Zedesa, AlP; Fumitoxin; Detia; Phos-Kill; L-Fume; Quik-Phos; Gastoxin; Quik-Fume; AL-PHOS; Celphine; Aluminum Phosphide, Tech

4.0.4 Molecular Weight: 58

4.0.5 Molecular Formula: AlP

4.0.6 Molecular Structure: Al≡P

4.1 Chemical and Physical Properties

4.1.1 General Dark gray to yellow crystals; density $2.9_{(water = 1)}$ melting point > 1000; hydrolyzes in water, acids

4.1.2 Odor and Warning Properties None if dry; reacts if contacts water or acids, hydrolyzing to

highly irritant products and garlic odor.
4.2 Production and Use
Because aluminum phosphide hydrolyzes to phosphine in the presence of moisture, it is used to sterilize grain against insect infestation and as a rodenticide in grain storage.
4.3 Exposure Assessment
NIOSH methods 7300 (10) and 7013 (9) can be used to analyze air.
4.4 Toxic Effects
4.4.1 Experimental Studies This compound exhibits toxicity as a consequence of its hydrolysis in water to phosphine (see Chapter covering "Phosphorus and Its Hydride Phosphine, sec —). Rats fed aluminum phosphide exhibited an LD_{50} of 11.5 mg/kg; inhalation exposures have previously indicated an LD_{50} of 15.5 mg/m^3 after 4 h of exposure (176); subsequent studies (177) suggested that these results may be overstated.

4.4.1.1 Acute Toxicity: NA

4.4.1.2 Chronic and Subchronic Toxicity: NA

4.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Aluminum phosphide is not apparently absorbed transcutaneously. Experimentally, its hydrolysis product has consistently produced severe systemic intoxications as a consequence of phosphine formation subsequent to hydrolysis to phosphine in gastric acid and/or respiratory moisture. From those junctures toxicity is due to phosphine.

4.4.2 Human Experience As with the animal data, toxicity stems from phosphine intoxication (see Chapter, sec —).
4.5 Standards, Regulations, or Guidelines of Exposure
See chapter,"phosphine".
5.0 Aluminum Fluoride
5.0.1 CAS Number: [*7784-18-1*]

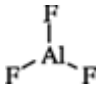
5.0.2 Synonyms: Aluminum trifluoride

5.0.3 Trade Names: NA

5.0.4 Molecular Weight: 83.98

5.0.5 Molecular Formula: AlF_3

5.0.6 Molecular Structure:



5.1 Chemical and Physical Properties
5.1.1 General

Hexagonal crystals, slightly soluble in water 0.6 g/100 mL
Melting point 250°C
Sublimes at 1272°C; sparingly soluble in acids and alkalis, even in hot H_2SO_4

5.2 Production and Use
Inhibitor in fermentation, in ceramics, as catalyst in organic reactions.

5.3 Exposure Assessment
NIOSH methods 7300 (10) and 7013 (9) can used to analyze air.
5.4 Toxic Effects
5.4.1 Experimental Studies No relatively recent animal experimentation data appear to be available. Aluminum fluoride has been considered to have low oral toxicity because of its low aqueous solubility. Evidence is contradictory regarding cutaneous and mucous membrane irritant properties, given this behavior.

5.4.2 Human Experience The report by Simonsson et al. (148) (see Section 3.4.2.2.2.1) included three individual workers who worked in a separate aluminum fluoride production facility. As was the case with the larger group of 19 employees at the other plant, these three individual developed asthma-like symptoms characteristic of reversible airway obstructive disease. Relatively few details of the conditions of exposure or the clinical course among these AlF_3 exposed individuals were reported, as was the clinical course of these few cases. Given the nature of these exposures, their responses, and the relative paucity of human exposure cases, this report remains only suggestive and requires confirmation.
5.5 Standards, Regulations, or Guidelines of Exposure
Both the ACGIH TLV and the OSHA PEL limit exposure to AlF_3, as a"soluble salt of aluminum," at a maximum concentration of 2.0 mg/m^3. It is open to question whether the same standard should apply to aluminum fluoride in view of its relatively minimal solubility compared to aluminum chloride or sulfate.
6.0 Sodium Aluminate
6.0.1 CAS Number: [*1302-42-7*]

6.0.2 Synonyms: Aluminum sodium oxide, aluminum sodium dioxide, sodium aluminum hydride

6.0.3 Trade Names: NA

6.0.4 Molecular Weight: 81.97

6.0.5 Molecular Formula: $AlNaO_2$

6.0.6 Molecular Structure:

6.1 Chemical and Physical Properties
6.1.1 General

White hygroscopic powder
Melting point 1650°C
Insoluble in alcohol
Solubility in water = very high, strongly alkaline
Density $_{(water = 1)}$ > 1.5
Reacts violently with acid
Corrosive with aluminum, zinc

6.2 Production and use
Printing on fabrics, sizing paper, water softners.
6.3 Exposure Assessment
NIOSH methods 7300 (10) and 7013 (9) can be used to analyze air.

6.4 Toxic Effects
Because of the highly alkaline nature of this compound in solution, it should be treated as a corrosive.
6.5 Standards, Regulations, or Guidelines of Exposure
ACGIH: TLV TWA—in view of its relatively high aqueous solubility, it would clearly be considered under the category of "soluble salt of aluminum." The ACGIH assigns a maximum concentration value of 2.0 mg/m^3.

Aluminum
Bertram D. Dinman, MD, Sc.D

D. Alkyl Aluminum Compounds
This class of chemicals represents a large and continuously expanding group of organometallic compounds with varied uses in industry. They have the following general structures: R_2AlH, R_3Al, R_2AlR', R_2AlX, $RAlX_2$, and $R_2AlR'X$, where R and R' are straight-or branched-chain, saturated or unsaturated or mixed alkyls, and X is a halogen. These are treated as a class of aluminum compounds having similar chemical properties that determine their physical behavior and consequently their potential health impacts. They are extremely reactive in air and especially in the presence of water, where they may decompose explosively. Such rapid decomposition is accompanied by rigorous rearrangements of their carbon skeletons with the formations of flammable and/or explosive concentrations of ethylene, propylene, and butylene.
7.0 Diisobutyl Aluminum
7.0.1 CAS Number: [*1191-15-7*]

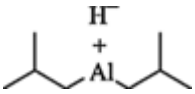
7.0.2 Synonyms: Aluminum, hydrobis (2-methylpropyl)-aluminum diisobutyl; diisobutyl alane

7.0.3 Trade Name: DIBAL-H

7.0.4 Molecular Weight: 142.22

7.0.5 Molecular Formula: $C_8H_{19}Al$

7.0.6 Molecular Structure:



7.1 Chemical and Physical Properties
7.1.1 General

Colorless liquid
Melting point –70°C
Boiling point 105°C at 2 mm Hg
Specific gravity 0.701 g/ml
Pyrophoric in air at concentrations > 25% by weight
Soluble with hydrocarbon solvents

7.2 Production and Use

Major uses as polymerization catalyst; intermediates in silicones, certain polymers and organic acid synthesis.

7.3 Exposure Assessment

NIOSH methods 7300 (10) and 7013 (9) can be used to analyze air.

7.4 Toxic Effects

Essentially no toxicity data have been reported, although the known corrosive properties of the family of compounds is well established. It has been reported that contact with solutions of < 20% concentration (172) may be without hazard. Corrosive action can be expected on eye contact (173).

Atmospheric exposures to fumes of Al_2O_3 will result following pyrophoric and/or explosive reactions as a consequence of oxidation of the aluminum of this compound. Although numerous investigators have suggested that metal-fume fever might result from the aluminum oxide fume so formed, no primary source can be found for that assertion.

7.5 Standards, Regulations, or Guidelines of Exposure

A TLV has been set by the ACGIH for the alkyl aluminum compounds as a class, recognizing the paucity of experimental and/or human exposure data. Although they recognize that their major thermal decomposition product of these metalloalkyls would be Al_2O_3, they also note that many species in this class are halogenated. (see introductory paragraph preceding Section 7.0). Consequently, it could be assumed that pyrolysis would also be accompanied by the formation of halogen acid gases. Given the (possible) presence of such acid gases, ACGIH recommended a blanket guideline lower than that set for aluminum welding fume, specifically 2 mg/m^3 for those alkyl aluminum compounds not otherwise classified (NOC).

8.0 Triisobutylaluminum

8.0.1 CAS Number: [*100-99-2*]

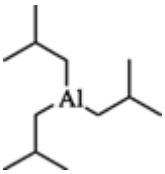
8.0.2 Synonyms: Aluminum triisobutyl; aluminum, tris (2-methylpropyl)-; Tibal; aluminum triisobutamide; triisobutylalane

8.0.3 Trade Names: NA

8.0.4 Molecular Weight: 198.33

8.0.5 Molecular Formula: $C_{12}H_{27}Al$

8.0.6 Molecular Structure:



8.1 Chemical and Physical Properties

8.1.1 General

Clear, colorless liquid
Melting point 6°C
Boiling point 86°C (at 10 mm Hg)
Vapor pressure 1 mm Hg (at 47°C)
Pyophoric or explosive in water
Explosive reactions with alcohols, benzene

8.1.2 Odor or Warning Properties White fumes with musty odor.
8.2 Production and Use
Major use is as a polymerization catalyst in synthesis of polybutadiene, polyisoprene, primary alcohols, and olefins; also as an intermediate in synthesis of phosphate insecticides, and as a reductant.
8.3 Exposure Assessment
NIOSH methods 7300 (10) and 7013 (9) can be used to analyze air.
8.4 Toxic Effects
See Section 7.4.
8.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH guideline TLV is 2.0 mg/m^3. (For discussion of rationale, see Section 7.5.)

Gallium, Indium, and Thallium
Guillermo Repetto, MD, Ana del Peso

A. Gallium and Gallium Compounds
1.0 Gallium
1.0.1 CAS Number: [*7440-55-3*]

1.0.2 Synonyms: Gallium, gallium metal

1.0.3 Trade Names: UN2803

1.0.4 Molecular Weight: 69.72

1.0.5 Molecular Formula: Ga
1.1 Chemical and Physical Properties
1.1.1 General The chemical element gallium (Ga), of atomic number 31, is a bluish metal of group IIIA in the periodic table. Gallium is a relatively rare metal that is becoming increasingly important in the manufacture of semiconductor electronic devices. Gallium was isolated for the first time from zinc sulfide ore in 1875 by the French chemist Lecoq de Boisbaudran, who named it after Gallia, the Latin name for France. Later the same year Dmitry Mendeleyev showed that gallium was the missing group IIIA element predicted in his theory of chemical periodicity, below aluminum and above indium.

Gallium is present in the earth's crust in a concentration of 5–15 ppm. It often occurs in small amounts in the sulfide ores of its neighbors in the periodic table, zinc and germanium; because of its chemical similarity to aluminum, it is a minor component of all aluminum ores. It is not present in significant concentrations in the ocean. The richest source, which is located primarily in southwestern Africa, is the mineral germanite, a sulfide. Germanite may contain 0.5–0.7% of gallium, but gallium is widely distributed in small amounts in zinc blends, aluminum clays, feldspars, and coal, and in the ores of iron, manganese, and chromium. Bauxite, the clay-like ore from which aluminum is obtained, contains 0.0002–0.008% gallium, whereas some tin ores contain 0.01–0.05% of gallium.

Gallium is a lustrous, silvery liquid or bluish metal or a gray solid. It is the only metal, except for mercury, caesium, and rubidium, that can be liquid near room temperatures; this makes possible its use in high-temperature thermometers. It has one of the longest liquid ranges of any metal and has a low vapour pressure even at high temperatures. Ultrapure gallium has a beautiful, silvery appearance, and the solid metal exhibits a conchoidal fracture similar to that of glass (1).

Molten gallium expands by as much as 3.2% on solidifying; therefore, it should not be stored in glass or metal containers, as they may break while the metal solidifies. Bismuth is the only other metal having this property. High purity gallium is attacked only slowly by mineral acids. Gallium arsenide is capable of converting electricity directly into coherent light, as it is a key component of LEDs (light-emitting diodes).

Gallium, Indium, and Thallium
Guillermo Repetto, MD, Ana del Peso

B. Indium and Indium Compounds
8.0 Indium
8.0.1 CAS Number: [*7440-74-6*]

8.0.2 Synonyms: Indium metal

8.0.3 Trade Names: NA

8.0.4 Molecular Weight: 114.82

8.0.5 Molecular Formula: In
8.1 Chemical and Physical Properties
8.1.1 General Indium is a rare, lustrous silver-white metal with atomic number 49 and In as its atomic symbol. It is widely distributed in the earth's crust in minute quantities (0.1 ppm) and is also found in the hydrosphere. Indium belongs to group IIIA in the periodic table. It was found and spectroscopically identified as a minor component in zinc ores and isolated in 1863 by Ferdinand Reich and Theodore Richter. Indium is so named for the indigo blue color that its salts lend to flames. Indium resembles tin in its physical and chemical properties and to some extent in its toxicological properties. It is extremely soft and malleable, with a Brinell test hardness of less than 1 and a Mohs scale hardness of 1.2. In the electromotive series it appears between iron and tin, and does not decompose in water at boiling temperature. It is stable in air, but when heated, it burns with a nonluminous, blue-red flame yielding indium oxide. The surface of indium remains bright up to its melting point; above this, it forms an oxide film.

Indium has a density of 7.3 g/mL (at 20°C), a melting point of 156.61°C, a boiling point of 2000°C, and a specific heat of 0.0568 cal g^{-1} $°C^{-1}$. Indium is insoluble in hot or cold water, soluble in acids,

and very slightly soluble in sodium hydroxide (163). There are two natural isotopes: 115 (95.77%) and 113 (4.23%). Indium-115 is a b-emitter, with a half-life of 6×10^{14} years. The artificial radioactive isotopes are 107–112, 114, and 116–124 (1–5). Indium forms mono-, di-, and trivalent compounds, of which the last is the most common. The trichloride is deliquescent; the sulfate is hygroscopic. Intermetallic semiconductors are formed from group III and group V elements. Most used are InSb, InAs, and InP. All require very high element purity (0.1 ppm). InSb is employed in infrared detectors and magnetoresistors. It wets glass, as does gallium. It is useful for making low melting alloys. An alloy of 24% indium and 76% gallium is liquid at room temperature.

8.1.2 Odor and Warning Properties Indium is flammable in the form of dust, yielding indium oxide when exposed to heat or flame. Mixtures of indium with sulfur ignite when heated. Indium reacts explosively with dinitrogen tetraoxide plus acetonitrile. Indium exhibits a violent reaction with mercury(II) bromide at 350°C. Indium is unaffected by water, is attacked by mineral acids and is very resistant to alkalies (7).

Gallium, Indium, and Thallium
Guillermo Repetto, MD, Ana del Peso

C. Thallium and Thallium Compounds
14.0 Thallium
14.0.1 CAS Number: [*7440-28-0*]

14.0.2 Synonyms: Thallium, rod; thallium metal, ramor

14.0.3 Trade Names: NA

14.0.4 Molecular Weight: 204.383

14.0.5 Molecular Formula: Th
14.1 Chemical and Physical Properties
14.1.1 General Thallium is a soft, gray-white metal. It is a member of group IIIA in the periodic table. The name derives from the Greek root *thallos*, meaning green or young twig. Thallium metal was isolated in 1861 by William Crookes and, independently, by the French chemist Claude-Auguste Lamy. Thallium's innate toxicity was recognized shortly after its discovery, when Crookes suffered from its effects. Thallium does not occur in nature in the elemental state but is present as a trace compound in many minerals, mainly associated with potassium and rubidium. Although thallium is widely distributed in the earth in an estimated abundance of 0.3 ppm, its wide distribution belies its availability, for it occurs chiefly as a minor constituent in iron, copper, sulfide and selenide ores, crooksite $(TlCuAg)_2Se$, orabite $(TlAs_2SbS_5)$, and lorandite $(TlAsS_3)$, mainly in Texas and Brazil. One exception is the occurrence of lorandite in gold ore in Nevada, which contains an average of 60% thallium. The deposits of thallium minerals are so small as to have no commercial significance at present.

Thallium metal is somewhat softer and more malleable than lead and, when freshly melted, resembles tin in whiteness. Thallium, however, oxidizes rapidly, turning gray, then brownish black from an oxide coating. For this reason thallium rods are often paraffin-coated. The metallurgical properties of thallium are unknown because of limited use of the metal. The most interesting properties include boiling point 1457°C, melting point 303.5°C, commencement of volatilization at 174°C, density 11.85, vapor pressure 1 mm Hg at 825°C and 20 mm Hg at 1040°C, specific heat at 20°C 0.13 J/g, first ionization energy 590 kJ/mol, fusion heat 21.1 J/g, atomic volume $5.15 \times 10^{+30}$ W/(C.m), thermal conductance 0.39 W/(cm·K), covalent radius 0.148 nm, electronegativity 1.8

according to Pauling's scale, linear coefficient of expansion 28×10^{-6}, electrical resistivity 18 mW/cm, tensile strength 9.0 MPa, bond strength <22 kcal/mol, heat of formation (gaseous) 43.55 kcal/mol. Easily fusible, thallium leaves a streak on paper; below 230°C it forms close-packed hexagonal crystals and above 230°C, body-centered cubic crystals. It may be distilled in a stream of hydrogen. Two natural isotopes of thallium have been found: 203 (29.50%) and 205 (70.50%) (1–5).

1.1 Chemical and Physical Properties
Germanium is a semiconducting metal from Group IVA of the periodic table.

The physical and chemical properties of germanium and some of its compounds are listed in Table 33.1.

Table 33.1. Physical and Chemical Characteristics of Germanium and Some of Its Compounds

Form	Germanium (Ge)	Germanium Dioxide (GeO_2)	Germanium Tetrachloride ($GeCl_4$)	Germane[a] (GeH_4)
Atomic or mol. wt.	72.60	104.6	214.4	76.63
Specific gravity	5.35 (20°C)	4.228 (25°C)	1.879 (20°)	—
Melting pt. (°C)	937.4	1115	–49.5	–165
Boiling pt. (°C)	2830	—	84.0	–90
Solubility	Insol. water, alkalis; sol. hot H_2SO_4	Sl. sol. water; sol. acids, alkalies	Dec. water; sol. dil. HCl, alcohol, ether	Insol. water; sol. NaClO

[a] Germanium tetrahydride.

In 1886 Clemens A. Winkler, a German chemist, isolated germanium from the mineral argyrodite, a mixed sulfide of silver and germanium. It was named after the country of the discoverer. In recent years various germanium compounds, for example, carboxyethyl germanium sesquoxide (Ge-132) and lactate–citrate–germanate, have been sold as nutritional supplements, thereby increasing exposure above predicted levels.

Germanium metal has the most unusual property of being highly transparent to infrared light. This characteristic, coupled with a high index of refraction, is used to advantage in making unique optical elements. Crystalline germanium is a true semiconductor; traces of impurities of 0.1 ppm such as antimony, tin, and lead will lower its electric resistivity from 50 to 0.1–10 ohm/cm. Germanium forms alloys with many metals, producing solid solutions or intermetallic compounds that expand on solidification. Germanium is not attacked by O_2 in air or by HF (aq.) or HCl (aq.), but reacts slowly with concentrated nitric and sulfuric acids. Alkaline H_2O_2 or aqueous NaClO rapidly oxidizes germanium. Germanium forms two series of salts, divalent and tetravalent, which chemically resemble stannous and stannic compounds. The tetravalent is the most common, stable form. Germanium does not form salts with the common inorganic oxy acids. In its tetravalent compounds germanium is in coordinate valence with neighboring atoms. Germanium forms a series of hydrides, germanes, by the reaction of HCl and Mg_2Ge. They possess pungent odors, are combustible, and are often explosive. Germanium tetrahydride, GeH_4, does not react with O_2 below 230°C or explode below 330°C; digermane (Ge_2H_6) is more explosive. A series of halogenated germanes are known that are colorless gases or liquids. Although germanium does not form a carbide, it forms strong bonds with carbon atoms to form a variety of organo compounds such as tetraalkyl- and

tetraarylgermanes. They are volatile, stable, colorless substances, insoluble in water, but soluble in organic solvents.

Germanium forms a series of hydrides that correspond chemically to the methane series of hydrocarbons and to silanes (silicon series of hydrides). The germanes are insoluble in hot and cold water, soluble in sodium hypochlorite (aq.), and slightly soluble in hot HCl (aq.).

There are numerous organogermanium compounds. Interest in the organogermanium compounds has centered around their antimicrobial activity and the fact that their mammalian toxicity is considerably lower than the corresponding derivatives of tin or lead.

1.2 Production and Use

Although it looks like metal, in the pure form it is fragile like glass. The concentration in the earth's crust is 1.5 to 7 ppm. Germanium is not found in the free state, but in combination with other elements as a mineral, such as in the principal minerals argyrodite (Ag_8GeS_6, 5–7% Ge) and germanite ($7CuS–FeS_2–GeS_2$, 8.7% Ge). Enargite, a Cu–As sulfide, is found in the western United States and contains as much as 0.03% Ge; but none of these minerals is utilized for recovery of germanium because of the small quantities available. Germanium is commonly distributed within the structure of other minerals, most abundantly in sphalerite (ZnS) in quantities of less than 1%. Some silver and tin ores contain germanium, as do some coals; the germanium content of coals in West Virginia, Illinois, and Kansas has been reported, but no commercial recovery has been made. A germaniferous lignite in the Unites States has been reported. Oak and beech humus in one locality in Germany contains 70 ppm Ge. Germanium is taken up by cereals, especially oats, from germanium-bearing soils. The principal domestic source of germanium is from the residues of cadmium derived from zinc ores. Commercial recovery of germanium has been chiefly from zinc and Zn–Cu–Pb ores, germanite, and flue dusts from coals.

Ores from the tristate area of Missouri, Oklahoma, and Kansas are concentrated and roasted to a crude zinc oxide by conventional means. Roasted ores mixed with salt and coal are sintered at a high temperature; germanium, cadmium, and some other impurities are vaporized. The vapors are then condensed and collected in an electrostatic precipitator. This by-product fume is chemically treated to obtain crude fractions of germanium, cadmium, and the other impurities.

The germanium concentrate is reacted with strong hydrochloric acid, and the resultant $GeCl_4$ (bp 86° C) is distilled off. The crude tetrachloride is purified further and finally distilled with chlorine (to hold back arsenic). The purified, redistilled $GeCl_4$ is then hydrolyzed in water to form GeO_2, which is reduced to a powdered metal by heating to 650°C in an atmosphere of hydrogen. The powdered metal is melted at 1100°C in an inert atmosphere to form ingots. When extreme metal purity is desired, multiple-zone melting and fractional crystallization are used, which make the impurities concentrate at one end of the bar.

The modern field of semiconductors owes much of its development to the early use of germanium. In 1948, William Shockley used germanium to make the first transistor. Many of the uses for which germanium is noted arise from its property as a semiconductor: in transistors, diodes, and rectifiers, replacing and exceeding the functions of vacuum tubes. Their development during World War II was responsible to a large extent for the “revolution in electronics.” Diodes are used in various types of electronic circuits, including ratio, television, telegraphy and telephony, multiposition switching, and in voltage-multiplier circuits. Small diodes are made by the millions; large ones for power generation are also produced. Transistors are utilized in radio and television as amplifiers and oscillators. Because germanium is only one of several substances with semiconductor properties, other substances such as silicon are competing with germanium as transistor diode material. Various combinations, such as arsenic and antimony alloyed with aliminum, gallium, and indium, also are being developed for these purposes.

In 1998 the largest use was in fiber optic systems (40%) followed by polymerization catalysts (20%), infrared optics (10%), electrical/solar operations (20%), with the remaining 10% used in metallurgy, chemotherapy or formation of phosphors (1).

Lenses of germanium have been made for industrial infrared work. $MgGeO_3$ is used as a phosphor. Glass in which germanium replaces silicon possesses a high refractive index and is used in wide-angle camera lenses and in microscope objectives.

Germanium is used as a catalyst in the hydrogenation of coal, and particularly as an extremely low-temperature catalyst. More recent uses are for gamma-ray detection, principally in nuclear research, activation analysis, and medical applications. It is used in gold alloys when precision casting is needed. Germanium catalysts are used in some petroleum refining operations and processes for the production of polyester fibers.

1.3 Exposure Assessment

Industrial exposures are to the dusts and fumes of the metal and its oxide during the separation and purification from the ore concentrate. Exposure to cadmium, lead, and zinc occur concomitantly during this process. In the electronics industry, exposures are confined to dopant application, diode production, and substrate production. No reports of hazardous industrial exposures have yet appeared in the literature.

Exposure assessment methods have been developed for measuring air levels of germanium tetrahydride and germanium dioxide. NIOSH does not have a method for either compound or any other germanium compounds (1a). The suggested sampling methods are given in Table 33.2.

Table 33.2. Chemical Sampling Methods and Related Data for Common Germanium Compounds

Name	Germanium Tetrahydride	Germanium Dioxide
CAS Number	[*7782-65-2*]	[*20619-16-3*]
Physical state	Gas	Solid
Monitoring media	Charcoal tube (100/50 mg sections, 20/40 mesh)	Mixed cellulose ester filter (MCEF) 0.8 mm pore size
Maximum volume	48 L	960 L
Minimum volume	24 L	480 L
Analytical method	Atomic absorption spectroscopy	Atomic absorption spectroscopy

1.3.5 Biomonitoring/Biomarkers Urine samples have been recommended as an effective medium for biological monitoring. The “tentative maximum persmissible concentration” in the urine is 40 mg/g creatinine with a reference value of 1 mg/100 g creatinine.

A molybdenum blue method has been used by Rosenfield (2) for the determination of microgram amounts of germanium in biologic samples. Although the procedure has not been reported in detail, a critical examination of the optimal conditions for analysis of microgram quantities with an error of 5% is given by Shaw and Corwin (3). A spectrographic procedure, adapted for the analysis of

germanium in silicon alloys over a concentration range of 1 to 98 mol.% Si, with a standard deviation of 8%, has been reported (4). Atomic absorption spectroscopy has not been reported for determining small quantities of germanium, but electron probe X-ray microanalysis has been employed to determine tissue concentrations (5).

1.4 Toxic Effects

There is no know biologic requirement for germanium, germanates, or any organogermanium compound. Germanium deficiency has not been demonstrated in any animal. The estimated average dietary intake of germanium in humans is 1.5 mg/d. Germanium is widely distributed in edible foods, such as baked beans (5 ppm), canned tomato juice (5 ppm), and canned tuna (3 ppm).

Neutron-activated, commercially cast germanium metal dust (Ge) with a mean particle size of 1.7 mm proved innocuous to rats exposed by inhalation for 1 h at an unspecified concentration, as did GeO_2 of particle size 0.45 mm (6). Harrold et al. (7) had previously reported that GeO_2 is innocuous, based on their results of intraperitoneal injection at large doses (100 mg) in guinea pigs and intrapleural or intravenous injections in rabbits. Dermal application of either pure or buffered solutions of GeO_2 in humans and animals are also not harmful. Later work by Rosenfeld and Wallace (8) found that the maximal tolerated single intraperitoneal dose of neutralized (pH 7.3) GeO_2 approximated 600 mg/kg for the rat; the corresponding minimal lethal and "absolute" lethal doses were 700 and 1200 mg/kg, respectively. The estimated intraperitoneal LD_{50} was 750 mg/kg. Similarly administered germanium–annitol and germanium–glycerin were tolerated at 140 mg/kg. Most of the deaths from GeO_2 were rapid, occurring within 12 h; the remaining deaths occurred within 24 h. Gross tissue changes consisted of edematous, hemorrhagic lungs, multiple petechiae in the walls of the small intestine, and peritoneal effusion. The peritoneal fluid was voluminous and rich in protein. Death was usually preceded by hypothermic shock (rectal temperatures sometimes below 80°F) and almost complete respiratory depression. No effects on the nervous system or on the blood were found. Loss of retroperitoneal fat was due to the alkalinity of Na_2GeO_3, and not to germanium per se, confirming the results of Harrold et al. (7).

Inhalation of GeH_4 in minimally effective concentrations (70 mg/m^3 for GeH_4) for 2–15 d resulted in nonspecific and nonpersistent changes in the nervous system and kidneys and in the blood composition. When adequate physiological loads were applied, a strain on the compensatory mechanisms was discernible after two to four inhalation periods. Under analogous conditions, $GeCl_4$ at 4 mg/m^3 caused changes in the respiratory system that persisted (9).

Acute (4-h) and subacute (4-wk) inhalation toxicity studies of germanium metal powder (purity 99.8%, mean particle size 2.0–2.4 mm) were carried out in young adult Wister rats. The 4-h LC_{50} value of germanium metal powder in rats is greater than 5.34 g/m^3. Rats were exposed to 0, 9.9, 65.1, or 251.4 mg/m^3 for 6 h/d, 5 d/w, for 30 d. At the end of the exposure period, fasting blood glucose was decreased in males exposed to the high concentration. In females of this group, blood creatinine and urea levels and urine volumes were increased, but urine density was decreased. Increased blood creatinine levels and urine volume and decreased urine density were also observed in females exposed to 65.1 mg/m^3. The absolute and relative lung weights were increased in rats in the mid- and high-concentration groups. Histopathological evaluation revealed accumulation of particulate material in the lungs of all treated groups, accumulation of alveolar macrophages in the mid- and high-concentration groups, and alveolitis, mainly in the high-concentration group. After a 4-w recovery period, urine volume was increased in males that had been exposed to germanium. In exposed rats of both sexes, lung weights were still increased and histopathological changes were present, but to a lesser extent than at the end of the exposure period. The no-adverse-effect level in the 4-w study was 9.9 mg/m^3 air (10).

Additional acute and subacute studies were performed on wistar-rats to assess the effects of exposure

to amorphous or hexagonal germanium dioxide. Exposures were for 4 h or 4 wk. A variety of biochemical and histopathological variables were examined at various times following exposures. At the end of the study, changes were identified consisting of gray spotted lungs with macrophage accumulation. In the subacute study, alterations included decreases in body weights, hematocrits, thrombocyte counts, fasting glucose levels, total protein concentrations, and urine density and pH, and increases in neutrophil and white blood cell counts, plasma alanine aminotransferase and aspartate aminotransferase activities, plasma urea nitrogen, plasma bilirubin, urinary volume, and kidney, spleen, heart, and lung relative weights. These changes occurred primarily in rats exposed to the highest germanium dioxide levels. Histological evaluation of the kidney revealed changes in the renal tubular epithelium. In the acute study, the LD_{50} for amorphous germanium dioxide was calculated to be 3.10 g/m^3 and 1.42 g/m^3 for hexagonal germanium dioxide, while the NOAEL (no observed adverse effect level) in the subacute study using hexagonal germanium dioxide was 72 mg/m^3 (10a).

Ohinishi (1989) used rats and monkeys to assess the neurotoxicity of germanium dioxide. Rats were administered orally and intraperitoneally doses of 100 mg/kg/d of germanium dioxide 3 days a week for 8 weeks and 400 mg/kg/d once a week for 8 weeks. No degeneration of the peripheral nerves was observed. In addition to the rats, two monkeys were also exposed via the oral route to 30–40 mg/mg/day, 5 days a week for 8 months. As with the rats, no degeneration of peripheral nervous system was observed. However, proteinuria and elevated blood urea nitrogen were observed (10b).

The effects of exposure to germanium dioxide and germanium tetrachloride were studied in chickens to assess whether germanium affected weight gain (10c). In one experiment there were 9 groups of birds. They were fed a basic diet supplemented with 0, 1, 10, 100 or 1000 ppm germanium (as germanium dioxide) and 1, 10, 100, 1000 ppm germanium (as germanium tetrachloride). Germanium dioxide at 10 ppm improved growth and feed conversion by 12% and 7.5% ($p < 0.05$), respectively. The fattening effect was not observed for any of the germanium tetrachloride exposed chickens. In the highest exposure group (1000 ppm germanium from either germanium dioxide or germanium tetrachloride) all the birds died in 17 and 28 d, respectively. In the second experiment, there were 8 groups of birds. They were also fed a basic diet and 0, 2, 5, 10, 20, 50, 100, and 200 ppm germanium as germanium dioxide. The 5 ppm group showed a slight growth-promoting effect (3.3%) over the controls. No adverse effects were observed in any of the groups in experiment 2.

A study on the suppressive effects of Ge-132 (carboxyethyl germanium sesquioxide) on protein glycation was undertaken to test the hypothesis that reduced protein glycation would result in reduced cataract formation. Sprague–Dawley rats were fed a 50% galactose diet, a diet that historically leads to development of cataracts in these rats. One group of rats received topical saline; the other group received Ge-132 in saline four times per day. The lenses were examined for cataract development starting on day 3 and continuing through day 21. The study found that the abnormalities associated with cataract formation were present in both groups but that the treated group experienced delayed cataract development (10d).

1.4.1.2 Chronic and Subchronic Toxicity Germanium dioxide (GeO_2) behaves as a potent antimutagen on frameshift-type reverse mutations induced by Trp-P-2 (3-amino-1-methyl-55H-pyrido[4,3-blindole]) in strains of *Salmonella typhimurium* TA98 and TA1538 (11). This observation has led to the investigation of the chronic nephrotoxicity in rats orally administered GeO_2 for 24 wk. Increased blood urea nitrogen (BUN) and serum phosphate, as well as decreased creatinine clearance, weight loss, anemia, and liver dysfunction, were apparent at week 24 only in the GeO_2-treated rats. Vacuolar degeneration and granular depositings were observed by light microscopy in the degenerated renal distal tubules of the rats. Electron microscopy revealed electron-dense inclusions in the swollen mitochondrial matrix of the distal tubular epithelium among the GeO_2-treated rats. Although systemic toxicities were reduced after GeO_2 was discontinued at week 24,

renal tubulointerstitial fibrosis became prominent even at week 40. A Ge-K alpha X-ray spectrum was clearly demonstrated in the mitochondrial matrix of the distal tubular epithelium in the GeO_2 rats by electron probe X-ray microanalysis. The renal tissue content of germanium was high at weeks 24 and 40 in the GeO_2-treated rats. It appears that residual GeO_2 remains for a long time, even after the cessation of intake (5).

Chronic nephrotoxicity was investigated in rats administered germanium dioxide and carboxyethyl germanium sesquioxide for 24 wk. The germanium dioxide group experienced increased blood urea nitrogen, increased serum phosphate, as well as decreased creatinine clearance, weight loss, anemia, and liver dysfunction. Degeneration of the renal distal tubules was observed. There was also observable granular deposition in the degenerated tubules. These effects were only observed in the germanium dioxide exposed group. It was concluded that germanium dioxide causes this characteristic nephropathy while carboxyethyl germanium sesquioxide does not (11a).

1.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Inorganic germanium as neutralized GeO_2 is readily absorbed following small (a few milligrams) oral, subcutaneous, intramuscular, or intraperitoneal doses in the rat (2). Blood concentrations somewhat less than 10 mg/g are attained within a few hours after administration. Following a single small dose, germanium leaves the bloodstream within a few hours. Germanium is transported via the blood unbound to protein. Germanium is widely distributed throughout the body and is not selectively retained in any tissue. After 1 wk following a moderate intraperitoneal dose (40 mg Na_2GeO_3/kg) all germanium that had gone to the tissues had disappeared. Germanium is excreted by both the kidneys and the gastrointestinal tract, but the kidney is the chief excretory organ (80 versus 13%).

Excretion studies of elemental Ge and GeO_2 in the rabbit and rat showed elimination chiefly via the urine (12). Essentially the same type of kinetic activity occurred with neutron-activated Ge and GeO_2 dusts by inhalation (13). Rats exposed to (unmeasured) atmospheres of Ge for 1 h at respiratory particle sizes (1.7 and 0.45 mm mean diameter, respectively) showed moderately fast elimination of the Ge from the lungs; 52% disappeared in 1 d and 82% in 7 d, the longest period of observation. The kidneys and liver contained only trace amounts at 7 d. Germanium dioxide-Ge was cleared somewhat more rapidly from the lungs, kidneys, and liver (79% in 1 d); and only trace amounts remained in these organs at 4 and 7 d.

Spirogermanium is a new metallic investigational anticancer drug. The metal germanium is substituted for a one-carbon moiety in the ring structure to form spirogermanium. This drug inhibits DNA and RNA synthesis in HeLa cells. The mode of action has not been fully elucidated; however, spirogermanium is not a phase- or cell-cycle-specific drug and inhibits DNA, RNA and protein synthesis, and protein synthesis being the most susceptible to this agent. Spirogermanium has revealed activity *in vivo* against intraperitoneally implanted Walker 256 sarcoma, 13762 mammary adenocarcinoma, and 11095 prostatic carcinoma in rats, but no antitumor activity *in vivo* was found in the murine tumors used in L 1210 and P 388 leukemia, B 16 melanoma, or Lewis lung carcinoma. In addition, spirogermanium has shown cytotoxic activity *in vitro* against several human tumor cell lines at concentrations (1 mg/mL) that were toxic to the cultured rat neurons. Although spirogermanium has no effect on normal bone marrow colony-forming cells in mice, dogs, or humans, it has shown cytotoxic activity *in vitro* against human myeloid leukemia cell line K 562 at clinically acceptable concentrations. These *in vitro* findings indicating selective cytotoxic activity against leukemia cells suggest this agent as a candidate for clinical studies in acute and chronic leukemias. Spirogermanium lacks bone marrow toxicity, unlike many other anticancer drugs. This has been confirmed in preclinical toxicology and clinical studies. However, moderate, predictable, and reversible CNS toxicity is dose limiting. Activity in malignant lymphoma, ovarian cancer, breast cancer, larger bowel cancer, and prostatic cancer was also reported in the clinical studies. A dose of 80–120 mg/m^2 (body surface) given by 60-min infusion three times a week was used in the clinical studies (14).

1.4.1.6 Genetic and Related Cellular Effects Studies Benzo(a)pyrene (BaP) is a known carcinogen and mutagen found in tobacco smoke and a number of other environmental sources. Olson et al. (1995) conducted a study to assess the ability of germanium dioxide to reduce the mutagenic potential of BaP in the Ames assay. In general, germanium dioxide was found to be relatively ineffective in reducing the mutagenic potential of BaP. In three out of four strains tested germanium showed some effect, and then only at highest concentrations, for example, 400–600 mg/plate (14a).

1.4.2 Human Experience There have been 18 reported cases of acute renal dysfunction or failure, including two deaths linked to oral intake of germanium elixirs containing GeO_2 or Ge. In these cases, biopsies show vacuolar degeneration of the renal tubular epithelial cells in the absence of glomercular changes, without proteinuria or hematuria. Serum creatinine levels have been well above 400 mmol/L in such patients. In 17 of 18 cases, accumulated elemental germanium intakes reportedly ranged between 16 and 328 g over a 4–36 mo period, or between 100 and 2000 times the average estimated dietary intake for humans. In surviving patients, renal function improved after discontinuation of germanium suplementation. However, in no case was recovery complete (15).

In a typical case a 55-year-old woman was admitted to a hospital, complaining of general malaise, muscular weakness, anorexia, and weight loss. She had a history of ingesting a germanium compound for the preceding 19 months, with a total dose of 47 g as Ge. The patient had renal failure (BUN, 44 mg/dL; serum creatinine, 2.6 mg/dL) without abnormal findings in urinalysis, and muscular and nervous damage. Polymyositis was diagnosed and prednisolone given. She did not improve. The neuromuscular signs continued to develop until she died. In the histopathological evaluation of the kidney, lipofuscin granules increased in the cells of the thick ascending limb of Henle's loop to the distal convoluted tubule accompanying mild tubular atrophy. Some of the tubules of these segments had vacuolar degeneration or desquamation. No glomercular and vascular changes were observed. Germanium was found in serum, urine, and various tissues, including the spleen, liver, kidney, adrenal gland, and myocardium, whereas in normal individuals germanium cannot be detected in serum, urine, or tissues (16). The principal clinical toxic effects observed were neurological, manifested as lethargy, dizziness, and ataxia; and a grand mal seizure was produced after an accidental overdose. A partial response was achieved in a patient with lymphocytic leukemia (17).

In another clinic, five patients were evaluated who had taken inorganic germanium preparations over a prolonged period. In each patient, renal function had deteriorated with no proteinuria or hematuria. Through histological examination the kidneys were found to have widespread tubular degeneration and interstitial fibrosis with minor glomercular abnormalities. The most common symptomatolgy included gastrointestinal symptoms such as vomiting, anorexia, and weight loss; however, one patient had peripheral neuropathy and myopathy. Germanium was detected in the hair or nails of the patients (17a).

Another case involved a 4-year-old female who had orally received 225–450 mg/kg/day of germanium dioxide for the previous 28 months. The child had suffered from gait disturbances and muscle weakness for the past 22 months. Findings were made of chronic renal failure, anemia, diffuse muscle atrophy, tongue fasciculation, and reductions in median and ulnar nerve conduction velocities. On the seventeenth day of hospitalization the child died of renal failure. Autopsy showed damage to the renal tubular cells, widespread nerve fiber loss, and axonal degeneration (17b).

No recent studies of the toxicity of the germanes appear to have reached the open literature, but early, limited toxicity tests (30 and 60 min) of GeH_4 indicated 610 mg/m^3 for 30 min was ultimately lethal to a mouse, whereas 480 mg/m^3 for 60 min was lethal to a mouse but not a guinea pig, and in a rabbit 310 mg/m^3 for 60 min produced only dyspnea, not death (18). Hemoglobinuria was noted in the animals, thus resembling AsH_3 in this respect. Thus the order of increasing toxicity would appear

to be GeH_4, AsH_3, and SnH_4, but comparisons on such limited data are very uncertain. The higher hydrides of Ge are noted (6) to be less toxic than GeH_4, but no supporting evidence is given.

1.5 Standards, Regulations, or Guidelines of Exposure

Germanium tetrahydride is the only germanium compound for which air standards have been established (19). The NIOSH REL and the ACGIH TLV are 0.2 ppm (approximately 0.63 mg/m^3). In Australia and the United Kingdom the permissible level is also 0.2 ppm. The toxicity, hemolysis, is similar to that of stibine, but GeH_4 is believed to be about half as toxic as stibine (20). No IDLH (immediately dangerous to life and health) level has been established for any of the germanium compounds, including germanium tetrahydride. The TLV for germanium tetrahydride was based on acute toxicity. There are currently no TLV, RELs, etc. for other germanium compounds.

2.1 Chemical and Physical Properties

Tin is a solid, rather unreactive metal in Group IVA of the periodic table. Its chemical symbol, Sn, is derived from stannum, the Latin word for tin. Tin is known as Etain in French and Zinn in German. Tin has 10 naturally occurring stable isotopes, the largest number of stable isotopes of any element. The most abundant stable isotope is one having a mass of 120 (32.85%). Tin has a large number of unstable isotopes with half-lives ranging from 2.2 min to 10^5 years.

Tin has played a major role in the development of civilization. The Bronze Age began approximately 3500 B.C. with the discovery that easily smelted soft copper could be made harder and stronger by alloying with tin. The first inclusion of tin in bronze was probably an accidental result of tin ore being found in copper ore; pure tin was most likely obtained at a later date.

The physical and chemical properties of tin and some of its compounds are listed in Table 33.3.

Germanium, Tin, and Copper

3.0 Copper

3.0.1 CAS Number:

[*7440-50-8*]

3.0.2 Synonyms:

NA

3.0.3 Trade Names:
NA
3.0.4 Moleculer Weight:
63.5
3.0.5 Molecular Formula:
Cu
3.1 Chemical and Physical Properties
Copper is located in Group IB of the of the periodic table and was one of the first metals used by humans and is second only to iron in industrial importance.

The electrical conductivity and malleability of copper are its most importance properties. The boiling point of copper is 2567°C, the melting point is 1083.4°C, and the density is 8.92. Other properties of copper compounds are shown in Table 33.5. Copper is slowly attacked by dilute hydrochloric acid or dilute sulfuric acid and is slowly soluble in ammonia water (56).

Table 33.5. Physical and Chemical Properties of Selected Cu Compounds

Form	At. or Mol. Wt.	Sp. Gr.	MP (°C)	BP (°C)	Solubility
Copper, Cu	63.57	8.92	1083	2567	Insol. water; sol. HNO_3, hot H_2SO_4; v. sl. sol. HCl, NH_4OH
Copper oxide, CuO	79.54	6.4	Dec. 1226	—	Insol. water; sol. NH_4Cl, KCN
Copper acetate, $Cu(C_2H_3O_2)_2 \cdot 6H_2O$	199.65	1.88	115	Dec. 240	72 g/L cold water; sl. sol. alcohol
Copper carbonate, $CuCO_3 \cdot Cu(OH)_2$	221.11	4.0	Dec. 200	—	Insol. cold water; dec. hot water
Copper chloride, $CuCl_2$	134.44	3.386 (25°C)	620	(93 dec. to CuCl	706 g/L (0°C); sl. sol. alcohol
Copper cyanide, $Cu(CN)_2$	115.58	—	Dec.	—	Insol. cold water, sol. acids, alkalies, KCN

3.2 Production and Use (128)
Copper, like silver and gold, the other members of the noble metals, is found free in nature. Because it was found free in nature, was malleable, and could be utilized in making tools copper was in use before 5000 B.C. A naturally forming “patina” of copper carbonate that covers exposed copper prevents further oxidation. The name *copper* is derived from the Latin word *cuprum*, which, in turn, is derived from an earlier word, *cyprium* or “Cyprium metal.” The Romans obtained much of their copper from Cyprus, as the name implies.

Copper is found at a concentration of 50 ppm in the earth's crust, and its concentration in seawater is 0.001 to 0.02 ppm. Although copper can also be obtained in an almost pure state in nature, about 85% of the copper mined today is derived from low-grade ores containing 2% or less of the metal. The major ore is chalcopyrite ($CuFeS_2$). Ores are removed by open-pit mining as well as underground mining. Ores containing as little as 0.4% Cu can be profitably recovered in open-pit mining. The sulfide ores such as chalcopyrite and chalcocite must be enriched before smelting

begins. In this ore-flotation procedure, the ore is crushed, powdered, and agitated with water containing a foaming agent and an agent to make the copper-bearing particulates water repellent. The particles are then accumulated on the foam, which is removed and heated to about 800°C to remove water, arsenic, antimony, and sulfur. The residue is mixed with silica and melted in a furnace at 1500°C. Of the two liquid layers produced, the upper layer of silicate slag is removed. The lower layer (matte) consists of copper sulfides and oxides. Silica or siliceous copper ore is added to the matte, and the liquid is aerated. The iron slag is removed, and the remaining copper sulfide is reduced to copper by heating in limited air. The remaining molten copper is about 98% pure. This material can be further purified by electrolytic refining. The impure copper is the anode in this process, and pure copper strips are the cathode. Aqueous copper serves as an electrolyte. The copper is transferred from the anode to the cathode. The anode sludge may contain silver and gold, making the process more economically feasible. Oxidized copper ores such as cuprite and tenorite can be directly reduced by heating with carbon in a furnace.

In the United States the major use (about 50%) for copper is an an electrical conductor, and copper piping is widely used in private and commercial plumbing.

Bronze, which is composed of copper and as much as 10% tin, was one of the first alloys used by humans. The brasses are also a most useful group of alloys. Copper and zinc are the main components of brass. Brasses having less than 58% copper are of limited application. Medicinally, copper sulfate has been used as an emetic, and copper is a component of several intrauterine devices, responsible for their contraceptive effects.

Copper, particularly copper sulfate, has many uses in agriculture. Copper sulfate is used as a fungicide, an algicide, a source for copper in animal nutrition, and in some fertilizers.

3.3 Exposure Assessment

U.S. Environmental Protection Agency (EPA) identified copper contamination at 210 of the 1177 total sites on the National Priorities List (NPL) (129). Workplace exposure to copper dust and fumes may be determined using NIOSH method 7029 (132).

Copper dusts and mists may be collected on a particulate filter (0.8 mm); the filter is digested with acid and analyzed. Atomic absorption spectrometry is the preferred method of analysis (132).

Copper is one of the metals to which workers have a great deal of occupational exposure. It is estimated that 46,481 workers are exposed to copper on a full-time basis. Of 12,035 combined federal and state OSHA samples, 7.8% were above the PEL, and 15% were above half of the PEL (130). The adverse health effects associated with copper production may be due to the large amounts of sulfur oxides generated or because of the impurities, such as arsenic and antimony, which are associated with the copper ores.

The Agency for Toxic Substances and Disease Research (129) estimated that the concentration of copper in air ranges from 1 to 200 ng/m^3. The average concentration in drinking water ranges from 20 to 75 ppb, although morning concentrations may reach 1 ppm due to water standing overnight in copper pipes and brass faucets. Uncontaminated soil may contain between 2 and 250 ppm of copper, although soil concentrations may reach nearly 7000 ppm in the vicinity of copper production facilities. The average daily dietary intake (water and food) is approximately 1 mg/d. Copper is essential to health and longevity in humans (131).

3.4 Toxic Effects

As with many essential metals, biochemical mechanisms have evolved that control the oral absorption and excretion of copper in order to maintain an appropriate balance. Copper is found in more than a dozen proteins, including cytochrome C oxidase. Relative to metabolic requirements, all human diets have sufficient copper. The daily requirement is 2–3 mg (133).

Clinically significant copper deficiency is rare and limited to instances of marked gastrointestinal

malabsorption, drastically reduced dietary intake, or to the presence of an X-linked disorder of copper absorption and transport known as Menkes's steely- or “kinky-hair disease”. Menkes's disease in males is characterized by physical and mental retardation, with widespread degeneration of the brain, hypothermia, and death occurring in the first few years of life (131).

The homeostatic mechanisms controlling oral absorption also make copper toxicosis rare. In humans, about half of the dietary copper is not absorbed, but is excreted in the feces. Urinary exretion accounts for approximately 3% of the absorbed dose. The fraction of the intake that is absorbed decreases as the dose increases. Thirty percent is absorbed at 100 mg, whereas about 56% is absorbed at doses of 0.4–4.5 mg.

After absorption, copper is transported via the plasma bound to albumin or amino acids. Almost all the copper is deposited in the liver. Free copper ions are not normally found in the body fluids. Eighty percent of absorbed copper is found in the cytosol bound to hepatocuprein, copper-chelatin, or metallothionein. Incorporation of copper into metallothionein apparently requires prior binding of the copper to glutathione, thus defining a requirement for intracellular availability of glutathione. Metallothionein, a cysteine-rich metal-binding protein, serves as a temporary, intracellular binding site for copper, which, as a free ionic metal, is a strong oxidizing agent, capable of generating hydroxyl radicals. The remaining 20% of absorbed copper is bound to other copper proteins, such as cytochrome C oxidase, or is sequestered by the lysosome. Despite absorption, the body burden of copper does not increase with age. The secretion of some copper into the blood and incorporation into ceruloplasmin, a copper-containing globulin of blood plasma, plays an important role in hematopoiesis and oxygen reduction. Copper excretion from the lysosome maintains a balance of about 150–300 mg of ceruloplasmin containing 0.5–1 mg of copper. Ceruloplasmin is broken down in the liver, and 0.1 mg is excreted into the intestine. Biliary copper may not be reabsorbed because it is bound to protein.

The body content of copper in animals on an average diet is about 2 ppm in fat-free tissue. The highest concentrations are in the liver and the brain, with lesser amounts in the heart, spleen, and kidneys. The concentration in the brain doubles from birth to maturity (131).

Copper toxicity in humans as a result of oral intake occurs only in cases of attempted suicide or when there is a genetic defect in copper metabolism, as in Wilson's disease. However, ingestion of large amounts of copper salts, most often copper sulfate, can result in death. Vomiting, sometimes with a blue-green color of the vomitus, hematemesis, hypotension, melena, coma, and jaundice are symptoms. Centrilobular hepatic necrosis may be an autopsy finding (134). The therapeutic emetic dose of copper sulfate is 300 mg in water.

In Wilson's disease, an autosomal recessive hereditary disease, the copper steadily accumulates first in the liver, and then in other tissues. Wilson's disease has been found in every racial group. The illness is inherited as an autosomal recessive trait, with a general prevalence of about 1 in 200,000. Approximately, there is a single “Wilson's disease gene” in every 200 people. The heterozygotes remain free of pathological manifestations of Wilson's disease. Relatives, particularly siblings of patients with Wilson's disease, must be examined, even if they appear perfectly healthy because of the autosomal recessive transmission of the illness. Fortunately, biochemical findings in patients with the manifest disease have made it possible to confirm the diagnosis in an asymptomatic individual when there are less than 20 mg ceruloplasmin/100 mL serum and more than 250 mg Cu/g dry liver (131). Decreased serum concentrations also have been found in about 20% of the healthy heterozygous carriers of the one abnormal “Wilson's disease gene” and in all newborns during the first 6 months of life. Ceruloplasmin is generally less than 20 mg/100 mL in those individuals with Wilson's disease, whereas it normally ranges from 20 to 50 mg/100 mL. Damage to the liver and central nervous system is usually fatal. Chelation with D-penicillamine is most often a successful treatment (131).

Almost all patients with Wilson's disease exhibit a lifelong deficiency of the plasma copper protien

ceruloplasmin and an excess of hepatic copper. This excess copper in the liver may be caused, in part, by impairment of lysosomal excretion of hepatic copper into bile, and is associated with diminished or absent hepatic synthesis of ceruloplasmin. It is remarkable that retaining only 1% of the dietary intake of copper (10–20 mg/year) is sufficient to cause Wilson's disease. During the early stages of Wilson's disease, the liver is capable of binding as much as 30 to 50 times its normal concentration of copper with little, if any, overt clinical disorder. Hepatic copper is released into the bloodstream, and in the face of massive necrosis of hepatic parenchyma, that action may suddenly infuse large amounts of copper into the plasma, inducing severe hemolysis and jaundice. In most patients, however, the metal diffuses into the circulation gradually, causing the plasma concentration of free copper to rise 5–10 times, to about 25–50 mg/100 mL. Characteristic ultrastructural changes, fatty degeneration of hepatocytes, necrosis, collapse of parenchyma, and postnecrotic cirrhosis occur in the liver. Later, the excess hepatocellular copper is sequestered by lysosomes, a process that seems to render the metal innocuous for other cytoplasmic organelles. Unless the patient with Wilson's disease succumbs to hepatic necrosis, the toxic effects of copper ultimately are manifested primarily in the central nervous system and kidneys. In the corneas, copper deposits are visible as Kayser–Fleischer rings, blue crescents. In about half of all patients, the first clinical evidence of Wilson's disease is dysfunction of the liver. Ascites, esophageal variceal hemorrhage, a syndrome mimicking toxic or infectious hepatitis, hemolysis caused by sudden release of sequestered copper, deficiency of clotting components, hypersplenism, or gonadal dysfunction may occur. In almost all other patients, neurological or psychiatric disorders are the initial clinical manifestation. The neurological picture may resemble Parkinsonism, multiple sclerosis, chorea, dystonia, or any combination of these diseases. The usual onset is insidious. Dysarthria is a frequent sign in children; and often subtle incoordination, resting or intentional tremors, athetoid movements, rigidity, or dystonic posturing, and distortion can occur at all ages. Epileptiform seizures have been reported but are unusual. Psychiatric disorders may accompany the neurological symptoms or may precede any other evidence of disease. In young adults the spectrum ranges from mild behavioral disturbance, through marked deterioration of schoolwork and neurosis, to a manic–depressive or schizophrenia like psychosis, which may appear in all age groups. The emotional disturbance may be partly a reaction to the somatic dysfunction (131).

Reports from India have indicated infants and children can develop a condition termed Indian Childhood Cirrhosis (ICC) from drinking milk boiled and stored in brass vessels. This condition has largely disappeared from India following preventive measures. Reports from the United States show children developing severe liver disorders from ingestion of 10 mg Cu in contaminated milk. It is possible that the homeostatic mechanisms controlling copper absorption are not developed early in life (135).

Copper is an important component of the human metalloezyme copper/zinc superoxide dismutase (cu/znSOD). This enzyme protects oxygen-metabolizing cells from the oxidizing actions of superoxide free radicals. It catalyzes the following reaction:

$$2O_2^- + 2H^+ \rightarrow O_2 + H_2O_2$$

The damaging superoxide ion (O^{2-}) is formed *in vivo* via reduction of O_2 during various enzymatic reactions, or by ionizing radiation. This ion has been implicated in aging, lipid peroxidation and such neurologic diseases as amyotrophic lateral sclerosis (ALS) and Alzheimer's Disease. Also, there is some evidence from animal studies that copper deficiency promotes oxidative damage. Hence, while free copper ions can be cytotoxic oxidizing agents, copper is important as an active component of the antioxidant enzyme, cu/znSOD.

Contact dermatitis associated with copper has been reported, but few cases of dermatitis caused by copper metal or its compounds occur in industry. A green coloration, noted more than a century ago among copper workers, is mentioned. A similar localized coloration is caused today from wearing jewelry made of copper or high-copper alloys. There have been occasional reports of allergic contact

dermatitis following patch testing with copper pennies or copper sulfate (136, 137). Eye irritation has been reported among sheet metal workers (138).

Copper's usefulness in contraception is based on its spermatocidal activity. For this application, copper concentrations must range from 8 to 60 mg/mL in human uterine fluid (139). *In vitro*, copper spermatocidal activity has been found to be potentiated by washing the spermatozoa free of seminal plasma. Once immobilized, spermatozoa do not regain motility, even after extensive washing, prolonged dialysis, or treatment with copper-specific chelating agents. Apparently, copper induces a change in the properties of the spermatozoa, which results in irreversible immobilization (140).

Occupational exposure to copper fume at 0.1 mg/m^3 causes nausea and metal fume fever, with reversible flulike symptoms (141). Metal fume fever (also called brass founder's ague) is a transient condition and is characterized by fever, chills, muscle pain, and vomiting. Recovery normally occurs within 24 to 48 h. Tolerance may develop, but is generally lost over the weekend. Metal fume fever has also been observed among workers exposed to freshly formed zinc fume.

Metal fume fever occurred among workers involved in cutting brass pipes with electric torches in an enclosed, poorly ventilated steam condenser. Symptoms most commonly reported among the 26 workers were fever (21), dyspnea (23), chills (21), headache (21), and nausea (19). Fourteen of the workers experienced the symptom of an unusual sweet or metallic taste in the mouth. Clinical signs were limited to wheezing or rales in eight patients; leukocytosis (21) and an elevation of band cell forms (20) were seen in a total of 24 workers. The average time between exposure and onset of symptoms was 5 h. None of three workers who spent less than 1 h in the condenser became ill, whereas 25 of the 26 who spent more than 1 h became ill. Five of 12 workers had urine copper levels in excess of 0.05 mg/L (142).

Reports of granulomatous and fibrotic changes among vineyard workers using a Bordeaux mixture containing 1–2% copper sulfate and hydrated lime have been made (143, 144). This mixture is no longer used in the United States.

Among hamsters, 3.3 mg/m^3 of copper sulfate decreased cilia activity and caused alveolar thickening. This effect was not present in mice (145).

Although an increase in lung cancer has been reported among workers in copper smelters, this is generally accepted as the result of exposure to arsenic trioxide and, perhaps, sulfur dioxide (146). The animal bioassays on copper and copper compounds do not provide any support for the classification of copper as an occupational carcinogen. The carcinogenicity of a copper-containing compound, copper hydroxyquinoline, was studied in two strains of mice ($B6C3F_1$ and $B6AKF_1$). Groups of 18 male and 18 female 7-day-old mice were administered 1000 mg copper hydroxyquinoline/kg (180.6 mg Cu/kg) suspended in 0.5% gelatin, daily until they were 28 days old, after which they were administered 2800 ppm (505.6 ppm Cu) in the feed for 50 additional weeks. No statistically significant increases in tumor incidence were observed in the treated 78-week-old animals. In the same study, a single subcutaneous injection of gelatin (control) or 1000 mg/kg of copper hydroxyquinoline (180.6 mg Cu/kg) suspended in 0.5% gelatin to groups of 28-day-old mice of both strains produced, after 50 days of observation, an increased incidence of reticulum cell sarcomas in the male $B6C3F_1$ mice, compared with controls. No tumors were observed in the treated male $B6AKF_1$ mice, and a low incidence of reticulum cell sarcomas was observed in the treated female mice of both strains (147). Intramuscular injections containing 20 mg of cupric oxide (16 mg Cu), cupric sulfide (13.3 mg Cu), and cuprous sulfide (16 mg Cu), into thighs of 2- to 3-month-old Wistar rats caused no injection-site tumors after 20 months of observation. Other tumors were observed at a very low incidence in the rats receiving cupric sulfide (2/30) and cuprous sulfide (1/30) (148). The International Agency for Research on Cancer does not list copper or any copper compounds as suspected carcinogens for animals or humans.

Mutagenic data are equivocal for copper or its salts. No increases in mutations in *E. coli* and *S. typhimurium* strains (TA98, TA1535, TA1537, and TA1538) incubated with up to 5 mg copper quinolinolate/plate and in *S. typhimurium* TA98 and TA100 incubated with up to 5 mg copper sulfate/plate were found (149). Negative results were also obtained with copper sulfate or copper chloride in assays using *S. cerevisiae* (150) and *Bacillus subtilis* (151–153). Dose-related mutagenic effects in *E. coli* with 2–10 ppm copper sulfate in a reverse mutation assay were reported (154). Errors in DNA synthesis from poly-(c)templates have been induced in viruses incubated with copper chloride or copper acetate (155). Chromosomal aberrations were induced in isolated rat hepatocytes when incubated with copper sulfate (156). Casto et al. (157) showed enhanced cell transformation in Syrian hamster embryo cells infected with simian adenovirus following the addition of cuprous sulfide and copper sulfate. Law (158) reported increases in the percent of lethals observed in Drosophila larvae and eggs when exposed to copper by microinjection (0.1% copper sulfate) or immersion (concentrated aqueous copper sulfate), respectively.

3.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV of 0.2 mg/m^3 for copper as copper fume and 1 mg/m^3 for copper dusts and mists is to prevent irritation (20). The OSHA PEL for copper dusts and mists 1 mg/m^3 and for copper fume is 0.1 mg/m^3, as an 8-h TWA (159). OSHA declined to increase its PEL to the concentration recommended by ACGIH because the latter's TLV was based on a 1972 personal communication. This communication stated that workers in the United Kingdom that were exposed to copper fumes at concentrations up to 0.4 mg/m^3 during welding and copper metal refining operations failed to experience ill effects. OSHA's position was that the Agency must demonstrate that exposed workers will not be placed at increased risk even after the limit has been raised. The National Institute for Occupational and Health recommended exposure level (REL) of 1 mg/m^3 applies to copper dusts and mists, with a REL of 0.1 mg/m^3 for copper fumes. The ACGIH TLV for copper dusts and mists is 1 mg/Cu and for copper fume is 0.2 mg/m^3.

Initial physical examinations for workers likely to be exposed to copper in the course of their employment should include respiratory and liver function tests and a screening for Wilson's disease. Normal concentrations of copper in blood from nonexposed workers range from 0.8 to 1.6 mg/L, with an average copper blood concentration of 1.2 mg/L.

Lead

Robert A. Goyer, MD

A. Inorganic Lead Compounds

1.0 Lead

1.0.1 CAS Number: [*7439-92-1*]

1.0.2 Synonyms: NA

1.0.3 Trade Names: NA

1.0.4 Molecular Weight: 207.19

1.0.5 Molecular Formula: Pb

1.0.6 Molecular Structure: Pb

1.1 Chemical and Physical Properties

Lead is a lustrous silvery metal that tarnishes in the presence of air and becomes a dull bluish gray.

The chemical symbol, Pb, is derived from *plumbum*, the Latin word for waterworks, because of lead's extensive use in ancient water pipes. Lead has four electrons in its valence shell, but only two ionize readily. The usual oxidation state of lead in inorganic compounds is therefore +2 rather than +4. Lead generally forms stable compounds. Four stable lead isotopes exist in nature (208, 206, 207, and 204 in order of abundance). Through the years lead mined from deposits of different geologic eras has entered the environment, so that today there are wide variations in isotopic ratios of lead in commerce and in the environment. These differences in isotopic ratios may be used as nonradioactive tracers in environmental and metabolism studies (14).

For the purposes of this chapter the toxicology of all lead compounds are considered similar once the lead has entered body tissues. Generally, it is the lead ion that interacts with the target organ or organelle. Solubility in body tissues affects rates of absorption. Exceptions are the industrially synthesized lead–carbon compounds such as tetraethyl lead (TEL) and tetramethyl lead (TML), which have major differences in the toxicological properties. These compounds were added to gasoline to improve engine efficiency and reduce gasoline consumption in automobiles. Although their use as fuel additives has diminished, there are still potential occupational exposures. Lead released from these compounds following combustion of gasoline forms inorganic lead compounds. The toxicology of TEL and TML is considered in a later section of this chapter. Chemical and physical properties of lead and some of its compounds are shown in Table 34.1 (15, 16).

Titanium, Zirconium, and Hafnium

Leela I. Murthy, Ph.D., David A. Dankovic, Raman C. Murthy

A. Titanium and Titanium Compounds

Titanium (Ti) [*7440-32-6*] is a silvery gray metal that resembles polished steel. Titanium a transition element, was first discovered as its oxide by William Gregor in 1791 and named in 1795 by Martin H. Klaproth after the Titans, the giants of Greek mythology. Nevertheless, the pure metal was not isolated until 1910 and remained a laboratory curiosity until an economical purification process was developed in 1946.

Because titanium is as strong as steel and 45% lighter in weight, it is especially suitable for use in aviation and astronautics. About 50% of the titanium produced is used for jet engine components (rotors, fins, and compressor parts). Titanium alloys readily with other metals such as aluminum and tin. The alloy composition Ti + 2.5% tin + 5% aluminum is used when high strength at high temperatures is required, and the alloy Ti + 8% aluminum + molybdenum + vanadium is used in low temperature applications. Each supersonic transport contains about 270,000 kg of titanium.

The most important titanium compound is titanium dioxide, TiO_2 [*13463-67-7*], a white substance that has a high reflective index. TiO_2 forms the basis of the titanium pigment industry because of its opacifying property, ready availability, and relatively low cost. TiO_2 is processed at very high

temperatures into artificial rutile, which is used as a semiprecious stone (titania). Titania has a light yellow color and a higher index of refraction than diamond, but is rather soft. TiO_2 has been used to some degree since 1918, but its use expanded after technological improvements in ore processing and because of expanded industrial need. Fifty percent of the TiO_2 used is as pigments, 20% in paper, and 12% in plastics. It is also used in cosmetics and sun screens. Additional uses of TiO_2 are as a catalyst, a dielectric in capacitors, and a source of titanium metal.

The remaining titanium compounds have a variety of special uses.

Titanium trichloride, a dark-violet deliquescent solid that decomposes in air and water, is used as a cocatalyst for polyolefin polymerization and in organometallic synthesis. The tetrachloride is a colorless liquid that fumes in moist air and forms a dense, persistent, white cloud used in smoke screens. The tetrachloride is used extensively in TiO_2 production.

Titanium disulfide, a yellow solid, is used as a solid lubricant, and titanous sulfate, green in the crystalline state but dark purple in acid solution, is used in the textile industry as a reducing agent for stripping or discharging colors.

The toxicity of titanium varies with the chemical form. Metallic titanium and TiO_2 are insoluble, unreactive, nonmetabolized, and virtually devoid of acute toxicity, though prolonged exposure to high concentrations of TiO_2 causes lung tumors in rats. In contrast, the soluble inorganic titanium salts are absorbed and metabolized and do show appreciable acute toxicity. A third titanium form, the oil-soluble organotitanium complex, titanocene, is metabolized by a still different pathway and is both toxic and tumorigenic in animals.

The toxicology of two other titanium compounds, titanium diboride and titanium carbide, is not discussed in this chapter. Titanium diboride [*12045-63-5*], an extremely hard substance (Mohs hardness 9 +) with oxidative resistance up to 1400°C, is used as a metallurgical additive for super alloys and nuclear steels, as a high-temperature electrical conductor, and in coatings resistant to attack by molten metals. Titanium carbide is extremely hard and as a crystalline solid has its chief use as an additive to tungsten carbide in cutting tools and other parts that are subjected to thermal shock.

Table 35.2. Physical and Chemical Properties of Titanium (Ti) and its Compounds

Compound	CAS Number	Molecular Formula	Mol. Wt.	Boiling Point (°C)	Melting Point (°C)	Specific Gravity	Solubility
Titanium	[*7440-32-6*]	Ti	47.87	3287	1660	4.5	Insol. cold water; dec. hot water
Titanium dioxide	[*13463-67-7*]	TiO_2	79.87	2500–3000	1830–1850	3.90 (anatase) 4.23 (rutile)	Sol. hot H_2SO_4,HF, alkali; insol. HCl, water, alcohol

59) isolated impure zirconium by heating a mixture of potassium zirconium fluoride with potassium in an iron tube. Zirconium occurs abundantly in stars and has been identified in the sun and in meteorites. It is present as a minor impurity during the extraction of beryllium from its ore, bertrandite.

Occurrence

Zirconium, one of the more abundant elements, is widely distributed in the earth's crust and occurs as the oxide, baddeleyite (ZrO_2), or as part of a complex of oxides as in zircon, $ZrO_2 \cdot SiO_2$, elpidite, $Na_2ZrSi_6O_{13} \cdot 3H_2O$, and eudialyte, $Na_{13}(Ca \cdot Fe)_6 \cdot (Zr \cdot Si)_{20}O_{52}Cl$ (60). Zircon is the most important commercial ore and baddeleyite also has some importance. It has been estimated that zirconium constitutes about 0.017% of the lithosphere.

Major world sources of zircon are Australia, the Republic of South Africa, and the United States. France, Japan, and the United States are producers of nuclear- and commercial-grade zirconium metals. About 50,000 tons of the world demand of 184,000 tons (27%) of zircon were consumed by the United States in 1983. Zircon occurs worldwide as an accessory mineral in igneous, metamorphic, and sedimentary rocks from which it is mined.

Commercial deposits occur only in Brazil and the Republic of South Africa, but it is also found in

East Africa, Sri Lanka, and the former Soviet Union. Zircon sand is produced in Australia, Republic of China, Korea, South Africa, India, and Brazil. All commercial sources of zircon are derived from mining ancient, unconsolidated beach deposits, the largest of which are in Kerala, India, in Sri Lanka, the east and west coasts of Australia, on the Trail Ridge in Florida, and at Richards Bay in the Republic of South Africa. These heavy mineral sands are processed to recover the titanium-bearing minerals ilmenite, rutile, and leucoxene, and zircon is obtained as a coproduct. The output of zircon depends mainly on the market for titanium minerals used in producing titanium oxide white pigment and titanium metal (59, 61). The production of zirconium metal is only a minor use of zircon.

In the United States, the zirconium content of zircon in beach sand and placer deposits in Florida and Georgia is estimated at 4 million tons. In addition, 4 million tons of marginal reserves and subeconomic resources are located principally in Tennessee, New Jersey, South Carolina, and California. Zircon is recovered from mineral sands by dredging and mining.

Zirconium is associated with other metals in many minerals but is recovered only from zircon (ZrO_4SiO_2), baddeleyite (brazilite) (ZrO_2), eudialyte [$Na_{13}(CaFe)_6 \cdot (ZrSi)_{20}O_{52}Cl$]. Hafnium is invariably associated with zirconium. Zircon occurs in all igneous rocks but is more common in granite, sylnite (complex silicates), and diorite (alkaline earth silicates). Zircon is a common constituent of river gravels and beach sands, from whence it is recovered as a coproduct of ilmenite (FeO_4TiO_2), rutile (TiO_2), and monazite (thorium and lanthanum phosphates). Baddeleyite usually occurs in phenolite and is also found in river gravels and beach sands (59).

Because of its very high chemical activity at temperatures just above normal ambient temperature, zirconium occurs only in the combined state (61). Zirconium is found in at least 37 different mineral forms (62), but the predominant commercial source is the mineral zircon, zirconium orthosilicate.

Baddeleyite, a natural zirconium oxide, has been found in Brazil and in Transvaal, South Africa. The Brazilian ore occurs frequently with zircon and may contain 65–85% zirconium oxide, 12–18% silica, and 0.5% uranium oxide. Currently, very little Brazilian ore is exported because all radioactive minerals are under the close scrutiny of the Brazilian government. The Transvaal ore is a complex ore composed of different sections; these are mined to recover magnetite, apatite (a copper concentrate), vermiculite, and baddeleyite. The baddeleyite ore contains a zirconium oxide concentration of 0.2% but when concentrated, it yields about 96% zirconium oxide with a hafnium content (Hf/Zr + Hf) of about 2%. Zirconium and hafnium are geochemically associated in the principal ore mineral, zircon, in a ratio of 50 to 1. The two elements are separated only for nuclear applications.

Eudialyte [$Na_{13}(Ca \cdot Fe)_6 \cdot (Zr \cdot Si)_{20}O_{52}Cl$], a third ore, is the source of pure zirconium oxide from large deposits in southwest Greenland. Two zirconium-containing minerals have been discovered in the past 20 years, welognite $(Sr_{2.8}Ca_{0.2})ZrNa_2(CO_3)_6 \cdot 3H_2O$ and gittinsite $CaZrSi_2O_7$. Unlike zircon, the zirconium content of these minerals and eudialyte can be dissolved by strong acid.

Zircon is the primary zirconium mineral of commercial significance. It is recovered solely as a by-product of mining and extracting of the titanium minerals, ilmenite and rutile, for which there is a much larger demand. Zircon has been known as a gem mineral since biblical times and was called *Jargon* in Sri Lanka and Hyacinth in France. The name zircon comes from the Arabic “zargun,” meaning gold color, describing the gemstone now known as zircon. Zircons may be colorless, amber, red, reddish brown, blue, green, or black. Analysis of the gemstone Jargon from Sri Lanka in 1789 by Klaproth revealed 68% of an unknown earth which he called zirkonerde (63). In 1797, Vauquelin studied this new earth, gave it the name zirconia, and published the preparation and properties of some of its compounds (64). It was only in 1824 that Berzelius prepared the first crude zirconium metal, a black powder, by heating potassium and potassium hexafluorozirconate in a closed pot (61).

The mineral zircon is mainly used for facings on foundry molds; foundries consume approximately one-half of the domestic zirconium production, and the remaining one-half is consumed by refractory, abrasive, ceramic, metal, and other industries. Domestic zirconium is marketed in proprietary mixtures for use as weighting agents, Zr–TiO_2 blends for welding-rod manufacture, and zirconium-refractory heavy-mineral (kyanite, sillimanite, and staurolite) sand blends for foundry sand and sandblasting applications. The zirconium-bearing foundry sand was reportedly designed to provide consistent high-quality performance at low cost for critical casting applications (65).

Zircon is widely used in furnaces and hearths as refractory bricks and blocks for containing molten metals. Zircon is also used in manufacturing fused cast and bonded AZS (alumina-zirconia-silica-base) refractories for glass tank furnace use and in alumina–zirconia snagging wheels used in heavy grinding on rough metal surfaces. Zircon is also used as a refractory material for dies used to extrude various materials (59).

[a] Adapted from *Chemical Economics Handbook*, SRI International, Menlo Park, CA, August 1996.

[b] Totals may not equal the sums of categories because of rounding.

[c] Data for United States and Western Europe do not include producers of zirconia metal and reprocessors of baddeleyite. Data for Japan include manufactured zirconia producers that use baddeleyite as a raw material.

[d] Data for United States and Western Europe include baddeleyite but not for Japan.

[f] Not available.

[e] Japan's export figures include germanium oxide which represents less than 5% of total volume.

10.1 Aluminum Zirconium Compounds
10.4.2 Human Experience 10.4.2.1 General Information

10.4.2.2 Clinical Cases Zirconium compounds have been associated with the development of hypersensitivity granulomas. However, aluminum zirconium complexes have not previously been shown to induce sensitization. The clinical and histologic findings of a case was described in which a patient developed an acute hypersensitivity reaction to an aluminum zirconium complex (134).

10.5 Standards, Regulations, or Guidelines of Exposure

NIOSH has a recommended exposure limit (REL) of 5 mg/m^3 as Zr and a STEL value of 10 mg/m^3 (45). As of July 1999, the OSHA TWA has remained at 5 mg/m^3 (43). The 2000 ACGIH TLV is 5 mg/m^3 and the STEL value is 10 mg/m^3 (44).

11.1 Zirconium Compounds (Combination Studies)
11.4.2 Human Experience 11.4.2.2 Clinical Cases Men who worked with zirconium compounds at one site in the North of England were monitored since 1975 to evaluate the effects of exposure on the lung (mainly < 10 mg/m^3) over many years. Chest radiographs (in 1975, 1978, and 1982) and lung function measurements (from 1975–1988) were carried out on all 178 men known to have worked with the compounds; an estimate of cumulative exposure was computed from job title and likely exposures. No evidence was found that zirconium exposure resulted in abnormal chest radiographs or impaired pulmonary function (135).

11.5 Standards, Regulations, or Guidelines of Exposure

NIOSH has a recommended exposure limit (REL) of 5 mg/m^3 as Zr and a STEL value of 10 mg/m^3 (45). As of July 1999, the OSHA TWA has remained at 5 mg/m^3 (43). The 2000 ACGIH TLV is 5 mg/m^3, and the STEL value is 10 mg/m^3 (44).

12.1 Sodium Zirconium Lactate
12.4.2 Human Experience 12.4.2.2 Clinical Cases By 1959 there were numerous reports of axillary granulomas following the use of stick deodorants containing NaZr lactate (136). These granulomas appear as underarm eruptions of small, indolent, flesh-colored papules, often in linear streaks. Several years later, zirconium oxide, as a cream, introduced as a treatment for poison ivy dermatitis, produced small papules in the skin which, on microscopic examination, revealed epithelioid cell granulomas (137). When the sensitizing Zr salt was removed from the preparation, healing occured.

12.5 Standards, Regulations, or Guidelines of Exposure

NIOSH has a recommended exposure limit (REL) of 5 mg/m^3 as Zr and a STEL value of 10 mg/m^3 (45). As of July 1999, the OSHA TWA has remained at 5 mg/m^3 (43). The 2000 ACGIH TLV is 5 mg/m^3 and the STEL value is 10 mg/m^3 (44).

13.1 Zirconium-Containing Aerosol Spray
13.4.2.2 Clinical Cases Epstein (138) developed a zirconium-containing aerosol spray that did not produce granulomas of the skin in an unsensitized person. However, Zr-containing antiperspirant sprays were ultimately banned following a panel statement of the FDA and subsequent hearings which concluded that (1) the respiratory tract is the deposition site for the antiperspirant in spray form, (2) no proof was presented on the metabolic fate or integrity of the deposited spray in the respiratory tract, and (3) zirconium chlorhydrate can elicit a hypersensitivity granulomatous response

in sensitized persons.
13.5 Standards, Regulations, or Guidelines of Exposure
NIOSH has a recommended exposure limit (REL) of 5 mg/m^3 as Zr and a STEL value of 10 mg/m^3 (45). As of July 1999, the OSHA TWA has remained at 5 mg/m^3 (43). The 2000 ACGIH TLV is 5 mg/m^3 and the STEL value is 10 mg/m^3 (44).
14.1 Lead Titanate Zirconate
14.2 Human Experience
14.4.2.2 Clinical Cases An Ontario plant with 101 workers who produced and used the ceramic compound lead titanate zirconate (LTZ), was the site of an investigation (139). Although air lead levels were high in most plant areas, 82 workers who were not exposed to lead oxide but to LTZ in the process had normal blood lead levels. In addition, no radiographic changes or abnormal pulmonary function test results were detected in 61 workers examined. The particle size of LTZ was less than 5 micrometers, and the solubility of LTZ in body fluids was significantly less than lead oxide. The authors postulated that the observed low toxicity of LTZ could be due to its low solubility in body fluids. Further studies of the toxicity of LTZ and other less soluble lead compounds were recommended by the authors (139).
14.5 Standards, Regulations, or Guidelines of Exposure
NIOSH has a recommended exposure limit (REL) of 5 mg/m^3 as Zr and a STEL value of 10 mg/m^3 (45). As of July 1999, the OSHA TWA has remained at 5 mg/m^3 (43). The 2000 ACGIH TLV is 5 mg/m^3 and the STEL value is 10 mg/m^3 (44).
15.1 Zircaloy
15.4.2 Human Experience 15.4.2.2 Clinical Cases A 51-year-old nonsmoking female suffered from relapsing progressive pneumonia for several years. She had worked for 16 years in the nuclear industry and was exposed to grinding particles and welding fumes from working with Zircaloy, an alloy that contains tin, iron, chromium, and zirconium. During an exacerbation of the pneumonia, radiography showed interstitial infiltration of both lower lobes. In addition, nodular and painful thickenings appeared in old operation scars on various parts of her body. Persistent infiltrations of the lung led to lobectomy of the right lower lobe to exclude a malignant disease in the worker. The histological picture of the lung tissue showed different stages of alterations and pronounced proliferation of the alveolar epithelium, epithelioid cell granulomas between well-preserved alveolar walls, and additional large areas of scar tissue (140). This observation was similar to that noted in another study published a few years previously, where the authors called it “Zirconium lung” (141).
15.5 Standards, Regulations, or Guidelines of Exposure
NIOSH has a recommended exposure limit (REL) of 5 mg/m^3 as Zr and a STEL value of 10 mg/m^3 (45). As of July 1999, the OSHA TWA has remained at 5 mg/m^3 (43). The 2000 ACGIH TLV is 5 mg/m^3, and the STEL value is 10 mg/m^3 (44).
15.6 Studies on Environmental Impact
Zircaloy hazards associated with the shear/leach operation at the second Thermal Oxide Reprocessing Plant (THORP) at the Sellafield factory were examined. Potential hazards of the process include Zircaloy dust explosions in the vicinity of the shear and either dry or submerged ignition layers. With respect to the development of the safety case for layer ignitions, the reaction kinetics were experimentally investigated by reproducing the conditions under which a thermal runaway could be seen. A mathematical model of the settled layer heat transfer characteristics was developed. It was shown that an oxide layer formed on particles of Zircaloy resulted in a slowing of explosive reactions of particulate Zircaloy (142).

Titanium, Zirconium, and Hafnium
Leela I. Murthy, Ph.D., David A. Dankovic, Raman C. Murthy

C. Hafnium and Hafnium Compounds

Hafnium (Hf), CAS Number: [*7440-58-6*], one of the transition elements, belongs to Group IV B of the periodic table along with titanium and zirconium. Hafnium is never found free in nature but is always associated with the more plentiful zirconium in natural minerals. Hafnium and zirconium are almost identical in nature and hence show close similarity in chemical properties not seen in any other pair of elements in the periodic table.

Hafnium is one of the less abundant elements in the earth's crust. It makes up 2% of the combined weight of hafnium and zirconium in zircon, $(ZrHf)O_2 \cdot SiO_2$, which is recovered from certain beach sands. Hafnium makes up about 0.5–2% of the combined weight with zirconium in the ore, baddeleyite, $(Zr.Hf)O_2$ (143). Because of its similarity to zirconium, no qualitative differences have been found that would permit separating them except for the production of hafnium-free nuclear-grade zirconium (61).

Hafnium was positively identified only in 1923 though zirconium was discovered in 1789. The theory that element 72 was tetravalent and not trivalent like the rare earth series elements was postulated by the Bohr atomic theory and by Moseley's X-ray spectra of several zircon concentrates (144). The name hafnium comes from Hafnia, the Latin name for Copenhagen where the discovery was made.

Hafnium was also identified by X-ray fluorescence analysis and by neutron activation analysis in a chronosequence of soils in the Indiana Dunes. It was leached along with titanium, selenium, and heavy lanthanides associated with heavy minerals, particularly, iron oxides, in the very fine sand fraction (0.05–0.1 mm) of the Indiana Dunes soils (145).

The primary commercial source of hafnium is zircon, zirconium orthosilicate, which is inert and refractory and is obtained during the mining of rutile and ilmenite mineral sands. Zircon sands contain 2% hafnium oxide but higher concentrations are found in altered zircons such as cyrtolite, malacon, alvite, and naëgite. The statistics of hafnium imports and prices for 1993–1997 are presented in Table 35.6.

Table 35.6. Statistics of Hafnium Imports and Prices—United States, 1993–1997[a]

	1993	1994	1995	1996	1997
Imports, metric tons					
Hafnium, unwrought, waste, and scrap	3	5	5	8	8
Prices	1993	1994	1995	1996	1997
Hafnium sponge, dollars per kilogram	165–210	165–210	165–210	165–210	165–210

[a] Adapted from U.S. Geological Survey, *Mineral Commodity Summaries*, 1998.

It is extremely difficult to separate hafnium from zirconium. Some of the methods used in the laboratory for separating it from zirconium are: (1) solvent extraction of thiocyanates by hexone, (2) solvent extraction of nitrates by tributyl phosphate and, (3) fractional crystallization of the double fluorides (146). Three industrial methods are normally used to separate hafnium and zirconium: (1) liquid-liquid extraction (2) molten salt distillation and (3) fluorozirconate crystallization. Different hafnium compounds are obtained from zircon using different procedures. Figure 35.1 presents a flowchart for obtaining the various hafnium compounds, as well as the different forms of hafnium

from zircon.

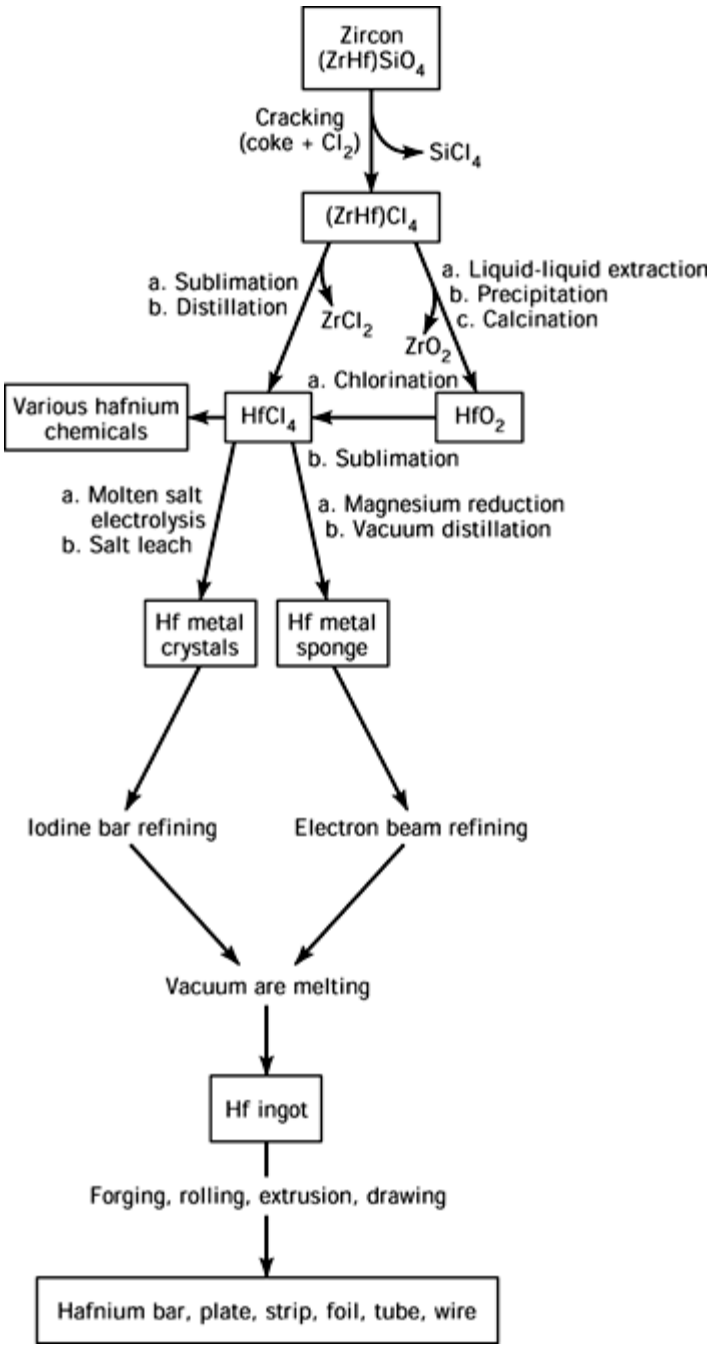

Figure 35.1. Flow sheet of hafnium production from zircon.

Another method used a pressurized ion-exchange column to separate hafnium from zirconium. Basically, the hafnium and zirconium sulfate complex was separated by chromatographic elution from Dowex 50W-X8 (15–25 mm) resin with sulfuric acid solutions. Fluorometric and colorimetric reagents were used to monitor the column effluents continuously. Because neither the fluorometric nor the colorimetric reagent was specific for either hafnium or zirconium, peak patterns were identified using the stable isotopes ^{90}Zr and ^{180}Hf as "fingerprints" of their elution position (147). An unseparated fraction was also obtained which was thought to be a polymeric hydrolytic product.

Some physical properties of hafnium and its compounds are presented in Table 35.7.

Table 35.7. Physical and Chemical Properties of Hafnium and Its Compounds[a]

Compound	CAS Number	Molecular Formula	Mol. Wt.	Boiling Point (°C)	Melting Point (°C)	Specific Gravity	Solubility in Water (68°F)	Ref.

Arsenic, Antimony, and Bismuth
Lisa Gallicchio, Bruce A. Fowler Ph.D., Emily F. Madden

1.0 Arsenic
1.0.1 CAS Number:
[*7440-38-2*]
1.0.2 Synonyms:
Inorganic arsenic, arsenite, arsenate, arsenic acid, arsine gas
1.0.3 Trade Names:
NA
1.0.4 Molecular Weight:
74.9
1.0.5 Molecular Formula:
As
1.0a Arsenic Trioxide
1.0.1a CAS Number: [*1327-53-3*]

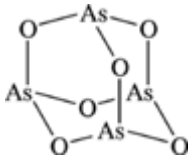
1.0.2a Synonyms: Arsenic oxide; arsenic (III) oxide; arsenous trioxide; arsenous acid; arsenous oxide; arsenic sesquioxide; white arsenic; diarsenic trioxide; crude arsenic; arsenic (white); arsenious oxide; arsenic (III) trioxide; arsenous anhydride; arsenite; arsenolite; arsenous acid anhydride; arsenous oxide anhydride; arsodent; claudelite; claudetite; arsenic oxide (3); arsenic oxide (As_2O_3); arsenic sesquioxide (As_2O_3); arsenicum album; diarsonic trioxide; diarsenic oxide; arsenious oxide, 99.999%

1.0.3a Trade Names: NA

1.0.4a Molecular Weight: 395.628

1.0.5a Molecular Formula: As_4O_6

1.0.6a Molecular Structure:



Arsenic, Antimony, and Bismuth
Lisa Gallicchio, Bruce A. Fowler Ph.D., Emily F. Madden

2.0 Antimony

2.0.1 CAS Number:
[*7440-36-0*]
2.0.1a Antimony Trioxide, [*1309-64-4*]
2.0.2 Synonyms:
Antimony is also known as stibine (gaseous form of antimony hydride).
2.0.3 Trade Names:
None.
2.0.4 Molecular Weight:
121.760
2.0.5 Molecular Formula:
Sb
2.1 Chemical and Physical Properties
2.1.1 General Sb as an element is a brittle, flaky, crystalline (hexagonal) silver-white metal. It does not react with air at room temperature but burns brightly when heated, and forms white fumes. It is a poor conductor of electricity and heat. Antimony occurs in tri- (+3) and pentavalent (+5) compounds and is found in the earth's crust mostly associated with sulfur as stibnite and in ores associated with arsenic. Antimony is a group VA element of the periodic table and it has many of the same chemical and biological properties as the element arsenic.

2.1.2 Odor and Warning Properties Stibine gas is odorless. Exposure to antimony at high levels may result in a variety of adverse health effects. For example, breathing high levels of antimony and some of its compounds can irritate the eyes and lungs and can cause problems with the heart, lungs, and stomach.
2.2 Production and Use
Antimony is used as a common constituent of metal alloys; antimony ores are mined and mixed with other metals such as lead and copper. Antimony is used frequently for hardening lead in lead storage batteries. Antimony is used in the manufacture of ceramics, paints, glass, solder, pewter, typemetal, bearings, castings, explosives, and semiconductors. Antimony compounds are also used as abrasives for flameproofing material such as textiles and plastics. Antimony trioxide is an important component of pigments and munitions primers (189).

Historically, antimony compounds were used as emetics and expectorants. Recently, antimony compounds, such as tartar emetic and sodium stibogluconate, are used as antihelminthic and antiprotozoic drugs in treating parasitic diseases and infections (190). It plays no role in nutrition and is a nonessential element.
2.3 Exposure Assessment
2.3.1 Air Antimony concentrations in the air of the order 1–10 mg/m^3 were reported from a number of different smelter operations (191). Average working zone concentrations of antimony ranging from 4.7 to 10.2 mg/m^3 have been reported in smelting works (192). In one abrasives plant, the average air concentration of antimony was 3.0 mg/m^3 (193). Currently, the Occupational Safety and Health Administration (OSHA) has set an occupational exposure limit of 0.5 mg of antimony per cubic meter of air for an 8-hour workday, 40-hour workweek.

2.3.2 Background Levels Data regarding daily intake of antimony are controversial. Reports range from about 10& mg in a Swedish study (194) (neutron activation), a weekly average of 23 mg in four normal German diets (195) (neutron activation) to 250–1250 mg in one U.S. study of institutional diets for children using atomic absorption spectrophotometry (AAS) without extraction (196). There is reason to believe that the AAS method may have given falsely high values (191). Antimony concentrations of 3 to 8 mg/kg have been found in milk and potato powder (195). Antimony occurs primarily as a suspended particulate in water, although hydrolysis is possible (197). Antimony is likely to accumulate in sediments, and although antimony concentrations have been observed in some marine and freshwater invertebrates (possibly in methylated forms), antimony does not biomagnify (198, 199). Antimony concentrations in fresh water fish are reportedly of the order of 3 mg/kg wet weight (200). Antimony levels of 0.2 mg/L were reported in

the northeastern Pacific Ocean, and in the Rhine River levels average 0.1 mg/L (201). The EPA currently allows 0.006 parts antimony per million parts of drinking water (ppm). In soil, antimony ranges from 0.1 to 10 mg/kg dry weight (202). Antimony is a common air pollutant and has an average concentration of 0.001 mg/m^3 (203). Antimony concentrations in air ranging from 1.4 to 55 ng per cubic meter (204) and an average of 32 ng per cubic meter (205) were reported in Chicago using neutron activation analysis. The combustion of fossil fuels and products that contain antimony compounds commonly release antimony into the air, most likely as the trioxide and possibly the tetroxide and pentoxide forms (198). In addition, antimony levels in cigarettes have been studied by neutron activation, and an average of 0.1 mg of antimony per kg dry weight of tobacco was estimated (206).

2.3.3 Workplace Methods The recommended method for determining workplace exposures to antimony is NIOSH Method PCAM #261 (207).

2.3.4 Community Methods: NA

2.3.5 Biomonitoring/Biomarkers 2.3.5.1 Blood Blood concentrations can be measured several days after antimony exposure by using atomic absorption spectrometry.

2.3.5.2 Urine Occupational exposure is monitored by measuring antimony in the urine and also for the clinical investigation of antimony therapeutics. Some tests are, however, not routinely performed in doctors' offices and may require specialized equipment and methods such as AAS to perform them.

2.4 Toxic Effects

The major targets in antimony poisoning are the gastrointestinal and respiratory tracts, and the effects have been documented in both animals and humans (203). Other targets include the liver and the hematopoietic system. Renal toxicity including histological changes have been observed in animals (203). Antimony is an irritant of the mucous membranes, skin, and eyes. Pulmonary injury is linked with heavy exposure to antimony trioxide and pentoxide, and antimony trisulfide is regarded as cardiotoxic. It has been suggested that the descending order of toxicity is the antimony metalloid (mainly as stibine gas), the trisulfide, the pentasulfide, the trioxide, and the pentoxide from (203). The chemical properties and biological activities of antimony are similar to arsenic, although it is considerably less toxic.

2.4.1 Experimental Studies 2.4.1.1 Acute Toxicity Acute antimony poisoning is a rare occurrence but can result in death within several hours (203). The symptoms of acute antimony poisoning are similar to those of arsenic poisoning: vomiting, diarrhea, colic, and a metallic taste (203). For example, acute symptoms such as vomiting and diarrhea were produced in cats and dogs when administered antimony potassium tartrate in doses of the order of 10 mg/kg (191). In acute peroral exposure, antimony potassium tartrate is more toxic than antimony tri- and pentoxide. Cats and dogs exposed to doses of 100 mg/kg antimony trioxide and pentoxide for months exhibited no toxic manifestations (208, 209). Acute exposure to antimony compounds by inhalation can produce respiratory effects. For example, guinea pigs that inhaled antimony trioxide at an average concentration of 45 mg/m^3 for 33 to 609 hours exhibited signs of interstitial pneumonitis (210). Acute antimony exposures induce circulatory system effects. For example, an acute circulatory response, with a drop in blood pressure was observed after intravenous injections of antimony (211, 212). Pathological ECG changes were observed in dogs injected for four days with 5 mg of antimony potassium tartrate; the most prominent change was inversion of the T-wave (213). Liver and kidney effects have been observed with acute exposure; fatty degeneration occurred in the convoluted tubules of the kidney and the liver after a single dose of 60 mg of antimony potassium tartrate solution was given to rabbits (214). The pathological kidney changes occurred a few hours after the administration but preceding the changes observed in the liver. Fatty degeneration of the liver, but not the kidneys, was observed in one inhalation study of guinea pigs (210). Exposure to antimony and its compounds reportedly causes mild but inconsistent hematological effects in animals. Rats fed

894 mg/kg/day of antimony trioxide for up to one month showed an increased red blood cell count (215). In contrast, decreased red blood cell counts were reported for rats that received antimony trioxide in doses of 418 mg/kg/day for 24 weeks (216). In addition, decreased hematocrit and hemoglobin levels, as well as decreased plasma protein concentrations were observed for rats exposed orally to metallic antimony at 500 to 1000 mg/kg/day for 12 to 24 weeks. The odorless toxic gas stibine (antimony hybride), like arsine, is a potent hemolytic agent. The lethal concentration of stibine in air for mice is reportedly about 100 ppm for 1.6 hours (217). The formation of Heinz bodies in red blood cells was associated with acute stibine exposure that may underlie its hemolytic effects.

2.4.1.2 Chronic and Subchronic Toxicity Antimony potassium tartrate is more toxic in chronic peroral exposure than antimony tri- and pentoxide (191). Rats given 5 mg/L antimony potassium tartrate in drinking water in a long term study showed a significant decrease in survival and average life span (about 15%) compared to control animals (218). Rats given a diet containing 0.5 to 2% antimony or antimony trioxide had a decreased weight gain (216). Rats and rabbits exposed to antimony trioxide for periods up to 14 months at 90 to 125 mg/m^3 of air during 100 h/month exhibited pneumonitis, lipoid pneumonia, fibrous thickening of alveolar walls, and focal fibrosis (219, 220). In this study, rabbits appeared more susceptible than rats (220). A study of the long-term toxicity of inhaled antimony trioxide using female CDF-rats and miniature swine, where animals were exposed to low (1.6 mg/m^3) and high (4.2 mg/m^3) doses for 6 hours a day at 5 days per week for one year, showed pronounced morphological changes in the lung in rats, but not in miniature pigs (221). The changes in the lung included focal fibrosis, adenomatous and pneumonocytic hyperplasia, and cholesterol clefts, and the changes were more pronounced in the high-exposure group. Circulatory system and cardiovascular effects from chronic antimony exposures were observed. Chronic effects, including parenchymatous degeneration in the myocardium, were reported upon histopathological examination of hearts from rabbits and rats exposed to 3.1 and 5.6 mg/m^3 antimony trisulfide for 6 weeks (193). In contrast, Watt (221) found no evidence of cardiovascular effects in his long-term study of miniature swine exposed to antimony trioxide. Long-term peroral exposure to high doses of antimony may induce liver toxicity in animals. For example, rats exposed to 0.5 to 2% antimony and antimony trioxide in the diet for up to 24 weeks had elevated serum levels of liver enzyme GOT for the higher exposure (216).

2.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms 2.4.1.3.1 Absorption Antimony is poorly absorbed from the gastrointestinal tract but is more readily absorbed through the respiratory tract (203). For example, at least 15% of a single oral dose of labeled antimony potassium tartrate given to mice is absorbed when recovered in the urine and tissues (222).

2.4.1.3.2 Distribution Antimony is distributed nonspecifically, although trivalent compounds tend to react with red blood cells and the liver, and the pentavalent form tends to remain in the plasma (203). Two hours after an intraperitoneal injection of 3 mg trivalent antimony in rats, more than 95% of the amount in blood was incorporated in the red blood cells, whereas for pentavalent antimony, 90% was mainly recovered in the plasma (223). After acute or chronic oral or parenteral exposure to antimony, the highest levels are recovered in the thyroid, adrenals, and kidneys. A study of rats fed a diet that contained 2% antimony for 1.5 months showed that highest antimony concentrations were found in the thyroid and adrenals at values of 88.9 and 67.8 mg/kg, respectively. For spleen, liver, lungs, and kidneys, the antimony concentrations ranged between 6.7 and 18.9 mg/kg (224). For humans, body surface scanning of persons given intravenous injections of labeled sodium antimony dimercaptosuccinate revealed highest antimony amounts in the thyroid, liver, and heart (225, 226). Forty-three days after the last injection, the liver showed values about one-sixth the maximum value reached one day after the last injection.

2.4.1.3.3 Excretion The rate and route of excretion depend on the valency of the antimony compounds, and certain species differences have also been observed (191). Pentavalent organic antimony is excreted mainly in the urine in a rapid manner, and trivalent is eliminated mainly

through the feces (223, 227). Antimony is also excreted in bile primarily conjugated to glutathione (228). For hamsters administered tri- and pentavalent antimony by intraperitoneal injection, after 24 hours about 15% of the trivalent and 65% of pentavalent antimony were found in the urine (229). For fecal excretion over the same period of time, about 50% of trivalent antimony and less than 10% pentavalent antimony was recovered. In addition, 6% of the trivalent and 88% of pentavalent antimony dose given to rats was eliminated via the urine within 24 hours of administration (223). No methylation of antimony has been reported in humans or in animals (228).

2.4.1.4 Reproductive and Developmental: NA

2.4.1.5 Carcinogenesis Existing data to date suggest that antimony may be an animal carcinogen; however, the data are not sufficient for a quantitative estimate of cancer potency (203). Inhalation of antimony dust in laboratory rats may increase the risk of lung cancer, but there is no evidence of an increased risk in animals fed an antimony-containing diet or drinking water. Female rats exposed to antimony trioxide at 4.2 and 3.2 mg/m^3 for 6 h/day, 5 days/week for one year, developed lung tumors after one additional year of observation (232). Similar results were reported in another study in which 27% of female rats were exposed to 45 mg/m^3 antimony trioxide for one year, and 25% of female rats exposed to 38 mg/m^3 antimony ore containing mostly antimony trisulfide developed lung neoplasms (233). In addition, no lung tumors were observed in male rats exposed to either antimony compound, or in the controls. The International Agency for Research on Cancer (IARC) has concluded that antimony trioxide is a possible carcinogen (234); antimony trioxide production has been given an A2 suspected human carcinogen designation by the ACGIH but no TLV has been assigned to date (207). There is still limited evidence for the carcinogenicity of antimony trisulfide (234).

2.4.1.6 Genetic and Related Cellular Effects Studies Both negative and positive results have been reported in genotoxic assays of antimony and its compounds (189).

2.4.2 Human Experience 2.4.2.1 General Information Most acute and chronic information about antimony toxicity, was obtained primarily from industrial airborne exposures; occupational exposures are usually by inhalation of dust containing antimony compounds, antimony tri- and pentachloride, trioxide, and trisulfide (235). Data on the adverse effects from treating parasitic diseases with antimony compounds were also reported.

2.4.2.2 Clinical Cases 2.4.2.2.1 Acute Toxicity Respiratory effects may be acute, particularly from airborne tri- and pentachloride exposures that induce rhinitis and even acute pulmonary edema (235). Acute respiratory exposure to antimony trichloride (73 mg/m^3) produced irritation and soreness of the upper respiratory tract in several workers (236). Cordasco and Stone (237) reported three cases, two of them fatal, of severe pulmonary edema induced by antimony pentachloride exposure, although no air concentrations were available. Gastrointestinal effects were recorded upon acute exposure to antimony compounds. Inhalation of dust containing antimony by factory workers induced gastrointestinal irritation, probably the result of antimony dust transported via the mucociliary escalator and swallowed (189). Acute symptoms, including abdominal cramps, diarrhea, and vomiting, among smelter workers subjected to heavy exposure to antimony fumes were reported by Renes (192). Potassium antimony tartrate at a dose of 0.53 mg/kg can induce vomiting (238). Vomiting, nausea, and diarrhea were reported in 150 children who drank an antimony-contaminated lemon drink (239). Acute antimony poisoning is rare but can result in death within several hours (203). Various toxic side effects and cases of sudden death were recorded in connection with medical treatment of tropical diseases using antimony compounds (240). Common features during treatment with antimony compounds are nausea and vomiting (241–243).

Acute antimony poisoning is rare, and hence little documentation is available. Symptoms such as vomiting, diarrhea, colic, and a metallic taste have been described in a number of reports of acute antimony poisoning. Seventy people became ill after drinking a lemonade drink containing 0.013%

antimony, and 56 people were taken to the hospital with burning stomach pains, nausea, vomiting and colic (238, 262). Werrin (239) reported acute antimony poisoning of 150 children who ingested a contaminated lemon drink (about 30 mg/L). In former times, drinks stored in antimony cups were used as expectorants and emetics, the dose ranged from 30 to 60 mg to induce vomiting (263).

2.4.2.2.2 Chronic and Subchronic Toxicity Workers chronically exposed to airborne antimony and antimony compounds can develop persistent symptoms such as dermatitis, eye irritation, obstructive lung alterations, and emphysema with increased pneumoconiosis (244, 245). Chronic respiratory effects related to antimony were reported among 78 smelter workers exposed to antimony concentrations ranging from 4.7 to 11.8 mg/m^3 for periods exceeding two weeks (192). Symptoms suffered by the workers included rhinitis (20%), pharynigitis (8%), pneumonitis (5.5%), and tracheitis (1%). In addition, 70% of the workers experienced soreness in the nose and nosebleeds. It must be noted that the workers were also exposed to arsenic concentrations around 0.7 mg/m^3, and hence several of the symptoms may have been caused by arsenic, considering the more toxic properties of the metal (246). Respiratory tract irritation was not mentioned by Brieger et al. (193) in an extensive study of workers exposed to antimony trisulfide ranging from 0.6 to 5.5 mg/m^3. Pneumoconiosis-like X-ray pictures obtained from workers who had long-term occupational exposure to antimony have been noted by several authors (244, 245, 247–251). It is likely that silica may have been present in some of these instances (191). An X-ray method for measuring inhaled antimony trioxide was developed by McCallum et al. (252), and a significant correlation between estimated lung antimony and the period of employment was found upon examining 113 antimony process workers. A report of the examination of 51 Yugoslavian antimony smelter workers showed X-ray changes that indicated antimony pneumoconiosis (antimoniosis); the X-ray findings were characterized by the presence of diffuse, densely distributed, punctate opacities whose diameter was less than 1 mm (245). In addition, pulmonary function tests showed obstructive changes and mixed restrictive-obstructive changes, along with increases of airway resistance and decreased forced expiratory flow rates. Chronic coughing was also another major complaint of the exposed workers. Other investigators also observed lung changes among antimony workers exposed to antimony trioxide for up to 28 years (247, 253); the prevalence of pneumoconiosis and symptoms of emphysema were given as 21 and 42%, respectively, among the workers (253). Antimony pneumoconiosis has been commonly regarded as a benign condition that had no detrimental effects upon health or life expectancy (251), but chronic respiratory effects were reported in a number of studies, and therefore heavy antimony exposure cannot be regarded as harmless (191). Skin effects from chronic antimony exposures have been reported. Pruritic skin papules progressing to skin eruptions, referred as “antimony spots,” are occasionally seen in workers chronically exposed to antimony and its salts. Of thirty-two antimony smelter workers examined by Potkonjak and Pavlovich (245), 67.2% had developed “antimony dermatosis.” The skin eruptions are transient and mainly affect skin areas exposed to heat and where sweating occurs (192, 248, 254, 255). Circulatory system and cardiovascular effects were reported by Brieger et al. (193) upon examining 124 abrasive industry workers exposed to airborne antimony trisulfide ranging from 0.6 to 5.5 mg/m^3 for 8 to 24 months. Six workers died suddenly, and two died from chronic heart disease during this period. In addition, ECG changes, mostly of the T-wave, were seen in 37 out of 75 workers examined. It must be noted that no control group was examined in this study. Cardiovascular effects, including arrhythmia, were also reported among antimony exposed persons in clinical settings (256, 257).

2.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms Single intramuscular or intravenous injections in human volunteers produced higher 24-hour urinary excretion of pentavalent (80%) than of trivalent (25%) antimony compounds, a similar pattern found in animal data (225, 258, 259). A study of elimination of a single intravenous administered dose of labeled antimony potassium tartrate (trivalent antimony) showed urinary excretion about four times higher than fecal elimination, and in one patient about 73% of the total dose was eliminated within 4 weeks (260). When pentavalent antimony in the form of sodium stibgluconate was administered intramuscularly to patients, about 95% of the dose is recovered in urine within 6 hours indicating that the initial excretion of antimony in humans is rapid (190). A study by Mansour et al. (261) suggested there may be a long-term

component of antimony elimination. They found average blood and urine antimony levels of 6.7 and 27.6 mg/L, respectively, in three patients clinically treated one year earlier for bilharzia with antimony. Because antimony is a group VA element, it has many of the same chemical and toxicological properties as arsenic, although it is less toxic. For example, the toxicity of trivalent compounds is greater than the pentavalent compounds. Hence, the metabolism of antimony is similar to that of arsenic, and antimony tends to bind to sulfhydryl groups of respiratory enzymes (203).

Much of the data from the studies of industrially exposed persons give information regarding the excretion of antimony by monitoring antimony levels in the urine of workers. Workers exposed to air containing around 3 mg/m^3 antimony showed urinary antimony values ranging from 0.08 to 9.6 mg/L, which are higher compared to normal values (193). Smith and Griffiths (269) found higher urinary concentrations of antimony ranging from 10–220 mg/L in urine samples from exposed workers compared to urine samples of nonexposed persons (less than 1 to 5 mg/L). A number of studies also examined the half-life of antimony retention in the lungs of industrial workers exposed to airborne antimony. A study by Gerhardsson and his group (270) of lung tissue obtained from former exposed smelter workers found that inhaled antimony may be deposited and retained in the lungs up to several years. Exposed workers had an average of 12 times higher lung concentrations of antimony (315 mg/kg) compared to nonexposed persons (26 mg/kg). Leffler and co-workers (271) studied lung retention of antimony and arsenic in hamsters after intratracheal instillation of industrial dust neutron-activated from a Swedish copper smelter. In this study, two phases in lung clearance of antimony were found: the half-life for the initial phase was 40 hours for antimony trioxide and 30 hours for antimony dust, and the half-life for the second phase was approximately 20 to 40 days for antimony trioxide and antimony dust. The low solubility of antimony in factory dust along with its long biological half-life may explain the observed lung accumulation and retention of antimony in industrially exposed workers (191).

2.4.2.2.4 Reproductive and Developmental A report from Russia reported an increase in the number of spontaneous abortions in women exposed to antimony in the workplace, but no exposure levels were available (189, 230). The often-cited Balyaera report (231) indicates an increase in the number of spontaneous abortions and menstrual cycle disturbances among female workers exposed to antimony-containing aerosols. In animal studies, no effects were observed in the offspring of rats administered low doses of antimony trichloride in drinking water.

Gynecological examinations were performed on women who were exposed to dust that contained metallic antimony, antimony trioxide, and antimony pentasulfide during a two-years period (231), and a higher incidence of “various sexual disturbances” was reported in exposed women compared to the controls (77.5% vs. 56.0%). Disturbances of the menstrual cycle, inflammatory disease, and other ailments of the sexual organs were reported. The incidence of spontaneous abortions was 12.5% in the exposed women as compared with 4.1% in the controls, and the incidence of premature births was 3.4% versus 1.2% in controls. Birth weights of children born to exposed women were comparable to the controls, but the body weight of children of exposed women began to lag after one year. It must be noted that the level of antimony exposure in this study was not specified, and it is not known how the control group was selected, whether confounding factors were controlled for, and if exposures to other toxic substances occurred.

The often cited Balyaera study (231) indicated that women workers exposed to dust containing antimony and antimony compounds experienced a greater incidence of spontaneous abortions than a control group of non-exposed females. Aiello (272) observed a high rate of premature deliveries among women workers in an antimony smelting and processing plant.

2.4.2.2.5 Carcinogenesis Existing experimental data suggest that antimony may be an animal carcinogen, but there is lack of data on the possible carcinogenic properties of antimony and antimony compounds for human exposures. The ACGIH (246) refers to unpublished data on a large antimony smelter in the United Kingdom in the 1960s where workers were exposed to antimony

trioxide ranging from 0.5 to 40 mg/m^3. The data may indicate increased mortality in lung cancer among the heavily exposed workers, but the workers were also exposed to zirconium making the data cited difficult to interpret (191, 246).

2.4.2.2.6 Genetic and Related Cellular Effects Studies No genotoxic effects from human exposure to antimony and antimony compounds were reported.

2.4.2.3 Epidemiology Studies Most epidemiological findings come from the studies of occupationally exposed industrial workers and of persons clinically exposed to antimony compounds for treating tropical diseases and parasitic infections.

Epidemiologic data regarding chronic antimony toxicity comes mainly from studies of occupationally exposed workers in the mining and extraction industries. Renes' (192) study of 78 smelter workers relates chronic respiratory effects, such as rhinitis, pharyngitis, pneumonitis, trachetiis, and chronic cough to antimony exposures. However, the workers were also exposed to arsenic concentrations that may have influenced the results. Brieger and co-workers (193) reported excess mortality and morbidity among 124 workers in the abrasive industry. The report describes respiratory, cardiovascular, and gastrointestinal effects among workers exposed to antimony trisulfide ranging from 0.6 to 5.5 mg/m^3 for 8 to 24 months. A study by McCallum and co-workers (252) using X-ray spectrometry for measuring inhaled antimony trioxide found a significant correlation between estimated antimony levels in the lung and the period of employment in years among 113 antimony process workers. X-ray changes indicating antimoniosis and altered pulmonary function tests were reported among 51 Yugoslavian smelter workers exposed for 9 to 31 years to dust containing antimony trioxide antimony pentoxide, and free silica (245). They also describe the development of “antimony dermatosis” among 62.7% of the workers. Two other groups reported lung effects (including pneumoconiosis and emphysema) in antimony workers (247, 253). Adverse effects during clinical antimony treatment for parasitic infections were described. ECG changes, particularly in the T-wave, were reported frequently during long-term treatments (264–268).

There are no epidemiological data available to suggest that antimony is genotoxic in humans.

2.5 Standards, Regulations, or Guidelines of Exposure

Approaches used to limit exposure to arsenic apply also to antimony and antimony compounds. The OSHA permissible exposure limit (PEL), the NIOSH recommended exposure limit (REL), and the ACGIH threshold limit value-weighted average (TLV-TWA) for antimony and its compounds 0.5 mg/m^3 (207). The ACGIH has listed antimony trioxide as a suspected source of human carcinogenicity with an A2 designation.

2.6 Studies on Environmental Impact

Antimony is a common air pollutant that occurs at an average concentration of 0.001 mg/m^3 (203). Antimony is released into the environment from burning fossil fuels and from industry (198). In the air, antimony is rapidly attached to suspended particles and thought to stay in the air for 30 to 40 days (198). Antimony is found at low levels in some lakes, rivers, and streams, and may accumulate in sediments. Although antimony concentrations have been found in some freshwater and marine invertebrates, it does not biomagnify in the environment (198, 199). The impact of antimony and antimony compounds on the environment has not been extensively studied to date.

Arsenic, Antimony, and Bismuth

Lisa Gallicchio, Bruce A. Fowler Ph.D., Emily F. Madden

3.0 Bismuth

3.0.1 CAS Number:

[*7440-69-9*]

3.0.2 Synonyms:
None
3.0.3 Trade Names:
None
3.0.4 Molecular Weight:
208.980
3.0.5 Molecular Formula:
Bi
3.1 Chemical and Physical Properties
3.1.1 General Bismuth is a brittle, white, crystalline metal that has a pinkish tint. It is the most diamagnetic of all metals, and its thermal conductivity is lower than any metal except mercury. In addition, bismuth has high electrical resistance and the highest Hall effect of any metal. Inorganic salts of bismuth are poorly water soluble; solubility is influenced by the acidity of the medium and the presence of additional certain compounds containing sulfhydryl or hydroxyl groups (273). Bismuth belongs to the VA group of the periodic system together with arsenic and antimony, and it forms compounds in the +3 and +5 oxidation states. Bismuth occurs in the native form; however, it is found largely in nature in minerals such as bismite, bismuthinite, and bismutite and is usually associated with sulfide ores of lead and copper and tin dioxide.

3.1.2 Odor and Warning Properties Human exposure to bismuth and bismuth compounds is quite limited, except for its use in medicine where it has been prescribed for more than a century. Occupational and environmental exposure to bismuth and its toxicological significance are still unknown.
3.2 Production and Use
Bismuth is used in low-melting alloys and metallurgical additives, including thermoelectric and electronic applications. It is also used for catalysts, pearlescent pigments in cosmetics, in industrial chemicals, and in pharmaceuticals. Bismuth compounds have been used as antiseptics, astringents, antacids, dusting powders, and as radio-opaque agents in X-ray diagnosis.

Organic bismuth compounds such as tartrate, gallate, nitrate, and salicylate were used in the treatment of syphilis before the advent of penicillin in the 1940s (274). Inorganic bismuth compounds such as Bi subnitrate, subcarbonate, and subgallate, are still used today in some countries for treating gastrointestinal complaints including diarrhea, constipation, cramps, and flatulence. Bi subsalicylate (BSS) is the principal ingredient of Pepto-Bismol, and is consumed worldwide in large quantities (275). Colloidal Bi subcitrate (CBS) is available by prescription for treating of peptic ulcer and has prove to be effective as a histamine H2-antagonist for treating gastric and duodenal ulcer when given in 4- to 8-week courses (273, 276). Bismuth subgallate (BSG) is still used as a topical antiseptic for the skin and as a hemostatic agent after adenotonsillectomy (273, 276). Bismuth subsalicylate (BSS) is used in treating and the preventing traveler's diarrhea in the United States (277), and also for treating *Helicobacter pylori* associated with gastritis (278).
3.3 Exposure Assessment
3.3.1 Air The concentration of bismuth in the air outside cities is less than 1 mg/m^3 (275). Bismuth concentrations in urban air range from 1 to 66 ng/m^3, and concentrations in rural air from 0.1 to 0.6 ng/m^3 (279). It is estimated that the daily intake of bismuth via inhalation is <0.01–0.76 mg (280, 281).

3.3.2 Background Levels Investigation of ambient concentrations of bismuth is limited because industrial and environmental bismuth poisonings are rare (275). Bismuth levels in seawater have been reported at 0.2 mg/L (282), and much lower values in the range of 0.053–0.63 ng/L have been reported for ocean surface waters (283). Levels of bismuth in soil have been reported at 1 mg/kg, and in rocks bismuth levels range from 0.1 mg/kg in coal to 3 mg/kg in sandstone (284). The daily intake of bismuth from food and water ranges from 5 to 20 mg (283). Representative food samples pooled from the main regions of the United Kingdom were analyzed, and it was estimated that the daily intake of bismuth is less than 5 mg (285). Woolrich (280) reported that the daily intake of bismuth

from food and water is about 20 mg, but data on bismuth concentrations in specific food items were not given in this report.

3.3.3 Workplace Methods Exposure to bismuth and bismuth compounds can occur in the manufacture of pharmaceuticals, cosmetics, and industrial chemicals. Information regarding occupational exposures to bismuth is lacking, but it may soon gain attention because bismuth is being increasingly used to replace lead in many chemical and technical applications (286). NIOSH Analytical Method #0500 is recommended for determining workplace exposures to bismuth telluride doped with selenium sulfide and undoped (10a).

3.3.4 Community Methods Human exposure to bismuth and bismuth compounds is frequently through the use of bismuth-containing medications, and consumption worldwide is often under uncontrolled situations. Though evidence shows that the risk of bismuth-related toxicity is low in the general population, clinicians should be aware of the possibility that bismuth is involved in neurotoxicity, although not much is known regarding its mechanisms (287).

3.3.5 Biomonitoring/Biomarkers 3.3.5.1 Blood Concentrations of Bi measured in the blood are not predictive of the severity of Bi-induced encephalopathy (288), but concentrations in the CSF and may reflect the clinical condition of an exposed individual better (289). It is unlikely to detect bismuth levels in the blood of persons recently exposed to Bi therapy for gastric ulcers (290).

3.3.5.2 Urine High Bi concentrations in the urine can also support the diagnosis of Bi-induced encephalopathy, but such measurements are more difficult to relate to the severity of the clinical condition (287). The methods of choice at present for quantifying bismuth in urine, blood, and serum are either electrothermal AAS or AAS with hydride generation (273). For the analysis, sample pretreatment is usually necessary because of matrix effects.

3.3.5.3 Other Intracellular inclusion bodies (metal-protein complexes), observed after exposure to bismuth occurs most frequently in the nuclei of cells in the proximal renal tubule (291–293). It is unclear what role the formation of these metal-protein complexes have in bismuth-induced nephrotoxicity (273). The clinical significance of these inclusion bodies may be as a diagnostic indicator of exposure (293).

3.4 Toxic Effects

The main target organs of bismuth toxicity are the brain, kidney, and bone. Common toxic effects that have been attributed to bismuth and bismuth compounds in humans are encephalopathy, nephropathy, osteoarthropathy, gingivitis, stomatitis, and colitis. (273). The liver could be a target organ of Bi toxicity, and whether hepatitis is an adverse side effect of bismuth intoxication is still in dispute (273). Adverse side effects on the various organ systems may depend on the chemical and biological characteritics of the bismuth compound. For example, neurotoxicity, it has been found, is caused by “insoluble” inorganic bismuth compounds, whereas bismuth compounds used in the past for treating syphilis caused nephrotoxicity and bone disease (273).

3.4.1 Experimental Studies 3.4.1.1 Acute Toxicity Application of trimethyl- and triethylbismuth to the skin of rabbits and rats reportedly produced intense inflammation and edema. In addition, local necrosis was also observed at the injection sites. Another local effect was eye irritation after inhalation exposure to alkylbismuth (294). Acute local effects of inhalation, including pulmonary edema, were observed after inhalation of trimethylbismuth by dogs, rats, and cats. Acute administration of bismuth salts produced both liver and kidney toxicity in both humans (274, 295–298) and animals (299). Toxicity in the kidney is observed primarily in the renal proximal tubule cells by the development of phosphaturia, amino aciduria, and glucosuria (296). More recent studies (299) demonstrated marked inhibition of enzymes in the heme biosynthetic pathway in both liver and kidney. The mechanisms of bismuth toxicity and target organelle damage are complex and involve disrupting a number of biochemical systems. Liver toxicity was observed as cloudy swelling, nuclear degeneration, and random small foci of necrosis after rabbits were given lethal injections of sodium and potassium tartro-bismuthate (i.v. 10–30 mg/kg; i.m. 150–350 mg/kg) and bismuth trioxide (i.m.

450 and 500 mg/kg) (300). Exposure to bismuth tri- or thioglycollamate and bismuth diallylacetate induced acute renal toxicity, and these compounds are no longer used in medicine (287). In some cases, bismuth-induced acute nephrotoxicity is reversible (295–297, 301–305). Kidney damage was produced in rats given single intramuscular injections of 13 different bismuth compounds at concentrations ranging from 0.03 to 1.5 g/kg (274). Histological examination of 104 rats showed that 36 or 37 of the animals that died before 21 days had varying degrees of nephritis as had 11 of the 67 surviving animals. The most prominent site of toxicity was the proximal tubule. Bismuth thioglycollate was the least toxic compound, although doses of 0.04–0.080 g/kg produced severe nephritis. Subcutaneous injections of 5 g bismuth subnitrate daily for up to 3 days produced degenerative changes, and intranuclear and cytoplasmic inclusion bodies were found in the renal proximal tubules of rabbits (291). The formation of pathognomonic bismuth-containing intranuclear inclusion bodies (291–293) in renal proximal tubule cells (Figure 36.2) is hence an important diagnostic indicator of elevated bismuth exposure. The relationship of the formation of these structures to bismuth binding to metallothionein-line proteins (306, 307) in the kidney is presently not clear but may be related to a process similar to that observed in renal lead-binding proteins (308, 309, 310, 311), and the formation of pathognomonic lead-containing intranuclear inclusions. The toxicological significance of the inclusion body phenomenon rests with the intracellular storage of these toxic metals in a target cell population such as the renal proximal tubular epithelium. They appear as sharply defined, round structures whose diameter is up to 5 mm and are found mainly in the cell nuclei, in the cytoplasm, and possibly in the lysosomes. Inclusion bodies were observed in 86% of the kidneys of syphilis patients medically treated with bismuth compounds (291). These inclusions contained bismuth, proteins, carbohydrates, lipids, and sulfur (292, 293, 312–314). Their implication in bismuth-induced renal toxicity still remains unclear (287). Enzymes in the heme biosynthetic pathway were highly sensitive to inhibition by bismuth both *in vivo* and *in vitro* (299). Specifically, rats injected with bismuth subnitrate over a dose range of 0, 20, 40, and 80 mg Bi/kg and sacrificed 16 hours later showed marked mitochondrial swelling and distortion of the inner mitochondrial membranes of both liver and kidney at the 40 and 80 mg Bi/kg dose levels. These morphological effects were associated with dose-related decreases in the activities of the mitochondrial enzymes ALA synthetase and heme synthetase and the cytosolic enzyme ALA dehydratase in liver. In kidneys, similar dose-related decreases in the activities of ALA synthetase and ALA dehydratse but not heme synthetase were observed. *In vitro* studies using bismuth concentrations from 0–0.4 mM for 1 hour demonstrated that the observed effects on the mitochodrial heme pathway enzymes are the result of both membrane distortion and the direct inhibitory action of bismuth on these essential enzymatic activities.

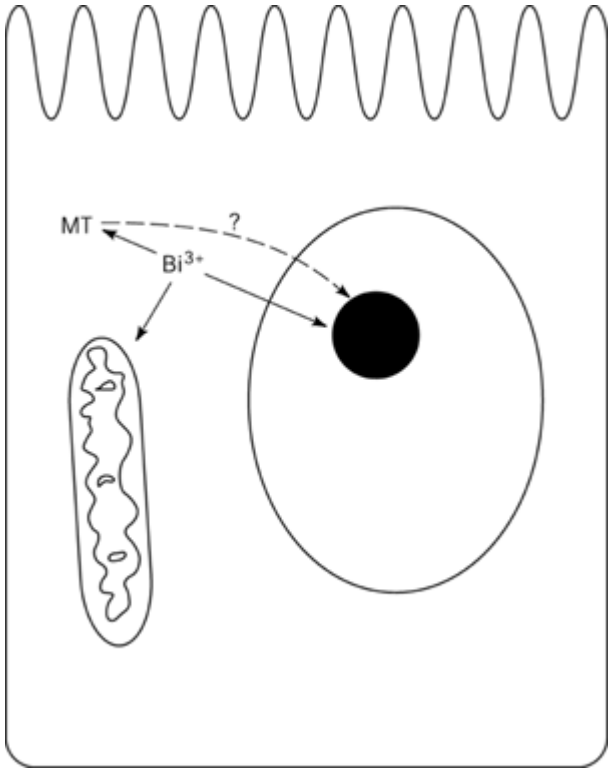


Figure 36.2. Diagram of renal proximal tubule cell showing a pathognomonic bismuth-containing intranuclear inclusion body, bismuth binding to methallothionein-like proteins, and reaction with heme biosynthetic pathway enzymes.

3.4.1.2 Chronic and Subchronic Toxicity With chronic ingestion, bismuth accumulates in a number of tissues until both nephrotoxicity and neurotoxicity develop (275). It has been found that patients who died of Bi encephalopathy had Bi concentrations in the gray matter (1.2 to 29 mg/g) that were generally twice as high as that in the white matter (1.3 to 15.9 mg/g) (315). The highest concentrations of Bi were found in the thalamus, frontal, and cerebellar cortex. In another body, the highest Bi concentrations were found in the brain stem and the pons (316). The precise mechanisms of Bi-induced neurotoxicity, including Bi encephalopathy, still remain unclear. One *in vitro* study showed that astrocytes are much more sensitive to Bi sodium tartrate than nerve cells in cultures of brain, meninges, and neuronal retina cells from chicks (317). Damage to astrocytes may be responsible for the early "vague" symptoms of Bi neurotoxicity, whereas nerve cells are damaged only after prolonged Bi exposure. Neuronal cell degradation in rat hippocampal slices was demonstrated from prolonged Bi exposures, whereas no effects on the bioelectric activity of pyramidal cells were observed for acute exposures (317). Chronic nephrotoxicity from bismuth exposure was observed in a number of animal studies. Hemorrhages in the cortical and cerebral layer of the kidney and lymphohistiocytic infiltrations were found in rats after 6 months of peroral treatment with potassium bismuthate and bismuth sulfate (0.025–5.0 mg/kg) (318). The administration of bismuth trichloride by subcutaneous injection at doses of 1.0, 2.0, and 3.0 mg/kg every other day for up to 2 weeks greatly increased renal concentrations of copper and concomitant levels of metallothionein-like proteins (306).

3.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms 3.4.1.3.1 Absorption Bismuth compounds are considered slightly to moderately absorbed through the respiratory and gastrointestinal tracts, depending on their solubility. Slikkeveer and de Wolff (319) divided pharmacologically active bismuth compounds into four toxicological groups: Groups 1: water-insoluble organic salts and subsalts that are absorbed minimally from the gut and cause no toxicity; Group 2: absorbable lipid-soluble organic compounds that can elevate Bi blood levels and cause neurotoxicity and hepatoxicity; Group 3: absorbable water-soluble organic compounds that elevate Bi blood levels and

cause nephrotoxicity; and Group 4: water-soluble complexes that hydrolyze in the gastrointestinal tract with some absorption of Bi and the hydrolyzed radical, elevating Bi and complex radical levels. The absorption of inorganic Bi compounds, it is suggested, depends on their solubility in the gastrointestinal tract (320–322). In one study, the bioavailability of radiolabeled Bi compounds corresponded with the solubility in artificial duodenal juice but not with the solubility in gastric juice (323). Citrate enhanced intestinal absorption of bismuth from Bi subnitrate, Bi subsalicylate, Bi citrate, $BiCl_3$, and colloidal Bi subcitrate during *in vivo* perfusion of rat intestine (273). In addition, the simultaneous intake of citrate and Bi subnitrate by human volunteers increased bismuth absorption significantly, and the absorption profiles for Bi in blood and citrate in serum were parallel, suggesting the formation of a bismuth citrate complex (273). A notable rise in bismuth blood levels was seen after oral administration of Bi subnitrate and sulfhydryl-containing compounds, the increase was largest for 3-mercaptopropionic acid, penicillamine, cysteine, and homocysteine (324). No effect on bismuth absorption was found for serine, alamine, and methione. Bismuth absorption was also increased by the simultaneous intraperitoneal administration of Bi subnitrate and cysteine (325). Promotion of bismuth absorption has also been suggested for several other hydroxy-containing compounds (287), for sorbitol (326), and for lactic acid (327), but experimental proof is lacking. Because bismuth is not an essential element, it is thought to share absorption routes with other different substances (287). Several unidentified bismuth species may form in the intestine that may then partake in counterion absorption, but the actual sites of bismuth absorption are not known (287).

3.4.1.3.2 Distribution The chemical form of bismuth in the blood is not known, and there are no data available on the specific carriers of bismuth in the blood after oral intake of bismuth compounds (287). It has been shown *in vitro* that 17% of radioactive bismuth citrate was associated with erythrocytes, and the remainder of the concentration was bound to serum proteins (328). Twenty days after an oral dose of colloidal Bi subcitrate, a relatively considerable amount was associated with red blood cells (about 8.7% of the dose) (323). Two hours after the addition of bismuth subnitrate to whole blood, about 82.3% was found in red blood cells at 25 mg/L, and about 97.7% was found at 2500 mg/L (329). For concentrations below 200–300 mg/L, overall binding to the blood components seemed to be stronger than above the level. Gel filtration of blood after incubation with bismuth subsalicylate exhibited an association of bismuth with the higher molecular weight fraction (>200,000 Da): a_2-macroglobulin, IgM, b-lipoprotein, and haptoglobulin (322). The distribution of bismuth in the various organs is mostly independent of the Bi compound administered or the route of administration because the highest concentration per gram wet weight was always recovered in the kidneys (328, 330–335). However, with more detailed studies of bismuth distribution, exceptions have been found. For example, when bismuth was administered as a colloid or adsorbed onto charcoal, the distribution after intravenous delivery depended on particle size where Bi-containing particles were found mainly in the lung and in the reticuloendothelial system (328, 336, 337). In a study of tissue distribution of Bi subnitrate, Bi subsalicylate, colloidal Bi subcitrate, Bi citrate, and Bi subnitrate with added citrate buffer in rats fed for 14 days to reach comparable Bi concentrations in the blood, it was found that rats fed Bi subsalicylate had lower Bi levels in the kidney and higher levels in the liver compared to other Bi compounds (273). Although Bi subsalicylate intake led to the lowest bismuth levels in the kidneys, it was the only compound to show transient kidney toxicity at the highest blood concentration. For dogs orally administered trimethylbismuth, the concentration of Bi was higher in the liver than in the kidneys, which is most likely due to the organic characteristics of the compound (294). The kidneys had the longest retention time of bismuth compared with any other organ (287). Russ et al. (328) found that 144 hours after intravenous injection of ^{206}Bi citrate, 12% of the injected dose remained in the kidneys, 0.9% in the bone, and no or very little of Bi remained in other organs. For rats exposed for 14 months to colloidal Bi subcitrate, bismuth levels ranked from high to low in the kidney, lung, spleen, liver, brain, and muscle respectively (338). The wet weight concentrations of Bi in the kidney were 13.9 mg/g and 0.13 mg/g in the muscle. In other studies where bismuth concentrations in the bone were measured, the concentrations in bone were usually 10 to 20 times lower than in the kidney (335, 339, 340). Elevated bismuth concentrations in the brain were observed in a number of studies

and may account for its neurotoxic effects. In animals and humans that received bismuth, the concentration in the brain tissue was higher than in the controls, showing that Bi can pass through the blood–brain barrier, although in small quantities (338, 341–343). In rats administered radiolabeled bismuth citrate intravenously, the highest activity was found in the spinal cord, medulla oblongata, hypothalamus, and pons after 2 hours (333).

3.4.1.3.3 Excretion Bismuth is eliminated from the body through the urine and feces, and the route may depend on the Bi compound and the dose (287). In one study where rats were intravenously injected with ^{206}Bi nitarte, 38% of the metal was excreted in four days: 21% in the urine and 17% in the feces (340). After intramuscular injection of bismuth butylthiolaureate to rats, equal amounts of Bi were excreted in the urine and feces after 90 days, and 10% of the dose remained in the body (344). In humans, the elimination of different Bi compounds was showed no differences; 99.9% of an oral dose of several radiolabeled Bi compounds was excreted in the feces (323). On day 12 after exposure, the ratio of Bi in the urine and feces (bile) was 1:1. In the presence of biliary drainage, Bi could still be found in the intestine after intravenous delivery, implying that Bi is eliminated into the intestine, partly through intestinal and partly through bile secretion (334). The cecum in rats is suggested as a location for intestinal secretion because after intravenous injection, a high amount of Bi was recovered there (333, 344, 345). A number of studies suggest a two- or three-compartment model to describe the elimination kinetics of Bi, and the kidney is the major compartment (287). For example, in one study of two human volunteers intravenously administered ^{206}Bi and of three patients recovered from Bi-induced encephalopathy, the half-lives of 3.5 min, 0.25 min, and 3.2 hours were established (346). For rats exposed to a single oral dose of ^{205}Bi as colloidal Bi subcitrate, a three-compartment model was used to describe urinary and fecal elimination; the biological half-lives were estimated at 10, 36, and 295 hours, respectively (323). The elimination half-life in human plasma after multiple dosing was estimated at about 20.7 days (347). It must be noted there is considerable variation and little consistency in the data, possibly due to the use of different bismuth compounds in the studies, some of them even unnamed (287).

3.4.1.4 Reproductive and Developmental There is no evidence to date that bismuth has any reproductive and developmental effects in humans or in animals.

3.4.1.5 Carcinogenesis An old life time study with rats fed 2% bismuth subcarbonate (BSC) in the diet did not show an increase of tumors or a decrease of survival (348).

3.4.1.6 Genetic and Related Cellular Effects Chromosomal aberrations with gaps were observed in the mouse bone marrow after an oral uptake of an aqueous suspension of Bi_2O_3 for up to 21 days (349). In addition, no abnormal sperm were detected in this experiment. It must be noted that in this mutagenicity study, no measurements of Bi blood levels were taken to ensure that bismuth had indeed reached the bone marrow because Bi_2O_3 absorption from the gastrointestinal tract is considered negligible (287).

3.4.1.7 Other Neurological, Pulmonary, Skin Sensitization Blood pressure of dogs, received hypodermic or intramuscular injections of trimethylbismuth (at 4 doses of 350 mg/kg) dropped to shock level without alteration of heart rate, arrhythmia, or blockage. The animals were anesthetized with barbiturates (294). A slight decrease of blood pressure and amplitude in heart rate was observed after intravenous injection of elemental bismuth (0.50 mg/kg). Higher bismuth doses of 1.8 mg/kg resulted in heart block, and all fundamental heart functions were affected, including excitability, conductivity, and contractility (350).

3.4.2 Human Experience 3.4.2.1 General Information There are very few reports of occupational exposure to bismuth and its compounds. An important source of bismuth exposure in the past has been through the therapeutic use of bismuth compounds to treat infections such as syphilis and gastrointestinal complaints. Because of problems associated with acute and chronic bismuth toxicity,

the medical use of bismuth compounds has been restricted in Europe, Canada, and Australia (275).

3.4.2.2 Clinical Cases 3.4.2.2.1 Acute Toxicity Clinical manifestations of acute bismuth intoxication are similar to those caused by mercury and lead: neurological abnormalities which include encephalopathy, and renal dysfunction with nephrotic syndrome that may progress to acute failure (275). The blood levels may reach 1500 to 2000 mg/L when large amounts of bismuth compounds are ingested acutely, resulting in encephalopathy with obtundation that can progress to coma, myoclonus, and abnormal electroencephalographic readings (351). Daily doses of 5 to 10 g of bismuth subsalicylate caused encephalopathy after 7 days in one patient, whose blood bismuth levels reached 200 mg/L and urine bismuth concentration was 2960 mg/L. Chelators such as British antilewisite or dimercaprol can be used for severe bismuth poisoning. Clinical symptoms of bismuth toxicity may resolve over a course of several weeks to months after a patient ceases using bismuth compounds (275). There are no reports of occupational exposure effects of bismuth (352).

Application of trimethylbismuth to human skin produced no effects, but irritation developed when the exposed skin had been scratched. Irritations of the eye and upper respiratory tract were also observed for humans (294).

3.4.2.2.2 Chronic and Subchronic Toxicity Chronic ingestion of bismuth compounds produces bismuth lines (pigmentation) on the gums and way cause stomatitis, excess salivation, osteoarthropathy, and pathological fractures (275). Generalized osteoporosis, sometimes in combination with osteomalacia, was observed after bismuth treatment for syphilis (287), Lesions were often localized in the pelvis, the head of the femur, and the vertebrate. It has been mentioned that the presence of bismuth in the bone can aggravate a preexisting tendency toward osteoporosis (353–355). Hepatotoxicity from bismuth intoxication is suggested from one case study of 121 inmates in an American prison who had liver damage after receiving bismuth therapy for syphilis (356). It must be noted that no bismuth concentrations were measured in this study, and hence the association of bismuth intake with hepatotoxicity is viewed as unconvincing (287). There are numerous cases that report the neurotoxicity of bismuth compounds, the clinical cases usually include Bi encephalopathy. Before the onset of encephalopathy, a “prodromal period” occurs of other varying symptoms such as deterioration of memory, impairment of walking, standing and writing, insomnia, changes in behavior, depression, anxiety, hallucinations, and excitation (287). The observed characteristic symptoms of Bi encephalopathy are myoclonia, changes of awareness, astasia and/or abasia, and dysarthria. Myoclonias were frequently observed in the distal parts of the arms but were also observed in the legs, trunk, face and tongue (287). One case history described a 69-year-old German patient who developed depression, insomnia, lack of concentration, nervousness, and panic attacks after the intake of Bi nitrate at 8 g/day for a period of 3 weeks. After 12 months of bismuth intake, he was diagnosed as suffering from major depression, and he gradually developed difficulty with short- and long-term memory, difficulty in reading and writing, tremor, vertigo, and dysarthria. After 15 months of bismuth intake the syndrome progressed into full myoclonic Bi encephalopathy. Another case hisotry describes a German woman who used a Bi subgallate containing stomach powder for more than 15 years and suffered from dementia, abnormal coordination, occasional tremors, and dysarthria. The Bi concentration in her blood was 70 mg/L six days after discontinuing Bi subgallate intake. The patient was discharged from the hospital after 4½ months in good medical condition, indicating the reversibility of Bi-induced encephalopathy. In France, where a wide range of bismuth compounds on the French market were used for gastrointestinal complaints, an epidemic outbreak of encephalopathy possibly related to bismuth intake drew public attention in 1974 (357). Bismuth subnitrate was involved most frequently in bismuth-induced encephalopathy because it was used by the majority of patients (358). Legal restrictions on the sale of Bi-containing compounds in France were imposed, overall Bi sales declined, and indirectly the number of patents who had Bi encephalopathy declined (359). In 1980, a total of 942 cases was reported in France, 72 of which ended in death (360). It has never been proven that these deaths were directly associated with bismuth intake.

3.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms There is very little known regarding the

mechanisms of toxicity of bismuth and bismuth compounds. Because the clinical signs of acute bismuth toxicity are similar to those of lead and mercury, the curent knowledge of the mechanisms of toxicity of these two metals may help to elucidate the mechanisms behind bismuth toxicity in animals and in humans (275).

3.4.2.2.4 Reproductive and Developmental Although bismuth can penetrate the placenta (361) there are no clinical reports of teratogenicity in humans.

3.4.2.2.5 Carcinogenesis There is no evidence of carcinogenicity of bismuth compounds in humans.

3.4.2.2.6 Genetic and Related Cellular Effects Studies Besides one animal study that may implicate bismuth as a possible mutagen (349), there is no evidence that bismuth is mutagenic in humans.

3.4.2.2.7 Other: Neurological, Pulmonary, Skin Sensitization Pityriasis, rosea-like eruptions, and other skin manifestations such as the “erythema of the ninth day” syndrome (Milian's syndrome) have been occasionally reported as a result of therapy with bismuth compounds (362, 363). Ulcerative stomatitis has been observed after bismuth treatment (364, 365). Bismuth pigmentation has been found in the colon, vagina, and the skin (366). Colitis, gastrointestinal bleeding, purpura, agranulocytosis, and aplastic anemia have also been reported after bismuth treatment (367).

3.4.2.3 Epidemiology Studies There are numerous case reports of bismuth toxicity, mostly of its medicinal use for treating syphilis and gastrointestinal complaints, but there have been no clearly defined epidemiologic studies of bismuth toxicity in the general population. An outbreak of encephalopathy in France in 1974 may possibly be related to Bi intake, but no cases were reported in the United States, the United Kingdom or in the Netherlands where large amounts of Bi were sold (289). It has never been proven that the etiology of this outbreak of encephalopathy can be attributed exclusively to Bi intake (287).

3.5 Standards, Regulations, or Guidelines of Exposure

The 1999 ACGIH threshold limit value-time weighted average (TLV-TWA) is 5 mg/m^3 for “doped” bismuth telluride, which is used in semiconductors and is “doped” with selenium sulfide to alter its conductivity and 10 mg/m^3 for undoped bismuth telluride. NIOSH has the same recommended exposure levels. OSHA has a PEL of 15 mg/m^3 for total undoped bismuth telluride and 5 mg/m^3 for respirable undoped bismuth telluride. Industrial bismuth poisoning is considered uncommon (275).

3.6 Studies on Environmental Impact

There is no evidence to date that bismuth in the environment alters the health of humans, other animals, or plants. The presence of bismuth in various organisms is not considered significant and probably results from its presence in trace amounts in soil, water, and food. Solubilization of bismuth in ground water by acid rain may increase its biological concentration and human exposure, but there is no evidence to date to suggest that this is occurring.

Arsenic, Antimony, and Bismuth

A. Fluorine and its Compounds

1.0 Fluorine

1.0.1 CAS Number: [*7782-41-4*]

1.0.2 Synonyms: Fluorine-19

1.0.3 Trade Names: NA

1.0.4 Molecular Weight: 37.99680

1.0.5 Molecular Formula: F_2

1.0.6 Molecular Structure:

1.1 Chemical and Physical Properties

Because of the small atomic radius (Table 48.1), the effective surface charge density of the fluorine atom is greater than that of any other element, making fluorine the most electronegative and the most reactive of the elements (1–3). Under appropriate conditions, it forms compounds with all other elements except argon, helium, and neon (4). Fluorine is univalent, and no compounds are known in which fluorine has a valence of > 1. Asbestos and finely dispersed water, glass, ceramics, carbon, and metals all burn in fluorine. In contact with massive mild steel, copper, nickel, or Monel metal, fluorine forms a film that prevents further attack, which means that these materials can be used to handle fluorine at ordinary temperatures (3). Fluorine reacts with water to form hydrogen fluoride and the highly toxic oxygen difluoride, OF_2. Fluorine in combination exists in either the ionic form or the covalent tetrahedral form. Compounds resulting from the interaction of fluorine and metals are usually ionic and have high melting and boiling points. Many fluorides, for example, the fluorides of lithium, aluminum, strontium, barium, magnesium, and manganese, are sparingly soluble or insoluble in water. Nonmetallic elements react with fluorine to yield covalent compounds, for examples are silicon tetrafluoride, sulfur hexafluoride, and complex anionic forms. These covalent compounds are characterized by low melting points and high volatility. The inorganic chemistry of fluorine is discussed in detail by Glemser (5) and by the World Health Organization in its Environmental Health Criteria 36 (6).

1.2 Production and Use

Fluorine is the most reactive of all the elements. Free fluorine is rarely, if ever, found in nature. Elemental fluorine is produced on a commercial scale by the electrolysis of anhydrous hydrogen fluoride in a molten solution of potassium fluoride (essentially the same process as that used by Moissan in 1886 to isolate fluorine for the first time). Fluorine gas is formed at the anode and hydrogen at the cathode. The principal impurity is hydrogen fluoride, most of which is removed by passing the gas stream through a condensation trap; the remaining traces are converted to sodium bifluoride ($NaHF_2$) on exposure to sodium fluoride pellets.

D. Iodine and Its Compounds
15.0 Iodine
15.0.1 CAS Number: [*7553-56-2*]

15.0.2 Synonyms: NA

15.0.3 Trade Names: NA

15.0.4 Molecular Weight: 253.8090

15.0.5 Molecular Formula: I_2

15.0.6 Molecular Structure:

I—I

15.1 Chemical and Physical Properties
Iodine is the heaviest of the halogens that are of industrial interest. Under ordinary conditions, iodine takes the form of gray-black plates or granules that have a metallic, crystalline luster. It volatilizes at

room temperature to yield a sublimed, violet vapor. Iodine's physical properties are shown in Table 48.1.

Although iodine resembles other members of the halogen group, it is the least electronegative; it is thus the least chemically reactive of the halogens and forms the weakest bonds with more electropositive elements. Like other halogens, iodine unites with all elements except sulfur, selenium, and the noble gases. It reacts directly with most elements (except carbon, nitrogen, oxygen, and some of the more unreactive metals), and reacts with numerous organic compounds that are of pharmaceutical interest. Iodine also forms compounds with other halogens, such as iodine bromide and iodine monochloride; these interhalogen compounds are used in organic synthesis (131). Iodine occurs in valence states from 1 to 7 (223). The most stable of the positive iodine compounds are the iodates, in which the valence of iodine is +5, and the periodates, in which it is +7. Thirty isotopes of iodine have been identified, although only one, 127I, occurs in nature (2).

15.2 Production and Use

Iodine is the 47th most abundant element in the earth's crust (133). The name iodine derives from the Greek word for violet-colored, *ioeides*, which was used to describe the purple vapor generated by heating iodine (133).

The major U.S. sources of iodine are natural and oil-field brines, such as those near Shreveport, Louisiana (oil field), in the Los Angeles basin of California, and in the natural brines of Midland, Michigan and Woodward, Oklahoma. Iodine occurs in trace quantities in seawater and igneous rocks (223).

Large iodine resources exist in foreign countries. Japan's natural gas-well brines are credited with as much as four-fifths of the world's iodine reserve. An estimate of the indicated reserve of Chilean nitrate minerals, from which iodine is obtained as a by-product, is about 1 billion short tons (~ 0.04% I_2). Unmeasured quantities of iodine are contained in brines in Indonesia, Germany, France, Italy, the United Kingdom, Norway, Ireland, and the former Soviet Union (297). In the United States, the principal method used to recover iodine from oil brines involves the oxidation of iodide by chlorine, followed by removal of the volatile iodine from solution with an airstream. The iodine is reabsorbed in solution and reduced to hidrotic acid with sulfur dioxide. The solution is then chlorinated to precipitate free iodine, which is further purified by treatment with concentrated sulfuric acid. The same process is used to recover iodine from natural brines. In the recovery of iodine from Chilean nitrate deposits, solutions containing the iodates are reduced with sodium bisulfite to precipitate the iodine, which is then purified by sublimation.

In 1984, an estimated 500 trillion lb of crude or resublimed iodine products were produced in the United States, and more than 2 billion lb were imported in 1985 (263). Approximately 22% of this total was used in organic synthesis, and another 20% found use in pharmaceutical applications. Other uses, and their percentages of total consumption, were as follows in 1984: animal feed supplements (18%), sanitary and industrial disinfectants (12%), stabilizers (11%), inks and colorants (6%), photographic chemicals (5%), and miscellaneous uses (6%) (263).

Iodine is used both in animal and human medicine, where its disinfectant and antiseptic properties are valued. The lack of iodine causes goiter (compensatory hypertrophy of the thyroid gland), and iodine is used both to treat iodine deficiency and hyperthyroidism (131). Table 48.18 shows the principal iodine compounds and their industrial uses. NIOSH has estimated that in 1983, 204,902 workers were exposed to iodine (7).

Table 48.18. Principal Iodine Compounds and Their Uses[a]

Compound	Principal Uses

Sodium iodide	Photography, organic chemical cloud seeding, iodized salt, medication, wet extraction of silver, feed additive, laboratory reagent
Potassium iodide	Photographic emulsions, treatment of radiation accidents, laboratory analysis, animal and poultry feed
Hidrotic acid	Reducing agent, manufacture of organic iodides, laboratory analysis, disinfectant
Potassium iodate	Oxidizing agent in chemical analysis, topical antiseptic, nutrient iodine source
Iodine chloride	Organic synthesis, laboratory analysis
Iodine monobromide	Organic synthesis
Iodine trichloride	Chlorinating agent, oxidizing agent, topical antiseptic
Iodine pentafluoride	Fluorinating agent, component of explosives
Hydrogen iodide	Manufacture of hidrotic acid and organic iodo compounds

[a] From Refs. 2, 131, 222.

16.0 Inorganic Compounds

The inorganic iodine compounds of commercial interest, and their physical properties, are shown in Table 48.19. The iodides, an important class of inorganic iodine compounds, have less tendency to form complexes than the other halides. Chlorine and bromine freely displace iodine from the iodides (133). Iodine forms industrially useful and important compounds with hydrogen, metals, the other halogens, and oxygen. The ones presented below are typical.

Table 48.19. Properties of Industrially Useful Inorganic Iodine Compounds

Compound	CAS Number	Formula	Mol. Wt.	Physical Properties	Sp. Gr. (°C)	MP (°C)	BP (°C)	Solubility
Hydrogen iodide (hidrotic acid)	[*10034-85-2*]	HI	127.91	Colorless gas	Gas 5.66°	–50.8	–35.88	425 cm^3/L H_2O, 0°C; soluble alcohol
Ammonium iodide	[*12027-06-4*]	NH_4I	144.94	Colorless, cubic, hygr.	2.514^{25}	Subl. 551	220 vac.	1.542 kg/L H_2O, 0°C; 2.503 kg/L, H_2O, 100°C; very soluble alcohol, acetone, NH_3
Potassium iodide	[*7681-11-0*]	KI	166.01	Colorless or white, cubic	3.13	681	1330	1.275 kg/L H_2O, 0°C; 2.08 kg/L, H_2O, 100°C; 18.8 g/L,

								alcohol, 25° C; slightly soluble ether
Sodium iodide	[*7681-82-5*]	NaI	149.89	Colorless cubic	3.667^{25}	661	1304	1.84 kg/L H_2O, 25°C; 3.02 kg/L H_2O, 100°C; 425 g/L, 25° C; sol. alcohol
Iodic acid	[*7782-68-5*]	HIO_3	175.91	Colorless or pale yellow cryst.	4.629^{0}	Dec. 110	—	2.8 kg/L H_2O, 0°C; 4.73 kg/L H_2O, 80°C; very soluble alcohol 87%
Potassium iodate	[*7758-05-6*]	KIO_3	214.0	Colorless, monoclinic	3.93^{32}	560	Dec.>100	47.4 g/L H_2O, 0°C; 323 g/L H_2O, 100°C; soluble KI; insol. alcohol
Sodium iodate	[*7681-55-2*]	$NaIO_3$	197.89	White, rhombic	$4.277^{17.5}$	Dec.	—	90 g/L H_2O, 20°C; 340 g/L H_2O, 100°C; insoluble. alcohol; soluble acetic acid
Periodic acid	[*10450-60-9*]	H_5IO_6	191.91	Colorless	—	Subl. 110	Dec. 138	Very soluble (decomposes) cold H_2O
Iodine bromide	[*7789-33-5*]	IBr	206.81	Dark gray cryst.	4.4157^{0}	(42) subl. 50	Dec. 116	Soluble (dec.) cold H_2O; soluble alcohol, ether, chloroform, CS_2
Iodine chloride	[*7790-99-0*]	ICl	162.36	Dark red needles	3.1822^{0}	27.2	97.4	Decomposes to HIO_3 cold H_2O; soluble alcohol, ether, CS_2, HCl
Iodine tribromide	—	IBr_3	366.63	Brown liquid	—	—	—	Soluble cold

								H_2O; soluble alcohol
Iodine pentafluoride	[*7783-66-6*]	IF_5	221.90	Colorless liquid	3.75	9.6	98	Decomposes cold H_2O; dec. acid, alkali

16.0a Hydrogen Iodide

Hydrogen iodide [HI (hidrotic acid)] gas dissolves in water at 10°C and 1 atm pressure to the extent of 70 wt% to form hidrotic acid. The technical grade, 47% HI, is a highly corrosive liquid that fumes in moist air. Its solutions, like others containing the iodide ion, can dissolve in large quantities of iodine (e.g., tincture of iodine, KIúI$_2$). Hidrotic acid is more stable than the gas and is one of the strongest acids; it dissolves metals, oxides, carbonates, and salts of the other weak, monoxidizing acids, causing the formation of iodides. The major uses of hidrotic acid are shown in Table 48.18.

16.0b Iodides

Of the commercially available iodides, potassium iodide (KI) is the most important. All iodides are highly water-soluble, stable, and high melting solids (Table 48.19). The tetraiodides of titanium and zirconium, however, decompose to their elements at elevated temperatures, yielding very high purity zirconium metal. According to NIOSH (7), there were 243,989 workers exposed to potassium iodide in 1983.

16.0c Iodates and Periodates

The iodates and periodates are among the most stable and well known of the iodine compounds. Except for the salts of the alkali metals, most iodates are sparingly soluble in water. Both iodates and periodates are powerful oxidizers in acid solution and are thus used as disinfectants. Other uses are as feed additives and in medicine. Approximately 193,692 workers were exposed to potassium iodate in 1983; the corresponding figure for sodium iodate is 8972 (7).

16.0d Iodine Halides

The four iodine halides of interest, iodine monobromide, iodine chloride, iodine trichloride, and iodine pentafluoride, are shown in Table 48.19.

16.1 Chemical and Physical Properties

Table 48.19 show their physical properties. All are high density substances.

16.2 Production and Use

The chief use of these halides is in organic synthesis and as halogenation catalysts. Iodine pentafluoride is a fluorinating and incendiary agent. The reaction of iodine pentafluoride with organic substances must be carefully controlled because explosions may occur.

16.3 Exposure Assessment

Occupational exposure to airborne iodine can be measured using a charcoal tube impregnated with alkali-metal hydroxide. The iodine is desorbed using sodium nitrate, and analysis is conducted by ion chromatography (143). This method has a limit of detection of 0.01 ppm for a 7.5-L air sample. The overall precision of the method (coefficient of variation) is 0.11. At iodine concentrations of 0.5 times the OSHA PEL of 0.1 ppm, the overall error of the method is 27%, which is slightly above the maximum acceptable error of 25%. At iodine concentrations of 1 and 2 times the limit, overall error is acceptable.

The NIOSH method for sampling iodine (method 6005) is similar to that described above, except that sodium carbonate is used as the desorption agent (25). The estimated limit of detection for this method is 1 mg per sample, and the overall precision is slightly better (coefficient of variation 0.085) than is obtained from the use of sodium nitrate as the desorption agent.

16.4 Toxic Effects

Because iodine is an essential nutrient that is required for the healthy development and functioning of the thyroid gland, it has been the subject of numerous metabolic studies in human volunteers and

experimental animals. However, information on the toxic effects of iodine and iodine compounds in the occupational setting is scarce.

In general, the vapor of iodine is reported to be more irritating than that of chlorine or bromine (129, 130), although case reports are few because iodine does not find wide industrial use. In one of the few available animal studies, dogs exposed to iodine vapor (concentration not specified) developed signs of pulmonary edema (129, 130). In humans, exposure to the vapor causes irritation of the eyes and eyelids, upper respiratory tract, lungs, and skin (129, 130).

Four volunteers exposed to a 0.57-ppm concentration of iodine vapor for 5 min reported no ill effects; at a concentration of 1.63 ppm, however, all volunteers reported experiencing eye irritation after 2 min (298). Exposures to the vapor have also been associated with headaches, lacrimation, chest tightness, and sore throat (129, 130). In a study of workers exposed to vapors emanating from a tank containing an iodine solution, concentrations of 1.0 ppm were reported to be ‘highly' irritating (129, 130), and early studies report that working in an atmosphere containing 0.15–0.2 ppm of the vapor was difficult and that work had to be discontinued when the concentration reached 0.3 ppm (129, 130).

Topical applications of iodine solutions have caused redness and inflammation; strong solutions may cause thermal burns (129, 130). There are reports of fatalities caused by skin absorption of iodine tinctures applied to wounds (298), and a fatality has been attributed to the use of an iodine solution to provide continuous postoperative irrigation of a hip wound (33). Two Dutch eel fishermen developed contact dermatitis attributed to the iodine in Japanese Sargasso weed in the local lake; both cases were confirmed by patch test (299).

Matt studied the effects of halogen gases on humans and animals. In a series of open-room exposure experiments he confirmed the known cutaneous, mucosal, and respiratory toxicities of the halogen gases, at relatively low concentrations. He estimated that workers could tolerate iodine exposures of 0.001%, but that concentrations of 0.005% could not be tolerated. He observed preferential irritation of the ocular membranes by iodine in this study (300).

Chronic absorption of iodine can lead to “iodism,” a condition characterized by sleeplessness, tremor, rapid heart rate, diarrhea, weight loss, conjunctivitis, rhinitis, and bronchitis (298). However, this syndrome is usually associated with long-term ingestion of iodine-containing medications (expectorants, diuretics) rather than with occupational exposure (129, 130).

There is little information on the acute toxicity of iodine and its compounds. Table 48.20 shows the available data, as well as the signs and symptoms associated with exposure to each substance.

Table 48.20. Acute Toxicity and Exposure-Related Signs and Symptoms for Iodine and Some of Its Compounds[a]

Substance	Acute Toxicity Data (Route, Species)	Signs and Symptoms of Exposure
Iodine	Oral LD_{50}, rat: 14 g/kg Inhalation LC_{LO}, rat: 800 mg/m^3 for 1 hr	Tearing, nasal secretions, sore throat, chest tightness, headache, skin burns, rash, allergic dermatitis
Iodine		Severe eye, skin, and respiratory tract

monochloride	Oral LD_{LO}, rat: 50 mg/kg Dermal LD_{LO}, rat: 500 mg/kg	irritation; pulmonary edema; burns of the eye and skin
Potassium iodate	Oral LD_{LO}, guinea pig: 400 mg/kg	Dust causes eye, skin irritaion
Potassium iodide	Oral LD_{LO}, mouse: 1862 mg/kg	Eye, skin irritation; in animals, teratogenic effects
Sodium iodide	Oral LD_{LO}, rat: 4340 mg/kg	Eye, skin irritation; cough
Hydrogen iodide	—	Severe eye, nose, throat irritation; laryngeal and broanchial spasms (sometimes fatal); pulmonary edema; necrosis of skin
Iodine pentafluoride	—	Severe eye, nose, and throat irritation, bronchial and laryngeal edema
Hidrotic acid	—	Lacrimation, sore throat, difficult breathing, cough, edema; burns, blisters, and necrosis of the skin

[a] From Refs. 129, 130, 151, 223, and 298.

The most significant concerns about iodine and iodine exposure have arisen from air contamination and food and waterborne radioiodine (radioactive iodine) from nuclear releases. These releases from atmospheric nuclear testing, and from accidents such as that at Three Mile Island (Pennsylvania, USA) and Chernobyl (Russia) have profound implications for the occurrence of thyroid cancer in the surrounding populations. Drift of radioiodine and contamination of potable-water and food supplies at great distances from the source of the material is also a major concern. The kinetics of these exposures, and their impact is beyond the scope of this chapter, but in any discussion of iodine as an industrial poison, the radioiodine forms produced and released by all of the uses of nuclear energy should be considered.

16.5 Standards, Regulations, or Guidelines of Exposure

OSHA (174), NIOSH (175), and the ACGIH (22) all have established a ceiling limit of 0.1 part per million (ppm) for iodine. NIOSH has also calculated an IDLH value for this element of 2 ppm (21). No limits have been established for the principal compounds of iodine.

The Halogens
Daniel Thau Teitelbaum, MD

E. Astatine

17.0 Astatine

17.0.1 CAS Number: [*7440-68-8*]

17.0.2 Synonyms: NA

17.0.3 Trade Names: NA

17.0.4 Molecular Weight: 210

17.0.5 Molecular Formula: At

17.1 Chemical and Physical Properties

The fifth halogen—astatine—is little known and has to date found few uses. The physical and chemical properties of astatine are as follows:

Atomic number	85
Atomic weight	210
Melting point	302°C
Boiling point	337°C (est.)

The name *astatine* derives from the Greek word for unstable, *astatos*. Astatine is believed to have four valence states: 1, 3, 5, and 7. Twenty-four isotopes have so far been identified, and the longest-lived of these, (301), At, has a half-life of only 8.1 h. The total amount of astatine in the earth's crust is believed to be less than 1 ounce (2).

Astatine behaves chemically in a manner much like iodine; however, it is believed to be more metallic than iodine. It is likely to accumulate in the thyroid gland, although this has not been demonstrated (2).

Aliphatic Hydrocarbons

Tania Carreón, MS

A. Alkanes (Saturated Hydrocarbons, Paraffins)

The alkanes have the generic formula of C_nH_{2n+2}. All the carbons have single covalent bonds between them. They are also called *saturated hydrocarbons*, which means that all the carbons have the maximum number of bonds (four). The alkane series is composed of gases (methane, ethane, propane, and butanes), liquids from pentanes (C5–C16 compounds), and longer-chain solids (1).

The toxicity of the alkanes is generally related to vapor pressure, viscosity, surface tension, and lipid solubility. Physical properties of saturated aliphatic hydrocarbons are listed in Table 49.1.

Table 49.1. Physicochemical Properties of Alkanes[a]

Compound	Molecular Formula	Molecular Weight	Boiling Point (°C)	Melting Point (°C)	Density (mg/cm^3) (at °C)	Refractive Index n_D	Solubility	Flash Point (°C)	I
Methane		16.042	–161.5	–182.5	0.4228 (–	—	w 3, al 3,	–187.8

[a] Molecular Formula—in Hill notation; molecular Weight—relative molar mass; Density—mass per unit volume in g/cm^3 at the temperature indicated in parentheses; Refractive Index—at the temperature indicated in parentheses, unless otherwise indicated, all values refer to a wavelength of 589 nm; Solubility—solubility in common solvents (w—water, al—ethanol, et—ethyl ether, ac—acetone, bz—benzene, ch—chloroform, ct—carbon tetrachloride, aa—acetic acid, pe—petroleum ether, os—organic solvents) on a relative scale: 1 = insoluble, 2 = slightly soluble, 3 = soluble, 4 = very soluble, 5 = miscible, 6 = decomposes; Flammability Limits—explosive limits (in percent by volume) at ambient temperature and pressure.

The aliphatic hydrocarbons are practically nontoxic for single exposures below the lower flammability limit. In general, the saturated hydrocarbons from propane through the octanes show increasingly narcotic properties. The margin between narcosis and lethal depression of vital centers is too narrow, and because of their explosive characteristics, these compounds are not used as surgical anesthetics. Narcotic effects may be accompanied by exhilaration, dizziness, and headache (1).

Virtually all paraffins will cause nausea, vomiting, abdominal pain, and occasionally diarrhea when ingested (2–4). Dermatitis, CNS depression, anesthesia, and cardiac sensitization have also been noted for many paraffins. Acutely, the most common toxic effects are CNS depression and asphyxia following inhalation and chemical pneumonitis after the aspiration of ingested alkanes. Asphyxia occurs when the oxygen in air is displaced by high concentrations of a gas or vapor. When the

oxygen concentration is lowered from ambient levels to ≤10%, hypoxia results and the body is starved for oxygen. At this level of oxygen deprivation, death occurs swiftly.

Dermal irritation and CNS depression are common problems with liquid aliphatic hydrocarbons in chronic exposures. Dermal irritation occurs in workers repeatedly exposed to liquid hydrocarbons as solvents. The paraffins are lipid solvents and dissolve or extract the fats from the skin, resulting in painful drying and cracking of the skin, that is, chronic eczematoid dermatitis, with itching and inflammation.

CNS depression occurs as the inhaled vapor or gas crosses the alveolar–capillary membrane to be absorbed into the bloodstream. At levels that cause CNS depression, the lung itself is spared injury (2–4). The CNS depressant properties of some alkanes have led to substance abuse in the form of "glue sniffing," usually toluene or *n*-hexane. Other abusers have utilized gasoline; paints containing solvents such as xylene, methyl ethyl ketone, acetone, ethyl acetate, ethyl benzene, and isobutyl acetate; typewriter correction fluids; aerosol can propellants, including propane and isobutane; and exhaust emissions. Abusers often exhibit a drunken appearance and suffer from learning or memory impairment, personality disorders, seizures, neuropsychological disorders, and tachycardia (2–4).

In general, branched-chain derivatives are less toxic than the corresponding parent straight-chain alkanes. Odorant properties increase whereas analgesic properties decrease with increasing chain length. Both dermal and pulmonary irritant properties increase with increasing chain length up to C14 derivatives (5).

Table 49.2. Occupational Exposure Limits for Propane in the United States[a]

Exposure Limits	OSHA PEL	NIOSH Exposure Limit	ACGIH TLV

Table 49.10. Summary of Subchronic Toxicity Studies in Animals Exposed to Hexane

Species	Exposure Route	Chemical	Approximate Dose (ppm)	Treatment Regimen	Observed Effect	Ref.
Fischer rat	Inhalation	Hexane	0, 3000, 6500, 10,000	6 h/day, 5 days/week, 13 weeks	Depression of body weight gain, lower brain weight, and axonopathy in males	130
B6C3F$_1$ mice	Inhalation	Hexane	0, 500, 1000, 4000, 10,000	6 h/day, 5 days/week, 13 weeks	No effect in survival	131
			0, 500, 1000, 4000, 10,000	6 h/day, 5 days/week, 13 weeks	Morphological alterations in the respiratory tract	
			1000	22 h/day, 5 days/week, 13 weeks	Paranodal axonal swelling in the tibial nerve	
SM-A male mice	Inhalation	Commercial-grade hexane	0, 100, 250, 500, 1000, 2000	6 days/week, 1 year	Peripheral neuropathy by electromyographic analysis	132
Sprague–Dawley rats	Inhalation	Hexane	0, 6, 26, 129	6 h/day, 5 days/week, 26 weeks	No signs of nervous system degeneration	133
			0, 5, 27, 126	21 h/day, 7 days/week, 26 weeks	No signs of nervous system degeneration	
Sprague–Dawley rats	Inhalation	Hexane	0, 126, 502	22 h/day, 7 days/week, 6 month	Abnormal gait, axonal degeneration, myelin vacuolization	134
		Hexane + hexane mixtures	125 + 125, 375, 1375	22 h/day, 7 days/week, 6 month	No neuropathic/myopathic alterations	
Wistar male rats	Inhalation	Hexane	0, 500, 1200, 3000	12 h/day, 7 days/week, 16 weeks	Dose-dependent peripheral neurotoxicity and body weight decrease	135
Sprague–Dawley	Inhalation	Hexane	0, 500, 1500, 5000	9 h/day, 5 days/week,	Decrease in weight gain, axonal	91

rats			14–30 weeks	degeneration, swelling of axons	
		2500	10 h/day, 6 days/week, 14–30 weeks	Axonal degeneration, swelling of axons	
Rabbits	Inhalation Hexane	3000	8 h/day, 5 days/week, 24 weeks	Ocular and upper respiratory tract irritation, respiratory difficulties	136

Table 49.11. Summary of Neurotoxicity Studies in Human Exposed to Hexane

Type of Facility/Population	Mixture Composition	Exposure Levels	Persons Affected	Findings	Ref.
Laminating plant	Solvents containing 65–95% hexane	500–2000 ppm	17 cases	Polyneuritis	159
Vinyl sandal manufacture	Glues containing 70% hexane	500–25007 ppm, 48 h/week	93 of 296	Progressive polyneuropathy, symmetrical sensorimotor disorder, no deaths	171
Shoe industry	Hexane and other solvents	196 ppm, 1–25 years	15 studied	Reductions in maximal motor and distal sensory nerve conduction velocities Changes in somatosensory evoked potentials	172
Press proofing workers	Solvents containing hexane	190 ppm	15 of 59 studied	Overt peripheral neuropathy, CNS malfunction, residual abnormalities after exposure removal; no neuropathy at <100 ppm	173–175
Tungsten carbide	Tungsten	58 ppm 8-h	14 + 5	No signs of	176

milling	carbide + hexane or acetone	TWA/2 years	past exposed	neuropathy; headaches, hyperaesthesia of limbs, and muscle weakness	
Printers and spray painters	Solvents containing hexane	1–39 ppm, 6 years	16% of 240 exposed	Not clinically significant signs of peripheral neuropathy	177

Aliphatic Hydrocarbons
Tania Carreón, MS

B. Alkenes (Olefins)
Alkenes differ from alkanes in the presence of a double covalent bond in the carbon chain. They have the generic formula C_nH_{2n}. They represent the simplest of the *unsaturated hydrocarbons*.

Alkenes are chemically more reactive than alkanes, primarily through addition reactions across the double bonds (5). When heated or in the presence of catalysts, most olefins will polymerize. They have higher boiling points than the parent paraffins as shown in Table 49.19.

Table 49.19. Physicochemical Properties of Alkanes[a]

Compound	Molecular formula	Molecular weight	Boiling point (°C)	Melting point (°C)	Density (mg/cm^3) (at °C)	Refractive index n_D	Solubility	Flash Point (°C)	Fla L

[a] Molecular Formula—in Hill notation; Molecular Weight—relative molar mass; Density—mass per unit volume in g/cm^3 at the temperature indicated in parentheses; Refractive Index—at the temperature indicated in parentheses, unless otherwise indicated, all values refer to a wavelength of 589 nm; Solubility—solubility in common solvents (w—water, al—ethanol, et—ethyl ether, ac—acetone, bz—benzene, ch—chloroform, ct—carbon tetrachloride, aa—acetic acid, pe—petroleum ether, os—organic solvents) on a relative scale: 1 = insoluble, 2 = slightly soluble, 3 = soluble, 4 = very soluble, 5 = miscible, 6 = decomposes; Flammability Limits—explosive limits (in percent by volume) at ambient temperature and pressure.

Alkenes, except for butadiene, are only slightly more toxic than alkanes. Ethene, propene, butene, and isobutene are weak anesthetics and simple asphyxiants. Pentene has been used for surgical anesthesia. Because of increasing mucous membrane irritancy and cardiac effects with increasing chain length, the hexylenes and higher members are unsuitable as anesthetic agents. The higher members may cause CNS depression, but are not sufficiently volatile to be considered vapor hazards at room temperature (267). Branching decreases the toxicity of C3 alkenes, does not appreciably affect the C4 and C5 alkenes, and increases the toxicity of C6–C18 alkenes. Unlike the hexanes, the olefins do not produce axonopathy. Repeated exposure to high concentrations of the lower members of the alkenes results in hepatic damage and hyperplasia of the bone marrow in animals. However, no corresponding effects have been noted in humans. Alpha olefins are more reactive and toxic than beta isomers. The alkadienes are more irritant and generally more toxic than the corresponding alkanes (268).

1,3-Butadiene is probably the most toxic member of the alkene family. The toxicological properties of butadiene have been studied extensively in both experimental animals and humans. Epidemiological studies on cancer among people exposed to butadiene have suggested increased risks for leukemia and lymphoma (269).

Table 49.20. Summary of Carcinogenicity Studies and Tumors Developed in Animals Exposed to 1,3-Butadiene

Exposure	Approximate Treatment

Species	Gender	Route	Dose (ppm)	Regimen	Neoplasm	Ref.
Sprague–Dawley rats	Female	Inhalation	0, 1000, 8000	6 h/day, 5 days/week, 105 weeks	Mammary gland adenoma and carcinoma Thyroid follicular cell adenoma Uterine sarcoma Zymbal gland carcinoma	362
Sprague–Dawley rats	Male	Inhalation	0, 1000, 8000	6 h/day, 5 days/week, 111 weeks	Pancreatic exocrine adenoma Testicular Leydig cell tumors	362
$B6C3F_1$ mice	Female	Inhalation	0, 625, 1250	6 h/day, 5 days/week, 60–61 weeks	Lethal thymic lymphomas Acinar cell carcinomas of the mammary gland Granulosa cell neoplasms of the ovary Hepatocellular neoplasms Heart hemangiosarcomas Malignant lymphomas Alveolar–bronchiolar neoplasms Squamous-cell neoplasms of the forestomach	388
$B6C3F_1$ mice	Male	Inhalation	0, 625, 1250	6 h/day, 5 days/week, 60–61 weeks	Lethal thymic lymphomas Heart hemangiosarcomas Alveolar–bronchiolar neoplasms Squamous-cell neoplasms of the forestomach	388
$B6C3F_1$ mice	Female	Inhalation	0, 6.25, 20, 62.5, 200, 625	6 h/day, 5 days/week, 104 weeks	Lethal thymic lymphomas Heart hemangiosarcomas Alveolar–	389

					bronchiolar neoplasms Hepatocellular neoplasms Harderian gland adenoma and carcinoma Granulosa cell neoplasms of the ovary Mammary gland carcinomas Squamous-cell neoplasms of the forestomach	
$B6C3F_1$ mice	Male	Inhalation	0, 6.25, 20, 62.5, 200, 625	6 h/day, 5 days/week, 104 weeks	Lethal thymic lymphomas Alveolar–bronchiolar neoplasms Harderian gland adenoma and carcinoma Heart hemangiosarcomas Hepatocellular neoplasms Squamous cell neoplasms of the forestomach Preputial gland adenoma or carcinoma	389

Table 49.21. Summary of Mutation Induction Studies in Transgenic Animals Exposed to 1,3-Butadiene

Species	Exposure route	Approximate Dose (ppm)	Treatment	Gene Mutation	Ref.
$CD2F_1$ transgenic mice	Inhalation	625	6 h/day, 5 days/week, 1 weeks	Increased mutant frequency of the *lacZ* transgene from the lung, no increase in bone marrow and liver	407

$B6C3F_1$ mice	Inhalation	625	6 h/day, 5 days/week, 2 weeks	Increased frequency of *hprt* mutant T lymphocytes	408
$(102/E_1$ X C3H/E1)F_1 mice	Inhalation	200, 500, 1300	6 h/day, 5 days/week, 1 weeks	Increased frequency of *hprt* mutant T lymphocytes at higher dose	409
$B6C3F_1$ transgenic mice	Inhalation	62.5, 625, 1250	6 h/day, 5 days/week, 4 weeks	Concentration-dependent increase in bone marrow *lacI* mutant frequency	410
$B6C3F_1$ transgenic mice	Inhalation	62.5, 625, 1250	6 h/day, 5 days/week, 4 weeks	Increase in bone marrow *lacI* mutant frequency at all levels of exposure	411
$B6C3F_1$ mice	Inhalation	20, 62.5, 625	6 h/day, 5 days/week, 4 weeks	Increased frequency of *hprt* mutant T lymphocytes	412
F344 rats	Inhalation	20, 62.5, 625	6 h/day, 5 days/week, 4 weeks	Increased frequency of *hprt* mutant T lymphocytes, rate of mutation accumulation greater in rats	412

Table 49.22. Summary of Epidemiological Studies in Human Exposed to 1,3-Butadiene[a]

Study Design	Industry	Workers (*N*)	Study Period	Main Result—SMR (95% C1) unless indicated	Ref.
Cohort	SBR	2756	11943–1976	All LHC: 1.3 (0.9–1.4) Leukemia: 1.7 (0.8–1.5) Lymphosarcoma: 1.7 (0.7–1.7)	437, 438
Cohort	BDM	2795	1943–1994	All LHC: 1.5 (1.1–2.0) Leukemia: 1.1 (0.6–1.9) Lymphosarcoma: 1.9 (0.9–3.6)	439
Cohort	SBR	12,110	1943–1982	All LHC: 1.0 (0.9–1.4) Leukemia: 1.0 (0.8–1.5) Lymphosarcoma: 0.6 (0.7–1.7)	440
Case-control	SBR	59 (LHC cases)	1943–1982	OR (95% CI)	441

		193 (controls)		All LHC: 2.3 (1.1–4.7) Leukemia: 9.4 (2.1–22.9) Lymphosarcoma: 0.5 (0.1–4.2)	
Case-control	SBR	59 (LHC cases) 1242 (controls)	1943–1982	OR (95% Cl) at 1 ppm butadiene Leukemia: 1.5 (1.1–2.1)	442
Cohort	SBR	15,649	1943–1991	All LHC: 1.1 (0.9–1.3) Leukemia: 1.3 (1.0–1.7) Lymphosarcoma: 0.8 (0.4–1.4)	443
Cohort	SBL	420	1947–1986	All LHC: 1 obs, 2.2 exp Leukemia: 1 obs, 0.9 exp	444
Cohort	BDM	614	1948–1989	All LHC: 0 obs, 1.2 exp	445
Cohort	BDM	364	1943–1970	All LHC: 1.7 (0.7–3.6) Leukemia: 1.2 (0.2–4.4) Lymphosarcoma: 5.8 (1.6–14.8)	446

[a] Key: ABS—acrylonitrile-butadiene-styrene plastic; BDM—butadiene monomer; CI—confidence integral; exp.—expected; LHC—lymphohematopoietic cancer; obs—observed; OR—odds ratio, SBL—styrene–butadiene latex; SBR—styrene–butadiene rubber; SMR—standardized mortality ratio.

Table 49.23. Occupational Exposure Limits for 1,3-Butadiene in the United States[a]

Exposure Limits	OSHA PEL	NIOSH REL	ACGIH TLV
Time-weighted average	1 ppm (2.2 mg/m^3)	Lowest feasible concentration	2 ppm (4.4 mg/m^3)
Short-term exposure limit	5 ppp (11 mg/m^3)	—	—
Ceiling limit	—	—	—

[a] OSHA and ACGIH—8-h TWA; NIOSH—10-h TWA.

Table 49.24. Occupational Exposure Limits for 1,3-Butadiene in Different Countries[a]

Country	Exposure Limit

Australia	TWA 10 ppm (22 mg/m^3); carcinogen
Belgium	TWA 10 ppm (22 mg/m^3); carcinogen
Denmark	TWA 10 ppm (22 mg/m^3); carcinogen
Finland	TWA 50 ppm (73 mg/m^3); carcinogen
France	TWA 10 ppm (22 mg/m^3)
Germany	Carcinogen
Hungary	STEL 10 mg/m^3; carcinogen
Ireland	TWA 10 ppm (22 mg/m^3); carcinogen
Mexico	TWA 1000 ppm (2200 mg/m^3); STEL 1250 ppm (2750 mg/m^3)
The Netherlands	TWA 21 ppm (46.2 mg/m^3)
The Philippines	TWA 1000 ppm (2200 mg/m^3)
Poland	TWA 10 mg/m^3; STEL 40 mg/m^3; carcinogen
Russia	STEL 100 mg/m^3
Sweden	TWA 10 ppm (22 mg/m^3); STEL 20 ppm (40 mg/m^3); carcinogen
Switzerland	TWA 5 ppm (11 mg/m^3); carcinogen
Turkey	TWA 1000 ppm (2200 mg/m^3)
United Kingdom	TWA 10 ppm (22 mg/m^3)

Aliphatic Hydrocarbons
Tania Carreón, MS

C. Alkynes

The presence of a triple covalent bond in the carbon chain gives rise to the compounds called *alkynes*. They have the generic formula C_nH_{2n-2}. Physical properties for selected alkynes are listed in Table 49.25.

Table 49.25. Physicochemical Properties of Alkanes[a]

Compound	Molecular formula	Molecular weight	Boiling point (°C)	Melting point (°C)	Density (mg/cm^3) (at °C)	Refractive Index n_D	Solubility	Flash Point (°C)	Flan Lir
Acetylene	C_2H_2	26.02	–84	–80.8	0.337	—	w 2, al 2,	–17.7	2.5–

			(subl. pt.)	(trip. pt.)	(25)		ac 3, bz 3	(closed cup)	
Propyne	C_3H_4	40.07	–23.2	–103	0.607 (25)	1.3863 (–40)	w 2, al 4, bz 3, ch 3	—	2.1–
3-Methylbutyne	C_5H_8	68.12	26.3	–89.7	0.6660 (20)	1.3723 (20)	w 1, al 5, et 5	—	—
1-Buten-3-yne	C_4H_4	52.08	5.1	—	0.7094 (0)	1.4161 (1)	w 1, bz 3	—	21.0
1,6-Heptadiyne	C_7H_8	92.14	112.0	–85.0	0.8164 (17)	1.4510 (17)	w 1, bz 3, aa 3	—	—
1-Decyne	$C_{10}H_{18}$	138.25	174.0	–44.0	0.7655 (20)	1.4265 (20)	w 1, al 3, et 3, os 3	—	—

[a] Molecular Formula—in Hill notation; Molecular Weight—relative molar mass; Density—mass per unit volume in g/cm^3 at the temperature indicated in parentheses; Refractive Index—at the temperature indicated in parentheses, unless otherwise indicated, all values refer to a wavelength of 589 nm; Solubility—solubility in common solvents (w-water, al-ethanol, et-ethyl ether, ac-acetone, bz-benzene, ch-chloroform, ct-carbon tetrachloride, aa-acetic acid, pe-petroleum ether, os-organic solvents) on a relative scale: 1 = insoluble, 2 = slightly soluble, 3 = soluble, 4 = very soluble, 5 = miscible, 6 = decomposes; Flammability limits—explosive limits (in percent by volume) at ambient temperature and pressure; subl. pt.—sublimation point; trip. pt.—triple point.

The alkynes do not exert any acute local toxicity. The lower members are anesthetics and cause CNS depression. They are practically nonirritating to the skin, but cause pulmonary irritation and edema at very high concentrations. The higher molecular weight members can be aspirated into the lungs when ingested (5).

Table 49.26. Occupational Exposure Limits for Propyne in the United States

Exposure Limits	OSHA PEL	NIOSH REL	ACGIH TLV
Time-weighted average	1000 ppm (1650 mg/m^3)	1000 ppm (1650 mg/m^3)	1000 ppm (1640) mg/m^3)
Short-term exposure limit	—	—	—
Ceiling limit	—	—	—

OSHA and ACGIH—8-h TWA; NIOSH—10-h TWA. From Ref. 19.

Table 49.27. Occupational Exposure Limits for Propyne in Different Countries[a]

Country	Exposure Limit
Australia	TWA 1000 ppm (1650 mg/m^3); STEL 1250 ppm

Belgium	TWA 1000 ppm (1650 mg/m^3); STEL 1250 ppm (2050 mg/m^3)
Denmark	TWA 1000 ppm (1650 mg/m^3)

Alicyclic Hydrocarbons
C. Stuart Baxter, Ph.D.

A. Cycloalkanes or Cycloparaffins

The alicyclic hydrocarbons include the cycloalkanes, also called *cycloparaffins*, *cyclanes*, and

naphthenes, and the cycloalkenes, also known as *cycloolefins* and *cyclenes*, and their alkyl and alkenyl derivatives. Some of these derivatives occur naturally in plants and are commonly known as *terpenes*. Other compounds can be isolated from crude petroleum refinery distillates or catalytically cracked petroleum products. Cycloalkanes are extensively used to produce re-formed aromatics (1) and as solvents or synthesis intermediates. Some physical properties of the cycloalkanes are given in Table 50.1 (2–18).

Table 50.1. Physical and Chemical Properties of Cycloalkanes

Compund	Molecular Weight	Boiling Point (° C)	Melting Point (° C)	Refractive Index (20° C)	Vapor Pressure (mm Hg) (°C)	Density g/mL, at 20 ° C	Flash Point (°C)	Solubilit w/al/et[a]
Cyclopropane	42.08	–76	–128	1.37	—	0.6769	—	s/v/v
Cyclobutane	56.10	13	–91	1.426	—	0.72	<10	i/v/v
Cyclopentane	70.13	49	–94	1.4065	400 (31)	0.7454	–37	i/v/v
Methylcyclopentane	84.16	71.8	–142.4	1.4097	100 (17.9)	0.7486	–10	i/v/v
Ethylcyclopentane	98.18	103	–138	1.4198	—	0.7665	15	i/v/v
Cyclohexane	84.16	80.74	6.6	1.4262	100 (60.8)	0.7786	–18	i/v/v
Methylcyclohexane	98.19	100.93	–126.3	1.42056	43 (20.5)	0.7694	–3	i/s/s
Ethylcyclohexane	112.21	131.78	–111	–33.5	—	0.788	18	i/s/s
1,1-Dimethylcyclohexane	112.21	120	—	1.428	—	0.781	7	i/s/s
1,2-Dimethylcyclohexane	112.21	124	—	1.432	10 (10.2)	0.778	15	i/s/s
1,3-dimethylcyclohexane	112.21	121-4	—	1.426	—	0.767	9	i/s/s
1,4-Dimethylcyclohexane	112.21	120	–87	1.426	—	0.773	15	i/s/s
Cycloheptane	98.19	118.4	–12	1.445	—	0.8098	6	i/v/v
Cyclooctane	112.21	151/740 m	15	1.458	—	0.836	30	i/v/v
Cyclononane	126.24	126.24	11	—	—	0.854	—	i/v/v
Cyclododecane	168.32	239	61	—	—	0.863	—	i/v/v

[a] Solublity in water/alcohol/ether: v = very soluble; s = soluble; i = insoluble.

A.1 Toxicity

Cyclopropane and cyclobutane are gases and have been used as anesthetics. Cyclopentane and higher members are liquids with low acute and chronic toxicity overall, but still able to induce many toxic responses characteristic of lipophylic compounds, including central nervous system (CNS) depression, dizziness, and headache. For cyclohexane and higher analogs, the margin of safety between CNS depression and death is very narrow and symptomatically barely recognizable. Following ingestion or inhalation cycloalkanes are exhaled in unchanged form or rapidly metabolized into water-soluble metabolites, usually glucuronides. Exposure of humans and laboratory animals to high concentrations may cause excitement, loss of equilibrium, stupor, and

coma, but rarely death. Oral administration of high doses to animals has additionally resulted in severe diarrhea, vascular collapse, and heart, lung, liver, and brain degeneration. Cycloparaffins and cycloalkenes are also ocular and dermal irritants since, as lipophylic agents, they defat the skin. In many cases they are also skin sensitizers; their sensitizing activity increases with the number of double bonds. The liquid members up to cyclooctane, and to a lesser exent cyclododecane, are aspiration hazards.

A number of alicyclic hydrocarbons are nephrotoxic in male rats. Repeated dose oral (19) or inhalation (20) studies result in tubular degeneration characterized by hyaline droplet formation, necrosis, intratubular casts, and medullary mineralization. These effects are associated with the presence of a_2-u-globulin in the males of a number of rat strains including Fischer 344, Sprague–Dawley, Wistar, Buffalo, and Norway Brown. It is not produced in the NCI–Black–Reiter (NBR) strain (21) or in female rats (22), and nephropathy is not produced by alicyclic hydrocarbons in these animals. This type of hydrocarbon nephropathy has been produced by cyclohexane (23, 24), 2,2,4-trimethylpentane (25), JP-5 jet fuel (25), JP-10 jet fuel (26), *d*-limonene (27), decalin (22, 28), and tetralin (29). The nephropathy has been studied extensively using a short-term decalin inhalation model (20). The nephropathy is not seen in mice or dogs (24).

This protein was of primary interest in carcinogenesis studies of unleaded gasoline (30). Kidney tumors were produced only in males and were associated with a_2-u-globulin. Further study revealed that humans do not produce this protein. On this basis, the National Toxicology Program stated that the kidney tumors seen in male rats were not relevant to carcinogenesis in man (31). Unleaded gasoline did not produce kidney tumors in male NBR rats (32).

Alicyclic Hydrocarbons
C. Stuart Baxter, Ph.D.

B. Cycloalkenes or Cycloolefins

The cyclic olefins are more highly reactive than their paraffin counterparts. They contribute to photochemical smog by reacting with ozone and other small molecular or ionic species (105). Selected physical properties are given in Table 50.2 (2–17). In C4–C7 cycloalkenes, toxicity increases with molecular weight. Cycladienes and polyenes appear to possess increasingly irritant, toxic, and sensitizing properties, peaking somewhat higher for cycladienes than for monocyclic alkenes. The aspiration hazard also appears higher for the cycloalkenes than the cycloalkanes (53).

Table 50.2. Physical and Chemical Properties of Cycloalkenes and Polycyclic Hydrocarbons

Compund	Molecular Weight	Boiling Point (°C) (mm Hg)	Melting Point (°C)	Refractive Index (20°C)	Vapor Pressure (mm Hg) (°C)	Density g/mL, at 20°C	Flash Point (°C)	Vapor Density

Alicyclic Hydrocarbons
C. Stuart Baxter, Ph.D.

C. Alkenyl Cycloalkenes
C.1 Vinylcyclohexenes
13.0 1-Vinylcyclohex-1-ene
13.0.1 CAS Number: [*2622-21-1*]

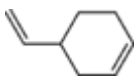
13.0.2 Synonyms: Cyclohexenylene, 1-ethenylcyclohexene, or tetrahydrostyrene

13.0.3 Trade Names: NA

13.0.4 Molecular Weight: 108.18

13.0.5 Molecular Formula: C_8H_{12}

13.0.6 Molecular Structure:



13.1 Chemical and Physical Properties
13.1.1 General Vinylcyclohex-1-ene is a flammable liquid (33). Selected physical properties are given in Table 50.2.
13.2 Production and Use
Vinylcyclohex-1-ene is a common component of tobacco smoke thought to be formed by dimerization from butadiene (119). It serves as an important chemical intermediate.
13.3 Exposure Assessment:
NA
13.4 Toxic Effects
13.4.1 Experimental Studies 13.4.4.1 Acute Toxicity Vinylcyclohex-1-ene is an irritant and CNS depressant at high concentrations. In mice exposed to 1-vinylcyclohexene, CNS depression was noted at a concentration of 7.5 mg/L. The 4-h LC_{50} in mice is 13.7 mg/L (120). It has a low degree of toxicity following ingestion or dermal absorption.

13.4.2 Human Experience No information is available; CNS depressant activity anticipated.
14.0 4-Vinylcyclohexene
14.0.1 CAS Number: [*100-40-3*]

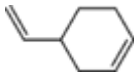
14.0.2 Synonyms: Butadiene dimer; 4-ethenylcyclohexene; cyclohexene, 4-ethenyl-; cyclohexene, 4-vinyl-; cyclohexenylethylene; ethenyl-1-cyclohexene; ncic54999; 1,2,3,4-tetrahydrostyrene; vinylcyclohexene; 1-vinylcyclohexene-3; 4-vinylcyclohexene; 4-vinylcyclohexene-1

14.0.3 Trade Names: NA

14.0.4 Molecular Weight: 108.18

14.0.5 Molecular Formula: C_8H_{12}

14.0.6 Molecular Structure:



14.1 Chemical and Physical Properties
14.1.1 General 4-Vinylcyclohexene is a colorless liquid. Selected physical properties are given in Table 50.2.
14.2 Production and Use
4-Vinylcyclohexene produced by dimerization of butadiene, as a by-product of chlorination of butadiene, or from butadiene on long storage (121). It is present in the offgases from tire curing (122) and is used as an intermediate for the production of vinylcyclohexene dioxide, which is used as a reactive diluent in epoxy resins. Previous uses of 4-vinyl-1-cyclohexene include comonomer in the polymerization of other monomers and for halogenation to polyhalogenated derivatives that are used as flame retardants. It is a precursor for ethyl cyclohexyl carbinol plasticizers, and is used as an intermediate for thiocyamate insecticides and as an antioxidant (122)
14.3 Exposure Assessment
14.3.1 Air Gas chromatography was used to determine the quantity formed from butadiene by its dimerization in the GC (123).

14.3.2 Background Levels: NA

14.3.3 Workplace Methods: NA

14.3.4 Community Methods: NA

14.3.5 Biomonitoring/Biomarkers No information is available. Metabolites may be quantitated in tissues and urine following exposure.

14.4 Toxic Effects

14.4.1 Experimental Studies 14.4.1.1 Acute Toxicity 4-Vinylcyclohexene is an irritant and CNS depressant at high concentrations, with a low degree of toxicity following ingestion or dermal absorption. The oral LD_{50} in the rat is 3080 mg/kg, and the dermal LD_{50} in the rabbit is 20 mL/kg. Time to death for rats was 15 min in the saturated vapor, and a concentration of 8000 ppm for 4 h proved lethal to four of six rabbits (107). The 4-h LC_{50} in mice is 27 mg/L (124).

14.4.1.2 Chronic and Subchronic Toxicity In one study, 1 g/m^3 administered by inhalation for 6 h/day over 4 months, inhibited weight increase and caused leukocytosis, leukopenia, and impairment of hemodynamics in rats and mice. Exposure of rats and mice to 1000 mg/m^3 (226 ppm) by inhalation for 6 h per day over 4 months was reported to inhibit weight gain and to cause leukocytosis, leukopenia, and impairment of haemodynamics (122).

14.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Incubation *in vitro* with liver microsomal enzymes yields the major metabolic products 4-vinyl-1,2-epoxycyclohexane and 4-epoxyethyl-1,2-dihydroxycyclohexane, with trace amounts (<0.001%) of vinylcyclohexene diepoxide (125). Metabolism in mice was reported to proceed to the mono- and diepoxides, and the latter was proposed to be the ultimate ovotoxic metabolite (126). To further investigate the role of metabolism in 4-vinylhexene toxicity, microsomal preparations were prepared from liver, lung, and ovaries obtained from female Crl:CD rats and B6C3F1 mice, rat, and mouse liver and lung, but not ovarian microsomes, metabolized 4-vinylcyclohexene to the 1,2-epoxide at detectable rates. Compared to the rat, the mouse appeared to be more efficient at metabolism to epoxides, and less efficent at hydrolysis of epoxides to diols, which may explain the higher ovotoxicity of 4-vinylcyclohexene to this species (125).

14.4.1.3.1 Adsorption See Section 14.4.1.3.2.

14.4.1.3.2 Distribution No information is available, but facile absorption and distribution of nonpolar compounds of this type is expected.

14.4.1.3.3 Excretion Excretion of the compound as conjugated metabolites is expected in the urine.

14.4.1.4 Reproductive and Developmental 4-Vinylcyclohexene is toxic to ovaries; following intraperitoneal administration to $B6C3F_1$ mice for 30 days a signicant deletion of ovarian follicles was reported (127).

14.4.1.5 Carcinogenesis A dose of 145 g/kg applied to mouse skin for 54 weeks provided weak evidence of carcinogenicity (109). Administration by gavage of doses of 0, 200, or 400 mg/kg body weight, 5 days per week, to groups of 50 F344/N rats for 103 weeks induced a slightly increased incidence of epithelial hyperplasia of the forestomach (1/50; 3/50; 5/47) and squamous-cell papillomas or carcinomas (combined) of the skin, in males receiving the highest dose. Low dose female rats whose survival was more similar to that of the vehicle controls had a marginally increased incidence of adenomas or squamous-cell carcinomas (combined) of the clitoral gland. Under these conditions, the 2-year gavage studies in male and female rats were considered inadequate because of extensive and early mortality at the high dose or at body doses and the lack of conclusive evidence of a carcinogenic effect (125).

14.4.1.6 Genetic and Related Cellular Effects Studies No mutagenicity was observed in *Salmonella*

typhimurium strains TA100, TA1535, TA1537, or TA98 in the presence or absence of Aroclor 1254–induced male Sprague–Dawley rat or male Syrian hamster liver S9 when tested according to the preincubation protocol. Several recognized metabolites, including 4-vinylcyclohexene diepoxide, 4-vinyl-1,2-epoxycyclohexane, and 4-epoxyethyl-1,2-dihydroxycyclohexane, were mutagenic in *Salmonella* and/or produced chromosomal damage *in vitro* (124). 4-Epoxyethyl-1,2-epoxycyclohexane, but not 4-vinyl-1,2-epoxycyclohexane or 4-epoxyethycyclohexane-1,2-diol, induce 6-thioguanine-resistant mutants in cultured Chinese hamster V79 cells when tested at 0.3–20 mM. 4-Vinyl-1,2-epoxycyclohexane and 4-epoxyethylcyclohexane-1,2-diol, tested at 2.0 mM, induced micronuclei, but 4-epoxyethyl-1,2-epoxycyclohexane did not; all three metabolites induced chromosomal damage (bridges and lagging chromosomes in anaphase) in V79 cells(109).

14.4.2 Human Experience 14.4.2.1 General Information 4-Vinylcyclohexene is an irritant in high concentrations, and possibly a CNS depressant. It has a low degree of toxicity via ingestion and skin penetration (128).

14.4.2.2 Clinical Cases 14.4.2.2.1 Acute Toxicity Exposed workers experienced keratitis, rhinitis, headache, hypotonia, leukopenia, neutrophilia, lymphocytosis, and impairment of pigment and carbohydrate metabolism (129).

14.4.2.2.2 Chronic and Subchronic Toxicity: NA

14.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms: NA

14.4.2.2.4 Reproductive and Developmental: NA

14.4.2.2.5 Carcinogenesis There is inadequate evidence in humans for carcinogenicity (109). Classification is A2: Suspected human carcinogen (130).
14.5 Standards, Regulations, or Guidelines of Exposure
Neither NIOSH nor OSHA have established limits for this chemical. The ACGIH has establish an 8 h TWA TLV of 0.1 ppm with an A3 notation. The A3 notation indicates that the chemical is a confirmed animal carcinogen with unknown relevance to humans (130). 4-Vinylcyclohexene is included on the TSCA list. A testing consent order is in effect for health effects and chemical fate testing (131).
C.2 Terpenes
Further side-chain substitution of cyclohexene, with a methyl, isopropenyl, ethenyl, or other group, forms a class of chemicals named terpenes. Limonene is a C10 cyclic olefin and a-pinenes are common monoterpenes.
15.0 Limonene
15.0.1 CAS Number: [*138-86-3*]

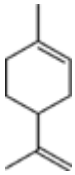
15.0.2 Synonyms: Carvene; cinene; cajeputene; eulimen; kautschin; a-limonene; *p*-mentha-1,8-diene; 1,8(9)-*p*-menthadiene; cyclohexene; 1-methyl-4-(1-methylethenyl)- or 1-methyl-4-isopropenyl-cyclohex-1-ene; 4-isopropenyl-1-methyl-1-cyclohexene; nesol; d-1,8-terpodiene; ciene; 1-methyl-4-(1-methylethenyl)cyclohexene; acintene DP dipentene; cyclil decene; 4-isopropenyl-1-methyl-; Dipenten; DL-*p*-mentha-1,8-diene; mentha-1,8-diene; mentha-1,8-diene, DL; menthadiene; methyl-4-(1-methylethenyl)cyclohexene; methyl-4-isopropenyl-1-cyclohexene; methyl-4-isopropenylcyclohexene; monocyclic terpene hydrocarbons; terpodiene; 4-(1-methylethenyl)-1-methyl-cyclohexene; dipentene, mixt. of limonene, 56–64%, and terpinolene, 20–25%; DL-Limonene

15.0.3 Trade Names: NA

15.0.4 Molecular weight: 136.24

15.0.5 Molecular Formula: $C_{10}H_{16}$

15.0.6 Molecular Structure:



15.1 Chemical and Physical Properties
15.1.1 General Selected physical properties are given in Table 50.2.

15.1.2 Odor and Warning Properties A highly fragrant, pleasant, lemon-like odor free from camphoraceous and turpentine-like notes has been noted.
15.2 Production and Use
Limonene occurs in the oil of many plants (132), and is the main constituent (≤86%) of the terpenoid fraction of fruit, flowers, leaves, bark, and pulp from shrubs, annuals, or trees including anise, mint, caraway, polystachya, pine, lime, and orange oil (118, 133). It occurs as a by-product in the manufacture of terpineol and in various synthetic products made from a-pinene or turpentine oil. It is found in the gas phase of tobacco smoke (134) and has been detected in urban atmospheres (135). It has antimicrobial, antiviral (136), antifungal (137), antilarval (138), and insect attractant (139) and repellent (140) properties. In Japan, it has been used to dissolve gallstones (141) and in wound healing (142). Used to add fragrance and taste to fruit and essence to flowers and leaves, as an odorant (143), a solvent (144), an aerosol stabilizer (145), and a wetting and dispersing agent (4). Polylimonene is used as a flavor fixative (12).
15.3 Exposure Assessment
GC or HPLC can be used with both microbore and standard columns in reversed and normal phase. Fractions are detected spectrophotometrically at 220 and 320 nm before and after evaporation of samples (146).
15.4 Toxic Effects
15.4.1 Experimental Studies 15.4.1.1 Acute Toxicity Acute toxicity is low; *d*-limonene solution injected as bolus into biliary tract of cats produced hepatobiliary tissue damage, depending on contact time, volume, and flow direction (147).

15.4.1.2 Chronic and Subchronic Toxicity Administration of 2-3.6 mL/kg per day to dogs for 1 for 6 months caused frequent vomiting, nausea, and decrease in body weight, blood sugar, and cholesterol. No significant change was observed in organs except in the kidney (148).

15.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The major metabolite in Sprague–Dawley rats is limonene 1,2-oxide. A metabolite isolated from rabbit urine was identified as *p*-mentha-1,8-dien-10-ol (149). After oral administration, the major metabolite in urine was perillic acid 8,9-diol in rats and rabbits, perillyl-b-*d*-glucopyranosiduronic acid in hamsters, *p*-menth-1-ene-8,9-diol in dogs, and 8-hydroxy-*p*-menth-1-en-9-yl-b-*d*-glucopyranosiduronic acid in guinea pigs and man (150).

15.4.1.3.1 Adsorption Monoterpenes are poorly resorbed in the GI tract. Exposure to limonene from in a foam bath led to a maximum blood level after 10 min of exposure and with a concentration proportional to the skin exposed (151). Limonene is absorbed 100 times more rapidly than water and 10,000 times faster than sodium and chloride ions (152).

15.4.1.3.2 Distribution The resorbed portion of agents of this type accumulates in the lipophilic body compartments and is then metabolized and excreted by the kidneys.

15.4.1.3.3 Excretion Metabolic studies in humans and animals demonstrated 75–95% of the material

to be excreted in the urine and ≤10% in the feces (153). In another study, 25% of the administered limonene was excreted in the bile within 48 h (154).

15.4.1.4 Reproductive and Developmental When dosed with 2869 mg/kg during days 9–15 of gestation, rats exhibited a decrease in body weight gain and the fetuses exhibited prolonged ossification of the metacarpal bone and proximal phalanx and slightly decreased spleen and ovarian weights (155). In mice given 2363 mg/kg orally on days 7–12 of gestation, fetuses exhibited a decrease in weight gain and increase in the incidence of abnormal bone formation (156). Rabbits showed decreased body weight gain and six deaths of 21 animals administered 1000 mg/kg during gestation. A dose of 250 mg/kg resulted in no teratogenic effects (157, 158).

15.4.1.5 Carcinogenesis Induction of kidney neoplasias has been observed in male rats of strains that have significant concentrations of the protein a2u-globulin (159). This protein is not expressed in females or species other than the rat; therefore limonene carcinogenicity appears to be limited to the male of specific strains of this species. Subcutaneous injection of the compound or its hydroperoxide into C57BL/6 mice decreased the incidence of dibenzopyrene-induced tumors appreciably (160). Given orally either 15 min or 1 h prior to nitrosodiethylamine, d-limonene reduced forestomach tumor formation by about 60% and pulmonary adenoma formation by about 35%.

15.4.1.6 Genetic and Related Cellular Effects Studies Limonene was found to be non-mutagenic in four strains of *Salmonella typhimurium* (TA98, TA100, TA1535, or TA1537) and not to significantly increase the number of trifluorothymidine resistant cells in the mouse L5178Y/TK + or–assay, and not to induce chromosomal aberrations or sister chromatid exchanges (SCEs) in cultured Chinese hamster ovary (CHO) cells. All assays were conducted in the presence and absence of exogenous metabolic activation (S9) (159).

15.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization Activity as a dermal irritant and possible skin sensitizer has been reported (4). Dunkin–Hartley guinea pigs were induced by topical application of air oxidation products of limonene: (+)-limonene oxide, or (*R*)-(–)-carvone, (–)-carveal, or air-exposed *d*-limonene. Air oxidation of *d*-limonene is necessary for its sensitizing potential due to the production of potent allergens such as limonene oxide and carvone (161).

Administration of single oral doses of 0, 0.1, 0.3, 1, or 3 mmol in corn oil resulted in a dose–response relationship for the exacerbation of hyaline droplet formation in the kidneys of male Sprague–Dawley rats (27). The male rat hydrocarbon nephropathy should not be predictive of a normal human renal response. In a 24-h single-dose experiment on the renal toxicity of mercuric chloride, potassium dichromate, *d*-limonene, and hexachloro-1:3-butadiene administered simultaneously in 12-week-old male Wistar rats, absence of both dose additivity and potentiating interaction at subeffective levels of the individual nephrotoxicants was suggested (162).

15.4.2 Human Experience 15.4.2.1 General Information Toxicity is most likely low, although mild dermal irritation and skin sensitization may occur. Hematuria and albuminuria might occur if large amounts are ingested.

15.4.2.2 Clinical Cases 15.4.2.2.1 Acute Toxicity Liquid has been reported to irritate eyes and skin; ingestion causes irritation of GI tract (16).

15.4.2.2.2 Chronic and Subchronic Toxicity No information available; toxicity is most likely to be low. Mild dermal irritation and skin sensitization may occur. Hematuria and albuminuria might occur if large amounts are ingested.

15.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms In human volunteers exposed by inhalation (2 h, workload 50 W) in an exposure chamber on three different occasions to concentrations approximately 10, 225, and 450 mg/m^3 the relative pulmonary uptake was high,

approximately 70% of the amount supplied. A decrease in vital capacity was observed after exposure at a high exposure level. The subjects did not experience any irritative symptoms or symptoms related to the CNS (163). Metabolic studies in humans and animals demonstrated that 75–95% of the material was excreted in the urine and ≤10% in the feces (153). In another study, 25% of the administered dose was excreted in the bile within 48 h (154).

15.4.2.2.4 Reproductive and Developmental: NA

15.4.2.2.5 Carcinogenesis No data are available on carcinogenicity to humans. The overall evaluation is “Not classifiable as to its carcinogenicity to humans” (group 3). (164).

15.4.2.2.6 Genetic and Related Cellular Effects Studies: NA

15.4.2.2.7 Other: Neurological, Pulmonary, Skin Sensitization, *etc* Allergic contact dermatitis from honing oil containing the compound was reported (165).

15.5 Standards, Regulations, or Guidelines of Exposure

The odor threshold in water is 10 ppb (165). It is quantified using gas chromatography. With proper handling precautions, this material presents no health hazard. On the EPS TSCA Chemical Inventory and Test Submission Data Base (41).

15.6 Studies on Environmental Impact

If limonene is released to soil, limited data indicate resistance to biodegradation under aerobic conditions and low to slight mobility in soil. Expected to rapidly volatilize from both dry and moist soil to the atmosphere, although adsorption to soil may attenuate the rate of this process. If limonene is released to water, limited data indicate resistance to biodegradation under aerobic conditions. It may bioconcentrate in fish and aquatic organisms and significantly adsorb to sediment and suspended organic matter. It is expected to rapidly volatilize from water to the atmosphere. The estimated half-life for volatilization from a model river is 3.4 h, although adsorption to sediment and suspended organic matter may attenuate the rate of this process. If released to the atmosphere, expected to rapidly undergo gas-phase oxidation reactions with photochemically produced hydroxyl radicals, ozone, and at night with nitrate radicals. Calculated lifetimes for these processes in a clean and moderately polluted atmosphere are 2.0 h and 30 min, 36 min and 11 min, and 9 min and 0.9 min, respectively. Limonene is readily degraded in soil (26).

Alicyclic Hydrocarbons
C. Stuart Baxter, Ph.D.

D. Cyclopolyenes

16.0 1,3-Cyclopentadiene

16.0.1 CAS Number: [*542-92-7*]

16.0.2 Synonyms: **R**-Pentine, pentole, pyropentylene or cyclopentdiene

16.0.3 Trade Names: NA

16.0.4 Molecular Weight: 66.10

16.0.5 Molecular Formula: C_5H_6

16.0.6 Molecular Structure:

16.1 Chemical and Physical Properties
16.1.1 General 1,3-Cyclopentadiene is a colorless liquid that dimerizes easily in the presence of peroxides and trichloroacetic acid to a colorless solid (4). Selected physical properties are given in Table 50.2.

16.1.2 Odor and Warning Properties It has a sweet odor resembling turpentine. Low odor threshold = 5.0 mg/m^3; high threshold = 5.0 mg/m^3. (154).
16.2 Production and Use
This compound occurs in the C6–C8 petroleum distillation fraction (1), and in coke-oven light oil fractions (4). It is produced by dehydrogenation of cyclopentadiene or monomerization of its dimer. It is used as an intermediate in resin manufacture and chemical syntheses, especially for Diels–Alder reactions (4).
16.3 Exposure Assessment
NIOSH method 2523. Matrix: air. Sampler: solid sorbent tube (maleic anhydride on Chromosorb 104, 100 mg/50 mg). Flow rate: 0.01–0.05 L/min. Sample size: 3 L (63a).
16.4 Toxic Effects
16.4.1 Experimental Studies 16.4.1.1 Acute Toxicity The 1-h LC_{50} is 39 mg/L in the rat and 15 mg/L in the mouse (41). The LD_{50} for the dimer in rats is 0.82 g/kg orally. When injected subcutaneously into the rabbit, 3.0 mL caused CNS depression with fatal convulsions. Signs and symptoms during CNS depression include primary motor unrest and decreased, intermittent respiration rate prior to death. Its vapors produce CNS depression in the frog in 10 min, but recovery is complete in 70 min (35).

16.4.1.2 Chronic and Subchronic Toxicity In a total of 35 exposures of 7 h/day over a period of 53 days at an average concentration of 500 ppm, mild centrolobular cloudy swelling of liver cells and cloudy vacuolization of renal tubular epithelium was noted in rats (167).

16.4.2 Human Experience 1,3-Cyclopentadiene is irritating to eyes and mucous membranes (118). It has caused contact dermatitis and sensitization (168). No other information is available.
16.5 Standards, Regulations, or Guidelines of Exposure
The OSHA (55) PEL is 75 ppm (200 mg/m^3), and the ACGIH (56) TLV is 75 ppm (203 mg/m^3). The NIOSH recommendation is 8-h TWA: 75 ppm (200 mg/cm^3) (87). Cyclopentadiene is on the EPA TSCA Chemical Inventory and the Test Submission Data Base (41).
16.6 Studies on Environmental Impact
1,3-Cyclopentadiene may be released to the environment in emissions from waste incineration, polymer manufacturing plants, combustion of polymers, biomass, gasoline, and cigarettes and also in wastewater from manufacturing plants. If concentrated solutions are spilled, this compound is expected to polymerize spontaneously to dicyclopentadiene. If released to soil in small amounts, it may undergo extensive leaching or rapid volatilization. If released to water in dilute amounts, cyclopentadiene is expected to undergo rapid volatilization (estimated half-life 2.4 h from a model river). The significance of biodegradation in either soil or water is unknown. Chemical hydrolysis, oxidation, bioaccumulation in aquatic organisms, and adsorption to suspended solids and sediments are not expected to be significant fate processes in water. If released to the atmosphere, cyclopentadiene is expected to exist almost entirely in the vapor phase. This compound is expected to rapidly react with ozone molecules, photochemically generated hydroxyl radicals, and possibly nitrate radicals. The atmospheric half-life for cyclopentadiene is estimated to be about 40 min.
17.0 Cyclooctadienes
17.0a **cis**, **cis**-1,3-Cyclooctadiene
17.0.1a CAS Number: [*3806-59-5*]

17.0.2a Synonyms: NA

17.0.3a Trade Names: NA

17.0.4a Molecular Weight: 108.18

17.0.5a Molecular Formula: C_8H_{12}

17.0.6a Molecular Structure:

17.0b Cycloocta-1,5-diene
17.0.1b CAS Number: [*111-78-4*]

17.0.2b Synonyms: 1,5-cyclooctadiene; COD

17.0.3b Trade Names: NA

17.0.4b Molecular Weight: 108.18

17.0.5b Molecular Formula: C_8H_{12}

17.0.6b Molecular Structure:

17.1 Chemical and Physical Properties
17.1.1 General Cyloocta-1,5-diene is a flammable, highly reactive liquid; selected physical properties are given in Table 50.2. Cycloocta-1,3-diene exhibits the same properties as the 1,5 isomer but is more reactive.

17.1.2 Odor and Warning Properties Aromatic odor. Threshold 10 ppb.
17.2 Production and Use
Cycloocta-1,5-diene is produced from petroleum distillation fractions and is used as an intermediate in the plastics industry, as a synthetic lubricant, and in numerous other applications.
17.3 Exposure Assessment
No information is available, but methods similar to those used for other cyclic alkenes are applicable.
17.4 Toxic Effects
17.4.1 Experimental Studies 17.4.1.1 Acute Toxicity: NA

17.4.1.2 Chronic and Subchronic Toxicity: NA

17.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms 1,5-Cyclooctadiene has been shown to reduce glutathione concentration in the rat liver. In the rat and rabbit both the 1,3 and 1,5 isomers are metabolized to dihydroxycyclooctylmercapturic acids and to sulfate and glucuronide conjugates (169).

17.4.1.4 Reproductive and Developmental: NA

17.4.1.5 Carcinogenesis None of the components present in this material at concentrations of ≤0.1% are listed by IARC, NTP, OSHA, or ACGIH as a carcinogen.

17.4.1.6 Genetic and Related Cellular Effects Studies: NA

17.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization Cyclooctadiene is corrosive to the skin, with necrosis of the epidermis and ulceration and marked inflammation of the dermis. Nonoccluded applications of cyclooctadiene to the skin of rabbits, guinea pigs, and hairless mice produced an immediate erythematous reaction. It is also a skin sensitizer (170). Cyclooctadiene applied to the guinea pig skin on 3 alternate days was irritating to the skin, causing erythema, dry appearance, slight dermal weight increase, and increased arginase activity (54).
17.5 Standards, Regulations, or Guidelines of Exposure:
NA
17.6 Studies on Environmental Impact
Aquatic toxicity:

24-h LC_{50}, goldfish: 14 mg/L

24-h LC_{50}, *Daphnia magna*: 0.9 mg/L

96-h LC_{50}, rainbow trout: 30–38 mg/L

18.0 1,3,5-Cycloheptatriene
18.0.1 CAS Number: [*544-25-2*]

18.0.2 Synonyms: Cyclohepta-1,3,5-triene, tropilidene

18.0.3 Trade Names: NA

18.0.4 Molecular Weight: 92.14

18.0.5 Molecular Formula: C_7H_8

18.0.6 Molecular Structure:

18.1 Chemical and Physical Properties
18.1.1 General 1,3,5-Cycloheptatriene is a flammable liquid. Selected physical properties for this compound triene are given in Table 50.2.

18.1.2 Odor and Warning Properties Aromatic odor.
18.2 Production and Use
This compound is found as an environmental air pollutant and is used in chemical synthesis.
18.3 Exposure Assessment
18.3.1 Air See Section 18.3.4.

18.3.2 Background Levels See Section 18.3.4.

18.3.3 Workplace Methods See Section 18.3.4.

18.3.4 Community Methods 1,3,5-Cycloheptatriene is identifiable and quantifiable by gas

chromatography. Gas chromatographic retention properties are applied to the identification of environmental contaminants (171).

18.3.5 Biomonitoring/Biomarkers Information is unavailable; methods have been reported for the detection of other cycloalkenes and their metabolites.
18.4 Toxic Effects
18.4.1 Experimental Studies 18.4.1.1 Acute Toxicity The oral LD_{50} of 1,3,5-cycloheptatriene is 57 mg/kg in the rat and 171 mg/kg in the mouse. The dermal LD_{50} in the rat is 442 mg/kg (172).

18.4.1.2 Chronic and Subchronic Toxicity: NA

18.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms

18.4.1.4 Reproductive and Developmental: NA

18.4.1.5 Carcinogenesis: NA

18.4.1.6 Genetic and Related Cellular Effects Studies: NA

18.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization This compound is a severe dermal irritant but not a sensitizer. When applied to the guinea pig skin on three alternate days, it causes erythema, thickening, and increased weight of the epidermal layer and increased dermal arginase activity. All dermal effects were less remarkable than for the cyclooctadienes (54). The compound was immediately irritant to the rabbit eye, producing mild conjunctivitis, which cleared within 48 h. The eyelids became swollen and exuded a discharge. Blephanitis resolved somewhat more slowly than for cyclododecatriene 1 week after the application.
18.5 Standards, Regulations, or Guidelines of Exposure
Analytical procedures are available for quantifying a number of the cycloalkenes. Protective garments should be worn to prevent contact with the skin and eyes. Cycloheptatriene is on the EPA TSCA Test Submission Data Base (41).
19.0 Cyclododecatriene
19.0a 1,5,9-Cyclododecatriene
19.0.1a CAS Number: [*2765-29-9*]

19.0.2a Synonyms: 1,5,9-Cyclododecatriene (mixed isomers); *cis,trans,trans*-1,5,9-cyclododecatriene; (*E,Z,Z*)-1,5,9-cyclododecatriene

19.0.3a Trade Names: NA

19.0.4a Molecular Weight: 162.27

19.0.5a Molecular Formula: $C_{12}H_{18}$

19.0.6a Molecular Structure:

19.0b **trans**, **trans**, **trans**-1,5,9-Cyclododecatriene
19.0.1b CAS Number: [*676-22-2*]

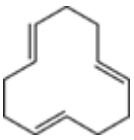
19.0.2b Synonyms: 1,5,9-Cyclododecatriene, (*E,E,E*)-

19.0.3b Trade Names: NA

19.0.4b Molecular Weight: 162.27

19.0.5b Molecular Formula: $C_{12}H_{18}$

19.0.6b Molecular Structure:



19.0.1 CAS Number: [*27070-59-3*]

19.0.2 Synonyms: 1,5,9-Cyclododecatriene, cyclododeca-1,5,9-triene

19.0.3 Trade Names: None known

19.0.4 Molecular Weight: 162.27

19.0.5 Molecular Formula: $C_{12}H_{18}$

19.1 Chemical and Physical Properties

19.1.1 General Cyclododeca-1,3,5-trienes are flammable, corrosive low-melting solids or liquids.

19.1.2 Odor and Warning Properties Oily aromatic odor.

19.2 Production and Use

These compounds are used in chemical synthesis.

19.3 Exposure Assessment

No information is available; methods used for other cycloalkenes are applicable.

19.4 Toxic Effects

19.4.1 Experimental Studies Application to guinea pig skin on 3 alternate days caused erythema, thickening, and increased weight of the epidermal layer and increased dermal arginase activity. All dermal effects were less remarkable than for the cyclooctadienes (54); however, cyclododecatriene is a more potent skin sensitizer (170). The compound is immediately irritant to the rabbit eye, producing mild conjunctivitis, which cleared within 48 h. The eyelids became swollen and exuded a discharge. Blephanitis resolved faster for cyclooctadiene, but was still apparent 1 week after application.

19.4.2 Human Experience 19.4.2.1 General Information: NA

19.4.2.2 Clinical Cases This compound was found to be an immediate irritant and corrosive agent toward the eyes and skin, and a skin sensitizer.

Alicyclic Hydrocarbons
C. Stuart Baxter, Ph.D.

E. Dicyclic Alkanes

20.0 Decalin
20.0a **cis**-Decalin
20.0.1a CAS Number: [*493-01-6*]

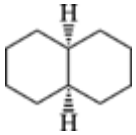
20.0.2a Synonyms: *cis*-Bicyclo[4.4.0]decane; *cis*-decahydronaphthalene

20.0.3a Trade Names: NA

20.0.4a Molecular Weight: 138.25

20.0.5a Molecular Formula: $C_{10}H_{18}$

20.0.6a Molecular Structure:



20.0b **trans**-Decalin
20.01b CAS Number: [*493-02-7*]

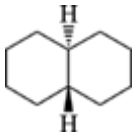
20.02b Synonyms: *trans*-Bicyclo[4.4.0]decane; *trans*-decahydronaphthalene; Decahydronapthalene-*trans*

20.03b Trade Names: NA

20.04b Molecular Weight: 138.25

20.05b Molecular Formula: $C_{10}H_{18}$

20.06b Molecular Structure:



20.0.1 CAS Number: [*91-17-8*]

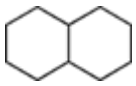
20.0.2 Synonyms: Bicyclo[4.4.0]decane, decahydronaphthalene, naphthalane, naphthane, perhydronaphthalene, Dec or DeKalin

20.0.3 Trade Names: NA

20.0.4 Molecular weight: 138.25

20.0.5 Molecular Formula: $C_{10}H_{18}$

20.0.6 Molecular Structure:



20.1 Chemical and Physical Properties
20.1.1 General Decalin is a flammable liquid. Selected physical properties are given in Table 50.2. On standing or storage, peroxides form that can cause explosions during distillation (4).

20.1.2 Odor and Warning Properties Slight odor resembling menthol.
20.2 Production and Use
Decalin occurs naturally in crude oil and is produced commercially by the catalytic hydrogenation of naphthalene. It is also a product of combustion and is released from natural fires (12). Of the dicyclic alkanes, decalin is the most important member industrially. It is widely used as a solvent for naphthalene, fats, oils, resins, and waxes, as an alternate for turpentine in lacquers, shoe polish, and floor waxes, as a component in motor fuels and lubricants, and as a fuel for stoves (4).
20.3 Exposure Assessment
20.3.1 Air: NA

20.3.2 Background Levels: NA

20.3.3 Workplace Methods: NA

20.3.4 Community Methods Decalin may be collected on charcoal, desorbed with carbon disulfide, and quantified by gas chromatography or mass spectroscopy.

20.3.5 Biomonitoring/Biomarkers Brownish green urine has been reported in workers exposed to a mixture of decalin and tetralin (68). Metabolites may be quantitated in the urine.
20.4 Toxic Effects
20.4.1 Experimental Studies 20.4.1.1 Acute Toxicity The oral LD_{50} is 4.17 g/kg in the rat, and the dermal LD_{50} is 5.9 g/kg in the rabbit. Exposure to the saturated vapor was lethal to rats in 2 h (180). The 4-h LC_{50} is 500 ppm for the rat and 993 ppm for the mouse (48). Exposure to 500 ppm for 4 h was lethal to four out of six rats (173).

20.4.1.2 Chronic and Subchronic Toxicity Of three guinea pigs exposed to 319 ppm (1.8 mg/L) for 8 h/day, one died on day 1, the second on day 21, and the third on day 23 (62). Gross and microscopic evaluation revealed lung congestion, kidney, and liver injury. Application to the skin of guinea pigs on 2 successive days resulted in death within 10 days of exposure. The systemic tissue injury was identical to injury from inhaled decalin (62).

20.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Both *cis*- and *trans*-decalin gave rise in the rabbit to racemic decanols (142, 174), which were excreted in the urine, conjugated with glucuronic acid. Guinea pigs dosed orally with decalin exhibited a brownish green urine, an occurrence also reported in workers exposed to a mixture of decalin and tetralin (62). This was not seen in inhalation or dermal studies.

20.4.1.4 Reproductive and Developmental Forty-eight pregnant CD-1 mice given 2700 mg/kg decalin daily in corn oil by gavage on days 6–13 of gestation and allowed to deliver experienced 14% maternal mortality associated with a significant increase in maternal weight gain. No effect in the offspring of treated mice for the parameters assayed was noted (175).

20.4.1.5 Carcinogenesis: NA

20.4.1.6 Genetic and Related Cellular Effects Studies: NA

20.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization Decalin is irritating to the eyes, skin, and mucous membranes. Vapor exposures in guinea pigs and application of the liquid to rabbit eyes

caused cataracts (107).

20.4.2 Human Experience 20.4.2.1 General Information Systemic toxicity is not well defined, but no serious industrial poisonings are known (107).

20.4.2.2 Clinical Cases 20.4.2.2.1 Acute Toxicity Decalin induces dermatitis and conjunctival irritation.

20.4.2.2.2 Chronic and Subchronic Toxicity The lowest vapor concentration to affect humans was 100 ppm (10). Excessive exposure to high concentrations causes numbness, nausea, headache, and vomiting (149)

20.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms A brownish green urine was reported in workers exposed to a mixture of decalin and tetralin (68). This was not seen in inhalation or dermal studies.

20.4.2.2.4 Reproductive and Developmental: NA

20.4.2.2.5 Carcinogenesis: NA

20.4.2.2.6 Genetic and Related Cellular Effects Studies: NA

20.4.2.2.7 Other: Neurological, Pulmonary, Skin Sensitization, *etc* Dermatitis without serious systemic poisoning has been reported in painters (68). When used as a cleaning agent, decalin has caused eczema, pruritis, and skin sensitization (93).
20.5 Standards, Regulations, or Guidelines of Exposure
Decalin is on the EPA TSCA Chemical Inventory and the Test Submission Data Base (41).
20.6 Studies on Environmental Impact
Limited marine water and sediment grab sample data suggest that decalin will biodegrade in acclimated soils under the proper conditions. It is not expected to undergo hydrolysis or photolysis in soil, but to be slightly mobile to immobile. Volatilization from moist soils with a low organic matter content may be rapid. Limited data suggest biodegradation in acclimated aquatic systems under the proper conditions and little hydrolysis or photolysis in environmental waters. Decalin has the potential to bioconcentrate in aquatic systems, and may also partition from the water column to organic matter contained in sediments and suspended solids. Volatilization from environmental waters should be rapid. The volatilization half-life from a model river has been estimated to be 3.4 h. The volatilization half-life from a model pond, which considers the effect of adsorption, has been estimated to be about 28.1 days (48).

Decahydronaphthalene is expected to exist entirely in the vapor phase in ambient air. In the atmosphere, direct photolysis or hydrolysis is unlikely to occur. Reactions with photochemically produced hydroxyl radicals is likely to be an important fate processes in ambient air. An estimated rate constant at 25°C of $1.90 \times 10^{-11} cm^3 molecule^{-1} s^{-1}$ for the vapor-phase reaction with hydroxyl radicals corresponds to a half-life of 20.3 h at an atmospheric concentration of 5×10^5 hydroxyl radicals (48). The aquatic TLm96 was 10–100 ppm (60). Marine organisms can utilize decalin as their sole carbon source (176). *Pseudomonas fluorescens* and *Corynbacterium* degraded decalin more slowly than alkanes and alkenes (177).

Alicyclic Hydrocarbons
C. Stuart Baxter, Ph.D.

F. Dicyclic Alkenes
21.0 Tetralin
21.0.1 CAS Number: [*119-64-2*]

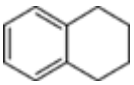
21.0.2 Synonyms: Naphthalene, 1,2,3,4-, tetrahydrobenzocyclohexane, naphthalene 1,2,3,4-tetrahydride, $d^{5,7,9}$-naphthantriene, tetrahydronaphthalene 1,2,3,4-, 1,2,3,4-tetrahydronaphthalin, tetraline, THN, bacticin

21.0.3 Trade Names: Tetranap

21.0.4 Molecular Weight: 132.20

21.0.5 Molecular Formula: $C_{10}H_{12}$

21.0.6 Molecular Structure:



21.1 Chemical and Physical Properties
21.1.1 General Tetralin or 1,2,3,4-tetrahydronaphthalene is a flammable liquid. Selected physical properties are given in Table 50.2.

21.1.2 Odor and Warning Properties These properties resemble those of benzene and menthol (4). Detection threshold 18 ppm in water; purity not specified (178).
21.2 Production and Use
Tetralin is prepared by the catalytic hydrogenation of naphthalene or during acidic, catalytic hydrocracking of phenanthrene (1). At 700°C, tetralin yields tars that contain appreciable quantities of 3,4-benzopyrene (179). Tetralin is used widely as a solvent for fats and oils, as an alternative to turpentine in polishes and paints (180), and as a pesticide (12).
21.3 Exposure Assessment
21.3.1 Air Tetralin is quantified by gas chromatography and mass spectrometry.

21.3.2 Background Levels In avian tissues pentane extraction followed by GLC and GLC-MS is used, and in fish samples by vacuum distillation and fused-silica capillary GC/MS (156).

21.3.3 Workplace Methods: NA

Alicyclic Hydrocarbons
C. Stuart Baxter, Ph.D.

G. Other Cyclic Olefins
25.0 Ethylidene Norbornene
25.0.1 CAS Number: [*16219-75-3*]

25.0.2 Synonyms: 5-Ethylidenebicyclo[2.2.1]hept-2-ene; bicyclo(2,2,1)hept-2-ene; 5-ethylidene-; ENB; 5-ethylidenebicyclo(2,2,1)hep-2-ene; 5-ethylidenebicyclo(2,2,1)hept-2-ene; ethylidenenorbornene, 2-norbornene, 5-ethylidene-; 5-ethylidene-2-norbornene; ethylidene-2-norbornene; 5-ethylidene-8,9,10-trinorborn-2-ene; 5-ethylidene-2-norbornene, mixture of endo and exo isomers, stabilized

25.0.3 Trade Names: NA

25.0.4 Molecular Weight: 120.19

25.0.5 Molecular Formula: C_9H_{12}

25.0.6 Molecular Structure:

25.1 Chemical and Physical Properties
25.1.1 General Colorless, mobile liquid.

25.1.2 Odor and Warning Properties Ethylidene norbornene has a pungent turpentine-like odor.
25.2 Production and Use
Ethylidene norbornene is the third monomer in EPDM (ethylene–propylene diene monomer) elastomers (13).
25.3 Exposure Assessment
Ethylene norbornene is quantitated by absorption in glacial acetic acid and determined by absorption at 536 nm (236). It can also be determined in air by absorption in toluene and subsequent chromatography of the solution on 60–80-mesh Chromosorb impregnated with 2,3-tris(cyanoethoxy) propane (237).
25.4 Toxic Effects
25.4.1 Experimental Studies 25.4.1.1 Acute Toxicity An oral LD_{50} of 3.2 g/kg was originally reported in rats (238). Slight toxicity by dermal route and moderate toxicity by oral route were reported in single-dose studies in rats, rabbits, mice, and dogs (238). On the basis of exposures of 7 h/day for 3 months in dogs, a TLV of 5 ppm for an 8-h workday has been suggested (239). In one study (240), peroral LD_{50} values of 2.54 and 5.66 mL/kg were reported for male and female rats, respectively. Percutaneous toxicity in the rabbit was low by 24 h occluded contact, with no mortalities below 8.0 mL/kg. Saturated vapor LT_{50} values in the rat were 75 (male) and 125 (female) min, and 4 h LC_{50} values were 2717 (male) and 3015 (female). Intravenously the LD_{50} ranged from 0.09 (male rabbit) to 0.11 ml/kg (female). The 4-h LD_{50} was 732 ppm for the female mouse and 3100 ppm for the male rabbit. Acute neurotoxic signs were seen by the intravenous and inhalation routes of exposure, including tremors, ataxia, and convulsions. Moderate skin irritation was observed with erythema and edema, but not necrosis, in rabbits. There was also slight conjunctival hyperemia and chemosis without corneal injury (240).

25.4.1.2 Chronic and Subchronic Toxicity Renal lesions occurred in rats at 90 or 237 ppm and at higher dose liver lesions. At concentrations of 61 or 93 ppm for 7 h/day for 89 days, hepatic lesions were observed in dogs. Inhalation of 61 ppm for 7 h daily for 88 days decreased weight gain in male, but not female, rats, whereas weght gains in dogs were not affected by 1.5 times this concentration (238). Repeated 7-h exposures to 237 ppm, days per week, were fatal to 21/24 rats. In a later study male and female rats were exposed for 6 h per day over an 11-day period to vapor concentrations of 52, 148, or 359 ppm, or 66–67 days over 4 weeks to 4.9, 44.8, and 149 ppm. Clinical signs were limited to periocular swelling and/or encrustation and urogenital area wetness. Body weight gain was decreased in the 359-ppm females and the subchronic 24.8- and 149-ppm males, and there was an increase in liver weight associated with minimal centrilobular hepatocytomegaly in the 9-day study. The principal effect noted was a hypertrophic and hyperplastic response of the follicular epithelium of the thyroid gland, for which there was a no-effect concentration of 4.9 ppm (241).

Necrosis was observed following application to rat skin. Inhalation of 0.11–0.43 mg/L by mice or rats 4 h/day for 7–12.5 weeks decreased the soporific effects of hexenal and caused morphological changes in heart, liver, and endocrine glands. Hormonal dysfunction of ovaries was observed in female rats (221).

25.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms: NA

25.4.1.4 Reproductive and Developmental: NA

25.4.1.5 Carcinogenesis: NA

25.4.1.6 Genitic and Related Cellular Effects Studies At doses of 0, 3, 10, 33, 100, and 333 mg/plate in four *Salmonella typhimurium* strains (TA98, TA100, TA1535, and TA1537) in the presence and absence of Aroclor-induced rat or hamster liver S9, no mutagenicity was observed. The highest ineffective dose level tested (without causing a slight clearing of the background lawn) in any *Salmonella* tester strain was 100 mg/plate (242). In a later study no activity was found again toward the *Salmonella strains*, nor in Chinese hamster ovary (CHO) cell HGPRT mutation, sister chromatid exchange (SCE), or cytogenetic assays, with or without metabolic activation (243).

25.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization At 90-ppm exposure of rats, kidney lesions were noted

25.4.2 Human Experience 25.4.2.1 General Information Human exposure data are very limited. Vapors are moderately irritating such that personnel seldom tolerate moderate or high concentrations. Odor threshold ranges between 0.007 and 0.014 ppm (244). No specific treatment is available.

25.4.2.2 Clinical Cases 25.4.2.2.1 Acute Toxicity Human volunteers noted some irritation of eyes and nose in 30-min exposures at 11 ppm, and transient eye irritation at 6 ppm (244). If swallowed, liquid will cause nausea and vomiting. Inhalation of vapors causes headache, confusion, and respiratory distress. Ingestion causes irritation of entire digestive system. Aspiration causes severe pneumonia. Contact with liquid causes irritation of eyes and skin. The vapor is irritating to the throat. If inhaled, it will cause coughing or difficult breathing. If spilled on clothing and allowed to remain, it may cause smarting and reddening of skin.

25.5 Standards, Regulations, or Guidelines of Exposure

Based on exposures of 7 h/day for 3 months in dogs, a exposure limit of 5 ppm for an 8-h workday was suggested (239). ACGIH and NIOSH have a ceiling value of 5 ppm as of 1983/84.

26.0 Vinylnorbornene

26.0.1 CAS Number: [*3048-64-4*]

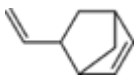
26.0.2 Synonyms: 5-ethenylbicyclo[2.2.1]hept-2-ene; vinylnorbornene; 5-vinylbicyclo[2.2.1]hept-2-ene; 5-vinyl-2-norbornene

26.0.3 Trade Names: NA

26.0.4 Molecular Weight: 120.19

26.0.5 Molecular Formula: C_9H_{12}

26.0.6 Molecular Structure:



26.1 Chemical and Physical Properties
26.1.1 General Vinylnorbornene is a colorless, mobile liquid.

26.1.2 Odor and Warning Properties Vinylnorbornene has an oily lachrymator-like odor.
26.2 Production and Use
Vinylnorbornene is the third monomer in EPDM (ethylene-propylene diene monomer) elastomers (13).
26.3 Exposure Assessment
Vinylnorbornene is quantitated by absorption in glacial acetic acid and determined by absorption at 536 nm (236). It can also be determined in air by absorption in toluene and subsequent chromatography of the solution on 60–80-mesh Chromosorb impregnated with 2,3-tris(cyanoethoxy) propane (237).
26.4 Toxic Effects
26.4.1 Experimental Studies 26.4.1.1 Acute Toxicity An oral LD_{50} of 5.9 mL/kg (male) and 11.9 mL/kg (female) was reported in rats (238). Percutaneous toxicity in the rabbit was low by 24 h occluded contact, with one mortality up to 16.0 mL/kg. Saturated vapor LT_{50} values in the rat were 28 (male) and 37 (female) min, and 4-h LC_{50} values were 2231 (male) and 2518 (female). Intravenously the LD_{50} ranged from 0.10 to 0.05. Acute neurotoxic signs were seen by the intravenous and inhalation routes of exposure, including tremors, ataxia, and convulsions. Moderate skin irritation was observed with erythema and edema, but not necrosis, in rabbits. There was also slight conjunctival hyperemia and chemosis without corneal injury (192). The inhalation mouse LC_{50} was 17700 mg/m^3 in 2 h; oral LD_{50} was 5667 mg/kg.

26.4.1.2 Chronic and Subchronic Toxicity: NA

26.4.1.3 Metabolism, and Mechanisms: NA

26.4.1.4 Reproductive and Developmental: NA

26.4.1.5 Carcinogenesis: NA

26.4.1.6 Carcinogenetic and Related Cellular Effects Studies No activity was found toward the Ames *Salmonella* strains, nor in CHO cell HGPRT mutation, SCE, or mouse bone marrow micronucleus assays, with or without metabolic activation (237).

26.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization Necrosis was reported when applied to the skin of the mouse tail (221).
27.0 Camphene
27.0.1 CAS Number: [*79-92-5*]

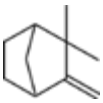
27.0.2 Synonyms: 3,3-Dimethyl-2-methylene norcamphone, bicyclo(2.2.1)heptane, 2,2-dimethyl-3-methylene-; 2,2-dimethyl-3-methylene-norbornane; 2,2-dimethyl-3-methylenebicyclo[2.2.1]heptane; 2,2-dimethyl-3-methylenenorbornane; 3,3-dimethyl-2-methylenenorcamphane; (+/–)-camphene; camphene, remainder mainly a-fenchene

27.0.3 Trade Names: NA

27.0.4 Molecular Weight: 136.24

27.0.5 Molecular Formula: $C_{10}H_{16}$

27.0.6 Molecular Structure:



27.1 Chemical and Physical Properties
27.1.1 General Cubic crystals (4) form flammable vapors (7). Selected physical properties are given in Table 50.2.

27.1.2 Odor and Warning Properties Camphene has an insipid odor, with a camphoraceous taste.
27.2 Production and Use
Occurs naturally in the oils of several plants; can be prepared from a-pinene. Isolated as, and used in tablet form for mothproofing (245). Also used in the manufacture of camphor and in the cosmetic, perfume, and food flavoring industries (246).
27.3 Exposure Assessment
27.3.1 Air Camphene concentration is determined in ambient air by gas chromatographic method (247) and is analyzed by GC/MS (248).

27.3.5 Biomonitoring/Biomarkers Urinary conjugates of diol metabolites have been analyzed by gas chromatography or mass spectrometry following hydrolysis.
27.4 Toxic Effects
27.4.1 Experimental Studies 27.4.1.1 Acute Toxicity The oral LD_{50} value in the rat is >5 g/kg, and the dermal LD_{50} is >2.5 g/kg in the rabbit (190).

27.4.1.2 Chronic and Subchronic Toxicity: NA

27.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Camphene is metabolized in the rabbit to the glycol, conjugated, and excreted in the urine (249). Metabolites are analyzed by gas chromatography or mass spectrometry.

27.4.1.3.1 Adsorption Camphene is readily absorbed following inhalation, ingestion, or topical application.

27.4.1.3.2 Distribution: NA

27.4.1.3.3 Excretion In one study, 3.6% was eliminated unchanged in expired air within 3 h following dermal application or IV injection of 0.6 mg/kg body weight (0.05 mL in 2.5 mL of 1,2-propanediol) into a young pig. The major portion appeared within 5 minutes and 90% within 30 min.

27.4.1.3.4 Reproductive and Developmental: NA

27.4.1.3.5 Carcinogenesis: NA

27.4.1.3.6 Genetic and Related Cellular Effects Studies No mutagenic activity found toward Ames *Salmonella* tester strains in the presence or absence of S9 rat liver fraction (201).

27.4.2 Human Experience 27.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms In one study, 3.6% was eliminated unchanged in expired air within 3 h following dermal application or IV injection of 0.6 mg/kg body weight (0.05 mL in 2.5 mL 1,2-propanediol) into a human subject. The major portion appeared within 5 min and 90% within 30 min. The compound was absorbed through the skin and was also partially excreted in expired air, appearing within 20 min of the start of a 30-min full bath containing 150 mL pine bath oil in 450 L water, and was still detectable 1 day after the bath, although inhalation of volatiles from the bath was prevented. A maximal level was reached

after 75 min, with 60% exhaled within first 2 h and a total of 0.67 mL exhaled during the first 5 h. This study suggested a major route of elimination of unchanged compound in bile with excretion through intestinal tract, followed by glucuronide formation and excretion via the kidney (246).

27.4.2.2.4 Reproductive and Developmental: NA

27.4.2.2.5 Carcinogenesis: NA

27.4.2.2.6 Genetic and Related Cellular Effects Studies: NA

27.4.2.2.7 Other: Neurological, Pulmonary, Skin Sensitization, *etc* Tests at 4% in petrolatum camphene produced no irritation after a 48-h closed-patch test on human subjects. Camphene was also found not to be a sensitizer for human skin (246).

27.5 Standards, Regulations, or Guidelines of Exposure

Limits in foods are nonalcoholic beverages, 40–90 ppm; ice cream, ices, and similar, 20 ppm; candy, 160 ppm; baked goods, 27 ppm. FDA requirement 121.1164 (250). Protective clothing including gloves and face shield are recommended when handling this agent (16). Camphene is on the EPA TSCA Chemical Inventory and the Test Submission Data Base (41)

27.6 Studies on Environmental Impact

The LC_{50} for sheepshead minnows is 1.9 ppm/96 h (95% confidence limit 1.6–2.2 ppm) (251).

Camphene is converted by *Aspergillus niger* into 2-nonene-2,3-dicarboxylic acid anhydride, with formation of diacetone alcohol as an artifact (246).

28.0 Caryophyllene

28.0.1 CAS Number: [*87-44-5*]

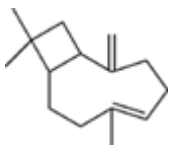
28.0.2 Synonyms: 4,11,11-Trimethyl methylenebicyclo[7.2.0]undec-4-ene; caryophylene; b-caryophyllene; tricyclo[8.2.0.0(4,6)]dodecane; 4,12,12-trimethyl-9-methylene-, (1*R*-(1*R**, 4*R**, 6*R**, 10*S**))-; tricyclo[8.20.0(4,6)]dodecane; 4,12,12-trimethyl-9-methylene-, (1*R*, 4*r*, 6*r*, 10*s*)-; humulene; b-caryophyllene; bicyclo[7.2.0]undec-4-ene; 4,11,11-trimethyl-8-methylene-, [1*R*-(1*R**, 4*E*, 9*S**)]-; bicyclo[7.2.0]undec-4-ene, 4,11,11,-trimethyl-8-methylene-, (*E*)-(1*R*, 9*S*)-(–)-; bicyclo [7.2.0]undec-4-ene, 8-methylene-4,11,11-trimethyl-, (*E*)-(1*R*, 9*S*)-(–)-; *trans*-caryophyllene; 1-caryophyllene; (–)-b-caryophyllene; (–)-caryophyllene; (–)-*trans*-caryophyllene; 8-methylene-4,11,11-(trimethyl)bicyclo[7.2.0]undec-4-ene; 2-methylene-6, 10,10-trimethyl bicyclo[7.2.0]undec-5-ene

28.0.3 Trade Names: NA

28.0.4 Molecular Weight: 204.35

28.0.5 Molecular Formula: $C_{15}H_{24}$

28.0.6 Molecular Structure:



28.1 Chemical and Physical Properties

Caryophyllene is a liquid with a boiling point of 129–130°C.

28.1.1 General Selected physical properties for a-caryophyllene are given in Table 50.2.

28.1.2 Odor and Warning Properties Fragrant cloves and turpentine odor are charactersitic.
28.2 Production and Use
This compound occurs naturally in many plants (4, 132) in the a, b, and iso forms (4). It is widely used in the perfume industry, and in the manufacture of its epoxide.
28.3 Exposure Assessment
Caryophyllene is quantifiable using thin-layer and gas chromatography.

28.3.1 Air: NA

28.3.2 Background Levels: NA

28.3.3 Workplace Methods: NA

28.3.4 Community Methods: NA

28.3.5 Biomonitoring/Biomarkers 14-Hydroxycaryophyllene oxide and other metabolites can be quantitated in the urine.
28.4 Toxic Effects
28.4.1 Experimental Studies 28.4.1.1 Acute Toxicity Caryophyllene is reported to be a skin irritant in the rabbit (41).

28.4.1.2 Chronic and Subchronic Toxicity: NA

28.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms 14-Hydroxycaryophyllene oxide was isolated from the urine of rabbits treated with (–)-caryophyllene and the X-ray crystal structure reported. The metabolism was shown to progress through (–)-caryophyllene oxide since the latter compound also afforded 14-hydroxycaryophyllene as a metabolite (252).

Caryophyllene is expected to be readily absorbed and systemically distributed by inhalation or gastric or topical administration. It is excreted as 14-hydroxycaryophyllene oxide from the urine of rabbits treated with (–)-caryophyllene.

28.4.1.4 Reproductive and Developmental: NA

28.4.1.5 Carcinogenesis Caryophyllene showed significant activity as an inducer of the detoxifying enzyme glutathione *S*-transferase in the mouse liver and small intestine. The ability of natural anticarcinogens to induce detoxifying enzymes has been found to correlate with their activity in the inhibition of chemical carcinogenesis (251).
28.5 Standards, Regulations, or Guidelines of Exposure
Caryophyllene is on the EPA TSCA Chemical Inventory (48).

Aromatic Hydrocarbons—Benzene and Other Alkylbenzenes

Rogene F. Henderson, Ph.D., DABT

A. Introduction

Benzene and its alkyl derivatives are monocyclic aromatic compounds (arenes). The compounds are of considerable economic importance as industrial raw materials, solvents, and components of innumerable commercial and consumer products. The aromatics differ vastly in chemical, physical, and biologic characteristics from the aliphatic and alicyclic hydrocarbons. The aromatics are more toxic to humans and other mammals; of prime importance are (*1*) the hematopoietic toxicity of benzene resulting in aplastic anemia in humans and other mammalian species, (*2*) benzene-induced leukemia in humans, and (*3*) the cerebellar lesions and loss of central nervous system (CNS) integrative functions in "glue sniffers" exposed to high levels of toluene.

The simplest single-ring aromatic hydrocarbon compound is benzene, the nonsubstituted ring system. When one methyl group is attached to the ring, toluene is formed, and with two attached methyl groups, xylene is formed. Xylene occurs in three isomeric forms. The hemimellitines and mesitylenes possess three methyl groups, durene four, and the penta- and hexamethylbenzenes, five and six methyl groups, respectively. Other industrially important compounds are ethylbenzene and isopropylbenzene or cumene.

1.0 Benzene and its Compounds in General

1.1 Physical and Chemical Properties

Benzene and its alkyl derivatives occur in liquid or vapor form. The lower molecular weight derivatives possess higher vapor pressures, volatility, absorbability, and solubility in aqueous media than do the comparable aliphatic or alicyclic compounds. Studies by Cometto-Muniz and Cain (1, 2) indicate that eye irritation thresholds were well above odor thresholds for a series of alkylbenzenes (toluene, ethylbenzene and propylbenzene) and that both sensory thresholds declined with carbon chain length. Selected physical data of benzene and its alkyl derivatives are given in Table 51.1 (3–23). These properties contribute to their biological activities. The compounds are characterized by miscibility or conversion to compounds soluble in aqueous body fluids, high lipid solubility, and donor–acceptor and polar interactions (24). Because of their low surface tension and viscosity, benzene and its alkyl derivatives may be aspirated into the lungs during ingestion, where they cause chemical pneumonitis.

Table 51.1. Physical Properties for Benzen

Compound	B P (° C)	CAS Registry No.	Density (at 20.4°C)	Empirical Formula	Flammability Limits[a] (%)	Flash point [°C (°F)]	Freezing point (° C)	MP (°C)	Mol W

[d] Closed cup.
[c] –100°C.

1.2 Production and Use

Benzene and its alkyl derivatives are obtained as products or by-products in petroleum or coal refining, burning, or pyrolysis processes. From coke-oven operations, the aromatics are recovered from the gases and the coal tars. From crude oil distillation, they are produced by fractionated distillation, solvent extraction, naphthenic dehydrogenation, alkylation of benzene or alkenes, or from alkanes by catalytic cyclization or aromatization.

Benzene and its alkyl derivatives are used widely as chemical raw materials, intermediates, solvents, in oil and rosin extractions, as components of multipurpose additives, and extensively in the glue and veneer industries owing to their rapid drying characteristics. The compounds are also used in the dry-cleaning industry, in the printing and metal processing industries, and for many other similar applications. They can be found as constituents of aviation and automotive gasolines and represent important raw materials in the preparation of pharmaceutical products. The use of benzene as a solvent is decreasing because of its known leukemogenic properties (25, 26).

1.3 Exposure Assessment

Benzene and its alkyl derivatives are volatile enough to be monitored in air by adsorption on charcoal or resins, followed by desorption and analysis by gas chromatography. Methods for analysis in water and soil are also available. Benzene has been detected in cigarette smoke at concentrations of approximately 50 ppm (27, 28). Benzene and toluene have been detected in rainwater at concentrations of 0.1–0.5 mg/L, and ≤1.0 mg/L in the ambient air (29). Biomonitoring of exposures in occupational settings depends mainly on assessment of urinary metabolites.

1.4 Toxic Effects

Benzene is a known hematotoxin and leukemogen. The alkyl derivatives of benzene are not hematotoxic. The unique effects of benzene on bone marrow and blood-forming mechanisms are of major importance.

Benzene and its alkyl derivatives are primary skin irritants, and repeated or prolonged skin contact may cause dermatitis, dehydrating, and defatting of the skin. Eye contact with the liquids may cause lacrimation, irritation, and on prolonged contact, severe burns. Conjunctivitis and corneal burns have been reported for the C6–C8 members. The alkylbenzenes, with side chains C1–C4, are readily aspirated and can produce instant death, via cardiac arrest and respiratory paralysis. For example, in hexylbenzene exposure, death occurred in 18 min, during which time extensive pulmonary edema occurred (30), resulting in a considerable increase in lung weight. The higher alkylbenzenes showed few or no effects.

For the alkylbenzenes in general, the acute toxicity is greatest for toluene and decreases further with increasing chain length of the substituent, except for highly branched C8–C18 derivatives. The toxicity increases again for the vinyl derivatives. Pharmacologically, the alkylbenzenes are CNS depressants, and exhibit a particular affinity to nerve tissues.

1.4.1 Acute Toxicity The acute toxicities of benzene and its alkyl derivatives are CNS effects and irritancy. Benzene is more toxic than any of the substituted benzene derivatives, except for toluene and styrene. Benzene and alkylbenzenes cause local irritation and changes in endothelial cell permeability, and are absorbed rapidly. Secondary effects have been observed in the liver, kidney, spleen, bladder, thymus, brain, and spinal cord in animals (31). The aromatic hydrocarbons, even from a single dose, exhibit a special affinity to nerve tissue. Animals dosed with alkylbenzenes exhibit signs of CNS depression, sluggishness, stupor, anesthesia, and coma. A study of acute

behavioral effects of alkylbenzenes in mice (32) indicated that concentrations between 2000 and 8000 ppm for 20 min produced changes in posture, decreased arousal and rearing, increased ease of handling, disturbances of gait, mobility, and righting reflex, decreased forelimb grip strength, increased landing foot splay, and impaired psychomotor coordination. This is in sharp contrast with benzene, which is a neuroconvulsant, producing tremors and convulsions. The CNS depressant potency of the alkylbenzenes depends on branching or side-chain length. It diminishes with increasing numbers of substituents or side-chain carbon number up to dodecylbenzene, which has practically no CNS depressant activity (31).

1.4.2 Chronic Toxicity The hematotoxicity and leukemogenicity of benzene in humans have been established by a large body of epidemiological evidence (25, 26). Because of its affinity to blood-forming tissue and myelotoxic activity, chronic exposure to benzene is considered more serious than for all other alkylbenzenes. All substituted benzene derivatives tested are devoid of this myelotoxicity. This has been clearly demonstrated with toluene, which does not alter leukocyte count or bone marrow nucleation in the rat (31). In lifetime studies, benzene is carcinogenic in rodents (25, 26); benzene is a known human carcinogen (leukemogen) (25, 26).

1.4.3 Metabolism Benzene and its derivatives are readily hydroxylated, and their alkyl side chains are oxidized to carboxylic acids. Benzene may also be metabolized by ring opening. Benzene immediately increases the urinary excretion of organic sulfate. Of the alkylbenzenes, only m-xylene and mesitylene follow this trend. Metabolism is required for the expression of benzene toxicity (34).
1.5 Standards, Regulations or Guidelines of Exposure
From an industrial hygiene standpoint, benzene and its alkyl derivatives require close monitoring and evaluation, particularly benzene, toluene, xylene, ethylbenzene, cumene, and p-*tert*-butyltoluene. In the late 1990s, threshold limit values (TLVs) were lowered incrementally for some of the aromatic compounds. This was a consequence of the development of better sampling and analytic techniques and more extensive toxicity testing. Industrial monitoring programs should be continually evaluated. Where excursion values are found, biologic monitoring should be carried out in addition to regular medical surveillance programs.
1.6 Studies on Environmental Impact
Aromatic hydrocarbons appear to accumulate in marine animals to a greater extent and are retained longer than are alkanes (35). In all species tested, the accumulation of aromatic hydrocarbons depended primarily on the octanol/water partition coefficient. Once absorbed, higher molecular weight hydrocarbons are released more slowly (35). The concentration to produce deep CNS depression in barnacle larvae after immersion for 15 min was 3.1% for benzene and 4.5% for toluene (36). To some bacteria, as little as 0.01% of toluene, xylene, mesitylene, phenol, or cresol may be bacteristatic or bactericidal (37), whereas other microorganisms tolerate concentrations of ≤0.5% hydrocarbon. Benzene is the least susceptible to bacterial oxidation; increasing substitution and chain length, especially to even numbers, promotes the ease of oxidation (37).

Aromatic Hydrocarbons—Benzene and Other Alkylbenzenes
Rogene F. Henderson, Ph.D., DABT

B. Specific Substances
2.0 Benzene
2.0.1 CAS Number: [*71-43-2*]

2.0.2 Synonyms: Phenyl hydride; coal naphtha; benzol; cyclohexatriene; benzine; benzolene; phene; (6)annulene; bicarburet of hydrogen; carbon oil; mineral naphtha; motor benzol; nitration benzene; pyrobenzol

2.0.3 Trade Name: NA

2.0.4 Molecular Weight: 78.113

2.0.5 Molecular Formula: C_6H_6

2.0.6 Molecular Structure:

2.1 Chemical and Physical Properties
Benzene, benzol, or phene is a clear, colorless liquid with a characteristic sweet odor at low concentrations, disagreeable and irritating at high levels. Selected physical data are summarized in Table 51.1. The odor threshold for benzene is 2.0 mg/L in water and is 1.5–4.5 ppm in air (38). The odor is irritating at 9000 ppm (39). The taste threshold is 0.5–4.5 mg/L in water (38). Its solubility in water is 1.78 g/L at 25°C. The octanol/water partition coefficient for benzene is 2.13–2.15, and the organic carbon partition coefficient is 1.8–1.9. Henry's law constant for benzene at 25°C is 5.5×10^{-3} atm·m^3/mol. Benzene forms a highly flammable (40) and explosive mixture with air at 1.4–8.0%. The autoignition temperature for benzene is 580°C. It is an excellent solvent. Chemically, it is fairly stable, but it readily undergoes substitution reactions to form halogen, nitrate sulfonate, and alkyl derivatives. Commercial benzene has three standard grades and usually contains varying concentrations of toluene, xylene, and phenol, and traces of carbon disulfide, thiophene, alkenes, naphthalene, and related compounds.

The photochemical formation of nitrobenzenes and nitrophenols from benzene has been observed in the presence of nitrogen oxides. Benzene also combines photochemically with halogens to produce eye and mucous membrane irritants (41). Ozone reacts 10–20 times more slowly with benzene than with toluene or other methyl-substituted derivatives (42).

Polycyclic and Heterocyclic Aromatic Hydrocarbons
David Warshawsky, Ph.D.

Introduction to Class of Chemicals
Aromatic hydrocarbons are the class of chemicals that include multiring aromatic compounds. Smaller aromatic hydrocarbons, one to two rings, are of considerable economic importance as industrial raw materials, solvents, and components of innumerable commercial and consumer products. However, aromatics differ vastly in chemical, physical, and biological characteristics from the aliphatic and alicyclic hydrocarbons. In addition, aromatics are more toxic to humans and other mammals. Of prime importance are the carcinogenicity of styrene and the polycyclic aromatic hydrocarbons (1–11).

Chemically, aromatic hydrocarbons can be divided into three groups: (a) alkyl-, aryl-, and alicyclic-substituted benzene derivatives, (b) di- and polyphenyls, and (c) polycyclic compounds composed of two or more fused benzene ring systems. The basic chemical entity is the benzene nucleus, which occurs alone, substituted, joined, or fused.

Aromatics are moderately reactive and undergo photochemical degradation in the atmosphere. Aromatic compounds occur in liquid, vapor, or solid form. The lower molecular weight derivatives possess higher vapor pressures, volatility, absorbability, and solubility in aqueous media than the comparable aliphatic or alicyclic compounds. These properties contribute to their biological activities. They are characterized also by miscibility or conversion to compounds soluble in aqueous body fluids, high lipid solubility, and donor–acceptor and polar interaction. Because of their low surface tension and viscosity, aromatics may be aspirated into the lungs during ingestion, where they cause chemical pneumonitis.

Benzene and its alkyl derivatives, the polyphenyls, and polycyclic aromatics (PAHs) are obtained as products or by-products in petroleum or coal refining, burning, or pyrolysis. In coke-oven operations, the aromatics are recovered from the gases and the coal tars. In crude oil distillation, they are produced by fractionated distillation, solvent extraction, naphthenic dehydrogenation, alkylation of benzene or alkenes, or from alkanes by catalytic cyclization or aromatizations.

Aromatic hydrocarbons are used widely as chemical raw materials, intermediates, solvents, in oil and rosin extractions, as components of multipurpose additives, and extensively in the glue and veneer industries because of their rapid drying characteristics. Aromatics serve in the dry-cleaning industry, in the printing and metal processing industries, and for many other similar applications. They are important constituents of aviation and automotive gasolines and represent important raw materials in the preparation of pharmaceutical products.

Aromatics are primary skin irritants, and repeated or prolonged skin contact may cause dermatitis, dehydrating, and defatting of the skin. Eye contact with aromatic liquids may cause lacrimation, irritation, severe burns and from prolonged contact. Naphthalene causes cataracts in the eyes of experimental animals. Its vapors are respiratory and mucous membrane irritants and may cause severe systemic injury. Direct aerosol deposition or contact from ingestion and subsequent aspiration can cause severe pulmonary edema, pneumonitis, and hemorrhage (12, 13). Alkylbenzenes that have C_1 to C_4 side chains are readily aspirated and can produce instant death via cardiac arrest and respiratory paralysis.

Polycyclic and Heterocyclic Aromatic Hydrocarbons

Phenol and Phenolics

Ralph Gingell, Ph.D., DABT, John O'Donoghue, Ph.D., DABT, Robert J. Staab, Ph.D., DABT, Ira W. Daly, Ph.D., DABT, Bruce K. Bernard, Ph.D., Anish Ranpuria, MS, E. John Wilkinson, Daniel Woltering, Ph.D., Phillip A. Johns, Ph.D., Stephen B. Montgomery, Ph.D., Larry E. Hammond, Ph.D., Marguerita L. Leng, Ph.D.

1.0 Phenol

1.0.1 CAS Number:

[*108-95-2*]

1.0.2 Synonyms:

Hydroxybenzene; carbolic acid; phenic acid; phenylic acid; phenyl hydroxide; Phenic; monohydroxy benzene; oxybenzene; benzenol; monophenol; phenyl hydrate; phenylic alcohol; phenyl hydroxide; baker's p and s; phenol alcohol; phenyl alcohol; phenol reagent

1.0.3 Trade Names:

Phenol

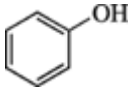
1.0.4 Molecular Weight:

94.11

1.0.5 Molecular Formula:

C_6H_6O

1.0.6 Molecular Structure:



1.1 Chemical and Physical Properties

Physical state	white crystalline mass of hygroscopic, translucent, needle-shaped crystals; pink or red when impurities are present; darkens on exposure to light.
Odor	Acrid odor, with threshold 0.04 ppm
Specific gravity	1.071
Melting point	43°C
Boiling point	182°C
Vapor density	3.24 (air = 1)
Vapor pressure	0.357 mmHg (20°C) 0.35 torr at 25°C
Refractive index	1.54 (45°C)
Concentration in "saturated" air	0.046% by volume (0.77g/m^3) (25°C)
Density of "saturated" air	1.00104 (air = 1)
Conversion	3.84 mg/m^3 = 1 ppm; 1 mg/m^3 = 0.26 mg/m^3
Flash point	Closed cup, 79°C; open cup, 85°C

Additional properties are as follows:

Flammability. Phenol presents a marked fire hazard. Phenol fires can be extinguished with water, carbon dioxide, or dry chemicals. Mixtures of air and 3–10% phenol are explosive (1).

Solubility. Phenol forms a true aqueous solution when present in concentrations of ≤8%, and also in concentrations ranging from about 71–97%, in terms of both weight and volume; it is miscible with water above 68°C. Phenol is soluble to >50% in ethyl alcohol, chloroform, ethyl ether, ethyl acetate, toluene, glycerol, and olive oil (2).

1.1.1 General: NA

1.1.2 Odor and Warning Properties Phenol has a distinct, aromatic, somewhat sickening sweet and acrid odor discernable at 0.5–5 ppm. It has a sharp and burning taste.

Phenol and Phenolics

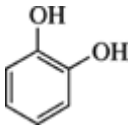
2.0 Pyrocatechol
2.0.1 CAS Number:
[*120-89-9*]
2.0.2 Synonyms:
Catechol; 1,2-benzenediol; *o*-dihydroxybenzene; pyrocatechin; 1,2-dihydroxybenzene; *o*-benzenediol; benzcatechin; Catechol–pyrocatechol; 1,2-dihydroxybenzene (Catechol)
2.0.3 Trade Names:
Catechol
2.0.4 Molecular Weight:
110.11
2.0.5 Molecular Formula:
$C_6H_6O_2$
2.0.6 Molecular Structure:



2.1 Chemical and Physical Properties
2.1.1 General

Physical state	Colorless to white crystalline solid that discolors in air and light; sublimes readily; volatile in steam
Specific gravity	1.344 (4°C)
Melting point	105°C
Boiling point	245.5°C (decomposes at 240 to 245°C)
Vapor density	3.79 (air = 1)
Solubility	Soluble in water, alcohol, ether
Flash point	137°C (closed cup)

2.1.2 Odor and Warning Properties There is a faint, characteristic odor.
2.2 Production and Use
Pyrocatechol may be obtained by the fusion of *o*-phenolsulfonic acid with alkali, by heating chorophenol with a solution of sodium hydroxide at 200°C in an autoclave, or by cleavage of the methyl ether group of guaiacol (obtained from beechwood tar) with hydroidic acid (107). Pyrocatechol is used for various purposes, but particularly as an antioxidant in the rubber, chemical, photographic, dye, fat, and oil industries. It is also employed in cosmetics as couplers in oxidative hair dyes (108, 109), but is no longer used as an antiseptic.
2.3 Exposure Assessment
2.3.1 Air: NA

2.3.2 Background Levels: NA

2.3.3 Workplace Methods: NA

2.3.4 Community Methods: NA

2.3.5 Biomonitoring/Biomarkers 2.3.5.1 Blood

2.3.5.2 Urine The methods of Baernstein or Tompsett can be used to determine pyrocatechol in urine and in other biologic materials (13). In another study, 24 h urine samples examined after 7–9 h of exposure to air polluted with pyrocatechol and phenol gave pyrocatechol levels of 24.2 mg, but control values of 19.2 mg, which were considered background (110). The 24-h urinary levels of pyrocatechol were 4.4 mg in nonsmokers, and 6.8 mg in smokers, indicating that diet is a major factor in determining pyrocatehcol intake (111).

2.4 Toxic Effects

2.4.1 Experimental Studies 2.4.1.1 Acute Toxicity Pyrocatechol is moderately toxic in acute studies. Phenol-like signs of illness are induced in experimental animals given toxic or lethal doses. Unlike phenol, large doses of pyrocatechol can cause a predominant depression of the central nervous system (CNS) and a prolonged rise of blood pressure (13). Pyrocatechol is more toxic than phenol except by inhalation (111). The oral LD_{50} in rats is 0.3 g/kg. The dermal LD_{50} in rabbits is 0.8 g/kg. It is an irritant to eyes and skin, but less irritating to the skin than phenol. After 8h of inhalation at concentrations of 2 or 2.8 g/m^3 rats showed signs of intoxication (irritation and tremors) for ~24 h after exposure. At 1.5 g/m^3 no signs were observed (111). Flickinger (17) reported hyperemia of the stomach and intestines after lethal oral doses in rats, and loss of toes and tips of tails of rats after exposure to high concentrations (2 or 2.8 g/m^3) in a chamber. Dietering reported degenerative changes in the kidney tubules (13).

2.4.1.2 Chronic and Subchronic Toxicity The repeated absorption of sublethal doses by animals may also induce methemoglobinemia, leukopenia, and anemia.

2.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Pyrocatechol is readily absorbed from the GI tract and through the intact skin of mice, and probably through the lungs (13). Part of the catechol is oxidized with polyphenol oxidase to benzoquinone. Another fraction conjugates in the body with glucuronic, sulfuric, and other acids and is excreted in the urine, with a little “free” pyrocatechol. The conjugates hydrolyze easily in the urine with the liberation of the “free” catechol, which is oxidized by air with the formation of dark-colored substances that impart to the urine a “smokey” appearance (13).

Rabbits administered pyrocatechol orally excreted in the urine 18% as sulfate, 70% as monoglucuronide, and 2% as free pyrocatechol (112). When mice were exposed to cigarette smoke containing radiolabeled pyrocatechol, pyrocatechol was distributed readily into the blood and tissues; 90% of the radioactivity was excreted in the urine within 24 hrs (113).

2.4.1.4 Reproductive and Developmental Pyrocatechol was reported to be a moderately active maternal toxicant, and an active developmental toxicant in a preliminary screening assay (114). Sprague–Dawley rats were administered pyrocatechol at oral doses of 333, 667, or 1000 m g/kg on day 11 of gestation, and allowed to deliver normally. Both mid and high doses caused maternal lethality and weight gains. Litter size and weights were reduced at the maternally toxic doses. Malformations involving limbs, tail and urogenital systems were reported at all doses (114).

2.4.1.5 Carcinogenesis Pyrocatechol has been extensively studied for its role in carcinogenesis of the rat glandular stomach; it was concluded that pyrocatechol was carcinogenic (109). When rats and mice were administered 0.8% pyrocatechol in their feed for life, there was an increase in glandular stomach adenocarcinoma in both male and female rats. Pyrocatechol also caused hyperplasia of the glandular stomach in both rats and mice, a mechanism that could cause promotion of carcinogen-initiated cells (115); no effects on the esophagus or urinary bladder were reported. There were no cutaneous neoplasms when pyrocatechol was applied in dermal studies. Pyrocatechol may be classified as a cocarcinogen because it enhanced the number and/or incidence of lesions in the stomach induced by several carcinogenic nitrosamines, and cutaneous neoplasms when administered dermally together with several carcinogens (109).

2.4.1.6 Genetic and Related Cellular Effects Studies Pyrocatechol has been tested in a variety of bacterial and mammalian tests systems, and both positive and negative results were obtained (summarized in Ref. 109). For example, pyrocatechol was negative in the Ames assay, but induced SCEs (sister chromatid exchanges) in CHO (Chinese hamster ovary) V79 cells (116). In *in vivo* mouse micronucleus assays, in which the conjugation enzymes responsible for detoxication were present, both positive (117, 118) and negative results (119) were reported.

2.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization Undiluted pyrocatechol was severely irritating to rabbit eyes, with permanent changes including corneal opacity (17). Pyrocatechol was a skin sensitizer in guinea pigs (120). In *in vitro* studies, pyrocatechol has been shown to affect several immunologic and other properties of murine bone marrow cells, both alone and when combined with hydroquinone (summarized in Ref. 108).

2.4.2 Human Experience 2.4.2.1 General Information: NA

2.4.2.2 Clinical Cases 2.4.2.2.1 Acute Toxicity Inhalation results in a burning sensation in the throat and lungs and, subsequently, a pronounced increase in the rate of breathing (13).

2.4.2.2.2 Chronic and Subchronic Toxicity Cases of industrial or accidental poisoning have been rare.

2.4.2.2.3 Pharmacokinics, Metabolism, and Mechanisms The calculated biological half-life of pyrocatechol in humans was 3–7h (110).

2.4.2.2.4 Reproductive and Developmental: NA

2.4.2.2.5 Carcinogenesis: NA

2.4.2.2.6 Genetic and Related Cellular Effects Studies: NA

2.4.2.2.7 Other: Neurological, Pulmonary, Skin Sensitization, *etc* Contact with the skin has been known to cause an eczematous dermatitis. Absorption through the skin, in a few instances, has resulted in symptoms of illness resembling closely those induced by phenol, except for certain central effects (convulsions) that were more marked (13). Apparently pyrocatechol acts by mechanisms similar to those reported for phenol. The rise of blood pressure appears to be due to peripheral vasoconstriction. Death apparently is initiated by respiratory failure (13).

A woman developed acute contact dermatitis after using a permanent cream for eyelashes and eyebrows; when she was patch-tested, pyrocatechol evoked strong positive reactions (121). Another woman became allergic to pyrocatechol from her occupational exposure as a radiographer (122).

2.4.2.3 Epidemiology Studies 2.4.2.3.1 Acute Toxicity: NA

2.4.2.3.2 Chronic and Subchronic Toxicity: NA

2.4.2.3.3 Pharmacokinetics, Metabolism, and Mechanisms: NA

2.4.2.3.4 Reproductive and Developmental: NA

2.4.2.3.5 Carcinogenesis Between 35 and 45% of American women dye their hair, often at monthly intervals, over a period of years. A number of epidemiological studies have investigated the association between cancer and occupation as a hairdresser or barber, or personal use of hair dyes. IARC (123) concluded that there is inadequate evidence that personal use of hair colorants entails exposures that are carcinogenic. However, IARC concluded that “occupation as a hairdresser or barber entails exposures that are probably carcinogenic.”

2.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA for pyrocatechol is 5 ppm (23 m g/m^3) (124). The NIOSH REL is also 5 ppm (20 m g/m^3) (105). The "S" skin notation in the listing refers to the "potential significant contribution to the overall exposure by the cutaneous route, including mucous membrane and the eyes, either by contact with vapors or, of probable greater significance, by direct skin contact with the substance (124)".

2.6 Studies on Environmental Impact

The EC_{50} for *Pimephales promelas* (fathead minnow) was 9.00 mg/L for 96 h; the effect determined was loss of equilibrium. Similarly, the LC_{50} was reported to be 9.22 mg/L for 96 h (125).

3.0 Resorcinol

3.0.1 CAS Number:

[*108-46-3*]

3.0.2 Synonyms:

1,3-Benzenediol; *m*-dihydroxybenzene, resorcin, 1,3-dihydroxybenzene, 3-hydroxyphenol, CI 76505; *m*-hydroquinone

3.0.3 Trade Names:

Eskamel

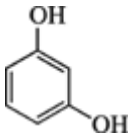
3.0.4 Molecular Weight:

110.11

3.0.5 Molecular Formula:

$C_6H_6O_2$

3.0.6 Molecular Structure:



3.1 Chemical and Physical Properties

White, needle-shaped crystals or rhombic tablets and pyramids, which turn pink on exposure to light and air. It is an acid with pK_a values of 9.51 and 11.32 in water at 30°C.

Specific gravity	1.2717
Melting point	109–111°C
Boiling point	280°C
Vapor density	3.79 (air = 1)
Percent in "saturated" air	2.64% by volume (25.1°C)
Density of "saturated" air	1.0739 (air = 1)
Solubility	Soluble in water, alcohol, glycerol, ether (1)

Flash point	127°C (closed cup)	127°C (closed cup)

3.1.1 General

3.1.2 Odor and Warning Properties Resorcinol has a faint, characteristic odor and a sweetish, followed by a bitter, taste.

3.2 Production and Use

Resorcinol is usually prepared by fusing sodium *m*-benzenedisulfonate with sodium hydroxide. The major use is in the production of resorcinol–formaldehyde adhesives used in tires, automobile belts and hoses, bonding wood products, and neoprene rubbers. It is also used in tanning, in photography, and in the manufacture of explosives, dyes, cosmetics, organic chemicals, antiseptics, resins, and adhesives (13). A minor use is as a bacteriocide in pharmaceuticals for the treatment of acne, psoriasis, eczema, seborrheic dermatitis etc. Resorcinol is used to remove warts, corns, and calluses. Resorcinol is most effective when delivered as an aerosol spray germicide (126).

3.3 Exposure Assessment

NIOSH (127) estimated that 100,000 workers are potentially exposed to resorcinol.

3.3.1 Air: NA

3.3.2 Background Levels: NA

3.3.3 Workplace Methods Air samples can be collected with impingers containing distilled water. If Millipore™ filters are used, about 50% may pass through the filter (17). Analysis can be performed with ultraviolet spectroscopy at 273.5 nm using a 10-cm cell.

3.3.4 Community Methods: NA

3.3.5 Biomonitoring/Biomarkers 3.3.5.1 Blood Detection of free resorcinol in plasma and urine requires the use of HPLC and a simple ethanol extraction. This method is useful to concentrations as low as 0.5%, at which it gives recoveries of greater than 90% with good reproducibility (13).

3.4 Toxic Effects

3.4.1 Experimental Studies 3.4.1.1 Acute Toxicity The primary signs of intoxication resemble those induced by phenol, and include initial stimulation of the CNS, followed by depression, renal glomerular and tubular degeneration, central hepatic necrosis, myocardial depression, pruitis and reddening of the skin. Resorcinol has been reported to be less toxic than phenol or pyrocatechol by oral and dermal routes.

The oral LD_{50} in rats is 0.98 g/kg, and the dermal LD_{50} in rabbits is 3.36 g/kg (17). It is irritating to the eyes and skin; eye irritation included corneal ulcerations that were not reversible. At high dermal doses, it causes irritation and necrosis in a dose-related response (17). Inhalation of aqueous aerosols by rats for 1h at 7.8 g/m^3 (1733 ppm) or 8 h at 2.8 g/m^3 (625 ppm) caused no deaths or gross lesions.

3.4.1.2 Chronic and Subchronic Toxicity Groups of 10 male and female F344 (Fischer 344) rats were given 0, 32, 65, 130, 260, or 520 m g/kg resorcinol by gavage 5 days/week for 13 weeks (126). Most animals at the top dose died. Daily doses of 65 m g/kg produced increased liver weights, but no other toxic effects were reported. When B6C3F1 mice were similarly treated, most mice at the high dose died, but only reduced adrenal weight was noted at other dose levels (126). In subacute inhalation studies rats, rabbits, and guinea pigs were exposed to 34 m g/m^3 (8 ppm) 6 h daily for 2 weeks without any gross toxic effects (17).

3.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Resorcinol was readily absorbed from the GI tract after oral administration to rats, rapidly metabolized and excreted in the urine (128). After an

oral dose of 122–225 m g/kg, >90% of the dose was excreted in the urine and 2% in the feces; 50% of the administered dose underwent enterohepatic circulation. The monoglucuronide conjugate accounted for 70% of the urinary metabolites, together with the monosulfate, diglucronide, and mixed sulfate/glucuronide. There was no evidence of bioaccumulation. Essentially identical results occurred after five pretreatment doses, indicating that conjugation was not saturated at these doses (128).

Similar results were obtained after subcutaneous (SC) administration of 50 or 100 m g/kg of resorcinol to rats (129). Resorcinol was distributed to all tissues but did not accumulate. After 1 h, 62% of the radiolabel appeared in the urine, and 98% within 24 h. Elimination was biphasic with half-lives of 20 min and 8–10hrs. Essentially the same results were obtained after a 30-day pretreatment of 100 m g/kg resorcinol (129).

3.4.1.4 Reproductive and Developmental Resorcinol is not a primary developmental toxicant. When pregnant rabbits were administered resorcinol orally at 40, 80, or 250 m g/kg per day on days 6–18 of gestation, there was no increase in embryonic or fetal deaths, or in congenital malformations (130). Oral administration to pregnant rats on days 6–15 of gestation at 125, 250, or 500 m g/kg per day caused maternal toxicity (reduced body weight) at the top dose, but there was no evidence of developmental toxicity. In a subsequent study rats were dosed with 80 m g/kg per day throughout gestation, producing overt maternal toxicity and some evidence of embryotoxicity; 40 m g/kg per day was a NOEL (130). In another study, daily doses of 125, 250 or 500 m g/kg were administered orally to Sprague–Dawley rats during days 6–15 of gestation (131). There was a slight reduction in maternal body weight gain at the top dose, but no effect on the number of litters, nor on the number of fetal anomalies or malformations.

3.4.1.5 Carcinogenesis Resorcinol was administered in water by gavage 5 days per week for 104 weeks to F344 rats and B6C3F1 mice at maximally tolerated doses; there was no evidence of carcinogenicity in any sex or species (126). Resorcinol at concentrations of 5, 10, or 50% in acetone was applied twice weekly to the ears of rabbits for 180 weeks; there were no local tumors or evidence of systemic toxicity (132).

Orally administered resorcinol did not induce proliferative lesions in hamster forestomach or bladder (133), and was not a promoter of carcinogenesis by other chemicals in these organs in rats (134). However, intraperitoneal (IP) injections of resorcinol did increase the incidence of esophageal tumors induced by a carcinogenic nitrosamine (135).

3.4.1.6 Genetic and Related Cellular Effects Studies Despite positive genotoxic findings in some *in vitro* genotoxicity assays, no positive findings have been reported in any *in vivo* studies in which the conjugation pathways are active (see see Table 53.2) (136–146).

Table 53.2. Genotoxicity of Resorcinol

Test System	Results	Ref.
In vitro Assays		
Salmonella typhimurium bacterial mutagenicity	Negative	14–19, 47, 60, 136–139
Drosophila melanogaster sex-linked recessive lethal	Negative	75
Mouse lymphoma mammalian mutagenicity	Positive	140
Chinese hamster ovary chromosomal	Positive	141

aberrations		
Human lymphocytes chromosomal aberrations	Positive	142
In vivo Assays		
Mouse bone marrow micronucleus	Negative	75, 143
Inhibition of rat DNA synthesis in rat testicular cells	Negative	144
Rat bone marrow micronucleus	Negative	145
Rat bone marrow sister chromatid exchange	Negative	146

3.4.2 Human Experience 3.4.2.1 General Information Few reports of the toxicity of resorcinol have been published. Oral ingestion in humans may cause methemoglobinemia, cyanosis, and convulsions, whereas dermal exposure has been reported to cause dermatitis, hyperemia, and pruritis (13). Industrial inhalation exposures are rather rare, but could occur in any industry if the compound is heated beyond 300°F.

3.4.2.2 Clinical Cases 3.4.2.2.1 Acute Toxicity Pathology reported for humans includes anemia, marked siderosis of the spleen and marked tubular injury in the kidney, fatty changes of the liver, degenerative changes in the kidney, fatty changes of the heart muscle, moderate enlargement and pigmentation of the spleen, and edema and emphysema of the lungs (13).

The cutaneous application of solutions or salves containing 3–5% resorcinol may result in local hyperemia, itching, dermatitis, edema, corrosion, and the loss of the superficial layers of the skin. The allergic/sensitization reactions also include eczematous reactions, erythema, edema, and the formation of vesicles. Burning sensations may also be noted (13). These changes, if they are severe, may be associated with some or all of the following effects: enlargement of regional lymph glands, restlessness, methemoglobinemia, cyanosis, convulsions, tachycardia, dyspnea, and death (13). Ingestion of resorcinol induces similar signs and symptoms. Thus a child, after accidentally swallowing 4 g, complained of dizziness and somnolence. The ingestion of 8 g, in another case, induced an almost immediate hypothermia, fall in blood pressure, and decrease in the rate of respiration, with tremors, icterus, and hemoglobinuria. Recovery was noted 2 h after the poisoning (13). Other cases are on record in which similar doses apparently had no ill effects (13).

3.4.2.2.2 Chronic and Subchronic Toxicity: NA

3.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms Resorcinol is believed to be readily absorbed from the GI tract and, in a suitable solvent, is readily absorbed through the human skin. The compound is excreted in the urine, as are other phenols, in a free state and conjugated with glucuronic, sulfuric, or other acids (13).

3.4.2.3 Epidemiology Studies 3.4.2.3.1 Acute Toxicity In a study of 268 workers in a motorcycle tire manufacturing plant, the presence of dermatitis was directly correlated with exposure to the processes involving resorcinol use (147).

3.4.2.3.2 Chronic and Subchronic Toxicity Resorcinol in certain resins was reported to cause respiratory problems in the rubber industry (13). An epidemiologic study of rubber workers exposed to a hexamethylenetetramine–resorcinol rubber system revealed no specific symptoms caused by resorcinol. The concentrations of resorcinol in air were less than 0.3 m g/m^3 (148). In another study there were no reports of irritation or discomfort by workers when concentrations were 10 ppm or less for periods of 30 min (17).

3.4.2.3.3 Pharmacokinetics, Metabolism, and Mechanisms: NA

3.4.2.3.4 Reproduction and Developmental: NA

3.4.2.3.5 Carcinogenesis: NA

3.4.2.3.6 Genetic and Related Cellular Effects Studies: NA

3.4.2.3.7 Other: Neurological, Pulmonary, Skin Sensitization, *etc* Resorcinol has been reported to cause sensitization and cross-sensitization with other phenolic materials and to cause goiter (13).
3.5 Standards, Regulations, or Guidelines of Exposure
The TLV TWA is 10 ppm (45 m g/m^3). The STEL (short-term exposure limit) is 20 ppm (90 m g/m^3) (149). There is no proposed biological exposure index (BEI). NIOSH REL TWA 10 ppm (45 m g/m^3) STEL/CEIL(c) 20 ppm (90 m g/m^3).

5.1 Chemical and Physical Properties

Physical state	Large, yellow, monoclinic prisms
Specific gravity	1.318 (20°C)
Melting point	115.7°C
Boiling point	293°C
Vapor pressure	Considerable; sublimes readily on gentle heating
Flash point	38°C
Solubility	Soluble in alcohol and ether.
Solubility in water	2.5% at 38°C, 1.4% at 25°C, 1% at 12°C

5.1.1 General Quinone can decompose violently at elevated temperatures and has combustible vapors.

5.1.2 Odor and Warning Properties Quinone has an acrid odor similar to that of chlorine. The vapors are irritating enough to cause sneezing.
5.2 Production and Use
Quinone was produced as early as 1838 by oxidation of quinic acid with manganese dioxide (302). Quinone can be prepared by oxidation starting with aniline or by the oxidation of hydroquinone with bromic acid. More recently quinone has been made biosynthetically from D-glucose (302). The compound has been used in applications in the dye, textile, tanning, and cosmetic industries primarily because of its ability to transform certain nitrogen-containing compounds into a variety of colored substances. In the past, large amounts of quinone were produced as an intermediary for hydroquinone production. Newer production methods eliminate the need for quinone.

5.3 Exposure Assessment
Methods of controlling exposure during manufacture are largely a matter of reducing release by using containment systems and adequate ventilation. Severe local damage to the skin and mucous membranes may occur following contact with solid quinone, solutions of quinone, or quinone vapors condensing on exposed parts of the body (particularly moist surfaces) (303). Thus, skin contact is to be avoided and contaminated clothing should be removed immediately. Personal protection (full-face mask, air-supplied respirator) may be necessary in operations where other controls are not feasible (303). Quinone may be present in areas in which hydroquinone is used, as hydroquinone can be oxidized to quinone under moist or alkaline conditions.

5.3.1 Air Airborne quinone levels in a hydroquinone manufacturing operation have been reported to have declined from a high of 0.27 ppm to 1995 levels, which were <0.05 ppm (280).

5.3.2 Background Levels Quinone occurs naturally in a variety of arthropods that appear to use its irritating properties as a defense mechanism. Quinone containing *Tribolium* (order Coleoptera) beetles may result in contamination of food products, particularly flour (304, 305). Quinone is one of many constituents of tobacco smoke.

Quinone is chemically and photolytically extremely labile, and is assumed to be short-lived in the environment (306). A number of surveys and studies have failed to detect quinone in surfaces waters in the United States (301, 307, 308).

5.3.3 Workplace Methods See section 5.3.4.

5.3.4 Community Methods Air samples can be collected in a midget impinger containing isopropranol. A colored reaction product can be produced with phloroglucinol and read at 520nm (270). This method does not distinguish between quinone and hydroquinone.

5.3.5 Biomonitoring/Biomarkers Quinone forms adducts with cysteine residues of proteins such as hemoglobin and albumin. Background levels of these adducts in blood from people without occupational exposure to quinone are relatively high at >20 nm adducts/g protein (309). Quinone precursors from dietary and endogenous sources are proposed to explain high background levels. Quinone is a metabolite of benzene, phenol, hydroquinone, and acetaminophen; therefore, hemoglobin and albumin adducts do not represent biomarkers specific to quinone. Because of the high level of background adducts in blood, hemoglobin and albumin adducts are not likely to be useful biomarkers for occupational exposure to quinone.

Quinone and hydroquinone are closely related metabolically as quinone can be readily converted enzymatically and nonenzymatically to hydroquinone. Because of this close relationship, background levels of hydroquinone metabolites detected in the blood and urine of individuals without occupational exposure to either quinone or hydroquinone would include background levels of quinone (154).
5.4 Toxic Effects
5.4.1 Experimental Studies 5.4.1.1 Acute Toxicity Single dose oral LD_{50} values of 130 and 165 mg/kg have been reported for rats (4, 13, 14). Unlike hydroquinone, quinone does not produce tremors or convulsions, and death may be delayed for days after dosing (310, 311). Respiratory impairment was the primary effect observed as acute effects following quinone exposure (304). Parenteral exposure results in an LD_{50} value (IV LD_{50} – 25 mg/kg) that is significantly less than the oral LD_{50} (310, 311). No dermal toxicity studies were found in the literature. Woodard reported that quinone vapor was very irritating, causing coughing and sneezing (311). Solid quinone or relatively concentrated solutions are very irritating to the rabbit eye (312). Ocular sensory irritation is seen at a concentration of 0.0001% and acute conjunctivitis at 0.001%. A solution of 0.002% produced cloudiness of the cornea in 24 h and neovascularization in 4 days. The airborne concentration of

quinone that decreases the respiratory rate of mice by 50% (RD_{50}) is reported to be 22.5 m g/m^3 (313).

5.4.1.2 Chronic and Subchronic Toxicity Rats given 25 mg/kg quinone twice a week by SC injection for 2.5–5 months had anemia, methemoglobinemia, decreased serum albumin, and decreased serum cholinesterase (314).

Rats exposed to 2.7–3.6 m g/m^3 quinone 4 h/day for 4 months lost weight, showed easy tiredness, transient anemia, and thrombopenia (314). Two of eight rats exposed to 0.27–0.36 m g/m^3 quinone, 4 h/day for 4 months showed thrombopenia (314).

Mice given 2 mg/kg quinone IP, 6 days/week for 6 weeks manifested decreased red blood cells and lymphocytes, and increased polymorphonuclear leukocytes in their peripheral blood (184). Decreased bone marrow cellularity, decreased relative thymus weight, and increased relative spleen and lymph node weights were also observed in the quinone-dosed mice when compared to a control group.

The usefulness of these data is diminished by incomplete reporting of results. Parenteral administration of quinone is a confounding factor in interpreting these data as the hemogram can be expected to be altered in response to tissue inflammation and destruction caused by exposure to a highly irritating material.

5.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms There are no data available on the pharmacokinetics and metabolism of quinone using expected routes for occupational or environmental exposures. Much of the available mechanistic information has been collected using *in vitro* systems that attempt to model quinone interactions relevant to benzene toxicity.

Quinone vapor can be expected to be readily absorbed through the lungs, and quinone solutions should be readily absorbed from the GI tract. Absorption of solid quinone is likely to be slow because of its low water-solubility unless ingestion with an organic solvent occurs. Absorption of quinone through the skin can be expected; however, binding of quinone to epidermal proteins may reduce absorption when dilute solutions are encountered. Concentrated solutions of quinone may damage the barrier properties of the skin enhancing absorption.

Quinone can be expected to undergo transformations, including (*1*) enzymatic or nonenzymatic reduction and conjugation with glucuronide or sulfate resulting in detoxication and metabolites that are readily excreted in the urine; (*2*) covalent binding to proteins such as hemoglobin and albumin; (*3*) binding to glutathione, which may lead to detoxication or activation depending on the electrochemical state of the metabolite, and (*4*) one-electron reduction by reductases or diaphorases, which may produce a semiquinone and reactive oxygen species via redox cycling. Mean half-lives of 0.68 and 3.5 h have been reported following incubation of 50 mM quinone with fresh F344 rat or human blood at 37°C (309, 315). Hemoglobin and albumin have second-order rate constants of 18 and 76L mol^{-1} h^{-1} for human samples and 180 and 74L mol^{-1} h^{-1} for rat samples (309, 315).

Covalent binding of quinone to critical proteins is an expected mode of action *in vivo*. However, because of its reactive nature, it may not be possible to achieve a toxicologically significant internalized dose at systemic target sites when exposures occur via occupationally or environmentally relevant routes of exposure.

5.4.1.4 Reproductive and Developmental Studies Studies on reproductive and developmental effects for quinone have not been reported. However, these endpoints have been studied for hydroquinone, which is a precursor to quinone (228–230). On the basis of analogy with hydroquinone, quinone would not be expected to be a reproductive or developmental toxicant by common routes of occupational and environmental exposure. In an *in vitro* system, quinone was lethal to rat embryos at

100 mM and reportedly dysmorphogenic at 10 mM but not 50 mM (220).

5.4.1.5 Carcinogenesis Quinone has been tested for carcinogenicity in mice by skin application or inhalation and in rats by subcutaneous injection. None of these studies were considered sufficient to evaluate carcinogenicity (316, 317). A cancer bioassay of tribolium infested flour has been conducted but lack of quantification of quinone and methodological issues make the data difficult to interpret (305).

Quinone has produced negative results in studies designed to examine its ability to promote carcinogenicity. In a liver bioassay, quinone did not increase the formation of GGT-positive foci in the liver (241). Quinone did not promote induction of stomach or skin tumors in mice dosed with 7,12-dimethylbenzanthracene (318, 319).

5.4.1.6 Genetic and Related Cellular Effects Studies Genotoxicity assays with quinone have recently been reviewed by IARC (317). The results of several Ames/*Salmonella* assays were as a group inconclusive; however, mutations in *Neurospora* were increased. DNA strand breaks, mutations at the *hgprt* locus, and micronuclei were induced in mammalian cells *in vitro*. Weakly positive micronuclei responses were observed in mice dosed by gavage. A dominant lethal assay in mice given quinone IP was negative at a dose level of 6.25 mg/kg. These test results indicate that quinone is weakly positive for genotoxicity *in vivo*.

5.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization Quinone produced an extreme skin sensitization response in the guinea pig maximization test (Magnusson–Kligman test) and positive response in the mouse local lymph node assay (261). Rajka and Blohm (256) found that quinone sensitized 19 of 20 guinea pigs given 10 daily injections of 0.001% quinone. Studies on cross sensitization with *p*-phenylenediamine are inconclusive (320, 321).

Numerous cytotoxicity tests have been conducted with quinone (314). Most of these studies have examined bone marrow cells in attempts to elucidate the mode of action of benzene, as quinone is one of the metabolites of benzene. These studies do not provide information that is readily applicable to common routes of quinone exposure.

5.4.2 Human Experience 5.4.2.1 General Information Skin contact with quinone can be expected to temporarily stain the skin a brownish color.

5.4.2.2 Clinical Cases 5.4.2.2.1 Acute Toxicity Reports of acute toxicity following exposure to quinone have not been published.

5.4.2.2.2 Chronic and Subchronic Toxicity Sterner et al. (270), Anderson (272), Anderson and Oglesby (275), and Oglesby et al. (271) reported that in a manufacturing process that produced hydroquinone by reduction of quinone, discoloration of the eyes and in some cases more serious ocular damages were seen among production workers. The changes occurred over a period of years, and no serious ocular cases were observed with less than 5 years of exposure.

Initially, there was brown staining of the conjunctiva. This pigment deposition in the conjunctiva did not impair vision; however, its presence was evidence of exposure, and its increase or decrease was used as an indication of the severity of exposure to hydroquinone dust and quinone vapor.

With continued eye exposure to high concentrations of hydroquinone and quinone, pigment deposition extended into the cornea, and structural alterations of the cornea occurred that impaired vision. One of the first complaints of individuals with corneal involvement was difficulty driving at night as light beams from oncoming automobiles were scattered and reflected by the corneal alterations.

The reports by Sterner et al. (270), Anderson (272), and Oglesby et al. (271) led to the establishment

of an ACGIH TLV of 0.1 ppm quinone vapor.

No evidence of systemic toxicity was seen in a group of hydroquinone production workers who were exposed to quinone vapor and hydroquinone dust (154, 280).

5.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms Pharmacokinetics and metabolism studies with quinone have not been published.

5.4.2.2.4 Reproductive and Developmental Studies Case studies of reproductive or developmental toxicity following quinone exposure have not been reported.

5.4.2.2.5 Carcinogenesis Case studies of carcinogenicity following exposure to quinone have not been reported.

5.4.2.2.6 Genetic and Related Cellular Effects Studies Case studies of adverse genotoxic effects following exposure to quinone have not been reported.

5.4.2.2.7 Other: Neurological, Pulmonary, Skin Sensitization, etc Case studies of neurologic, pulmonary, sensitization or other adverse health effects following quinone exposure have not been reported.

5.4.2.3 Epidemiology Studies A cohort study of hydroquinone production workers who were also exposed to quinone reported significantly lower mortality due to a number of disease endpoints including cancer when compared to a general population control (279).

Pifer et al. (280) reported that a cohort of 879 men and women involved in manufacturing hydroquinone using a process that included production of quinone had significantly lower death rates for malignant and nonmalignant diseases when compared to general population and employed referent groups.

5.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV, OSHA PEL, NIOSH REL, and German MAK values for quinone are 0.1 ppm as an 8 h TWA. The NIOSH IDLH value was 100 mg/m^3.

5.6 Studies on Environmental Impact

In the past, large amounts of quinone were produced in the United States as an intermediary for hydroquinone production. Newer production methods eliminate the need for quinone. Therefore, releases of quinone from U.S. manufacturing sites to the environment have been decreasing steadily for several years according to Toxic Release Inventory (TRI) reports. TRI reports for the year 1997 included no releases of quinone to air, water, or land (322). In countries such as China, and India, where the aniline oxidation method continues to be used to produce hydroquinone, releases of quinone to the environment may occur. Environmental surveys of industrial sites in the United States have failed to detect quinone in surface waters (301, 307, 308).

Because of its low water solubility and vapor pressure, quinone is likely to partition into the atmosphere, if released. As a result of photolysis and chemical lability, quinone is expected to be short-lived in the environment following release (306). Since chemical structures such as quinone are readily metabolized by microorganisms, biodegradation is expected to be rapid. Polymeric forms of quinone are known as humic acids, which are common constituents of soil.

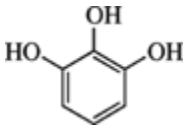
6.0 Pyrogallol
6.0.1 CAS Number:
[*87-66-1*]
6.0.2 Synonyms:
Pyrogallic acid; pyro; 1,2,3-trihydroxybenzene; 1,2,3-benzenetriol; fouramine base ap; Benzenetriol
6.0.3 Trade Names:
CI 76515; CI Oxidation Base 32; Fouramine Brown AP; Fourrine 85; Fourrine PG; Piral
6.0.4 Molecular Weight:
126.11
6.0.5 Molecular Formula:
$C_6H_6O_3$
6.0.6 Molecular Structure:



6.1 Chemical and Physical Properties

Physical state	White, or nearly white needle or leaf-shaped crystals or crystalline powder
Specific gravity	1.453 (4°C)
Melting point	131–134°C
Boiling point	309°C (decomposes at 293°C)
Solubility	Soluble in water (1–2), alcohol (1–1.5), and ether (1–2) at 25°C

6.1.2 Odor and Warning Properties Pyrogallol is practically odorless.
6.2 Production and Use
Pyrogallol is prepared by heating dried gallic acid at about 200°C with the loss of carbon dioxide (13) or by the chlorination of cyclohexanol to tetrachlorocyclohexanone, followed by hydrolysis (323). Pyrogallol's commercial use is based primarily on the fact that it is easily oxidized in alkaline solutions (even by atmospheric oxygen), so that such solutions become potent reducing agents. It is used specifically as a developer in photography and for maintaining anaerobic conditions for bacterial growth. It is additionally used in dyeing operations, the oxidized products being dark blue, process engraving, and as a topical antibacterial agent (13).
6.3 Exposure Assessment
6.3.1 Air: NA

6.3.2 Background Levels: NA

6.3.3 Workplace Methods: NA

6.3.4 Community Methods: NA

6.3.5 Biomonitoring/Biomarkers 6.3.5.1 Blood: NA

6.3.5.2 Urine The content of pyrogallol in the urine can be determined by various methods (324).
6.4 Toxic Effects

6.4.1 Experimental Studies 6.4.1.1 Acute Toxicity The oral LD_{50} for technical synthetic pyrogallol (92%, as a 500 mg/kg aqueous solution) in Sprague–Dawley rats was 1270 (males) and 800 (females) mg/kg (summarized in Ref. 323). Clinical observations included cyanosis, reduced activity, reduced muscle tone, body tremors, ataxia, lacrimation, salivation, piloerection, coolness to touch, hunched posture, pale extremities, and general soiling. General observations on gross necropsy included cyanosis, dark and/or enlarged spleen, dark kidneys, brown or pale liver and lungs, distension of the stomach and bladder, and fluid in the intestines.

Because of its marked reducing action, pyrogallol has a tremendous affinity for the oxygen of the blood. There was extensive destruction and fragmentation of the erythrocytes. Death is initiated by respiratory failure. The urine of poisoned animals may contain casts, glucose, hemoglobin, methemoglobin, urobilin, and other compounds that cause discoloration (323).

The dermal LD_{50} in rats administered pyrogallol in aqueous solution for 24 h under occlusion exceeded 2100 mg/kg (323). Clinical observations in females included cyanosis and pale extremities; the treated skin and surrounding fur of all animals was stained brown.

6.4.1.2 Chronic and Subchronic Toxicity Repeated absorption of toxic but sublethal concentrations into the tissues of animals has been found to cause severe anemia, icterus, nephritis, and uremia. The approximate lethal dosages of pyrogallol in aqueous solution for various animals species, under varying conditions of administration, was reported to be (324) rabbit, 1.1 g/kg (orally); rabbit or guinea pig, 10 g/kg (SC); dog or cat, 0.35 g/kg (SC); and dog, 0.09 g/kg (IV). Pathological changes in animals caused by pyrogallol include edema and hyperemia of the lungs, and moderate fatty degeneration, round cell infiltration, and necrosis of the liver. The kidneys may show hyperemia, necrosis of the epithelium, granular pigmentation, and glomerular nephritis (13). Changes of the bone marrow and myeloid changes in the spleen were noted after chronic administration of this compound (13).

6.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Pyrogallol is readily absorbed from the GI tract and from parenteral sites of injection. Little is absorbed through the intact skin. The bulk of absorbed pyrogallol is readily conjugated with glucuronic, sulfuric, or other acids and excreted within 24 h via the kidneys (13). When rats were administered 100 mg/kg pyrogallol, both pyrogallol and 2-*O*-methylpyrogallol were recovered in the urine as hydrolyzable conjugates; there was no unconjugated pyrogallol. Traces of resorcinol were detected in the feces suggesting that pyrogallol could be reduced (325).

6.4.1.4 Reproductive and Developmental A multigeneration rat reproduction study was conducted with a hair dye containing 0.4% pyrogallol applied to the skin twice per week during mating, gestation, and lactation through weaning (323). There were no treatment-related effects on reproduction, and only mild skin reactions at the application site noted intermittently.

Pyrogallol in propylene glycol was administered to pregnant Sprague–Dawley rats during days 6–15 of gestation at doses of 100, 200, or 300 mg/kg. There were no maternal mortalities, but at the top dose there was a decrease in maternal body weight gain, smaller fetuses, and an increase in the number of fetal resorptions. The numbers of fetal implants and abnormalities were not affected (326).

6.4.1.5 Carcinogenesis Pyrogallol was not carcinogenic in mouse and rabbit chronic dermal studies. Mice were treated twice weekly with pyrogallol in acetone (50%) on the shaved flank for life. There was no increase in dermal or systemic tumors (327). A similar study in rabbits also revealed no skin tumors, although positive controls showed an increase in tumors in both mice and rabbits (132).

Pyrogallol was considered to be cocarcinogenic when administered dermally three times a week together with the skin carcinogen benzo[a]pyrene for 440 days; pyrogallol administered alone caused

no increase in skin tumors (231).

6.4.1.6 Genetic and Related Cellular Effects Studies Pyrogallol was mutagenic in nearly all systems (323). Most of the assays were performed *in vitro*, but pyrogallol was also positive in *in vivo* assays. There was an increase in sex-linked recessive lethal mutations in *Drosophila melanogaster*, in mouse micronuclei (75), and in chromatid breaks in bone marrow cells of mice injected intraperitoneally with pyrogallol (323).

6.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization Powdered pyrogallol was an ocular irritant, but not when tested at a concentration of 1% in propylene glycol (323). Powdered pyrogallol was slightly irritating when tested under dermal occlusion for 24 h in rabbits, and a 50% aqueous solution was slightly irritating in guinea pigs (323). Pyrogallol was reported to be a skin sensitizer when tested in guinea pigs by one unconventional procedure, but was negative in a second study using intradermal and dermal induction, and topical challenge applications (323).

6.4.2 Human Experience 6.4.2.1 General Information: NA

6.4.2.2 Clinical Cases 6.4.2.2.1 Acute Toxicity Cases of human poisoning have not been frequent. Cases reported in the older literature include one man who ingested an aqueous solution containing 8g of pyrogallol and who recovered after suffering an acute intoxication; another, who ingested 15 g of this compound, died despite prompt vomiting (13). Signs of acute intoxication include vomiting, hypothermia, fine tremors, muscular incoordination, diarrhea, loss of reflexes, coma, and asphyxia (13). When applied to the human skin in the form of a salve, it can cause local discoloration, irritation, eczema, and even death. Repeated contact with the skin has been reported to cause sensitization (13). The symptoms observed in acute intoxications in humans resemble closely the signs of illness displayed by experimental animals.

6.4.2.2.2 Chronic and subchronic Toxicity: NA

6.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms Pyrogallol detected in human urine presumably results from intestinal bacterial decarboxylation of gallic acid, an ingredient in tea (324).

6.4.2.2.4 Reproductive and Developmental: NA

6.4.2.2.5 Carcinognesis: NA

6.4.2.2.6 Genetic and Related Cellular Effects Studies: NA

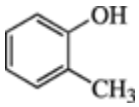
6.4.2.2.7 Other: Neurological, Pulmonary, Skin Sensitization, *etc* Positive skin sensitization reactions to pyrogallol were reported in 25 patch-tested patients with leg ulcers (328). In contrast, there were no positive responses when 8230 patients with allergic contact dermatitis were patch tested with pyrogallol (1% in petrolatum) (329).

Phenol and Phenolics

Ralph Gingell, Ph.D., DABT, John O'Donoghue, Ph.D., DABT, Robert J. Staab, Ph.D., DABT, Ira W. Daly, Ph.D., DABT, Bruce K. Bernard, Ph.D., Anish Ranpuria, MS, E. John Wilkinson, Daniel Woltering, Ph.D., Phillip A. Johns, Ph.D., Stephen B. Montgomery, Ph.D., Larry E. Hammond, Ph.D., Marguerita L. Leng, Ph.D.

7.0 **o**-Cresol
7.0.1 CAS Number:

[*95-48-7*]
7.0.2 Synonyms:
2-Methylphenol; phenol, 2-methyl; 2-cresol; *o*-cresylic acid; 1-hydroxy-2-methylbenzene; 2-hydroxytoluene; *o*-hydroxytoluene; *o*-methylphenol; *o*-methylphenylol; *o*-oxytoluene; *o*-toluol
7.0.3 Trade Names:
NA
7.0.4 Molecular Weight:
108.14
7.0.5 Molecular Formula:
C_7H_8O
7.0.6 Molecular Structure:



7.1 Chemical and Physical Properties

Physical state	colorless, yellowish, or pinkish crystals, darkens with age and exposure to light and air (330, 331). *o*-Cresol can also appear as a liquid
Odor	Phenolic odor, with an odor threshold of 5 ppm; sometimes referred to as an *empyreumatic* odor
Specific gravity	1.030–1.038 (*o*-), (*m*-), (*p*-)
Melting point	11–35°C (mixture)/31°C (*o*-)/12°C (*m*-)/35°C (*p*-) (330, 332)
Boiling point	191–203°C (mixture)/191°C (*o*-)/202°C (*m*-)/202°C (*p*-) (330)
Vapor density	3.72 (air = 1) (332)
Vapor pressure	(25°C) 0.29torr (*o*-)/0.14torr (*m*-)/ 0.11torr (*p*-) at 25°C
Refractive index	1.537
Density of saturated air	1.00089 [air = 1]
Flash point	82°C (mixture)/81°C (*o*-)/86°C/*m*- *p*-) (all closed cup) (332)

Other characteristics are as follows:

Flammability. o-Cresol is combustible and presents a marked fire hazard. Fires can be extinguished with water, carbon dioxide, appropriate foam, or dry chemicals. Mixtures of air and 1.47% *o*-cresol are explosive (332).

Solubility. o-Cresol is soluble in organic solvents, vegetable oils, alcohol, ether, glycerin, chloroform, and dilute alkali; also in 40 parts water (330, 333).

7.1.1 General: NA

7.1.2 Odor and Warning Properties *o*-Cresol has a distinct phenolic odor discernible at 5 ppm. Taste has not been noted in the available literature.
7.2 Production and Use
The cresols (cresylic acids) are methyl phenols and generally appear as a mixture of isomers (330). *o*-Cresol is a 2-methyl derivative of phenol (335) and is prepared from *o*-toluic acid or obtained from coal tar or petroleum (333, 336). Crude cresol is obtained by distilling “gray phenic acid” at a temperature of ~180–201°C. *o*-Cresol may be separated from the crude or purified mixture by

repeated fractional distillation *in vacuo*. It can also be prepared synthetically by diazotization of the specific toluidine, or by fusion of the corresponding toluenesulfonic acid with sodium hydroxide.

o-Cresol is used as a disinfectant and solvent (330). Lysol™ disinfectant is a 50% v/v mixed-cresol isomer in a soap emsulion formed on mixing with water. Besides disinfection products at solutions of 1–5% (333), the cresols are used as degreasing compounds, paintbrush cleaners, and additives in lubricating oils (334). Cresols were previously widely used for disinfection of poultry houses, but this use was discontinued because of their toxicity; they cause respiratory problems and abdominal edema in young chicks (337). *o*-Cresol has been used in synthetic resins, explosives, petroleum, photographic, paint, and agricultural industries.

7.3 Exposure Assessment

With rare exceptions, human exposure in industry has been limited to accidental contact of *o*-cresol with the skin or inhalation of vapors (335).

7.3.1 Air: NA

7.3.2 Background Levels: NA

7.3.3 Workplace Methods Air sampling and analytical methods for personal monitoring are essentially the same manner as for phenol. Cresol is absorbed in dilute alkali and determined colorimetrically with diazotized *p*-nitroaniline reagent (339), absorbed in spectrograde alcohol with direct determination by ultraviolet spectrophotometry (340), or absorbed on silica and determined by gas–liquid chromatography (341). One sampling procedure consists of drawing a known volume of air through a silica gel tube consisting of two 20/40-mesh silica-gel sections, 150 and 75 mg, separated by a 2-mm portion of urethane foam. Acetone desorbed samples can be analyzed using gas chromatography with a flame ionization detector. The column is packed with 10% free fatty-acid polymer in 80/100 mesh, acid-washed DMCS Chromosorb W. The useful range of this method is 5–60 mg/m^3 (341).

7.3.4 Community Methods: NA

7.3.5 Biomonitorng/Biomarkers A sensitive method for the detection of cresol and metabolites in serum has been reported (342).

7.4 Toxic Effects

7.4.1 Experimental Studies 7.4.1.1 Acute Toxicity

Dermal. The dermal LD_{50} of *o*-cresol was 890 mg/kg in rabbits (18). Toxic symptoms are similar after oral and dermal routes.

Inhalation. No verifiable LC_{50} values have been reported, but rats survived a 1-h, exposure to 1220 mg/m^3 (340) and mice apparently survived a 2-h exposure [179 mg/m^3] to *o*-cresol (340).

Irritation and Sensitization. o-Cresol, undiluted and in solution, can cause severe local irritation and corrosion following dermal and ocular exposure. Irritant effects include severe skin lesions, edema, erythema, and necrosis. In a study using rabbits that were dosed with 524 mg *o*-cresol for 24 h under occlusion, severe skin effects were produced (340). Eye irritation can be severe and include corneal opacity.

7.4.1.2 Chronic and Subchronic Toxicity *o*-Cresol was tested for subchronic toxicity in animal studies of 28 and 90days' duration by dietary administration.

Ingestion by Diet In a 28-day study, F344/N rats and B6C3F$_1$ mice of both sexes (5/sex/group) were given *o*-cresol at concentrations of 300–30,000 ppm in the diet. All rats survived until study termination; some mice died at the 10,000- and 30,000-ppm dietary levels. Increased liver weights and kidney weights were noted in both species at doses as low as 3000 ppm. No microscopic

changes were associated with the organ weight changes. Bone marrow hyperplasia and atrophy of the uterus, ovary, and mammary gland were seen in the 10,000- and 30,000-ppm dietary groups (343).

In a 90-day study, F344/N rats (20/sex/dose) and $B6C3F_1$ mice (10/sex/dose) of both sexes received dietary administration of ≤30,000 ppm *o*-cresol (rats) and ≤20,000 ppm *o*-cresol (mice). No deaths in either species were related to administration of *o*-cresol. Hematology, clinical chemistry, and urinalysis were unremarkable; however, bile acid accumulation in the high dose rats was observed. Mild bone marrow hypocellularity in rats and forestomach hyperplasia in mice was revealed in animals with the higher doses (343).

7.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Cresol is absorbed through the skin, open wounds, and mucous membranes of the gastroenteric and respiratory tracts. The rate of absorption through the skin depends on the size of the area exposed rather than the concentration of the material applied (340). The metabolism and the rate of absorption, detoxification, and excretion of the cresols are much like those for phenol; they are oxidized and excreted as glucuronide and sulfate conjugates.

7.4.1.3.1 Absorption: NA

7.4.1.3.2 Distribution: NA

7.4.1.3.3 Excretion The major route of excretion of the cresols is in the urine. The *o*- and *m*- cresols are ring-hydroxylated to a small extent, whereas the *p*-cresol gives rise to the formation of some *p*-hydroxybenzoic acid. 2,5-Dihydroxytoluene has been isolated from the urine of rabbits fed *o*- and *m*-cresols, and *p*-hydroxybenzoic acid and *p*-cresylglucuronide from those administered *p*-cresol (340).

7.4.1.4 Reproductive and Developmental Although no reproductive or developmental toxicity studies were conducted on *o*-cresol, two subchronic assays did investigate the effect on the reproductive organs. In a 28-day subchronic study of *o*-cresol at doses of ≤30,000 ppm in the diet to both sexes of rats and mice, reproductive tissue evaluations showed no indication of adverse effects in the male reproductive system. The estrus cycle was, however, lengthened in rats and mice receiving 10,000 or 20,000 ppm *o*-cresol (343). In a 90-day study of *o*-cresol administered in the diet to rats and mice of both sexes, the reproductive organs were evaluated. Atrophy of the female reproductive organs was noted occasionally at 10,000 ppm, but more consistently at 30,000 ppm (343).

7.4.1.5 Carcinogenesis *o*-Cresol has been investigated for tumor promotion following induction by polycyclic aromatic hydrocarbons, but does not appear to be a tumorigen.

Skin Application Female Sutter mice (27–29/group) were dosed with a single application of dimethylbenzanthracene followed one week later by 25 mL of a 20% solution of *o*-cresol in benzene twice weekly for 12 weeks. Benzene-treated controls did not experience mortality, although many of the cresol mice died. *o*-Cresol produced 10/17 tumors (papillomas) on surviving mice (234). In another promotion study, mice were painted with a 20% solution of *o*-cresol for 11 weeks following initiation with dimethylbenzanthracene. No carcinomas were produced (344).

7.4.1.6 Genetic and Related Cellular Effects Studies In an unscheduled DNA synthesis assay, *o*-cresol was shown to be negative using rat hepatocytes (345). A cell transformation assay using BALB/3T3 cells showed *o*-cresol to be negative (346). *Salmonella* assays of various strains, both with and without liver homogenate, showed no mutagenic activity (59, 60, 347). In a mouse lymphoma forward mutation assay with liver homogenate, *o*-cresol was not mutagenic (345). Sister chromatid exchange (SCE) assays produced no evidence of mutagenicity in CHO (Chinese hamster ovary) cells (346). *o*-Cresol induced sister chromatid exchange in human lung fibroblasts (345, 348).

7.4.2 Human Experience 7.4.2.1 General Information Cresols can cause local and systemic toxicity in humans after exposure by oral or dermal exposure.

7.4.2.2 Clinical Cases Approximately 20 mL of a 90% solution of mixed cresol solution caused chemical burns, cyanosis, unconsciousness, and death within 4h when accidentally poured on an infant's head. Hepatic necrosis; cerebral edema; acute tubular necrosis of the kidneys; and hemorrhagic effusions from the peritoneum, pleura, and pericardium were observed postmortem. Blood cresol concentration was 120 mg/mL (349).

7.4.2.2.1 Acute Toxicity Oral lethality data from Lysol™ (which contains 50% mixed cresols) has been estimated to be between 60 and 120 mL (352). Ingestion is associated with corrosivity to body tissues and toxicity to the vascular system, liver, kidneys, and pancreas (344).

7.4.2.2.2 Chronic and Subchronic Toxicity Chronic cresol poisoning has been infrequently reported. About 10 subjects were exposed to *o*-cresol at 1.4 ppm and complained of respiratory tract irritation (350). Documentation was not confirmed. Seven workers who were exposed to mixed cresols vapor for 1.5–3 years experienced headaches, nausea, and vomiting. Some of those exposed also had elevated blood pressure, signs of impaired kidney function, blood calcium imbalance, and marked tremors (350).

7.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms Cresols are normally present in human urine.
7.5 Standards, Regulations, or Guidelines of Exposure
The American Conference of Governmental Industrial Hygienists (ACGIH) TLV TWA for cresol is 5 ppm (22 mg/m^3) with a “skin” notation (351). The OSHA permissible exposure limit (PEL) is also 5 ppm (22 mg/m^3) with a skin notation (351). The “skin” notation in the listing refers to “the potential significant contribution to the overall exposure by the dermal route, including mucous membranes and the eyes, either by contact with vapors or, of probable greater significance, by direct skin contact with the substance. The NIOSH REL TWA is 2.3 ppm (10 mg/m^3); the IDLH is 250 ppm.

Treatment of Cresol Ingestion Treatment should be supportive and symptomatic. There are no known antidotes (335).

Skin Decontamination Treatments after Accidental Exposure of Phenol Skin contact should be treated by washing with copious amounts of water, then bathing in glycerol, propylene glycol, or polyethylene glycol. Patients may require ventilatory support (335).

hydroxytoluene; *m*-hydroxytoluene; *m*-methylphenol; *m*-methylphenylol; *m*-oxytoluene; *m*-toluol; *m*-cresylic; 3-methyl-1-hydroxybenzene; 1-hydroxy-3-methylbenzene; *m*-kresol; hydroxy-3-methylbenzene

8.0.3 Trade Names:

NA

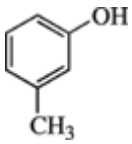
8.0.4 Molecular Weight:

108.14

8.0.5 Molecular Formula:

C_7H_8O

8.0.6 Molecular Structure:



8.1 Chemical and Physical Properties

Physical state	Colorless, yellowish, or pinkish liquid, darkens with age and exposure to light and air (330, 331)
Odor	Phenolic odor, with an odor threshold of 5 ppm; sometimes refered to as an *empyreumatic* odor
Specific gravity	1.030–1.038 (mixture)
Melting point	11–35°C (mixture)/31°C (*o*-)/12°C (*m*-)
Boiling point	191–203°C (mixture)/191°C (*o*-)/202°C (*m*-)
Vapor density	1.034 air = 1
Flash point	82°C (mixture)/81°C (*o*-)/86°C (*m*-, *p*-) (all closed cup)

Other properties are as follows:

Flammability. *m*-Cresol is combustible and presents a marked fire hazard. *m*-Cresol fires can be extinguished with water, carbon dioxide, appropriate foam, or dry chemicals. Mixtures of air and 1.47% *m*-cresol are explosive (332).

Solubility. *m*-Cresol is soluble in organic solvents, vegetable oils alcohol, ether, glycerin, chloroform, and dilute alkali; also in 40 parts water (330, 331).

8.1.1 General: NA

8.1.2 Odor and Warning Properties *m*-Cresol has a distinct phenolic odor discernable at 5 ppm.

8.2 Production and Use

The cresols (cresylic acids) are methyl phenols and generally appear as a mixture of isomers (334). *m*-Cresol is prepared from *m*-toluic acid or obtained from coal tar or petroleum (331, 335, 336). Crude cresol is obtained by distilling "gray phenic acid" at a temperature of ~180–201°C. The *m*-cresol may be separated from the crude or purified mixture by repeated fractional distillation *in vacuo*. It can also be prepared synthetically by diazotization of the specific toluidine, or by fusion of the corresponding toluenesulfonic acid with sodium hydroxide.

m-Cresol is used as a disinfectant and solvent (330). Lysol™ disinfectant is a 50% v/v mixed-cresol isomer in a soap emulsion formed on mixing with water. The isomer *m*-cresol is an oily liquid with

low volatility. Besides disinfection at solutions of 1–5% (331), the cresols are used in degreasing compounds, paintbrush cleaners, and additives in lubricating oils (334). Cresols were once widely used for disinfection of poultry houses but this use has been discontinued because they cause respiratory problems and abdominal edema in young chicks (337). *m*-Creosl has been used in synthetic resins, explosives, petroleum, photographic, paint, and agricultural industries.

8.3 Exposure Assessment

With rare exceptions, human exposure in industry has been limited to accidental contact of *m*-cresol with the skin or inhalation of vapors (335).

8.3.1 Air: NA

8.3.2 Background Levels: NA

8.3.3 Workplace Methods Air sampling and analytical methods for personal monitoring are essentially the same as for phenol. Cresol is absorbed in dilute alkali and determined colorimetrically with diazotized *p*-nitroaniline reagent (339), absorbed in spectrograde alcohol with direct determination by ultraviolet spectrophotometry, or absorbed on silica and determined by gas–liquid chromatography (340). One sampling procedure consists of drawing a known volume of air through a silica-gel tube consisting of two 20/40-mesh silica gel sections, 150 and 75 mg, separated by a 2-mm portion of urethane foam. Acetone-desorbed samples can be analyzed using gas chromatography with a flame ionization detector. The column is packed with 10% free fatty-acid polymer in 80/100-mesh, acid-washed DMCS Chromosorb W. The useful range of this method is 5–60 mg/m^3 (341).

8.3.4 Community Methods

8.3.5 Biomonitoring A sensitive method for the detection of cresol and metabolites in serum has been reported (342).

8.4 Toxic Effects

8.4.1 Experimental Studies 8.4.1.1 Acute Toxicity

Ingestion. Orally administered *m*-cresol is moderately to acutely toxic in animals. After oral administration to rats, the LD_{50} value was determined to be 2.02 g/kg body weight (340). It is considered to have about the same general degree of toxicity as phenol, but to be slightly less corrosive than phenol with slower absorption, which accounts for slightly milder systemic effects. *m*-Cresol is somewhat less toxic and less irritating than phenol (340). Corrosion to the GI tract and mouth is expected following cresol exposure with similar effects as phenol. Following oral administration, kidney tubule damage, nodular pneumonia, and congestion of the liver with pallor and necrosis of the hepatic cells is seen. Acute exposure can cause muscular weakness, GI disturbances, severe depression, collapse, and death.

Dermal. The dermal LD_{50} in rabbits of *m*-cresol was 2050 mg/kg (340). Toxic symptoms are similar after oral and dermal routes.

Inhalation. No verifiable LC_{50} values have been reported, but rats survived 1 h exposure to 710 mg/m^3 (340).

Irritation and Sensitization. m-Cresol, undiluted and in solution, can cause severe local irritation and corrosion following dermal and ocular exposure. Irritant effects include severe skin lesions, edema, erythema, and necrosis. In a study using rabbits that were dosed with 517 mg *m*-cresol for 24 h under occlusion, severe skin effects were produced (340). Eye irritation can be severe and include corneal opacity.

8.4.1.2 Chronic and Subchronic Toxicity *m*-Cresol was tested for subchronic toxicity in animal studies of 28 and 90 days duration by dietary administration.

Ingestion by Diet In a 28-day study, F344/N rats and B6C3F$_1$ mice of both sexes (5/sex/group) were given *m*-cresol at concentrations of from 300–30,000 ppm in the diet. All rats survived until study termination; some mice died at the 10,000 and 30,000 ppm dietary levels. Increased liver weights and kidney weights were noted in both species at doses as low as 3000 ppm. No microscopic changes were associated with the weight changes. Bone marrow hyperplasia and atrophy of the uterus, ovary, and mammary gland were seen occasionally in both the 10,000- and 30,000-ppm groups (343).

8.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Cresol is absorbed through the skin and open wounds and mucous membranes of the gastroenteric and respiratory tracts. The absorption rate through the skin depends on the size of the area exposed rather than the concentration of the material applied (340).

The metabolism and the rate of absorption, detoxification, and excretion of the cresol are much like those for phenol; they are oxidized and excreted as glucuronide and sulfate conjugates.

8.4.1.3.1 Absorption: NA

8.4.1.3.2 Distribution: NA

8.4.1.3.3 Excretion The major route of excretion of the cresols is in the urine. Both *o*- and *m*-cresols are ring-hydroxylated to a small extent, whereas *p*-cresol gives rise to the formation of some *p*-hydroxybenzioc acid. 2,5-Dihydroxytoluene has been isolated from the urine of rabbits fed *o*- and *m*-cresols, and *p*-hydroxybenzoic acid and *p*-cresylglucuronide from those administered *p*-cresol (340).

8.4.1.4 Reproductive and Developmental: NA

8.4.1.5 Carcinogenesis *m*-Cresol has induced a few papillomas but no carcinomas in tumor studies.

Skin Application Female Sutter mice (27–29/group) were dosed with a single application of dimethylbenzanthracene followed one week later by 25 mL of a 20% solution of *m*-cresol in benzene twice weekly for 12 weeks. Benzene-treated controls did not experience mortality, although many of the cresol-treated mice died. *m*-Cresol produced 7/17 tumors (papillomas) in surviving mice (234). In another promotion study, mice were painted with a 20% solution of *m*-cresol for 11 weeks following initiation with dimethylbenzanthracene; no carcinomas were produced (344).

8.4.1.6 Genetic and Related Cellular Effects studies *Salmonella* assays of various strains, both with and without liver homogenate, showed no mutagenic activity (57, 60, 345–348). Sister chromatid exchange assays produced no evidence of mutagenicity in CHO cells (346).

8.4.2 Human Experience 8.4.2.1 General Information Cresols can cause local and systemic toxicity in humans after exposure by oral or dermal routes.

8.4.2.2 Clinical Cases Approximately 20 mL of a 90% solution of mixed-cresol solution caused chemical burns, cyanosis, unconsciousness, and death within 4h when accidentally poured on an infant's head. Hepatic necrosis; cerebral edema; acute tubular necrosis of the kidneys; and hemorrhagic effusions from the peritoneum, pleura, and pericardium were observed postmortem. Blood cresol concentration was 120 mg/mL (349).

8.4.2.2.1 Acute Toxicity Oral lethality data from Lysol™, which is 50% mixed cresols, has been estimated to be between 60 and 120 mL (352). Ingestion is associated with corrosivity to body tissue and toxicity to the vascular system, liver, kidneys, and pancreas (344).

8.4.2.2.2 Chronic and Subchronic Toxicity Chronic cresol poisoning has been infrequently reported.

Seven workers who were exposed to mixed-cresol vapor for 1.5–3 years experienced headaches, nausea, and vomiting. Some of those exposed also had elevated blood pressure, signs of impaired kidney function, blood calcium imbalance, and marked tremors (344).

8.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms Cresols are normally present in human urine.

8.4.2.2.4 Reproductive and Developmental: NA

8.4.2.2.5 Carcinogenesis: NA

8.4.2.2.6 Genetic and Related Cellular Effects Studies: NA

8.4.2.2.7 Other: Neurological, Pulmonary, Skin Sensitization, *etc* All isomers of cresol cause renal toxicity, hepatic toxicity, and CNS and cardiovascular disturbances (335).
8.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV TWA for cresol is 5 ppm (22 mg/m^3) with a "skin" notation (351). The OSHA PEL is also 5 ppm with a "skin" notation (350). The "skin" notation in the listing refers to "the potential significant contribution to the overall exposure by the dermal route, including mucous membranes and the eyes, either by contact with vapors or, of probable greater significance, by direct skin contact with the substance." The NIOSH REL TWA is 2.3 ppm (10 mg/m^3); the IDLH value is 250 ppm.

Treatment of Cresol Ingestion Treatment should be supportive and symptomatic. There are no known antidotes (335).

Skin Decontamination Treatments after Accidental Exposure of Phenol Skin contact should be treated by washing with copious amounts of water, then bathing in glycerol, propylene glycol, or polyethylene glycol. Patients may require ventilatory support (335).

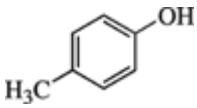
9.0.6 Molecular Structure:



9.1 Chemical and Physical Properties

Physical state	Colorless, yellowish, or pinkish liquid, darkens with age and exposure to light and air (330, 331); *p*-cresol can also appear as a liquid
Odor	Phenolic odor, with an odor threshold of 5 ppm; sometimes refereed to as an *empyreumatic* odor
Specific gravity	1.034
Melting point	32–34°C
Boiling point	202°C (330)
Vapor density	3.7 (air = 1) (332)
Vapor pressure	0.11 torr (25°C)
Refractive index	1.537
Flash point	86°C (closed cup)

Other characteristics are as follows:

Flammability. *p*-Cresol is combustible and presents a marked fire hazard. Fires can be extinguished with water, carbon dioxide, appropriate foam, or dry chemicals. Mixtures of air and 1.47% *p*-cresol are explosive (332).

Solubility. *p*-Cresol is soluble in organic solvents, vegetable oils, alcohol, ether, glycerin, chloroform, and dilute alkali; also in 40 parts water (330, 333).

9.1.1 General: NA

9.1.2 Odor and Warning Properties *p*-Cresol has a distinct phenolic odor discernable at 5 ppm. Taste has not been noted in the available literature.

9.2 Production and Use

The cresols (cresylic acids) are methyl phenols and generally appear as a mixture of isomers (334). *p*-Cresol is a 4-methyl deriviative of phenol (335) and is prepared from *m*-toluic acid or obtained from coal tar or petroleum (333, 336). Crude cresol is obtained by distilling "gray phenic acid" at a temperature of ~180–201°C. *p*-Cresol may be separated from the crude or purified mixture by repeated fractional distillation *in vacuo*. It can also be prepared synthetically by diazotization of the specific toluene, or by fusion of the corresponding toluenesulfonic acid with sodium hydroxide.

p-Cresol is used as a disinfectant and solvent (330). Lysol™ disinfectant is a 50% v/v mixed-cresol isomer in a soap emulsion formed on mixing with water. Besides disinfection products at solutions of 1–5% (333), the cresols are used as degreasing compounds, paintbrush cleaners, and additives in lubricating oil (334). Cresols were previously widely used for disinfection of poultry houses, but this use was discontinued because they cause respiratory problems and abdominal edema in young chicks (337). *p*-Cresol has been used in synthetic resins, explosives, petroleum, paint, photographic and agricultural industries. *p*-Cresol is used safety in foods as a synthetic flavoring substance and adjuvant (338).

9.3 Exposure Assessment

With rare exceptions, human exposure in industry has been limited to accidental contact of *p*-cresol with the skin or to inhalation of vapors (335).

9.3.1 Air: NA

9.3.2 Background Levels: NA

9.3.3 Workplace Methods Air sampling and analytical methods for personal monitoring are essentially the same manner as for phenol. Cresol is absorbed in dilute alkali and determined colorimetrically with diazotized *p*-nitroaniline reagent (339), absorbed in spectrograde alcohol with direct determination by ultraviolet spectrophotometry, or absorbed on silica and deteremined by gas–liquid chromatography (340). One sampling procedure consists of drawing a known volume of air through a silica-gel tube consiting of two 20/40-mesh silica-gel sections, 150 and 75 mg, separated by a 2-mm portion of urethane foam. Acetone desorbed samples can be analyzed using a gas chromatography with a flame ionization detector. The column is packed with 10% free fatty-acid polymer in 80/100-mesh, acid washed DMCS Chromosorb W. The useful range of this method is 5 to 60 mg/m^3 (341).

9.3.4 Community Methods: NA

9.3.5 Biomonitoring/Biomarkers A sensitive method for the detection of cresol and metabolites in serum has been reported (342).

9.4 Toxic Effects

9.4.1 Experimental Studies 9.4.1.1 Acute Toxicity

Ingestion. Orally administered *p*-cresol is moderately acutely toxic in animals. After oral administration to rats, the LD_{50} value was 1.8 g/kg body weight (340). This is considered to have about the same degree of toxicity as phenol but to be slightly more corrosive than phenol with slower absorption, which accounts for slightly milder systemic effects (340). Corrosion of the GI tract and mouth is expected following oral cresol exposure similar to phenol. Following oral administration, kidney tubule damage, nodular pneumonia, and congestion of the liver with pallor and necrosis of the hepatic cells is seen. Acute exposure can cause muscular weakness, GI disturbances, severe depression, collapse, and death.

Dermal. The dermal LD_{50} in rats was 750 mg/kg (340). Toxic symptoms are similar after oral and dermal routes.

Inhalation. No verifiable LC_{50} values have been reported, but rats survived 1 h exposure to 710 mg/m^3 (340).

Irritation and Sensitization. p-Cresol, undiluted and in solution, can cause severe local irritation and corrosion following dermal and ocular exposure. Irritant effects include severe skin lesions, edema, erythema, and necrosis. Eye irritation can include severe irritation with corneal opacity.

9.4.1.2 Chronic and Subchronic Toxicity *p*-Cresol has been tested for subchronic toxicity in animal studies of 28 days' duration by dietary administration.

Ingestion by Diet In a 28-day study, F344/N rats and $B6C3F_1$ mice of both sexes (5/sex/group) were given *p*-cresol at concentrations of 300–30,000 ppm in the diet. All rats survived until study termination; some mice died at the 10,000 and 30,000 ppm dietary levels. Increased liver weights and kidney weights were noted in both species at doses as low as 3000 ppm, but no microscopic changes were associated with the organ weight changes. Bone marrow hyperplasia, and atrophy of the uterus, ovary, and mammary gland were seen in the 10,000- and 30,000-ppm dietary groups (343).

9.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms 9.4.1.3.1 Absorption Cresol is absorbed through the skin, open wounds, and mucous membranes of the GI and respiratory tracts. The rate of absorption through the skin depends on the size of the area exposed rather than the concentration of the material applied (340).

The metabolism and the rate of absorption, detoxification, and excretion of the cresols are much like those of phenol; they are oxidized and excreted as glucuronide and sulfate conjugates.

9.4.1.3.2 Distribution: NA

9.4.1.3.3 Excretion The major route of excretion of the cresols is in the urine. Both *o*- and *m*-cresols are ring-hydroxylated to a small extent, whereas *p*-cresol gives rise to the formation of some *p*-hydroxybenzoic acid. 2,5-Dihydroxytoluene has been isolated from the urine of rabbits fed *o*- and *m*-cresols, and *p*-hydroxybenzoic acid and *p*-cresylglucuronide from those administered *p*-cresol (340).

9.4.1.4 Reproductive and Developmental Toxicity: NA

9.4.1.5 Carcinogenesis *o*-Cresol has been induced a few papilloma but no carcinomas in tumor studies.

Skin Application Female Sutter mice (27–29/group) were dosed with a single application of dimethylbenzanthracene followed one week later by 25 mL of a 20% solution of *p*-cresol in benzene twice weekly for 12 weeks. Benzene treated controls did not experience mortality, although many of the cresol mice did die. *p*-Cresol produced 7/20 tumors (papillomas) on surviving mice (234). In another promotion study, mice were painted with a 20% solution of *p*-cresol for 11 weeks following initiation with dimethylbenzanthracene. Four of fourteen mice treated with *p*-cresol produced papillomas; no carcinomas were produced (344).

9.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms: NA

9.4.1.4 Reproductive and Developmental: NA

9.4.1.5 Carcinogenesis: NA

9.4.1.6 Genetic and Related Cellular Effects Studies *In Vitro* Effects In an unscheduled DNA synthesis assay, *p*-cresol was shown to be negative using rat hepatocytes (345). A cell transformation assay using BALB/3T3 cells showed *o*-cresol to be negative (346). *Salmonella* assays of various strains, both with and without liver homogenate, showed no mutagenic activity (59, 60, 347). In a mouse lymphoma forward mutation assay with liver homogenates, *o*-cresol was not mutagenic (345). Sister chromatid exchange assays produced no evidence of mutagenicity in CHO cells (346). *o*-Cresol induced SCEs in human lung fibroblasts (345, 348).

9.4.1.7 Other: Neurological, Pulmonary, Sensitization Depigmentation occurred when CBA/J mice were treated topically with a laundry ink containing *p*-cresol (353).

9.4.2 Human Experience 9.4.2.1 General Information Cresols can cause local and systemic toxicity in humans after exposure by oral or dermal routes.

9.4.2.2 Clinical Cases Approximately 20 mL of a 90% solution of mixed-cresol solution caused chemical burns, cyanosis, unconsciousness, and death within 4h when accidentally poured on an infant's head. Heptaic necrosis; cerebral edema; acute tubular necrosis of the kidneys; and hemorrhagic effusions from the peritoneum, pleura, and pericardium were observed postmortem. Blood cresol concentration was 120 micrograms/ml (349).

9.4.2.2.1 Acute Toxicity Oral lethality data from Lysol™ (which contains 50% mixed cresols) has been estimated to be between 60 and 120 mL (352). Ingestion is associated with corrosivity to body tissue and toxicity to the vascular system, liver, kdineys, and pancreas [Proctor 88].

9.4.2.2.2 Chronic and Subchronic Toxicity Chronic cresol poisoning has been reported infrequently. About 10 subjects were exposed to *o*-cresol at 1.4 ppm and complained of respiratory tract irritation (350). Documentation was not confirmed. Seven workers who were exposed to mixed-cresol vapor for 1.5–3 years experienced headaches, nausea, and vomiting. Some of those exposed also had elevated blood pressure, signs of impaired kidney function, blood calcium imbalance, and marked tremors (344).

9.4.2.2.3 Pharmacokineics, Metabolis, and Mechanisms Cresols are normally present in human urine. The normal human excretes 16–39 mg *p*-cresol/day (340).

9.4.2.2.4 Reproductive and Developmental: NA

9.4.2.2.5 Carcinogenesis: NA

9.4.2.2.6 Genetic and Related Cellular Effects Studies: NA

9.4.2.2.7 Other: Neurological, Pulmonary, Skin Sensitization, *etc* All isomers of cresol cause renal toxicity, hepatic toxicity, and CNS and cardiovascular disturbances (335).
9.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV TWA for cresol is 5 ppm (22 mg/m^3) with a "skin" notation (351). The OSHA PEL is also 5 ppm with a "skin" notation (351). The "skin" notation in the listing refers to "the potential significant contribution to the overall exposure by the dermal route, including mucous membranes and the eyes, either by contact with vapors or, of probable greater significance, by direct skin contact with the substance." The NIOSH REL TWA is 2.3 ppm (10 mg/m^3); the IDLH value is 250ppm.

Treatment of Cresol Ingestion Treatment should be supportive and symptomatic. There are no known antidotes (335).

Skin Decontamination Treatments after Accidental Exposure of Phenol Skin contact should be treated by washing with copious amounts of water, then bathing in glycerol, propylene glycol, or polyethylene glycol. Patients may require ventilatory support (335).

10.0.6b Molecular Structure: NA
10.1 Chemical and Physical Properties
Coal-tar creosote is a translucent black or brown, oily liquid. It is heavier than water. Wood creosote is a colorless or yellowish oily liquid.

	Wood Creosote	Coal-Tar Creosote
Specific gravity	1.09	1.1
Melting point	–4°C	Not available
Boiling point	428°C at 0mmHg	203–220°C (decomposes)
Vapor pressure	39mmHg (51°C)	42mmHg (22°C)
Flash point		
Closed cup	74°C	73.9°C
Open cup	—	85°C

10.1.1 General: NA

10.1.2 Odor and Warning Properties Coal-tar creosote has a characteristic aromatic smoky odor. Wood creosote has a characteristic smoky odor and a caustic burning taste.
10.2 Production and Use
Wood creosote is obtained from wood tars, from beech and the resin from leaves of the creosote bush, and by distillation and is composed mainly of phenols, xylenols, guaiacol, and creosol. Coal-tar creosote is produced by high temperature carbonization and distillation of bituminous coal. Coal-tar creosote contains liquid and solid aromatic hydrocarbons, tar acids, and tar base (354). At least 75% of the coal-tar creosote mixture is polyaromatic hydrocarbons (355). Purification of the crude preparation is accomplished by distillation and extraction from suitable oils.

Coal-tar creosote has been used as a wood preservative pesticide in the United States since the late 1890s. This accounts for over 97% of coal tar creosote production (356). Coal-tar creosote prevents animal and plant growth on concrete marine pilings and is a component of roofing pitch. (355). Other uses include animal and bird repellent, insecticide, animal dip, fungicide, and pharmaceutical applications (357). Beechwood creosote has, in the past, been used for medicinal purposes. It is rarely used in the United States for medical purposes today (355).

10.3 Exposure Assesment

Workers most likely to be exposed are carpenters, railroad workers, farmers, tar distillers, glass- and steel-furnace attendants, and engineers. Injuries to the skin or eyes have occurred mainly among male workers engaged in dipping and handling mine timbers and woods for floors and other purposes. Recent studies indicate that dermal exposure to creosote contribute more significantly to total body burden than respiratory exposure (358). There is limited risk of exposure to wood creosote due to its limited commercial use.

10.3.1 Air According to the Toxic Release Inventory (TRI), coal-tar creosote manufacturing and processing facilities listed for 1993, the major portion of creosote released to the environment is released to the air. An estimated total of 1,152,129lb of coal-tar creosote, amounting to 99.2% of the total environmental release, was discharged to the air from manufacturing and processing facilities in the Unites States in 1993. No major sources of wood creosote releases to the environment have been reported (355).

10.3.2 Background Levels No information was found on atmospheric ambient concentrations of wood or coal-tar creosote components. Results from 2 years of groundwater monitoring at a wood treatment facility in Conroe, Texas, where coal-tar creosote had been used for about 20 years showed that monitoring wells were contaminated with naphthalene, methylnaphthalene, dibenzofuran, and fluorene (359).

10.3.3 Workplace Methods GC/MS has been employed to determine creosote levels in workplace air from impregnated wood. Detection levels of $10–50 \times 10^{-6}$g creosote/m^3 sample, and recoveries of 82–102% were acheived (360).

10.3.4 Community Methods: NA

10.3.5 Biomonitoring/Biomarkers No biomarkers uniquely specific to wood creosote or coal-tar creosote have been identified (355). The levels of creosote in biological mateials can be estimated by measuring the polycyclic aromatic hydrocarbon (PAH) content in biological samples. Available methods include GC/FID, GC/MS, and HPLC. GC/MS and HPLC have been employed to detect creosote derived polyclyclic aromatic hydrocarbon complexes in human tissues, including adipose tissue, blood, and urine (361, 362).

10.3.5.1 Blood NA

10.3.5.2 Urine NA

10.3.5.3 Other NA

10.4 Toxic Effects

10.4.1 Experimental Studies 10.4.1.1 Acute Toxicity Ingestion The acute toxicity of wood creosote in both rats and mice was evaluated following single-gavage administration of a 10% aqueous solution (363). The oral LD_{50} of wood creosote was 885 mg/kg (males) and 870 mg/kg (females) in rats and 525 mg/kg (male) and 433 mg/kg (female) in mice. Most animals died within 24 h. The oral LD_{50} for coal tar creosote is reported to be 725 mg/kg in rats and 433 mg/kg in mice (355). A study by Pfitzer (364) reported a rat LD_{50} of 1700 mg/kg. The acute lethal dose of coal tar creosote in sheep and calves is 4 g/kg (365).

Dermal The dermal LD_{50} of coal-tar creosote is >7950 mg/kg following 24-h application to intact and abraided skin (364).

Inhalation Pfitzer (364) exposed rats by inhalation to near-saturated vapors generated from coal-tar creosote for one day. The animals exhibited dyspnea, slight nasal irritation, and eye irritation. The dose level was not determined.

10.4.1.2 Chronic and Subchronic Toxicity Ingestion No treatment related deaths were observed when rats were administered wood creosote in the feed at dose levels up to 1224 mg/kg/day in males or 768 mg/kg per day in females for 3 months (363). Male and female Wistar rats fed diets containing up to 313 or 394 mg/kg wood creosote per day for 96 weeks exhibited deaths in all groups. Treatment related deaths were observed in the males at the high dose only and were attributed to chronic progressive nephropathy (366).

10.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Generally, the PAH components of coal-tar creosote are metabolized by oxidative enzymes in the liver and lungs to generate active metabolites that can bind to macromolecules. The principal products include phenols, dihydrodiols, quinones, anhydrides, and conjugates of these products (355).

10.4.1.3.1 Absorption No studies specific to the absorption of wood creosote or coal tar creosote were found.

10.4.1.3.3 Distribution No studies specific to the distribution of wood creosote or coal tar creosote were found.

10.4.1.3.3 Excretion Creosote appears to be excreted in the urine mainly in conjugation with sulfuric, hexuronic, and other acids (367, 368). Oxidation also occurs with the formation of compounds that impart a “smoky” appearance to the urine. Traces are excreted by way of the lungs.

10.4.1.4 Reproductive and Developmental The only available study in animals reported dermal contact with coal-tar-creosote-treated wood by pregnant sows (369). Four sows were confined in wooden crates for 2–10 days before delivery. The crates were coated with three applications of 98.5% coal-tar creosote. Of 41 pigs delivered, 21 were dead at birth; 11 pigs died by day 3 post-farrowing. No toxic effects were evident in the sows. These findings were considered suggestive of developmental toxicity.

10.4.1.5 Carcinogenesis The carcinogenicity of creosote oils has been studied quite thoroughly using mice (370, 371). Studies indicate that coal-tar cresosote and several of its fractions can be carcinogenic when applied to the skin of mice and rabbits. Dermally applied coal-tar creosote can also act as a tumor-initiating agent when applied prior to croton-oil treatment (355).

10.4.1.6 Genetic and Related Cellular Effects Studies The genotoxic potential of coal-tar creosote has been investigated using *in vitro* assays of the material and of urine from exposed animals. The available genotoxicity data indicate that creosote is an indirect mutagen and induces gene mutation in bacteria and mouse lymphoma cells (355). Bos et al. (372) identified fluoranthene as one of the major volatile components of creosote responsible for the genotoxicity observed in *Salmonella typhimurium* strains.

10.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization

Neurological Effects. Rats and mice treated via gavage administration of a single high dose of beechwood creosote (300 mg/kg rats) exhibited muscle twitching followed by convulsions within 1–2 min. This was followed by asphyxiation, coma, and death (363).

Pulmonary Effects. Beechwood creosote failed to produce an adverse effect on lung weights when

fed to rats (1224 mg/kg per day males; 1570 mg/kg per day females) in the feed for 3 months (363). Thickening of tracheal mucous membrane was observed in mice who ingested feed (474 mg/kg males, 532 mg/kg females) containing beechwood creosote for 52 weeks. This was attributed by the author to inhalation of volatile components rather than to oral toxicity (363).

Immunological and Lymphoreticular Effects. Daily exposures to beechwood creosote at 805 or 1224 mg/kg in the diet for 3 months resulted in increased relative spleen weight of male rats. Similar effects were not seen in mice (363).

10.4.2 Human Experience 10.4.2.1 General Information: NA

10.4.2.2 Clinical Cases 10.4.2.2.1 Acute Toxicity Ingestion Fatalities have occurred 14–36 h after the ingestion of about 7g of coal-tar creosote by adults or 1–2 g by children (373). The symptoms of systemic illness included salivation, vomiting, respiratory difficulties, thready pulse, vertigo, headache, and loss of pupillary reflexes, hypothermia, cyanosis, and mild convulsions. The repeated absorption of therapeutic doses from the GI tract may induce signs of chronic intoxication, characterized by disturbances of vision and digestion (increased peristalsis and excretion of bloody feces). In isolated cases of "self-medication," hypertension, and general cardiovascular collapse have been described (374). Acute toxic hepatitis has been attributed to the ingestion of chaparral, an herbal supplement derived from the leaves of the creosote bush (375). Icterus and jaundice were observed in a 42-year-old male who consumed 500 mg of chaparral a day for 6 weeks. Elevated bilirubin, g-glutamyltranspeptidase, AST, and LDH were observed. Recovery occurred in approximately 3 weeks.

Dermal Creosote burns were observed in construction workers who handled creosote-treated wood (376). The majority of these cases were mild and were characterized by erythema of the face. Coal-tar creosote is capable of inducing phototoxicity of the skin (355).

10.4.2.2.2 Chronic and Subchronic Toxicity: NA

10.4.2.2.5 Pharmacokinetics, Metabolism, and Mechanisms: NA

10.4.2.2.4 Reproductive and Developmental No studies on reproductive or developmental effects of wood creosote or coal-tar creosote were identified. A site-surveillance program was conducted by the Texas Department of Health in 1990 at a housing development that was built on an abandoned creosote wood treatment plant. No reproductive or developmental findings were evident (355).

10.4.2.2.5 Carcinogenesis Cookson (377) described a 66-year-old coal-tar creosote factory worker who developed a squamous-cell carcinoma of the right hand after 33 years of heavy exposure. Autopsy revealed metastases to the lungs, liver, kidneys, heart, and lymph nodes. A similar case was reported in which a worker developed squamous-cell papillomas of the hands, nose, and thighs after several years of employment in the creosote impregnation of logs (378). Lenson (379) reported on a 64-year-old creosote shipyard worker who developed several primary carcinomas of the face.

10.4.2.2.6 Genetic and Related Cellular Effects Studies: NA

10.4.2.2.7 Other: Neurological, Pulmonary, Skin Sensitization, *etc* Contact of creosote with the skin or condensation of vapors of creosote on the skin or mucous membranes may induce an intense burning and itching with local erythema, grayish yellow to bronze pigmentation (376), papular and vesicular eruptions, gangrene, and cancer (380–382). Heinz bodies were noted in the blood of a patient 1 year after his exposure to creosote (379). Jonas (376) made similar observations following percutaneous absorption. On contact with the eyes, creosote caused protracted keratoconjunctivitis. This involves loss of corneal epithelium, clouding of the cornea, miosis, irritability, and photophobia. Subsequently, both blurring of vision and superficial keratitis can occur (334).

10.4.2.3 Epidemiology Studies Most of the available information on the effects of coal-tar creosote in humans comes from cases of acute poisoning following accidental or intentional exposure to coal-tar creosote and from occupational exposures in the wood preserving and construction industries. These studies are limited by lack of exposure concentrations and duration and by exposure to other potentially toxic substances. The few available studies are limited by small sample size, short follow-up periods, and brief exposure periods. These studies suggest that coal-tar creosote is a dermal irritant and a carcinogen following dermal exposure. Additional well-controlled epidemiological studies are needed (355).

10.4.2.3.1 Acute Toxicity: NA

10.4.2.3.2 Chronic and Subchronic Toxicity: NA

10.4.2.3.3 Pharmacokinetics, Metabolism, and Mechanisms: NA

10.4.2.3.4 Reproductive and Developmental A site-surveillance program was conducted by the Texas Department of Health in 1990 at a housing development that was built on an abandoned creosote wood treatment plant. No reproductive or developmental findings were evident (355).

10.4.2.3.5 Carcinogenesis Case reports and occupational surveys associate occupational creosote exposure with the development of skin cancer (355). These reports outline a similar disease etiology for different groups of workers exposed to creosote that include the development of dermatoses that progressed to carcinoma, usually squamous-cell carcinoma. Cancer of the scrotum in chimney sweeps has been associated with prolonged exposure to coal-tar creosote. The latency period for the development of dermatoses was usually 20–25 years (377, 383, 384). More recent studies suggest that prolonged exposure to coal-tar creosote and other coal-tar products may cause cancer of the skin and other organs (385–387).

10.4.2.3.6 Genetic and Related Cellular Effects Studies: NA

10.4.2.3.7 Other: Neurological, Pulmonary, Skin Sensitization, *etc* Leonforte (388) reported several cases of acute allergic dermatitis subsequent to contact with a creosote bush and confirmed by a patch test.

10.5 Standards, Regulations, or Guidelines of Exposure

The USEPA has classified coal-tar creosote as a class B1 carcinogen (Probable human carcinogen) (389). IARC classifies creosote as a human carcinogen (class 2A) (390). Creosotes are listed by the California Environmenal Protection Agency under Proposition 65 as chemicals known to cause cancer (391). The Occupational Safety and Health Administration (OSHA) has set an exposure limit of 0.2 mg/m^3 of coal-tar pitch volatiles in the workplace during an 8 h workday, 40 h workweek. The American Conference of Governmental Industrial Hygienists (ACGIH) recommends the same level for coal tar pitch volatiles. The National Institute for Occupational Safety and Health (NIOSH) recommends a maximum level of 0.1 mg/m^3 of coal-tar pitch volatiles for a 10 h workday, 40 h workweek (392).

10.6 Studies on Environmental Impact

Coal-tar creosote materials encountered in old production facilities or waste-disposal sites within the top several feet of soil have become weathered, as virtually all of the phenolic and heterocyclic fractions have volatilized, oxidized, or biodegraded (355, 393). The lighter fractions of PAH will have degraded, and the remaining material shows limited ability to migrate. Johnston et al. (394) concluded that aqueous partitioning and volatilization are probably the main processes that control modification of coal-tar at gasworks sites. Spills of newly produced creosote may pose a more serious toxicity concern.

Table 53.8. Uses of Various Chlorophenols

Compound	Use
2,3,4,5-Tetrachlorophenol	Fungicide
2,3,4,6-Tetrachlorophenol	Pesticide; wood preservative; slimicide for paper mills
2,4,5,6-Tetrachlorophenol	Fungicide

2,4,5-Trichlorophenol	Chemical intermediate for herbicides, insecticides, preservative for adhesives, textiles, rubber, wood, paints, in paper manufacture; cooling towers, on swimming-pool surface, veterinary medication
2,4-Dichlorophenol	In synthesis of anthelmintic bithionol sulfoxide; chemical intermediate
2,5-Dichlorophenol	Chemical intermediate for 3,6-dichloro-*O*-anisic acid, the herbicide dicamba
2,6-Dichlorophenol	This compound is used as a starting material for the manufacture of trichlorophenol, tetrachlorophenols and pentachlorophenol; used as sex pheromone with pesticide control
3,5-Dichlorophenol	Known uses: used in veterinary medicine as an anthelmintic
3,4-Dichlorophenol	Chemical intermediate for 2-chloro-1,4-dihydroxyanthraquinone and 2,3,4-Trichlo
o-Chlorophenol	Component of disinfectant, soil sterilant, organic synthesis of dyes
m-Chlorophenol	Intermediate in organic synthesis and phenolformaldehyde resins, catalyst for a polymers, vet antiseptic
p-Chlorophenol	In synthesis of dyes, pharmaceuticals, solvent in refining mineral oils, intermediate for use in dental practice, bacterial agent, topical antiseptic ointment, soil sterilant

13.0 2,4-Dichlorophenoxyacetic Acid

13.0.1 CAS Number:

[*94-75-7*]

13.0.2 Synonyms:

Dichlorophenoxyacetic acid; phenoxy herbicide; 2,4-D; 2,4-D acid; phenoxyacetic acid herbicide.

13.0.3 Trade Names:

Formula 40*, Esteron* 99* Concentrate, HiDep, Weedar 64, Weedone, Aqua-Kleen, LV400 2,4-D Weed Killer, Salvo, Savage, Weed Rhap A-4D, Weedestroy AM-40, DMA* 4

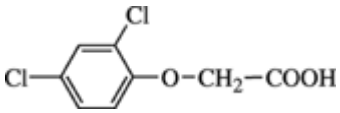
13.0.4 Molecular Weight:

221.01

13.0.5 Molecular Formula:

$C_8H_6Cl_2O_3$

13.0.6 Molecular Structure:



13.1 Chemical and Physical Properties

13.1.1 General

Color	White to light tan
Physical state	Crystalline solid or flake
Density	1.565
Boiling point	160°C at 0.4 mm Hg
Melting point	140–141°C
Hydrolysis (per day)	Stable in water at 25°C at pH 5 Stable in water at 25°C at pH 7 Stable in water at 25°C at pH 9
Photolysis (per day)	Aqueous: $t_{½}$ 13 days in water at 25°C, pH 7.0 Soil: $t_{½}$ 68 days in loam soil at 25°C, pH 7.8
Vapor pressure (mPa)	1.4×10^{-7}mmHg at 25°C
Water solubility (ppm)	311 ppm in water at 25°C and pH 1 20,031 ppm in water at 25°C and pH 5 23,180 ppm in water at 25°C and pH 7 34,196 ppm in water at 25°C and pH 9
Henry's law ($Pa \cdot m^3/mol$)	1.3×10^{-10} in water at 25°C, pH 1 5.7×10^{-11} in water at 25°C, pH 3 1.0×10^{-12} in water at 25°C, pH 5

Octanol/water partitioning (log K_{ow})	385 in water at 25°C, pH 1
	1.10 in water at 25°C, pH 5
	0.12 in water at 25°C, pH 7
	0.09 in water at 25°C, pH 9
Acid dissociation (pK_a)	2.87 in water at 25°C

13.1.2 Odor and Warning Properties Phenolic odor (odorless when pure).

13.2 Production and Use

2,4-Dichlorophenoxyacetic acid (2,4-D) is an organic herbicide that has provided economical, selective, postemergence control of broadleaf weeds in grass crops and non-cropland since the late 1940s and it is still the most widely used herbicide throughout the world. The Environmental Protection Agency (EPA) has approved 2,4-D registered products for weed control in farming, forestry, powerline maintenance, roadside brush control, aquatics, on home lawns, and for other end uses. The various forms of 2,4-D are absorbed through both the roots and leaves of most plants, especially broadleaf species (606).

The structure of 2,4-D is similar to that of the plant-specific hormone indole acetic acid and thus acts as a plant growth regulator. The acid is the parent compound, but many of the 2,4-D formulations in use contain the amine salts, which are more water-soluble than the acid, or the ester derivatives, which are readily dissolved in an organic solvent.

Phenoxy herbicides play a major role in weed management when used either alone or in combination with other herbicides. Applied as a foliar spray at 10–24 ppm in water, it acts as a fruit-drop-prevention agent in citrus. In contrast, 2,4-D is used at higher concentrations (0.25–4lb acid equivalent per acre) to control weeds in the crop and non-cropland areas. The herbicide 2,4-D is registered for use on over 65 crops in the United States: raw agricultural commodity (RAC) residue tolerances have been established (607). Also, 2,4-D is registered for numerous non-cropland and aquatic uses. The first year of sales and testing in the United States was 1945, and 917,000lb were produced. Production rose to 5.5 million lb in 1946 and 14, 36, 54, 52–67 million lb in 1950, 1960, 1964, and 1990, respectively. At the time of writing, the annual production of 2,4-D for use of the United States is approximately 47 million lb and greater than 100 million lb worldwide (608, 609). The major manufacturers are Dow AgroSciences (United States), Nufarm (Australia), Atanor (Argentina), A. H. Marks (England) UFA (Russia), Rokita (Poland), and Polaquimia (Mexico).

13.3 Exposure Assessment

13.3.1 Air Based on *EPA Toxicology Endpoint Selection Document*, 1996, exposure via inhalation (acute, short-term, or long-term) is not a concern based on the LC_{50} = >1.79 mg/L; acute inhalation tox category III (610).

13.3.2 Background Levels: NA

13.3.3 Workplace Methods NIOSH/OSHA Occupational Health Guideline for 2,4-D is 10 mg 2,4-D per m^3 exposure averaged over an 8 h shift (611).

13.3.4 Community Methods The EPA drinking-water maximum contaminant level goal (MCLG) for 2,4-D is 0.070 mg/L (ppm) (612).

13.3.5 Biomonitoring/Biomarkers 13.3.5.1 Blood In rats ^{14}C-2,4-D was rapidly and almost completely absorbed, as peak plasma levels were attained about 4 h after treatment, and 85–94% of the dose was excreted in the urine. The feces are a minor excretory pathway (2–11%). Rapid excretion of radiolabeled 2,4-D is also corroborated by the approximate half-life of 5 h for urinary excretion after oral administration (163). The rapid clearance of 2,4-D from plasma and its rapid excretion in the urine indicate that it has little potential to accumulate in mammals. Analysis of all

major tissues and organs for residual ^{14}C activity indicated that only a small fraction of the dose was still present 48 h after treatment. Tissues and organs from animals at the low dose contained <0.7% of the administered dose (613). These results indicate that the fate of 2,4-D in the rat is independent of dose and sex, that the compound is rapidly and almost completely eliminated, essentially by the urinary route, and that it has little potential to accumulate.

13.3.5.2 Urine See section 13.3.5.1.
13.4 Toxic Effects
13.4.1 Experimental Studies 13.4.1.1 Acute Toxicity The acute toxicity of 2,4-D is summarized in Table 53.12 (614–620). After oral administration, the clinical signs of toxicity observed consistently were ataxia, myotonia, and decreased limb tone. No dermal or systemic toxicity was seen in rabbits treated dermally, and no deaths were seen after inhalation. Clinical signs of toxicity seen during eye exposure were decreased activity and closed eyes. Signs seen at the end of and during the week after exposure were salivation, lacrimation, mucoid nasal discharge, labored breathing, dried red or brown material around the eyes and nose, matted fur, and staining of the fur in the anogenital region. None of these signs was seen within 3–7 days of treatment. There was no significant finding postmortem (614).

Table 53.12. Acute Toxicity of 2,4-D

Route	LD_{50} (mg/kg bw) or LC_{50} (mg/L)	Ref.
Oral—rat	699	614, 615
Dermal—rabbit	>2000	614, 616
Inhalation—rat	>1.8	614, 617
Eye irritation—rabbit	Irritation >21 days	618, 619
Dermal irritation—rabbit	Nonirritant	619, 620
Dermal sensitization	Negative/nonsensitizing	619

13.4.1.2 Chronic and Subchronic Toxicity Subchronic rat and dog toxicity studies were conducted on all three forms of 2.4-D: 2,4-D acid, dimethylamine salt [DMA], and 2-ethylhexyl ester [2-EHE]. Toxicity was comparable for the three forms in both species, and suport a rat subchronic NOEL of 15 mg/kg per day, and a dog subchronic NOEL of 1 mg/kg per day (629, 630). A one year chronic study in the dog with 2,4-D acid at doses of 0, 1.0, 5.0 and 7.5 mg/kg per day showed no indication of immunotoxic or oncogenic effects; the chronic dog NOEL was 1.0 mg/kg per day (629). Doses in the 2-year chronic/oncogenicity rat study were 0, 5, 75, and 150 mg/kg per day. The chronic toxicity NOEL of 5 mg/kg per day was established. A slight increase in astrocytomas observed (in males only) at 45 mg/kg per day in a previously conducted chronic rat study was not confirmed in the Jeffries 1995 study (621) at daily doses as high as 150 mg/kg the MTD. Daily doses in the 2-year mouse oncogenicity studies were 0, 5, 62.5, and 125 mg/kg for males. No oncogenic effect was noted in the study. In summary, the finding of these studies indicate low chronic toxicity of 2,4-D and the lack of oncogenic response to 2,4-D following chronic dietary exposure of 2,4-D in the rat and the mouse (622). EPA states in its review of the chronic rat and mouse studies, “2,4-D acid was not carcinogenic in male or female rats or mice” (623).

13.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms 13.4.1.3.1 Absorption 2,4-D was rapidly absorbed, distributed, and excreted after oral administration to mice, rats, and goats. At least 86–94% of an oral dose was absorbed from the gastrointestinal tract in rats. 2,4-D was excreted rapidly and

almost exclusively (85–94%) in urine by 48 h after treatment, primarily as unchanged 2,4-D. In rats no metabolites have been reported apart from conjugates (613). In goats minor metabolites were free and conjugated 2,4-dichlorophenol (2,4-DCP). Pharmacokinetic studies with salts and esters of 2,4-D have shown that the salts dissociate and the esters are rapidly hydrolyzed to 2,4-D. The similarity in the fate of 2,4-D and its salts and esters explains their similar toxicities (614, 619).

Absorption of 2,4-D appears to be rapid and complete from the GI tracts of humans and experimental animals (624, 625). Although ingestion is usually a relatively minor route of exposure, most toxicity testing of 2,4-D has been conducted by oral exposure. Because 2,4-D is absorbed more efficiently through the GI tract than through the skin, 2,4-D should be more toxic when ingested than when applied to the skin. Therefore, using oral studies of 2,4-D to test toxicity may add some margin of safety when these data are used to predict risk from exposure to 2,4-D through skin contact.

13.4.1.3.2 Distribution Once absorbed, 2,4-D was widely distributed throughout the body, but did not accumulate because of its rapid clearance from the plasma and rapid urinary excretion (614, 626). The excretion, tissue residues, and metabolism of ^{14}C-2,4-D were investigated in a lactating goat given an oral dose of 483 ppm for three consecutive days in a capsule. About 90% of the dose was recovered in the urine and feces. Milk, liver, kidneys, composite fat, and composite muscle accounted for <0.1% of the total dose received. The residues in the milk were 0.22–0.34 ppm at the morning milking and 0.04–0.06 ppm in the evening. Kidneys accounted for the highest residue concentration, 1.4 ppm; liver contained 0.22 ppm, fat contained 0.09 ppm, and muscle contained 0.04 ppm (614, 627). Binding of 2,4-D to plasma proteins can occur and may affect distribution (625). When 2,4-D is bound to the plasma proteins, it cannot reach tissues where it might cause damage. High doses of 2,4-D can saturate or use up all the plasma protein binding sites, which could result in a dramatic rise in the concentration of "free" 2,4-D. Free 2,4-D may be excreted; however, at very high doses of 2,4-D, the rate of excretion may slow down, and therefore the concentration of 2,4-D that can reach tissues in the body may increase and cause toxicity.

13.4.1.3.3 Excretion In animals and humans who have ingested 2,4-D, it was quickly absorbed and excreted rapidly in the urine; about 84–94% of the administered dose was found in the urine within 48h. No metabolites were detected (613, 614, 626). Also refer to Sections 13.4.1.3.1, 13.4.3.2, and 13.4.2.2.3.

13.4.1.4 Reproductive and Developmental Reproductive The reproductive toxicity of 2,4-D has been studied at dietary doses of 0, 5, 20, and 80 mg/kg/day in a two-generation reproductive study in Fischer 344 rats (628). The parental F_0 group was treated with 2,4-D for 15 weeks prior to mating. No adverse effects on fertility were observed in the 5- and 20-mg/kg daily dose groups, although reduced pup weights were noted in the 20-mg/kg F_{2a} litters. A daily NOAEL of 5 mg/kg for reproductive toxicity was established from this study. In addition to this reproduction study, recent subchronic and chronic studies in rats, mice and dogs produced no evidence of treatment-related histopathological changes in the testes at any of the dose levels tested (622, 629, 630).

Developmental The teratogenic potential of 2,4-D acid and a variety of its salt and ester derivatives have been evaluated in a series of studies in both rats and rabbits. In rats, the lowest daily no-observed-effect-level (NOEL) doses were 25 mg/kg for 2,4-D acid and 50 mg/kg (acid-equivalent dose) for the various 2,4-D derivatives. Observations of embryo or fetal toxicity, which were observed only in the presence of maternal toxicity, were limited to decreased fetal body weights and increased incidences of minor-skeletal variations. In rabbits, no gross, soft-tissue, or skeletal malformations or variations were observed up to a top daily dose of 90 mg/kg of 2,4-D acid, or at top daily doses equal to or greater than 90 mg/kg of 2,4-D derivatives (acid-equivalent doses). The NOAEL daily doses for rabbit maternal toxicity were 30 mg/kg for 2,4-D and 10 mg/kg for the derivative acid-equivalents. Thus, these extensive series of studies support the conclusion that 2,4-D has a very minimal potential for inducing developmental toxicity, and that such toxicity only occurs in the presence of maternal toxicity. Importantly, the minimal developmental toxicity of 2,4-D in rats

was reported only at daily doses equal to or above 50 mg/kg, the dose level at which 2,4-D has been shown to exhibit nonlinear pharmacokinetic behavior in rats due to saturation of renal 2,4-D clearance (631).

13.4.1.5 Carcinogenesis The carcinogenicity of 2,4-D has been assessed in two recent rat studies conducted according to good laboratory practice (GLP) requirements (621, 632). In the 1986 study conducted in Fischer 344 rats, the kidney was the primary organ affected by 2,4-D treatment (632). The minor kidney lesions constituted the basis for establishment of an overall rat NOEL of 5 mg/kg per day. A low incidence of astrocytomas was observed only in high dose males of this study. However, a follow-up analysis of the astrocytoma findings led to the conclusion that the brain tumors were not likely treatment-related for several reasons, including (*1*) no earlier tumor appearance in treated versus nontreated rats, (*2*) no evidence of tumor multiplicity, (*3*) similar tumor size and anaplastic characteristics of astrocytomas in control and treated rats, and (*4*) no evidence of brain lesions or brain toxicity in treated rats not exhibiting tumors (624). Astrocytomas were not confirmed in the Jeffries 1995 study at the threefold higher daily dose of 150 mg/kg (621, 622).

The EPA Carcinogenicity Peer Review Committee (CPRC) met in 1996 to discuss and evaluate the weight of the evidence on 2,4-D with particular reference to its carcinogenic potential. The CPRC concluded that 2,4-D should remain classified as a Group D—Not classifiable as to human carcinogenicity. That is, the evidence is inadequate or no human and animal evidence of carcinogenicity (623).

13.4.1.6 Genetic and Related Cellular Effects Studies The genotoxic potential of 2,4-D has been adequately evaluated in a range of assays *in vivo* and *in vitro*. Overall, the responses observed indicate that 2,4-D is not genotoxic, although conflicting results were obtained for mutation in *Drosophila*. In a more extensive range of assays, several amine and ester formulations of 2,4-D were evaluated and were not genotoxic *in vivo* or *in vitro*. The World Health Organization concluded that 2,4-D and its salts and esters are not genotoxic (614, 626).

13.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization Neurological Single-dose acute and 1-year chronic neurotoxicity screening studies in rats were conducted on 2,4-D according to the USEPA guidelines in 1991. The studies emphasized a functional observation battery, automated motor activity testing, and comprehensive neurohistopathology of perfused tissues. Daily doses were ≤250 mg/kg by gavage for the single-dose study and ≤150 mg/kg in the diet for 52 weeks in the repeated-dose study. In the acute study, slight transient gait and coordination changes were observed along with decreased motor activity at the time of maximal effect on the day of treatment (day 1). No gait, coordination, or motor activity effects were noted by day 8. In the chronic study, the only finding of neurotoxicologic significance was retinal degeneration in females in the high dose group. In summary, the findings of these studies indicated a mild, transient locomotor effect from high level chronic exposure. The results from these two studies, indicated that the NOAEL for acute neurotoxicity was 67 mg/kg per day and for chronic neurotoxicity was 75 mg/kg per day (610, 614, 626, 633). The mechanism by which the effects occur at high doses appears to be dependent on the inhibition of the organic acid transport system and/or damage to the blood–brain barrier. Exposures to 2,4-D below the threshold for inhibition of the organic acid transportation pathway (approximately 40–100 mg/kg body weight) are not associated with increased concentrations of 2,4-D in the brain, alterations to brain neurochemistry, behavioral effects, or CNS pathology. This provides a very large margin of safety (>20,000-fold) when compared to estimation of bystander exposures (0.0005 mg/kgbw per/day) following commercial aerial application of 2,4-D (634). Therefore, when application of 2,4-D is conducted in compliance with recommended uses and rates, it is not expected to result in detrimental impacts on the nervous system (624).

Pulmonary The pulmonary effects reported in case studies of extreme human exposure cannot be associated with 2,4-D exposures that would be expected to occur following routine and recommended use of this herbicide. Assessment of the potential impact of 2,4-D on human pulmonary system is based mainly on anecdotal and uncontrolled case studies in which pulmonary

effects as a result of exposure to very high levels of 2,4-D have been reported. Some pulmonary effects such as labored breathing and respiratory tract irritation have been reported in herbicide sprayers who were exposed to extremely high levels of 2,4-D. However, these workers were exposed to a number of different chemical formulations, including other herbicides and solvents, at undetermined concentrations. Thus, these pulmonary effects cannot be attributed, directly or indirectly, to 2,4-D exposure. Animal studies indicate that pulmonary effects can be considered to be secondary to other impacts, such as kidney toxicity. A comparison of the NOEL to estimated bystander exposures following commercial aerial application of 2,4-D (0.0005 mg/kgbw/day) (634) yields a margin of safety of over 10,000-fold (624).

Dermal Dermal exposure data support the conclusion that exposure to 2,4-D under recommended conditions and application rates would not be expected to cause adverse dermal effects. Several studies have quantified typical bystander exposure to (634, 635). On the basis of these studies, bystander exposure to 2,4-D from various sources, including home and garden use and commercial aerial application, was estimated to range from less than the detection limit to 0.0005 mg/kgbw/day. These bystander exposures to 2,4-D are >20,000-fold lower than the most conservative daily NOAEL of 10 mg/kgbw for dermal toxicity determined from subchronic animal studies (624).

Immunotoxicity The available animal and human studies do not provide evidence that 2,4-D adversely affects the immune system nor does it act as a dermal sensitizer (624).

Thyroid The reported effects of 2,4-D on the rodent thyroid following administration at high doses in the subchronic and chronic studies are considered to be of no relevance to humans. This conclusion was based on the known differences between rodents and humans with respect to thyroid hormone carrier proteins, thyroid hormone turnover, TSH levels, and responsiveness to goitrogens and/or anti-thyroid substances. Also supporting this conclusion were data indicating that thyroid effects in rodents occur only at doses that are at, or exceed, the capabilities of clearance mechanisms (624).

Testes and Ovaries No definitive human studies are available describing potential effects of 2,4-D exposure on the testes or ovaries (624). An exhaustive series of animal studies provide strong evidence that 2,4-D does not adversely affect the testes or ovaries under recommended conditions of use.

13.4.2 Human Experience 13.4.2.1 General Information The phenoxy herbicides are low in toxicity to humans and animals (636, 637). No scientifically documented human health risks, either acute or chronic, exist from the approved uses of phenoxy herbicides, including 2,4-D. Acute toxicity to humans, based on oral, dermal, ocular, or inhalation administration, may vary with the 2,4-D formulation. However, phenoxy herbicides have been used widely by numerous individuals (637) from homeowners to farmers and ranchers, and even with significant exposure, humans have shown essentially no acute toxicity (624).

13.4.2.2 Clinical Cases See section 13.4.2.1

13.4.2.2.1 Acute Toxicity: See section 13.4.2.1

13.4.2.2.2 Chronic and Subchronic Toxicity: NA

13.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms Absorption After dermal application of ^{14}C-2,4-D to the forearm of five male volunteers, 5.8% of the dose was absorbed within 120h (610, 638). When the acid and its dimethylamine salt (DMA) were applied to the back of the hand, 4.5% of the acid and 1.8% of the salt were absorbed, and of this 85% of the acid and 77% of the salt were recovered in the urine within 96 hours after application (639). The rate of excretion depends on the dose. Excretion of 2,4-D is through the organic acid transport system in the kidney (624). Low doses of 2,4-D are excreted more rapidly than high doses, which can saturate this active kidney transport

system. Munro et al. (624) point out that the doses of 2,4-D that most humans are exposed to should be below doses that saturate active kidney transport. Therefore, they suggested the toxicologic results from animals treated with high doses of 2,4-D that saturate renal transport should be interpreted with caution because they may not be relevant to typical human exposures (624). Studies conducted in a variety of species show that, after oral dosing, 2,4-D is found in the liver, kidney, lung, and to a lesser extent in the brain (624). The distribution of 2,4-D through the human body appears to be similar to that in test species. When organs were examined following fatal poisonings (suicides), the highest levels of 2,4-D were found in kidney and liver, and lower levels are found in brain, muscle, and heart (625).

13.4.2.2.4 Reproductive and Developmental: NA

13.4.2.2.5 Carcinogenesis Collectively, the epidemiological and toxicological data show that 2,4-D is not likely to be carcinogenic in humans unless it is acting through an unknown mechanism that is not evident in animals. According to the calculated RfD and data from exposure studies, the general public should not experience toxic effects from exposure to 2,4-D. Because workers involved in the manufacture or application of 2,4-D may be exposed to levels above the RfD, appropriate protective equipment should be used (640).

13.4.2.2.6 Genetic and Related Cellular Effects Studies: NA

13.4.2.2.7 Other: Neurological, Pulmonary, Skin Sensitization, *etc* Neurotoxicity Some case reports have suggested an association between exposure to 2,4-D and the development of nervous system effects ranging from peripheral polyneuropathy and reduced nerve conduction velocity to depression, anxiety, and other symptoms of post-traumatic stress syndrome in Vietnam veterans (624). In test animals, doses of 2,4-D above 100 mg/kg can cause myotonia of the skeletal muscle (624), and oral doses above 150 mg/kg of 2,4-D can damage the blood–brain barrier (641). Toxicologic studies in rats and rabbits indicate, however, that neurotoxic effects of 2,4-D do not occur at doses below those that saturate the kidney transport system. Therefore, neurotoxic effects would only be expected to occur at high doses of 2,4-D.

13.4.2.3 Epidemiology Studies 13.4.2.3.1 Acute Toxicity See section 13.4.1.1.

13.4.2.3.2 Chronic and Subchronic Toxicity See section 13.4.1.2.

13.4.2.3.3 Pharmacokinetics, Metabolism, and Mechanisms See section 13.4.1.3.

13.4.2.3.4 Reproductive and Developmental See section 13.4.1.4.

13.4.2.3.5 Carcinogenesis: See section 13.4.1.5. The following observations are also germane.

Epidemiological studies have suggested an association between the development of non-Hodgkin's lymphoma and exposure to chlorophenoxy herbicides, including 2,4-D. The results of these studies are not consistent; the associations found are weak, and conflicting conclusions have been reached by the investigators. Most of the studies did not provide information on exposure specifically to 2,4-D, and the risk was related to the general category of herbicides. Case-control studies provide little evidence of an association between the use of 2,4-D and non-Hodgkin's lymphoma. Cohort studies of exposed manufacturing workers have not confirmed the hypothesis that 2,4-D causes this neoplasm (642). Findings of three agencies are as follows:

IARC. A working group convened by the International Agency for Research on Cancer (643) concluded that there was limited evidence that chlorophenoxy herbicides are carcinogenic to humans. 2,4-D could not be clearly distinguished from the chlorophenoxy herbicides.

Canada. The Ontario Pesticide Advisory Committee of the Ontario Ministry of the Environment

(644) concluded that “there is limited evidence of carcinogenicity in man from exposure to phenoxyacetic acid herbicides. In terms of exposure to 2,4-D specifically, the evidence must still be regarded as inadequate to classify it as a carcinogen.”

Harvard School of Public Health. A panel at the Harvard School of Public Health (645, 646) concluded: “Although a cause-effect relationship is far from being established, the epidemiological evidence for an association between exposure to 2,4-D and non-Hodgkin's lymphoma is suggestive and requires further investigation. There is little evidence of an association between 2,4-D use and any other form of cancer.”

13.4.2.3.6 Genetic and Related Cellular Studies. See section 13.4.1.6.

13.4.2.3.7 Other: Neurological, Pulmonary, Skin Sensitization, etc See section 13.4.1.7. The following findings are also relevant.

Dermal There are no studies reported in the epidemiological literature directly linking 2,4-D with dermal effects in humans. One report (647) provides evidence of a possible association, but the effect reported may be attributable to other factors. Caution must be exercised in the interpretation of epidemiological data because exposure cannot be quantified, and exposures to mixtures of herbicides or solvents cannot be excluded. The only evidence for dermal sensitization to 2,4-D is based on a group of 30 farmers, all of which were already diagnosed with contact dermatitis (648). Although three of this group reported positive patch test results for 2,4-D, the interpretation of this study is confounded by preexisting dermal conditions of unknown origin.

Immunotoxicity Current epidemiology studies do not provide evidence that 2,4-D affects the immune system of humans (624). A study conducted in farm workers applying a mixture of 2,4-D and 4-chloro-2-methylphenoxyacetic acid (MCPA) suggested that phenoxy herbicides may exert short-term immunosuppressive effects (649). Since this study did not include a control group matched to the same work conditions (*i.e.*, normal variations in immune system parameters were not characterized), and also did not provide any information on actual worker exposure to 2,4-D, the results are uninterpretable.

13.5 Standards, Regulations, or Guidelines of Exposure:

Absorption. Based on dermal absorption data from a ^{14}C-labeled 2,4-D acid human study (638) EPA set maximum absorption at 5.8% (610).

Acute Dietary Endpoint (1-day exposure). Dose and endpoint for use in risk assessment: NOEL = 67 mg/kg per day (610).

Short-Term Occupational or Residential Exposure (1–7 days). Dose and endpoint for use in risk assessment: NOEL = 30 mg/kg per day (610).

Intermediate-Term Occupational or Residential Exposure (1 week to several months). Dose and endpoint for risk assessment: NOEL = 1 mg/kg per day (610).

Chronic Occupational or Residential Exposure (several months to lifetime). Dose and endpoint for risk assessment: NOEL = 1 mg/kg per day (610, 614).

Inhalation Exposure (any time period). Exposure via inhalation is not a concern based on the LC_{50} = >1.79 mg/L. This risk assessment will not be required by EPA (610).

Air. NIOSH/OSHA Occupational Health Guideline for 2,4-D is 10 mg 2,4-D/m^3 air averaged over an 8-h shift (611). (ACGIH TLV TWA = 10 mg/m^3; NIOSH REL IDLH value = 100 mg/m^3).

Water. EPA drinking-water regulations and health advisory lifetime standard for 2,4-D: 0.070 mg/L (ppm) (612).

13.6 Studies on Environmental Impact
Terrestrial Environment

Soil. As part of the 2,4-D EPA reregistration process in the Unites States, 30 soil dissipation studies were conducted with 2,4-D dimethylamine salt (2,4-D DMA) and 2,4-D 2-ethylhexyl ester (2,4-D 2-EHE) over a 2-year period. The data from the current and former studies show that ester and amine forms have little effect on the rate of dissipation of 2,4-D *per se* because they are converted rapidly to the same anionic form. The average half-life ($t_{½}$) in the soil is 4.4 days for 2,4-D DMA and 5.1 days for 2,4-D 2-EHE (650).

Groundwater. The rapid dissipation of 2,4-D in soil and its affinity to attach to soil colloids significantly reduce the potential for downward movement. 2,4-D is not expected to be a concern for groundwater contamination (607).

Microorganisms. The most significant routes of exposure of soil microorganisms to 2,4-D are likely to be from its use by ground or aerial applications. Data from laboratory studies indicate that the risk to soil microorganisms should be low even at excessive application rates of 7.4 and 18.75 kg 2,4-D/ha (651, 652).

Bees. Honeybees may be exposed to 2,4-D by foraging flowering weeds present in treated crops. Oral and contact LD_{50} study values for 2,4-D DMA and 2,4-D 2-EHE were all >100 mg/bee, which is considered low bee toxicity (651, 652).

Earthworms. Earthworms may be exposed from either single or multiple applications of 2,4-D to a wide variety of crops but in particular from its use on grass, fallowland, and stubble. A 14-day LC_{50} study exposed earthworms to 2,4-D DMA at 350 mg/kg soil, with no mortality noted at concentrations less than or equal to 100 mg a.e./kg. The risk to earthworms from the use of 2,4-D is low (651, 652).

Birds. The risk to birds based on foraging on grass or insects is considered low. The acute avian LD_{50} values range from 200 to >2000 mg/kgbw for mallards, bobwhite quail, Japanese quail, pheasants, partridges, and doves. Dietary LC_{50} values exceed 4640 mg/kg diet for mallards, bobwite quail, Japanese quail, and pheasants. At doses greater than recommended application rate, 2,4-D did not adversely affect the reproductive performance of pheasants, quail, partridges, or chickens (651, 652).

Aquatic Environment

Bioaccumulation. There was no evidence of bioaccumulation of 2,4-D in aquatic organisms (651, 652).

Fish. The main risk to aquatic organisms from the use of 2,4-D is from overspray during aerial use, spray drift from ground-based applications, or use to control aquatic weeds. Because of the very rapid degradation of the salts and esters of 2,4-D in water, the long-term risk to aquatic organisms is considered to be low. Embryos and larvae of fathead minnow, were exposed to up to 416.1 mg/L of 2,4-D ester for 32 days; the NOEC was 80.5 mg/L. Generally, 2,4-D and its salts are less toxic to fish than are the esters. Typical 96 h LC_{50} values for adult fish were 5–10 mg acid equivalentsa.e./L for the ester, 200–400mga.e./L for 2,4-D, and from 250–500 mg a.e./L for 2,4-D salts (651, 652). Highest applications in water are expected to be approximately 2 ppm for weed control. Significant safety margins exist between maximum water concentration and toxic levels to fish.

Amphibians. Frog and toad tadpole 96 h LC_{50} values ranged from 8 mg/L for 2,4-D 2-EHE (maximum solubility of ester) to 477 mg/L for the 2,4-D DMA salt. No effects were noted, indicating that 2,4-D is considered low toxicity to amphibians (651, 652).

Phenol and Phenolics

14.0.6 Molecular Structure:

14.1 Chemical and Physical Properties
14.1.1 General

Physical	Light brown powder; monoclinic prisms or needles
Melting point	229.5°C
Solubility	Insoluble in water; miscible in ether, hot alcohol, benzene (653).

14.2 Production and Use
Flame retardant, molluscicide, and chemical intermediate.
14.3 Exposure Assessment:
NA
14.4 Toxic Effects
14.4.1 Experimental Studies 14.4.1.1 Acute Toxicity The approximate (oral) LD_{50} in the rat of pentabromophenol is slightly more than 200 mg/kg when administered as the sodium salt in aqueous solution. The signs and symptoms from pentabromophenol included increased respiratory rate and amplitude with general body tremors, occasional convulsions, and death (13).

14.4.1.2 Chronic and Subchroic Toxicity Sodium and copper pentachlorophenate were given in drinking water to three young bulls at a daily dosage of 7.6 mg/kgbw for 5 weeks. No significant signs of intoxication and no micropathological changes were noted (13).

14.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms These compounds are rapidly absorbed from the gastroenteric tract (13).
14.5 Standards, Regulations, or Guidelines of Exposure:
NA
14.6 Studies on Environmental Impact
The EC_{50} for *Pimephales promelas* (fathead minnow) was 93.0 mg/L for 96 h. The effect was loss of

equilibrium; the LC_{50} for *P. promelas* was 93.0 mg/L for 96 h (654).

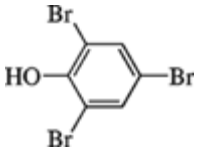
15.0 2,4,6-Tribromophenol
15.0.1 CAS Number:
[*118-79-6*]
15.0.2 Synonyms:
Bromol; tribromophenol
15.0.3 Trade Names:
Bromol
15.0.4 Molecular Weight:
330.82
15.0.5 Molecular Formula:
$C_6H_3Br_3O$
15.0.6 Molecular Structure:



15.1 Chemical and Physical Properties

Appearance	Long, soft white crystals
Specific gravity	2.55 at 20°C
Density	2.55 g/mL
Boiling Point	244°C
Melting point	95–96°C

Additional parameters were as follows:

Solubility. Water—excess amounts of ^{14}C-labeled 2,4-6-tribromophenol were shaken in a water bath at 35°C overnight. Samples were centrifuged at 15°C, 25°C or 35°C at 12,000g for 1 h. Solubility was determined by radioassay. Solubility (ppm): 996 (15°C), 969 (25°C), and 884 (35° C) (655).

Partition Coefficient. The *n*-octanol/water coefficient of radiolabeled 2,4,6-tribromophenol was 2198 (log 10 = 3.342) (655).

Photolysis. A photolysis study using ^{14}C-labeled 2,4,6-tribromophenol was conducted on silica-gel TLC plates under UV light. The half-life was estimated to be 4.6h. The disappearance of 2,4,6-tribromophenol followed apparent first-order kinetics. A degradation product was tentatively identified as 2,6-dibromo-3,5-dihydroxy-*p*-quinoimine (655).

15.1.1 General: NA

15.1.2 Odor and Warning Properties 2,4,6-Tribromophenol has a penetrating bromine odor.
15.2 Production and Use
2,4,6-Tribromophenol is produced by the controlled bromination of phenol (655).
15.3 Exposure Assessment:
NA
15.4 Toxic Effects
15.4.1 Experimental Studies 15.4.1.1 Acute Toxicity Ingestion Single doses of 2,4,6-tribromophenol in 0.5% Methocel (hydroxypropylmethylcellulose) were administered by intubation to groups of five male and five female rats each at levels of 1585, 2512, 3980, 6308, 10,000, and 15,848 mg/kg. Reactions noted between 0 and 4 h after dosing at ≥6308 mg/kg included decreased motor activity, tachypnea, tachycardia, ataxia, and tremors. There were no effects on body weight. Death occurred between 0 and 4 h on the day of the dosing. The oral LD_{50} values (with 95% confidence limits) in mg/kg were 5012 (4034–6227) in males and females and 5012 (4178–6013) for males and females combined (655).

Three groups of five male rats each received single oral doses of 2,4,6-tribromophenol suspended in corn oil at levels of 50, 500, and 5000 mg/kg. All rats died at 5000 mg/kg within 24 h of treatment. 2,4,6-Tribromophenol was considered toxic but not highly toxic by the oral route of administration (655).

Groups of five male and five female rats received single oral doses by gavage of 2,4,6-tribromophenol suspended in corn oil. Levels tested were 631, 1000, 1585, 2512, 3980, and 6308 mg/kg. Deaths occurred on the day of dosing (0–4h) and on day 1. The oral LD_{50} values (with 95% confidence limits) in mg/kg were 1995 (1728–2304) in males and 1819 (1513–2187) in females. The combined male–female value was 1905 (1738–2089) (655).

Dermal Administration A single topical application of 8000 mg/kg of 2,4,6-tribromophenol to the shaved backs of two male and two female New Zealand white rabbits was used to evaluate dermal toxicity. The skin of one rabbit of each sex was abraded while the skin of the other remained intact. Afer application of 2,4,6-tribromophenol, the sites were wrapped with occlusive dressings for 24 h. Following the exposure period, the wrappings were removed and the area washed with tepid tap water. There were no effects on body weights or survival during the 14-day observation period. The dermal LD_{50} for 2,4,6-tribromophenol in rabbits is >8000 mg/kg (655).

A single topical application of either 200 or 2000 mg/kg of 2,4,6-tribromophenol was administered to two groups of four New Zealand white rabbits each. The trunks of the animals were then wrapped for a 24 h exposure. There were no deaths. 2,4,6-Tribromophenol was not considered to be toxic by the dermal route of administration (655).

Inhalation A single group of five male and five female rats was exposed to a dust atmosphere of 2,4,6-tribromophenol at an analytical concentration of 1.63 mg/L for 4h. Reactions noted during exposure were ptosis and red nasal discharge. All rats survived the 14-day observation period. The inhalation LC_{50} was reported as >1.63 mg/L (655).

One group of five rats per sex was exposed to a dust atmosphere of 2,4,6-tribromophenol at 50 mg/L (highest attainable concentration). During exposure, reactions noted included decreased motor activity, eye squint, slight dyspnea, erythema, and ocular porphyrin discharge. At 24 h, diarrhea, ocular porphyrin discharge, and slight dyspnea were noted. Some of the observations continued for most of the 14-day observation period. The inhalation LC_{50} was calculated as >50 mg/L (655).

Groups of 10 male rats each were exposed to dust atmospheres of 2,4,6-tribromophenol at either 2 or 200 mg/L for 1 h. Reactions noted during exposure were eye squint, increased followed by decreased respiration, prostration, nasal discharge, lacrimation, erythema, decreased motor activity, and salivation. No deaths occurred. 2,4,6-Tribromophenol was not considered to be toxic by the inhalation route of administration (655).

Eye Irritation The potential of 2,4,6-tribromophenol to produce eye irritation was evaluated in rabbits in accordance with regulations of the Federal Hazardous Substances Act (FHSA). A single application of 100 mg of 2,4,6-tribromophenol was placed into the conjunctival sac of the right eye of each of three male and three female New Zealand white rabbits. Eyes were scored for irritation at 24, 48, and 72 h and at 7 days post-instillation according to the method of Draize. Instillation elicited slight to moderate conjunctival redness in four of six rabbits at 24 h, six of six rabbits at 48h, and slight redness in one of six rabbits at day 7. Very slight to slight chemosis and very slight to marked discharge were observed in four of six rabbits at 48h. Dulling of the cornea was observed in one of six rabbits at 48 and 72h. Examination with fluorescein and UV light at 72 h indicated slight corneal damage in five of six rabbits. 2,4,6-Tribromophenol was considered an eye irritant (655).

Additionally, 100 mg of 2,4,6-tribromophenol was instilled into the conjunctival sac of three male and three female New Zealand white rabbits. Conjunctival and iridal irritation was observed. Very slight opacity was noted at 24 h, and dulling of the cornea at 48 h was noted in one rabbit. Fluorescein examination under UV light revealed corneal damage in one rabbit at the 72 h examination. 2,4,6-Tribromophenol was considered a moderate eye irritant (655).

Primary Skin Irritation 2,4,6-Tribromophenol was evaluated for primary skin irritation in rabbits in accordance with the regulations of the Federal Hazardous Substances Act (FHSA). A single application of 500 mg of 2,4,6-tribromophenol was made to the shaved backs of three male and three female New Zealand white rabbits (skin was abraded on three rabbits) and the sites occluded for 24 h. Sites were scored for irritation at 24 and 72 h post-application. The primary irritation score was 0.3. 2,4,6-Tribromophenol was not considered a primary irritant, nor was it expected to pose a corrosive hazard (655).

15.4.1.2 Chronic and Subchronic Toxicity 28-Day Dermal Toxicity 2,4,6-Tribromophenol was evaluated for toxicity in a 28-day dermal study with New Zealand white rabbits. The material was ground to a fine powder and prepared as a suspension in 1.0% (w/v) aqueous methylcellulose. The material suspensions and control (1000 mg/kg aqueous methylcellulose) were applied topically to the clipped unoccluded skin. Groups consisted of four rabbits each (2/sex/group with the skin of two males and two females/group abraded). Doses were applied 5 days/week for 4 weeks (20 applications) at levels of 100, 300, and 1000 mg/kg. One rabbit died after 15 applications. The cause of death could not be determined. There were no pharmacotoxic signs, but 2,4,6-tribromophenol was slightly irritating to the skin following repeated exposure. No effects on body weight, hematology, clinical chemistry, urinalysis, and organ weights and ratios were produced. Microscopically, dose-related lesions were noted at the treated skin sites. The lesions consisted of epidermal acanthosis and hyperkeratosis, and were accompanied by multifocal to diffuse inflammatory infiltrates (655).

21-Day Dust Inhalation Toxicity 2,4,6-Tribromophenol was evaluated for toxicity in a 21-day dust inhalation study. Two groups of five male and five female rats were exposed to dust atmospheres of 2,4,6-tribromophenol for 6 h/day, 5 days/week (15 exposures). A concurrent control received no dust exposures. Test concentrations were 0.1 and 0.92 mg/L. One male and one female at 0.92 mg/L died after 10 and 11 exposures, respectively. Reactions noted in treated groups included hypoactivity, salivation, lacrimation, and red nasal discharge. Body weight gain of high level males and females were lower than that of the controls. No effects were noted in hematology, clinical chemistries, and urinalysis evaluations. At necropsy, four of five males and all females from the high exposure group were emaciated. In the high test concentration, tan discoloration was observed on the kidney of one male and an area described as fibrotic was observed in the liver of one female. Histopathologic evaluation revealed dilation of the renal tubules in three of five animals of each sex and a solitary

area of hepatic necrosis in one female. The changes were considered to be related to treatment (655).

15.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The rates of absorption, distribution, and excretion of 2,4,6-tribromophenol were determined in rats. Single oral doses of radiolabeled 2,4,6-tribromophenol were administered and animals sacrificed at various intervals post-treatment. 2,4,6-Tribromophenol was rapidly absorbed. The bulk of radioactivity (77.0%) was readily excreted in the urine and 2–14% eliminated in the feces within 48h. Blood concentrations peaked at 4.57 ppm after 1 h and plunged to 0.002 ppm by 24 h. The only detectable residues after 48 h were in the kidneys, liver, and lungs. The pharmacokinetics appeared to follow a one-compartment open-model system. 2,4,6-Tribromophenol was rapidly distributed in the body, and the rate of elimination in urine was proportional to the concentration in the blood. The rate constant for elimination (K_e) was 0.3 and the $t_{½}$ in the blood was 2.03h. The results indicate that 2,4,6-tribromophenol should be neither persistent nor accumulative in mammalian systems (655).

Bioaccumulation in Fat Tissue Six test groups of five rats each and six control groups of three rats each were used. In all test groups 2,4,6-tribromophenol was fed at 1000 ppm. Increases in fat residue content were noted after 7 days of feeding. Small quantities of residue were found in fat tissue of animals allowed a 7-day recovery after 7 days of feeding. Animals fed 21 days showed similar increases in fat residues as animals fed for 7 days. However, no detectable residues were noted in animals allowed recovery of 14 days or longer (655).

15.4.1.4 Reproductive and Developmental 2,4,6-Tribromophenol was ground with a mortar and pestle, suspended in corn oil, and administered via gavage to groups of five female rats each. Test concentrations of 0 (corn oil), 10, 30, 100, 300, 1000, and 3000 mg/kg were administered on days 6–15 of gestation. All animals were sacrificed on day 20 of gestation. All females died after 1 day of treatment at 3000 mg/kg. Slight decreases in body weight gains between days 6 and 12 of gestation, an increase in post-implantation loss, and slight decrease in the number of viable fetuses were noted at 1000 mg/kg. The maximum dose suggested for a teratology study was 1000 mg/kg (655).

Lyubimov et al. (656) exposed Wistar rats to 2,4,6-tribromophenol by whole-body inhalation at concentrations of 0.03, 0.1, 0.3, and 1.0 mg/m^3, 24 h/day, 7 days/week from day 1 to 21 of gestation. Significant decreases were observed in orientation reactions at a concentration of 1.0 mg/m^3. Nonsignificant trends toward decreased horizontal movement and emotionality in the open field and increased electrical impulse skin pain threshold were observed. Preimplantation and postimplantation embryo losses were significantly increased in a dose-dependent manner and were seen at all concentrations except the lowest (0.03 mg/m^3). Significant effects were found for lower incisor eruption and ear unfolding at 0.3 mg/m^3. Grooming behavior was decreased in males at all concentrations and in females at 0.3 mg/m^3. The NOEL for developmental neurotoxicity in this study was >0.03 mg/m^3. The results of this study suggest that 2,4,6-tribromophenol may cause developmental neurotoxicity, embryotoxicity and fetal toxicity.

15.4.1.5 Carcinogenesis: NA

15.4.1.6 Genetic and Related Cellular Effects Studies 2,4,6-Tribromophenol was evaluated for mutagenicity in the *Salmonella*/microsome assay using *S. typhimurium* tester strains TA98, TA100, TA1535, and TA1537 and *Saccharomyces cerevisiae*, strain D4 with and without metabolic activation. 2,4,6-Tribromophenol was not mutagenic in any strain tested (657).

15.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization The potential of 2,4,6-tribromophenol to produce dermal sensitization was evaluated in guinea pigs. Doses were administered by intradermal injections in the right flank of 8 guinea pigs every other day 3 days/week, until 10 induction doses were given. 2,4,6-Tribromophenol was administered as a 1% solution in 0.9%

sodium chloride (NaCl). a concurrent positive control, DNCB (dinitrochlorobenzene), was administered to a group of four guinea pigs using the same regimen, and 0.9% NaCl solution was administered in a like manner to the left flank of each animal. The first sensitizing dose was administered at a volume of 0.05 and 0.1 mL for the remaining nine doses. The challenge dose (0.05 mL) was administered 2 weeks after the last dose. Four of eight 2,4,6-tribromophenol-treated animals exhibited a flare response that was slightly greater than that seen during the induction phase. 2,4,6-Tribromophenol was considered to be potentially sensitizing in humans, producing slight sensitization in the occasionally susceptible individual (655).

15.5 Standards, Regulations, or Guidelines of Exposure:

NA

15.6 Studies on Environmental Impact

First-instar (24-h-old) daphnids were exposed to 2,4,6-tribromophenol at concentrations of 1.8, 3.2, 5.6, 10.0, and 18 ppm for 48 h under dynamic conditions. A solvent control (acetone) and untreated control were run concurrently. Four vessels containing five *Daphnia* each were used for each test and control group. The 48 h median tolerance limit (TL_{50}) was 5.5 (4.4–7.0) ppm (655).

2,4,6-Tribromophenol was tested in two species of fish (trout—0.18, 0.21, 0.24, 0.28, 0.32 ppm; bluegill—0.18, 0.24, 0.32, 0.42, 0.56 ppm). Static bioassays were conducted at 10°C for trout and 18°C for bluegill. Each group (control untreated and acetone solvent control) consisted of 10 fish each. Rapid or shallow respiration was noted in trout at all concentrations; quiescence was noted at concentrations of ≥0.21 ppm; and loss of equilibrium, lying on bottom of the vessel, and dark discoloration were noted at concentrations of 0.24 ppm and above. The median tolerance limit [TL_{50}] value for trout was 0.24 ppm. At concentrations of ≥0.24 ppm, bluegills exhibited quiescence and flaccid and dark discoloration. Fish at 0.42 and 0.56 ppm displayed loss of equilibrium, shallow respiration, and lying on the bottom of the vessel. The median tolerance limit [TL_{50}] value for bluegills was 0.28 ppm.

Bluegills were exposed to radiolabeled 2,4,6-tribromophenol in a flow-through bioassay. The fish were exposed to a concentration of 0.0092 ppm for 28 days followed by a 28-day withdrawal period. Samples of water and edible tissue and viscera were taken and analyzed periodically. Bioaccumulation in the edible tissue was 20-fold and viscera 140-fold over the concentration in the water. The plateau levels in the edible tissue and viscera were reached in 3–7 days of exposure. The half-life for radiolabeled carbon residue (withdrawal phase) was <24 h in both the edible tissue and viscera (655).

Oxygen uptake by microorganisms was measured in the presence of 2,4,6-tribromophenol using the Warburg respirometer. The biological seed culture was prepared from fresh sewage and topsoil. Nine concentrations were tested: 1, 10, and 100 ppb; 1, 10, and 100 ppm; and 0.1, 1.0, and 10%. Incubation was at ambient temperatures (water bath at 23°C) with constant shaking for 96h. Test concentrations of 100 ppm, 0.1, 1.0, and 10% exhibited slight inhibition of microbial respiration. After 96h, the average oxygen uptake in samples with concentrations ranging from 1 ppb to 10 ppm was 26.5 mg O_2/L media. Amount O_2 utilized in control (seeded dilution water) was 21.1 mg/L. The highest volume of absorbed oxygen was 75.9 mg/L with 1 ppm glucose (PC). Concentrations of oxygen at 100 ppm, 0.1, 1.0, and 10% TBP were decreased, indicating inhibited endogenous respiration (655).

Octanol	529	439
Toluene	466	0.53
Hexane	48.6	0.047

16.1.1.3 Vapor pressure (at 25°C)

OPP: 1.62×10^{-3}mmHg or 2.16×10^{-4}kPa
SOPP: 1.8×10^{-9}mmHg or 2.4×10^{-10}kPA

16.1.1.4 Partition Coefficient (Octanol/Water)

OPP: $\log_{10}K_{ow} = 3.0$ at pH 7

16.1.1.5 Dissociation Constant

SOPP: $pK_a = 9.84$ (20°C), pH of 1% solution = 11.2–11.6

16.1.1.6 Appearance

OPP: White to pink solid or crystals
SOPP: Available only as the tetrahydrate
SOPP · $4H_2O$: White to buff solid or flakes

16.1.1.7 Stability

OPP: Stable to hydrolysis and photolysis
SOPP · $4H_2O$: Dissociates in water to OPP^- and Na^+

16.1.2 Odor and Warning Properties

OPP: Phenolic odor
SOPP · $4H_2O$: Strongly alkaline solution in water

16.2 Production and Use
OPP is produced as a by-product in the manufacture of diphenyloxide or by aldol condensation of hexazinone. Current global production is estimated to be less than 10 millionlb per year. Chief uses of products containing OPP are as disinfectants, antimicrobials, preservatives, antioxidants, and sanitizing solutions in various industries.

SOPP is produced as its tetrahydrate by reaction of OPP with NaOH, followed by flaking. This water-soluble form is used primarily for sanitation of equipment and for postharvest treatment of fresh fruits and vegetables to control microbial and fungal infections during prolonged storage and distribution worldwide.
16.3 Exposure Assessment
16.3.1 Air No exposure limits established by OSHA, ACGIH, or NIOSH

16.3.2 Background Levels: NA

16.3.3 Workplace Methods: NA

16.3.4 Community Methods: NA

16.3.5 Biomonitoring/Biomarkers 16.3.5.1 Blood: NA

16.3.5.2 Urine OPP is rapidly and almost completely excreted in urine as water-soluble conjugates that can be quantitated using any of several chromatographic methods (658, 659). In an occupational exposure study, 11 volunteers were treated with 10 consecutive 3- mL applications of an undiluted hand disinfectant containing 2% OPP. Each time, the formulation was rubbed on the hands for 1 min, then water was added and the hands were rinsed under running water for 30s before drying on a paper towel. Total 24-h urine samples were collected over a 4-day period after treatment and were analyzed by steam distillation followed by gas chromatography. The total OPP excreted by the 11 subjects ranged from 2.95 to 7.22 mg, with an average of 4.45 mg on the first day, 1.08 mg on the second day and only traces on the third and fourth days. Since the total OPP applied was ~600 mg, most was washed off and only about 1% was absorbed through the skin under the conditions of this study (660).
16.4 Toxic Effect
16.4.1 Experimental Studies 16.4.1.1 Acute Toxicity OPP is slightly toxic, with reported oral LD_{50} values of 1100–3500 mg/kg in male and female mice, and 2600–2800 mg/kg in male and female rats. It is essentially nonirritating to skin but may cause moderate eye irritation and corneal injury. The dermal LD_{50} of OPP is >5 g/kg in rabbits. Repeated applications did not cause delayed hypersensitivity in guinea pigs (658, 659).

The sodium salt (SOPP) is slightly more toxic, with LD_{50} values of 800–900 mg/kg bw in male and female mice, and 850–1700 mg/kgbw in male and female rats. It can cause severe skin burns and severe eye irritation with corneal injury due to its high alkalinity; a 1% solution of SOPP has a pH of 11.2–11.6 (658, 659).

16.4.1.2 Chronic and Subchronic Toxicity OPP and its sodium salt (SOPP) have been studied extensively in Japan, Germany, and the United States as required for pesticide registration and reregistration. Only subchronic and chronic studies with OPP are reviewed here; humans are not exposed to SOPP in the diet, such as on washed fruit, because it readily hydrolyses to OPP during the fungicidal treatment. The many feeding studies conducted with SOPP at high levels in the diet of rats are considered to be of little relevance for the assessment of potential toxicity in humans

exposed to low levels of OPP (658, 659).

16.4.1.2.1 Subchronic Toxicity Two similar short-term studies were conducted in Japan in which groups of 10–12 rats of each sex were fed OPP at dietary levels of 0.125 or 0.156, 0.313, 0.625, 1.25, and 2.5% for 12 or 13 weeks. The dietary NOEL was 0.625% in each study, reported to be equivalent to a dose level of ~780 mg/kgbw per day in one study (661) and to ~420 mg/kgbw per day in the other (662). Body weights and body weight gains were severely depressed in males and females fed 2.5% OPP in the diet. Only 73% of males survived compared to 92% of females at this high dietary level equivalent to a dose level of ~2500 mg/kgbw per day, and all rats in lower dose groups lived to the end of these short-term studies. Absolute and relative weights of many organs were depressed in male rats fed 2.5% OPP, and proliferative lesions of the urinary bladder and slight nephrotoxic lesions were noted (662).

In a U.S. study, 30 male rats were fed a diet containing 2% OPP (~1250 mg/kgbw daily) and were sacrificed at intervals for ≤90 days. Food consumption was greatly reduced with consequent weight loss during the first week, which improved but remained somewhat depressed throughout the study. Seven of the rats died of apparent malnutrition. Observations included small amounts of blood in the urine, significantly decreased urine specific gravity at 65 and 90 days, increased sizes of liver and kidneys, and discolored focal areas of the kidneys at the end of the study. On microscopic examination slightly swollen liver cells were seen, as well as signs of kidney pathology that were not considered severe enough to seriously impair renal function and did not increase in severity on days 30–90 of treatment. No treatment-related urinary bladder lesions were seen in this study (663).

16.4.1.2.2 Chronic Toxicity Groups of 50 mice of each sex were fed diets to provide dose levels of 0, 250, 500, and 1000 mg/kgbw daily for 2 years. Satellite groups of 10 mice/sex/dose level were sacrificed at 1 year for evaluation of general chronic toxicity. In-life observations, mortality, hematology, clinical chemistry, and urinalyses were not affected. Significantly decreased body weights and body weight gains were noted in all groups except low dose males. The primary target organ was the liver, based on increased absolute and/or relative weights at all dose levels, and on gross and histopathology. Microscopic changes in the liver suggested adaptation to OPP metabolism, associated with a statistically significant increased incidence of liver cell adenomas in middle and high dose males. No oncogenic effects were observed in low dose males or in females at any dose level. The minor effects observed in the low dose groups suggest that a long-term NOEL would likely be 100 mg/kgbw OPP daily in mice (664).

To confirm the adverse findings in male rats in short-term studies, several longer-term studies were conducted with OPP in Japan using small groups of male rats. In a 91-week study at dietary levels of 0.63, 1.25 and 2.5% OPP, survival rates and mean body weights were significantly lower in mid-dose and high-dose groups. Bladder tumors were seen in 23/24 males in the mid-dose group, but in only 4/23 of high dose group. Moderate to severe nephrotic lesions were found in 3/24 of the group fed 1.25% OPP and in all 23 of the male rats fed 2.5% OPP for 91 weeks (662). In another study, no tumors were induced when male rats were fed 2% OPP for 36 or 64 weeks, or 1.25% for 96 weeks followed by 8 weeks on untreated diet. In the latter 104-week study, only papillary or nodular hyperplasia of the bladder was seen in 3/27 male rats fed 1.25% OPP (665).

In a recent study conducted according to U.S. pesticide guidelines, groups of 70–75 rats of each sex per dose level were fed OPP at constant nominal dietary concentrations of 0, 0.08, 0.4, and 0.8% (males) or 1.0% (females). These levels were equivalent to average daily dose levels of 39/49, 200/248, and 402/647 mg/kgbw in male and female rats, respectively. Satellite groups of 20 rats/sex/dose level were sacrificed at 1 year to evaluate interim toxicity; remaining rats were sacrificed at 2 years to evaluate long-term toxicity and carcinogenicity. Food consumption remained unchanged, but mean body weights were decreased in mid-dose and high dose males and females. Increased mortality was noted in highdose males fed 0.8% but not in females fed 1.0% OPP. Clinical observations included abnormal urine color and various staining, and an increased incidence of blood in the urine of high dose males. Postmortem findings included wet/stained ventrum, urinary bladder

masses, and pitted zones and abnormal texture in the kidney. No effect on organ weights was noted. Histopathological findings in mid-dose and high dose males were characterized as structural alterations in the kidney and urinary bladder, including evidence of urothelial hyperplasia and/or neoplasia (papilloma and transitional-cell carcinoma). Neoplastic changes were not observed in high-dose females at a dose level ~60% higher than in males. The NOEL for systemic chronic toxicity was 0.08% OPP in the diet, equivalent to daily dose levels of 39 and 49 mg/kgbw in male and female rats, respectively (666).

16.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Extensive studies have been conducted in the United States and Japan on the metabolism of OPP in mice, rats, cats, and dogs given relatively high single or multiple oral doses. The results are compared in a recent publication, which also reports a metabolism study in human male volunteers exposed to a low dermal dose of radiolabeled OPP (667).

16.4.1.3.1 Absorption When single oral doses of 500 mg/kg of ^{14}C-OPP or ^{14}C-SOPP were given to male rats, both compounds were absorbed rapidly as demonstrated by recovery of ~90–95% of the radioactivity in urine and 5–6% in feces, chiefly in the first 24 h. The disposition of the radioactivity was not greatly affected by preconditioning the rats by feeding equimolar amounts of unlabeled OPP (1.3%) or SOPP · $4H_2O$ (2.0%) in the diet for 2 weeks before administration of the labeled compounds. SOPP appeared to be eliminated somewhat more rapidly than OPP (663).

16.4.1.3.2 Distribution OPP is distributed rapidly via enterohepatic circulation and does not bioaccumulate in tissues after either oral or dermal exposure in experimental animals (658, 659).

16.4.1.3.3 Excretion Absorbed OPP is excreted rapidly in urine primarily as the sulfate and glucuronide conjugates. Administration of high doses results in saturation of the sulfation pathway and some conversion of OPP to 2,5-dihydroxybiphenyl (phenylhydroquinone), which is also excreted as sulfate and glucuronide conjugates (663, 667).

16.4.1.4 Reproductive and Developmental In a reproduction study, groups of 30 rats of each sex were fed OPP at dietary concentrations to provide dose levels of 0, 20, 100 or 500 mg/kgbw daily over two generations. Animals in the high dose groups exhibited parental toxicity consisting of reduction in male and female body weights, urine staining in males, bladder calculi in males, and histological changes in the kidneys, bladder, and ureter of males. No reproductive effects were observed at any dose level. The parental and neonatal NOEL was 100 mg/kgbw per day, and the NOEL for reproductive effects was 500 mg/kgbw per day (659, 668).

A teratogenicity study was conducted in which groups of 25–27 female rats were bred and given daily doses of 100, 300, or 700 mg OPP/kgbw by gavage on days 6–15 of gestation. No evidence of maternal or fetal toxicity was produced by administration of the two lower dose levels. The high dose did not cause embryotoxic or teratogenic effects, but was slightly toxic to the dams as evidenced by decreased body weight gain and food consumption during the treatment period (659, 669).

Another teratogenicity study was conducted in groups of 16–24 artificially inseminated female New Zealand white rabbits by oral gavage of OPP in corn oil at targeted daily dose levels of 0, 25, 100, or 250 mg/kgbw on days 7–19 of gestation. The high dose caused increased mortality (13%), gross pathological alterations of the GI tract, and histopathological alterations of the kidneys. The NOEL for maternal toxicity was 100 mg/kgbw per day and the embryonal/fetal NOEL was 250 mg/kgbw per day, the highest dose level tested in rabbits (659, 670).

16.4.1.5 Carcinogenesis IARC classified SOPP as a B2 carcinogen in 1983, based on reports from Japan that high dietary levels of this sodium salt caused bladder tumors in male rats (671, 672). Both sodium saccharin and sodium cyclamate also cause bladder tumors at high doses in male rats, but

classification of these food additives as B2 carcinogens was recently rescinded by IARC at a meeting in 1998.

OPP was not classified by IARC because little published data were available when this form was evaluated in 1983 (671, 672). Since then, several conventional long-term studies have been conducted with OPP in both sexes of mice and rats. Groups of 50 mice/sex were fed dietary levels of OPP to provide dose levels of 0, 250, 500, or 1000 mg/kgbw daily for 2 years. The liver was identified as the target organ, with microscopic changes suggestive of adaptation to OPP metabolism. No oncogenic effects were observed in females at any dose level or in low dose males, but a statistically significant increased incidence of liver cell adenomas was seen in male mice given 500 or 1000 mg/kgbw daily for 2 years. These dose levels also caused significantly decreased body weights and body weight gains, indicating that the MTD had been exceeded (664). OPP was also administered to groups of 50 rats/sex/dose level at nominal dietary concentrations of 0, 800, 4000, and 8000 ppm in males and at 0, 800, 4000, and 10,000 ppm in females for 2 years. The equivalent dose levels in both male and female rats were reported to be 39/49, 200/248, and 402/647 mg/kg bw per day. No neoplastic changes were observed in females, including the high-dose group given 60% more than the high-dose males. Histopathological findings in mid-dose and high-dose males were characterized as structural alterations in the kidney and urinary bladder, including urothelial hyperplasia and/or neoplasia (papilloma and transitional cell carcinoma). A statistically significant increase in incidence of these neoplasms was seen only in male rats given 402 mg OPP/kgbw daily for 2 years (666).

The U.S. National Toxicology Program conducted a skin-painting study with OPP in groups of 50 mice per sex. The OPP was applied as an acetone solution on 3 days per week for 2 years, both alone and as a promoter with 7, 12-dimethylbenz(*a*)anthracene (DMBA). No skin neoplasms were observed in either sex treated with OPP alone, and there were no tumor enhancing or inhibiting effects when OPP and DMBA were given in combination (673).

16.4.1.6 Genetic and Related Cellular Effects Studies OPP, SOPP, and the oxidative metabolites phenylhyroquinone (PHQ) and phenylbenzoquinone (PBQ) have been tested for genotoxic properties in a variety of test systems. Most *in vitro* and *in vivo* assays were negative, but the metabolites had a tendency to bind with DNA. OPP is probably not genotoxic, but SOPP and PBQ are possibly genotoxic at high doses (658, 659).

16.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization No evidence of delayed contact hypersensitivity was found in standard Buehler tests with OPP and SOPP in guinea pigs (658, 659). In an early study in humans, the potential for skin sensitization was tested in 200 unselected subjects, 100 males and 100 females, by placing patches impregnated with OPP or SOPP in direct contact with the skin on the back, covering with an impervious film and taping into place. The first application was kept in constant contact with the skin for 5 days before removal, and any reaction was recorded. A second application was made in the same way 3 weeks later and kept in direct contact for 48 h before removal. Each subject was examined immediately and again 3 days and 8 days later. OPP did not cause primary irritation when tested as a 5% solution in sesame oil, and did not cause sensitization. Applications of aqueous solutions of SOPP caused no irritation at 0.1% and very slight simple irritation at 0.5%, but were significantly irritating at 1 and 5%. However, no skin sensitization was produced by SOPP at these concentrations (674).

16.4.2 Human Experience 16.4.2.1 General Information Products containing OPP or SOPP have been used extensively as antimicrobials and sanitizers, and for fungicidal treatment of fruits and vegetables since the 1940s without adverse effects.

16.4.2.2 Clinical Cases 16.4.2.2.1 Acute Toxicity: NA

16.4.2.2.2 Chronic and Subchronic Toxicity: NA

16.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms OPP was rapidly eliminated following dermal exposure to a single dose of ~0.4 mg on the forearm of six human male volunteers. The radiolabeled test substance was applied to a 4 × 6-cm area of shaved volar surface as a 100-mL aliquot of a 0.4% w/v solution in isopropyl alcohol. A protective dome was placed over the treatment site and was left in place for 8h. The treated sites were then wiped with cotton swabs dipped in isopropanol, rinsed with alcohol, and stripped with tape at ~1, 23, and 46 h after removal of the protective dome to determine the amount of residual activity associated with surface layer of skin. The radioactivity in blood, urine, and feces was measured at intervals for 5 days. Under the conditions of this study, ~43% of the applied OPP was absorbed through the skin, and 99% of the absorbed dose was recovered in the urine collected within the first 48 h after exposure. The urinary metabolites consisted of 69% OPP sulfate, 4% OPP glucuronide, 15% as conjugated phenylhydroquinone (PHQ), and 13% as the sulfate of 2,4'-dihyroxybiphenyl. Little or no free OPP, and no free PHQ or PBQ metabolites were found in urine following this dermal exposure to a representative low level in humans (667).

Using data from this dermal exposure study, a pharmacokinetic model was developed to simulate the potential for bioaccumulation of OPP from repeated dermal exposures. A worst-case occupational scenario was selected, with continuous occluded dermal exposure to 6 mg OPP/kg body weight for 8 h per day on 5 consecutive days per week. The calculated half-lives for absorption and excretion were 10 and 0.8h, respectively, indicating that OPP is unlikely to bioaccumulate in exposed workers (675).

16.5 Standards, Regulations, or Guidelines of Exposure

National and international tolerances or maximum residue limits (MRLs) were established in many countries during the past 45 years for residues remaining on the surface of fresh fruits and vegetables treated post-harvest with either OPP or SOPP to retard spoilage during storage and transportation to market. These MRLs have ranged from 3 ppm in/on cherries and nectarines to 25 ppm in/on apples and pears (676), but many have been rescined in the absence of new data reflecting current good agricultural practice. At their joint meeting in Rome in September 1999, the United Nations food and Agriculture Organisation (FAO) and the World Health Organization (WHO) recommended withdrawl of remaining MRLs except for 10 ppm in/on citrus fruits, and added 0.05 ppm for orange juice and 60 ppm for dried citrus pulp. FAO/WHO also increased the Acceptable Daily Intake (ADI) to 0.4 mg/kg bw for humans and agreed that an acute RfD was not necessary (659).

16.6 Studies on Environmental Impact

Metabolism on OPP in soil and and by aquatic microorganisms is fairly rapid and is complete under conditions resembling those of activated sludge systems, under both aerobic and anaerobic conditions. Complete degradation OPP of was obtained within 2 days under simulated biological wastewater treatment conditions for loadings at 30 and 100 mg/L. However, the antimicrobial properties of OPP slowed its degradation at levels higher than 100 mg/L in wastewater. Studies with ^{14}C-OPP showed that it is readily degraded to CO_2 at the low concentrations likely to occur in the natural environment, such as in river water, and that the rate of degradation is enhanced in activated sludge, especially after acclimation (678).

17.0 Di-**tert**-Butylmethylphenol

17.0.1 CAS Number:

[*29759-28-2*]

17.0.2 Synonyms:
DBMP, 4-methyl-2,6-di-*tert*-butylphenol, 2,6-di-*tert*-butyl-*p*-cresol, di-*tert*-butylhydroxytoluene
17.0.3 Trade Names:
Deenax, Paranox, DBPC Antioxidant, Ionil
17.0.4 Molecular Weight:
17.0.5 Molecular Formula:
17.0.6 Molecular Structure:
17.1 Chemical and Physical Properties
17.1.1 General

Physical state	Slightly yellow, crystalline solid
Melting Point	70°C
Boiling point	265°C

17.2 Production and Use
Di-*tert*-butylmethylphenol (DBMP) is an antioxidant that prevents the deterioration of fats, oils, waxes, resins, and plastic films. It is incorporated into many edible vegetable or animal fats and oils, into baked and fried foods, and into waxes or plastic films used for coating food wrappers or containers. It acts as an anti-skidding agent when added to paints and inks, and its antioxidant qualities allow it to be used in cosmetics and pharmaceuticals (11).
17.3 Exposure Assessment:
NA
17.4 Toxic Effects
17.4.1 Experimental Studies 17.4.1.1 Acute Toxicity When absorbed in toxic concentrations into the tissues of unanesthetized animals, DBMP induced signs of intoxication resembling those seen after absorption of a toxic dose of a parasympathetic drug (salivation, a mild degree of miosis, unsteadiness, restlessness, hyperexcitability, diarrhea, and tremors) (13). When given intravenously to a dog under pentobarbital anesthesia, DBMP (25 mg/kg) induced a prompt reduction of blood pressure. Atropine sulfate partially antagonized this depressor effect. Large doses of DBMP produced a gross disturbance of sodium, potassium, and water balance in the rabbit (13). It was concluded that the increase in sodium and aldosterone excretion was due to pyelonephritis, and that death was due to potassium depletion.

17.4.1.2 Chronic and Subchronic Toxicity From the results of chronic toxicity studies using dogs and rats (13), it was concluded that DBMP is a relatively innocuous compound for occupational handling.

17.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Metabolism studies in rats, dogs, and humans showed some differences in excretion patterns (13). In the rat there was slower excretion than in humans, and evidence of enterohepatic circulation was not apparent in humans. In humans more metabolites are excreted in the urine and overall excretion is more rapid than in rats (13).

17.4.1.4 Reproductive and Developmental: NA

17.4.1.5 Carcinogenesis The oral feeding of DBMP increased the detoxification and inhibited cancer induction by known carcinogens (2).

18.0.2 Synonyms:
NA
18.0.3 Trade Names:
NA
18.0.4 Molecular Weight:
NA
18.0.5 Molecular Formula:
NA
18.0.6 Molecular Structure:
NA
18.1 Chemical and Physical Properties:
NA
18.2 Production and Use:
NA
18.3 Exposure Assessment:
NA
18.4 Toxic Effects
18.4.1 Experimental Studies 18.4.1.1 Acute Toxicity The acute toxicity of this material is of a low order. An intramuscular dose of 20 g/kg is not fatal in the rat; lethal oral doses range from 20 to 30 g/kg. When applied to the skin of the rat, rabbit, and guinea pig, the material induces loss of hair in 6–12 days. When applied to the human skin, the material may induce local eczema but apparently does not cause loss of hair (13).

Aliphatic Nitro, Nitrate, And Nitrite Compounds
Candace Lippoli Doepker, Ph.D.

A. Aliphatic Nitro Compounds

Nitroalkanes, or nitroparaffins, are derivatives of alkanes with the general formula C_nH_{2n+1}, in which one or more hydrogen atoms are replaced by the electronegative nitro group ($–NO_2$). Nitroalkanes are classed as primary, RCH_2NO_2, secondary, R_2CHNO_2, and tertiary, R_3CNO_2, using the same convention as for alcohols. Some examples of commercial nitroalkanes, are nitromethane, nitroethane, 1-nitropropane, and tetranitromethane (1).

The nitroalkanes are produced in large commercial quantities by direct vapor-phase nitration of propane with nitric acid or nitrogen peroxide. The reaction product is a mixture of nitromethane, nitroethane, and 1- and 2-nitropropane. The individual compounds are obtained by fractional distillation.

The chemical and physical properties of a number of nitroalkanes are described in Table 54.1 and in the individual summaries following. Nitroparaffins are colorless, oily liquids with relatively high vapor pressures. Their solubility in water decreases with increasing hydrocarbon chain length and number of nitro groups. As expected, their boiling and flash points are higher than their corresponding hydrocarbons.

Table 54.1. Properties of the Mononitroalkanes and Tetranitromethane

Name	Mol. wt.	B.p. (°C)	Specific gravity	Solubility in H_2O at 20°C (% by vol.)	Vapor pressure (mmHg) (°C)	Vapor density (Air = 1)	(Closed/open) flash point (° F)	Conver unit 1 mg/L (ppm)	1 (r
Nitromethane	61.04	101.2	1.139 (20/20°C)	9.5	27.8 (20)	2.11	95/110	400.7	
Tetranitromethane	196.04	125.7	1.6629 (25°C)	Insoluble	8.4(20)	0.8	—	124.7

2-Nitrobutane	103.12	139	0.9728 (15.6/15.6° C)	0.9	8(25)	3.6	—	237.1	

The uses of nitroalkanes depend on their strong solvent power for a wide variety of substances including many coating materials, waxes, gums, resins, dyes, and numerous organic chemicals. Most organic compounds, including aromatic hydrocarbons, alcohols, esters, ketones, ethers, and

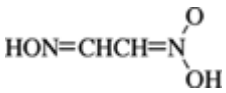
carboxylic acids, are miscible with nitroalkanes. Thus, they are used in products such as inks, paints, varnishes, and adhesives. Another important use is in the production of derivatives such as nitroalcohols, alkanolamines, and polynitro compounds. In some cases, they provide better methods of manufacturing well-known chemicals such as chloropicrin and hydroxylamine. They are also used as special fuel additives, rocket propellants, and explosives.

Nitroalkane vapor pressures are sufficient to produce high vapor levels in the workplace unless controlled. Thus, the chief industrial hazard is respiratory irritation when these compounds are inhaled. The odors of nitroalkanes are easily detectable, and concentrations below 200 ppm are disagreeable to most observers (2). However, the odor and sensory symptoms are not considered dependable warning properties.

The fire and explosion hazards of nitroalkanes are considered low for they have relatively high flash points. Despite these high flash points, shock explosion can result under certain conditions of temperature, chemical reaction, and confinement.

Nitroalkanes are acidic substances. Polynitro compounds are even stronger acids than the corresponding mononitroalkanes. They are rapidly neutralized with strong bases and readily titrated. Tautomerism, a general property of primary and secondary mononitroalkanes, gives rise to a more acidic “aci” form, or nitronic acid. In organic solvents, primary and secondary mononitroalkanes exist as neutral nitroalkanes. However, in aqueous solutions, they exist in a state of equilibrium between the protonated neutral nitroalkane, the nonprotonated nitronic acid and its anion, or nitronate. Tautomerism is important for understanding the biological effects of nitroalkanes and also forms the basis of a number of important chemical reactions through the formation of nitroalkane salts. Mercury fulminate, $Hg(ON{=}C)_2$, is one of the better-known compounds that is derived from the mercury salt of nitromethane $[(CH_2{=}NO_2)_2Hg]$.

Except for chloropicrin, the production of chloronitroparaffins, uses tautomerism. The important intermediate methazonic acid, which is a starting product for a number of



well-known compounds (e.g., nitroacetic acid and glycine) also uses tautomerism. Additionally, many nitro derivatives are a source of guanidine $[H_2NC({=}NH)NH_2]$ by reaction with ammonia. A number of other useful products such as primary amines, nitrohydroxy compounds, aromatic amines, and b-dioximes, which in turn can yield isoxazoles by hydrolysis, are also among the armamentarium of the nitroalkane reaction possibilities.

Early methods (1940–1959) of determining nitroalkanes used colorimetric procedures (see chemical summaries below for more details). Since 1970 these have been replaced by instrumental methods. References to the colorimetric procedures are included here because these procedures were used for monitoring animal exposures, which provide the toxicity data in Table 54.2. Instrumental methods of mass spectroscopy and gas chromatography are now used routinely, and infrared has been used in animal exposure studies (3).

[b] No animals exposed.
[c] One monkey exposed.

The primary mononitroalkanes on which toxicity data were determined, were analyzed colorimetrically by measuring the color developed from an HCl-acidified alkaline solution containing $FeCl_3$ (4). Analytical data on the secondary nitroalkanes were determined by measuring ultraviolet radiation at a wavelength of 2775 Å through an alcoholic solution in a Beckman spectrophotometer (5). A more sensitive spectrophotometric determination of primary nitroalkanes uses the coupling reaction with *p*-diazobenzenesulfonic acid (3). Simple, secondary nitroalkanes do not interfere as do some complex secondary nitro alcohols.

Mass spectrography, gas chromatography, and infrared spectroscopy are the current methods of choice for determining nitroalkanes in air (6). Mass spectra have been determined for eight C_1 to C_4 mononitroalkanes (6, p. 418). The different conditions recommended for analyzing nitroalkane mixtures including chloronitroparaffins by gas chromatography, along with their chromatograms, are given in Ref. 6 on pp. 425–429 and 430–433, and for nitroalcohols, on pp. 441–443.

Because nitroparaffins can cause respiratory irritation, inhalation toxicity data have always been of interest. The inhalation toxicity data on the nitroalkanes gathered in the late 1930s and summarized

below lacked some of the refinements of late work with these compounds. Exposure “chambers” consisting of steel drums of 233-liter capacity lacked the space to expose what is now considered an adequately sized complement of animal species (7). The exposure concentrations at levels of 5000 to 50,000 ppm must be considered “nominal” because of measurement by interferometer, the chamber airflow characteristics, and fan circulation of air.

Incomplete information on polynitroalkanes indicates that an increased number of nitro groups results in increased irritant properties. Thus, the chlorinated nitroparaffins are more irritating than the unchlorinated compounds (8). This reaches a severe degree with trichloronitromethane (chloropicrin). Unsaturation of the hydrocarbon chain in the nitroolefins also increases the irritant effects (9, 10).

The primary nitroalkanes fail to show significant pharmacological effects on blood pressure or respiration (11). Oral doses result in symptoms similar to those produced by inhalation except for the additional evidence of gastrointestinal tract irritation. They are less potent methemoglobin formers than aromatic nitro compounds.

In general, applications of nitroalkanes to the skin give no evidence of sufficient absorption to result in systemic injury. After application of the nitroalkanes in five daily treatments to the clipped abdominal skin of rabbits, no systemic effects or evidence of weight loss was reported (2).

Nitroalkanes are readily absorbed through the lungs and through the gastrointestinal tract (12). Animals that die following brief inhalation of the nitroalkanes show general visceral and cerebral congestion. After exposure at high concentrations, there is pulmonary irritation and edema, but the latter is inadequate to be the sole cause of death.

Oxidative denitrification of nitroalkanes occurs by two mechanisms. The microsomal cytochrome P450 monooxygenase system of rat and mouse liver metabolizes nitroparaffins *in vitro* (13, 14). Specific activities are greatest for 2-nitropropane, followed by 1-nitropropane, nitromethane, and tetranitromethane. One study found up to 25% of residual denitrifying activity with mouse liver microsomes under anaerobic conditions (15), suggesting that an oxygen-independent mechanism may exist. Dayal et al. found that 2-nitro-2-methylpropane was not denitrified by the monooxygenase system (16). This indicates that a hydrogen atom is required in the position alpha to the nitro group for oxidative cleavage of the neutral tautomeric form. They also showed that the nitronate anion of 2-nitropropane was denitrified 5 to 10 times faster than the neutral form. Because the tautomeric equilibrium of primary nitroalkanes, such as 1-nitropropane, lies far to the neutral side of physiological pH, the authors suggest that this may explain the slower reaction rate with these compounds relative to 2-nitropropane.

A second mechanism of oxidative denitrification has been demonstrated for various flavoenzyme oxidases (17–20). The relative reactivity rates of the nitroalkanes are similar to those of the microsomal systems, except that tetranitromethane was inert (18). The interesting aspect of this pathway is that a superoxide radical is produced either as an intermediate (18) or as an initiator/propagator of the reaction (20). Superoxide radical and other active oxygen species produced from it (oxygen free radicals, hydrogen peroxide, hydroxyl radical) have been associated with toxicity and mutagenicity.

Official Occupational Safety and Health Administration (OSHA) standards and ACGIH threshold limit values (TLVs) have been adopted for the seven nitroalkanes listed in Table 54.3. No TLVs have been established for any nitroolefin or nitroalcohol. For the basis of TLVs, see Documentation of TLVs published by the ACGIH.

Aliphatic Nitro, Nitrate, And Nitrite Compounds
Candace Lippoli Doepker, Ph.D.

B. Aliphatic Nitrates

Aliphatic nitrates are nitric acid esters of mono- and polyhydric aliphatic alcohols. The nitrate group has the structure –C–O–NO_2, where the N is linked to C through O, as contrasted to the nitroalkanes in which N is linked directly to C.

The nitric acid esters of the lower mono- di- and trihydric alcohols are liquids (methyl nitrate, ethylene glycol dinitrate, trinitroglycerin), whereas those of the tetrahydric alcohols (erythritol tetranitrate, pentaerythritol tetranitrate) and hexahydric alcohol (mannitol hexanitrate) are solids. They are generally insoluble, or only very slightly soluble in water, but are more soluble in alcohol or other organic solvents. Some chemical and physical properties of this group of compounds are shown in Table 54.16.

Table 54.16. Chemical and Physical Properties of Aliphatic Nitrates and Related Explosive Compounds

Name	Mol. wt.	Physical state	BP (°C)	Vapor density (air = 1)	H_2O solubility
Methyl nitrate	77.04	Volatile liquid	66 (explodes)	2.66	Slight
Ethyl nitrate	91.07	Colorless liquid	87.6	3.14	1.3% (55° C)
Isopropyl nitrate	105.09	Pale yellow liquid	110.5	3.62	Very slight
Amyl nitrate	133.15	Slightly yellow liquid	150 (unstable)	—	0.3%
Ethylene glycol dinitrate	152.07	Colorless liquid	114 (explodes)	5.24	0.52%
Glyceryl trinitrate (nitroglycerin)	227.10	Colorless oily liquid	260 (explodes)	7.80	Slight
Propylene glycol-1,2-dinitrate	166.09	Red-orange liquid	121 (decomp)	—	—
Pentaerythriol tetranitrate	316.15	Water-wet solid	180 (50 mm Hg)	—	Very slight
Cyclonite (RDX)	222.26	White crystalline solid	276–280 (mp)	—	Insoluble
HMX	296.16	Colorless crystalline solid	204 (mp)	—	Insoluble

Uses of aliphatic nitrates are chiefly as explosives and blasting powders. The lower aliphatic nitrates, methyl, ethyl, propyl, and isopropyl have also been used as rocket propellants and special jet fuels.

Trimethylenetrinitramine (cyclonite, RDX) and cyclotetramethylene tetranitramine (HMX) have been included in this section because they are also used as explosives.

Early methods used for determining aliphatic nitrate esters consisted of various colorimetric or spectrophotometric procedures. These have now been largely replaced by instrumental methods (since mid-1960). References to the colorimetric procedures are included here (29, 104–111) because they were used for monitoring animal or worker exposures in work, summarized later in the sections on specific compounds.

Colorimetric procedures used for determining "traces" of polynitrate esters were reported in the mid-1930s and early 1940s (106, 107). These procedures appear relatively crude by present-day standards, for they were based on the nitration of reagents by the aliphatic nitrate being determined. More precise methods were developed later (108) and used to monitor animal exposures. Colorimetric methods were still being used as late as 1966 for determining of aliphatic nitrates, nitroglycerin, and ethylene glycol dinitrate in workplace air (109).

Instrumental methods, such as infrared spectrography, are generally considered satisfactory for identifying of aliphatic nitrate esters (104, 105). Spectral correlations have been compiled by Pristera et al. using band assignments at 6.0, 7.8, and 12.0 mm. Gas chromatographic procedures have been used for determining certain aliphatic nitrates (isopropyl nitrate, ethylene glycol dinitrate, and nitroglycerin in blood and urine (112–114). A comparison of solid sorbents in air sampling using a chromatographic method has been published (115). These methods have the advantage of greater precision and ease of manipulation of samples and have thus largely replaced the colorimetric methods of the past. More advanced methods of liquid chromatography to measure RDX in biological fluids (116) and ion mobility spectrometry to measure ethylene glycol dinitrate in air (117) have been reported. More recently, the detection of C_1–C_5 alkyl nitrates in snow, frost, and surface water has been demonstrated with a new water co-distillation enrichment technique coupled with on-column head-space gas chromatography (118).

The chief physiological effects of the aliphatic nitrates are dilation of blood vessels and methemoglobin formation. Vascular dilation accounts for the characteristic lowering of blood pressure and headache. Animals given effective doses orally or parenterally exhibit such signs as marked depression in blood pressure, tremors, ataxia, lethargy, alteration in respiration (usually hyperpnea), cyanosis, prostration, and convulsions. When death occurs, it is either from respiratory or cardiac arrest. Animals that survive the acute exposure recover promptly.

Aliphatic nitrates (e.g., nitroglycerin, erythritol tetranitrate, pentaerythritol tetranitrate, and methyl nitrate) can produce varying degrees of hypotension in humans. Headache is the outstanding symptom produced in humans following exposure. This is usually described as very severe and throbbing and is often associated with flushing, palpitation, nausea, and less frequently, vomiting and abdominal discomfort. Temporary tolerance develops from continued or repeated daily exposures (119). Pentaerythritol tetranitrate is the least effective at inducing such headaches and nitroglycerin is considered the most potent for headache induction. Other pharmacological consequences of vasodilation are increased pulse rate, an increase in cardiac stroke volume, variable cardiac dilation and cardiac output, and a shift in blood distribution with increased stasis and pressure in pulmonary arteries (128).

For some members of the series, the ease of hydrolysis to the alcohol and nitrate and the degree of

blood pressure lowering are parallel. Early studies suggested little evidence that hydrolysis to nitrate is necessary for hypotensive action (120–122). It appears that this effect of the nitrate esters does not depend exclusively on the liberation of nitrite groups. Dilation can occur without measurable nitrite in the blood or when the amount measured is not sufficient to account for the effect observed. Direct effects of nitrates on smooth muscle cells include stimulation of guanylate cyclase producing increased cyclic guanosine monophosphate (cGMP) levels. cGMP in turn lowers intracellular calcium concentrations, thus relaxing contractile protein and causing vasodilation (119).

The *in vivo* formation of nitrite is commonly assumed to be the explanation for the methemoglobin-forming properties of the aliphatic nitrates (123). The mechanism of formation of nitrite is not clear (124). It is possible that reduction to nitrite occurs before hydrolysis as follows (125):

$$RONO_2 \xrightarrow{+2H} RONO \xrightarrow{+H_2O} ROH + NO_2^-$$

Some aliphatic nitrates cause methemoglobin formation in experimental animals. For example, ethyl nitrate is a weak methemoglobin former, nitroglycerin is a moderately active methemoglobin former, and ethylene glycol dinitrate is considerably more effective (approximately four times). Ethylene glycol mononitrate, on the other hand, is not very active in this respect (126).

Heinz body formation has been observed following treatment of animals with certain aliphatic nitrates (e.g., ethyl, propyl, and amyl nitrates, ethylene glycol dintrate, and nitroglycerin). The precise nature of these small, rounded inclusion bodies in the red blood cells, described by Heinz in 1890, is not clear. They have been observed in humans and animals after absorption of a variety of chemical compounds, the most prominent of which are the aromatic nitrogen compounds, inorganic nitrites, and the aliphatic nitrates. Their appearance is commonly associated with anemia and the production of methemoglobin. Some evidence indicates that they are proteins, possibly hemoglobin degradation products. Red blood cells containing the inclusion bodies have a shorter life span and are removed from the circulation by the spleen. Special stains are required to demonstrate their presence satisfactorily. In the case of the aliphatic nitrates, erythrocytes containing Heinz bodies disappear from the circulating blood more slowly than methemoglobin (108, 125, 127).

Alkyl nitrates are absorbed from the gastrointestinal tract (128). Certain alkyl nitrates are better absorbed (see following for detail) than others through the skin and through the lung. The nitric acid esters of the monovalent alcohols are rapidly absorbed from the lung. Pathological examinations of animals that died following acute intoxication have been negative or have revealed only slight nonspecific pathological changes consisting of congestion of internal organs.

No injuries to workers from exposure to any of the lower monohydric alcohol esters of nitric acid (methyl, ethyl, *n*-propyl, amyl isomers) have appeared in the published literature. However, for polynitrate esters such as nitroglycerin or ethylene glycol dinitrate, the occurrence of characteristic and severe headaches in workers was so frequent that such acquired names as “dynamite head” and “powder headache” were common. Similar effects were reported for exposure to ethylhexyl nitrate (129). Since the 1950s, hypotension and peripheral vascular collapse have been associated with these headaches (129). It is now clear that NG and especially EGDN increase the risk of cardiovascular disease through attacks due to nitrate withdrawal, 1 to 3 days after last exposure, and through a long-term risk which persists long after exposure ceases (130, 131). The short-term risk was noted first and termed “Monday morning angina.” This includes findings of angina, myocardial infarction, arrhythmia, and sudden death. Generally, symptoms are not induced by exercise or psychic arousal, and no vascular lesions have been found at autopsy. Occupational or other exposures to NG involving repeated dermal contact cause irritant contact dermatitis (72).

The mechanism for tolerance development, a common response to organic nitrates, has been elucidated generally (130). This work was performed because the treatment of angina is hindered by the development of tolerance to the vasodilator action of these esters. See nitoglycerin section later

for more detail.

Table 54.17. Acute Effects of *n*-Propyl Nitrate—Animals (117, 129)

Animal	Dose (g/kg)	Route	Effect
Rat	7.5	Oral	Approximate lethal dose (sample I)
Rat	5.0	Oral	Approximate lethal dose (sample II)
Rat	1.0	Oral	Weakness, incoordination, cyanosis
Rat	1.5 × 10	Oral	Weakness, cyanosis, weight loss (first week)
Rabbit	11, 17	Skin	Essentially none
Rabbit	0.2–0.25	IV	Approximate LD_{50}
Dog	0.005	IV	Slight fall in blood pressure
	0.050	IV	Hypotension, cyanosis
	0.2–0.25	IV	Death in respiratory arrest
Cat	0.1–0.25	IV	6/7 died in 1 min
	0.025–0.075	IV	Hypotension, methemoglobinemia, survived

Table 54.18. Response to Inhalation of Various Concentrations of Amyl Nitrates (116)

		Mortality[a]			
Concentration (ppm)	Duration (h)	Guinea pigs	Rabbits	Rats	Mice
3730	7	2/2	2/2	3/4	5/5

Aliphatic Nitro, Nitrate, And Nitrite Compounds
Candace Lippoli Doepker, Ph.D.

C. Alkyl Nitrites

Alkyl nitrites are aliphatic esters of nitrous acid. The nitrite group has the structure–CONO. Except for methyl nitrite, which is a gas, the lower molecular weight members of the series are volatile liquids. In general they are insoluble or only very slightly soluble in water but are soluble or miscible with alcohol and ether in most proportions. They tend to decompose to oxides of nitrogen when exposed to light or heat. Violent decomposition can occur. As a group, they tend to be flammable and potentially explosive. They are oxidizing materials that present the possibility of violent reactions from contact with readily oxidized compounds. The chemical and physical properties of alkyl nitrites are given in Table 54.19.

Table 54.19. Chemical and Physical Properties of Alkyl Nitrites

Name	CAS #	Molecular formula	Molecular weight	Physical state	Boiling point (° C)	Specific gravity
Methyl nitrite	[*624-91-9*]	CH_3NO_2	61.04	Gas	–12	0.991 (15°C)
Ethyl nitrite	[*109-95-5*]	$C_2H_5NO_2$	75.07	Colorless liquid	17	0.900 (15.5°C)
n-Propyl nitrite	[*543-67-9*]	$C_3H_7NO_2$	89.09	Liquid	57	0.935
Isopropyl nitrite	[*541-42-4*]	$C_3H_7NO_2$	89.09	Pale yellow oil	45	0.844 (25.4°C)
n-Butyl nitrite	[*544-16-1*]	$C_4H_9NO_2$	103.12	Oily liquid	78.2	0.9114 (0/4°C)
Isobutyl nitrite	[*542-56-3*]	$C_4H_9NO_2$	103.12	Colorless liquid	67	0.8702 (20/20°C)
sec-Butyl nitrite	[*924-43-6*]	$C_4H_9NO_2$	103.12	Liquid	68	0.8981 (0/4°C)
tert-Butyl nitrite	[*540-80-7*]	$C_4H_9NO_2$	103.12	Yellow liquid	63	0.8941 (0/4°C)
n-Amyl nitrite	[*463-04-7*]	$C_5H_{11}NO_2$	117.15	Pale yellow liquid	104	0.8528 (20/4°C)
Isoamyl nitrite	[*110-46-3*]	$C_5H_{11}NO_2$	117.15	Transparent liquid	97–99	0.872
n-Hexyl nitrite		$C_6H_{13}NO_2$	131.17	Liquid	129–130	0.8851 (20/4°C)
n-Heptyl nitrite		$C_7H_{15}NO_2$	145.20	Yellow liquid	155	0.8939 (0/4°C)

n-Octyl nitrite	$C_8H_{17}NO_2$	159.23	Greenish liquid	174–175	0.862 (17°C)

Aliphatic nitrites have been of interest mainly because of their pharmacological properties and therapeutic use. They have been used to treat angina. More recently they have been sold as "room odorizers" without prescription and abused for their euphoric effects by adolescents (178) and for their sexual stimulatory effects by homosexual men (179). Amyl nitrite has important use as an antidote in the clinical management of poisoning (180, 181). Aliphate nitrites are used also to a limited extent as intermediates in chemical syntheses. *n*-Propyl nitrite, isopropyl nitrite, and *tert*-butyl nitrite have been used as jet propellants and to prepare fuels.

The pharmacological and toxicological effects of aliphatic nitrites are chiefly characterized by vasodilation resulting in a fall in blood pressure and tachycardia. Methemoglobin is produced by larger doses. Severe complications have been described following ingestion of large quantities of certain nitrites (e.g., amyl, butyl, or isobutyl), including a deficiency in hemoglobin reductase (182). With respect to toxicological effects, alkyl nitrites resemble closely inorganic nitrites (sodium nitrite) and aliphatic nitrates. Inhalation by animals and humans results in smooth muscle relaxation, vasodilation, increased pulse rate, and decreased blood pressure progressing to unconsciousness with shock and cyanosis. Headache is often a prominent symptom and may be due to meningeal congestion and vascular dilation. The development of tolerance has been observed with the therapeutic use of amyl nitrite for angina pectoris. This disappears after a week or so after discontinuation of use. Methods for determining nitrites in air and in biological fluids have been described (128).

Branched-chain compounds are more effective than straight-chain compounds in lowering blood pressure. Isopropyl nitrite is considerably more effective than *n*-propyl nitrite and isobutyl nitrite more than *n*-butyl. Secondary and tertiary butyl compounds also have a more pronounced hypotensive effect than *n*-butyl nitrite. Methyl nitrite is more effective than ethyl and propyl nitrites, and amyl nitrite is more effective than ethyl nitrite. As far as the duration of the hypotensive effect is concerned, methyl and ethyl nitrites are more persistent, *n*-propyl is the least persistent of the lower alkyl nitrites, and the iso derivatives of propyl and butyl nitrite are more persistent than the normal compounds (128). However, the hypotensive effects of these compounds are relatively transient. Amyl nitrite, for example, produces a rapid fall in blood pressure, which lasts only a few minutes after inhalation.

Krantz et al. conducted extensive studies on the pharmacology of alkyl nitrites (120–122). They found that when administering 0.3 mL through an aspirating bottle into the trachea of exposed dogs, the degree of hypotension produced decreased from n-hexyl (58% fall) to *n*-heptyl (47%), *n*-octyl (30%), and *n*-decyl (16%). Alkyl nitrites that have 11 to 18 carbon atoms in their chains showed slight or no effect on blood pressure under these conditions. If injected, however, they produced hypotension. With chains longer than 2-ethyl-*n*-hexyl-1-nitrite, the duration of action became shorter. Cyclohexyl nitrite produced a fall in blood pressure equivalent to ethyl nitrite or amyl nitrite, but the duration was longer. In humans, it produced severe headache. Krantz et al. believe that the major effects are related to the relaxing action of the nitrites on smooth muscle.

Methemoglobin formation has been repeatedly observed following administration to humans and animals. Aliphatic nitrites act as direct oxidants of hemoglobin. One molecule of nitrite and two molecules of hemoglobin can react to form two methemoglobin molecules under appropriate conditions. Side reactions to form nitrosohemoglobin and nitrosomethemoglobin may occur. The amount of methemoglobin formed in cats is directly proportional to the intravenous dose (123). The longer chain compounds induce more methemoglobin formation relative to their hypotensive effect

(120).

The therapeutic usefulness of methylene blue in acute intoxications accompanied by methemoglobinemia remains controversial, even though support for its effectiveness in severe methemoglobinemia continues to appear (183, 184). Although methemoglobinemia is a prominent effect of nitrite absorption, the action of alkyl nitrites on the vascular system is also a major determinant in their toxicity.

Reports of industrial intoxications are limited (185–188), but reports of poisoning resulting from "recreational use" have been numerous during the past 15 years and have included fatalities (189).

Because of the widespread use of alkyl nitrites by homosexual men, prior to the discovery of the HIV virus as the causative agent, it was postulated that alkyl nitrites might be involved in the development of AIDS (179). This led to extensive research (190), particularly in the areas of genetic toxicity and immunotoxicity.

Methyl (191), ethyl (192), propyl (193), butyl (193, 194), isobutyl, *sec*-butyl, amyl, and isoamyl (193) nitrite are mutagenic in the Ames test. Of the six nitrites tested (propyl to isoamyl in the previous list), only amyl nitrite was not mutagenic in the mouse lymphoma assay (193). Ethyl nitrite also induced sex-linked recessive lethal mutations in *Drosophila* but did not induce micronuclei in mouse bone marrow cells (192). Isobutyl nitrite did not cause mutations in the *Drosophila* test (195).

Studies of the effects on immune parameters have produced contradictory results. Amyl nitrite caused functional deficits and structural alterations (seen by electron microscopy) in human mononuclear lymphocytes exposed *in vitro*(130). However, in a study of mice exposed to 50 or 300 ppm isobutyl nitrite 6.5 h/day, 5 day/week, for up to 18 weeks, no adverse effect on B-cell or T-cell function was detected (196). Another study in mice was done at higher exposure concentrations based on the expectation that abusers use higher concentrations for shorter durations (197). Mice were exposed to increasing isobutyl nitrite concentrations, 100 ppm for 1 day, 600 ppm for 3 days, then 900 ppm for 10 days. Specific decrements in T-cell responsiveness to mitogenic stimulants were seen, but B-cell responsiveness was unchanged.

The acute inhalation LC_{50}values for various alkyl nitrites are shown in Table 54.20. In general, potency decreases as alkyl chain length and branching increase. Very steep dose–response curves were seen for all compounds, indicating that relatively small increases of exposure concentration would produce large increases of mortality. Klonne et al. stated that the concentration range corresponding to 0 and 100% mortality in four exposures of rats was less than 100 ppm for most of the nitrites (198). The LC_{50}/EC_{50} (for decreased motor performance) ratio for a 30-min exposure of mice ranged from 2.0 to 2.4 (199). Therefore, acute inhalation exposure hazard for the alkyl nitrites is greater than would be indicated by their LC_{50}s alone.

Table 54.20. Acute Inhalation Toxicity of Alkyl Nitrites

Nitrite compound	4-h rat LC_{50} (ppm) (180)	1-h mouse LC_{50} (ppm) (181)	½-h mouse LC_{50} (ppm) (182)
Methyl	176	—	—
Ethyl	160	—	—
Propyl	300	—	—
Butyl	420	567	949

Isobutyl	777	1033	1346
sec-Butyl	—	1753	—
tert-Butyl	—	10,852	—
Isoamyl	716	—	1430

McFadden et al. measured methemoglobin levels *in vivo* and *in vitro* for butyl nitrite isomers (200). *tert*-Butyl was significantly less toxic than the other isomers and was the least potent methemoglobin inducer. Pretreatment with methylene blue before nitrite exposure also greatly increased the mean time to death for butyl, isobutyl, and *sec*-butyl, but only doubled the value for *tert*-butyl. The authors concluded from this that methemoglobin formation is the cause of death from butyl nitrite isomers except for *tert*-butyl. However, Klonne et al. point out that deaths occurred rapidly and always during exposure (198). This was a consistent finding of the other acute inhalation studies (199, 200). Animals recovered rapidly from all signs of exposure except for those associated with methemoglobinemia (cyanosis, bluish coloration of ears and feet). Exposure concentration rather than cumulative inhaled concentration was also the primary determination for mortality (198). Severe hypotension and cardiovascular collapse are more consistent with these findings as a cause of death. Most likely, both vasodilation and methemoglobinemia play a role in alkyl nitrite-induced mortality.

The lower aliphatic nitrites are promptly absorbed from the lung. Amyl nitrite is ineffective orally because it is destroyed in the gut. It is less effective by injection than by inhalation. Octyl nitrite (2-ethyl-*n*-hexyl-1-nitrite) is not absorbed through the mucous membranes and is ineffective sublingually. It appears that the nitrites are hydrolyzed *in vivo* to nitrite and the corresponding alcohol, which is then partly oxidized and partly exhaled unchanged.

The pharmacological properties determined in animals are so uniform within this group that information on the nitrites following can be taken as illustrative of the effects and potential hazards of the other members of the series (see Table 54.20 and Table 54.21).

Table 54.21. Comparative Toxicity Data for Aliphatic Nitro, Nitrate and Nitrite Compounds

Chemical group	Skin absorption	Irritation	Vascular dilatation	Methemoglobin formation	Industrial experience
Aliphatic nitro compounds (R_3CNO_2)					
Nitroalkanes	None	Moderate	None	Positive	Irritation, systemic symptoms
Chlorinated nitroparaffins	None	Marked	None	Unknown	Lung injury
Nitroolefins	Positive	Marked	Unknown	Not observed	None
Aliphatic nitrates (R_3CONO_2)	Positive	None	Marked	Positive	Systemic symptoms, possible deaths
Aliphatic	Unknown	None	Marked	Positive	Systemic

nitrites (R_3CONO)					symptoms, fatalities
Nitramines (R_3CNHNO_2)	None	None	None	None	Convulsions

Aliphatic Nitro, Nitrate, And Nitrite Compounds
Candace Lippoli Doepker, Ph.D.

D. Summary

Although aliphatic nitro compounds, aliphatic nitrates, and aliphatic nitrites have several features in common (nitrogen-oxygen grouping, explosiveness, methemoglobin formation), there are significant differences in their toxic effects. Some of their attributes are summarized in Table 54.21. The esters of nitric and nitrous acid, whose nitrogen is linked to carbon through oxygen, are very similar in their pharmacological effects. Both produce methemoglobinemia and vascular dilatation with hypotension and headache. These effects are transient. None of the series has appreciable irritant properties. Pathological changes occur in animals only after high levels of exposure and are generally nonspecific and reversible. The nitric acid esters of the monofunctional and lower polyfunctional alcohols are absorbed through the skin. Information is not available on the skin absorption of alkyl nitrites. Members of both groups are well absorbed from the mucous membranes and lungs. Heinz body formation has been observed with the nitrates but not with the nitrites.

Nitro compounds, like nitrates and nitrites, cause methemoglobinemia in animals. Heinz body formation parallels this activity within the series. Although some members are metabolized to nitrate and nitrite, there is no significant effect on blood pressure or respiration. As with the lower nitrates and nitrites, anesthetic symptoms are observed in animals during acute exposures, but these occur late. The prominent effect is irritation of the skin, mucous membranes, and respiratory tract. This is most marked with chlorinated nitroparaffins and nitroolefins. In addition to respiratory tract injury, cellular damage may be observed in the liver and kidneys. Skin absorption is negligible except for the nitroolefins.

The nitramines have entirely different activity. RDX is a convulsant for humans and animals. Skin absorption, irritation, vasodilatation, methemoglobin formation, and permanent pathological damage are either insignificant or absent after repeated doses.

Transient illness has been associated with the industrial use or manufacture of these materials, but fatalities and chronic intoxication have been uncommon. Some members of each group present extremely high fire and explosion hazards.

N-Nitroso Compounds

William Lijinsky

A. Toxicity of N-nitroso Compounds

As noted with other groups of carcinogens, the test species often showed considerable variation in toxic and carcinogenic responses to a particular *N*-nitroso compound. For example, nitrosodimethylamine (NDMA) is more toxic to rats than nitrosodiethylamine (NDEA), but NDEA is a more potent carcinogen to rats than NDMA (6); in the Syrian hamster, NDMA is a more potent carcinogen than NDEA (6), whereas NDEA is less toxic than NDMA in hamsters (6). Moreover, the acute toxicity of most nitrosamines was expressed in the liver or lung of rats, mice, and hamsters (and sometimes in the gastrointestinal tract), whereas carcinogenicity was expressed in a variety of organs including liver, lung, stomach, bladder, pancreas, esophagus, and kidney (32). The considerable number of nitrosamines that were toxic to the liver but did not induce liver tumors was curious and suggested that whatever mechanisms caused liver damage were not the same as those that caused liver cancer. Of course, it has long been known that nitrosamines do not act directly but have to be activated metabolically to cause toxicity or carcinogenicity (33). Nitrosamines, as distinct from the directly acting alkylnitrosamides, are not mutagenic to bacteria or cells in culture, nor cytotoxic without metabolic activation by enzyme mixtures (e.g., S9 fractions from liver or other organs). Strangely, single doses of nitrosamines, however large, rarely induce tumors, although single doses of alkylnitrosamides often do. Almost all of the carcinogenic studies referred to here involve frequent administration of small doses (too small to have noticeable toxic effects) for many weeks, after which the animals are maintained until death (from tumors). This mode of treatment is believed to mimic usual human exposure more closely than single or few larger doses.

In general—and counterintuitively—most alkylnitrosamides are less toxic than analogous nitrosamines that give rise by metabolic activation to the same reactive intermediate (an alkyldiazonium ion) that is formed spontaneously from the alkylnitrosamide. This suggests that the

alkyldiazonium ion which alkylates DNA and other macromolecules is not the common intermediate that is responsible for the toxicity, mutagenicity, and carcinogenicity of these compounds, but that alternative mechanisms might be involved (34) in one or more of these biological activities. What seem to be surprising and perhaps illogical is that toxic effects are seen by comparing methylnitrosourea with methylnitrosourethane, both given to rats by intravenous injection, in the case of MNU into the hepatic portal vein at 30 mg/kg body weight (and cause sufficient methylation of liver nucleic acids to be identified by mass spectrometry (35), but cause no liver tumors). The LD_{50} of MNU was 110 mg/kg body weight and that of methylnitrosourethane was 4 mg/kg, both by intravenous injection. Yet, no toxic effects were seen in the liver examined by electron microscopy.

The difference in acute toxicity in rats or in mice or hamsters between *N*-nitroso compounds that, according to conventional wisdom, exert their biological effects by forming of the same putative reactive intermediate (e.g., the methyldiazonium ion) poses a dilemma. For example, why is a directly acting *N*-nitroso compound (MNU, MNNG, or methylnitroso-urethane) less toxic than many methylnitrosoalkylamines which must be activated to form the toxic agent? Although numerous methylnitrosoalkylamines have similarly high toxicities, many are also considerably less toxic (Table 55.3) with no apparent explanation. However, the simple explanation of formation of the same toxic intermediate is probably wrong or at least incomplete.

Table 55.3. Toxicity and Carcinogenicity of Some *N*-Nitroso Compounds

	Toxicity			Carcinogenicity	
***N*-Nitroso-**	**Species**	**Route**	**LD_{50}[a]**	**Route**	**Organ**
dimethylamine	Mouse	i.p.	20	Oral	Liver, lung
	Rat	Oral, i.p.	30	Oral	Liver, kidney
	Hamster	s.c.	30	Oral	Liver, nasal
	G.pig	i.p.	16	Oral	Liver
diethylamine	Mouse	Oral	220	Oral	Liver, esoph.
	Rat	Oral	280	Oral	Liver, esoph.
	Hamster	s.c.	250	Oral	Liver, nasal
	G.pig	i.p.	190	Oral	Liver
methylethylamine	Rat	Oral	90	Oral	Liver, esoph.
di-*n*-butylamine	Rat	Oral	1,200	Oral	Liver, bladder
	Hamster	Oral	2,150	Oral	Liver, bladder
di-*n*-propylamine	Rat	Oral	480	Oral	Liver, esoph.
	Hamster	s.c.	600	Oral	Nasal, trachea
methylvinylamine	Rat	Oral	22	Oral	Lung, nasal
diethanolamine	Rat	Oral	>7,500	Oral	Liver, nasal
	Hamster	s.c.	11,300	Oral	Nasal
morpholine	Rat	Oral	280	Oral	Liver, esoph.
	Hamster	Oral	1050	Oral	Nasal, trachea
2,6-dimethyl-morpholine	Rat	s.c.	430	Oral	Esoph, nasal
	Hamster	Oral	370	Oral	Pancreas, liver
piperidine	Rat	Oral	200	Oral	Esoph, nasal

pyrrolidine	Rat	Oral	900	Oral	Liver
diphenylamine	Rat	Oral	3,000	Oral	Bladder
sarcosine	Rat	Oral	5,000	Oral	Esophagus
proline	Rat	Oral	5,000	Oral	Inactive -
dibenzylamine	Rat	Oral	900	Oral	Inactive -
nornicotine	Rat	s.c.	1,000	Oral	Esoph, nasal
methylurea	Rat	Oral	180	Oral i.v.	Brain, stomach, uterus, breast
	Hamster	s.c.	70	Oral	Spleen, stomach
ethylurea	Rat	Oral	300	Oral	Breast, stom. etc
methylnitro-guanidine	Rat	Oral	100	Oral	Gland. stomach

[a] mg/kg body weight as a single dose by gavage or injection.

Although it is understandable that some nitrosamines might be toxic but not carcinogenic (e.g., nitrosiminodiacetonitrile, methylnitroso-*tert*-butylamine, methylnitrosomethoxyamine, nitrosodiallylamine in rats) because their toxicity is through some unconventional mechanism, it is more difficult to understand why some reasonably potent carcinogens (e.g., nitrososarcosine, nitrosodiethanolamine, ethylnitrosoethanolamine) are not toxic (or not measurably so). The cyclic nitrosamines pose a particular dilemma because little is known about their activation, the products of their metabolism, or the reasons for the differences in their carcinogenicity. The simplest cyclic compound, nitrosoazetidine, is almost not toxic; toxicity increases up to nitrosopiperidine and nitrosohexamethyleneimine and declines as the ring grows larger. All are toxic to rat liver, although not all induce liver tumors in rats (5, 6). There are differences between species in response to the toxicity of a given *N*-nitroso compound, as there are to carcinogenicity; mice are often less responsive than rats, as mice are to carcinogenesis by many *N*-nitroso compounds. However, most *N*-nitroso compounds are both toxic and carcinogenic (6). As already mentioned, there is no parallel between toxicity and carcinogenicity among different species or within structurally related groups of *N*-nitroso compounds.

N-Nitroso Compounds
William Lijinsky

B. Mutagenesis and Cell Transformation

One *N*-nitroso compound, *N*-methyl-*N*-nitroso-*N*'-nitroguanidine (MNNG), was one of the first known chemical mutagens (36) and since then a large number of *N*-nitroso compounds have been examined for mutagenic and cell-transforming properties, apparently propelled by the wish to develop quick ways of identifying carcinogens instead of the lengthy and expensive chronic toxicity test in animals (rodents). In looking for parallels between carcinogenic and mutagenic activities, there are striking differences, even among groups of *N*-nitroso compounds of similar structure. It is almost always necessary to test a nitrosamine for mutagenicity by incorporating a metabolic activation system, usually the S-9 fraction of liver homogenate, called the "microsomal fraction," which was introduced by Ames into his microbial (*Salmonella*) mutagenic assay (37). It is assumed that this mimics the activation of nitrosamines *in vivo*.

Most alkylnitrosamides are directly acting mutagens (i.e., they do not need metabolic activation), although not proportional in activity to their carcinogenic activity. On the other hand, almost all nitrosamines require metabolic activation to uncover their mutagenic activity. A large proportion of the nitrosamines that have been tested for carcinogenic activity have also undergone mutagenic

testing, exhaustive in the case of some compounds, (e.g., NDMA, NDEA). NDMA with rat liver microsomal activation is not measurably mutagenic to *Salmonella* strain TA1535 in the simple "plate test," although it is powerfully carcinogenic to rat liver. Both NDMA and NDEA are more readily activated to bacterial mutagens by hamster liver microsomes than by rat liver microsomes, although by no means are these two nitrosamines more potent carcinogens in hamsters than in rats (38). The greater activity of hamster liver microsomes in this regard is true for a large proportion of nitrosamines tested, although most are more potent carcinogens in rats than in hamsters (6, 39), and includes the large series of methylnitrosoalkylamines, which, it is assumed, act (as mutagens and carcinogens) by metabolic formation of the same methylating intermediate. These comparisons throw into doubt the current concept of the close relationship—perhaps identity—of the mechanisms of carcinogenesis and mutagenesis.

These discrepancies also apply to the large number of cyclic nitrosamines that have been studied, in which the superiority of hamster liver microsomes over rat liver microsomes in activating them to mutagens is even greater to the extent that several compounds are activated to mutagens only by hamster liver enzymes, not by rat liver enzymes. This is also true of many acyclic nitrosamines, and especially so of those nitrosamines that have oxygen functions (hydroxyl- or carbonyl-) in their side chains. A number of carcinogenic nitrosamines are not activated by either rat or hamster liver microsomes to mutagens (39); these include such liver carcinogens as nitrosodiethanolamine, methylnitrosoethylamine, nitroso-3-hydroxypyrrolidine, and methylnitrosoethanolamine, as well as methylnitrosoaniline, methylnitroso-3-carboxypropylamine, and nitrosodiphenylamine, which induce tumors in other organs, but not in the liver (40). Most of the noncarcinogenic nitrosamines (which include most nitrosamino acids) are not mutagenic, but some that are mutagenic are not carcinogens (nitrosoguvacoline, nitrosophenmetrazine, nitrosodi-*n*-octylamine). The usefulness of the mutagenic assays in predicting the probable carcinogenicity of *N*-nitroso compounds is obvious, although there is no quantitative parallel, but the many unexpected exceptions (e.g., MNEA) indicate that mutagenesis is not a guide to understanding the carcinogenic mechanisms of these compounds.

This conclusion is fortified by the mutagenic studies of alkylnitrosamides, which show a huge disparity between carcinogenic potency and mutagenic effectiveness. For example, a series of methylnitrosocarbamate esters (most of which are *N*-nitroso derivatives of pesticides, e.g., nitrosocarbaryl) vary 10- to 200-fold in mutagenicity (41, 42), but have very similar carcinogenic potencies (43); the ratio of their mutagenicities is similarly large versus methylnitrosourea, which is a much more potent carcinogen. Yet, all of these compounds, it is believed, act as mutagens or carcinogens by directly forming the same alkylating intermediate, the methyldiazonium ion. Part of the discrepancies might be explained by differences in uptake by the bacteria, as shown in *Hemophilus influenzae* (44).

Among the many alkylnitrosoureas tested as bacterial mutagens, which, it is believed, act by forming the corresponding alkyldiazonium ion, there is not a large difference among most of them in mutagenic potency, although this tends to increase with increasing molecular weight (45). Some unusual structures such as hydroxyethylnitrosourea, isopropanolnitrosourea, and 2-phenylethyl-nitrosourea are especially potent, whereas benzylnitrosourea and *n*-tridecylnitrosourea are almost inactive, but overall there is no parallel between mutagenicity and carcinogenicity among these directly acting *N*-nitroso compounds. The same is true of the limited number of alkylnitrosoguanidines tested, of which MNNG is almost the standard mutagen but is not a particularly potent carcinogen; the nitroso derivative of a widely used drug, nitrosocimetidine, is quite mutagenic but is not a carcinogen (46).

N-nitroso compounds act as mutagens or transforming agents in mammalian cells in culture or in bacteriophage induction. It is claimed that their activity depends largely on the formation, directly or following enzymic activation, of an alkyldiazonium ion that alkylates DNA. All have the same or similar drawbacks and discrepancies which have been discussed earlier in connection with bacterial mutagenic assays. The cell transformation assays (47) seem to have some characteristics that do not depend on alkylation of DNA because compounds such as nitrosodiphenylamine, which do not form

an alkylating product, produce positive results in these assays. However, the results do not uniformly parallel the carcinogenic activity of these compounds, indicating again that the mechanisms of the various biological activities differ (47).

N-Nitroso Compounds
William Lijinsky

C. Metabolism and Activation

Although there are differences and discrepancies among the mutagenicity, carcinogenicity, and other biological activities of the directly acting alkylnitrosamides, it is credible that one of the underlying actions is the direct formation of a reactive intermediate, such as an alkyldiazonium ion, common to many of them (e.g., the methylating compounds). On the other hand, in the case of the nitrosamines, it is not readily apparent that formation of a simple alkylating intermediate (such as an alkyldiazonium ion) is the underlying process. Rather, there is evidence that extensive and varied metabolism is frequently required to bring about carcinogenesis, or even mutagenesis. As shown by the lower activity as mutagens or carcinogens of nitrosamines labeled with deuterium in the positions alpha to the nitroso group, alpha-oxidation is a rate-limiting step in the biological activation of most nitrosamines (48–50). This finding is fortified by the observation that substituting methyl or other alkyl groups in the alpha positions of nitrosamines, cyclic or acyclic, reduces or abolishes carcinogenic or mutagenic activity. In the case of acyclic nitrosamines, alpha-oxidation forms an unstable alpha-hydroxy derivative (51), which is reactive and decomposes to release an alkyldiazonium ion, that can alkylate macromolecules (and presumably the alpha-hydroxy derivative can also). In the case of cyclic nitrosamines, such as nitrosomorpholine or nitrosopiperidine, the fate of the alpha-hydroxy derivative is much less clear, particularly the identity of the products related to carcinogenesis or mutagenesis, and those that are simply products of detoxication.

There have been many studies of the metabolism and activation of nitrosamines, including those of the series of methylnitroso-*n*-alkylamines, that show striking differences in the target organ for carcinogenesis as the chain becomes longer. In fact, it is through beta-oxidative chain shortening (Knoop) that the longer chain compounds produce a metabolite (methylnitroso-2-oxopropylamine) that induces bladder tumors in rats (39), whereas the short-chain compounds induce tumors of the liver or esophagus.

Oxidation of nitrosamines in animals can be extensive, as shown by the formation and excretion of derivatives of nitroso dialkylamines such as nitrosodi-*n*-propylamine and nitrosodi-*n*-butylamine hydroxylated at most positions of the alkyl chain (52) and in the studies of metabolites of methylnitroso-*n*-amylamine by Mirvish (53).

The complex interrelationships between 2,6-dimethylnitrosomorpholine (DMNM—which unlike nitrosomorpholine induces no liver tumors in rats, although it does in hamsters, together with pancreas tumors), nitrosobis-2-oxopropylamine (NBOPA), nitrosobis-2-hydroxypropylamine (nitrosodi-isopropanolamine—NBHPA) and nitrosohydroxypropyl-oxopropylamine (NHPOPA) pose another unsolved problem in explaining their carcinogenic properties (54, 55).

The conventional wisdom is that *N*-nitroso compounds exert their carcinogenic (and probably toxic) effects by forming of an alkylating intermediate (alkyldiazonium compound) that alkylates DNA, causes mutations (and leads to cancer), but this is an oversimplified and unsatisfactory explanation of the experimental data. For example, the compounds in the preceding paragraph all methylate DNA of the liver and other organs *in vivo* in rats and hamsters to similar extents (somewhat lower with DMNM). They all induce liver tumors in hamsters (but to different extents) but in rats DMNM and NBHPA induce only tumors of the esophagus, NBOPA induces liver tumors, and NHPOPA induces both (39, 56). These results indicate that alkylation of DNA by these nitrosamines might

play a role in inducing of tumors (in the liver, for example), that alone is insufficient and other factors and properties of the nitrosamine are equally or more important, but these are largely unknown. And so it is with a large number of *N*-nitroso compounds that methylate DNA, for example, in rat liver. Only some of them give rise to liver tumors, but often to tumors in other organs in which they produce less methylation of DNA. Examples are methylnitrosourea, MNNG, NDMA in high doses (at which kidney tumors are induced) (57), although at low doses liver tumors are induced, and not kidney tumors (58); the same is true of azoxymethane (isomeric with NDMA), which induces tumors in the colon, as well as the liver (59).

Most *N*-nitroso compounds are both carcinogenic and mutagenic, but about 10% of those tested (more than 300) are not carcinogenic. Few of the noncarcinogens are mutagens, but several carcinogens are not mutagenic. Particularly interesting are those nitrosamines that are rat liver carcinogens, yet are not activated to mutagens by rat liver enzymes (e.g., nitrosodiethanolamine, nitrosodi-isopropanolamine, and methylnitrosoethylamine), although several of them are activated by hamster liver enzymes. In the context of this volume, this fact is important only because there is increasing reliance on "short-term" assays for predicting the carcinogenicity of newly discovered substances, and it would be easy to overlook a nonmutagenic nitrosamine as unlikely to be a carcinogen, forestalling a chronic toxicity test. Whether a nonmutagen (e.g., NDELA) alkylates DNA to a very small extent, usually remains to be determined (60).

Another important consideration is that there are considerable differences in susceptibility to toxicity and carcinogenicity among species, even those as closely related as rats, mice, and hamsters. In general, rats are more susceptible than either hamsters or mice (in that order). In the case of NDELA, massive doses are needed to induce liver tumors in mice, whereas modest doses are adequate in rats; NDELA did not induce liver tumors in hamsters, but did induce tumors of the nasal cavity (61, 62). This suggests that it might be unwise to consider that rats represent the species most sensitive to *N*-nitroso compounds and that humans are no more sensitive. In fact there is evidence from the great effectiveness of tobacco-specific nitrosamines in cigarette smokers and in smokeless tobacco users (in whom exposure is small, but the cancer incidence high) compared with the comparable responsiveness of rats or hamsters to much higher doses, that humans might be considerably more susceptible to the carcinogenic effects of *N*-nitroso compounds than the routinely used test animals.

N-Nitroso Compounds
William Lijinsky

D. Chronic Effects—Carcinogenicity

From the extensive literature on the biological testing and evaluation of *N*-nitroso compounds, numerous results frustrate the proposal of a single mechanism by which these compounds induce tumors because of the complexity of the tumor responses in different species to a particular *N*-nitroso compound. For example, consider the series of methylnitroso-*n*-alkylamines from C_2 (methylnitrosoethylamine, MNEA) to C_{12} (methylnitroso-*n*-dodecylamine) all of which are metabolized to form a methylating agent that methylates DNA in rat liver (63) (although not necessarily to the same extent) and all of which are carcinogenic (64). In contrast, methylnitroso-*tert*-butylamine, which cannot be metabolized to form a methylating agent, is not carcinogenic; on the other hand, methylnitrosoaniline, which also cannot be metabolized to form a methylating agent is carcinogenic to rats and forms esophageal tumors. However, there the simplicity ends because the lowest members of the homologous series, NDMA and MNEA, induce tumors of the liver and lung in rats (as well as tumors of the esophagus in the case of MNEA). The C_3, C_4 and C_5 compounds give rise only to tumors of the esophagus in rats, whereas the C_6, C_7 and C_8 compounds induce tumors of the esophagus, liver, and lung in rats, the proportions depend on whether the nitrosamine

is administered in drinking water or by gavage. Methylnitroso-*n*-octylamine (C_8) also causes bladder tumors in many rats. The larger C_9 to C_{12} molecules are almost insoluble in water and had to be administered by gavage in oil, and compounds with an odd number of carbons in the chain induced liver and lung tumors in rats. Those with an even number of carbons in the chain induced tumors of the bladder and lung, but seldom liver tumors, although these nitrosamines are extensively metabolized in the rat liver. The metabolism (beta-oxidation) of those compounds with even-numbered carbon chains terminates at methylnitroso-3-carboxypropylamine, which is beta-oxidized and decarboxylates to form methylnitroso-2-oxopropylamine, which induces bladder tumors in rats when injected into the bladder (65). Beta-oxidation of nitrosamines that have odd-numbered carbon chains produces a different end product. In contrast with their varied carcinogenic properties in rats, the response to this series of methylnitroso-*n*-alkylamines is quite uniform in hamsters and consists of liver and lung tumors and occasionally tumors of the nasal cavity and bladder tumors with the even-numbered carbon chain compounds larger than C_6; there were no esophageal tumors in hamsters (no *N*-nitroso compound induces esophageal tumors in hamsters, although a large proportion of nitrosamines given to rats has induced tumors of the esophagus).

This leads to another perplexing finding, that no alkylnitrosamide—although they are directly acting alkylating agents—induces tumors of the esophagus or nasal cavity in rats, even when given in drinking water; many nitrosamines induce tumors of the esophagus in rats, whether given in drinking water or by gavage, even when administered by intraurethral injection or by subcutaneous injection. Such findings led to the conclusion that *N*-nitroso compounds usually act systemically, rather than locally. However, several alkylnitrosamides produce skin tumors when painted frequently on the skin of mice (66), as well as systemically in rats by oral administration (6). No nitrosamine has produced skin tumors by local action, although when painted on the skin, they can be absorbed and in some cases induce tumors of internal organs. Alkylnitrosoureas in rats induce tumors of the nervous system, of the glandular stomach (similar to human stomach), and of the mammary gland and mesotheliomas (in males), which have not been induced by any nitrosamine; in hamsters, alkylnitrosoureas have induced hemangiosarcomas of the spleen almost exclusively (together with tumors of the forestomach, probably induced locally); in splenectomized hamsters, few tumors were induced by 2-hydroxyethylnitrosourea, mainly some forestomach tumors (67). Alkylnitrosoureas did not induce tumors of the nervous system, glandular stomach, mammary gland or mesotheliomas in hamsters, although they are directly acting alkylating agents. There has been no adequate explanation of these profound differences, which do not depend primarily on the presence of particular activating enzymes in certain tissues or organs, and the results make it difficult to accept the conventional simple alkylation of DNA as the mechanism of such organ and species-specific carcinogenesis by *N*-nitroso compounds.

The difference in response of different species to *N*-nitroso compounds has been discussed using rats and hamsters as examples. Mice tend to follow rats in the pattern of tumors induced by particular *N*-nitroso compounds, although rats seem to be more sensitive than mice or hamsters (perhaps by a factor of 10). The limited evidence that can be used to compare humans with rats suggests that humans might be considerably more sensitive (68).

Perhaps the most important property of carcinogens in relation to human health is the ability to induce tumors transplacentally because a fetus is more susceptible (i.e., responsive to smaller doses) to the action of many carcinogens than adults (as is true also of infants and young children). In the case of *N*-nitroso compounds, there has been considerable interest in this aspect, particularly by Ivankovic who induced tumors of the nervous system in rats transplacentally by treating their mothers with alkylnitrosoureas during the last third of pregnancy (21). The same result was achieved using *N*-methylnitroso ethyl carbamate (methylnitrosourethane) (69). This use of an alkylnitrosamide is one of the few models for human childhood brain cancer. No nitrosamine administered to pregnant animals has induced brain cancer in offspring, although several nitrosamines have induced other types of tumor transplacentally, albeit not with as great efficacy as alkylnitrosoureas. Usually, one or two mice or rats per litter with tumors has resulted, even after a substantial dose to the mother.

Because humans are exposed to rather small quantities of *N*-nitroso compounds, the importance of transplacental exposure to other than alkylnitrosamides might be small.

The large difference in the incidence of many common cancers between the industrialized world and the "less-developed" world (70) is a conundrum, compounded by the studies of vast populations of migrants, who within one or two generations often develop the pattern of cancer of their new country, instead of that of their ancestors. This suggests that environmental exposure to carcinogens is a large factor in many common cancers, compared with a smaller genetic factor. (The difference in the incidence of some cancers, such as breast cancer, in black Americans compared with West African women can be as much as tenfold or more higher in the United States.)

A subject of great interest is the extent to which tumor models in animals can be used as surrogates for human cancers. In some cases, *N*-nitroso compounds represent the best or only models. For example, derivatives of *N*-nitroso-2-oxopropylamine given to hamsters give rise to tumors of the pancreatic ducts, a common and nasty human cancer, prevalent in idustrialized countries (Western Europe and North America). A number of nitrosamines that have this structure (or convertible metabolically into it) have induced pancreatic tumors more or less effectively; the most effective is nitrosobis-(2-oxopropyl)-amine; strangely, 2-oxopropylnitrosoureas, although quite carcinogenic, do not have this property (71). Many nitrosamines have induced tumors of the esophagus in rats (although not in hamsters) and provide a model for the human tumor, which is common in certain areas of the world and is often associated with smoking tobacco and drinking alcoholic beverages. The linking of alkylnitrosoureas (and probably alkylnitrosocarbamate esters) with transplacentally induced brain and nervous system tumors in rats provides another rare model of common human cancers. The same alkylnitrosoureas in rats give rise to tumors of the colon and other parts of the lower gastrointestinal tract, another rare model of common human tumors, whereas in hamsters they induce mainly hemangioendothelial sarcomas of the spleen (but not of other organs) and few other tumors. This and other species differences in response to *N*-nitroso compounds is one of the intriguing aspects of carcinogenic studies and has a probable bearing on understanding the induction and development of cancer in general. Perhaps less important in relevance to human cancer is the large number of nitrosamines that induce tumors of the nasal cavity in rats, mice and hamsters and that do not have to be inhaled to do so (these tumors appear when the nitrosamines are given by gavage or even when injected into the bladder), in contrast with formaldehyde, acetaldehyde, and numerous halogenated hydrocarbons.

The marked difference in response of different species to many *N*-nitroso compounds make it impossible to predict which organs or tissues in humans would be responsive to those same compounds. But it is unwise to assume that any *N*-nitroso compound that is carcinogenic in rodents would be inactive in humans. Indeed, it is not improbable that humans are more susceptible to carcinogenic *N*-nitroso compounds than rats, which are more susceptible than hamsters or mice. The great effectiveness of cigarette smoke in producing lung cancer (and other cancers) in human smokers is surprising because cigarette smoke has a low content of carcinogens, of which nitrosamines are the most important. The dose of nitrosamines to a heavy cigarette smoker is approximately 0.06 mg/kg body weight/day (72), compared with the minimal effective dose of the most potent carcinogenic nitrosamines in rats (NDMA and NDEA) of 20–40 mg/kg body weight/day (58). Like most carcinogens, with increasing doses, *N*-nitroso compounds show an increase in the proportion of animals with tumors or a decrease in the time before tumors appear, or both (4, 73). Dose–response studies, mainly in rats, with a number of nitrosamines (including nitrosodiethylamine, nitrosomorpholine, nitrosopiperidine, nitrosopyrrolidine, nitrosodiethanolamine, nitroso-1,2,3,6-tetrahydropyridine, dinitrosohomopiperazine, and nitrosoheptamethyleneimine) have shown the same effect, often down to very low doses of a few micrograms per day. At this level there was virtually no life-shortening effect because tumors arose toward the end of the life span. These compounds induced a variety of tumors including those of liver, esophagus, and lung at the higher dose rates.

E. Risk Assessment

Because NDMA is the *N*-nitroso compound that has the most widespread human exposure (but possibly not the largest), risk assessment has focused on this compound and the possibility that exposure to it increases the risk of cancer. Although it is highly toxic, the possibility nowadays that exposure to it could be in such high concentrations as to lead to immediate toxic effects is essentially nil (other than deliberate poisoning) (74). In few cases, governmental regulatory agencies have calculated the long-term cancer risks of exposure, based on the results of tests in animals. The U. S. Environmental Protection Agency has declared that a concentration of 7 parts per trillion (10^{12}) of NDMA in drinking water or water for recreation represents a cancer risk of 1 in 10^6, and the State of California claims that exposure to 0.004 mg of NDMA per day presents a cancer risk of 10^{-6}. In the case of nitrosodiethanolamine (NDELA), the EPA has determined that the cancer risk of occupational exposure to 10^{-5} mg per kg per day is 10^{-6}, and in Europe a similar risk is posed by exposure to 0.0002 mg of NDELA per kg per day in cosmetics. These numbers are quite approximate.

Aliphatic and Alicyclic Amines
Finis L. Cavender, Ph.D., DABT, CIH

1 General Considerations

Aliphatic and alicyclic amines are nonaromatic amines that have a straight chain, a branched chain, or a cyclic alkyl moiety attached to the nitrogen atom.

Aliphatic amines are highly alkaline and tend to be fat soluble. As such, they have the potential to produce severe irritation to skin, eyes, and mucous membranes. Corrosive burns as well as marked

allergic sensitization may also occur (1). Volatile amines, which are characterized by boiling points lower than 100°C, are highly irritating and include methylamine, dimethylamine, trimethylamine, ethylamine, diethylamine, triethylamine, *n*-propylamine, isopropylamine, diisopropylamine, allylamine, *n*-butylamine, isobutylamine, *sec*-butylamine, *tert*-butylamine, and dimethylbutylamine. Workplace practice must consider these properties in developing strategies to protect workers. Toxicity information in humans continues to be limited. Although great strides in understanding the process of carcinogenicity have been made in recent years, controversies regarding potential aliphatic amine carcinogenicity are far from being resolved. Of considerable interest is the possibility of nitrosamine formation, which is both compound specific and pH dependent.

1.1 Chemical and Physical Properties

Aliphatic amines are highly alkaline derivatives of ammonia where one, two, or three of the hydrogen atoms are replaced by alkyl or alkanol radicals of six carbons or fewer. In addition, primary and secondary amines can also act as very weak acids (K_a approximately 10–33) (2). Many of the lower aliphatic amines have low flash points and are flammable liquids or gases. Branching of the alkyl chain tends to enhance volatility, whereas hydroxy substitution as in the alkanolamines decreases volatility (2a–2c). Methylamine solutions are good solvents for many inorganic and organic compounds.

Most aliphatic amines have a distinctly unpleasant odor. The fishy or fishlike odor of methylamines increases from mono- to trimethylamine, and in high concentrations they all have the odor of ammonia (2). Olfactory fatigue occurs readily. No symptoms of irritation are produced from chronic exposures to less than 10 ppm (1). Deodorization of ammonia and amines can be achieved with the use of dihydroxyacetone, which is reportedly nontoxic to humans and domestic animals and reacts rapidly with ammonia or amines (1b).

Amoore and Furrester reported that about 7% of humans are unable to smell (Anosmic) trimethylamine (1c). Odor threshold measurements on 16 aliphatic amines were made with panels of specific anosmics and normal observers. The anosmia was most pronounced with low-molecular-weight tertiary amines, but was also observed to a lesser degree with primary and secondary amines. This specific anosmia apparently corresponds with the absence of a new olfactory primary sensation, the fishlike odor.

The aliphatic amines are conveniently classified as primary, secondary, and tertiary amines according to the number of substitutions on the nitrogen atom. If only one hydrogen is replaced with an alkyl group, the amine is a primary amine, even though the alkyl substituent may have a secondary or tertiary structure (1).

Aliphatic and Alicyclic Amines

2 Methylamine

2.0.1 CAS Number:

[*74-89-5*]

2.0.2 Synonyms:

Monomethylamine, anhydrous monomethylamine, aminomethane, methanamine, and MMA

2.0.3 Trade Names:

NA

2.0.4 Molecular Weight:

31.06

2.0.5 Molecular Formula:

CH_5N

2.0.6 Molecular Structure:

2.1 Chemical and Physical Properties
2.1.1 General Methylamine is a colorless, flammable gas at room temperature and atmospheric pressure. It is readily liquefied and is shipped as a liquefied gas under its own vapor pressure.

2.1.2 Odor and Warning Properties It has a characteristic fishlike odor in lower concentrations, readily detectable at 10 ppm, becomes strong at 20–100 ppm, and becomes intolerably ammoniacal at 100–500 ppm (8b). The odor threshold reportedly ranges from 0.0009 to 4.68 ppm, and becomes irritating at 24 mg/m^3 (62, 63).
2.2 Production and Use
Methylamine can be manufactured by reacting ammonia and methyl alcohol in the presence of silica–alumina catylst at elevated temperature and pressure; by reductive amination of formaldehyde; or by heating methyl alcohol, ammonium chloride, and zinc chloride to about 300°C. It is used in tanning, fuel additives, photographic developers, and rocket propellants (64), in the manufacture of dyestuffs, in the treatment of cellulose acetate rayon, and in organic synthesis.
2.3 Exposure Assessment
2.3.1 Air NIOSH (65).

2.3.2 Background Levels Bouyoucos and Melcher (66).

2.3.3 Workplace Methods Fuselli et al. (67). OSHA method #40 is recommended for determining workplace exposure (OSHA Analytical Methods, 1990, 1993).

2.3.4 Community Methods Leenheer et al. (68).
2.4 Toxic Effects
2.4.1 Experimental Studies 2.4.1.1 Acute Toxicity Methylamine has been reported to cause liver toxicity in laboratory animals (69). A drop of 5 percent solution in water applied to animal eyes was reported to cause hemorrhages in the conjunctiva, superficial corneal opacities, and edema (70, 71, p. 680).

2.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms When administered to humans, dogs, or rabbits as the hydrochloride, methylamine is rapidly absorbed and only traces of the unchanged compound was observed to be excreted in the urine by early investigators (Salkowski, 1877; Schiffer, 1880) (15). Salkowski claimed that very small amounts of methylurea were excreted by rabbits, but this was not observed in the case of dogs by Schmiedeberg (1878) (15). In 1893, Pohl claimed that small amounts of formate were excreted by dogs receiving methylamine hydrochloride (15), and urea formation was demonstrated in a perfused dog liver experiment by Loffler in 1918 (15). Kapellar-Adler and Krael (1931) were the first to postulate that the amino group was probably split off as ammonia (26).

In 1937 Richter put the two concepts together and proposed that the reaction may be split into two stages in which the amine is first dehydrogenated to the corresponding intermediate imine, which reacts spontaneously with water forming an aldehyde and ammonia. Richter believed that most amines were oxidized by amine oxidase, according to the following reaction in the case of primary amines (26):

$$RCH_2NH_2 + O_2 \rightleftharpoons RCH{=}NH + H_2O_2 RCH{=}NH + H_2 \rightleftharpoons RCHO + NH_3 \quad (1)$$

Methylamine and trimethylamine are also reportedly metabolized to a small extent to dimethylamine in the body (8), and Alles and Heegaard (1943) demonstrated that methylamine could be oxidized, although with difficulty, *in vitro* by MAO (9, 10).

2.4.1.4 Reproductive and Developmental Treatment of CD-1 mice by daily intraperitoneal injection of 0.25, 1, 2.5, or 5 mmol/kg from day 1 to day 17 of gestation demonstrated no adverse reproductive effects. In the same experiment, dimethylamine was also without effect; trimethylamine decreased fetal weight without affecting maternal body weight gain. None of the amines caused a significant increase in external or internal organ or skeletal abnormalities (8).

2.4.2 Human Experience Brief exposures to 20–100 ppm produce transient eye, nose, and throat irritation; no symptoms of iritation are produced from longer exposures at less than 10 ppm; olfactory fatigue occurs readily (8b).

In one plant a case of allergic or chemical bronchitis occurred in a worker exposed to 2–60 ppm, although masks or respirators were reportedly worn during "greatest exposures" (64).
2.5 Standards, Regulations, or Guidelines of Exposure
An ACGIH threshold limit value (TLV)-time-weighted average (TWA) value of 5 ppm (6.4 mg/m^3) and a short-term exposure limit (STEL) of 15 ppm (19 mg/m^3) have been adopted (72). The OSHA PEL and NIOSH REL is 10 ppm.
2.6 Studies on Environmental Impact
Aliphatic amines including methylamine were determined in oil-shale retort water (68).

Aliphatic and Alicyclic Amines
Finis L. Cavender, Ph.D., DABT, CIH

3 Dimethylamine
3.0.1 CAS Number:
[*124-40-3*]
3.0.2 Synonyms:
DMA, *N*-methylmethanamine
3.0.3 Trade Names:
NA
3.0.4 Molecular Weight:
45.08
3.0.5 Molecular Formula:
C_2H_7N
3.0.6 Molecular Structure:

3.1 Chemical and Physical Properties
3.1.1 General The molecular formula for dimethylamine is $(CH_3)_2NH$. DMA is a flammable, alkaline, colorless gas at room temperature and atmospheric pressure (73, 74). It is readily liquefied and is shipped in steel cylinders as a liquefied gas under its own vapor pressure (75).

3.1.2 Odor and Warning Properties DMA has a characteristic rotten fishlike odor in lower concentrations (62, 63). The odor threshold ranges from 0.00076 to 1.6 ppm, and becomes irritating

at 175 mg/m^3 (62, 63). In higher concentrations (100–500 ppm) the fishlike odor is no longer detectable and the odor is more like that of ammonia.

3.2 Production and Use

Dimethylamine is manufactured by reaction of ammonia and methanol over dehydrating catalysts at 300–500°C or by catalytic hydrogenation of nitrosodimethylamine (51). DMA has been used as an accelerator in vulcanizing rubber, in the manufacture of detergent soaps, and for attracting boll weevils for extermination (73, 74). It has been used as a depilating agent in tanning, as an acid gas absorbent, in dyes, as a flotation agent, as a gasoline stabilizer, in pharmaceuticals, in soaps and cleaning compounds, in the treatment of cellulose acetate rayon, in organic syntheses, and as an agricultural fungicide (75).

3.3 Exposure Assessment

3.3.1 Air NIOSH (65).

3.3.2 Background Levels NIOSH (76).

3.3.3 Workplace Method NIOSH Method 201D (65).

3.3.4 Community Methods Cross et al. (77).

3.4 Toxic Effects

3.4.1 Experimental Studies Dimethylamine is irritating and corrosive to both the eyes and skin of test animals (78).

Several DMA inhalation studies have been reported. Exposure of rats, mice, guinea pigs, and rabbits to 97 or 185 ppm of DMA 7 h/d, 5 d/wk for 18–20 wk revealed corneal injury in eyes of guinea pigs and rabbits as well as central lobular fatty degeneration and necrosis of the liver in all species (79). However, histopathological examination of rats, guinea pigs, rabbits, monkeys and dogs exposed to 9 mg/m^3 of DMA continuously for 90 d produced only mild inflammatory changes in the lungs of all species; dilated bronchi in rabbits and monkeys were noted (80).

Steinhagen et al. reported an acute 6-h whole-body exposure of male F344 rats to DMA concentrations ranging from 600 to 6000 ppm for 6 h, which produced a spectrum of pathological changes in the nasal passages, including severe congestion, ulcerative rhinitis, and necrosis of the nasal turbinates (81). Lesions outside the respiratory tract were evident in livers of rats exposed to 2500–6000 ppm, and corneal edema was observed in the eyes of rats at 1000 ppm; corneal ulceration, keratitis, edema, and loss of Descement's membrane was present at 2500–6000 ppm; in addition, many rats exposed to 4000 or 6000 ppm had necrosis of the iris and severe degeneration of the lens, suggestive of acute cataract formation. From a 10-min head-only exposure of male F344 rats to DMA concentrations ranging from 49 to 1576 ppm, a concentration–response curve indicated that a 10-min exposure of 600 ppm would be expected to result in a 51% decrease in respiratory rate; the corresponding calculated response dose, RD50, was 573 ppm.

In an experiment to determine whether pathological changes occurred in the respiratory tract of mice after inhalation exposure to various sensory irritants at their respective RD50 concentrations, 16–24 male Swiss–Webster mice were exposed to 510 ppm DMA, 6 h/d for 5 d; lesions induced in the respiratory epithelium ranged from epithelial hypertrophy or hyperplasia to erosion, ulceration, inflammation, and squamous metaplasia (82).

In a 1-year inhalation study, male and female F344 rats and B6C3F$_1$ mice were exposed to 0, 10, 50, or 175 ppm DMA for 6 h/d, 5 d/wk for 12 months. The mean body weight gain of rats and mice exposed to 175 ppm was depressed to 90% of control after 3 weeks of exposure. The only other treatment-related effects were the dose-related lesions confined to the nasal passages, which were very similar in rats and mice; however, after 12 months of exposure, rats had more extensive olfactory lesions (83).

DMA was not shown to have reproductive effects in mice by intraperitoneal injection (8).

3.4.1.5 Carcinogenesis In a 2-year inhalation study in male F344 rats exposed to 175 ppm, no evidence of carcinogenicity was observed, and in addition, despite severe tissue destruction in the anterior nose following a single 6-h exposure, the nasal lesions exhibited very little evidence of progression, even at 2 years of exposure; it was concluded that this indicated possible regional susceptibility to DMA toxicity or a degree of adaptation by the rat to continued DMA exposure.

A detailed evaluation of mucociliary apparatus function and response to alterations of nasal structure was presented by the authors (84).

3.4.2 Human Experience DMA is considered to be a severe lung and skin irritant in humans (85). Occupational exposure to vapors of DMA at concentrations too low to cause discomfort or disability during several hours of exposure have been associated with misty vision and halos that appeared several hours after the exposure occurred. Therefore, DMA does not have good warning properties. Edema of the corneal epithelium, the effect principally responsible for disturbance of vision, usually clears without treatment within 24 h. However, after exceptionally intense exposures, the edema and blurring have taken several days to clear and have been accompanied by photophobia and discomfort from roughness of the corneal surface (86).
3.5 Standards, Regulations, or Guidelines of Exposure
An ACGIH TLV-TWA value of 5 ppm (9.2 mg/m^3) and a STEL of 15 ppm (27.6 mg/m^3) have been adopted (72). The NIOSH REL and OSHA PEL is 10 ppm.

Aliphatic and Alicyclic Amines
Finis L. Cavender, Ph.D., DABT, CIH

4 Trimethylamine
4.0.1 CAS Number:
[*75-50-3*]
4.0.2 Synonyms:
TMA, *N*,*N*-dimethylmethanamine, and *N*,*N*-dimethylmethamine
4.0.3 Trade Names:
NA
4.0.4 Molecular Weight:
59.11
4.0.5 Molecular Formula:
C_3H_9N
4.0.6 Molecular Structure:

4.1 Chemical and Physical Properties
4.1.1 General It is readily soluble in water and is also soluble in ether, benzene, toluene, xylene, ethylbenzene, and chloroform. TMA is a flammable, alkaline, colorless gas at ambient temperature and atmospheric pressure. Trimethylamine is shipped as a liquefied compressed gas in cylinders, tank cars, and cargo tank trucks.

4.1.2 Odor and Warning Properties The odor threshold reportedly ranges from 0.00011 to 0.87 ppm and the odor is a characteristic pungent, fishlike one in low concentrations, but in higher

concentrations (100–500 ppm) the fishy odoer is no longer detectable, and the odor is more like that of ammonia (63, 75).

4.2 Production and Use

Trimethylamine is manufactured by heating methanol and ammonia over a catalyst at high temperatures; or by heating paraformaldehyde and ammonium chloride; or by the action of formaldehyde and formic acid on ammonia (51). TMA is used primarily in the manufacture of quaternary ammonium compounds, in the manufacture of disinfectants, as a corrosion inhibitor, in the preparation of choline chloride, in various organic syntheses (75), and as a warning agent for natural gas (64).

4.3 Exposure Assessment

4.3.1 Air None available.

4.3.2 Background Levels Bouyoucos and Melcher (66).

4.3.3 Workplace Methods None available.

4.3.4 Community Methods Hoshika (77).

4.4 Toxic Effects

4.4.1 Experimental Studies A 1% solution applied to animal eyes resulted in severe irritation, 5% causes hemorrhagic conjunctivitis, and 16.5% causes a severe reaction with conjunctival hemorrhages, corneal edema, and opacities, followed by some clearing but much vascularization (71, p. 1060).

In contrast to MMA and DMA, TMA has been demonstrated to cause embryo toxicity in mice (decreased fetal weight of CD-1 pups) (8).

4.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms TMA can be detected in mammalian urine and may arise from choline. When administered to humans, dogs, or rabbits (Linzel, 1934; Hoppe-Seyler, 1934), it is partly degraded to ammonia and subsequently to urea, and oxidized to trimethylamine oxide (15); according to Muller (1940) about 50% of the dose of trimethylamine hydrochloride (administered orally to dogs) was eliminated unchanged together with traces of dimethylamine, suggesting that trimethylamine was N-dealkylated (26).

In 1941, Green reported that tertiary amines are also oxidized by amine oxidase to the corresponding formaldehyde and secondary amine and proposed the following reaction (26):

$$RCH_2NR'R'' \rightleftharpoons RCHO + R'R''NH$$

It was also proposed that the secondary amine can then form a primary amine and this eventually would yield ammonia. *In vivo*, therefore, the nitrogen of a tertiary amine could be expected to appear in part as urea.

The second reaction involved the oxidation of the amine to the amine oxide as follows (15):

$$RR'R''N \rightleftharpoons RR'R''NO$$

N-dealkylation can be expected to occur with most amines, with an available a-carbon hydrogen. The reaction is essentially the same as oxidative deamination, that is, cleavage of the carbon–nitrogen bond with transfer of two electrons with the formation of a carbonyl compound and a dealkylated amine. It is therefore unlikely that tertiary aliphatic amines will be easily N-dealkylated to secondary amines. However, it may depend on the size of the alkyl groups. For example, trimethylamine has been reported to be N-dealkylated to dimethylamine, and studies have also shown that a *t*-butyl group can be removed through initial hydroxylation of one of the *t*-methyl groups, resulting in C-dealkylation to the corresponding carbinol or alcohol product (87).

In cases, therefore, where tertiary amines have a small, easily removed group (methyl, ethyl, isopropyl), then oxidative N-dealkylation can probably proceed with preferential removal of the smaller substituents, dissociating into a secondary amine and aldehyde via microsomal P450 (88, 89).

Trimethylamine oxide occurs in large amounts in the tissues of fish, and its transformation into trimethylamine by bacteria containing trimethylamine oxide reductase is largely responsible for the spoiling of fish (15).

4.4.2 Human Experience In humans, N-oxidation to trimethylamine oxide is apparently the major route of metabolism; although N-demethylation to dimethylamine can also occur, it is a virtually negligible minor route (8, 90).
4.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV-TWA value of 5 ppm (12 mg/m^3) and a STEL of 15 ppm (36 mg/m^3) have been adopted (72). The NIOSH REL is 10 ppm.
4.6 Studies on Environmental Impact
In conjugated form, TMA is widely distributed in animal tissue and especially in fish (73, 74). It is also found in nature as a degradation product of nitrogenous plant and animal residues and is responsible for the odor of rotting cartilaginous marine fish (64).

Aliphatic and Alicyclic Amines
Finis L. Cavender, Ph.D., DABT, CIH

5 Ethylamine
5.0.1 CAS Number:
[*75-04-7*]
5.0.2 Synonyms:
MEA, monoethylamine, aminoethane, ethanamine, and EA
5.0.3 Trade Names:
NA
5.0.4 Molecular Weight:
45.08
5.0.5 Molecular Formula:
C_2H_7N
5.0.6 Molecular Structure:

5.1 Chemical and Physical Properties
5.1.1 General It is a flammable, colorless gas.

5.1.2 Odor and Warning Properties The odor threshold reportedly ranges from 0.027 to 3.5 ppm, having a sharp fishy, ammoniacal odor, which becomes irritating at 180 mg/m^3 (62, 63). It is miscible with water, alcohol, and ether (71, p 76; 73, 74).
5.2 Production and Use
Ethylamine is manufactured by the hydrogenation of nitroethane; the reaction of ethyl chloride and alcohol ammonia under heat and pressure; or by the hydrogenation of aziridines in the presence of catalysts (51). It is used in resin chemistry, as a stabilizer for rubber latex, as an intermediate for dyestuffs, and in pharmaceuticals, and in oil refining and organic syntheses (73, 74).

5.3 Exposure Assessment
5.3.1 Air: NA

5.3.2 Background Levels: NA

5.3.3 Workplace Methods Analytical method S144 is recommended for determining workplace exposures to ethylamine (103).

5.3.4 Community Methods Hoshika (77).
5.4 Toxic Effects
5.4.1 Experimental Studies Ethylamine is a primary skin irritant (85), as well as an eye and mucous membrane irritant (77a), and when tested on rabbit eyes, was severely damaging (86). A 70% solution applied to the skin of guinea pigs resulted in prompt skin burns leading to necrosis; when it was held in contact with guinea pig skin for 2 h, there was severe skin irritation with extensive necrosis and deep scarring (8b).

In a comparative inhalation study, Brieger and Hodes exposed rabbits repeatedly to measured concentrations of ethylamine, diethylamine, and triethylamine (91, 92). The three amines produced lung, liver and kidney damage at 100 ppm. The triethylamine produced definite degenerative changes in the heart at 100 ppm, whereas this was an inconstant finding with ethylamine and diethylamine; 50 ppm of these amines was sufficient to produce lung irritation and corneal injury (delayed until 2 weeks with ethylamine).

Ethylamine has been reported to cause adrenal cortical gland necrosis, which, according to Ribelin (93), can also be expected following exposure to short three- or four-carbon chain alkyl compounds bearing terminal electronegative groups. Of the three adrenal gland areas, medulla, zona glomerulosa, and zona fasciculata/reticularis, the last is most sensitive to toxic injury, which is the case with ethylamine. Sensitivity of endocrine glands to toxic insult occurs in the following decreasing order: adrenal, testis, thyroid, ovary, pancreas, pituitary, and parathyroid (93).

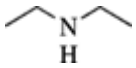
5.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Monoethylamine (MEA) is less readily metabolized than methylamine, and although a large proportion may be destroyed, its nitrogen being converted into urea (Schmiedeberg, 1878; Loffler, 1918), nearly one-third of the dose may be excreted unchanged by humans when administered as the hydrochloride. Schmiedeberg suggested that dogs might excrete traces of ethylurea after ethylamine (15).

5.4.2 Human Experience Ethylamine vapor has also reportedly produced vision disturbances and decreased olfaction sensitivity in humans (94); therefore, the warning properties associated with odor should not be relied upon.
5.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV-TWA value of 5 ppm (9 mg/m^3) has been adopted as well as a STEL of 15 ppm (72, 78). Both the NIOSH REL and OSHA PEL are 10 ppm.

Aliphatic and Alicyclic Amines
Finis L. Cavender, Ph.D., DABT, CIH

6 Diethylamine
6.0.1 CAS Number:
[*109-89-7*]
6.0.2 Synonyms:
DEA, *N*,*N*-diethylamine, diethamine, and *N*-ethylethanamine

6.0.3 Trade Names:
NA
6.0.4 Molecular Weight:
73.14
6.0.5 Molecular Formula:
$C_4H_{11}N$
6.0.6 Molecular Structure:



6.1 Chemical and Physical Properties
6.1.1 General The molecular formula for diethyalmine is $(C_2H_5)_2NH$. It is a colorless, flammable, strongly alkaline liquid, miscible with water and alcohol (73, 74).

6.1.2 Odor and Warning Properties The odor threshold ranges from 0.02 to 14 ppm, having a fishlike odor that becomes ammoniacal and irritating at 150 mg/m^3 (62, 63).
6.2 Production and Use
Diethylamine is manufactured by heating ethyl chloride and alcoholic ammonia under pressure or by hydrogenation of aziridines in the presence of catalysts (51). DEA is used as a solvent, as a rubber accelerator, in the organic synthesis of resins, dyes, pesticides, and pharmaceuticals, in electroplating, and as a polymerization inhibitor (73, 74). Other applications include uses as a corrosion inhibitor. It was reported noneffective as a skin depigmentator (95).
6.3 Exposure Assessment
6.3.1 Air: NA

6.3.2 Background Levels: NA

6.3.3 Workplace Methods NIOSH method 2010 is recommended for determining workplace exposures to diethylamine (65).

6.3.4 Community Methods Hoshika (77).
6.4 Toxic Effects
6.4.1 Experimental Studies DEA is an eye and mucous membrane irritant and primary skin irritant (85). Smyth et al. reported an acute 4-h LC_{50} value of 4000 ppm, the oral LD_{50} for rats was reported as 540 mg/kg, and the dermal LD_{50} in rabbits was reported to be 580 mg/kg; a 10% dilution caused severe eye burns (96). Drotman and Lawhorn reported histological evidence of liver damage and elevations of serum enzymes following intraperitoneal administration to rats (97). In addition to these acute studies, Brieger and Hodes exposed rabbits at 50 and 100 ppm DEA vapor for 7 h/d, 5 d/wk for 6 wk and all animals survived (91). Lungs exposed to 100 ppm exhibited cellular infiltration and bronchopneumonia, livers showed marked parenchymatous degeneration, and kidneys showed nephritis. Similar changes to a lesser degree were observed in animals exposed to 50 ppm. There was slight cardiac muscle degeneration at 50 ppm.

Lynch et al., in a followup study to investigate heart muscle degeneration reported by Brieger and Hodes were unable to find any evidence of cardiac muscle degeneration or any changes in electrocardiograms in F344 rats of both sexes exposed to DEA vapor concentrations of 25 or 250 ppm for 6.5 h/d, 5 d/wk for 30, 60, or 120 exposure days (91, 92). Rats exposed at 25 ppm showed no effect in any measured parameter. In contrast to DMA observations previously discussed the incidence of histopathological effects (bronchiolar lymphoid hyperplasia) was noted in both controls and the 25-ppm dosage groups; however, the incidence was not dose-related and did not increase with increasing DEA exposure (81). The authors therefore concluded that the lesions of the

respiratory epithelium (consisting of squamous metaplasia, suppurative rhinitis, and lymphoid hyperplasia) were not considerd to be of toxicologic significance but were considered a result of irritation. No evidence of cardiac muscle degeneration or of changes in electrocardiograms were seen for up to 24 weeks. It was noted that these negative findings may reflect a species difference in susceptibility to DEA cardiotoxicity previously reported by Brieger (91).

In a followup parallel inhalation study with DEA and triethylamine, no respiratory lesions were observed with triethylamine in F344 rats exposed to 25 or 250 ppm (98).

6.4.2 Human Experience Adverse ocular effects have been reported following human exposure (94).

6.4.2.2.3 Pharmacokinetis, Metabolism, and Mechanisms Diethylamine (DEA) is mainly excreted unchanged by humans when it is administered as the hydrochloride (15).
6.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV-TWA value of 5 ppm (15 mg/m^3) and a STEL of .5 ppm (37.5 mg/m^3) have been adopted (72). The NIOSH REL is 10 ppm and the OSHA PEL is 25 ppm.

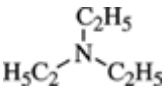
7 Triethylamine
7.0.1 CAS Number:
[*121-44-8*]
7.0.2 Synonyms:
N,*N*-diethylethanamine and TEA
7.0.3 Trade Names:
NA
7.0.4 Molecular Weight:
101.19
7.0.5 Molecular Formula:
$(C_2H_5)_3N$
7.0.6 Molecular Structure: Liquid,



7.1 Chemical and Physical Properties
7.1.1 General It is a colorless, flammable, volatile liquid. It is slightly soluble in water and miscible with alcohol and ether (73, 74).

7.1.2 Odor and Warning Properties The odor threshold reportedly ranges from 0.10 to 29 ppm, having a fishlike, pungent odor, which becomes ammoniacal and irritating at 200 mg/m^3 (62, 63).
7.2 Production and Use
Triethylamine is manufactured by heating ethyl chloride and alcoholic ammonia under pressure or by hydrogenation of aziridines in the presence of catalysts (51). TEA is used as a solvent and in the synthesis of quaternary ammonia wetting agents (73, 74); it is also reportedly used in penetrating and waterproofing agents, as a corrosion inhibitor, and in the synthesis of other organic compounds (73, 74).
7.3 Exposure Assessment
7.3.1 Air: NA

7.3.2 Background Levels: NA

7.3.3 Workplace Methods NIOSH method S152 is recommended for determining workplace exposure to triethylamine (103).

7.3.4 Community Methods Hoshika (77).
7.4 Toxic Effects
7.4.1 Experimental Studies TEA is a skin and eye irritant (85). The acute oral LD_{50} in rats has been reported to be 0.46 g/kg; the rabbit dermal LD_{50}, 0.57 mL/kg; and the acute 4 h LC_{50}, apparently 500 ppm (64). Chronic exposure of rabbits to TEA vapors at concentrations as low as 50 ppm causes multiple erosions of the cornea and conjuctiva, as well as injuries of the lungs in the course of 6 weeks (91).

Male and female F344 rats exposed to vapor concentrations of 0, 25, or 250 ppm up to 28 weeks showed no physiological or pathological evidence of cardioxicity; no treatment-related effects were observed (99). However, as in the case with diethylamine, this may be species dependent.

7.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Biotransformation metabolites eliminated in human urine following inhalation at 10, 20, 35, and 50 mg/m^3 for 4 or 8 h included unchanged TEA and triethylamine *N*-oxide (100).

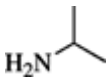
Pharmacokinetics in four male volunteers have been studied. The doses of TEA and TEAO were 25 and 15 mg orally and 15 mg/h × 1 h intravenously, respectively. TEA was efficiently absorbed from the gastrointestinal (GI) tract (90–97%), no significant first-pass metabolism. The apparent volumes of distribution during the elimination phase were 192 L for TEA and 103 L for TEAO. TEA was metabolized into triethylamine *N*-oxide (TEAO) by addition of oxygen to the nucleophilic nitrogen. TEAO was also absorbed from the GI tract. Both TEA and diethylamine (DEA) appeared in the urine after ingestion of TEAO, but not after an intravenous route of administration. This indicates that TEAO is reduced into TEA or dealkylated into DEA only within the GI tract. The TEA and TEAO had plasma half-lives of about 3 and 4 h, respectively. Exhalation of TEA was minimal; more than 90% of the dose was recovered in the urine as TEA and TEAO. The authors recommend that the sum of TEA and TEAO be used for biologic monitoring (101). Previously reported symptoms of visual disturbances in humans (foggy vision, blue haze) (102) were not observed following systemic administration (101).

7.4.2 Human Experience It has also been reported that TEA inhalation in humans has resulted in EEG changes (94).
7.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV-TWA value of 1 ppm (4.1 mg/m^3) and a STEL of 3 ppm (12.5 mg/m^3) have been adopted (72). The OSHA PEL is 25 ppm. NIOSH questions whether the OSHA PEL is adequate to protect workers.

Aliphatic and Alicyclic Amines
Finis L. Cavender, Ph.D., DABT, CIH

8 Isopropylamine
8.0.1 CAS Number:
[*75-31-0*]
8.0.2 Synonyms:
MIPA, 2-aminopropane, 2-propanamine, monisopropylamine, 2-propylamine, and *sec*-propylamine

8.0.3 Trade Names:
NA
8.0.4 Molecular Weight:
59.08
8.0.5 Molecular Formula:
$(CH_3)_2CHNH_2$
8.0.6 Molecular Structure:



8.1 Chemical and Physical Properties
8.1.1 General It is a colorless, flammable liquid. Isopropylamine is miscible with water, alcohol, and ether (73, 74).

8.1.2 Odor and Warning Properties The odor threshold reportedly ranges from 0.21 to 0.70 ppm; the pungent, ammoniacal odor becomes irritating at 24 mg/m^3 (63).
8.2 Production and Use
Isopropylamine is manufactured by reacting isopropanol and ammonia in the presence of dehydrating catalysts; by reacting isopropyl chloride and ammonia under pressure; or by the action of acetone and ammonia (51). It is used as a solvent, as a depilating agent (64), in the chemical synthesis of dyes and pharmaceuticals, and in other organic syntheses (64a).
8.3 Exposure Assessment
8.3.1 Air NIOSH Method S147 (103).

8.3.2 Background Levels Kuwata et al. (104).

8.3.3 Workplace Methods NIOSH Method S147 is recommended (103).

8.3.4 Community Methods Koga et al. (105).
8.4 Toxic Effects
8.4.1 Experimental Studies Isopropylamine in either liquid or vapor form is irritating to the skin and may cause burns; repeated lesser exposures may result in dermatitis (1, 85). The acute oral LD_{50} in rats is reportedly 820 mg/kg (96, in Ref. 73, 74).

Dudek (106) reported a no observable effect level (NOEL) in Sprague–Dawley rats to be 0.1 mg/L in air following a 30-d inhalation study.

8.4.2 Human Experience Humans exposed briefly to isopropylamine at 10–20 ppm experienced irritation of the nose and throat. Workers complained of transient visual disturbances (halos around lights) after exposure to the vapor for 8 h, probably owing to mild corneal edema, which usually cleared within 3–4 h. The liquid can cause severe eye burns and permanent visual impairment (107)
8.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV-TWA value of 5 ppm (12 mg/m^3) and a STEL of 10 ppm (24 mg/m^3) have been adopted (72). The OSHA PEL is 5 ppm. NIOSH questions whether 5 ppm is adequate.

Aliphatic and Alicyclic Amines
Finis L. Cavender, Ph.D., DABT, CIH

9 *n*-Propylamine
9.0.1 CAS Number:
[*107-10-8*]
9.0.2 Synonyms:
1-aminopropane, MNPA, 1-propanamine, propylamine, monopropylamine, propyl amines, propan-1-amine, and mono-*n*-propylamine
9.0.3 Trade Names:
NA
9.0.4 Molecular Weight:
59.11
9.0.5 Molecular Formula:
C_3H_9N
9.0.6 Molecular Structure:

9.1 Chemical and Physical Properties
9.1.1 General It is a colorless, flammable, alkaline liquid, and is miscible with water, alcohol, and ether (73, 74).

9.1.2 Odor and Warning Properties MNPA has a strong ammoniacal odor (73, 74).
9.2 Production and Use
n-Propylamine is manufactured by reacting propanol and ammonia in the presence of dehydrating catalysts; by reacting *n*-propyl chloride and ammonia under pressure; or by the action of acetone and ammonia (51). It is used as a solvent and in organic syntheses.
9.3 Exposure Assessment
9.3.1 Air NIOSH Method S147 (103).

9.3.2 Background Levels Kuwata et al. (104).

9.3.3 Workplace Methods None is recommended.

9.3.4 Community Methods Koga et al. (105).
9.4 Toxic Effects
9.4.1 Experimental Studies During lethal exposure in rats, *n*-propylamine caused clouding of the cornea at 800 ppm (108). Application to rabbit eyes caused severe injury after 24 h (109). The acute oral LD_{50} in rats is reportedly 0.57 g/kg (109, in Refs. 73, 74). It is a possible skin sensitizer (73, 74).

9.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms *n*-Propylamine appears to be more readily metabolized than ethylamine in humans, and in dogs Bernhard (1938) found none of the administered amine to be excreted unchanged (15).
9.5 Standards, Regulations, or Guidelines of Exposure
Standards have not been adopted.

Aliphatic and Alicyclic Amines
Finis L. Cavender, Ph.D., DABT, CIH

10 *n*-Dipropylamine

10.0.1 CAS Number:
[*142-84-7*]
10.0.2 Synonyms:
di-*n*-propylamine, DNPA, *N*-propyl-1-propanamine, and *N*,*N*-dipropylamine
10.0.3 Trade Names:
NA
10.0.4 Molecular Weight:
101.19
10.0.5 Molecular Formula:
$C_6H_{15}N$
10.0.6 Molecular Structure:

10.1 Chemical and Physical Properties
10.1.1 General It is a colorless, flammable liquid. *n*-Dipropylamine is freely soluble in water and alcohol (73, 74).

10.1.2 Odor and Warning Properties The odor threshold reportedly ranges from 0.08 to 227 mg/m^3; the odor is ammoniacal (62).
10.2 Production and Use
Di-*n*-propylamine is manufactured by reacting propanol and ammonia in the presence of dehydrating catalysts; *n*-propyl chloride and ammonia under pressure; or by the action of acetone and ammonia (51). Specific uses were not identified in the literature (51).
10.3 Exposure Assessment
10.3.1 Air None is recommended.

10.3.2 Background Levels None is recommended.

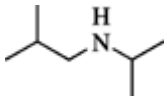
10.3.3 Workplace Methods None is recommended.

10.3.4 Community Methods Hoshika (77).
10.4 Toxic Effects
10.4.1 Experimental Studies Dipropylamine is a severe eye irritant (86), and the acute oral LD_{50} in rats is reportedly 0.93 g/kg (109, in Refs. 73, 74); it may also be a possible skin sensitizer (73, 74).
10.5 Standards, Regulations, or Guidelines of Exposure
Standards have not been adopted.

Aliphatic and Alicyclic Amines
Finis L. Cavender, Ph.D., DABT, CIH

11 Diisopropylamine
11.0.1 CAS Number:
[*108-18-9*]
11.0.2 Synonyms:
N,*N*-diisopropylamine and DIPA
11.0.3 Trade Names:
NA
11.0.4 Molecular Weight:

101.19
11.0.5 Molecular Formula:
$(CH_3)_2CHNHCH(CH_3)_2$
11.0.6 Molecular Structure:



11.1 Chemical and Physical Properties
11.1.1 General It is a flammable, strongly alkaline liquid. Diisopropylamine is soluble in water and alcohol (73, 74).

11.1.2 Odor and Warning Properties The odor threshold ranges from 0.017 to 4.2 ppm; the fishlike odor becomes irritating at 100 mg/m^3 (62, 63, 86).
11.2 Production and Use
Diisopropylamine is manufactured by reacting isopropanol and ammonia in the presence of dehydrating catalysts; by reacting isopropyl chloride an ammonia under pressure; or by the action of acetone and ammonia (51). It is used as a solvent and in the chemical synthesis of dyes, pharmaceuticals, and other organic syntheses (64a, 73, 74).
11.3 Exposure Assessment
11.3.1 Air NIOSH (65).

11.3.2 Background Levels Kuwata et al. (104).

11.3.3 Workplace Methods NIOSH Methods S141 (103).

11.3.4 Community Methods Koga et al. (105).
11.4 Toxic Effects
11.4.1 Experimental Studies The acute oral rat LD_{50} is reportedly 0.77 g/kg (110); the compound is irritating to the eyes, skin, and mucous membranes (73, 74, 85).

Experimental exposures of rabbits, guinea pigs, rats, and cats have established that the vapor is injurious to the corneal epithelium; this presumably is the cause of the visual disturbances observed in humans. Exposure of experimental animals to vapor concentrations from 260 to 2200 ppm for several hours causes clouding of the cornea from epithelial injury and stromal swelling. The highest concentrations were lethal in many instances, owing to severe pulmonary damage, but the corneas of surviving animals ultimately returned to normal (111).

Exposure of several species of animals to 2207 ppm for 3 h was fatal; effects were lacrimation, corneal clouding, and severe irritation of the respiratory tract. At autopsy, findings were pulmonary edema and hemorrhage (111a).

11.4.2 Human Experience Temporary impairment of vision has occurred in humans after exposure to vapor concentrations possibly as low as 25–50 ppm during distillation of diisopropylamine (111, 112).

Diisopropylamine is considered to be a severe pulmonary irritant in animals and humans (85). Workers exposed to concentrations between 25 and 50 ppm complained of disturbances of vision described as “haziness,” or “halos” around lights (85). Therefore, the warning properties of diisopropylamine are not protective. There have also been reports of nausea and headache (85a, 85b). Prolonged skin contact is likely to cause dermatitis (85c).

11.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV-TWA value of 5 ppm (21 mg/m^3) has been adopted (72). The NIOSH REL and OSHA PEL are the same.

Finis L. Cavender, Ph.D., DABT, CIH

13 **n**-Butylamine
13.0.1 CAS Number:
[*109-73-9*]
13.0.2 Synonyms:
MNBA, 1-butanamine, 1-aminobutane, aminobutane, butyl amine, 1-butanamine, norralamine, mono-*n*-butylamine, tutane, and monobutylamine
13.0.3 Trade Names:
NA
13.0.4 Molecular Weight:
73.14
13.0.5 Molecular Formula:
$C_4H_{11}N$
13.0.6 Molecular Structure:

13.1 Chemical and Physical Properties
13.1.1 General *n*-Butylamine is a flammable volatile liquid. It is miscible with water, alcohol, and ether (73, 74).

13.1.2 Odor and Warning Properties The odor threshold ranges from 0.24 to 13.9 ppm; the sour, fishlike, ammoniacal odor becomes irritating at 30 mg/m^3 (62, 63).
13.2 Production and Use
n-Butylamine is manufactured by the reaction of ammonia and *n*-butanol at elevated temperature and pressure in the presence of silica–alumina, by reductive amination of *n*-butyraldehyde; or by reduction of butyraldoxime. It is used as a solvent and as an intermediate for pharmaceuticals, dyestuffs, rubber chemicals, emulsifying agents, insecticides, and synthetic tanning agents (73, 74). It is also present in fertilizer manufacture, rendering plants, fish processing plants, and sewage plants (51) and has been reported to be effective (0.1*M*) in inhibiting the corrosion of iron in concentrated perchloric acid (6).
13.3 Exposure Assessment
13.3.1 Air: NA

13.3.2 Background Levels Kuwata et al. (104).

13.3.3 Workplace Methods NIOSH method 2012 is recommended for determining workplace exposure.

13.3.4 Community Methods Petronio and Russo (113).
13.4 Toxic Effects
13.4.1 Experimental Studies *n*-Butylamine vapor is only mildly irritating to the eyes, but the liquid tested on animals' eyes is as severely injurious as ammonium hydroxide; the injurious effect seems to be attributable to the alkalinity of butylamine because, as with other amines, its damaging effects on the cornea is prevented if it is neutralized with acid before testing (114–116). Other references indicate that *n*-butylamine is a potent skin, eye, and mucous membrane irritant, and direct skin contact causes severe primary irritation and blistering (73, 74). The acute oral LD_{50} for Sprague–Dawley rats (male + female) has been reevaluated and reported as 371 mg/kg (117).

n-Butylamine at measured concentrations of 3000–5000 ppm produces an immediate irritant response, labored breathing, and pulmonary edema, with death of all rats in minutes to hours. Ten and 50% vol/vol aqueous solutions and the undiluted base produce severe skin and eye burns in animals. The immediate skin and eye reactions are not appreciably altered by prolonged washing or

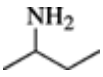
attempts at neutralization when these are commenced within 15 sec after application (8b).

13.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms *n*-Butylamine is as readily metabolized in humans as methylamine, and Pugh (1937) demonstrated in guinea pig liver slices that one of its metabolites is acetoacetic acid (15).

13.4.2 Human Experience Direct skin contact with the liquid causes severe primary irritation and deep second-degree burns (blistering) in humans. The odor of butylamine is slight at less than 1 ppm, noticeable at 2 ppm, moderately strong at 2–5 ppm, strong at 5–10 ppm, and strong and irritating at concentrations exceeding 10 ppm. Workers with daily exposures of from 5 to 10 ppm complain of nose, throat, and eye irritation, and headaches. Concentrations of 10–25 ppm are unpleasant to intolerable for more than a few minutes. Daily exposures to less than 5 ppm (most often between 1 and 2 ppm) produce no complaints or symptoms.
13.5 Standards, Regulations, or Guidelines of Exposure
NIOSH, OSHA, and the ACGIH have all adopted a ceiling value of 5 ppm (72).

Aliphatic and Alicyclic Amines
Finis L. Cavender, Ph.D., DABT, CIH

14 2-Butylamine
14.0.1 CAS Number:
[*13952-84-6*]
14.0.2 Synonyms:
2-aminobutane, *sec*-butylamine, 2-butanamine, 1-methylpropylamine, and Butafume. Butafume is available as (R) B.P. 63°C, (+/–) B.P. 63°C, and (S) B.P. 62.5°C; the corresponding CASRNs are [*13250-12-9*], [*33966-50-6*], and [*513-49-5*] (73, 74)
14.0.3 Trade Name:
NA
14.0.4 Molecular Weight:
73.14
14.0.5 Molecular Formula:
$CH_3CH_2CH(NH_3)CH_3$
14.0.6 Molecular Structure:



14.1 Chemical and Physical Properties
14.1.1 General It is a flammable liquid.
14.2 Production and Use
2-Butylamine is manufactured by the condensation of methyl ethyl ketone with ammonia–hydrogen in the presence of Ni catalyst (51). It has been used as a fungistat (73, 74).
14.3 Exposure Assessment
14.3.1 Air None available, however, NIOSH methods may be applicable.

14.3.2 Background Levels Kuwata et al. (104).

14.3.3 Workplace Methods NIOSH method 2012 may be used.

14.3.4 Community Methods Hoshika (77).

14.4 Toxic Effects
14.4.1 Experimental Studies The acute oral LD_{50} for Sprague–Dawley rats (males + females) has been reported to be 152 mg/kg (117). An earlier acute study reported an LD_{50} value of 380 mg/kg (female, Harlan Wistar rats) (118).

2-Butylamine is irritating to the skin and mucous membranes (73, 74). Seven male rats exposed to saturated vapor (280 mg/L) for 5 h exhibited intense eye and nose irritation, respiratory difficulty, and convulsions; all died. Cornea lesions were opaque and white, and all other organs appeared normal. All amines examined showed irritant and central nervous system stimulant effects; these increased with the degree of substitution, but the higher members had too low a volatility to present a significant vapor hazard. Other amino compounds studied included di-*sec*-butylamine, tributylamine, nonylamine, dinonylamine, trinonylamine, hexamethylenediamine, diethylenetriamine, 2-aminobutan-1-ol, and 1-diethylaminoentan-2-one (119).
14.5 Standards, Regulations, or Guidelines of Exposure
Standards have not been adopted.

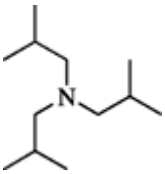
19.3.4 Community Methods Hoshika (77).
19.4 Toxic Effects
The acute oral LD_{50} for Sprague–Dawley rats (males + females) has been reported to be 80 mg/kg (117). Liver toxicity NOEL was reported to be 0.20 mg/L for female Sprague–Dawley rats (122).
19.5 Standards, Regulations, or Guidelines of Exposure
Standards have not been adopted.

Aliphatic and Alicyclic Amines
Finis L. Cavender, Ph.D., DABT, CIH

20 Triisobutylamine
20.0.1 CAS Number:
[*1116-40-1*]
20.0.2 Synonyms:
TIBA (73, 74), 2-methyl-*N*,*N*-*bis* (2-methylpropyl)-1-propanamine, and tris(2-methylpropyl)amine
20.0.3 Trade Names:
NA
20.0.4 Molecular Weight:
185.36
20.0.5 Molecular Formula:
$C_{12}H_{27}N$
20.0.6 Molecular Structure:



20.1 Chemical and Physical Properties
20.1.1 General
20.2 Production and Use
Triisobutylamine is manufactured from isobutanol and ammonia under heat and pressure (51).
20.3 Exposure Assessment
20.3.1 Air: NA

20.3.2 Background Levels Kuwata et al. (104).

20.3.3 Workplace Methods: NA

20.3.4 Community Methods Hoshika (77).
20.4 Toxic Effects
No toxicology information was located in the literature (51).
20.5 Standards, Regulations, or Guidelines of Exposure
Standards have not been adopted.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

General
Logically, aromatic nitro and amino compounds should be discussed together because their toxic responses are often similar due to a common metabolic intermediate. Synthetically, amines are generally derived from nitro compounds, but in some cases nitro compounds can be prepared through amines when other methods fail to afford specific compounds. There are good and bad attributes to these types of compounds. Some act as sensitizers and contingent on physical properties, may be absorbed through the skin or mucous membranes. They may also cause methemoglobinemia, depending on such factors as the structure and the particular organism. Some members of this class are known as animal and human carcinogens; for humans the urinary bladder is the most prominent target organ. Nevertheless, these compounds and their derivatives have enlivened our world through their use as dyestuff intermediates or as photographic chemicals, they alleviate pain as components of widely used analgesics, and they cushion or insulate us through their use in flexible and rigid foams. Other important uses include production of pesticides, including herbicides and fungicides, as ingredients in adhesives, paints and coatings, antioxidants, explosives, optical brighteners, rubber ingredients, and as intermediates in many other products.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

Aromatic Nitro Compounds
Aromatic nitro compounds are generally made by nitrating an aromatic hydrocarbon such as benzene

or toluene. Production has moved to continuous processes; in some facilities, jet impingement reactors allow more rapid production and lower formation of unwanted by-products; in vapor phase reactors, nitric acid and benzene flow through a solid catalyst in a continuous phase. These processes are beneficial in reducing waste. Production figures vary from year to year, depending on economic conditions, but in 1994 U.S. production of nitrobenzene was of the order of 740,000 tons (1). The nitro aromatics are starting materials for further syntheses. Most are reduced to the corresponding amines that provide convenient substituents or "handles" for many other syntheses.

The toxic properties of aromatic nitro compounds were discussed in the previous edition of this series (2). These attributes of the compounds are well-known and various regulatory agencies worldwide have set exposure limits for them.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

Aromatic Amino Compounds
Reduction of aromatic nitro compounds afford the amines that are starting materials for further syntheses. The amines share many of the toxic properties of the nitro compounds, as discussed previously (2), including skin sensitization, anemia, methemoglobinemia, irritation, hematuria, and for certain ones, bladder carcinogenesis. This aspect of aromatic amines has led to banning the manufacture of some and strict exposure limits on others. Nonetheless, research on some aromatic amines, especially 2-acetylaminofluorene (2-AAF), has led to a better understanding of the steps involved in carcinogenesis (3).
1.1 Chemical and Physical Properties
This topic was discussed fairly extensively in the previous edition, and no significant new information was found.
1.4 Toxic Effects
1.4.1 Experimental Studies One of the initial toxic responses to aromatic amines or nitro compounds is the formation of methemoglobin within the red blood cells and subsequent deleterious effects. There are decided species differences in response to methemoglobin formers (2). The complete tertiary structures of hemoglobin and its subunits have been mapped and described. Normal adult hemoglobin is an oligomeric protein (MW about 67,000) that has four separate globin peptide chains: two alpha chains and two beta chains (4). Each of these peptide chains has a noncovalently bound porphyrinic heme group that is enclosed in a hydrophobic pocket by the globin chain. If oxidation of the ferrous iron to ferric occurs in the center of the protoporphyrin IX ring, the resulting greenish-brown to black pigment cannot combine reversibly with oxygen, leading to symptoms of oxygen deficiency such as cyanosis and a consequent bluish tinge to the skin. There are three types of substances that produce methemoglobin (5):

1. Those active either *in vitro* or *in vivo* include sodium nitrite, aminophenols, phenyl- and other hydroxylamines, and amyl nitrite. Phenylhydroxylamine can act cyclically; after reducing oxyhemoglobin, it generates nitrosobenzene that is reduced again to phenylhydroxylamine by the red cell enzymes, thus generating more methemoglobin.
2. Those active only *in vivo*, indicating the need for some process before the primary compound interacts with hemoglobin; this group encompasses aromatic nitro and amino compounds. An example is that the *N*-hydroxy metabolite of *p*-aminopropiophenone (PAP) is recognized as the moiety actually responsible for the methemoglobin-inducing action of PAP.
3. A third group includes compounds that are more active in lysates or in solutions of hemoglobin than in intact cells; specific examples are potassium ferricyanide, molecular oxygen, and methylene blue.

Although methemoglobinemia from exogenous substances can induce a dramatic change in skin color and can be serious condition, a relatively benign hereditary type can also occur due to a genetic deficiency in cytochrome b_5 (6). Treatment of methemoglobinemia involves cessation of exposure to the toxin and limited intravenous administration of methylene blue due to possible hemolysis if more than two doses are given. Methemoglobin reductase enzyme or cytochrome b_5 is the electron carrier between NADH and methemoglobin, facilitated by formation of a complex between the two molecules. The cytochrome binds to four lysine moieties in the heme pocket in both chains, and a hydrogen bond between one of the lysines of the cytochrome is a bridge between two heme propionic acid side chains of both heme proteins and affords a micropath for electron transport.

In this chapter, occupational exposure to aromatic amines and nitro compounds is the primary concern. However, medicinal agents that contain aromatic amino or acetylamino groupings may also cause methemoglobinemia, especially from continued exposure (7–9). Thus, methemoglobinemia, besides being an occupational concern, can be an environmental one, if one considers the total environment.

1.4.2 Human Experience Research on aromatic amines has usually emphasized the adducts of the active metabolic intermediates with deoxyribonucleic acid (DNA) as indicators of possible genetic damage. It has been recognized that the metabolites also form hemoglobin adducts that are present in much larger amounts than DNA adducts. These adducts are not repaired as are DNA adducts, and they have a finite half-life (10–12). Using gas chromatography/mass spectrometry, hemoglobin-aromatic amine adducts can be measured fairly readily. These types of studies have demonstrated that aromatic amines, including aniline derivatives and the carcinogens 4-aminobiphenyl, 2-naphthylamine, and 2-aminofluorene, are present in tobacco smoke and form hemoglobin adducts (12, 13). Although there appeared to be a baseline level, adduct levels were increased 3- to 10-fold in the blood of smokers (9, 11) and were found in fetuses exposed to tobacco smoke in utero (12). Persons who acetylated aromatic amines more slowly had higher levels of the adducts than those who were rapid acetylators (10), implying that the free amine was necessary to initiate hemoglobin binding. This was supported by an extensive study of more than 20 nitroarenes and the corresponding amines that aimed at developing structure-activity relationships for hemoglobin binding in rats. The amine bound to a greater extent than the nitroarene. The highly substituted nitroarenes 2,4-dimethyl-, 3,4-dimethyl-, 2,6-dimethyl- and 2,4,6-trimethylnitrobenzene and 2,3,4,5,6-pentachloronitrobenzene did not bind to hemoglobin. All of the corresponding amines, except for pentachloroaniline, bound to hemoglobin. The implications were that due to structural interference, nitro reductase enzymes were prevented from acting on these nitroarenes, and thus hemoglobin binding was blocked (14).

1.4.3 Pharmacokinetics, Metabolism, and Mechanisms During metabolism, aromatic nitro and amino compounds may go by either of two pathways, detoxication or activation to toxic intermediates. Hydroxylation on the aromatic ring to yield a phenol is the first phase of detoxication. Further oxidative reactions may lead to demethylation of dimethylanilines or formation of quinoid derivatives of aminophenols. Conjugation of the phenol thus formed with glucuronic and/or sulfuric acid affords more soluble compounds that are readily excreted. Acetylation of an aromatic amine or formation of *N*-glucuronides are also detoxication pathways. Removal of a nitro group from some dinitroarenes and conjugation with glutathione ending as a mercapturic acid occurred (2, 15–17).

Activation to a toxic intermediate often leads to a common substance from nitro- or aminoarenes. Amines/amides undergo oxidation of the nitrogen to form *N*-hydroxylamines or amides; nitro compounds are reduced through nitroso and hydroxylamine stages. The hydroxylamines are largely responsible for the methemoglobinemia from these materials. Overall, many metabolites may be formed from one compound, depending on the structure and the animal species.

Carcinogenic aromatic amines follow the same metabolic paths as other amines, namely ring hydroxylation, conjugation, and excretion. Hydroxylation of the nitrogen, followed by formation of a

reactive sulfate or acetate ester that yields a reactive electrophilic arylnitrenium ion (Ar-N^+-H) is involved. The nitrenium ion can arylate DNA, which is considered a crucial event in carcinogenesis (17), at least for genotoxic carcinogens. Further discussion follows in Section 1.4.5.

Although the P450 system is a major factor in oxidative detoxication and activation of nitro- and aminoarenes (15, 18–20), flavine-dependent enzymes and peroxidases such as prostaglandin H synthase also oxidize amines, including benzidine and 2-aminofluorene (21).

The P450 system was so named for the wavelength of the carbon monoxide derivative of the reduced form of the hemoprotein, namely, 450 nm (20). Originally though to be only one protein, further research aided by better separation methods has indicated there may be several hundred, if not more, isoforms of this enzyme, depending on the species. Thus P450 consists of a superfamily of hemoproteins that are important in metabolizing both xenobiotics and endogenous substances.

Nomenclature of the P450 enzymes was originally based on the method used to induce them; this changed to a system based on the protein and now based on the chromosomal location (19, 20). Accordingly, P450IIA1 is being replaced by CYP2A1; corresponding changes for other isoforms hold.

There are seven steps involved in the oxidation of a chemical by a P450 isoform: (1) binding of the substrate to the ferric form of the enzyme, (2) reduction to the ferrous form by NADPH-cytochrome P450 reductase, (3) binding of molecular oxygen, (4) introduction of a second electron from P450 reductase and/or cytochrome b_5, (5) dioxygen cleavage that releases water and forms the active oxidizing species, (6) substrate oxygenation, and (7) product release (18).

The P450 enzymes can be induced by numerous substances, including phenobarbital, ethanol, aromatic hydrocarbons such as 3-methylcholanthrene, dioxin, and the pesticides DDT and chlordane. Likewise, they can be inhibited by certain benzoflavones, thiocarbamates, disulfiram, and some heterocyclic nitrogen compounds. Selective induction and inhibition of the P450 isoforms has been demonstrated in laboratory experiments. Experimentally, the carcinogenicity of aromatic amines could be decreased or inhibited by simultaneous administration of certain enzyme inducers. Similarly, deleterious effects in humans have sometimes occurred from drug/drug or drug/environmental substance interactions due to induction/inhibition of P450 enzymes. Environmental substances include those from occupations, hobbies, food, alcohol, and tobacco smoke.

P450 isozymes important in metabolizing nitro- and aminoarenes include CYP1A2 for phenacetin, 4-aminobiphenyl, 2-naphthylamine, and 2-AAF; CYP2A6 for 6-aminochrysene and 4,4'-methylene bis(2-chloroaniline) MOCA®; CYP2B for the same two compounds; CYP2E1 for aniline, acetaminophen, and *p*-nitrophenol. CYP3A is involved in oxidative metabolism of MOCA®, 6-amino- and 6-nitrochrysene, and 1-nitropyrene, among others (20).

The expression of the P450 enzymes is also mediated by the genetic background that leads to differences in the rate of oxidation. One study showed that most Australians were rapid metabolizers, but some were in the slow and intermediate categories. Chinese and Japanese were mostly intermediate, whereas residents of Arkansas and Georgia in the southern United States were largely intermediate, although persons in the slow and rapid classes were also in this population (22).

The relationships among aromatic amine acetylation, genetic background, and susceptibility to the carcinogenic effect of amines were recognized some decades ago. Interest in this area has been fairly intensive and led to many publications on *N*-acetyl-transferases. The acetyl transferase enzyme has at least two forms: NATI that is monomorphic and acetylates aromatic amines; NAT2 that is polymorphic and *N*-acetylates aromatic amines but also *O*-acetylates hydroxylamines. These enzymes have molecular weights of approximately 29 and 31 kDa (23, 24). Slow human acetylators

are associated with increased risk of bladder cancer, and rapid acetylators are associated with higher rates of colorectal cancer. The implication is that localized metabolic activation of arylamine type carcinogens is facilitated by NAT2 in colon tissue. Apart from occupational exposure to aromatic amines, other sources of exposure to such compounds are from smoking tobacco or eating large amounts of meat. Various heterocyclic amines are formed by the ordinary methods for cooking meat (grilling, frying) which are animal carcinogens and act like aromatic amines in their metabolic pathways. Only NAT2 acetylated these compounds (25).

Besides leading to partial identification of the acetyl transferase enzymes, molecular techniques, led to construction of transgenic animals which delineated the characteristics of the isozymes to a greater extent (26, 27). Experiments with such animals supported the human epidemiological results; animals that were rapid acetylators showed a higher response to colon carcinogens (28, 29).

1.4.4 Carcinogenesis The United States, as do many other developed countries, has an aging population and increased age leads to a higher risk of cancer. It is estimated that 565,000 people will die of cancer in 1998. During many decades of life, the cells in individual organs undergo trillions or more of cell divisions, and opportunities for error occur in each one of those divisions. Biologically, cell proliferation or division is considered a risk factor for cancer. In addition, many factors in the environment may be responsible for human cancer. A monumental epidemiological study concluded that 2-4% of cancers in the United States were ascribable to occupation, 8–28% to the use of tobacco, 40–57% to diet, 8% to exposure to sunlight, and unknown or undefined factors were responsible for 16–20% (30). Less well defined influences include genetic background, viruses, certain medicinal agents, radiation, alcohol use, certain types of behavior, socioeconomic status, and even methods for cooking or preserving foods (31, 32).

Although the estimate of the percentage of cancers ascribed to occupation is relatively low, it still is necessary to follow the guidelines promulgated by various regulatory and advisory agencies to minimize the risk of developing cancer. For nitro- and aminoarenes, avoidance of direct contact is important because they are fairly readily absorbed through the skin at levels sufficient to cause toxicity. Thus, the numerous “skin” notations in the advisory listings of the American Conference of Governmental and Industrial Hygienists (ACGIH) are necessary.

The carcinogenicity of aromatic amines for the human bladder was noted about 30 years after widespread use of these compounds occurred in dyestuff factories. After another 40 years, animal studies supported this premise (2, 3). Even with improved workplace conditions and much lower exposures than the original dyestuff workers had, more current surveys still indicate an increased risk of bladder cancer (33). Aromatic amines generally did not induce tumors at the point of application, but at distant sites, including liver, intestine, and bladder. The actual organs affected varied with the species and strain; 2-naphthylamine targets the bladder in humans, monkeys, dogs, and hamsters but has little effect in rabbits. 2-AAF affected the liver and mammary gland in most strains of rats and mice, but X/Gf mice and guinea pigs were resistant. Metabolic and mechanistic studies provided clues for the differences in some cases (i.e., guinea pigs do not *N*-hydroxylate 2-AAF) but not in others (34).

The carcinogenicity of any particular molecular structure can often be altered dramatically by adding substituents (35). A premise that adding a methyl group ortho to the amino moiety in 2-naphthylamine would reduce carcinogenicity was shown erroneous when 3-methyl-2-naphthylamine turned out to be more active than the parent amine (36). On the other hand, adding polar moieties has nullified carcinogenic action. Sulfonic acid derivatives of 2-naphthylamine (37) and 4,4'-diaminostilbene were inactive (38). However, even if an aromatic amine is not carcinogenic, other possible toxic effects such as methemoglobinemia should be kept in mind.

Carcinogens are divided into groupings, depending on their mode of action. Because of their structures, direct acting ones react as such with cellular macromolecules, especially DNA. Usually such compounds are not stable and are not a hazard to the general population. In contrast, nitro- and

aminoarenes, are indirect acting because they require metabolic activation before they interact with cellular targets. Metabolic activation is influenced by many factors: species, strain, sex, age, diet, enzyme inducers/inhibitors, and immune status, plus others. Once activated, the intermediates react with the cell's genetic material and thus are considered genotoxic carcinogens. Some carcinogens such as chloroform, trichloroacetic acid, and unleaded gasoline caused animal tumors but did not attach to cellular DNA. These compounds are called nongenotoxic or epigenetic carcinogens (39). Mechanisms for the action of epigenetic carcinogens are varied and usually show little or no relevance to human risk.

Classification of carcinogens has been addressed before (2), but changes have occurred to some extent in how governmental and other groups have developed systems for classifying the degree of risk associated with chemical carcinogens. In 1969, the International Agency for Research on Cancer (IARC) initiated a program to evaluate the risk in humans according to the following system: Group 1—The agent (mixture) is carcinogenic to humans; Group 2A—The agent is probably carcinogenic to humans; Group 2B—The agent is possibly carcinogenic to humans; Group 3—The agent is not classifiable as to its carcinogenicity to humans; Group 4—The agent is probably not carcinogenic to humans (40).

The National Toxicology Program (NTP) of the U.S. Department of Health and Human Services has only two categories in its various reports on carcinogens: (1) substances or groups of substances, occupational exposures associated with a technological process, and medical treatments that are known to be carcinogenic; and (2) substances or groups of substances and medical treatments that may reasonably be anticipated to be carcinogens. Known carcinogens are defined as those for which the evidence from human studies indicates that there is a causal relationship between exposure to the substance and human cancer. Reasonably anticipated to be carcinogens encompasses those for which there is limited evidence of carcinogenicity in humans or sufficient evidence from tests in experimental animals (41).

The U.S. Environmental Protection Agency (EPA) formerly had an A to E system as follows: A—known human carcinogen; B—probably carcinogenic to humans; C—possibly carcinogenic to humans; D—not adequately tested; E—tested and negative. The EPA is moving toward a narrative system that takes into account differences between humans and experimental animals in metabolism and mechanism of action. The system is as follows:

Known/likely—the available tumor effects and other key data are adequate to convincingly demonstrate carcinogenic potential for humans.

Cannot be determined—available tumor effects or other essential data are suggestive or conflicting or limited in quality and thus are not adequate to demonstrate a carcinogenic potential convincingly in humans.

Not likely—Experimental evidence is satisfactory to decide that there is no basis for concern as to human hazard.

The EPA system is not final, and new EPA classifications for industrial/environmental chemicals have not been published.

The U.S. Occupational Safety and Health Administration (OSHA) included the following aromatic amines or derivatives in its 1974 standards to minimize or control exposure: 2-AAF, 4-aminobiphenyl, benzidine, 3,3'-dichlorobenzidine, 4-dimethylaminoazobenzene, 1-naphthylamine, 2-naphthylamine, and 4-nitrobiphenyl (2).

The ACGIH, which is active in setting exposure limits for workplace chemicals, adopted the following system approximately 10 years ago:

1. Confirmed human carcinogen. The agent is carcinogenic to humans based on the weight of the evidence from epidemiologic studies.

2. Suspected human carcinogen. The agent is carcinogenic in experimental animals at dose levels, by route(s) of administration, at site(s) of histologic type(s), or by mechanism(s) that are considered relevant to worker exposure. Available epidemiological studies are conflicting or insufficient to confirm an increased risk of cancer in exposed humans.
3. Animal carcinogen. The agent is carcinogenic in experimental animals at a relatively high dose, by route(s) of administration, at site(s), of histological type(s) or by mechanisms(s) that are not considered relevant to worker exposure. Available epidemiological studies do not confirm an increased risk of cancer in exposed humans. Available evidence suggests that the agent is not likely to cause cancer in humans except under uncommon or unlikely routes or levels of exposure.
4. Not classifiable as a human carcinogen. There are inadequate data on which to classify the agent in terms of carcinogenicity in humans and/or animals. Substances for which animal tests are negative without further evidence of relevant mechanisms fall into this category.
5. Not suspected as a human carcinogen. The agent is not suspected to be a human carcinogen on the basis of properly conducted epidemiological studies in humans. These studies have sufficiently long follow-up, reliable exposure histories, sufficiently high dose, and adequate statistical power to conclude that exposure to the agent does not convey a significant risk of cancer to humans. Evidence that suggests a lack of carcinogenicity in animals will be considered if it is supported by other relevant data (42).

Increased emphasis on cooperation between countries and the formation of the European Union make it expedient to be informed of the systems employed by the Union and the German MAK (Maximum allowable concentration) Commission (43). The European Union proposes the following:

1. Substances known to be carcinogenic to humans
2. Substances that should be regarded as if they are carcinogenic to humans
3. Substances that cause concern for humans owing to possible carcinogenic effects

    1. Substances that are well investigated
    2. Substances that are insufficiently investigated

The German MAK system is as follows:

1. Substances that cause cancer in humans.
2. Substances that are considered carcinogenic to humans.
3. Substances that cause concern that they could be carcinogenic to humans but which cannot be assessed conclusively because of lack of data.
4. Substances with carcinogenic potential for which genotoxicity plays no or at most a minor role. No significant contribution to human cancer risk is expected, provided that the MAK value is observed.
5. Substances with carcinogenic and genotoxic potential, the potency of which is considered to be so low, provided that the MAK value is observed, that no significant contribution to human cancer risk is to be expected.

In the MAK system, more emphasis is placed on the genotoxicity of substances, as detected by mutagenicity or other short-term tests, than on animal tests for carcinogenicity. For reasons of cost and time, determining the mutagenic potential of a substance in specific strains of bacteria has become a surrogate for long-term studies. The most widely used of these tests involves measuring the ability of a substance to induce mutations and thus bacterial colony growth in strains of *Salmonella typhimurium*. Of the *S. typhimurium* strains, TA1538, which has a frameshift mutation, is more likely to respond to aromatic amines. New strains are developed frequently, but baseline data for many compounds have been obtained for strains TA100, TA98, TA1535, TA1537, and TA1538.

Addition of a liver fraction (S9) to the test culture allows measuring the effect of metabolic activation on mutagenicity (44).

However, the correlation between mutagenicity in bacteria and carcinogenicity in animals is not absolute and holds in approximately 60% of cases. It was found that using additional types of short-term tests involving animal cells or systems did not appreciably increase the accuracy of the test. Accordingly, the *Salmonella* system represents the easiest and least expensive of the short-term systems and has an accuracy comparable to other more expensive and more complicated tests.

On the downside, the *Salmonella* system is not totally accurate in detecting carcinogens, and the opposite can occur. Sodium azide was an active mutagen, but it was inactive in animal tests for carcinogenicity. Conversely, benzene and hexamethylphosphoramide are not mutagens in the usual test systems, but they are carcinogens in humans and animals, respectively. The fairly potent animal carcinogens *o*-anisidine and *p*-cresidine were not genotoxic in three animal-based short-term tests, namely, unscheduled DNA synthesis, DNA single-strand breaks, and effects in micronuclei. The tests were performed with four strains of rats and two strains of mice (45). Thus, total reliance on short-term tests can be misleading. Many potentially useful compounds have been discarded along the path to development because of positive mutagenicity tests. But the results from short-term tests, if used judiously, can afford clues as to which compounds are more likely to be active in long-term animal studies. Such efforts are costly and require several years and involvement from people trained in many disciplines to complete a study well (46). In the United States, the NTP is the one agency that is primarily responsible for testing compounds in chronic studies.

1.4.5 Genetic and Related Cellular Effects Studies The advances in knowledge about the association between specific enzymes and the possible increased risk of developing cancer from occupational exposure have led to a new social concern. Employers may wish to use genetic screening to differentiate workers at greater risk from those less likely to be affected, but there are many uncertainties in the screening tests that make total reliance on them problematic (47–49). Furthermore, because of the genetic polymorphisms that involve enzymes which metabolize xenobiotics such as aromatic amines, matters of individual variation and individual rights must be considered. As mentioned previously, there are slow, intermediate, and rapid metabolizers of xenobiotics due to levels of expression of CYP1A2 in most populations. Likewise, although persons of certain backgrounds are more likely to acetylate aromatic amines rapidly, this is not absolute. Based on the identification of up to 9 different alleles for the slow acetylator phenotype, 45 different slow acetylator genotypes, 9 heterozygous rapid genotypes, and 1 homozygous wild-type rapid genotype, all combined with the slow, intermediate and rapid CYP1A2 types, it becomes evident that many combinations are possible. Thus an observed “polymorphism” may reflect a great number of genotypes. Instead of a well-defined genetic polymorphism, there can be much biochemical individuality in a population (22, 50).

Any test to differentiate individuals into the different categories must be accurate, but false negatives and false positives complicate the picture. In addition, enzyme induction by dietary or other exposures, including alcohol, tobacco, and medications is a further complication. Available genetic screening tests are not sufficiently validated for routine use.

For the individual, matters of decisional autonomy, confidentiality of medical information, beneficence, nonmaleficence, and equity are issues of concern. Possible discrimination, protection of equal employment opportunity, and potential stigmatization must also be considered. These concerns have been raised worldwide (51–55). Experts in this area concluded that in view of the uncertainties, removing the chemical carcinogen from the workplace by substituting a noncarcinogenic compound or achieving a zero level of exposure is more effective in preventing occupational cancer than genetic screening (50). These issues will probably remain a matter of discussion for years to come.

1.4.6 Reproductive and Developmental The previous edition of this chapter pointed out the toxicity of nitrobenzene for the male reproductive system when given at doses up to 30 times the limit set for

occupational exposure (2). The related substance, 1,3-dinitrobenzene, also produces testicular toxicity, affecting the Sertoli cells of the testis. Further studies have implicated the metabolite 3-nitrosonitrobenzene as the prime candidate for the toxic effect because the other metabolites 3-nitrophenylhydroxylamine and 3-nitroaniline were not active (56). Similarly, other nitroarenes such as 2,4- and 2,6-dinitrotoluene were toxic to the testis, indicating that workplace exposures to such compounds should be kept to a minimum.

Additional investigation revealed that nitrobenzene at 300 mg/kg and 1,3-dinitrobenzene at 30 mg/kg suppressed the formation of proteins usually secreted during spermatogenesis. With labeled methionine incorporation as a marker, nitrobenzene decreased formation of proteins usually secreted during stages VI-VIII and IX-XII, but had no effect in the earlier stages II–IV. Results were comparable for 1,3-dinitrobenzene except that incorporating methionine at stages II-V was increased. Six marker proteins for which secretion was reduced greatly after the nitobenzenes were studied; two of these proteins corresponded to two androgen-regulated proteins thought to be products of the Sertoli cell (57).

A survey of aromatic nitro and amino compounds tested for reproductive/teratogenic effects indicated that in general, relatively high doses of most aromatic amines to the maternal organism were required to produce a result. In some cases, doses of 5 g/kg or more were needed (2, 58). Thus, by observing hygienic guidelines, the risk of reproductive toxicity would be relatively small. However, aromatic amines may lead to “oxidative stress,” methemoglobinemia, anemia, and other types of toxicity. They may also target the hypothalamus and pituitary (59). Collectively, these actions are likely to influence fertility or successful completion of a pregnancy.

1.5 Studies on Environmental Impact

Although nitroarenes and amines are toxic to many species, biodegradation of such compounds is facilitated by the nitro reductase and oxidative enzymes present in sewage bacteria (60). Most of the aromatic amines are oxidatively degraded by bacteria in wastewater unless adsorbed to soil, where they are more resistant to action. However, in the presence of denitrifying and methanogenic microbial activity, aniline was released from the soil and degraded readily (61). Additional substituents in the molecule often led to slower breakdown (62). Acclimating activated sludge with both aniline and toluenediamine, which has been considered a resistant-type compound, led to a reasonable rate of biodegradation of the toluenediamine (63). Biodegradation of multiring aromatic amines was highly dependent on microbial activity, as shown by increases in decomposition at higher temperatures (30°C). Consistent relationships between breakdown of the amines and soil properties were not noted (64).

2,4,6-Trinitrotoluene (TNT) and associated compounds that occur in wastewaters are both toxic and phototoxic to many organisms usually found in streams; one metabolite 2-amino-4,6-dinitrotoluene was more phototoxic than TNT and 4-amino-2,6-dinitrotoluene. The toxicities of TNT and the two derivatives to stream organisms were decreased by glutathione conjugation (65).

Although 4-chloroaniline delayed somewhat the various lifestages of small fish (66), 3,4-dichloroaniline, a degradation product of the herbicide propanil, is of special concern. It affects various benthic invertebrates, leading to complete extinction of some and reduction in the number of surviving individuals in others (67, 68). A mixture of 3,4-dichloroaniline and lindane had an additive effect and influenced growth somewhat in early life stages of small fish (69). If the fish were exposed for the whole life span, they stopped reproducing (70). There was no single clear-cut mechanism to explain the toxicity of 4-nitro- and 2,4-dinitroaniline to various environmental eukaryotes and prokaryotes (71).

Currently, there are many efforts to develop special strains of bacteria to degrade industrial wastes. Similarly, production of bacterial strains with enhanced P450 protein expression has been suggested as a useful tool to biodegrade industrial and other contaminants (72). Such methods of cleaning industrial sites and waste dumps are less disruptive than other methods currently used or proposed.

Although most of the nitroarenes mentioned in this chapter generally are industrial materials, some have been detected in ambient airborn particulates, including those from diesel engine exhausts (Table 57.1). Nitrogen oxides react with polycyclic aromatic hydrocarbons (PAHs) in the heated engine exhaust to form nitroarenes at nano- to picogram/m^3 levels; at least 25 have been detected in such exhausts (73–76). Almost 100 PAHs have been found in engine exhausts (75), and the number of nitroarenes formed is correspondingly large because each PAH is amenable to nitration at several positions. However, only about 25 have been positively identified (74, 75). Nitroarenes generally are mutagens in *Salmonella* (77–79). Tests for carcinogenicity have shown varying potencies. 1-Nitronaphthalene was inactive in a feeding study with rats and mice (80), but most of the other environmental nitroarenes have shown surprising potency (81–84). Many organ systems were affected, including lung, colon, and breast. There have been any number of investigations on the metabolism and DNA binding of nitroarenes and only a few are cited here (85, 86). In general, these compounds are hydroxylated to phenols that are excreted as sulfate and glucuronide conjugates. Reduction to the amine with *N*-hydroxylation and DNA binding also occurs (87). The metabolic pattern and degree of DNA binding did not always correlate with the carcinogenic potency of a particular nitroarene (86).

Table 57.1. Physical Properties of Some Nitroarene Air Pollutants[a]

Compound	CAS Number	Molecular Weight	Melting Point (°C)	Physical Form
3,7-Dinitrofluoranthene	[*105735-71-5*]	292.3	203–204	Yellow needles
3,9-Dinitrofluoranthene	[*22506-53-2*]	292.3	275–276	Yellow-orange crystals
2,7-Dinitrofluorene	[*5405-53-8*]	256.2	334	Light yellow solid
2,7-Dinitrofluorenone	[*31551-45-8*]	270.2	292–295	Deep yellow solid
1,3-Dinitropyrene	[*75321-20-9*]	292.3	297–298	Orange crystals
1,6-Dinitropyrene	[*42397-64-8*]	292.3	310	Yellow crystals
1,8-Dinitropyrene	[*42397-65-9*]	292.3	300	Fluffy yellow crystals
9-Nitroanthracene	[*602-60-8*]	223.2	145–146	Yellow needles
7-Nitrobenzo[a] anthracene	[*20268-51-3*]	273.3	160–163	Yellow crystals
1-Nitrobenzo[a] pyrene	[*70021-99-7*]	297.3	250–250.5	Orange solid
3-Nitrobenzo[a] pyrene	[*70021-98-6*]	297.3	211–212	Orange solid
6-Nitrobenzo[a] pyrene	[*63041-90-7*]	297.3	255–256	Orange solid
6-Nitrochrysene	[*7496-02-8*]	273.3	209	Orange-yellow needles
3-Nitrofluoranthene	[*892-21-7*]	247.3	156–160	Yellow crystals
2-Nitrofluorene	[*607-57-8*]	211.2	156	Light yellow

				needles
4-Nitronaphthalene	[*86-57-7*]	173.2	61.5	Yellow needles
2-Nitronaphthalene	[*581-89-5*]	173.2	79	Yellow needles
3-Nitroperylene	[*20589-63-3*]	297.3	210–212	Brick-red crystals
1-Nitropyrene	[*5522-43-0*]	247.3	155	Yellow needles or prisms
2-Nitropyrene	[*789-07-1*]	247.3	197–199	Yellow crystals
4-Nitropyrene	[*57835-92-4*]	247.3	190–192	Orange needles

[a] Data bases: AIDSLINE, DART, EINECS, GENE-TOX, CANCERLIT, CCRIS, EMIC, EMICBACK, IARC, MEDLINE, MESH, RTECS, TSCAINV, TOXLINE, SUPERLIST.

The relevance to human cancer has been addressed both theoretically (88) and practically (89). Assays of excised lung tumors from nonsmoking Japanese demonstrated the presence of 1-nitropyrene, 1,3-dinitropyrene, and 1-nitro-3-hydroxypyrene in the tissues (89). In similar specimens from rural Chinese who had been exposed to open cooking fires, some 1-nitropyrene was detected, but the levels of PAHs were many times higher than in the Japanese specimens.

Nitroarenes could thus be a possible factor in lung and other types of cancers. Reduction in both PAHs and nitrogen oxides in engine exhausts is needed to decrease this possible cancer risk.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

Specific Compounds
In this section, compounds with one aromatic ring will be discussed first, then those with two rings, et cetera. Any new developments regarding toxicity or mechanisms of action are emphasized. Because this is an age of computerized databases or inventories, for each compound, the bases/inventories which list that specific compound will be mentioned. The codes for these lists or inventories are given in Table 57.2.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

Single-Ring-Compounds
1.0 Nitrobenzene
1.0.1 CAS Number: [*98-95-3*]

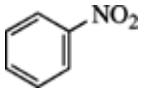
1.0.2 Synonyms: Nitrobenzol, and an old name of uncertain origin is oil of mirbane.

1.0.3 Trade Names: NA

1.0.4 Molecular Weight: 123.11

1.0.5 Molecular Formula: $C_6H_5NO_2$

1.0.6 Molecular Structure:



Databases or inventories where listed: CAA1, CA 65, CANCERLIT, CCRIS, CGN, DART, DOT, DSL, EINECS, HSDB, IARC, MA, MI, MPOL, NJ, PA, PEL, REL, RQ, RTECS, S302, TLV, TSCAINV
1.1 Chemical and Physical Properties (2)

Physical state	Colorless to pale yellow liquid
Density	1.2037 (20/4°C)
Melting point	5.7°C
Boiling point	210.9°C
Vapor density	4.1
Refractive index	1.55291
Solubility	Slightly soluble in water: very soluble in ethanol, ether; soluble in benzene, oils
Flash point	88°C (closed cup)
Odor	Bitter almond

1.2 Production and Use
Nitrobenzene is generally made by a continuous reaction process involving nitric acid and benzene in vapor-phase or jet-impingement reactors (1).

Nitrobenzene is an intermediate in the preparation of aniline, in making cellulose esters and acetate, in shoe and metal polishes, in soap perfumes, paint solvents, leather dressings, and in refining lubricating oils to the extent of close to 2 billion pounds/year.
1.3 Exposure Assessment
Analytical methods: NMAM 4th ed. method # 5053.
1.4 Toxic Effects
The previous edition of this chapter mentioned the toxic effects of nitrobenzene which include skin and eye irritation, cyanosis, methemoglobinemia, hemolytic anemia, spleen and liver damage, jaundice, neural toxicity with renal and testicular damage also present. Although nitrobenzene depressed the immune response of female $B6C3F_1$ mice, their resistance to microbial/viral infection

was not markedly altered (90).

Noteworthy new information on nitrobenzene is that it also is carcinogenic in mice and rats (91). The study included male and female $B6C3F_1$ mice, male and female F344 rats, and male CD rats. The mice were exposed by inhalation to 0,5, 25, or 50 ppm for 6 h/day, 5 days/week for 2 years, and rats were exposed to 0,1,5, or 25 ppm under the same time span as the mice. Survival of test animals was not significantly affected by nitrobenzene exposure, and body weights did not exceed a 10% deviation from controls.

The exposure affected hematic parameters in both mice and rats, and there were significant differences in the incidences of nonneoplastic and neoplastic lesions. The incidence of alveolar/bronchiolar adenomas increased to a significant degree in 25- and 50-ppm exposed male mice, and the number of mice that had either adenomas or carcinomas was higher in all exposed groups. Alveolar/bronchiolar hyperplasia was increased in the 25- and 50-ppm males. Follicular cell adenomas of the thyroid were significantly higher in the 50-ppm males, and hyperplasia occurred in the 25- and 50-ppm males.

In the female mice, mammary gland adenocarcinomas were increased at the 50-ppm level, plus a positive trend for hepatocellular adenoma related to nitrobenzene concentration.

Hepatocytomegaly, multinucleated hepatocytes, inflammatory lesions of the nose, epididymal hypospermia, and other nonneoplastic effects were noted in the mice.

In male F344 rats, nitrobenzene at 25 ppm led to increases in hepatocellular adenoma or carcinoma, renal tubular adenomas, or either renal adenoma or carcinoma with a positive trend for follicular cell adenoma or adenocarcinoma of the thyroid. Female F344 rats had a significant increase in endometrial stromal polyps of the uterus at 25 ppm. In both male and female rats, nitrobenzene exposures led to a striking decrease in mononuclear cell leukemia. Male F344 rats showed increases in extramedullary hematopoiesis (1 and 5 ppm) and pigmented macrophages (25 ppm). Increased focal inflammation of the olfactory region with pigment deposition was noted in both sexes.

The male CD rats responded to nitrobenzene with significant increases in hepatocellular adenomas and spongiosis hepatis in the 25-ppm group. Centrilobular hepatocytomegaly and Kupffer cell pigmentation, atrophy of the testes, and nasal pigment deposition also occurred.

The locations where tumors were induced differed based on species, sex, and for rats, on strain also. Some of the differences could possibly be related to differences in the metabolism of nitrobenzene, but the actual mechanism for the carcinogenicity of nitrobenzene has not been delineated. Because carcinogenic effects were noted at 25 ppm, industrial hygienists should monitor carefully so that workplace exposure does not exceed the permissible limit.

1.5 Standards, Regulations, or Guidelines of Exposure

The current ACGIH TLV-TWA is 1 ppm with a skin and A3 notation; Australia 1 ppm, skin; Germany (BAT value), 100 mg/l; Sweden, 1 ppm; United Kingdom, 1 ppm; OSHA PEL and NIOSH REL is 1 ppm.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

A. Monochloronitrobenzenes

2.0 1-Chloro-2-nitrobenzene

2.0.1 CAS Number: [*88-73-3*]

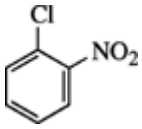
2.0.2 Synonyms: *o*-Chloronitrobenzene, 2-chloro-1-nitrobenzene, 2-chloronitrobenzene, 2-nitrochlorobenzene, 1-nitro-2-chlorobenzene, o-CNB, 2-CNB

2.0.3 Trade Names: NA

2.0.4 Molecular Weight: 157.56

2.0.5 Molecular Formula: $C_6H_4NO_2Cl$

2.0.6 Molecular Structure:



Databases or inventories where listed: CGB, CGN, DOT, IARC, MA, NTPT, PA, WHMI, CANCERLIT, CCRIS, DART, EINECS, EMIC, EMICBACK, ETICBACK, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

2.1 Chemical and Physical Properties (2)

Physical state	Yellow crystals
Melting point	34–35°C
Boiling point	245–246°C
Solubility	Soluble in ethanol, benzene, ether, acetone

2.2 Production and Uses

1-Chloro-2-nitrobenzene is an important intermediate in preparing dyes and lumber preservatives and in making photographic chemicals, corrosion inhibitors, and agricultural chemicals (92).

2.4 Toxic Effects

A 13-week inhalation study in male and female F344/N rats and male and female B6C3F$_1$ mice at levels of 0, 1.1, 2.3, 4.5, 9, and 18 ppm for 6 h/day 5 days a week, demonstrated that hepatocellular necrosis and inflammation occurred in mice along with lesions of the spleen and hemosiderin deposition. In rats, these exposures led to hyperplasia of the epithelium lining the nasal cavity. Methemoglobinemia was noted in the rats (93).

In the male mice and rats, there were decreases in sperm motility or spermatid count (92). A continuous breeding study in Swiss mice given 40, 80, or, 160 mg/kg by gavage showed no reproductive toxicity, but methemoglobinemia was observed in the parental animals (94).

1-Chloro-2-nitrobenzene was absorbed through the skin of male F344 rats to the extent of 33–40% in 72 h (92).

Metabolism studies with ^{14}C-labeled compound showed rapid excretion in the urine with up to 23 metabolites. Only about 5% remained in the animals by 72 h, mostly in the liver. Older rats absorbed and metabolized and then excreted the labeled compound at approximately the same rate as young rats. Hepatocytes from male F344 rats converted the nitro compound to 2-chloroaniline to a major extent, but 2-chloroaniline *N*-glucuronide, and S-(2-nitrophenyl)glutathione were also formed to an appreciable extent (92).

Oral administration to male and female CD-1 mice at 3000 or 6000 ppm for 8 months followed by 1500 or 3000 ppm for 10 months led to increases in hepatocellular carcinomas in both males and females. In male CD rats, 1000 or 2000 ppm for 6 months, followed by 500 or 1000 ppm for 12

months, led to increased numbers of rats with multiple tumors (92).

2.5 Standards, Regulations, or Guidelines of Exposure

Standards not assigned.

3.0 1-Chloro-3-nitrobenzene

3.0.1 CAS Number: [*121-73-3*]

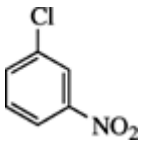
3.0.2 Synonyms: 1-Chloro-3-nitrobenzene, *m*-chloronitrobenzene, 3-chloro-1-nitrobenzene, 3-nitrochlorobenzene; 1-nitrochlorobenzene, MNCB, 3-CNB, *m*-CNB, nitrochlorobenzene

3.0.3 Trade Names: NA

3.0.4 Molecular Weight: 157.56

3.0.5 Molecular Formula: $C_6H_4NO_2Cl$

3.0.6 Molecular Structure:



Databases or inventories where listed: DOT, IARC, MA, PA, WHMI, CANCERLIT, CCRIS, DART, EINECS, EMIC, EMICBACK, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST

3.1 Chemical and Physical Properties (2)

Physical state	Yellow prisms from ethanol
Melting point	46°C
Boiling point	235–236°C
Solubility	Soluble in hot ethanol, chloroform, ether, carbon disulfide, benzene; insoluble in water
Flash point	103°C

3.2 Production and Use

1-Chloro-3-nitrobenzene is an intermediate in the production of dyes and fungicides (92).

3.4 Toxic Effects

In hepatocytes isolated from male rats, 1-chloro-3-nitrobenzene was converted mainly to 3-chloroaniline with much lower amounts of 3-chloroaniline *N*-glucuronide. No glutathione conjugate was found (92).

3.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

4.0 1-Chloro-4-nitrobenzene

4.0.1 CAS Number: [*100-00-5*]

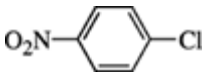
4.0.2 Synonyms: PNCB; nitrochlorobenzene; 1,4-chloronitrobenzene; 4-nitrochlorobenzene; 4-chloro-1-nitrobenzene; *para*-nitrochlorobenzene

4.0.3 Trade Names: NA

4.0.4 Molecular Weight: 157.56

4.0.5 Molecular Formula: $C_6H_4NO_2Cl$

4.0.6 Molecular Structure:



Databases and inventories where listed: DOT, IARC, IL, MA, MTL, NTPT, PA, PEL, PELS, REL, TLV, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, HSDB, MEDL, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

4.1 Chemical and Physical Properties (2)

Physical state	Yellow crystals
Specific gravity	1.52
Melting point	82–84°C
Boiling point	242°C
Vapor pressure	0.009 torr at 25°C
Flash point	127°C (closed cup)
Solubility	Sparingly soluble in water; soluble in ether, carbon disulfide, ethanol, acetone

4.2 Production and Use

1-Chloro-4-nitrobenzene is employed in producing dyes, drugs, herbicides, antioxidants, and as an intermediate in synthesizing various compounds (92).

4.4 Toxic Effects

A 13-week inhalation study in male and female F344/N rats and $B6C3F_1$ mice at levels of 0, 1.5, 3, 6, 12, and 24 ppm, 6 h/day for 5 days/week led to increases in liver and spleen weights in rats, along with changes in kidney tubules and hematopoiesis. Methemoglobinemia was more severe than with the 2-isomer. Mice also showed changes in liver and spleen, and in females hyperplasia of the forestomach epithelium was noted (93).

In male rats, spermatid counts were lower, but females were not affected. Mice showed no significant change (92). In a continuous breeding study with Swiss mice, exposure to 62.5, 125, or 250 mg/kg by gavage reduced the birth weight and viability of the pups (95).

A dermal absorption study with F344 rats demonstrated that 51–62% of labeled 1-chloro-4-nitrobenzene was absorbed within 72 h, and 43–45% was excreted in the urine. As with the 2-isomer, the metabolism of the 4-isomer was not greatly influenced by age (92).

In longshoremen accidentally exposed to 1-chloro-4-nitrobenzene, the same urinary metabolites were identified as in rats, namely, *N*-acetyl-S-(4-nitrophenyl)-L-cysteine, 4-chloroaniline, 4-chloroacetanilide, 4-chloro-oxanilic acid, 2-amino-5-chlorophenol, 4-chloro-2-hydroxyacetanilide, 2,4-dichloroaniline and 2-chloro-5-nitrophenol (96).

In a longer term study of 1-chloro-4-nitrobenzene, CD male and female mice fed 3000 or 6000 ppm in the diet for 18 months showed increases in hepatocellular carcinomas and vascular tumors in the males and vascular tumors in the females. Male CD rats given levels from 250 to 4000 ppm showed no increase in tumors (92).

4.5 Standards, Regulations, or Guidelines of Exposure

The current ACGIH TLV-TWA is 0.1 ppm (0.64 mg/m^3) with a skin notation; Australia, 0.1 ppm (skin); United Kingdom, 1 ppm (skin)

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

B. Chlorodinitrobenzenes
5.0 2-Chloro-1,3-dinitrobenzene
5.0.1 CAS Number: [*606-21-3*]

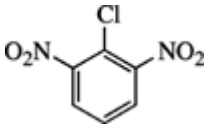
5.0.2 Synonyms: 1-Chloro-2,6-dinitrobenzene

5.0.3 Trade Names: NA

5.0.4 Molecular Weight: 202.55

5.0.5 Molecular Formula: $C_6H_3N_2O_4Cl$

5.0.6 Molecular Structure:



Databases or inventories where listed: EINECS, EMICBACK, GENETOX, HSDB, RTECS, TOXLINE, TSCAINV
5.1 Chemical and Physical Properties (2)

Physical state	Yellow crystals
Melting point	86–87°C
Boiling point	315°C
Solubility	Soluble in ethanol, ether, toluene

5.2 Production and Use
No specific uses were found, but the commercial mixture of chlorodinitrobenzenes is used to synthesize other compounds (2).
5.4 Toxic Effects
No toxicological information was found.
5.5 Standards, Regulations, or Guidelines of Exposure
None assigned.
6.0 2-Chloro-1,4-dinitrobenzene
6.0.1 CAS Number: [*619-16-9*]

6.0.2 Synonyms: 1-Chloro-2,5-dinitrobenzene

6.0.3 Trade Names: NA

6.0.4 Molecular Weight: 202.55

6.0.5 Molecular Formula: $C_6H_3N_2O_4Cl$

6.0.6 Molecular Structure: NA

Databases or inventories where listed: TOXLINE.
6.1 Chemical and Physical Properties (2)

Physical state	Light yellow crystals
Melting point	64°C
Solubility	Soluble in ethanol, ether; insoluble in water

6.2 Production and Use
Uses are the same as other isomers such as 4-chloro-1,2-dinitrobenzene (2).
6.4 Toxic Effects
No specific information found.
6.5 Standards, Regulations, or Guidelines of Exposure
None assigned.
7.0 3-Chloro-1,2-dinitrobenzene
7.0.1 CAS Number: [*602-02-8*]

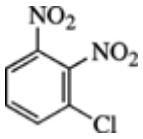
7.0.2 Synonyms: 1-Chloro-2,3-dinitrobenzene

7.0.3 Trade Names: NA

7.0.4 Molecular Weight: 202.55

7.0.5 Molecular Formula: $C_6H_3N_2O_4Cl$

7.0.6 Molecular Structure:



Databases or inventories where listed: None listed.
7.1 Chemical and Physical Properties (2)

Physical state	Crystals
Melting point	78°C
Boiling point	315°C
Refractive index	1.6867 (16.5°C)
Solubility	Soluble in ethanol, ether; insoluble in water

7.2 Production and Use
Uses are same as other isomers.
7.4 Toxic Effects
No specific information located.
7.5 Standards, Regulations, or Guidelines of Exposure
None assigned.
8.0 4-Chloro-1,2-dinitrobenzene
8.0.1 CAS Number: [*610-40-2*]

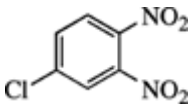
8.0.2 Synonyms: 1,2-Dinitro–4-chloro benzene; 3,4-dinitrochlorobenzene; 1-chloro-3,4-dinitrobenzene

8.0.3 Trade Names: NA

8.0.4 Molecular Weight: 202.55

8.0.5 Molecular Formula: $C_6H_3N_2O_4Cl$

8.0.6 Molecular Structure:



Databases or inventories where listed: EINECS, ETICBACK, TOXLINE, TSCAINV
8.1 Chemical and Physical Properties (2)

Physical state	Monoclinic prisms, needles
Melting point	a, 36°C; b, 37°C; g 40–41°C
Boiling point	16°C; 4 mmHg
Solubility	Soluble in ether, benzene, carbon disulfide, hot ethanol; insoluble in water

8.2 Production and Use
No specific uses found.
8.4 Toxic Effects
This compound is a sensitizer (2).
8.5 Standards, Regulations, or Guidelines of Exposure
None assigned.
9.0 1-Chloro-2,4-dinitrobenzene
9.0.1 CAS Number: [*97-00-7*]

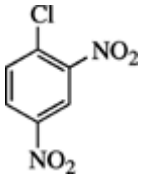
9.0.2 Synonyms: 2,4-Dinitro-1-chlorobenzene, 2,4-dinitrochlorobenzene, 1,3-dinitro-4-chlorobenzene, dinitrochlorobenzene, chlorodinitrobenzene, DNCB, 4-chloro-1,3-dinitrobenzene

9.0.3 Trade Names: NA

9.0.4 Molecular Weight: 202.55

9.0.5 Molecular Formula: $C_6H_3N_2O_4Cl$

9.0.6 Molecular Structure:



Databases or inventories where listed: AIDSDRUGS, AIDSLINE, AIDSTRIALS, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, HSDB, MA, MEDLINE, MESH, PA, RTECS, TOXLINE, TSCAINV, SUPERLIST.
9.1 Chemicals and Physical Properties (2)

Physical State	Yellow crystals
Melting point	a, 53°C; b, 43°C
Boiling point	315°C (762 mmHg)

Solubility Soluble in ether, benzene, hot ethanol; insoluble in water

9.2 Production and Use

DNCB is used in the manufacture of dyes and explosives, as a reagent, and as an algicide (2).

9.4 Toxic Effects

This compound is a potent sensitizer (2), and it has been used as such in many experiments. Examples include dose-response studies (97, 98), the effect of vehicle on absorption (99), and the effect of rat strain on sensitivity to DNCB (100). This compound depletes liver glutathione levels (2), and more recent data show that it irreversibly inhibits another enzyme involved with sulfur. Human thioredoxin, a dimeric enzyme that catalyzes reduction of the disulfide in oxidized thioredoxin, was inhibited and the effect persisted after removal of DNCB (101).

9.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

10.0 5-Chloro-1,3-dinitrobenzene

10.0.1 CAS Number: [*618-86-0*]

10.0.2 Synonyms: 1-Chloro-3,5-dinitrobenzene

10.0.3 Trade Names: NA

10.0.4 Molecular Weight: 202.55

10.0.5 Molecular Formula: $C_6H_3N_2O_4Cl$

10.0.6 Molecular Structure: NA

Databases or inventories where listed: None found.

10.1 Chemical and Physical Properties (2)

Physical state Colorless needles

Melting point 59°C

Solubility Soluble in ethanol, ether; insoluble in water

10.2 Production and Use

No specific uses were noted, but it reportedly could be used for the same purposes as 4-chloro-1,2-dinitrobenzene (2).

10.4 Toxic Effects

No new information was located.

10.5 Standards, Regulations, or Guidelines of Exposure

No standards assigned.

11.0 Pentachloronitrobenzene

11.0.1 CAS Number: [*82-68-8*]

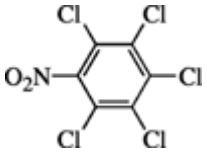
11.0.2 Synonyms: Avical; Eorthcicle; Fortox; Kobu; Marison Forte; Pkhnb; Terrafun; Tri PCNB; PCNB; Quintozine; quintobenzene; Terrachlor; Terraclor; Avicol; Botrilex; Earthcide; Kobutol; Pentagen; Tilcarex; SA Terraclor 2E; SA Terraclor; nitropentachlorobenzene; brassicol; quintocene; batrilex; fartox; fomac 2; fungiclor; gc 3944-3-4; KP 2; olpisan; quintozen; saniclor 30; tritisan

11.0.3 Trade Names: NA

11.0.4 Molecular Weight: 295.34

11.0.5 Molecular Formula: $C_6Cl_5NO_2$

11.0.6 Molecular Structure:



Databases or inventories where listed: CAA1, FIFR, IARC, MA, MI, NJ, NTPT, PA, RQ, TLV, TRI, CANCERLIT, CCRIS, DART, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.

11.1 Chemical and Physical Properties (2)

Physical state	Colorless solid
Specific gravity	1.718 at 25°C
Melting point	142–145°C technical grade
Boiling point	328°C at 760 mmHg
Solubility	Soluble in benzene, carbon disulfide, chloroform

11.2 Production and Uses

PCNB has been used as a fungicide for seeds, soil, and turf (2).

11.4 Toxic Effects

The previous edition provided a thorough account of the toxicity and metabolism of PCNB (2). It was not carcinogenic and did not act as a reproductive toxicant or a teratogen. It does lead to methemoglobinemia in cats. However, in a rat study, PCNB did not form an adduct with hemoglobin (14). probably due to steric hindrance from the chlorine substituents.

11.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA is 0.5 mg/m^3 with A4 notation.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

C. Dinitrobenzenes

12.0 1,2-Dinitrobenzene

12.0.1 CAS Number: [*528-29-0*]

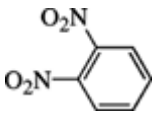
12.0.2 Synonyms: *o*-Dinitrobenzene; 1,2-dinitrobenzol

12.0.3 Trade Names: NA

12.0.4 Molecular Weight: 168.11

12.0.5 Molecular Formula: $C_6H_4N_2O_4$

12.0.6 Molecular Structure:



Databases or inventories where listed: CA65, DOT, MA, MTL, NJ, PA, PEL, RQ, TLV, TRI, WHMI, CANCERLIT, CCRIS, EINECS, EMIC, EMICBACK, HSDB, IRIS, MEDLINE, MESH,

RTECS, TOXLINE, SUPERLIST.
12.1 Chemical and Physical Properties (2)

Physical state	White to yellow, monoclinic plates
Density	1.565 (17/4°C)
Melting point	117–118.5°C
Boiling point	319°C (773 mm Hg)
Vapor density	5.79 (air = 1)
Flash point	302°F (closed cup)
Solubility	Soluble in ethanol, chloroform, benzene, methanol; slightly soluble in water

12.2 Production and Use
Dinitrobenzene is usually made as a mixture of three isomers that are used in producing dyestuffs, explosives, and other intermediates.
12.3 Exposure Assessment
NMAM IInd ed., vol 4, 1978 #S214.
12.4 Toxic Effects
1,2-DNB is the least toxic of the three isomers, but it is absorbed through the skin and can cause methemoglobinemia. It did not lead to testicular damage in rats at doses where 1,3-DNB had such an effect.
12.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV-TWA, NIOSH REL and OSHA PEL is 0.15 ppm (1 mg/m^3) with a skin notation.
13.0 1,3-Dinitrobenzene
13.0.1 CAS Number: [*99-65-0*]

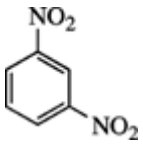
13.0.2 Synonyms: Dinitrobenzol; *m*-dinitrobenzene; 2,4-dinitrobenzene; binitrobenzene; 1,3-dinitrobenzol

13.0.3 Trade Names: NA

13.0.4 Molecular Weight: 168.11

13.0.5 Molecular Formula: $C_6H_4N_2O_4$

13.0.6 Molecular Structure:



Databases or inventories where listed: CA65, DOT, MA, MTL, NJ, PA, PEL, REL, RQ, S110, TLV, TRI, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, GENETOX, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE TSCAINV, SUPERLIST.
13.1 Chemical and Physical Properties (2)

Physical state	Colorless to yellow rhombic needles or plates
Density	1.571 (0/4°C)
Melting point	89–90°C
Boiling point	302.8°C (770 mmHg)

Flash point	302°F (closed cup)
Solubility	Soluble in ethanol, ether, benzene, toluene, chloroform, ethyl acetate; slightly soluble in water

13.2 Production and Uses

1,3-DNB is used in producing nitroaniline, 1,3-phenylenediamine, dye intermediates, and some explosives.

13.3 Exposure Assessment

NMAM IInd ed., vol. 4, 1978 method #S214.

13.4 Toxic Effects

The toxicity and metabolic reactions of 1,3-DNB were discussed in the previous edition (2). A major concern is testicular toxicity (56, 57) and reproductive effects. Additional studies showed that the toxicity of 1,3-DNB was greater in older rats, probably due to their slower rate of excretion (102). Route of administration, whether oral vs. i.p. had little effect on the degree of testicular damage in rats, although more was excreted in the feces after an oral dose (103). Examination of the metabolic capacity of different tissues from rats revealed that besides intestinal mucosa (104), rat brain also metabolized 1,3-DNB, presumably to toxic intermediates (105). The net result was that 1,3-DNB caused brain stem lesions in rats (106), which may explain the neurotoxicity noted in some previous studies (2).

13.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA, NIOSH REL and OSHA PEL is 0.15 ppm (1 mg/m^3), with a skin notation.

14.0 1,4-Dinitrobenzene

14.0.1 CAS Number: [*100-25-4*]

14.0.2 Synonyms: *p*-Dinitrobenzene

14.0.3 Trade Names: NA

14.0.4 Molecular Weight: 168.11

14.0.5 Molecular Formula: $C_6H_4N_2O_4$

14.0.6 Molecular Structure:

Databases or inventories where listed: CA65, DOT, MA, MTL, NJ, PA, PEL, RQ, TLV, TRI, WHMI, CCRIS, DSL, EINECS, EMIC, EMICBACK, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

14.1 Chemical and Physical Properties (2)

Physical state	Colorless to yellow monoclinic needles
Density	1.625 (20/4°C)
Melting point	173–174°C
Boiling point	298–299°C (777 mmHg) sublimes
Solubility	Soluble in chloroform, benzene, ethanol; somewhat soluble in water

14.2 Production and Use

Uses are identical with those of 1,2-dinitrobenzene (2).

14.3 Exposure Assessment

NMAM IInd ed., vol. 4, 1978 method #S214.

14.4 Toxic Effects

Although 1,4-DNB did not cause testicular toxicity in rats, it led to cyanosis, splenic enlargement,

and methemoglobinemia from prolonged exposure (2).

14.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA, NIOSH REL and OSHA PEL is 0.15 ppm (1 mg/m^3) with a skin notation.

15.0 Trinitrobenzene

15.0.1 CAS Number: [*99-35-4*]

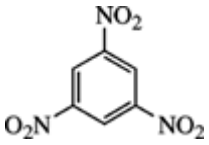
15.0.2 Synonyms: Benzite; 1,3,5-trinitrobenzene; *sym*-trinitrobenzene; trinitrobenzene, TNB

15.0.3 Trade Names: NA

15.0.4 Molecular Weight: 213.11

15.0.5 Molecular Formula: $C_6H_3N_3O_6$

15.0.6 Molecular Structure:



Databases or inventories where listed: DOT, MA, NJ, PA, RQ, S110, CANCERLIT, CCRIS, DART, EINECS, EMIC, EMICBACK, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

15.1 Chemical and Physical Properties (2)

Physical state	Orthorhombic bipyramidal plates
Melting point	121–122.5°C
Boiling point	315°C
Solubility	Soluble in acetone, benzene

15.2 Production and Use

Trinitrobenzene occurs as a by-product of trinitrotoluene (TNT) production and as a contaminant in water systems where it is formed by photolysis of TNT. It is not biodegraded readily and thus occurs in water, in TNT production waste disposal sites, and in soils at many military installations (107). It is not manufactured except for research purposes.

15.4 Toxic Effects

Since the previous edition, there has been appreciable interest in the toxicity of TNB. TNB was given to male and female rats at 0, 50, 200, 400, 800, or 1200 mg/kg diet for 14 days. Levels of 400 mg/kg and higher led to reduced food intake and lower body weights. Testicular weights were lower in males, and an increase in spleen weights was noted in both sexes. Susceptible organs were kidney (hyaline droplets), spleen (extramedullary hematopoiesis), brain (hemorrhage, malacia, and gliosis), and testes (seminiferous tubular degeneration). Red blood cell counts and hematocrit decreased while Heinz bodies and methemoglobin increased (107). Additional studies were done on the organ systems thus affected. TNB-treated male F344 rats had a dose-related accumulation of hyaline droplets with alpha-2-m-globulin in the proximal tubules of the kidney, but this did not occur in female F344 or male NBR rats (108). There was a steep dose-response curve for the effect on the brain (109). In a similar manner, the testicular effects were explored; 71 mg/kg for 10 days led to cessation of spermatogenesis, and half that dose for 10 days led to testicular lesions. The effects were partially reversible after a recovery period of 10 to 30 days (110, 111). However, although a reproductive toxicity screen with Sprague–Dawley rats given 30, 150, or 300 TNB mg/kg of diet for 14 days showed spleen depletion and degeneration of seminiferous tubules in males and methemoglobinemia and splenic hemosiderosis at higher doses in both sexes, no adverse effects were noted in mating or fertility indices, length of gestation, sex ratio, gestation index, or mean

number of pups per litter (112).

Absorption studies with human, rat, and hairless guinea pig skin showed that absorption through rat skin was very similar with either acetone or aqueous solutions of TNB. In human skin, absorption from water was much greater than from acetone, whereas the reverse held for guinea pig skin. The fluid in the receptor cell from human or rat skin contained 3,5-dinitroaniline and 1,3,5-triacetylaminobenzene. Guinea pig skin also metabolized TNB to 1-nitro-3,5-diacetamidobenzene and 3,5-diaminonitrobenzene to a minor extent (113). Thus, TNB was absorbed and metabolized to a similar extent by human and rodent skin. Liver microsomes from male F344 rats produced 3,5-diaminobenzene as a major metabolite of TNB (114).

15.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

D. Nitrophenols

16.0 2-Nitrophenol

16.0.1 CAS Number: [*88-75-5*]

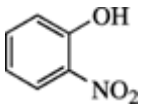
16.0.2 Synonyms: 2-Hydroxynitrobenzene; ONP

16.0.3 Trade Names: NA

16.0.4 Molecular Weight: 139.11

16.0.5 Molecular Formula: $C_6H_5NO_3$

16.0.6 Molecular Structure:



Databases and inventories where listed: CCRIS, EINECS, RTECS, TSCAINV, HSDB, CGB, MA, WHMI, NJ, TRI, RG, CGN, UN 1663, DOT, PA, EMIC, EMICBACK, GENETOX, MEDLINE, TOXLINE, SUPERLIST.

16.1 Chemical and Physical Properties (2)

Physical state	Light yellow crystals
Density	1.657 (20°C)
Melting point	44–46°C
Boiling point	214–216°C
Solubility	Soluble in ethanol, ether, acetone, benzene, alkali; somewhat soluble in water

16.2 Production and Use

2-Nitrophenol is an intermediate in dyestuff production and a chemical indicator.

16.4 Toxic Effects

No new information was found. *o*-Nitrophenol causes central and peripheral vagus stimulation, central nervous system (CNS) depression, methemoglobinemia, and dyspnea in animal experiments.

The oral LD_{50} in mice is 1.297 g/kg; in rats, 2.828 g/kg (2).

o-Nitrophenol was negative in the Ames mutagenicity test (115), and it was metabolically reduced less readily to the corresponding amino derivative than the *meta* or *para* isomers (116).

16.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

17.0 3-Nitrophenol

17.0.1 CAS Number: [*554-84-7*]

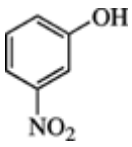
17.0.2 Synonyms: 3-Hydroxy-nitrobenzene; 3-hydroxy-1-nitrobenzene

17.0.3 Trade Names: NA

17.0.4 Molecular Weight: 139.11

17.0.5 Molecular Formula: $C_6H_5NO_3$

17.0.6 Molecular Structure:



Databases and inventories where listed: CCRIS, DART, EINECS, EMIC, EMICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

17.1 Chemical and Physical Properties (2)

Physical state	Colorless to yellowish crystals
Density	1.485 (20°C)
Melting point	97°C
Boiling point	194°C (70 mmHg)
Solubility	Soluble in ether, benzene, alkali, ethanol, acetone; appreciably soluble in water

17.2 Production and Use

3-Nitrophenol is also used in synthesizing some dyestuffs and drugs and as an indicator, (117).

17.4 Toxic Effects

No new information found. In contrast to the ortho isomer, *m*-nitrophenol is more readily biotransformed to its corresponding amino derivative; however, it is reportedly nonmutagenic in the Ames bacterial mutagenicity test (2, 116).

17.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

18.0 4-Nitrophenol

18.0.1 CAS Number: [*100-02-7*]

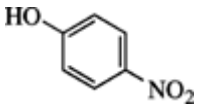
18.0.2 Synonyms: 4-Hydroxynitrobenzene; Niphen; PNP; mononitrophenol

18.0.3 Trade Names: NA

18.0.4 Molecular Weight: 139.11

18.0.5 Molecular Formula: $C_6H_5NO_3$

18.0.6 Molecular Structure:



Databases and inventories where listed: CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.

18.1 Chemical and Physical Properties (2)

Physical state	Colorless to yellowish monoclinic prisms
Density	1.479 (20°C)
Melting point	113–116°C
Boiling point	279°C (sublimable)
Solubility	Soluble in ethanol, ether, benzene, acetone, alkali; somewhat soluble in water

18.2 Production and Use

4-Nitrophenol is used in dyestuff and pesticide synthesis, as a fungicide, bactericide, and wood preservative, as a chemical indicator, and as a substrate for experiments on cytochrome P450 2E1 (118).

18.4 Toxic Effects

p-Nitrophenol undergoes glutathione and glucuronide conjugation (119, 120). Isolation of a rat liver glucuronosyltransferase isozyme has also been reported; this enzyme is responsible for the glucuronide formation (121). In addition, *p*-nitrophenol can readily undergo reduction to its amino derivative. However, *in vivo* nitro reduction conditions require bacterial enzymes in the natural anaerobic environment of the gut (possibly in localized cellular ischemic conditions); *in vitro*, mammalian enzymes are required under artificial anaerobic conditions (116).

p-Nitrophenol is nonmutagenic in the Ames assay (2). The oral LD_{50} in mice is 467 mg/kg, and in rats, 616 mg/kg.

Since the last edition, there have been additional studies with 4-nitrophenol. Differences in sulfate conjugation by different species and organs were noted, using guinea pig, rat, and rabbit liver and platelets from rats, guinea pigs, rabbits, and dogs. Biphasic effects were observed in platelets and liver from rats and guinea pigs, similar to the result in humans (122). Abnormal physiological states such as bile duct ligation of rats increased 4-nitrophenol glucuronide formation at high doses; at low doses, ligation decreased conjugation (123). Hyperglycemia led to increased sulfate conjugation (124), but formation of a sulfate was practically nil in isolated rat intestinal loops (125). Cytochrome P450 2E1-mediated 4-nitrophenol hydroxylation was inhibited by benzene, toluene, and 2-bromophenol (126), whereas ethanol treatment of rats increased hydroxylation (127). When applied to porcine skin flaps, 4-nitrophenol did not evaporate significantly; there was greater penetration with acetone than with ethanol solutions (128). Data from a single chemical did not predict of absorption of binary mixtures of 4-nitrophenol and phenol (129). 4-Nitrophenol was tested by the NTP in a dermal study with mice; the results were negative for carcinogenicity (130).

18.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

E. Dinitrophenols

19.0 2,3-Dinitrophenol

19.0.1 CAS Number: [*66-56-8*]

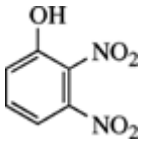
19.0.2 Synonyms: NA

19.0.3 Trade Names: NA

19.0.4 Molecular Weight: 184.11

19.0.5 Molecular Formula: $C_6H_4N_2O_5$

19.0.6 Molecular Structure:



Databases or inventories where mentioned: CANCERLIT, CCRIS, EINECS, MESH, RTECS, TOXLINE.

19.1 Chemical and Physical Properties (2)

Physical state	Yellow monoclinic prisms, flammable
Melting point	144–145°C
Solubility	Soluble in ether, benzene, ethanol; slightly soluble in water

19.2 Production and Use

Specific uses were not located.

19.4 Toxic Effects

No new information was found. Dermal exposure to 2,3-dinitrophenol causes yellow staining of skin and it may also cause dermatitis or allergic sensitivity. Systematically, it disrupts oxidative phosphorylation causing increased metabolism, oxygen consumption, and heat production. Chronic exposure may result in kidney and liver damage and cataract formation (2, 131).

19.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

20.0 2,4-Dinitrophenol

20.0.1 CAS Number: [*51-28-5*]

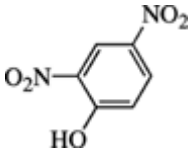
20.0.2 Synonyms: alpha-Dinitrophenol; aldifen; Fenoxyl Carbon N; 1-hydroxy-2,4-dinitrobenzene; 2,4-DNP; solfo black b; solfo black bb; tertrosulfur black pb; dinofan; maroxol-50; solfo black 2b supra; solfo black g; solfo black sb; tertrosulfur pbr; nitro kleenup; fenoxyl; dinitrophenols

20.0.3 Trade Names: NA

20.0.4 Molecular Weight: 184.11

20.0.5 Molecular Formula: $C_6H_4N_2O_5$

20.0.6 Molecular Structure:



Databases or inventories where mentioned: CAA, FIFR, MA, NJ, PA, RQ, S110, TRI, WHMI, AIDSLINE, CANCERLIT, CCRIS, DART, DSL, EINECS, EMICBACK, ETICBACK, GENETOX, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TRI, TSCAINV, SUPERLIST.

20.1 Chemical and Physical Properties (2)

Physical state	Pale yellow rhombic crystals or needles, flammable
Melting point	115–116°C
Solubility	Soluble in ethanol, ether, chloroform, benzene; somewhat soluble in water

20.2 Production and Use

Dinitrophenol is a dyestuff intermediate and is used as an insecticide, fungicide, bactericide, and wood preservative.

20.4 Toxic Effects

The action of 2,4-dinitrophenol in increasing metabolic rate was presented in the previous edition (2). Further work indicated that it could damage the myofilaments of the rat heart (132) and that various metabolic systems were activated in response (133, 134). High levels of environmental contamination could lead to adverse consequences in some wildlife.

20.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

21.0 2,5-Dinitrophenol

21.0.1 CAS Number: [*329-71-5*]

Physical state	Colorless monoclinic prisms, flammable
Melting point	134°C
Solubility	Soluble in ethanol, ether, chloroform, benzene

24.2 Production and Use
No specific uses located.
24.4 Toxic Effects
No new information located. No specific studies were located. Toxicity is assumed to be identical to that of 2,3-dinitrophenol (2, 131).
24.5 Standards, Regulations, or Guidelines of Exposure
None assigned.
25.0 Picric Acid
25.0.1 CAS Number: [*88-89-1*]

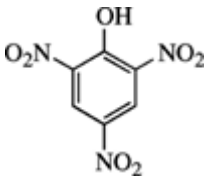
25.0.2 Synonyms: Picronitric acid; Melinite; pertite; carbazotic acid; 2,4,6-trinitrophenol; trinitrophenol; lyddite; shimose; phenol trinitrate; 2-hydroxy-1,3,5-trinitrobenzene; C. I. 10305; TNP

25.0.3 Trade Names: NA

25.0.4 Molecular Weight: 229.11

25.0.5 Molecular Formula: $C_6H_3N_3O_7$

25.0.6 Molecular Structure:



Databases or inventories where mentioned: DOT, IL, INER, MA, NJ, PA, PEL, REL, TLV, TRI, WHMI, AIDSLINE, CANCERLIT, CCRIS, DART, DSL, EINECS, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.

25.1 Chemical and Physical Properties (2)

Physical state	White to yellowish needles, flammable
Melting point	122–123°C
Boiling point	>300°C (sublimes, explodes)
Solubility	Soluble in ethanol, ether, benzene, acetone; slightly soluble in water

Cautionary note: Picric acid is very explosive when dry; for safety it is usually mixed with 10–20% water; it explodes when heated rapidly or subjected to percussion.

25.2 Production and Use

Picric acid is used in making explosives; as a burster in projectiles; in rocket fuels, fireworks, colored glass, batteries, and disinfectants; in the pharmaceutical and leather industries; as a fast dye for wool and silk; in metal etching and photographic chemicals; and as a laboratory reagent.

25.3 Exposure Assessment

NMAM IInd edition, vol 4, 1978 method #S228.

25.4 Toxic Effects

Picric acid causes sensitization dermatitis (135). Allergic hepatitis has been induced in guinea pigs by picric acid (136). Dust or fumes cause eye irritation, that can be aggravated by sensitization (137). It dyes animal fibers yellow (including skin) upon contact (2, 131).

Systemic absorption can cause weakness, myalgia, anuria, polyuria, headache, fever, hyperthermia, vertigo, nausea, vomiting, diarrhea, and coma. High doses may cause destruction of erythrocytes, hemorrhagic nephritis and hepatitis, yellow coloration of the skin ("pseudojaundice"), including conjunctiva and aqueous humor, and yellow vision (138, 139).

The strange visual effects where objects appear yellow may be related to the fact that systemic toxicity results in coloring all tissues yellow, including the conjunctiva and aqueous humor, so that yellow vision appearing under these circumstances is explained by optical effects (137). It is reportedly nonmutagenic in the Ames assay (115). Picric acid is metabolized largely to picramic acid.

A more definitive study of the metabolism of picric acid has appeared (140). In male F344 rats, the oral LD_{50} was 290 mg/kg; in females 200 mg/kg. After a single oral dose of ^{14}-C labeled compound, 56–60% appeared in the urine of the rats by 24 h, and 6–10% in feces. Gut contents accounted for

23% of the dose, and 3–6% remained in blood, muscle, and gut tissue. Up to 60% of the picric acid was excreted unchanged in the urine, and *N*-acetylisopicramic acid accounted for 15% of urinary activity, picramic acid 18.5%, and *N*-acetylpicramic acid for almost 5%, respectively. Thus, metabolic reactions consisted of reduction of the nitro to amino groups and conjugation with acetate.
25.5 Standards, Regulations, or Guidelines of Exposure
ACGIH TLV-TWA, 0.1 mg/m^3; OSHA PEL and NIOSH REL, 0.1 mg/m^3 (skin); Australia, 0.1 mg/m^3 (skin); Germany, 0.1 mg/m^3 (skin); United Kingdom, 0.1 mg/m^3.

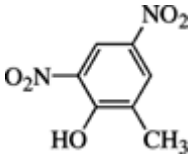
26.0.5 Molecular Formula: $C_7H_6N_2O_5$

26.0.6 Molecular Structure:



Databases or inventories where listed: CAA1, DOT, FIFR, IL, MA, MI, MPOL, PA, PEL, REL, RQ, S110, S302, TLV, TRI, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.
26.1 Chemical and Physical Properties (2)

Physical state	Yellow prisms
Melting point	86.5°C
Solubility	Soluble in ether, acetone; slightly soluble in water

26.2 Production and Use
This compound and its isomers are used as herbicides, fungicides, and wood preservatives. Release into aquatic environments can be harmful to various organisms.
26.3 Exposure Assessment
NMAM, IInd edition, vol 5, 1979 Method #S166.
26.4 Toxic Effects

No new information was located.
26.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV-TWA, NIOSH REL and OSHA PEL is 0.2 mg/m^3 with a skin notation. A similar value holds for Australia, Germany, and the United Kingdom.
27.0 2,6-Dinitro-**p**-cresol
27.0.1 CAS Number: [*609-93-8*]

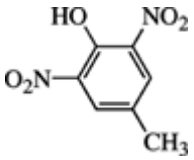
27.0.2 Synonyms: 2,6-DNPC; 4-methyl-2,6-dinitrophenol; 2,6-dinitro-*p*-cresol, moist solid containing up to 10% water

27.0.3 Trade Names: NA

27.0.4 Molecular Weight: 198.13

27.0.5 Molecular Formula: $C_7H_6N_2O_5$

27.0.6 Molecular Structure:



Databases or inventories where listed: DSL, EINECS, EMICBACK, HSDB, RTECS, TOXLINE, TSCAINV.
27.1 Chemical and Physical Properties (2)

Physical state	Long yellow prisms
Melting point	85°C
Solubility	Soluble in benzene, ethanol, ether; insoluble in water

27.2 Production and Use
Uses are the same as those of the isomer 4,6-dinitro-*o*-cresol.
27.4 Toxic Effects
No new information was located. The toxicity of 2,6-dinitro-*p*-cresol is reportedly identical to that of the ortho isomer (131). Peripheral neuropathy (dying back) has been reported following exposure (2) but was not definitive.
27.5 Standards, Regulations, or Guidelines of Exposure
None assigned.
28.0 2-Nitroanisole
28.0.1 CAS Number: [*91-23-6*]

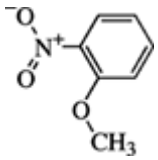
28.0.2 Synonyms: 2-Methoxynitrobenzene, *o*-nitrophenyl methyl ether, 1-methoxy-2-nitrobenzene

28.0.3 Trade Names: NA

28.0.4 Molecular Weight: 153.14

28.0.5 Molecular Formula: $C_7H_7NO_3$

28.0.6 Molecular Structure:



Databases and inventories where listed: CA65, IARC, NTPA, NTPT, WHMI, CANCERLIT, CCRIS, EINECS, EMIC, EMICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

28.1 Chemical and Physical Properties (92)

Physical state	Colorless to yellowish liquid
Boiling point	277°C
Melting point	10.5°C
Density	1.254 (20°C/4°C)
Solubility	Soluble in ethanol, ether; moderately soluble in water

28.2 Production and Use

2-Nitroanisole is used as an intermediate in dyestuff and pharmaceutical production.

28.4 Toxic Effects

The oral LD_{50} is 740 mg/kg body weight in rats and 1300 mg/kg in mice. In 14-day studies in F344 rats (583–9330 ppm) and $B6C3F_1$ mice (250–4000 ppm), the male rats showed methemoglobinemia at levels of 1166 ppm or more. Body weights were lower and absolute liver weights higher in both male and female rats. Aside from lower body weights, mice had no treatment-related effects. In 13-week studies at 200, 600, 2000, 6000, or 18,000 mg/kg diet, various manifestations of toxicity were noted, and rats were more susceptible (92). Administration in the diet at levels of 0, 666, 2000, or 6000 mg/kg to male and female $B6C3F_1$ mice for 103 weeks led to significant increases in hepatocellular adenomas and carcinomas in both sexes, in addition to hepatic hemorrhages, Kupffer cell pigmentation, focal necrosis, and cytological alteration. Levels of 0, 222, 666, or 2000 mg/kg to F344 rats for 103 weeks caused increases in mononuclear cell leukemia in both sexes. When F344 rats were fed a 6000 or 18,000 mg/kg diet for 27 weeks and kept on a control diet for 77 weeks more, the incidences of carcinomas of the urinary bladder, adenomatous polyps of the large intestine, and transitional cell tumors of the kidney increased in both sexes (92).

Metabolism studies in rats with labeled 2-nitroanisole showed about 7% excreted in the feces and 70% in the urine after 7 days. Urinary metabolites identified were 2-nitrophenyl sulfate (63%), 2-nitrophenyl glucuronide (11%), 2-nitrophenol (1.5%), and *o*-anisidine (0.6%) (92).

28.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

Aromatic Nitro and Amino Compounds

Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

G. Nitrotoluenes

29.0 2-Nitrotoluene

29.0.1 CAS Number: [*88-72-2*]

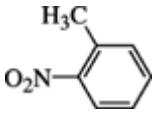
29.0.2 Synonyms: Methylnitrobenzene; 2-methyl-1-nitrobenzene; 1-methyl-2-nitrobenzene; 2-methylnitrobenzene; ONT; 2-nitrotoluol; *o*-nitrophenylmethane; alpha-methylnitrobenzene, *o*-nitrotoluene, 2NT

29.0.3 Trade Names: NA

29.0.4 Molecular Weight: 137.14

29.0.5 Molecular Formula: $C_7H_7NO_2$

29.0.6 Molecular Structure:



Databases and inventories where listed: CGN, DOT, IARC, MA, MPOL, MTL, NTPT, PA, PEL, REL, RQ, TLV, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

29.1 Chemical and Physical Properties (2)

Physical state	Yellow liquid
Density	1.163 (20/4°C)
Melting point	–9.5°C
Boiling point	221.7°C
Vapor pressure	1.6 mmHg (60°C)
Refractive index	1.54739 (20.4°C)
Solubility	Soluble in ethanol, ether, benzene, chloroform; slightly soluble in water

29.2 Production and Use

2-Nitrotoluene is used to produce dyestuff intermediates and in manufacturing agricultural and rubber chemicals.

29.3 Exposure Assessment

NMAM IV ed., Method #2005.

29.4 Toxic Effects

The single oral LD_{50} in male Sprague–Dawley rats is 891 mg/kg, in male Wistar rats 2100 mg/kg, in female Wistars 2100 mg/kg, and in male CF1 mice 2463 mg/kg. In a 13-week subchronic study, male and female F344 rats and male and female B6C3F_1 mice were given diets containing 0, 625, 1250, 2500, 5000 or 10,000 mg/kg (ppm) of 2-NT. Several male rats at the two highest dose levels had mesotheliomas of the tunica vaginalis on the epididymis, an unusual finding (141). Hyaline droplet nephrotoxicity also increased in the male rats; in this respect, 2-NT was the most toxic of the three isomers. In the mice there was degeneration and metaplasia of the olfactory epithelium but no hepatic toxicity. In a 14-day study, 2-NT was given to F344 rats at levels from 625 to 20,000 mg/kg in the diet. Livers of 4/5 male rats at 10,000 ppm showed minimal oval-cell hyperplasia (92). Male and female B6C3F_1 mice in the 14-day study received 2-NT at doses of 388 to 10,000 mg/kg; this led to an increase in relative liver weights of the males on the highest dose. Rats given labeled 2-NT excreted 86% in the urine and nine metabolites were identified. A low percentage was 2-aminobenzoic acid; all other metabolites were nitrobenzyl derivatives conjugated with glutathione, cysteine, sulfate, and glucuronic acid (92). The NTP has done a chronic study of 2-NT in rats and mice, but the report is not yet available.

29.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA and NIOSH REL is 2 ppm (11 mg/m^3) with a skin notation. The OSHA PEL is 5 ppm.

30.0 3-Nitrotoluene

30.0.1 CAS Number: [*99-08-1*]

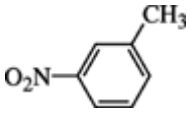
30.0.2 Synonyms: *m*-Nitrotoluol, 1-methyl-3-nitrobenzene; 3-methylnitrobenzene, *m*-nitrophenylmethane, 3-NT

30.0.3 Trade Names: NA

30.0.4 Molecular Weight: 137.14

30.0.5 Molecular Formula: $C_7H_7NO_2$

30.0.6 Molecular Structure:



Databases and inventories where listed. DOT, IARC, MA, MPOL, MTL, NTPT, PA, PEL, REL, RQ, TLV, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

30.1 Chemical and Physical Properties (2)

Physical state	Pale yellow liquid
Density	1.157 (20/4°C)
Melting point	15.5°C
Boiling point	232.6°C
Vapor pressure	1.0 mmHg (60°C)
Refractive index	1.5475 (20°C)
Solubility	Soluble in ethanol, ether, benzene; slightly soluble in water

30.2 Production and Use

3-NT is also used in producing dyestuffs, rubber and agricultural chemicals, explosives, and as a chemical intermediate.

30.3 Exposure Assessment

NMAM IV ed., 1994 Method #2005.

30.4 Toxic Effects

The single dose oral LD_{50} in male Sprague–Dawley rats was 1072 mg/kg, in male Wistars 2200 mg/kg, in female Wistars 2000 mg/kg, and in male CF-1 mice 330 mg/kg (92).

3-NT was given in the diet to male and female F344 rats (625–20,000 mg/kg in the diet) and $B6C3F_1$ mice (388–10,000 mg/kg in the diet) for 14 days. At the 2500-mg level, weight gains of male rats were less than that of controls, and the relative liver weights of mice were increased at 2500 and 5000 ppm 3-NT. In a 13-week study, hyaline droplet nephropathy was noted in male rats. In mice on 3-NT for 13 weeks, no hepatic toxicity was noted, even though liver weight increased. 3-NT decreased testicular function in male rats at the higher dose levels and increased the length of the estrus cycle in females, but there was no adverse effect on reproduction. The exposed mice showed no change in reproductive system evaluations, compared with controls (92, 141). 3-NT at 200–600 mg/kg to female B6C3F1 mice decreased the IgM response and response to *Listeria monocytogenes* but response to other bacteria was not affected (142).

After a dose of labeled 3-NT, male rats excreted 68% in the urine. Eight metabolites were separated; 3-aminobenzoic acid and its acetyl derivative were among them; the other metabolites were nitrobenzyl conjugates (92).

30.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA and NIOSH REL is 2 ppm with a skin notation (11 mg/m^3). The OSHA PEL is 5 ppm.

31.0 4-Nitrotoluene

31.0.1 CAS Number: [*99-99-0*]

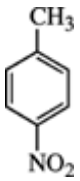
31.0.2 Synonyms: 4-Methylnitrobenzene; 1-methyl-4-nitrobenzene; 4-nitrotoluol; PNT; *p*-nitrophenylmethane, 4-NT

31.0.3 Trade Names: NA

31.0.4 Molecular Weight: 137.14

31.0.5 Molecular Formula: $C_7H_7NO_2$

31.0.6 Molecular Structure:



Databases and inventories where listed: CGN, DOT, IARC, MA, MPOL, MTL, NTPT, PA, PEL, REL, RQ, TLV, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, HSDB, MEDLINE, MESH, RTECS, TOXLINE, SUPERLIST.

31.1 Chemical and Physical Properties (2)

Physical state	Yellowish rhombic needles
Density	1.280 (20°C)
Melting point	54.5°C
Boiling point	238.3°C
Vapor density	4.72 (air = 1)
Vapor pressure	1.3 mmHg (65°C)
Refractive index	1.5346 (62.5°C)
Solubility	Soluble in ethanol, benzene, acetone, chloroform, ether; slightly soluble in water

31.2 Production and Use

4-NT is used as a dyestuff intermediate in producing rubber and agricultural chemicals and explosives, and as a chemical intermediate.

31.3 Exposure Assessment

NMAM IV ed., 1994 Method #2005.

31.4 Toxic Effects

The single-dose oral LD_{50} in male Sprague–Dawley rats was 2144 mg/kg, in male Wistar rats 4700 mg/kg, in female Wistars 3200 mg/kg, and in male CF-1 mice 1231 mg/kg (92).

In 14-day studies, male and female F344 rats had doses of 625–20,000 mg/kg in the diet, and $B6C3F_1$ mice had doses of 388–10,000 mg/kg. In male rats, doses over 5000 mg led to decreased body weight gain, but females were less susceptible. Although no treatment-related gross lesions were noted after 4-NT, in male rats liver weights were increased in a dose-related fashion. No hepatic toxicity was seen in mice (92).

A 13-week feeding study in F344 rats (625–10,000 ppm) and B6C3F$_1$ mice led to hyaline droplet nephropathy in male rats and mild enlargement of proximal tubule epithelium in both male and female rats, testicular degeneration in male rats at 10,000 ppm, no discernible estrus cycle in female rats at 10,000 ppm, increased liver weights in mice but no hepatic toxicity or effect on reproductive parameters (92, 141). Administration of 200–600 mg/kg daily for 14 days led to suppression of the IgM response and resistance to *Listeria monocytogenes* but not to other bacteria (143).

After a single dose of ^{14}C-labeled 4-NT to male rats, about 77% was excreted in the urine within 72 h and eight metabolites were separated; 4-nitrobenzoic acid and 4-acetamidobenzoic acid were the chief metabolites (92).

31.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA NIOSH REL is 2 ppm (11 mg/m^3) with a skin notation. The OSHA PEL is 5 ppm.

32.0 Dinitrotoluene Technical Grade

32.0.1 CAS Number: [*25321-14-6*]

32.0.2 Synonyms: DNT; dinitrotoluene (mixed isomers); methyl dinitrobenzene (mixed isomers); dinitrotoluene mixture; dinitrotoluene, all isomers; dinitritoluene (mixed isomers); methyldinitrobenzene; dinitrotoluene (2,4 and 2,6 mix); dinitrophenylmethane; TDNT; toluene, ar,ar-dinitro

32.0.3 Trade Names: NA

32.0.4 Molecular Weight: 182.14

32.0.5 Molecular Formula: $C_7H_6N_2O_4$

Commercial or technical grade dinitrotoluene is a mixture of about 76% of the 2,4- isomer, 19% of the 2,6- compound and 5% is made up of 2,3-, 2,5-, 3,4- and 3,5-dinitrotoluenes (2). The mixture is absorbed through the skin and can cause toxic effects.

32.3 Exposure Assessment

OSHA method #44 uses filter with linax GC tube and GC with thermal energy analyzer detection.

32.5 Standards, Regulations, or Guidelines of Exposure

OSHA PEL and NIOSH REL is 1.5 mg/m^3.

33.0 2,4-Dinitrotoluene

33.0.1 CAS Number: [*121-14-2*]

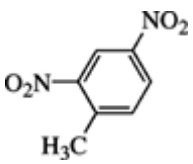
33.0.2 Synonyms: DNT; 2,4-DNT; dinitrotoluol; 1-methyl-2,4-dinitrobenzene; 2,4-dinitrotoluol

33.0.3 Trade Names: NA

33.0.4 Molecular Weight: 182.14

33.0.5 Molecular Formula: $C_7H_6N_2O_4$

33.0.6 Molecular Structure:



Databases and inventories where listed: CAA1, CA65, IARC, MA, MTL, NJ, NTPT, PA, RQ, S110, TRI, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.

33.1 Chemical and Physical Properties (2)

Physical state	Yellow or orange crystals
Boiling point	300°C
Melting point	71°C
Density	1.3208
Solubility	Soluble in ethanol, ether, acetone, benzene

33.2 Production and Use

2,4-Dinitrotoluene is used largely, along with the 2,6-isomer, to make toluene diisocyanate. The DNT mixture is hydrogenated to yield the diamine which is reacted with phosgene to form the diisocyanate which is reacted with polyols to make polyurethane foams (2). DNT is also employed to some extent in manufacturing explosives.

33.4 Toxic Effects

The toxicity of 2,4-DNT was discussed thoroughly in the previous edition (2) and by IARC (92). Although there are conflicting reports on carcinogenicity, depending on the animal model, 2,4-DNT is not a hepatocarcinogen. It can affect testicular function, but the toxicity is half that of the 2,6-isomer.

The various isomers of DNT are considerably less toxic to the mouse, with the possible exception of 2,3-dinitrotoluene, indicating widely differing capacities for metabolism. The oral LD_{50}s for 2,4-dinitrotoluene are 268 (rat) versus 1625 (mouse) (144). 2,4-DNT is reportedly a nonsensitizer (145).

2,4-DNT is rapidly absorbed via skin exposure, and repeated dermal applications to rabbits have produced cyanosis, lipemic plasma, depressed hemoglobin and red blood cells, liver hyperplasia and focal necrosis, bone marrow damage, congested spleen, distended bladder, and brain edema; testicular atrophy and aspermatogenesis were reported in beagles. Adverse neuromuscular effects, tremors, and brain lesions in dogs following oral administration have also been reported (145).

2,4-Dinitrotoluene is also rapidly absorbed after oral administration. Little reduction of dinitrotoluene occurs in isolated perfused liver preparation, in isolated hepatocytes, or in microsomal preparations incubated under air (146). The first step in metabolism in male or female Fischer 344 rats is oxidation at the methyl group to yield dinitrobenzyl alcohols, followed by conjugation with glucuronic acid, preparing the alcohol for bile excretion, which occurs to a much greater degree in male than in female rats (146). Intestinal microflora hydrolyze the glucuronides and reduce one of the nitro groups (to an amino group via nitroso intermediates) (147); the reduced metabolites, aminonitrobenzyl alcohols, are then reabsorbed, whereby, it is postulated, the 2,6 isomer is activated (146). All six dinitrotoluene isomers were metabolized to aminonitrotoluenes by an *Escherichia coli* isolated from human intestinal contents (148), as well as by the intestinal microflora of rats and mice (147). The human urinary metabolites of 2,4-dinitrotoluene in volunteers exposed to dinitrotoluene are 2,4-dinitrobenzoic acid, 2-amino-4-nitrobenzoic acid, 2,4-dinitrobenzyl glucuronide, and 2-(*N*-acetyl)amino-4-nitrobenzoic acid. The first three of these are found in rat urine; the last differs in the position of reduction and acetylation. The most abundant metabolites of dinitrotoluenes in human urine were the dinitrobenzoic acids; in rats the most abundant metabolites were dinitrobenzyl glucuronides. The appearance of a reduced metabolite of 2,4-dinitrotoluene indicates either that human hepatic enzymes are capable of nitro group reduction of dinitrotoluene or that 2,4-dinitrotoluene (or one of its metabolites) gains access to the intestinal microflora (146). The biliary excretion/nitro reduction pathway for bioactivation of 2,6-DNT may occur to a lesser extent in humans than in rats, making an important difference in risk assessment (149).

In a dominant lethal mutation study of 2,4-DNT (60, 180, or 240 mg/kg/day for 5 days, Sprague–Dawley male rats by gavage), lethal mutations were not detected, and no changes were observed in the number of preimplantation losses or implantation sites; however, reproductive performance was adversely affected at the 240 mg dose level (150).

Reproductive toxicity evaluation of 2,4-dinitrotoluene in adult male rats fed 0.1 or 0.2% DNT for 3 weeks demonstrated a marked change in Sertoli cell morphology following 0.2% DNT exposure. Circulating levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) were increased in 0.2% DNT-treated animals. Raised serum levels of FSH reportedly are frequently, if not always, associated with Sertoli cell malfunction. Reduced weights of the epididymides and decreased epididymal sperm reserves were also observed. The authors concluded that DNT can induce testicular injury, directly or indirectly disturb pituitary function, and exert a toxic effect at the late stages of spermatogenesis. A direct effect on the hypothalamic-hypophyseal axis was not precluded, according to the authors, because testosterone concentrations remained within the normal range, whereas LH levels were elevated (151).

Exposure to 2,4-DNT reportedly decreased human sperm count and increased spontaneous abortions in the workers' wives (technical-grade dinitrotoluene is assumed) (145); however, in a follow-up epidemiological study, no effect on sperm levels was found in workers (152).

The initial carcinogenicity study in 1978 was conducted by NCI and involved a dietary feeding study of 2,4-DNT continuously for 18 months to male and female F344 rats and B6C3F$_1$ mice at 0.008 or 0.02% (and 0.008 or 0.04%, respectively), followed by a 6-month observation period. Because the incidence of hepatic neoplasms in treated animals and control animals was not significantly different, the NCI bioassay was considered negative for hepatocarcinogenesis in both rats and mice. In this study, 2,4-DNT was the primary component (95% 2,4-DNT, < 5% 2,6-DNT) (153). However, there was an increased incidence of fibroma of the skin and subcutaneous tissue in the high- and low-dose male rats and an increased incidence of mammary gland fibroadenoma in high-dose female rats (153, 154).

A second study evaluated 2,4-DNT (containing approximately 2% 2,6-DNT) in Sprague–Dawley (CD) rats and mice (CD-1) for 2 years (155). The high doses were toxic to both mice and rats, and the life span of mice was shortened by 50%. About half of the high-dose and approximately 25% of the control male rats died by the end of the 20th month. 2,4-DNT was hepatocarcinogenic, resulting in a 21% incidence of hepatocellular carcinomas in male rats of the high-dose (34 mg/kg/day) group dying or killed after 1 year of age. By comparison, high-dose female rats had a 53% incidence of hepatocellular carcinomas (155). The reason for the higher incidence of hepatocellular carcinoma in female rats compared with male rats, the inverse of that observed in a third study, is not clear; differences in strain of rat, the isomeric composition of the DNT, or other unspecified variances in protocols may be the basis for the differences in sex response between these two studies (154).

The results of further study demonstrated that 2,6-DNT is a complete hepatocarcinogen; in contrast, 2,4-DNT was not hepatocarcinogenic when fed at twice the high dose of 2,6-DNT during the same time period. The authors concluded that 2,4-DNT may act as a promoter but cannot initiate carcinogenesis. The hepatocarcinogenicity of technical-grade DNT is mainly due to 2,6-DNT (154, 155).

In an analytically controlled comparative bioassay 2,4-dinitrotoluene was not carcinogenic in male F344 rats (155); the lack of hepatocarcinogenicity of 2,4-DNT was consistent with the conclusion that 2,4-DNT is not a hepatocarcinogen. The difference between these studies could simply be due to strain differences, the greater amount of 2,6-DNT contaminating the 2,4-DNT used, the slightly higher dose of 2,4-DNT used (34 versus 27 mg), or the extended duration of feeding (2 years versus 1 year) (155). The positive response by 2,4-dinitrotoluene in the Ames assay is unclear (115).

IARC, NIOSH, OSHA, and ACGIH have not classified this isomer as a potential carcinogenic risk.

33.5 Standards, Regulations or Guidelines of Exposure

The ACGIH TLV-TWA is 0.2 mg/m^3 with a skin notation and an A3 rating. The actual listing is for the technical grade mixture, but it applies to the components.

34.0 2,6-Dinitrotoluene

34.0.1 CAS Number: [*606-20-2*]

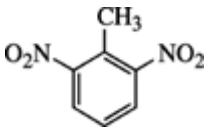
34.0.2 Synonyms: 2-Methyl-1,3-dinitrobenzene; 2,6-DNT; 1,3-dinitro 2-methylbenzene

34.0.3 Trade Name: NA

34.0.4 Molecular Weight: 182.14

34.0.5 Molecular Formula: $C_7H_6N_2O_4$

34.0.6 Molecular Structure:



Databases or inventories where listed: CA65, IARC, MA, NJ, PA, RQ, S110, TRI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

34.1 Chemical and Physical Properties (2)

Physical state	Yellow rhombic crystals
Melting point	64–66°C
Density	1.2833
Solubility	Soluble in ethanol

34.2 Production and Use

2,6-Dinitrotoluene is used primarily, along with the other isomers, in producing toluene diisocyanate; production of the diisocyanate ranges from 100 million to almost a billion pounds each year.

34.4 Toxic Effects

The toxicity and metabolic interactions of 2,6-dinitrotoluene have been reviewed in the previous edition (2) and by IARC (92). In F344 rats, the 2,6-isomer gave four distinct DNA adducts versus three for the 2,4-isomer, and with a much higher level of binding than 2,4-DNT (92, 156). In male B6C3F1 mice, only two such adducts were detected (157). A metabolite, 2-amino-6-nitrotoluene, gave the same adducts as 2,6-DNT, but at 30-fold lower levels (158). Intestinal microflora were important in activating 2,6-DNT to mutagenic metabolites (159), and the genotoxicity was increased by pretreating the rats with the enzyme inducers Aroclor 1254 or creosote (160, 161).

35.0 3,5-Dinitrotoluene

35.0.1 CAS Number: [*618-85-9*]

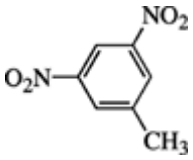
35.0.2 Synonyms: 1-Methyl-3,5-dinitrobenzene

35.0.3 Trade Name: NA

35.0.4 Molecular Weight: 182.14

35.0.5 Molecular Formula: $C_7H_6N_2O_4$

35.0.6 Molecular Structure:



Databases or inventories where listed: IARC, CANCERLIT, DART, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, SUPERLIST.

35.1 Chemical and Physical Properties (92)

Physical state	Yellow rhombic needles
Boiling point	Sublimes
Melting point	93°C
Density	1.2772 (11/4°C)
Solubility	Soluble in benzene, chloroform, ether, ethanol

35.2 Production and Use

3,5-Dinitrotoluene occurs in technical grade dinitrotoluene and has no specific uses by itself.

35.4 Toxic Effects

No specific studies of the toxicity of this isomer were located, although it may contribute to the effects of technical grade dinitrotoluene. The 3,5-isomer was mutagenic in the *Salmonella* test without metabolic activation and in some strains with the rat liver S9 fraction. It was not active in causing mutation in Chinese hamster ovary cells, and it did not induce unscheduled DNA synthesis in rat liver cells in culture (92).

For the remaining dinitrotoluenes, the only data found related to the databases in which they were listed.

36.0 2,3-Dinitrotoluene

36.0.1 CAS Number: [*602-01-7*]

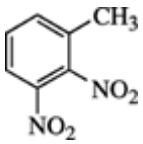
36.0.2 Synonyms: 1-Methyl-2,3-dinitrobenzene

36.0.3 Trade Names: NA

36.0.4 Molecular Weight: 182.14

36.0.5 Molecular Formula: $C_7H_6N_2O_4$

36.0.6 Molecular Structure:



Databases and inventories where listed: CCRIS, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MESH, RTECS, TOXLINE, TSCAINV.

37.0 2,5-Dinitrotoluene

37.0.1 CAS Number: [*619-15-8*]

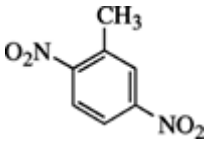
37.0.2 Synonyms: 2-Methyl-1,4-dinitrobenzene

37.0.3 Trade Names: NA

37.0.4 Molecular Weight: 182.14

37.0.5 Molecular Formula: $C_7H_6N_2O_4$

37.0.6 Molecular Structure:



Databases and inventories where listed: CCRIS, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, RTECS, TOXLINE, TSCAINV.

38.0 3,4-Dinitrotoluene

38.0.1 CAS Number: [*610-39-9*]

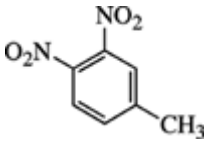
38.0.2 Synonyms: 4-Methyl-1,2-dinitrobenzene; 1,2-dinitro–4-methylbenzene

38.0.3 Trade Names: NA

38.0.4 Molecular Weight: 182.14

38.0.5 Molecular Formula: $C_7H_6N_2O_4$

38.0.6 Molecular Structure:



Databases and inventories where listed: MA, PA, RQ, CANCERLIT, CCRIS, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MESH, RTECS, TOXLINE, TSGAINV, SUPERLIST.

39.0 2,4,6-Trinitrotoluene

39.0.1 CAS Number: [*118-96-7*]

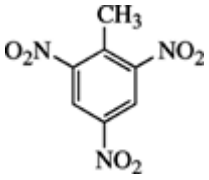
39.0.2 Synonyms: TNT; trinitrotoluol; *sym*-trinitrotoluene; trinitrotoluene; 2-methyl-1,3,5-trinitrobenzene; entsufon; 1-methyl-2,4,6-trinitrobenzene; methyltrinitrobenzene; tolite; trilit; *s*-trinitrotoluene; *s*-trinitrotoluol; trotyl; *sym*-trinitrotoluol; alpha-trinitrotoluol

39.0.3 Trade Names: NA

39.0.4 Molecular Weight: 227.13

39.0.5 Molecular Formula: $C_7H_5N_3O_6$

39.0.6 Molecular Structure:



Databases and inventories where listed: DOT, IARC, IL, MA, NJ, PA, PEL, REL, S110, TLV, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, GENETOX, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

39.1 Chemical and Physical Properties (2)

Physical state	Colorless to pale yellow crystals or monoclinic prisms
Specific gravity	1.654 (20°C)
Melting point	82°C
Boiling point	240°C (explodes)
Vapor pressure	0.046 mmHg (82°C)
Solubility	Soluble in ether, benzene, chloroform, carbon tetrachloride, toluene, acetone; slightly soluble in water

39.2 Production and Use

TNT has been used in explosives for almost 100 years. It must be exploded by a denonator, but it can be poured into shells when molten.

39.3 Exposure Assessment

OSHA Analytical method # 44 using linax GC tube and analysis by GC with thermal energy analyzer detection with explosives package.

39.4 Toxic Effects

The toxic effects of TNT in exposed workers are well known and include hepatitis, irritation of eyes, nose, throat and skin, methemoglobinemia, and cararacts, in addition to other symptoms (2). Workers exposed to TNT in a packing site, where levels of TNT exceeded 1 mg/m^3 had skin levels after each shift that were threefold those of unexposed workers. This correlated with total blood levels of TNT and the metabolites 4-amino-2,6-dinitrotoluene and 2-amino-4,6-dinitrotoluene (162). Furthermore, the levels of Cu, Zn, Na, Mg, and Se in the semen of these workers were significantly decreased, and sperm viability was less. Sperm malformations increased (162). A county in Germany contaminated with TNT residues from explosives manufacture had a higher risk for leukemia than neighboring counties (92). Thus, biodegradation of TNT residues from military or manufacturing sites is a matter of interest. One study found that reduction to nitroamines (2-amino-4,6-dinitrotoluene, 4-amino-2,6-dinitrotoluene 2,4-diamino-6-nitrotoluene), reduction to 2,4,6-triaminotoluene, and formation of azoxy compounds (2,2', 6,6'-tetranitro-4,4'azoxytoluene and 4,4', 6,6'-tetranitro-2,2'-azoxytoluene) occurred. In addition, *p*-cresol and methylphloroglucinol were identified, indicating removal of the nitrogens (163). Labeled TNT residues in compost from TNT-contaminated soil were not excreted readily in rats and accumulated in the kidneys, indicating that a unique TNT derivative had formed (164). A 6-month oral toxicity study in beagle dogs at levels of 0.5, 2, 8, or 32 mg/kg/day led to anemia, methemoglobinemia, splenomegaly, and effects on the liver, similar to those in exposed workers. Only the highest dose was lethal, despite the toxicity (165). Reportedly a 24-month chronic study in mice and rats led to tumors in female rats but not in mice or male rats (164). The toxicity, mutagenicity, and metabolism of TNT have been covered in a review by IARC (92).

39.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV is 0.1 mg/m^3 with a skin notation. The OSHA PEL is 1.5 mg/m^3 with a skin notation and the NIOSH REL is 0.5 mg/m^3 with a skin notation.

40.0 Tetryl

40.0.1 CAS Number: [*479-45-8*]

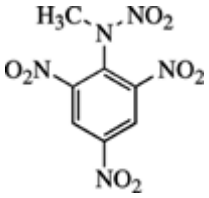
40.0.2 Synonyms: 2,4,6-Trinitrophenylmethylnitramine; *N*-methyl-*N*,2,4,6-tetranitroaniline; nitramine; tetralite; trinitrophenylmethylnitramine; 2,4,6-tetryl

40.0.3 Trade Names: NA

40.0.4 Molecular Weight: 287.15

40.0.5 Molecular Formula: $C_7H_5N_5O_8$

40.0.6 Molecular Structure:



Databases and inventories where listed: DOT, IL, MA, NJ, PA, PEL, REL, TLV, WHMI, CANCERLIT, CCRIS, EINECS, EMIC, EMICBACK, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

40.1 Chemical and Physical Properties (2)

Physical state	Yellow monoclinic crystals
Density	1.57 at 19°C
Melting point	130°C
Boiling point	187°C, explodes
Solubility	Soluble in ethanol, ether; insoluble in water

40.2 Production and Use

Tetryl is used in various types of explosive devices.

40.3 Exposure Assessment

NMAM IInd ed., vol 3, 1977 Method #S225.

40.4 Toxic Effects

Tetryl is a sensitizer and causes dermatitis (2). Practically no information on toxicity studies was located, but tetryl reportedly is under study by the U.S. EPA and military groups (115). Plant oxidoreductase enzymes under anaerobic conditions could remove the *N*-nitro group as nitrite, yielding *N*-methyl-trinitroaniline (166).

40.5 Standards, Regulations, or Guidelines of Exposure

The OSHA-PEL, NIOSH REL and ACGIH TLV-TWA are 1.5 mg/m^3 with a note that it causes dermatitis.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

H. Aniline and Derivatives

41.0 Aniline

41.0.1 CAS Number: [*62-53-3*]

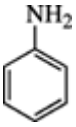
41.0.2 Synonyms: Benzamine; aniline oil; phenylamine; aminobenzene; aniline oil; phenylamine; aminophen; kyanol; benzidam; blue oil; C.I. 76000; C.I. oxidation base 1; cyanol; krystallin; anyvim; arylamine

41.0.3 Trade Names: NA

41.0.4 Molecular Weight: 93.13

41.0.5 Molecular Formula: C_6H_7N

41.0.6 Molecular Structure:



Databases and inventories where listed: CAA1, CA65, CGB, DOT, IARC, IL, MA, MI, MTL, NJ, PA, PELS, REL, RQ, S302, TLV, TRI, WHMI, AIDSLINE, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.

41.1 Chemical and Physical Properties (2)

Physical state	Oily liquid
Density	1.002 (20/4°C)
Melting point	–6.3°C
Boiling point	184.4–186°C
Vapor density	3.22 (air = 1)
Vapor pressure	15 mm Hg (77°C)
Refractive index	1.5863 (20°C)
Solubility	Soluble in ethanol, ether, benzene, chloroform, carbon tetrachloride, acetone; somewhat soluble in water

41.2 Production and Use

In 1992, more than 900 million pounds were produced, mostly by hydrogenation of nitrobenzene (167). Aniline is used in manufacture of dyestuffs, various intermediates, in rubber accelerators and in antioxidants, pharmaceuticals, photographic chemicals, plastics, isocyanates, hydroquinones, herbicides, fungicides, ion-exchange resins, whitening agents, and as an intermediate for various other chemicals.

41.3 Exposure Assessment

NMAM IVth ed., 1994 Method #2002.

41.4 Toxic Effects

The toxic effects of aniline have been discussed (2); in humans, they include headaches, methemoglobinemia, tremors, narcosis and coma. Although historically bladder cancers in dyestuff workers were called aniline cancers, recent epidemiological studies indicate that *o*-toluidine, a probable contaminant, was more likely the cause of the bladder tumors (168). Although high doses of aniline hydrochloride led to no excess tumors in B6C3F1 mice, levels of 3000 or 6000 ppm in the diet led to hemangiosarcomas or fibrosarcomas of the spleen in rats. Several publications have addressed the mechanism of this effect of aniline. Study of the hematopoietic toxicity of aniline in rats showed that blood methemoglobinemia peaked at 37% in 0.5 h and increased lipid peroxidation occurred in the spleen (169). Tests for up to 90 days with 600 ppm aniline hydrochloride showed that the spleens of test rats had striking histopathological changes and damage to erythrocyte iron was

increased (170). It was surmised that reaction of aniline or a metabolite with erythrocytes led to their accumulation, as well as iron deposition in the spleen (171); thus oxidative stress was responsible for the splenotoxicity of aniline (172). Exposure of rats to an atmosphere of 15,000 ppm aniline for 10 minutes, a situation simulating an industrial accident, also caused an increase in lipid peroxidation in the mitochondrial portions of the cerebellum, brain stem, and brain cortex (173).

Treatment of rats with 10% ethanol in the drinking water for 12 or 36 weeks stimulated the level of P450 and the degree of aniline hydroxylation (127). Human hemoglobin, as well as P450, cause aniline to be metabolized to the 2- and 4-aminophenols (174), but *in vitro*, exclusive 4-hydroxylation of aniline occurred in the presence of singlet oxygen (175). Aniline is readily absorbed through the skin. Thus the various occupational and industrial hygiene "skin" notations are necessary.

41.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA is 2 ppm (7.6 mg/m^3) with A3 and skin notations. The OSHA PEL is 5 ppm. NIOSH considers it a carcinogen.

42.0 **N**-Methylaniline

42.0.1 CAS Number: [*100-61-8*]

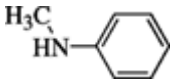
42.0.2 Synonyms: MA, *N*-methylbenzeneamine, monomethylaniline, *N*-methyl-phenylamine, *N*-monomethylaniline, methyl aniline, methylphenylamine, anilinomethane, (methylamino) benzene, *N*-methylaminobenzene, *N*-phenylmethylamine

42.0.3 Trade Names:

42.0.4 Molecular Weight: 107.15

42.0.5 Molecular Formula: C_7H_9N

42.0.6 Molecular Structure:



Databases and inventories where listed: DOT, IL, MA, PA, PEL, REL, TLV, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMICBACK, ETICBACK, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

42.1 Chemical and Physical Properties (2)

Physical state	Colorless to slightly yellow liquid; turns brown on exposure to air
Specific gravity	0.989 at 20°C
Melting point	–57°C
Boiling point	194.6–196°C
Flash point	79.4°C (closed cup)
Solubility	Soluble in ethanol, ether; slightly soluble in water

42.2 Production and Use

N-Methylaniline is used as a solvent and an intermediate.

42.3 Exposure Assessment

NMAM IVth ed., 1994, Method #3511.

42.4 Toxic Effects

No new information was located.

42.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA and NIOSH REL is 0.5 ppm with a skin notation. OSHA PEL is 2 ppm.

43.0 **N**,**N**-Dimethylaniline

43.0.1 CAS Number: [*121-69-7*]

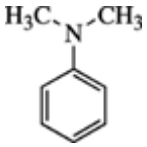
43.0.2 Synonyms: Dimethylaniline, Versneller NL 63/10, *N*,*N*-dimethylbenzenamine; (dimethylamino)benzene, dimethylphenylamine, *N*,*N*-dimethylphenylamine, dimethylphenylamine, DMA

43.0.3 Trade Names: NA

43.0.4 Molecular Weight: 121.18

43.0.5 Molecular Formula: $C_8H_{11}N$

43.0.6 Molecular Structure:



Databases and inventories where listed: CAA1, DOT, IARC, IL, MA, MTL, NJ, NTPT, PA, PEL, REL, TLV, TRI, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TRI, TSCAINV, SUPERLIST.

43.1 Chemical and Physical Properties (2)

Physical state	Yellow liquid
Density	0.9557 (20/4°C)
Melting point	2.45°C
Boiling point	192.5°C
Vapor density	4.17 (air = 1)
Refractive index	1.55819 (20°C)
Solubility	Soluble in ethanol, ether; slightly soluble in water
Flash point	145°F (closed cup)
	170°C (open cup)

43.2 Production and Use

N,*N*-Dimethylaniline is used in production of dyestuffs, as a solvent, a reagent in methylation reactions, and a hardener in fiberglass reinforced resins.

43.3 Exposure Assessment

NMAM IVth ed., 1994 Method #2002.

43.4 Toxic Effects

The previous edition reported that *N*,*N*-dimethylaniline can undergo both *N*-oxidation and *N*-demethylation (2). Further studies showed that P4502B1 from rats converts this compound to the *N*-oxide or dealkylates it in the ratio of 6 parts *N*-oxide to 1020 parts of dealkylated product, probably by one-electron oxidation (176, 177). In another metabolic system (rabbit liver microsomes), superoxide and P4502B4 were considered the active entities (178); this was reviewed by IARC (179).

43.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA NIOSH REL is 5 ppm with a STEL of 10 ppm and skin and A4 notations. OSHA PEL is also 5 ppm with skin notation.

44.0 **N**-Ethylaniline

44.0.1 CAS Number: [*103-69-5*]

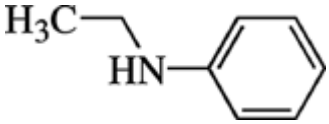
44.0.2 Synonyms: Ethylphenylamine; *N*-ethyl aniline; anilinoethane; *N*-ethylaminobenzene

44.0.3 Trade Names: NA

44.0.4 Molecular Weight: 121.18

44.0.5 Molecular Formula: $C_8H_{11}N$

44.0.6 Molecular Structure:



Databases and inventories where listed: DOT, MA, PA, WHMI, CCRIS, EINECS, EMICBACK, HSDB, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

44.1 Chemical and Physical Properties (2)

Physical state	Colorless liquid, darkens in air
Boiling point	204.5°C
Melting point	–63.5°C
Solubility	Soluble in acetone, benzene; miscible with ethanol, ether; insoluble in water

44.2 Production and Use

N-Ethylaniline is used an an explosive stabilizer and in dyestuff manufacture.

44.4 Toxic Effect

No specific new information located.

44.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

45.0 **N**,**N**-Diethylaniline

45.0.1 CAS Number: [*91-66-7*]

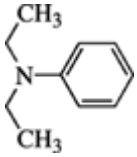
45.0.2 Synonyms: Diethyl aniline, *N*,*N*-diethylbenzenamine, *N*,*N*-diethylaminobenzene, diethylphenylamine,

45.0.3 Trade Name: NA

45.0.4 Molecular Weight: 149.24

45.0.5 Molecular Formula: $C_{10}H_{15}N$

45.0.6 Molecular Structure:



Databases and inventories where listed: CAA1, DOT, MA, PA, WHMI, CCRIS, DSL, EINECS, EMIC, EMICBACK, HSDB, RTECS, TOXLINE, TSCAINV, SUPERLIST.

45.1 Chemical and Physical Properties (2)

Physical state	Colorless or yellow or brown oil (flammable)
Density	0.93507 (20/4°C)
Melting point	–38.8°C
Boiling point	215.5-216°C
Refractive index	1.54105 (22°C)
Solubility	Soluble in ethanol, ether; fairly soluble in water

45.2 Production and Use

Diethylaniline is used as an intermediate in synthesizing of dyestuffs and pharmaceuticals.

45.4 Toxic Effects

During oxidative metabolism, as with *N*,*N*-dimethylaniline, a much greater proportion of the diethylaniline was dealkylated, rather than forming an *N*-oxide (176).

45.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

I. Chlorinated Anilines

46.0 2-Chloroaniline

46.0.1 CAS Number: [*95-51-2*]

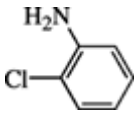
46.0.2 Synonyms: 2-Chlorobenzenamine; 1-amino-2-chlorobenzene; fast yellow gc base; OCA

46.0.3 Trade Name: NA

46.0.4 Molecular Weight: 127.57

46.0.5 Molecular Formula: C_6H_6ClN

46.0.6 Molecular Structure:



Databases and inventories where listed: CCRIS, DSL, EINECS, EMIC, EMICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV.

46.1 Chemical and Physical Properties (2)

Physical state	Colorless liquid
Density	1.2125 (20/4°C)
Melting point	a, –14°C; b, –1.9°C
Boiling point	208.8°C
Refractive index	1.5895 (20°C)
Solubility	Soluble in acetone, ether; miscible with ethanol; insoluble in water

46.2 Production and Use

It is reportedly used as an intermediate in dyestuffs (2).

46.4 Toxic Effects
The NTP has done short-term toxicity studies of 2-chloroaniline in rats and mice, but the reports were in peer review. 2-Chloroaniline was the most potent of the isomeric chloroanilines in F344 rats with regard to nephrotoxic and hepatoxic effects (2). In contrast, when the chloroanilines were acetylated, the toxicity was greatly decreased and 2-chloroacetanilide was the least toxic of the isomers (180). Possible metabolites were tested for nephrotoxicity, but they were less potent than the parent chloroaniline (181).
46.5 Standards, Regulations, or Guidelines of Exposure
None assigned.
47.0 3-Chloroaniline
47.0.1 CAS Number: [*108-42-9*]

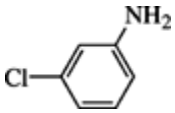
47.0.2 Synonyms: 3-Chlorobenzenamine, MCA, *m*-aminochlorobenzene, 1-amino-3-chlorobenzene, 3-chlorophenylamine, fast orange gc base, orange gc base

47.0.3 Trade Names: NA

47.0.4 Molecular Weight: 127.57

47.0.5 Molecular Formula: C_6H_6ClN

47.0.6 Molecular Structure:



Databases and inventories where listed: WHMI, CCRIS, DART, DSL, EINECS, EMICBACK, GENETOX, HSDB, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.
47.1 Chemical and Physical Properties (2)

Physical state	Colorless liquid
Melting point	–10.3°C
Boiling point	229.8–230.5°C
Refractive index	1.59424 (20°C)
Solubility	Soluble in acetone, benzene, ether; miscible with ethanol; insoluble in water

47.2 Production and Use
Uses are reportedly the same as those of the other isomers.
47.4 Toxic Effects
Although 3-chloroaniline is readily absorbed through the skin and thus can cause the toxicity associated with aromatic amines, in F344 rats, it had the lowest nephrotoxicity of the isomeric chloroanilines. However, the situation was reversed for the acetyl derivatives, and 3-chloroacetanilide was the most toxic (180). The various 3-haloanilines (iodo, bromo, chloro, and fluoro) had different orders of nephrotoxic potential *in vivo* and *in vitro* for unknown reasons. They were not potent nephro- or hepatotoxicants at sublethal doses (182). Tests of possible phenolic metabolites of 3-chloroaniline did not show hepatotoxicity, but 4-amino-2-chlorophenol retained nephrotoxic activity at the highest dose level tested (183).
47.5 Standards, Regulations, or Guidelines of Exposure
None assigned.
48.0 4-Chloroaniline
48.0.1 CAS Number: [*106-47-8*]

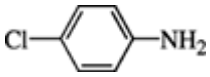
48.0.2 Synonyms: *p*-Chlorophenylamine; 4-chlorobenzenamine, 4-chloro-1-aminobenzene, 1-amino-4-chlorobenzene, *p*-aminochlorobenzene

48.0.3 Trade Names: NA

48.0.4 Molecular Weight: 127.57

48.0.5 Molecular Formula: C_6H_6ClN

48.0.6 Molecular Structure:



Databases and inventories where listed: CA65, IARC, MA, NJ, NTPT, PA, RQ, TRI, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

48.1 Chemical and Physical Properties (2)

Physical state	Colorless solid, rhombic crystals
Density	1.427 (19/4°C)
Melting point	72.5°C
Boiling point	231-232°C
Solubility	Soluble in ether; miscible with ethanol; insoluble in water

48.2 Production and Use

4-Chloroaniline is used as a dye intermediate.

48.4 Toxic Effects

The metabolism, excretion pattern, and carcinogenicity of 4-chloroaniline were discussed (2, 179). A patient who was acutely poisoned by 4-chloroaniline excreted conjugates of the parent compound and 2-amino-5-chlorophenol in the urine, indicating that ortho-hydroxylation had occurred, similar to results in other species (179). 4-Chloroaniline was somewhat less toxic to the liver and kidney of F344 rats than 2-chloroaniline, but upon acetylation, it had higher nephrotoxic potential (180). A study of possible phenolic metabolites showed that they had lower renal toxicity than the parent chloroanilines but still retained some toxicity (181, 184). P450 enzymes cause removal of the chlorine to yield 4-aminophenol (185, 186). Contrary to the situation with many halogen-substituted compounds, a fluoro substituent in the 4-position was removed more easily than other halogens (185).

48.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

49.0 2,3-Dichloroaniline

49.0.1 CAS Number: [*608-27-5*]

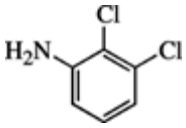
49.0.2 Synonyms: 2,3 Dichlorobenzenamine

49.0.3 Trade Names: NA

49.0.4 Molecular Weight: 162.02

49.0.5 Molecular Formula: $C_6H_5NCl_2$

49.0.6 Molecular Structure:



Data bases and inventories where listed: EINECS, HSDB, RTECS, TOXLINE, TSCAINV.

49.1 Chemical and Physical Properties (2)

Boiling point	252°C
Melting point	24°C
Solubility	Soluble in acetone, ethanol, ether

49.2 Production and Use

No specific uses were located.

49.4 Toxic Effects

2,3-Dichloroaniline was the least nephrotoxic of the dichloroaniline isomers (187).

49.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

50.0 2,4-Dichloroaniline

50.0.1 CAS Number: [*554-00-7*]

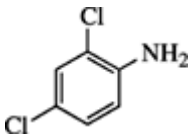
50.0.2 Synonyms: 2,4 -Dichlorobenzenamine, 2,4-dichloroaniline, pract.

50.0.3 Trade Names: NA

50.0.4 Molecular Weight: 162.02

50.0.5 Molecular Formula: $C_6H_5NCl_2$

50.0.6 Molecular Structure:



Data bases and inventories where listed: CCRIS, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MESH, RTECS, TOXLINE, TSCAINV.

50.1 Chemical and Physical Properties (2)

Boiling point	245°C
Melting point	63–64°C
Solubility	Soluble in ethanol, ether

50.2 Production and Use

Specific uses not located.

50.4 Toxic Effects

2,4-Dichloroaniline was one of the isomers considered to have low nephrotoxicity, compared with the 3,5-isomer (187). The relative order of toxicity was the same *in vitro* as *in vivo* (188).

50.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

51.0 2,5-Dichloroaniline

51.0.1 CAS Number: [*95-82-9*]

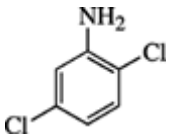
51.0.2 Synonyms: 2,5-Dichlorobenzenamine, amarthol fast scarlet gg base; azoene fast scarlet 2g base; C.I. 37010; C.I. azoic diazo component 3; fast scarlet 2g; scarlet base gg; 1-amino-2, 5-dichlorobenzene; 2-amino-1, 4-dichlorobenzene; 2,5-dichlorobenzamine

51.0.3 Trade Names: NA

51.0.4 Molecular Weight: 162.02

51.0.5 Molecular Formula: $C_6H_5NCl_2$

51.0.6 Molecular Structure:



Databases and inventories where listed: CCRIS, EINECS, EMIC, EMICBACK, HSDB, RTECS, TOXLINE, TSCAINV.

51.1 Chemical and Physical Properties (2)

Boiling point	251°C
Melting point	50°C
Solubility	Soluble in ethanol, ether, benzene

51.2 Production and Use

No specific uses were located.

51.4 Toxic Effects

The nephrotoxicity of 2,5-dichloroaniline in F344 rats was somewhat lower than that of the 3,5-isomer but greater than that of the other isomers (187). A possible metabolite, 2-amino-4-chlorophenol, had low nephrotoxic potential (183).

51.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

52.0 2,6-Dichloroaniline

52.0.1 CAS Number: [*608-31-1*]

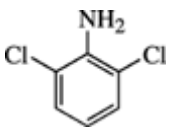
52.0.2 Synonyms: 2,6-Dichlorobenzenamine

52.0.3 Trade Name: NA

52.0.4 Molecular Weight: 162.02

52.0.5 Molecular Formula: $C_6H_5NCl_2$

52.0.6 Molecular Structure:



Databases and inventories where listed: EINECS, TOXLINE, TSCAINV.

52.1 Chemical and Physical Properties (2)

Melting point 39°C

Solubility Soluble in ether

52.2 Production and Uses

No specific uses located.

52.4 Toxic Effects

2,6-Dichloroaniline had moderately low nephrotoxic effects in F344 rats, compared with the 3,5-isomer (187).

52.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

53.0 3,4-Dichloroaniline

53.0.1 CAS Number: [*95-76-1*]

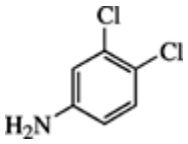
53.0.2 Synonyms: 1-Amino-3, 4-dichlorobenzene, 3,4-dichlorobenzenamine; 3,4-DCA; 4,5-dichloroaniline

53.0.3 Trade Names: NA

53.0.4 Molecular Weight: 162.02

53.0.5 Molecular Formula: $C_6H_5NCl_2$

53.0.6 Molecular Structure:



Databases and inventories where listed: MA, MTL, PA, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

53.1 Chemical and Physical Properties (2)

Melting point 71–72°C

Boiling point 272°C

Solubility Soluble in ethanol, benzene; almost insoluble in water

53.2 Production and Use

It has some use in herbicide production.

53.4 Toxic Effects

3,4-Dichloroaniline causes methemoglobinemia in mice and chloracne in humans (2). However, its nephrotoxic effect was relatively low, compared with that of the 3,5-isomer (187). A possible metabolite had some renal toxicity at a high dose (183).

53.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

54.0 3,5-Dichloroaniline

54.0.1 CAS Number: [*626-43-7*]

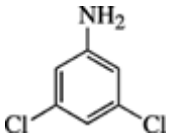
54.0.2 Synonyms: 3,5-Dichlorobenzenamine; *m*-dichloroaniline; BF 352-31

54.0.3 Trade Names: NA

54.0.4 Molecular Weight: 162.02

54.0.5 Molecular Formula: $C_6H_5NCl_2$

54.0.6 Molecular Structure:



Databases and inventories where listed: CCRIS, DART, EINECS, EMICBACK, HSDB, MEDLINE, MESH, TOXLINE, TSCAINV.

54.1 Chemical and Physical Properties (2)

Boiling point	260°C
Melting point	51–53°C
Solubility	Soluble in ethanol, benzene, ether

54.2 Production and Use

No specific uses were located apart from its use in research.

54.4 Toxic Effects

Of all of the dichloroanilines, the 3,5-isomer had the highest nephrotoxic action in F344 rats (187). Further studies examined this effect more throughly. When administered intraperitoneally in dimethyl sulfoxide solution, the rats died within 24 hrs; if given as a solution in saline or sesame oil, no renal toxicity was noted (189). Treatment of rats with various enzyme inducers and inhibitors and then 3,5-dichloroaniline did not cause much change in the renal or hepatic effects of the 3,5-isomer. These results indicated that the parent compound was directly toxic (190). A putative metabolite, 4-amino-2, 6-dichlorophenol, retained the nephrotoxic action of the parent (191). However, another possible metabolite, 3,5-dichlorophenylhydroxylamine, was the most potent inducer of hemoglobin oxidation, the parent 3,5-dichloroaniline was the least active, and 4-amino-2, 6-dichlorophenol was intermediate in activity (192).

54.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

J. Nitroanilines

55.0 2-Nitroaniline

55.0.1 CAS Number: [*88-74-4*]

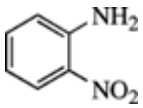
55.0.2 Synonyms: 1-Amino-2-nitrobenzene; 2-nitrobenzenamine; azoene fast orange gr base; azoene fast orange gr salt; azofix orange gr salt; azogene fast orange gr; azoic diazo component 6; brentamine fast orange gr base; brentamine fast orange gr salt; C.I. azoic diazo component 6; devol orange b; diazo fast orange gr; fast orange base gr; fast orange base jr; fast orange gr base; fast orange gr salt; fast orange o base; fast orange o salt; fast orange salt jr; hiltonil fast orange gr base; hiltosal fast orange gr salt; hindasol orange gr salt; natasol fast orange gr salt; *o*-nitraniline; C.I. 37025; orange base ciba ii; orange base irga ii; orange grs salt; orange salt ciba ii; orange salt irga ii

55.0.3 Trade Names: NA

55.0.4 Molecular Weight: 138.13

55.0.5 Molecular Formula: $C_6H_6N_2O_2$

55.0.6 Molecular Structure:



Databases and inventories where listed: DOT, WHMI, CCRIS, DSL, EINECS, EMIC, EMICBACK, HSDB, RTECS, TOXLINE, TSCAINV, SUPERLIST.

55.1 Chemical and Physical Properties (2)

Physical state	Golden yellow to orange rhombic needles
Density	1.442 (20/4°C)
Melting point	69–71.5°C
Boiling point	284.1°C
Solubility	Soluble in ethanol, ether, acetone, benzene; somewhat soluble in water

55.2 Production and Use

2-Nitroaniline is an intermediate for dyestuffs.

55.4 Toxic Effects

Although 2-nitroaniline was not mutagenic in four strains of *Salmonella* (TA97, TA98, TA100, TA102), with or without metabolic activation, it was clastogenic *in vitro* and induced chromosomal aberrations in Chinese hamster ovary cells (193).

55.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

56.0 3-Nitroaniline

56.0.1 CAS Number: [*99-09-2*]

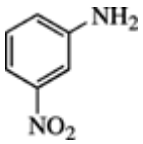
56.0.2 Synonyms: 1-Amino-3-nitrobenzene; 3-nitrobenzenamine; *m*-nitrophenylamine; *m*-nitroaminobenzene; amarthol fast orange r base; *m*-aminonitrobenzene; azobase mna; C.I. 37030; C.I. azoic diazo component 7; daito orange base r; devol orange r; diazo fast orange r; fast orange base r; fast orange m base; fast orange mm base; fast orange r base; hiltonil fast orange r base; naphtoelan orange r base; nitranilin; *m*-nitraniline; orange base irga 1

56.0.3 Trade Names: NA

56.0.4 Molecular Weight: 138.13

56.0.5 Molecular Formula: $C_6H_6N_2O_2$

56.0.6 Molecular Structure:



Databases and inventories where listed: DOT, MTL, WHMI, CCRIS, DSL, EINECS, EMIC, EMICBACK, GENETOX, HSDB, RTECS, TOXLINE, TSCAINV, SUPERLIST.

56.1 Chemical and Physical Properties (2)

Physical state	Yellow rhombic needles
Density	1.430 (20/4°C)
Melting point	114°C
Boiling point	305–307°C
Solubility	Soluble in ethanol, ether; slightly soluble in water

56.2 Production and Use

It is used as an intermediate in the production of dyestuffs.

56.4 Toxic Effects

As reported in the previous edition, 3-nitroaniline causes methemoglobinemia and associated effects; the vapor is toxic, and it is absorbed through the skin (2). A 28-day repeated dose toxicity study in F344 rats has been undertaken (194). Male and female F344 rats received oral doses of 15, 50, or 170 mg/kg/day; lower body weight gain, but no deaths, occurred. Testicular atrophy, reduction in spermatogenesis, hemolytic anemia, and increases in liver, spleen and kidney weight occurred, but ovarian function was not affected. After a 14-day recovery period, the conditions eased or disappeared. The NOEL was less than 15 mg/kg/day.

56.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

57.0 4-Nitroaniline

57.0.1 CAS Number: [*100-01-6*]

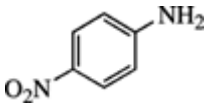
57.0.2 Synonyms: *p*-Aminonitrobenzene; 4-nitrobenzenamine; PNA; C.I. 37035; 1-amino-4-nitrobenzene; *p*-nitrophenylamine; azofix red gg salt; azoic diazo component 37; C.I. developer 17; developer P; devol red gg; diazo fast red gg; fast red base 2j; fast red base gg; fast red 2g base; fast red 2g salt; shinnippon fast red gg base; fast red salt 2j; fast red salt gg; nitrazol cf extra; red 2g base; fast red gg base; fast red mp base; fast red p base; fast red p salt; naphtoelan red gg base; azoamine red 2H; C.I. azoic diazo component 37

57.0.3 Trade Names: NA

57.0.4 Molecular Weight: 138.13

57.0.5 Molecular Formula: $C_6H_6N_2O_2$

57.0.6 Molecular Structure:



Databases and inventories where listed: DOT, IL, MA, MTL, NJ, NTPT, PA, PEL, REL, RQ, TLV, TRI, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, MESH, MEDLINE, RTECS, TOXLINE, TSCAINV, SUPERLIST.

57.1 Chemical and Physical Properties (2)

Physical state	Pale yellow crystals
Specific gravity	1.442
Melting point	146–149°C
Boiling point	331.7°C
Vapor pressure	<1 torr at 20°C
Flash point	198.9°C (closed cup)

57.2 Production and Use
4-Nitroaniline is used in synthesizing dyes, as a corrosion inhibitor, and in synthesizing of antioxidants.
57.3 Exposure Assessment
NMAM IVth ed., 1994, method #5033 NIOSH for determining human exposure.
57.4 Toxic Effects
4-Nitroaniline was tested in a 2-yr study in B6C3F$_1$ mice using doses of 3, 30, or 100 mg/kg/day in corn oil by gavage. At the two higher dose levels, there was some increase in hepatic hemangiomasarcoma in the male mice, leading NTP to conclude that there was equivocal evidence for carcinogenicity. Female mice showed no increase in tumors (195). In the *Salmonella* test, 4-nitroaniline was positive at high levels in TA98 and TA98NR; it was inactive in TA100 and TA100NR (196). In a series of anilines and phenylenediamines, the nitro group had no specific effect on toxicity (196).
57.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV-TWA is 3 mg/m^3 with skin and A4 notations. NIOSH REL is 3 mg/m^3 with skin notation and OSHA PEL is 6 mg/m^3 with skin notation.
58.0 2,6-Dichloro-4-nitroaniline
58.0.1 CAS Number: [*99-30-9*]

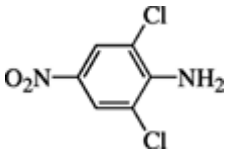
58.0.2 Synonyms: Dicloran; DCNA; Botran 75W; Dichloran; Dicloron; Allisan; ditranil; Kiwi Lustr 277; Resisan; rd-6584; AL-50; U-2069; bortran; CDNA; CNA; Resissan; Botran

58.0.3 Trade Names: NA

58.0.4 Molecular Weight: 207.02

58.0.5 Molecular Formula: $C_6H_4Cl_2N_2O_2$

58.0.6 Molecular Structure:



Databases and inventories where listed: FIFR, NJ, TRI, WHMI, CANCERLIT, CCRIS, DART, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TSCAINV, SUPERLIST.
58.1 Chemical and Physical Properties (2)

Melting point	191°C
Boiling point	275°C
Solubility	Soluble in ethanol, ether, benzene

58.2 Production and Use
Dichloran is used as an agricultural fungicide.
58.4 Toxic Effects
No new information located.
58.5 Standards, Regulations, or Guidelines of Exposure
None assigned.
59.0 4-Chloro-2-nitroaniline
59.0.1 CAS Number: [*89-63-4*]

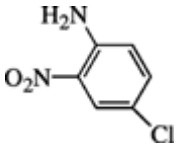
59.0.6 Molecular Structure:



Databases and inventories where listed: CANCERLIT, CCRIS, DSL, EINECS, EMIC, EMICBACK, HSDB, MESH, RTECS, TOXLINE, TSCAINV.

59.1 Chemical and Physical Properties (2)

Physical state	Dark orange crystals
Melting point	116–117°C
Solubility	Soluble in ethanol, ether

59.2 Production and Use

4-Chloro-2-nitroaniline is an intermediate for synthesizing other compounds.

59.4 Toxic Effects

The NTP apparently has done prechronic studies with this compound, but no toxicity technical report was prepared.

59.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

K. Phenylenediamines

60.0 1,2-Phenylenediamine

60.0.1 CAS Number: [*95-54-5*]

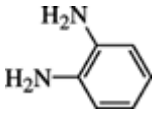
60.0.2 Synonyms: Orthamine; *o*-diaminobenzene; 1,2-diaminobenzene; *o*-phenylenediamine; 1,2-benzenediamine; 2-aminoaniline; C.I. 76010; C.I. oxidation base 16; *o*-phenylendiamine

60.0.3 Trade Names: NA

60.0.4 Molecular Weight: 108.14

60.0.5 Molecular Formula: $C_6H_8N_2$

60.0.6 Molecular Structure:



Databases and inventories where listed: DOT, MA, MTL, NJ, TLV, TRI, WHMI, CANCERLIT, CCRIS, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

60.1 Chemical and Physical Properties (2)

Physical state	Yellow crystals
Melting point	102–104°C
Boiling point	256–258°C
Solubility	Soluble in benzene, ethanol, ether, chloroform; slightly soluble in water

60.2 Production and Use

1,2-Phenylenediamine is used in to synthesize dyes and fungicides and as an oxidative hair and fur dye.

60.4 Toxic Effects

In a plant-based system, 1,2-phenylenediamine had the highest mutagenic activity of the three isomers (197). It is also the only phenylenediamine to show carcinogenic activity.

60.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA is 0.1 mg/m^3 with an A3 notation.

61.0 1,3-Phenylenediamine

61.0.1 CAS Number: [*108-45-2*]

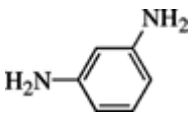
61.0.2 Synonyms: *m*-Diaminobenzene; *meta*-phenylenediamine; Developer C; Developer H; Developer M; Direct Brown GG: Direct Brown BR; 3-aminoaniline; m-benzenediamine; 1,3-benzenediamine; C.I. Developer 11; C.I. 76025; 1,3-diaminobenzene; benzenediamine-1,3; developer 11; apco 2330; MPD

61.0.3 Trade Names: NA

61.0.4 Molecular Weight: 108.14

61.0.5 Molecular Formula: $C_6H_8N_2$

61.0.6 Molecular Structure:



Databases and inventories where listed: DOT, IARC, MA, MTL, NJ, TLV, TRI, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

61.1 Chemical and Physical Properties (2)

Physical state	White rhombic crystals, turn red with air exposure
Density	1.1389 (5°C); 1.107 (58°C)
Melting point	63–64°C
Boiling point	282–284°C
Refractive index	1.63390 (57.7°C)
Solubility	Soluble in water, methanol, acetone, chloroform, dimethylformamide, dioxane, methyl ethyl ketone: slightly soluble in ether, carbon tetrachloride; less soluble in benzene, toluene, xylene

61.2 Production and Use

1,3-Phenylenediamine is used in to synthesize various dyes, as a curing agent for rubber and epoxy resins, as a corrosion inhibitor and as a photographic chemical, petroleum additive, and reagent.

61.4 Toxic Effects

Although 1,3-phenylenediamine is a sensitizer, it was not a teratogen or carcinogen in animal tests. It was less mutagenic than the 1,2-isomer in a plant system (197).

61.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA is 0.1 mg/m^3 with an A4 notation.

62.0 1,4-Phenylenediamine

62.0.1 CAS Number: [*106-50-3*]

62.0.2 Synonyms: *p*-Diaminobenzene; Pelagol D; Renal PF; Futramine D; Fur Black 41866; C.I. Developer 12; Developer PF; PPD; Peltol D; BASF Ursol D; Tertral D; 4-aminoaniline; 1,4-diaminobenzene; phenylhydrazine; 1,4-benzenediamine; *para*-phenylenediamine; C.I. 76076; Orsin; *p*-aminoaniline; phenylenediamine base; Rodol D; Ursol D; *p*-benzenediamine; benzofur d; C.I. 76060; C.I. developer 13; C.I. oxidation base 10; developer 13; durafur black r; fouramine d; fourrine d; fourrine i; fur black r; fur brown 41866; furro d; fur yellow; Mako h; oxidation base 10; pelagol dr; pelagol grey d; santoflex ic

62.0.3 Trade Names: NA

62.0.4 Molecular Weight: 108.14

62.0.5 Molecular Formula: $C_6H_8N_2$

62.0.6 Molecular Structure:

Databases and inventories where listed: CAA1, DOT IARC, IL, MA, MTL, NJ, PA, PEL, REL, RQ, TLV, TRI, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.

62.1 Chemical and Physical Properties (2)

Physical state White to slightly red monoclinic crystals

Melting point	139.7°C
Boiling point	267°C
Solubility	Soluble in ethanol, chloroform, ether, acetone, benzene; slightly soluble in water

62.2 Production and Use

PPDA is used to synthesize dyes and intermediates, in fur and hairdye formulations, and as a photographic developer.

62.3 Exposure assessment

Monitoring of employee exposure may be evaluated by using OSHA method #87.

62.4 Toxic Effects

As discussed previously (2), PPDA is a sensitizer and has toxic effects in humans, but it was not carcinogenic in rats and mice after dietary administration. It was reported that patients with an allergy to PPDA were more likely to be slow acetylators of aromatic amines; no rapid acetylators were in the sensitive group (198). As with other aromatic amines, acetylation is a detoxication mechanism.

An investigation of the mutagenicity of PPDA and derivatives found that mutagenicity and toxicity did not correlate with the oxidation potential (199). Another study of mutagenicity with numerous PPDA derivatives led to the conclusion that the mutagenicity of substituted PPDAs depends both on the substituent groups and their positions in the molecule (200, 201).

62.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA is 0.1 mg/m^3 with an A4 notation; dermatitis and sensitization are listed as critical effects for the TLV.

63.0 2-Nitro-1,4-phenylenediamine

63.0.1 CAS Number: [*5307-14-2*]

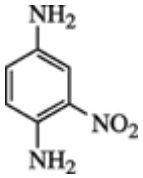
63.0.2 Synonyms: 1,4-Diamino-2-nitrobenzene; *o*-nitro-*p*-phenylenediamine; 4-amino-2-nitroaniline; nitro-*p*-phenylenediamine; 2-nitro-1,4-benzenediamine; 2-nitro-1,4-diaminobenzene; C.I. 76070; durafur brown; C.I. oxidation base 22; durafur brown 2R; Dye gs; fouramine 2R; fourrine 36; fourrine brown 2R; 2-NDB; oxidation base 22; ursol brown rr; zoba brown rr; 2-*n*-*p*-pda; 2-NPPD

63.0.3 Trade Names: NA

63.0.4 Molecular Weight: 153.14

63.0.5 Molecular Formula: $C_6H_7N_3O_2$

63.0.6 Molecular Structure:



Databases and inventories where listed: IARC, MA, NTPT, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

63.1 Chemical and Physical Properties (2, 187)

Physical state	Reddish-brown crystalline powder
Melting point	137–140°C

Solubility Soluble in acetone, ether; slightly soluble in water, ethanol, benzene

63.2 Production and Use

This compound is used in hair and fur dyes.

63.4 Toxic Effects

The oral LD_{50} in an oil/water suspension was 3080 mg/kg body weight in CD rats; the level for i.p. administration in dimethyl sulfoxide was 348 mg/kg body weight; in water, the level was 2100 mg/kg body weight in male Wistar rats. For mice, the i.p. LD_{50} was 214 mg/kg body weight (179).

After an i.p. dose of ^{14}C-labeled compound, 37% of the label was excreted in the urine and 154% in the feces within 24 h.; urinary metabolites identified were N^1, N^4-diacetyl-1,2,4-triaminobenzene (13% of urinary label) and N^4-acetyl-1,4-diamino-2-nitrobenzene (6% of urinary label) (179). This compound was a direct-acting mutagen in the *Salmonella* system (196).

63.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

64.0 4-Nitro-1,2-phenylenediamine

64.0.1 CAS Number: [*99-56-9*]

64.0.2 Synonyms: 1,2-Diamino-4-nitrobenzene; 4-nitro-1,2-benzenediamine; 2-amino-4-nitroaniline; 4-nitro-1,2-diaminobenzene; 4-nitro-*o*-phenylenediamine; 3,4-diaminonitrobenzene; 4-NO; 4-NOP; 4-NOPD; 4-*n*-*o*-pda; 4-NDB; C.I. 76020

64.0.3 Trade Name: NA

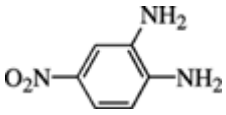
64.0.5 Molecular Formula: $C_6H_7N_3O_2$

64.0.6 Molecular Structure:



Databases and inventories where listed: IARC, NTPT, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

64.1 Chemical and Physical Properties (2, 202)

Physical state Dark red needles

Melting point 199–200°C

Solubility Soluble in acetone; slightly soluble in water

64.2 Production and Use

4-Nitro-1,2-phenylenediamine is used in inks, fur and hair dyes, and as a reagent for determining keto acids and ascorbic acid in foods (202).

64.4 Toxic Effects

This compound was not carcinogenic when given in the diet to rats and mice for two years (2), but it was a direct-acting mutagen in *Salmonella* (196), and it induced chromatid breaks and chromosomal aberrations in certain cell lines (202).

64.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

65.0 4-Chloro-1,2-phenylenediamine
65.0.1 CAS Number: [*95-83-0*]

66.1 Chemical and Physical Properties (2,209)

Physical state	Crystals
Melting point	91°C
Solubility	Soluble in ethanol; slightly soluble in water; insoluble in petroleum ether

66.2 Production and Use

This compound has uses in dye production and in rubber processing.

66.4 Toxic Effects

The effects of 4-chloro-1,3-phenylenediamine have been discussed (2, 203), and no new information was located.

66.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

67.0 2-Chloro-1,4-phenylenediamine

67.0.1 CAS Number: [*615-66-7*]

67.0.2 Synonyms: 2-Chloro-*p*-phenylenediamine; 2-chloro-1-4-benzenediamine

67.0.3 Trade Name: NA

67.0.4 Molecular Weight: 142.06

67.0.5 Molecular Formula: $C_6H_7N_2Cl$

67.0.6 Molecular Structure: NA

Databases and inventories where listed: WHMI, DART, EINECS, EMIC, EMICBACK, ETICBACK, HSDB, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

67.1 Chemical and Physical Properties (2)

67.2 Production and Use

This compound had some uses in hair dye formulations.

67.4 Toxic Effects

The previous edition mentioned that this compound was not carcinogenic in rats or mice in two-year feeding studies. No new information was located.

67.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

68.0 2,6-Dichloro-1,4-phenylenediamine

68.0.1 CAS Number: [*609-20-1*]

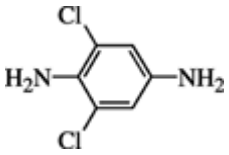
68.0.2 Synonyms: 1,4-Diamino-2,6-dichlorobenzene; 2,6-dichloro-1,4-benzenediamine; 2,5-diamino-1,3-dichlorobenzene; C.I. 37020; daito brown salt rr; fast brown rr salt; 2,6-dichloro-*para*-phenylenediamine

68.0.3 Trade Names: NA

68.0.4 Molecular Weight: 177.03

68.0.5 Molecular Formula: $C_6H_6Cl_2N_2$

68.0.6 Molecular Structure:



Databases and inventories where listed: IARC, NTPT, CANCERLIT, CCRIS, DART, EINECS, EMIC, EMICBACK, HSDB, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

68.1 Chemical and Physical Properties (204)

Physical state	Gray, microcrystalline powder, needles or prisms
Melting point	124–126°C
Solubility	Soluble in acetone, benzene, ethanol, ether

68.2 Production and Use

The compound has been used as an intermediate for dyes, to some extent in preparing certain polyamide fibers, and as a curing agent for polyurethane (204).

68.4 Toxic Effects

No new information on toxicity was located. 2,6-Dichloro-1,4-phenylenediamine is a metabolite of the herbicide/fungicide 2,6-dichloro-4-nitroaniline in humans, monkeys, goats, dogs, mice, rats, and bacteria (204).

68.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

L. Aminophenols

69.0 2-Aminophenol

69.0.1 CAS Number: [*95-55-6*]

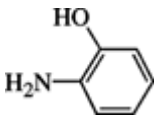
69.0.2 Synonyms: 2-Amino-1-hydroxybenzene; basf ursol 3 ga; benzofur gg; C.I. 76520; C.I. oxidation base 17; fouramine op; *o*-hydroxyaniline; nako yellow 3 ga; paradone olive green b; pelagol 3 ga; pelagol grey gg; zoba 3 ga; 2-aminobenzenol

69.0.3 Trade Name: NA

69.0.4 Molecular Weight: 109.13

69.0.5 Molecular Formula: C_6H_7NO

69.0.6 Molecular Structure:



Databases and inventories where listed: DOT, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

69.1 Chemical and Physical Properties (2)

Physical state	Colorless rhombic needles or plates
Melting point	170–174°C
Boiling point	Sublimes
Solubility	Soluble in ethanol, ether; somewhat soluble in water

69.2 Production and Use

2-Aminophenol is used as a dye intermediate, in fur and hair dyes, and in making cosmetics and drugs.

69.4 Toxic Effects

Compared with 4-aminophenol, 2-aminophenol induced only mild changes in renal function (181). A comprehensive review of the toxicology and biological properties, including absorption, distribution, metabolism, and excretion of the three isomeric aminophenols, has appeared (205).

69.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

70.0 3-Aminophenol

70.0.1 CAS Number: [*591-27-5*]

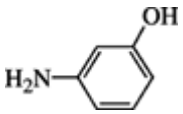
70.0.2 Synonyms: 3-Amino-1-hydroxybenzene; 3-hydroxyaniline; *m*-hydroxyaminobenzene; basf ursol bg; C.I. 76545; C.I. oxidation base 7; fouramine eg; fourrine 65; fourrine eg; furro eg; futramine eg; nako teg; pelagal eg; renal eg; tetral eg; ursol eg; zoba eg; *m*-hydroxyphenylamine

70.0.3 Trade Name: NA

70.0.4 Molecular Weight: 109.13

70.0.5 Molecular Formula: C_6H_7NO

70.0.6 Molecular Structure:



Databases and inventories where listed: DOT, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMICBACK, ETICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

70.1 Chemical and Physical Properties (2)

Physical state	Colorless prisms
Melting point	122–123°C
Solubility	Soluble in ethanol, ether, water

70.2 Production and Uses

3-Aminophenol is an intermediate in the production of photographic and pharmaceutical chemicals, and in synthesizing dyes. It is also a stabilizer of chlorine-containing thermoplastics (206).

70.4 Toxic Effects

The toxicity of 3-aminophenol has been reviewed (2, 205). It is the least toxic of the three isomers.

Intraperitoneal administration (100 to 200 mg/kg) of *m*-aminophenol to Syrian golden hamsters on day 8 of gestation produced inconsistent results. A teratogenic response was demonstrated, expressed as a percentage of the total number of litters with one or more live fetuses, at a dose of 150 mg/kg in only one (six malformed fetuses) of six litters, and teratogenicity was not evident at a dose of 200 mg/kg (207).

In a follow-up teratology study in which Sprague–Dawley rats were fed a diet of 0.1, 0.25, and 1.0% for 90 days prior to mating, maternal toxicity was demonstrated at the highest dose level, and a significant reduction in body weight was noted in the 0.25% group, but there was no evidence of teratogenic or embryo-fetal toxicity at any dose level tested. Accumulation of iron-positive pigment within the liver, kidneys, and spleen was observed in dams fed a 1% diet, together with significant reduction in red blood cell count and hemoglobin level, as well as an increase in mean corpuscular volume, indicating a hemolytic effect; histomorphologic appearance of the thyroid indicated hyperactive activity (at 0.25 and 1.0% diet) (208). In contrast to *o*- and *p*-aminophenol and their glucuronides, neither *m*-aminophenol nor its conjugate with glucuronic acid forms methemoglobin *in vitro* (2).

70.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

71.0 4-Aminophenol

71.0.1 CAS Number: [*123-30-8*]

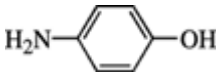
71.0.2 Synonyms: *p*-Hydroxyaniline; 4-amino-1-hydroxybenzene; Azol; Certinal; Citol; Paranol; Rodinal; Unal; Ursol P; paramidophenol; Kodelon; Energol; Freedol; Indianol; Kathol; basf ursol p base; benzofur p; C.I. oxidation base 6a; fouramine p; fourrine 84; PAP; Pelagol grey p base; tertral p base; ursol p base; zoba brown p base; C.I. 76550; durafur brown rb; fourrine p base; furro p base; nako brown r; pelagol p base; renal ac; 4-hydroxyaniline; 4-aminobenzenol

71.0.3 Trade Names: NA

71.0.4 Molecular Weight: 109.13

71.0.5 Molecular Formula: C_6H_7NO

71.0.6 Molecular Structure:



Databases and inventories where listed: DOT, MTL, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

71.1 Chemical and Physical Properties (2)

Physical state	Colorless prisms
Melting point	189.6–190.2°C

71.2 Production and Use

4-Aminophenol is used in preparing dyes and photographic chemicals; the *N*-acetyl derivative is a widely used analgesic.

71.4 Toxic Effects

4-Aminophenol is the most toxic of the three isomers (205, 206) and is the nephrotoxic metabolite of aniline and the medicinal agent acetaminophen (2). Examination of the mechanism of the effect of 4-aminophenol has yielded some conflicting views. Nephrotoxicity has been linked to the 4-

aminophenol 3-*S*-glutathionyl conjugate which was more toxic than the parent 4-aminophenol (209, 210).

These toxicants are formed endogenenously (211). 4-Aminophenol caused selective necrosis to the pars recta of the proximal tubules of the kidney (212), but ascorbic acid decreased the degree of oxidation of the aminophenol and the toxic effect (213). It was postulated that a 4-aminophenoxy free radical formed that was converted to a benzoquinoneimine which binds to cellular macromolecules. However, incubation of renal tubules with 4-aminophenol caused relatively little effect (214), which strengthened the concept that glutathione conjugates rather than autooxidation in the kidney are responsible.

71.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

72.0 2-Amino-5-nitrophenol

72.0.1 CAS Number: [*121-88-0*]

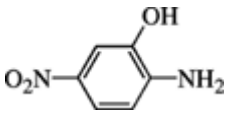
72.0.2 Synonyms: 2-Hydroxy-4-nitroaniline; 5-nitro-2-aminophenol; C.I. 76535; rodol yba; ursol yellow brown a

72.0.3 Trade Names: NA

72.0.4 Molecular Weight: 154.13

72.0.5 Molecular Formula: $C_6H_6N_2O_3$

72.0.6 Molecular Structure:



Databases and inventories where listed: IARC, NTPT, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

72.1 Chemical and Physical Properties

Physical state	Olive-brown to orange crystals
Melting point	207–208°C
Solubility	Soluble in acetone, benzene, ethanol; slightly soluble in water

72.2 Production and Use

2-Amino-5-nitrophenol is used in hair dyes and as an intermediate in preparing azo dyes (187).

72.4 Toxic Effects

The toxicity of 2-amino-5-nitrophenol is relatively low (LD_{50} over 4000 mg/kg orally) (179). The compound has been studied in a two-year test in rats and mice and was not active in mice. Some tumors were noted in male rats but were not convincing (179).

72.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

73.0 2-Amino-4-nitrophenol

73.0.1 CAS Number: [*99-57-0*]

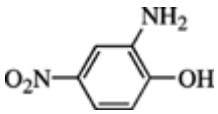
73.0.2 Synonyms: 3-Amino-4-hydroxynitrobenzene; 2-hydroxy-5-nitroaniline; p-nitro-o-aminophenol; C.I. 76530; ursol 4 gl

73.0.3 Trade Names: NA

73.0.4 Molecular Weight: 154.13

73.0.5 Molecular Formula: $C_6H_6N_2O_3$

73.0.6 Molecular Structure:



Databases and inventories where listed: IARC, NTPT, CANCERLIT, CCRIS, DART, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, SUPERLIST, TOXLINE, TSCAINV.

73.1 Chemical and Physical Properties (179)

Physical state	Yellow-brown to orange prisms
Melting point	143–145°C
Solubility	Soluble in acetone, acetic acid, ethanol, ether; slightly soluble in water

73.2 Production and Use

2-Amino-4-nitrophenol is used in preparing some mordant dyes and in some hair dyes (179).

73.4 Toxicity

This compound was tested (by gavage) at doses up to 250 mg/kg body weight for two years in F344 rats and B6C3F$_1$ mice (179). The incidence of tumors in mice was not increased, but in male rats there was a low but still significant (p = .035) incidence of renal tubular-cell adenomas. Nephropathy was also observed in the male rats. The compound was mutagenic in bacteria, fungi, and cultured mammalian cells. It also led to sister chromatid exchange and chromosomal aberrations in mammalian cells (179).

73.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

M. Toluenediamines

There are six possible toluenediamines formed from nitration of toluene. The commercial mixture contains about 28% of the 2,4-isomer, 18% of the 2,6-isomer with lesser amounts of the others.

74.0 2,3-Toluenediamine

74.0.1 CAS Number: [*2687-25-4*]

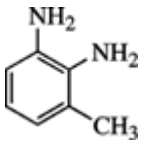
74.0.2 Synonyms: Toluene-2,3-diamine; 2,3-diaminotoluene; 3-methyl-1,2-benzenediamine

74.0.3 Trade Names: NA

74.0.4 Molecular Weight: 122.17

74.0.5 Molecular Formula: $C_7H_{10}N_2$

74.0.6 Molecular Structure:



Databases and inventories where listed: CANCERLIT, CCRIS, EINECS, EMICBACK, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV.

74.1 Chemical and Physical Properties (2)

Boiling point	255°C
Melting point	63–64°C
Solubility	Soluble in water, ethanol, ether

74.2 Production and Use

No specific applications were found except for research purposes.

74.4 Toxic Effects

In a series of toluenediamines, the 2,3-isomer was most active as an inducer of CYP 1A (215).

74.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

75.0 2,4-Toluenediamine

75.0.1 CAS Number: [*95-80-7*]

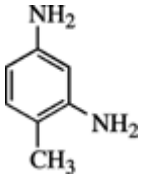
75.0.2 Synonyms: Toluene-2,4-diamine; toluenediamine; 2,4-diaminotoluene; 4-methyl-1,3-benzenediamine; 3-amino-*p*-toluidine; 5-amino-*o*-toluidine; tolylene-2,4-diamine; 1,3-diamino-4-methylbenzene; 2,4-diamino-1-methylbenzene; 2,4-diamino-1-toluene; 2,4-diaminotoluol; 4-methyl-*m*-phenylenediamine; C.I. 76035; C.I. oxidation base; C.I. oxidation base 20; C.I. oxidation base 35; C.I. oxidation base 200; developer 14; developer b; developer db; developer dbj; developer mc; developer mt; developer mt-cf; developer mtd; developer t; azogen developer h; benzofur mt; eucanine gb; fouramine; fouramine j; fourrine 94; fourrine m; MTD; nako tmt; pelagol j; pelagol grey j; pontamine developer tn; renal md; Tertral g; zoba gke; zogen developer h; 4-methylphenylene-1,3-diamine, TDA

75.0.3 Trade Names: NA

75.0.4 Molecular Weight: 122.17

75.0.5 Molecular Formula: $C_7H_{10}N_2$

75.0.6 Molecular Structure:



Databases and inventories where listed: CAA1, CA65, CGB, CGN, DOT, IARC, IL, MA, MI, MTL, NJ, NTPA, NTPT, PA, REL, RQ, TRI, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

75.1 Chemical and Physical Properties (2)

Physical state	Colorless needles
Melting point	99°C
Boiling point	292°C
Solubility	Soluble in water, ethanol, ether

75.2 Production and Use

The major use of toluenediamine is in producing toluene diisocyanate (TDI), the most important diisocyanate in the flexible polyurethane foam and elastomers industry. The use in hair dye formulations has generally been discontinued, but it is used in some other dyes.

75.3 Exposure Assessment

NMAM IVth ed., 1994 Method #5516.

75.4 Toxic Effects

Overt exposure in humans may lead to methemoglobinemia, especially when red blood cell-reducing mechanisms are impaired, such as in G6PD deficiency which occurs in humans in the absence of glutathione reductase, glutathione, or glutathione peroxidase, eye irritation that may cause corneal damage, and delayed skin irritation.

Reproductive toxicity in the rat has been demonstrated. Reduced fertility, arrested spermatogenesis, and diminished circulating testosterone levels have resulted in rats fed 0.03% 2,4-toluenediamine; electron microscopy revealed degenerative changes in Sertoli cells and a decrease in epididymal sperm reserves; after 3 weeks of 0.06% TDA feeding, sperm counts were further reduced and accompanied by a dramatic increase in testes weight, intense fluid accumulation, and ultrastructural changes in the Sertoli cells (216). In previous studies, testicular atrophy, hormonal effects, and aspermatogenesis were also observed in Sprague–Dawley rats given a 0.1% diet for 9 weeks (217, 218). However, epidemiological studies of workers exposed to commercial mixtures of dinitrotoluene and/or toluenediamine at three chemical plants indicated that the fertility of men had not been reduced significantly and reported no observable effects on the fertility of workers (152, 219).

2,4-Toluenediamine (and 2,6-toluenediamine) is mutagenic in the Ames assay requiring metabolic activation in the presence of S-9; it gave weakly positive results in the micronucleus test; however, this weak effect was detectable only at very toxic doses, and therefore the biological relevance is questionable. Thus the micronucleus test did not discriminate correctly between the carcinogenic 2,4- and the noncarcinogenic 2,6-toluenediamine (220, 221).

When 2,4-toluenediamine was administered in the diet to male and female F344 rats (79 ppm or 170 ppm) or B6C3F_1 mice (100 ppm or 200 ppm), hepatocellular carcinomas were produced in female mice, hepatocellular carcinomas in male rats, and mammary adenomas or carcinomas in female rats, but no carcinomas in the male mice (222). Male Wistar rats also reportedly developed hepatocarcinomas following treatment with 2,4-toluenediamine (223). A skin painting study in Swiss-Webster mice was reportedly noncarcinogenic (224). However, mice are less sensitive than rats; this may be based upon differences in metabolism (225). Biliary tract cancer, although reported in industrial workers was not increased significantly (226).

The IARC working group considered that although there are no human data for evaluation, there are sufficient animal data to classify 2,4-toluenediamine as a Group 2B compound—an agent possibly carcinogenic to humans (227).

2,4-TDA decreased somewhat the immune response of female B6C3F_1 mice given 25–100 mg/kg for 14 days (228). Most of the toxicity studies have attempted to elucidate the differences in mechanism of action between 2,4-TDA and the inactive 2,6 counterpart. In a liver microsomal system, 2,4-TDA was mutagenic, induced CYP 1A, and bound to the Ah receptor, whereas the other isomers were much less active (215). *In vivo*, 2,4-TDA had twice the mutagenic activity of 2,6-TDA,

which showed values like the controls (229).

2,4-TDA formed adducts with poly-d-(G) or poly-d-(C-G) in an *in vitro* assay, indicating that binding of 2,4-TDA to DNA involved guanine (230). Similarly, 2,4-TDA induced 6500 more DNA adducts in rat liver than the noncarcinogen 2,6-TDA (231). Although both of these isomers led to hemoglobin binding in F344 rats, only 2,4-TDA caused DNA adducts (231, 232).

2,4-TDA is the main starting material for TDI which is used in polyurethane foam production. These foams have been crafted into covers for breast implants; thus there is considerable interest in the ultimate fate of TDI and the possible release of 2,4-TDA from the implant. On a comparative basis, rats given labeled 2,4-TDA, either orally or intravenously, excreted 60–70% in the urine, as mono- and diacetyl derivatives, 20–30% in the feces, and only about 2% was retained in the carcass. In contrast, rats that inhaled labeled TDI retained all of the radioactivity from the TDI (233). Rats implanted with a TDI-polyester polyurethane foam did not form DNA adducts in the T lymphocytes, whereas rats fed 2,4-TDA formed DNA adducts in liver or mammary glands (234). In patients who had received breast implants covered with polyurethane, there was a lag period of 20–30 days; after this 2,4-TDA and 2,6-TDA were detected in plasma at levels up to 4 ng/mL and 1.5 ng/mL, respectively, up to two years after the implant (235). This demonstrated that the arylamines can be released slowly from the polyurethane products.

75.5 Standards, Regulations, or Guidelines of Exposure

NIOSH consider 2,4-TDA a carcinogen with lowest feasible exposure.

76.0 2,5-Toluenediamine

76.0.1 CAS Number: [*95-70-5*]

76.0.2 Synonyms: 2,5-Diaminotoluene; 2-methyl-1,4-benzenediamine

76.0.3 Trade Names: NA

76.0.4 Molecular Weight: 122.17

76.0.5 Molecular Formula: $C_7H_{10}N_2$

76.0.6 Molecular Structure: NA

Databases and inventories where listed: IARC, WHMI, CANCERLIT, DART, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

76.1 Chemical and Physical Properties (2)

Physical state	Colorless plates
Boiling point	273–274°C
Melting point	64°C
Solubility	Soluble in water, ethanol, ether, hot benzene

76.2 Production and Use

2,5-Toluenediamine is used in hair and fur dyes.

76.4 Toxic Effects

The sulfate salt of 2,5-toluenediamine was not carcinogenic in rats and mice (2). Likewise, it did not bind to the Ah receptor, induce CYP 1A, or have appreciable mutagenic activity (215).

76.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

77.0 2,6-Toluenediamine

77.0.1 CAS Number: [*823-40-5*]

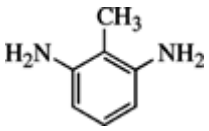
77.0.2 Synonyms: 2-Methyl-1,3-benzenediamine; 2,6-diaminotoluene; 1,3-diamino-2-methylbenzene; 2-methyl-*m*-phenylenediamine; 2,6-tolylenediamine; 2,6-diamino-1-methylbenzene; 2-methyl-1,3-phenylenediamine; 2,6-toluylenediamine; toluene-2,6-diamine

77.0.3 Trade Names: NA

77.0.4 Molecular Weight: 122.17

77.0.5 Molecular Formula: $C_7H_{10}N_2$

77.0.6 Molecular Structure:



Databases and inventories where listed: MA, PA, RQ, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

77.1 Chemical and Physical Properties (2)

Physical state	Colorless prisms
Melting point	106°C
Solubility	Soluble in water, ethanol

77.2 Production and Uses

2,6-Toluenediamine is used primarily for making TDI.

77.4 Toxic Effects

2,6-Toluenediamine induced formation of hemoglobin but not DNA adducts when given to F344 rats (231, 232). Likewise, it did not form DNA adducts in an *in vivo* system using transgenic mice (229). However, in a rat liver microsomal system (induced by Aroclor 1254), 2,6-toluenediamine was a potent mutagen, but it did not induce CYP 1A or bind the Ah receptor (215). An unexplained dichotomy is why 2,6-dinitrotoluene is a carcinogen, but the corresponding diamine is not.

77.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

78.0 3,4-Toluenediamine

78.0.1 CAS Number: [*496-72-0*]

80.1 Chemical and Physical Properties (2)

Physical state	Light yellow to reddish brown liquid
Density	0.9984 (20/4°C)
Melting point	–14.7°C
Boiling point	200.2°C
Refractive index	1.57276 (20°C)
Solubility	Soluble in ethanol, ether; slightly soluble in water

80.2 Production and Use

o-Toluidine and the hydrochloride salt are used as intermediates in manufacturing dyes, pharmaceuticals, pesticides, and in vulcanizing rubber.

80.3 Exposure Assessment

NMAM IV ed., 1994 Method #2002.

80.4 Toxic Effects

o-Toluidine was carcinogenic in animals and is suspected as being responsible for bladder cancers in exposed workers (168). However, it has been noted that the workers were also exposed to many other chemicals, and *o*-toluidine could not be identified specifically as the responsible agent (203, 236).

80.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA is 2 ppm with skin and A3 notations. The OSHA PEL is 6 ppm with a skin notation and NIOSH recommends lowest feasible exposure because it considers it a carcinogen.

81.0 **m**-Toluidine

81.0.1 CAS Number: [*108-44-1*]

Melting point	–30°C
Boiling point	203.3°C
Vapor pressure	1 torr at 41°C
Solubility	Soluble in acetone, ethanol, ether, benzene

81.2 Production and Use

m-Toluidine is used in dye production.

81.3 Exposure Assessment

Use NMAM, IVed., 1994 Method #2002.

81.4 Toxic Effects

m-Toluidine causes methemoglobinemia in exposed humans, but it was not carcinogenic in animals, even at high doses (2). No additional data were located.

81.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA is 2 ppm with skin and A4 notations.

82.0 **p**-Toluidine

82.0.1 CAS Number: [*106-49-0*]

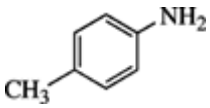
82.0.2 Synonyms: 4-Aminotoluene; 4-methylaniline; naphthol as-kgll; 4-methylbenzenamine

82.0.3 Trade Names: NA

82.0.4 Molecular Weight: 107.15

82.0.5 Molecular Formula: C_7H_9N

82.0.6 Molecular Structure:



Databases and inventories where listed: CA65, DOT, IL, MA, MTL, PA, PELS, REL, RQ, TLV, WHMI, CANCERLIT, CCRIS, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

82.1 Chemical and Physical Properties (2)

Physical state	Leaflets
Melting point	44–45°C
Boiling point	200.5°C
Refractive index	1.55324 (59.1°C)
Density	0.9619 (20/4°C); 0.973 (50/50°C)
Flash point	86°C (closed cup)
Specific gravity	1.046 (20°C)
Vapor pressure	1 torr at 42°C
Solubility	Soluble in ethanol, ether, methanol, carbon disulfide; somewhat soluble in water

82.2 Production and Use

p-Toluidine is used in the synthesis of dyes, as an intermediate, and as a reagent.

82.3 Exposure Assessment

NMAM, IV ed., 1994, Method #2002.
82.4 Toxic Effects
p-Toluidine caused methemoglobinemia and hematuria in exposed humans; it caused liver tumors in mice, but was not effective in rats. No new information was located in the literature.
82.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV-TWA is 2 ppm with skin and A3 notations. NIOSH considers it a carcinogen and recommends lowest feasible exposure limit.
83.0 4-Chloro-o-toluidine
83.0.1 CAS Number: [*95-69-2*]

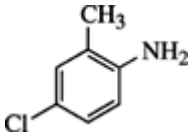
83.0.2 Synonyms: 4-Chloro-2-methylaniline; *para*-chloro-*ortho*-toluidine; 4-chloro-2-methylbenzenamine; 2-amino-5-chlorotoluene; azoene fast red tr base; brentamine fast red tr base, 5-chloro-2-aminotoluene; 4-chloro-6-methylaniline; daito red base tr; deval red k; deval red tr; deazo fast red tra; fast red base tr, fast red 5ci base; fast red tr 11; fast red tr. base; kako red tr base; kambamine red tr; 2-methyl-4-chloroaniline; mitsui red tr base; red base nir; red tr base; sonya fast red tr base; tula base fast red tr

83.0.3 Trade Names: NA

83.0.4 Molecular Weight: 141.60

83.0.5 Molecular Formula: C_7H_8ClN

83.0.6 Molecular Structure:



Databases and inventories where listed: CA65, IARC, MA, NJ, PA, TRI, WHMI, CANCERLIT, CCRIS, EINECS, EMIC, EMICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.
83.1 Chemical and Physical Properties

Physical state	Leaflets
Melting point	29–30°C
Boiling point	241°C
Specific gravity	1.14
Solubility	Soluble in ethanol

83.2 Production and Uses
4-Chloro-*o*-toluidine is used to produce dyes and pesticides.
83.4 Toxic Effects
4-Chloro-*o*-toluidine led to hemangiosarcomas when fed to mice as the hydrochloride salt; rats had increases in pituitary and adrenal tumors (237). In workers who had been exposed for many years, there were increases in bladder tumors (237). Testing in *Salmonella*, human lymphocytes, and V79 cells (238) showed little action in mammalian cells, but with microsomal activation, there was activity in *Salmonella*. Apparently, chlorines on the ring system of toluidine led toward increased hydroxylation of the side chain (239).
82.5 Standards, Regulations, or Guidelines of Exposure
None assigned.
84.0 5-Chloro-**o**-toluidine
84.0.1 CAS Number: [*95-79-4*]

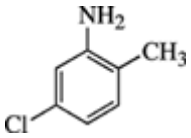
84.0.2 Synonyms: 5-Chloro-2-methylaniline; 5-chloro-2-methylbenzenamine; 2-amino-4-chlorotoluene; 1-amino-3-chloro-6-methylbenzene; 4-chloro-2-aminotoluene; 3-chloro-6-methylaniline; acco fast red kb base; ansibase red kb; azoic diazo component 32; azoene fast red kb base; fast red kb amine; fast red kb base; fast red kb salt; fast red kb salt supra; fast red kbs salt; genazo red kb soln; hiltonil fast red kb base; lake red bk base; metrogen red former kb soln; napthosol fast red kb base; pharmazoid red kb; red kb base; spectrolene red kb; stable red kb base; C.I. azoic diazo component No. 32; C.I. 37090; 2-methyl-5-chloroaniline; 5-chloro-2-methyl-benzamine

84.0.3 Trade Names: NA

84.0.4 Molecular Weight: 141.60

84.0.5 Molecular Formula: C_7H_8ClN

84.0.6 Molecular Structure:



Databases and inventories where listed: MA, MI, NTPT, CCRIS, EINECS, EMIC, EMICBACK, GENETOX, HSDB, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

84.1 Chemical and Physical Properties

Physical state	Off-white solid or light brown oil
Melting point	20–22°C
Boiling point	237°C

84.2 Production and Use

The compound is used in synthesizing dyes.

84.4 Toxic Effects

The compound was not carcinogenic in the rats when fed to rats and mice for up to two years, but it led to a positive response in both male and female mice.

84.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

85.0 6-Chloro-**o**-toluidine

85.0.1 CAS Number: [*87-63-8*]

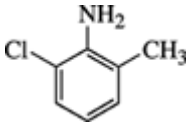
85.0.2 Synonyms: 2-Chloro-6-methylaniline; 2-chloro-6-methylbenzenamine; 2-amino-3-chlorotoluene; 6-chloro-2-methylaniline

85.0.3 Trade Names: NA

85.0.4 Molecular Weight: 141.60

85.0.5 Molecular Formula: C_7H_8ClN

85.0.6 Molecular Structure:



Datebases and inventories where listed: DSL, EINECS, EMICBACK, RTECS, TOXLINE, TSCAINV. No other information on this isomer was located.

86.0 5-Nitro-**o**-toluidine

86.0.1 CAS Number: [*99-55-8*]

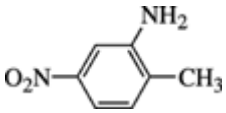
86.0.2 Synonyms: 2-Methyl-5-nitrobenzenamine; 2-methyl-5-nitroaniline; 2-amino-4-nitrotoluene; 1-amino-2-methyl-5-nitrobenzene; 4-nitro-2-aminotoluene; amarthol fast scarlet g base; amarthol fast scarlet g salt; azoene fast scarlet gc base; azoene fast scarlet gc salt; azofix scarlet g salt; azogene fast scarlet g; C.I. 37105; C.I. azoic diazo component 12; dainichi fast scarlet g base; daito scarlet base g; devol scarlet b; devol scarlet g salt; diabase scarlet g; diazo fast scarlet g; fast red sg base; fast scarlet base g; fast scarlet base j; fast scarlet g; fast scarlet g base; fast scarlet gc base; fast scarlet j salt; fast scarlet mN4t base; fast scarlet t base; hiltonil fast scarlet g base; hiltonil fast scarlet gc base; hiltonil fast scarlet g salt; kayaku scarlet g base; lake scarlet g base; lithosol orange r base; mitsui scarlet g base; naphthanil scarlet g base; naphtoelan fast scarlet g base; naphtoelan fast scarlet g salt; PNOT; scarlet base ciba ii; scarlet base irga ii; scarlet base nsp; scarlet g base; sugai fast scarlet g base; symulon scarlet g base; Fast Red G Base

86.0.3 Trade Names: NA

86.0.4 Molecular Weight: 152.15

86.0.5 Molecular Formula: $C_7H_8N_2O_2$

86.0.6 Molecular Structure:



Databases and inventories where listed: IARC, MA, NJ, NTPT, PA, RQ, TRI, WHMI, CANCERLIT, CCRIS, EINECS, EMIC, EMICBACK, HSDB, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

86.1 Chemical and Physical Properties

Physical state	Yellow monoclinic prisms
Melting point	107–108°C
Solubility	Soluble in acetone, benzene, ether, ethanol, chloroform
Solubility in water	1 g/100 mL at 19°C

86.2 Production and Use

5-Nitro-*o*-toluidine is used in the synthesis of numerous dyes.

86.4 Toxic Effects

5-Nitro-*o*-toluidine was carcinogenic in mice and caused liver tumors; in rats there was a weak effect in males (237). The compound was mutagenic in several strains of *Salmonella*.

86.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

O. Anisidines
87.0 **o**-Anisidine
87.0.1 CAS Number: [*90-04-0*]

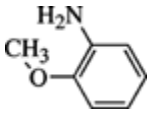
87.0.2 Synonyms: 2-Methoxybenzenamine; *o*-methoxyaniline; 2-anisidine; 2-methoxy-1-aminobenzene; 1-amino-2-methoxybenzene; *o*-anisylamine; *o*-methoxyphenylamine; *o*-aminophenol methyl ether; *o*-aminoanisole

87.0.3 Trade Names: NA

87.0.4 Molecular Weight: 123.15

87.0.5 Molecular Formula: C_7H_9NO

87.0.6 Molecular Structure:



Databases and inventories where listed: CAA1, CA65, IARC, IL, MA, MI, MPOL, MTL, NJ, PA, REL, TLV, TRI, WHMI, CANCERLIT, CCRIS, DSL, EINECS, EMIC, EMICBACK, GENETOX, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.
87.1 Chemical and Physical Properties (209)

Physical state	Yellowish liquid
Boiling point	224°C
Melting point	6.2°C
Density	1.0923
Refractive index	1.5713
Specific gravity	1.092
Solubility	Soluble in acetone, benzene, ether, ethanol; slightly soluble in water

87.2 Uses
The compound has been used in synthesizing dyes.
87.3 Exposure Assessment
For determining human exposure, the NMAM #2514 in the IV ed. is recommended.
87.4 Toxic Effects
When fed in the diet at levels of 2500 or 5000 mg/kg (as the hydrochloride salt), *o*-anisidine induced carcinomas of the bladder in male and female B6C3F$_1$ mice (203). F344 rats at levels of 5000 or 10,000 mg/kg of the salt showed a high incidence of bladder tumors in both males and females. Males also had an increased incidence of thyroid tumors. However, although *o*-anisidine was mutagenic in *Salmonella* (in the presence of a microsomal activating system), it was not genotoxic in four rat and two mouse strains in such tests as the micronucleus test, unscheduled DNA synthesis, and DNA single-strand breaks (45). Furthermore, even though *o*-anisidine was a bladder carcinogen in transgenic mice, there was no evidence of DNA binding, using two different isotopic labeling systems (240).
87.5 Standards, Regulations, or Guidelines of Exposure

The TLV-TWA is 0.1 ppm with skin and A3 notations. NIOSH considers it a carcinogen with a REL of 0.5 ppm. The OSHA PEL is also 0.5 ppm.

88.0 **p**-Anisidine

88.0.1 CAS Number: [*104-94-9*]

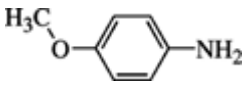
88.0.2 Synonyms: 4-Methoxybenzenamine, *p*-methoxyaniline, *p*-aminoanisole, 1-amino-4-methoxybenzene, *p*-anisylamine, *p*-methoxyphenylamine, 4-methoxy-1-aminobenzene

88.0.3 Trade Names: NA

88.0.4 Molecular Weight: 123.15

88.0.5 Molecular Formula: C_7H_9NO

88.0.6 Molecular Formula:



Databases and inventories where listed: IARC, IL, MA, MTL, NJ, PA, REL, TLV, TRI, WHMI, CANCERLIT, CCRIS, DSL, EINECS, EMIC, EMICBACK, HSDB, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

88.1 Chemical and Physical Properties (209)

Physical state	Crystals
Boiling point	243°C
Melting point	57.2°C
Density	1.071
Solubility	Soluble in acetone, benzene, ether, ethanol, water

88.2 Production and Use

p-Anisidine is used mostly for producing dyes, and some smaller quantities are employed in making pharmaceuticals and liquid crystals (203).

88.3 Exposure assessment

To determine a potential exposure to *p*-anisidine, NIOSH method #2514 found in NMAM IV can be used.

88.4 Toxic Effects

p-Anisidine is not very toxic; the LD_{50} ranged from 810 to 1300 mg/kg body weight in mice, 1400 mg/kg in rats and 2900 mg/kg in rabbits (203). When fed in the diet (as the hydrochloride salt) at levels of 5000 or 10,000 mg/kg for 103 weeks, B6C3F_1 mice showed some depression in body weight gain but no increases in tumor incidence. Under similar conditions at dietary levels of 3000 or 6000 mg/kg, F344 rats also had no increases in tumor incidence, although body weight gain was depressed. Results from tests for mutagenicity in the *Salmonella* system are conflicting (203).

88.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA is 0.1 ppm with A4 and skin notations. NIOSH considers it a carcinogen with a REL of 0.5 ppm. The OSHA PEL is also 0.5 ppm.

89.0 Xylidines

89.0.1 CAS Number: [*1300-73-8*]

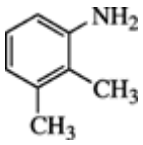
89.0.2 Synonyms: Xylidine isomers; aminodimethylbenzene (mixed isomers); xylidine (mixed isomers); dimethylaminobenzene; dimethylaniline (mixture); benzenamine, ar,ar-dimethyl-; aminodimethylbenzene.

89.0.3 Trade Names: NA

89.0.4 Molecular Weight: 121.18

89.0.5 Molecular Formula: $C_8H_{11}N$

89.0.6 Molecular Structure:



Databases and inventories where listed: DOT, IL, MA, MTL, PA, PEL, REL, TLV, WHMI, EINECS, HSDB, RTECS, TOXLINE, TSCAINV, SUPERLIST.

89.1 Chemical and Physical Properties (Commercial mixture)

Physical state	Pale yellow to brown liquid, with a weak aromatic odor
Boiling point	213–226°C
Vapor pressure	<1 torr at 20°C
Flash point	94.5°C
Density	0.97–0.99
Solubility	Soluble in ether, ethanol; slightly soluble in water

89.2 Production and Use

The mixed isomers that comprise commercial xylidine are mostly the 2,4-, 2,5-, and 2,6-isomers. Xylidine is used to manufacture dyes, pharmaceuticals, and other compounds.

89.3 Exposure Assessment

Human exposure may be monitered by use of NIOSH method #2002 found in NMAM IV.

89.4 Toxic Effects

Xylidine is absorbed through the skin and can cause methemoglobinemia, but it is less active in this regard than aniline. There are species differences in the toxicities of the different isomers, as well as in the metabolic patterns observed.

89.5 Standards, Regulations, or Guidelines of Exposure

The TLV-TWA is 0.5 ppm with skin and A3 notations. The NIOSH REL is 2 ppm and the OSHA PEL is 5 ppm. Both have skin notations as well.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

P. Xylidine Isomers

90.0 2,4-Xylidine

90.0.1 CAS Number: [*95-68-1*]

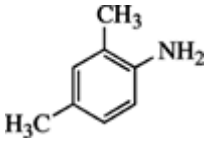
90.0.2 Synonyms: 2,4-Dimethylaniline, 2,4-dimethylaminobenzene; 4-amino-1,3-dimethylbenzene; 1-amino-2,4-dimethylbenzene; 4-amino-3-methyltoluene; 4-amino-1,3-xylene; 2,4-dimethylphenylamine; 2-methyl-*p*-toluidine; 4-methyl-*o*-toluidine; 4-amino-*m*-xylene

90.0.3 Trade Names: NA

90.0.4 Molecular Weight: 121.18

90.0.5 Molecular Formula: $C_8H_{11}N$

90.0.6 Molecular Structure:



Databases and inventories where listed: IARC, WHMI, CANCERLIT, CCRIS, EINECS, EMIC, EMICBACK, HSDB, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

90.1 Physical and Chemical Properties (202)

Physical state	Dark brown liquid
Boiling point	214°C
Melting point	16°C
Density	0.9723
Solubility	Soluble in ethanol, ether, benzene; slightly soluble in water

90.2 Production and Use

2,4-Xylidine, as part of the commercial mixture, has the same uses as xylidine.

90.4 Toxic Effects

The oral LD_{50} in mg/kg body weight for rats ranges from 470–1259; for mice the value is 250 (144). An intravenous dose of 30 mg/kg in cats led to methemoglobin levels almost 10-fold lower than the same dose of aniline. Repeated oral doses for 7 days led to liver damage in rats. The compound was absorbed through the skin of cats, and caused methemoglobinemia and liver damage. Of the three isomers described here, the 2,4- was most active in leading to liver damage and induction of P450 protein. When administered in the diet (as the hydrochloride) for 18 months, 2,4-xylidine was not carcinogenic in male CD rats. A similar study in CD-1 mice showed no increase in tumors in males, but the female mice at the higher dose level had an increase in lung tumors. The major metabolite in rats was 3-methyl-4-aminobenzoic acid (202). Minor amounts of acetyl and sulfate conjugates were also noted.

90.5 Standards, Regulations, or Guidelines of Exposure

As part of commercial xylidine, the ACGIH TLV-TWA is 0.5 ppm with skin and A3 notations; there is no specific standard for the 2,4-isomer.

91.0 2,5-Xylidine

91.0.1 CAS Number: [*95-78-3*]

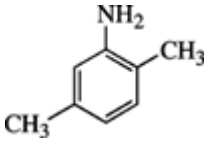
91.0.2 Synonyms: 2,5-Dimethylaniline; 1-amino-2,5-dimethylbenzene; 3-amino-1,4-dimethylbenzene; 2-amino-1,4-xylene; 2,5-dimethylphenylamine; 5-methyl-*o*-toluidine; 6-methyl-*m*-toluidine; *p*-xylidine; 2-amino-*p*-xylene

91.0.3 Trade Names: NA

91.0.4 Molecular Weight: 121.18

91.0.5 Molecular Formula: $C_8H_{11}N$

91.0.6 Molecular Structure:



Databases and inventories where listed: IARC, WHMI, CCRIS, EINECS, EMIC, EMICBACK, ETICBACK, HSDB, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

91.1 Chemical and Physical Properties (202)

Physical state	Colorless to yellow oil
Boiling point	214°C
Melting point	15.5°C
Density	0.9790
Solubility	Soluble in ether; slightly soluble in ethanol and water

91.2 Production and Use

The uses are the same as those of xylidines.

91.3 Exposure Assessment

May use NIOSH method #2002 for determination of potential human exposures (in NMAM IV).

91.4 Toxic Effects

The oral LD_{50} in mg/kg bw was 1300 for rats and 840 for mice (144). 2,5-Xylidine was active as a methemoglobin former but still was much less active than aniline. As with the other isomers, repeated doses caused liver damage. When given in the diet (as the hydrochloride salt) for 18 months, 2,5-xylidine was not carcinogenic in male rats; under a similar protocol, male mice showed an increase in vascular tumors. Rats converted 2,5-xylidine to 4-hydroxy-2,5-dimethylaniline and its conjugates, with minor amounts of 4-methyl-2 and -3-aminobenzoic acids. An oral dose of 200 mg/kg bw inhibited testicular DNA synthesis in male mice. Mutagenicity tests with the *Salmonella* system showed a response after metabolic activation (144).

91.5 Standards, Regulations, or Guidelines of Exposure

There is no specific standard for the 2,5-isomer; the ACGIH TLV-TWA for xylidines is 0.5 ppm.

92.0 2,6-Xylidine

92.0.1 CAS Number: [*87-62-7*]

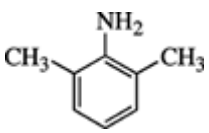
92.0.2 Synonyms: 2,6-Dimethylaniline, *o*-xylidine; DMA; 2-amino-1,3-dimethylbenzene; 1-amino-2,6-dimethylbenzene; xylylamine

92.0.3 Trade Names: NA

92.0.4 Molecular Weight: 121.18

92.0.5 Molecular Formula: $C_8H_{11}N$

92.0.6 Molecular Structure:



Databases and inventories where listed: CA65, CGB, CGN, IARC, MA, NJ, NTPT, PA, TRI, CANCERLIT, HSDB, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

92.1 Chemical and Physical Properties

Physical state	Colorless to reddish yellow liquid
Boiling point	214°C (739 mmHg)
Melting point	8.4°C
Density	0.9842 (20°C)
Solubility	Soluble in ethanol, ether; slightly soluble in water

92.2 Production and Use

2,6-Xylidine is an intermediate in manufacturing pesticides, dyes, antioxidants, pharmaceuticals, resins, fragrances, and other products.

92.3 Exposure Assessment

NIOSH Method #2002 can be used to determine workplace exposures.

92.4 Toxic Effects

The oral LD_{50} in mg/kg body weight ranges from 1050–1250 for rats; for mice the figures are 710–750. The methemoglobin-forming activity of 2,6-xylidine was similar to that of the 2,4-isomer. Male rats given 157 mg/kg body weight for 20 days developed hemosiderosis in the spleen. Continued administration for 30 days led to increased liver weight but no increase in P450 microsomal protein.

CD rats were fed 2,6-xylidine in the diet at levels of 300, 1000, or 3000 ppm; progeny received the same levels for 2 years. Adenomas and carcinomas of the nasal cavity occurred in both males and females, plus subcutaneous fibromas and fibrosarcomas (179).

The major urinary metabolite of 2,6-xylidine in rats was 4-hydroxy-2,6-dimethylaniline, and 3-methyl-2-aminobenzoic acid was a minor metabolite. Other reactive metabolites were tentatively identified (187). In human liver slices, 2,6-xylidine was a metabolite of lidocaine (241). Mutagenicity tests with 2,6-xylidine have given conflicting results.

92.5 Standards, Regulations, or Guidelines of Exposure

There is no specific standard for 2,6-xylidine; the ACGIH TLV-TWA for xylidines is 0.5 ppm with skin and A3 notations.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

Q. Two-Ring Compounds

93.0 Diphenylamine

93.0.1 CAS Number: [*122-39-4*]

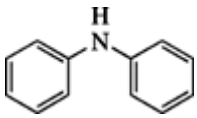
93.0.2 Synonyms: *N*-Phenylbenzenamine; *N*-phenylaniline; DFA; No Scald; DPA; anilinobenzene; (phenylamino)benzene; *N,N*-diphenylamine; big dipper; C.I. 10355; scaldip; phenylbenzenamine

93.0.3 Trade Names: NA

93.0.4 Molecular Weight: 169.23

93.0.5 Molecular Formula: $C_{12}H_{11}N$

93.0.6 Molecular Structure:



Databases and inventories where listed: CGB, CGN, FIFR, IL, INER, MA, MTL, NJ, PA, RQ, TLV, TRI, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

93.1 Chemical and Physical Properties (2)

Physical state	Colorless monoclinic leaflets
Density	1.159 (20/4°C)
Melting point	53–54°C
Boiling point	302°C
Solubility	Soluble in acetone, benzene, ethanol, ether, methanol; slightly soluble in water

93.2 Production and use

Diphenylamine is used as an antioxidant, fungicide, a prevention against apple scald, as a stabilizer, antihelmintic, and as a reagent.

93.3 Exposure Assessment

Potential exposures to diphenylamine may be measured using OSHA method #78.

93.4 Toxic Effects

Diphenylamine is absorbed through the skin; chronic studies by feeding in the diet of rats and beagle dogs showed some effects on the liver but no increase in tumors. However, dilatation of kidney kidney tubules occurred in rats, related to the impurity *N,N,N*'-triphenyl-*p*-phenylenediamine (2). Further investigation on a relationship between glutathione levels and renal papillary necrosis, using the Syrian hamster model, did not reveal a specific correlation. Within 1 h after a single dose from 200–600 mg/kg body weight there was a dose-dependent decrease in renal cortical glutathione, but significant changes in medullary or papillary glutathione were not seen (242). Ultrastructural studies of the kidney lesions were made (243). Interestingly, dimethyl sulfoxide lessened the incidence of papillary lesions from diphenylamine (244).

93.5 Standards, Regulations, or Guidelines of Exposure

The TLV-TWA is 10 mg/m^3 with an A4 notation. The NIOSH REL is also 10 mg/m^3.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

R. Benzidine and Derivatives

94.0 Benzidine

94.0.1 CAS Number: [*92-87-5*]

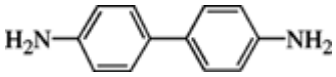
94.0.2 Synonyms: 4,4'-Diaminobiphenyl; 4,4'-diphenylenediamine; 4,4'-biphenyldiamine; 4,4'-bianiline; *p*-diaminodiphenyl; 1,1'-biphenyl-4,4'-diamine, 4,4'-diamino-1,1'-biphenyl; fast corinth base b; *p*-benzidine; benzidine base; C.I. azoic diazo component 112; C.I. 37225, BZ

94.0.3 Trade Names: NA

94.0.4 Molecular Weight: 184.24

94.0.5 Molecular Formula: $C_{12}H_{12}N_2$ or $NH_2C_6H_4C_6H_4NH_2$

94.0.6 Molecular Structure:



Databases and inventories where listed: CAA1, CA65, DOT, IARC, IL, MA, NJ, NTPA, PA, PEL, REL, RQ, S110, TLV, TRI, WHMI, CANCERLIT, CCRIS, DART, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.

94.1 Chemical and Physical Properties (2)

Physical state	White to slightly reddish powder or crystals
Density	1.250 (20/4°C)
Melting point	116/129°C (isotropic forms)
Boiling point	402°C
Vapor density	6.36
Solubility	Soluble in ether; slightly soluble in ethanol, hot water

94.2 Production and Use

Benzidine has been used as an intermediate for dyes with desirable properties, as a hardener for rubber, in security paper, and in small amounts as a laboratory reagent for blood testing. Because of its carcinogenicity in exposed workers, as well as the carcinogenicity of certain azo dyes derived from benzidine, manufacture for industrial use has been prohibited in the United States.

94.3 Exposure Assessment

Expsoure monitoring by NIOSH method #5509 is recommended (NMAM IV).

94.4 Toxic Effects

Epidemiological studies of exposed workers, which showed a higher risk of bladder cancer, along with the finding that three azo dyes derived from benzidine (BZ), namely, Direct Blue 6, CAS Number: [2602-46-20], Direct Black 38, CAS Number: [*1937-37-7*], and Direct Brown 95, CAS Number: [*1607-86-6*], were more potent carcinogens than BZ, led to a ban on production. However, BZ is still manufactured in some countries which has led to several mechanistic and epidemiological studies of exposed workers, especially in regard to acetyltransferase enzyme expression, *N*-glucuronide formation, and the role of BZ-DNA adducts in carcinogenesis.

Studies of *N*-acetylation of BZ and *N*-acetyl-BZ in human liver slices suggested that *N*-acetyl-BZ is a better substrate for NAT1 than BZ (245, 246). NAT1 and NAT2 catalyzed *N*-acetylation by a binary ping-pong mechanism, but NAT1 was the predominant acetylating enzyme. Another survey found NAT2-associated slow acetylation was not linked to increased risk of bladder cancer in humans and may even exert a protective effect (247). In rat liver slices, *N,N'*-diacetyl-BZ was formed preferentially; in dog liver, no acetylated adducts were found (248). With rat liver microsomes, *N*-acetyl-BZ was oxidized to *N'*-OH-*N*-acetyl-BZ, *N*-OH-*N*-acetyl-BZ, and ring oxidation products, mediated through cytochrome P450 1A1/1A2 (249, 250). The reaction of glutathione with one of the oxidation products, specifically BZ-diimine, led to the formation of 3-(glutathion-*S*-yl)-BZ and prevented complexing with DNA (251).

Formation of *N*-(3'-monophosphodeoxyguanosin-8-yl)-*N'*-acetyl-BZ occured with prostaglandin H synthase (from ram seminal vesicle microsomes) and *N*-acetyl-BZ (252). Levels of this adduct in human peripheral white blood cells correlated with levels in exfoliated urothelial cells from exposed workers (253); it was the only adduct significantly associated with total urinary metabolites of BZ, and it was thought unlikely that interindividual variations in NAT2 function were relevant for BZ-associated cancer (254).

Glutathione-*S*-transferase M1 expression had no apparent impact on bladder cancer from BZ (255), but an acidic urine was associated with higher levels of free BZ in urine and urothelial cell DNA adducts (256).

Glucuronide formation is also important in BZ disposition because splitting of a glucuronide by acidic urine may release free BZ at a susceptible site. However, the *N*-glucuronide of *N*-OH-BZ was stable at an acidic pH (257). Although dog liver slices made an *N*-glucuronide from BZ (258), dog liver did not form such a conjugate from *N*-acetyl-BZ, but human and rat liver did (259). It was noted that liver microsomes from aged rats were more susceptible to the effects of BZ than those from younger animals (260). However, experiments *in vivo* are needed to confirm this.

The disposition of BZ and its activation differ somewhat from that of other carcinogenic amines.

94.5 Standards, Regulations, or Guidelines of Exposure

OSHA does not have a PEL for benzidine. However, it does have a regulation for it: 29CFR1910.10. This regulation states that benzidine and benzidine dyes are potential carcinogens and worker exposures should be reduced to the lowest feasible level. No standard has been set by ACGIH, but BZ is given an Al notation. Persons who use BZ in research should follow guidelines for handling carcinogens.

95.0 3,3'-Dichlorobenzidine

95.0.1 CAS Number: [*91-94-1*]

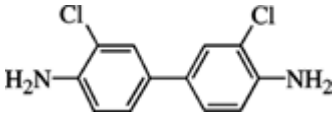
95.0.2 Synonyms: 3,3'-Dichloro-4,4'-biphenyldiamine; *o,o*'-dichlorobenzidine; 4,4'-diamino-3,3'-dichlorobiphenyl; dichlorobenzidine; DCB; 3,3'-dichloro-(1,1-biphenyl)-4,4'-diamine; C.I. 23060; 3,3'-dichlorobiphenyl-4,4'-diamine; 3,3'-dichloro-4,4'-diaminobiphenyl

95.0.3 Trade Names: NA

95.0.4 Molecular Weight: 253.13

95.0.5 Molecular Formula: $C_{12}H_{10}Cl_2N_2$ or $NH_2ClC_6H_3C_6H_3ClNH_2$

95.0.6 Molecular Structure:



Database and inventories where listed: CAA1, CA65, IARC, IL, MA, NJ, NTPA, PA, PEL, REL, RQ, S110, TLV, WHMI, CANCERLIT, CCRIS, DART, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, IRIS, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.

95.1 Physical and Chemical Properties (2)

Physical state	Grayish to purple crystals
Melting point	133°C
Boiling point	368°C
Solubility	Soluble in ethanol, ether, acetic acid; insoluble in water

95.2 Production and use

The compound is used as a curing agent for urethane plastics and for manufacturing yellow dyes.

95.3 Exposure Assessment

NIOSH method #5509 is recommended for determining potential exposures to this chemical (NMAM IV).

95.4 Toxic Effects

The toxicity, metabolism and carcinogenicity of dichlorobenzidine were reviewed by IARC (261). Essentially, the compound is carcinogenic in animals, but epidemiological studies in exposed

workers did not show an excess of tumors. However, the studies were deemed inadequate for a definitive conclusion (261). Of interest is the fact that a dichlorobenzidine-based azo dye, diarylanilide yellow, was fed to animals at 2.5 and 5% of the diet for two years and produced no increase in tumors (262). Presumably, the presence of the chlorine moieties may have interfered with the azo reductase enzyme so that free dichlorobenzidine was not produced.

95.5 Standards, Regulations, or Guidelines of Exposure

There is no TLV-TWA, but ACGIH has skin and an A3 notation for this compound. OSHA considers it a carcinogen and exposures are to be controlled their engineering controls, workpractices and protective equipment.

96.0 3,3'-Dimethoxybenzidine

96.0.1 CAS Number: [*119-90-4*]

96.0.2 Synonyms: *o*-Dianilidine; Fast Blue; Blue Base; C.I. 96.0.3 Trade Names: NA

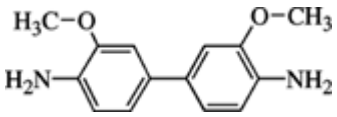
96.0.4 Molecular Weight: 244.29

96.0.5 Molecular Formula: $C_{14}H_{16}N_2O_2$

96.0.6 Molecular Structure:



Databases and inventories where listed: CA65, CAA1, IARC, IL, MA, NJ, NTPA, PA, RQ, TRI, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, SUPERLIST, TOXLINE, TSCAINV.

96.1 Chemical and Physical Properties (263)

Physical state	Colorless to violet crystals
Molecular weight	244.3
Melting point	171–174.5°C
Solubility	Soluble in ethanol, ether, acetone, benzene, chloroform; only very slightly soluble in water

96.2 Production and Use

This compound has been used in dye production.

96.3 Exposure Assessment

NIOSH method #5013 NMAM IV.

96.4 Toxic Effects

The early data on the carcinogenicity of 3,3'-dimethoxybenzidine were reviewed (263). The NTP has done a chronic study of the dihydrochloride salt given in drinking water at levels of 80, 170, or 330 ppm for 21 months to male and female F344 rats. This treatment led to various types of skin

tumors in males, plus tumors of the Zymbal gland, preputial gland, tongue or palate, and additional tumors of the intestines and liver. Females showed tumors of the clitoral and Zymbal glands, an increase in mammary adenocarcinoma, and various other internal tumors (264). Besides this clear evidence of carcinogenicity, the compound was positive in a *Salmonella* test (TA98) and in a sister chromatid exchange study (264).

96.5 Standards, Regulations, or Guidelines of Exposure

OSHA and NIOSH concluded this chemical may present a cancer risk and exposure should be minimized.

97.0 3,3'-Dimethylbenzidine

97.0.1 CAS Number: [*119-93-7*]

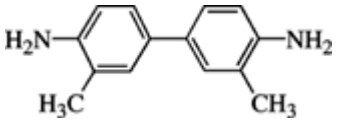
97.0.2 Synonyms: *ortho*-Tolidine; DMB; Fast Dark Blue Base R;3,3'-dimethyl-1, 1'-biphenyl-4, 4'-diamine; 3, 3'-dimethylbiphenyl-4, 4'-diamine; tolidine; dimethyl benzidine; 3, 3'-tolidine; 4, 4'-bi-*o*-toluidine; 4,4'-diamino-3,3'-dimethylbiphenyl; 3,3'-dimethyl-4,4'-biphenyldiamine; diaminoditolyl; bianisidine; *o*, *o*'-tolidine; C. I. 37230; C. I. azoic diazo component 113

97.0.3 Trade Names: NA

97.0.4 Molecular Weight: 212.29

97.0.5 Molecular Formula: $C_{14}H_{16}N_2$

97.0.6 Molecular Structure:



97.1 Chemical and Physical Properties (265)

Physical state	White to reddish crystals or crystalline powder
Melting point	131.5°C
Solubility	Soluble in ethanol, ether; somewhat soluble in chloroform, water

97.2 Production and Use

3,3'-Dimethylbenzidine is a dye intermediate.

97.3 Exposure Assessment

NIOSH method #5013 (NMAM IV).

97.4 Toxic Effects

The NTP did a long-term study of the dihydrochloride of 3,3'-dimethylbenzidine given in the drinking water to F344 rats at 30, 70, or 150 ppm. The study was terminated at 14 months because of the low number of surviving rats. Males had many types of skin tumors, neoplasms of the Zymbal gland, liver, and large intestine, and lower numbers of tumors of the preputial gland, oral cavity, small intestine, and lung. Females had a high incidence of tumors of the Zymbal and clitoral glands, in addition to lower incidences of neoplasms of the skin, liver, intestines, lung, and mammary glands. The compound also tested positive in *Salmonella* (TA98), in sister chromatid exchange, and as an inducer of chromosomal aberrations (266).

97.5 Standards, Regulations, or Guidelines of Exposure

NIOSH and OSHA jointly published a Health Hazard Alert concluding that *o*-tolidine was a potential carcinogen and recommended that worker exposure be reduced to lowest feasible level.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

S. Biphenyls
98.0 2-Nitrobiphenyl
98.0.1 CAS Number: [*86-00-0*]

98.0.2 Synonyms: *o*-Nitrobiphenyl; 2-nitro-1,1'-biphenyl; ONB

98.0.3 Trade Names: NA

98.0.4 Molecular Weight: 199.21

98.0.5 Molecular Formula: $C_{12}H_9NO_2$

Databases and inventories where listed: CCRIS, EINECS, EMIC, EMICBACK, RTECS, TOXLINE.
98.1 Physical and Chemical Properties (2)

Physical State	Colorless Crystals or yellow to reddish liquid
Molecular weight	199.21
Boiling point	320°C
Melting point	37.2°C
Density	1.44
Solubility	Soluble in acetone, ethanol, methanol, carbon tetrachloride, perchloroethylene; slightly soluble in water

98.2 Production and Use
2-Nitrobiphenyl is a plasticizer for resins, a fungicide for textiles, and a wood preservative.
98.4 Toxic Effects
The rat LD_{50} is 1230 mg/kg body weight and it is an irritant.
98.5 Standards, Regulations, or Guidelines of Exposure
None assigned.
99.0 4-Nitrobiphenyl
99.0.1 CAS Number: [*92-93-3*]

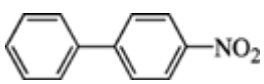
99.0.2 Synonyms: 4-Phenylnitrobenzene; 1-nitro-4-phenylbenzene; 4-nitro-1, 1'-biphenyl

99.0.3 Trade Names: NA

99.0.4 Molecular Weight: 199.21

99.0.5 Molecular Formula: $C_{12}H_9NO_2$

99.0.6 Molecular Structure:



Databases and inventories where listed: CAA1, CA65, IARC, IL, MA, NJ, PA, PEL, REL, TLV, TRI, WHMI, CANCERLIT, CCRIS, EINECS, EMIC, EMICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.
99.1 Chemical and Physical Properties (2)

Physical state	White to yellow needle-like crystals
Melting point	114–114.5°C
Boiling point	340°C
Solubility	Soluble in hot water, ethanol, ether, insoluble in acetone, benzene

99.2 Production and Use

4-Nitrobiphenyl has some uses as a plasticizer, fungicide, and wood preservative.

99.3 Exposure Assessment

NIOSH method P and CAM #273, (NMAM II(4)).

99.4 Toxic Effects

4-Nitrobiphenyl has produced bladder tumors in dogs and is a carcinogenic risk (227, 267). The oral LD_{50} for rabbits was reported to be 1.97 g/kg and for rats, 2.33 g/kg (144).

The IARC Working Group on the Evaluation of the Carcinogenic Risk of Chemicals to Man found no reports on the carcinogenicity of PNB to humans and that the animal data were inadequate to classify the compound as a human carcinogen; consequently IARC assigned 4-nitrobiphenyl to Group 3, not classifiable as to its carcinogenicity to humans (227). However, it is considered an occupational carcinogen by NIOSH and OSHA (267) and a "suspect carcinogen" (or A2) by ACGIH (144).

99.5 Standards, Regulations, or Guidelines of Exposure

None have been assigned, however, OSHA promulgated a standard for this chemical—exposure should be the lowest feasible level and ACGIH has skin and A2 (suspect carcinogen) notations for 4-nitrobiphenyl.

100.0 4-Aminobiphenyl

100.0.1 CAS Number: [*92-67-1*]

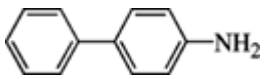
100.0.2 Synonyms: 4-Aminodiphenyl; xenylamine; 4-biphenylamine; [1,1'-biphenyl]-4-amine; *p*-phenylaniline; *p*-xenylamine

100.0.3 Trade Names: NA

100.0.4 Molecular Weight: 169.23

100.0.5 Molecular Formula: $C_{12}H_{11}N$

100.0.6 Molecular Structure:



Databases and inventories where listed: CAA1, CA65, IARC, IL, MA, MI, NJ, NTPA, PA, PEL, REL, S110, TLV, TRI, WHMI, CANCERLIT, CCRIS, DART, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.

100.1 Chemical and Physical Properties (2)

Physical state	Colorless crystals which turn purple on contact with air; floral odor
Melting point	53-54°C
Boiling point	302°C; 191°C (15 mmHg)
Solubility	Soluble in ethanol, ether, chloroform; slightly soluble in water

100.2 Production and Use

4-Aminobiphenyl was formerly used as a rubber antioxidant and dye intermediate; it is now a research chemical.

100.3 Exposure Assessment

NIOSH method P & CAM #269 (NMAM II(4)).

100.4 Toxic Effects

The carcinogenicity of 4-aminobiphenyl (4-ABP), especially with regard to induct bladder cancer in both animals and humans was discussed in the previous edition (2). In contrast to benzidine, 4-ABP should be a matter of concern for everyone. Although tobacco smoking is the major source of exposure to 4-ABP, there is a baseline exposure level, as indicated by hemoglobin adducts. Nonsmokers had levels of about 20 pg 4-ABP/g hemoglobin; levels in smokers could range from about 140-630 pg 4-ABP/g hemoglobin (268). Even human fetuses had such adducts; in nonsmoking women, fetuses had levels of about 9 pg 4-ABP/g hemoglobin; those from women who smoked had levels from about 75-320 pg 4-ABP/g hemoglobin (269). These data indicate that 4-ABP can cross the placental barrier and bind to fetal hemoglobin (270). The actual source of the 4-ABP in nonsmokers has not been identified; one possibility may be 4-nitrobiphenyl from engine exhausts.

As with other aromatic amine carcinogens, 4-ABP is acetylated and *N*-hydroxylated; the mechanism of its activation to DNA-reactive entities is a matter of much investigation. There have been many efforts to correlate 4-ABP-DNA adduct formation and subsequent induction of cancer. In some cases, adduct formation correlated with eventual tumorigenesis (271–277). But there were other situations where the correlation did not always hold, depending on the tissue and the analytical method (278). Acetylator status played a role with some types of adducts but not with all (279–281). Peroxidase-mediated activation was minor, compared to acetyltransferase effects (282). Acid-labile glucuronide conjugates were studied (283), as well as the possible role of glutathione transferase (284), which did not correlate with adduct levels. 4-ABP, as are other aromatic amines, was oxidized through cytochrome P4501A2 (285) and also through sulfotransferase (286). Even tissue from human fetuses of 14 weeks gestation had a sulfotransferase that activated the *N*-hydroxy derivatives of both 4-ABP and *N*-acetyl-4-ABP (287). The major DNA adduct from *N*-hydroxyacetyl-ABP was 3-(deoxyguanosin-N^2-yl)-4-acetylaminobiphenyl (282, 288). As with other genotoxic compounds, *in vivo* and *in vitro* results from mutagenicity assays did not always agree (289, 290). Even in bladder cancer patients, an important mutation (p53) did not correlate with the cancer stage, and there was no association among 4-ABP adducts, GSTM, and NAT2 genetic polymorphisms (291). Thus, the mechanism for the effects of 4-ABP provides issues for further investigation.

100.5 Standards, Regulations, or Guidelines of Exposure

Although ACGIH has set no TLV for this compound, it has the A1 notation and notes that bladder cancer is the reason for the notation. OSHA regulates this chemical as a carcinogen exposures must be controlled.

Aromatic Nitro and Amino Compounds

T. Methylenedianilines

101.0 4,4'-Methylenedianiline

101.0.1 CAS Number: [*101-77-9*]

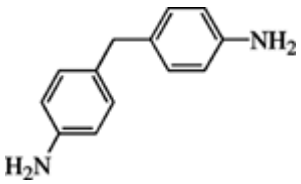
101.0.2 Synonyms: 4,4'-Methylenebisbenzeneamine; Tonox; HT 972; MDA; DDM; 4,4'-diaminodiphenylmethane; methylenebis(aniline); diaminodiphenylmethane; bis (*p*-aminophenyl) methane; DADPM; DAPM; dianilinomethane; 4,4'-diaminoditan; 4-(4-aminobenzyl)aniline; ancamine tl; araldite hardener 972; curithane; 4,4'-diphenylmethanediamine; epicure ddm; epikure ddm; jeffamine ap-20; sumicure M

101.0.3 Trade Names: NA

101.0.4 Molecular Weight: 198.27

101.0.5 Molecular Formula: $C_{13}H_{14}N_2$

101.0.6 Molecular Structure:



Databases and inventories where listed: CAA1, CA65, DOT, IARC, MA, MPOL, MTL, NJ, NTPA, PA, REL, TLV, TRI, WHMI, CANCERLIT, CCRIS, DSL, EINECS, EMIC, EMICBACK, ETICBACK, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.

101.1 Chemical and Physical Properties (2)

Physical State	Pale yellow crystals (darken on air exposure)
Melting point	91.5–92°C
Boiling point	398°C 768 mmHg
Solubility	Soluble in ethanol, benzene, ether, acetone, methanol; slightly soluble in water, carbon tetrachloride

101.2 Production and Use

Much of the 4,4'-methylenedianiline (MDA) produced is used as an intermediate for producing isocyanates and polyisocyanates, in making polyurethane foams, as a hardening agent for epoxy resins, as a curing agent, an antioxidant, and a fuel additive.

101.3 Exposure Assessment

NIOSH method #5029 (NMAM IV).

101.4 Toxic Effects

The toxicity of MDA has been discussed many times because it was the causative agent in the "Epping" jaundice incident (2, 3). The toxic effects were due to cholestasis, cholangitis, minor liver cell necrosis and hepatitis, but the exposed persons recovered within 7 weeks. After 24 years, a follow-up study of this group revealed one case of biliary tract carcinoma, two cases of retinal pathology, and four cases of recurrent jaundice, indicating long-term effects (292). Other deleterious effects in humans include contact dermatitis from a variety of products which contained MDA (293–296), allergic responses, and an increased risk of bladder cancer. However, a survey of workers who were exposed to MDA through its use as an epoxy curing agent showed no increases in bladder cancer (297). MDA was absorbed to a greater extent through human than through rat skin *in vitro* (298). Absorbed MDA was excreted in the urine as an acetyl-MDA and an unidentified conjugate (299). Workers exposed to MDA or to the diisocyanate of MDA excreted acetyl-MDA in the urine and albumin, and hemoglobin adducts were identified in the blood, indicating hydrolysis of the diisocyanate to MDA (300, 301).

In rats exposed to MDA, there was appreciable liver toxicity (302). It was determined that MDA leads to a cholangiodestructive effect and that the biliary toxicant from MDA is released into the bile (303, 304). As with humans, rats exposed to MDA or MDA diisocyanate excreted MDA and acetyl-MDA in the urine, besides forming hemoglobin adducts (305). In a rabbit liver microsomal system, MDA was metabolized to 4-nitroso-4'-aminodiphenylmethane plus both an azo and an azoxy

compound formed by combination of two MDA molecules after oxidation (306). These results indicate oxidation of MDA through hydroxylamine to a nitroso derivative, followed by condensation.

101.5 Standards, Regulations, or Guidelines of Exposure

The OSHA PEL (29CFR 1910, 1050) is 0.01 ppm with a STEL of 0.1 ppm. The current ACGIH TLV-TWA is 0.1 ppm with an A3 notation and a note that liver toxicity is a critical effect.

102.0 4,4'-Methylenebis(2-methylaniline)

102.0.1 CAS Number: [*838-88-0*]

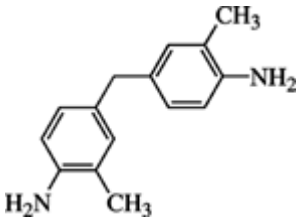
102.0.2 Synonyms: 3,3'-Dimethyl-4, 4'-diaminodiphenylmethane

102.0.3 Trade Names: NA

102.0.4 Molecular Weight: 226.32

102.0.5 Molecular Formula: $C_{15}H_{18}N_2$

102.0.6 Molecular Structure:



Databases and inventories where listed: CA65, IARC, IL, MA, MI, PA, CANCERLIT, CCRIS, EINECS, EMICBACK, GENETOX, MESH, RTECS, SUPERLIST, TOXLINE, TSCAINV.

102.1 Chemical and Physical Properties (263)

Physical state	White powder
Melting point	149°C
Solubility	Soluble in ethanol, hot water

102.2 Production and Use

The compound has been used in dyestuff production.

102.4 Toxic Effects

This compound has been tested by oral administration in rats and dogs (227). It led to high incidences of hepatocellular carcinomas in both species, and there were additional tumors of lung, skin, and mammary gland in rats and lung tumors in dogs. Workers exposed to this compound and others in dye production showed a higher risk of bladder cancer (227).

102.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

103.0 4,4'-Methylenebis(2-chloroaniline)

103.0.1 CAS Number: [*101-14-4*]

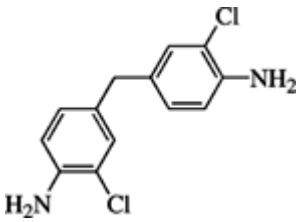
103.0.2 Synonyms: 3,3'-Dichloro-4, 4'-diaminodiphenyl methane; BOCA; bis-amine; Cyanaset; DACPM; MOCA; MBOCA; Curene 442; di(4-amino-3-chlorophenyl)methane; 4, 4'-diamino-3, 3'-dichlorodiphenylmethane; 4, 4'-methylenebis-(2-chlorobenzenamine); *p,p*'-methylenebis(alpha-chloroaniline); methylene-bis-orthochloroaniline; bis-amine A; Cl-mda; curalin M; 4, 4-methylene bis(2-chloroaniline)

103.0.3 Trade Names: NA

103.0.4 Molecular Weight: 267.16

103.0.5 Molecular Formula: $C_{13}H_{12}Cl_2N_2$

103.0.6 Molecular Structure:



Databases and inventories where listed: CAA1, CA65, IARC, IL, MA, MI, NJ, NTPA, PA, PELS, REL, RQ, S110, TLV, WHMI, CANCERLIT, CCRIS, DSL, EINECS, EMIC, EMICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.

103.1 Chemical and Physical Properties (2)

Physical state	Tan solid
Specific gravity	1.44 at 4°C
Melting range	99–110°C
Solubility	Soluble in benzene, ether, ethanol, methyl ethyl ketone, tetrahydrofuran, dimethylformamide, dimethyl sulfoxide; slightly soluble in water

103.2 Production and Use

The major use of 4,4'-methylenebis(2-chloroaniline) (MOCA) is as a curing agent for polyurethane prepolymers where high performance products are required.

103.3 Exposure Assessment

OSHA method #71.

103.4 Toxic Effects

The carcinogenicity of MOCA in animals and its involvement in an increased risk of bladder cancer in humans were reviewed (2, 307). Although MOCA was absorbed through human skin at a level only one-sixth that of MDA, the rate was still sufficient to cause concern (298). As with other aromatic amines, the metabolic process involves acetylation and *N*-hydroxylation (308); then MOCA or a derivative forms DNA adducts (309, 310). Factors such as species, route of administration, and enzyme induction were investigated (310). Use of ^{32}P-postlabeling techniques has facilitated the identification of DNA adducts (311–314). However, in animals, nontarget tissues such as liver often had a higher level of adducts than the target organ (312). The DNA adducts of MOCA differ somewhat from those of analogous amines such as benzidine. The major DNA adduct was identified as *N*-(deoxyadenosin-3',5'-bisphospho-8-yl) 4-amino-3-chlorobenzyl alcohol; the minor one was *N*-(deoxyadenosin–3', 5'-bisphospho-8-yl) 4-amino-3-chlorotoluene. These results indicate that an aromatic ring was cleaved from the molecule with subsequent oxidation to a benzyl alcohol or reduction to a toluene. *N*-OH-MOCA treatment of SV40 immortalized human uroepithelial cells led the cells to convert to a neoplastic form that caused tumors in athymic nude mice (315). It was suggested that an aryl nitrenium ion was the ultimate reactant from MOCA (315).

103.5 Standards, Regulations, or Guidelines Exposure

The current ACGIH TLV-TWA is 0.01 ppm with skin and A2 notations, as a suspect human carcinogen. NIOSH considers it a carcinogen with a REL of 0.003 mg/m^3.

Vapor density	4.93 (air = 1)
Refractive index	1.6703 (51.2°C)
Solubility	Soluble in ethanol, ether; slightly soluble in hot water

104.2 Production and Use
1-Naphthylamine is used as an intermediate in the synthesis of dyes, antioxidants, herbicides, some drugs, and other chemicals.
104.3 Exposure Assessment
Analytical method NIOSH method 5518 (NMAM IV).
104.4 Toxic Effects
Pure 1-naphthylamine was not carcinogenic in animal tests (2). The commercial material of the past usually contained from 4–10% 2-naphthylamine, a recognized human bladder carcinogen, which accounts for the excess risk of bladder cancer in exposed workers. There has been less research on 1-naphthylamine than some of the other aromatic amines, and most of that has emphasized the formation of glucuronide derivatives. In a rat hepatocyte system, 1-naphthylamine was converted mostly (68%) to the *N*-glucuronide and acetylation occurred to the extent of about 15%. The situation was the reverse for 2-naphthylamine which was mostly acetylated (316). Formation of the

N-glucuronide of 1-naphthylamine by rat and human phenol UDP-glucuronosyltransferase was increased by 3-methylcholanthrene induction (317).

104.5 Standards, Regulations, or Guidelines of Exposure

OSHA in 29CFR 1910.1004 set the level at the lowest feasible level.

105.0 2-Naphthylamine

105.0.1 CAS Number: [*91-59-8*]

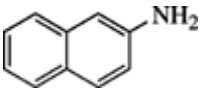
105.0.2 Synonyms: beta-Naphthylamine; NA; BNA; 2-aminonaphthalene; Fast Scarlet Base B; 2-naphthalenamine; 2,6-naphthylamine; C. I. 37270

105.0.3 Trade Names: NA

105.0.4 Molecular Weight: 143.19

105.0.5 Molecular Formula: $C_{10}H_9N$

105.0.6 Molecular Structure:



Databases and inventories where listed: CA65, DOT, IARC, IL, MA, MI, NJ, NTPA, PA, PEL, REL, RQ, TLV, TRI, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, SUPERLIST.

105.1 Chemical and Physical Properties (2)

Physical state	Colorless leaflets (darken)
Density	1.061 (98/4°C)
Melting point	113°C
Boiling point	306.1°C
Refractive index	1.64927 (98.4°C)
Solubility	Soluble in ethanol, ether, benzene; soluble in hot water

105.2 Production and Use

2-Naphthylamine had been used to synthesize dyestuffs and antioxidants. It is now a research chemical.

105.3 Exposure Assessment

NIOSH method #5518 (NMAM IV).

105.4 Toxic Effects

2-Naphthylamine is carcinogenic in animals and is one of the recognized human carcinogens due to its propensity to induce bladder tumors (2, 3, 227). Thus, it is no longer used commercially, but exposure may still occur in some industrial settings. Measurable levels were excreted in the urine by iron foundry workers, possibly through nitronaphthalene formed during foundry processes (318). Immune function in exposed workers was somewhat depressed, as measured according to various types of lymphocytes (319–321).

The *N*-hydroxy derivative of 2-naphthylamine is conjugated with glucuronic acid; the conjugate is transported to the bladder where hydrolysis releases the *N*-hydroxy derivative which is active at the site, probably through an arylnitrenium ion. Research on 2-naphthylamine has emphasized the mechanism of oxidation and glucuronide formation. Oxidation *in vitro* with prostaglandin H synthase indicated two distinct pathways (322). Ring oxygenation can occur by peroxyl radical-mediated attack on the arylamine and by direct transfer of peroxide oxygen from the enzyme to the amine. Horseradish peroxidase yielded polymeric monooxygenated derivatives of 2-naphthylamine

(322). *N*-Glucuronide formation from either the arylamine or the *N*-hydroxy derivative in rat hepatocytes was inducible by 3-methylcholanthrene. In rat hepatocytes, 2-naphthylamine was mostly acetylated; enzyme induction shifted the pattern from *N*-acetylation and some *N*-glucuronide formation to *N*- and C-oxidation (316). As with other aromatic amines, various nucleic adducts have been identified (3). Epidemiologic studies have fully confirmed the carcinogenic effects in humans (323, 324).

105.5 Standards, Regulations, or Guidelines of Exposure

OSHA standard 29CFR 1910.1009 sets the limit at the lowest feasible level, and ACGIH lists the compound as A1, with a note on bladder cancer.

106.0 1,5-Diaminonaphthalene

106.0.1 CAS Number: [*2243-62-1*]

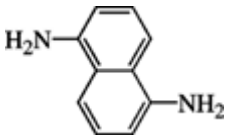
106.0.2 Synonyms: 1,5-Naphthalenediamine

106.0.3 Trade Names: NA

106.0.4 Molecular Weight: 158.20

106.0.5 Molecular Formula: $C_{10}H_{10}N_2$

106.0.6 Molecular Structure:



Databases and inventories where listed: IARC, MA, MI, NTPT, CCRIS, EINECS, EMIC, EMICBACK, GENETOX, HSDB, MESH, RTECS, SUPERLIST, TOXLINE.

106.1 Chemical and Physical Properties (2)

Melting point	190°C
Boiling point	Sublimes
Solubility	Soluble in ethanol, ether, chloroform

106.2 Production and Use

This compound has been used to produce diisocyanates for polyurethane production and some dyes.

106.4 Toxic Effects

An NCI bioassy (1978) in $B6C3F_1$ mice of both sexes, fed diets containing 1000 or 2000 mg/kg for 103 weeks, demonstrated statistically significant increases in *C*-cell carcinomas of the thyroid gland in females, neoplasms of the thyroid gland (follicular cell adenomas and papillary adenomas) in males and females, hepato-cellular carcinomas in females, and alveolar/bronchiolar adenomas and carcinomas in females. In F344 rats of both sexes fed diets containing 500 or 1000 mg/kg for 103 weeks, a statistically significant increase in the incidence of clitoral gland carcinomas was observed (325). 1,5-Naphthalenediamine is also mutagenic to *Salmonella typhimurium* strain TA100 without metabolic activation (204). No further information was located.

Based upon the lack of human data and limited evidence of carcinogenicity in animals, the IARC working group classified 1,5-naphthalenediamine as a Group 3 compound-not classifiable as to its carcinogenicity to humans (227).

106.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

107.0 4,4'-Oxydianiline

107.0.1 CAS Number: [*101-80-4*]

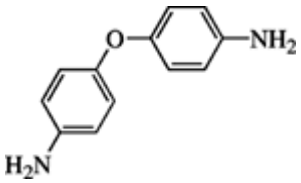
107.0.2 Synonyms: bis (*p*-Aminophenyl) ether; 4-aminophenyl ether; 4,4'-diaminodiphenyloxide; 4,4'-diaminodiphenyl ether; 4,4'-diaminophenyl ether; 4,4'-diaminophenyl oxide; ODA; oxydianiline; oxydi-*p*-phenylenediamine; oxybis(4-aminobenzene); 4,4'-oxydiphenylamine; DADPE; 4,4-dadpe; 4,4'-oxybisbenzenamine

107.0.3 Trade Names: NA

107.0.4 Molecular Weight: 200.24

107.0.5 Molecular Formula: $C_{12}H_{12}N_2O$

107.0.6 Molecular Structure:



Databases and inventories where listed: CA65, IARC, IL, MA, MI, NJ, NTPA, PA, TRI, CANCERLIT, CCRIS, DART, EINECS, EMIC, EMICBACK, GENETOX, HSDB, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.

107.1 Chemical and Physical Properties (2)

Physical state	Colorless crystals
Melting point	186–187°C
Boiling point	>300°C
Solubility	Soluble in acetone; insoluble in benzene, ethanol, carbon tetrachloride, water

107.2 Production and Use

4,4'-Oxydianiline has been used to produce polyimide resins.

107.4 Toxic Effects

The previous edition outlined the carcinogenic effects noted in rats and mice fed 4,4'-oxydianiline, where the thyroid and liver were target organs (2). Various other smaller scale studies also showed carcinogenic effects (261). 4,4'-Oxydianiline was mutagenic to *Salmonella* strains TA98 and TA100 in the presence of an activating system (261).

107.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

108.0 4-Aminodiphenylamine

108.0.1 CAS Number: [*101-54-2*]

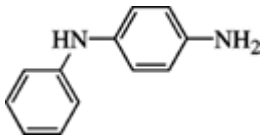
108.0.2 Synonyms: *N*-Phenyl-*p*-phenylenediamine; *p*-anilinoaniline; *N*-phenyl-1, 4-benzenediamine; C. I. azoic diazo component 22; C. I. 37240; acna black df base; azosalt R; C. I. developer 15; C. I. oxidation base 2; C. I. 76085; diphenyl black; fast blue r salt; luxan black R; naphthoelan navy blue; oxy acid black base; peltol br; pelton br ii; *N*-phenyl-*p*-aminoaniline; *p*-semidine; variamine blue salt rt; diphenyl black base P; phenyl 4-aminophenyl amine; *N*-phenyl-1, 4-phenylenediamine; *N*-(4-aminophenyl)aniline

108.0.3 Trade Names: NA

108.0.4 Molecular Weight: 184.24

108.0.5 Molecular Formula: $C_{12}H_{12}N_2$

108.0.6 Molecular Structure:



Databases and inventories where listed: MTL, NTPT, WHMI, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

108.1 Chemical and Physical Properties (2)

Melting point 73–75°C

Boiling point 354°C

108.2 Production and Use

This compound is used as an oxidation dye color in hair dyes (2). It is also promoted as an efficient reagent for oxidase enzymes, including glucose, lactate, xanthine, and lysine oxidases (32).

108.4 Toxic Effects

Alkyl derivatives of 4-aminodiphenylamine sometimes caused sensitization reactions, in keeping with the *p*-phenylenediamine structure.

A bioassay of *N*-phenyl-*p*-phenylenediamine for possible carcinogenicity was conducted by administering the test chemical in the diet to groups of 50 Fischer 344 rats and B6C3F1 mice.

The male and female rats were administered *N*-phenyl-*p*-phenylenediamine at either 600 or 1200 ppm for 78 weeks and were then observed for 26 additional weeks. Groups of 50 mice were initially administered *N*-phenyl-*p*-phenylenediamine at either 2,500 or 5,000 ppm for the males and either 5,000 or 10,00 ppm for the females for 31 weeks. Because of toxicity, the doses were lowered at that time and terminated at 48 weeks and the animals were observed for 43 additional weeks. All surviving mice were killed at 91 weeks.

Mean body weights of the dosed rats were only slightly lower than those of the matched controls during the bioassay but those of the dosed mice were appreciably lower than those of the matched controls. Mortality was high in the dosed groups before reduction of the doses, particularly in the females.

In the male and female rats, the incidences of neoplasms in the groups receiving the test chemical were not significantly different from those in the corresponding control groups.

In the male mice, the incidence of combined hepatocellular adenomas and carcinomas was significantly higher ($p = 0.022$) in the low-dose group than in the controls, but there was no significant dose-related trend and these neoplasms could not be established as being compound related. Unusually extensive hepatic inflammation occurred in large numbers of the dosed males and in lesser numbers of the dosed females. Under the conditions of this bioassay, *N*-phenyl-*p*-phenylenediamine was not carcinogenic for Fischer 344 rats or for B6C3F1 mice (327).

108.5 Standards, Regulations, or Guidelines of Exposure

None assigned.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

V. Three-Ring Compounds
109.0 2-Acetylaminofluorene
109.0.1 CAS Number: [*53-96-3*]

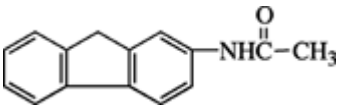
109.0.2 Synonyms: *N*-2-Fluorenylacetamide; N-9H-fluoren-2-yl-acetamide; *N*-acetyl-2-aminofluorene; fluorenylacetamide; *N*-fluoren-2-yl acetamide; 2-acetamidofluorene; 2-acetaminofluorene; 2-fluorenylacetamide; acetoaminofluorene; AAF; 2-AAF; FAA; 2-FAA; acetamidofluorene

109.0.3 Trade Names: NA

109.0.4 Molecular Weight: 223.27

109.0.5 Molecular Formula: $C_{15}H_{13}NO$

109.0.6 Molecular Structure:



Databases and inventories where listed: CAA1, CA65, IL, MA, MI, NJ, NTPA, PA, PEL, REL, RQ, TRI, WHMI, AIDSLINE, CANCERLIT, CCRIS, DART, EINECS, EMIC, EMICBACK, ETICBACK, GENETOX, HSDB, MEDLINE, MESH, RTECS, TOXLINE, TRIFACTS, TSCAINV, SUPERLIST.
109.1 Chemical and Physical Properties (2)

Physical state	White crystals
Melting point	194°C
Solubility	Soluble in ethanol, ether, acetic acid; insoluble in water

109.2 Uses
2-AAF is used as a research chemical.
109.4 Toxic Effects
2-AAF has been the subject of extensive research in many species, has been the basis of structure-activity efforts, and it has been used in model experiments on induction, promotion, and inhibition of chemical carcinogenesis. It also serves as a model compound for investigations in molecular carcinogenesis. Accordingly, any of the recent investigations of acetyltransferases were based on 2-AAF as the model (22–24, 26–28, 328). Similarly, for other transferases (329, 330), DNA adduct formation (331), or other mechanistic aspects of carcinogenesis (332), this compound is the model. Data from the ED_{01} study, where about 25,000 mice were given 2-AAF at various levels have yielded many papers; the data are still being reexamined (333–336). Various reviews on 2-AAF have appeared (34, 337, 338), but realistically the number of papers on 2-AAF and its derivatives (approximately 125 in 5 years) is so large that a review every 5 years or so would be needed to keep research personnel informed.
109.5 Standards, Regulations, or Guidelines of Exposure
Although none have been assigned, 2-AAF was one of the compounds on the original OSHA list of carcinogens in 29CFR1910.1014.
110.0 **N**-Phenyl-2-naphthylamine
110.0.1 CAS Number: [*135-88-6*]

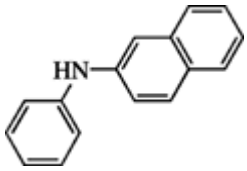
110.0.2 Synonyms: *N*-Phenyl-beta-naphthylamine; *N*-phenyl-2-naphthalenamine; PBNA; phenyl-beta-naphthylamine; Agerite; PBN; aceto pbn; anilinonaphthalene; 2-anilinonaphthalene; antioxidant 116; antioxidant pbn; N-(2-naphthyl)aniline; 2-naphthylphenylamine; beta-naphthylphenylamine; neozon d; neozone; nilox pbna; nonox d; 2-phenyl-aminonaphthalene; phenyl-2-naphthylamine; stabilizator ar; neosone d; vulkanox pbn; nonox dn; *N*-(2-naphthyl)-*N*-phenylamine; stabilizer ar; nocrac d; naftam 2; *N*-beta-naphthyl-*N*-phenylamine; 2-(*N*-phenylamino)naphthalene

110.0.3 Trade Names: NA

110.0.4 Molecular Weight: 219.29

110.0.5 Molecular Formula: $C_{16}H_{13}N$

110.0.6 Molecular Structure:



Databases and inventories where listed: IARC, IL, MA, NTPT, PA, REL, TLV, WHMI, CANCERLIT, CCRIS, DART, DSL, EINECS, EMIC, EMICBACK, ETICBACK, HSDB, MESH, RTECS, TOXLINE, TSCAINV, SUPERLIST.

110.1 Chemical and Physical Properties (202)

Physical state	Gray to tan flakes or powder
Boiling point	395°C
Melting point	108°C
Solubility	Soluble in acetone, benzene, ethanol; insoluble in water

110.2 Production and Use

N-Phenyl-2-naphthylamine has been used as an antioxidant in rubber and other polymers.

110.3 Exposure Assessment

OSHA method #96.

110.4 Toxic Effects

N-Phenyl-2-naphthylamine has been tested for carcinogenicity in various species, including dogs, hamsters, mice, and rats (227). A two-year chronic feeding study in mice and rats, conducted by the NTP, was negative (227), as were other tests in dogs and hamsters. However, this compound remains under a cloud because dogs and humans dephenylated up to 0.03% of a dose to 2-naphthylamine (202, 227). 2-Naphthylamine has induced bladder tumors in animals, is associated with bladder cancer in exposed humans, and was on the original OSHA list of carcinogens.

110.5 Standards, Regulations, or Guidelines of Exposure

None assigned, but ACGIH has an A4 designation for phenyl-2-naphthylamine, with a note on irritation by the compound.

111.0 Triphenylamine

111.0.1 CAS Number: [*603-34-9*]

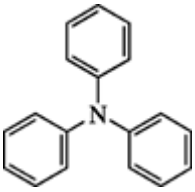
111.0.2 Synonyms: *N*,*N*-Diphenylbenzenamine; triphenyl amine (triphenylene)

111.0.3 Trade Names: NA

111.0.4 Molecular Weight: 245.32

111.0.5 Molecular Formula: $C_{18}H_{15}N$

111.0.6 Molecular Structure:



Databases and inventories where listed: IL, MA, PA, PEL, REL, TLV, WHMI, CCRIS, EINECS, EMICBACK, HSDB, RTECS, TOXLINE, TSCAINV, SUPERLIST.

111.1 Chemical and Physical Properties (2)

Specific gravity	0.774 (0°C)
Melting point	127–129°C
Solubility	Soluble in benzene, ether
Boiling point	348°C

111.2 Production and Use

Triphenylamine is used as a photoconductor on polymer film (2).

111.4 Toxic Effects

The previous edition gave data on acute toxicity which is low; the LD_{50} in rats was 3200–6400 mg/kg; in mice it was 1600–3200 mg/kg.

111.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV and NIOSH REL is 5 mg/m^3; there is no carcinogenicity designation because of the lack of a long-term test. Irritation is noted as the reason for the TLV.

Aromatic Nitro and Amino Compounds
Elizabeth K. Weisburger, Ph.D., Vera W. Hudson, MS

5 Conclusions

Besides the amino and nitro compounds discussed in the preceding sections, there are still others that are employed in research on mechanisms of various toxic effects.

3,2'-Dimethyl-4-aminobiphenyl leads to colon tumors in rodents; it is being used as a model to study any relationship between acetylator genotype and sequential steps in colon carcinogenesis (339, 340). Still other arylamines are unusual in their actions; 2-anthramine (2-aminoanthracene) is one of few aromatic amines to cause skin tumors when painted on rats or hamsters, but the mechanism of its action has not been elucidated (3). The nitroarenes in engine exhaust are models for investigating structure-activity relationships and the enzyme systems involved in the activation of these compounds (341, 342). However, the diversity of effects attributed to aryl nitro and amino compounds cannot consistently be explained on the basis of structure. Minimal changes often lead to marked differences in response. Furthermore, the correlation between mutagenicity and carcinogenicity is not absolute. And despite having a common moiety, the amino group, activation pathways for some of the carcinogenic arylamines differ.

The reactivity of aryl nitro and amino compounds makes them useful in the preparation of many valuable substances, including drugs, dyes, pesticides, and polymers. Reactivity with constituents of living tissue is also the reason for their toxicity, thus the need to avoid exposure and to observe the

exposure limits set by regulatory and other agencies.

Aromatic Amino and Nitro–Amino Compounds and their Halogenated Derivatives
Yin-Tak Woo, Ph.D., DABT, David Y. Lai, Ph.D., DABT

General Overview
1.0 Introduction
Aromatic amines are organic compounds that contain at least one amino group attached directly to an aryl moiety. Aromatic amines represent one of the most important classes of industrial and environmental chemicals. Many aromatic amines have been shown to be potent carcinogens and mutagens and/or hemotoxicants capable of inducing methemoglobinemia. Since the introduction of substituted anilines and naphthylamines as intermediates for the manufacture of azo dyes in the mid-1800s, aromatic amines have found numerous uses in various industries. Substantial worker exposure to aromatic amines with subsequent induction of bladder cancer occurred before preventive measures were instituted. Beyond occupational exposure, humans may also be exposed to aromatic amines through environmental sources. At least three carcinogenic aromatic amines (4-aminobiphenyl, 2-naphthylamine, and *o*-toludine) have been detected in cigarette smoke. Many commonly used pharmaceuticals contain or are aromatic amines. Owing to their hazard potential, aromatic amines have been the subject of many biomonitoring studies, making them model compounds in molecular dosimetry and epidemiology studies. Since extensive information is available on the metabolic pathways and, to a lesser extent, the mechanism(s) of action, aromatic amines have also become targets for genetic polymorphism studies with ultimate goals of identifying susceptible subpopulations, and designing of strategies for cancer prevention and intervention. The multifaceted interest in aromatic amines has continued to attract a tremendous amount of scientific studies and attention. Since the publication of the previous edition of Patty's on aromatic amines (1), many reviews and important research articles on aromatic amines have been published (2–102). In this chapter, we present an overview of the aromatic amine class as a whole with emphasis on recent studies, followed by an updated description on individual chemicals grouped into seven subgroups of structurally related compounds.
1.1 Production and Uses
After peaking during the past two decades, recent worldwide production and sales volume for aromatic amines have been growing only at the average rate of expansion of the chemical market as a whole. United States production of many aromatic amines has been declining or even ceased. Table 58.1 summarizes the recent estimates of U.S. production/import volume range of most of the aromatic amines covered in this chapter (103). Estimated worldwide production volumes of individual aromatic amines are also covered under discussion on specific chemicals when the information is available. In general, the supply of many aromatic amines is shifting from United States to East Asian countries along with textile and dye production (104).

Aromatic Amino and Nitro–Amino Compounds and their Halogenated Derivatives
Yin-Tak Woo, Ph.D., DABT, David Y. Lai, Ph.D., DABT

Specific Compounds
The compounds covered in this chapter are grouped into seven subgroups of structurally related

compounds: (1) aniline and derivatives, (2) toluidines and derivatives, (3) aminophenols and nitroaminophenols, (4) phenylenediamines and derivatives, (5) toluenediamines, (6) chlorinated nitrobenzene compounds and (7) bicyclic and tricyclic aromatic amines.

Aromatic Amino and Nitro–Amino Compounds and their Halogenated Derivatives

Yin-Tak Woo, Ph.D., DABT, David Y. Lai, Ph.D., DABT

A. Aniline and Derivatives

Aniline is the simplest of the aromatic amines with an amino group attached to a benzene. Aniline derivatives that are also widely used in industry as intermediates in chemical synthesis include *N*-alkyl-, *N,N*-dialkyl, nitro-, chloro-, and chloronitro-aniline. Aniline and its derivatives are hematotoxic and have a similar pattern of toxicity. Acute poisoning in humans and animals is manifested by symptoms secondary to methemoglobinemia; several of them have been shown to be potent methemoglobin-forming agents. Animal studies have shown that aniline and its monochloro derivatives are also nephrotoxic and hepatotoxic. In general, alkyl derivatives are less toxic than aniline; however, addition of chloro and nitro groups on the phenyl ring may increase the toxicity of aniline. For instance, a comparative nephrotoxicity study of aniline with its monochloro derivatives, *o-, m-*, and *p*-chloroaniline, has shown that chloro substituents on the phenyl ring of aniline increased the nephrotoxic potential of aniline, the *ortho* substitution producing the greatest enhancement. All three choroaniline isomers are hematotoxic in rodents, with rats being more sensitive than mice and with the relative toxicities following the order *p*- > *m*- > *o*-isomer. In genotoxicity assays, *p*-chloroaniline has been shown to yield positive results in virtually all assays, whereas only mixed results have been obtained on the *o*, and *m*-isomers (154). *m*-Nitro, *o*-chloro-, *m*-chloro, and 2,4-dichloroanilines are also irritants to the skin and mucous membrane. Several dichloro-anilines have been demonstrated to be skin sensitizers. Except for *p*-nitroaniline, there is no evidence that these compounds are reproductive or developmental toxicants. They are inactive in most mutagenicity tests in *Salmonella typhimurium* (except in strain TA98 with a co-mutagen), but have been shown to induce gene mutations and chromosomal aberrations in other genotoxicity assay systems. Although there is limited or equivocal evidence of carcinogenicity in rodent studies, they are considered suspect human carcinogens.

2.0 Aniline

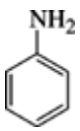
2.0.1 CAS Number: [*62-53-3*]

2.0.2–2.0.3 Synonyms and Trade Names: Benzamine, aniline oil, phenylamine, aminobenzene, phenylamine, aminophen, kyanol, benzidam; blue oil, C.I. 76000, C.I. oxidation base 1, cyanol, krystallin, anyvim, and arylamine

2.0.4 Molecular Weight: 93.128

2.0.5 Molecular Formula: C_6H_7N

2.0.6 Molecular Structure:



Aromatic Amino and Nitro–Amino Compounds and their Halogenated Derivatives
Yin-Tak Woo, Ph.D., DABT, David Y. Lai, Ph.D., DABT

B. Toluidines

Toluidines are aromatic amines with an amino group and a methyl group attached to benzene. There are three toluidine isomers: *o*-, *m*-, and *p*-toluidines, designated with respect to the positions of the amino group and the methyl group. They are used primarily as intermediates in the manufacture of azodyes for the textile industry. Major clinical signs of toxicity observed in humans exposed to toluidines and their chloro and nitro derivatives are methemoglobinemia and hematuria. Toluidines are suspected human carcinogens, with *o*-toluidine being the strongest suspect. An excess of bladder tumors has often been found in workers exposed to varying combinations of dyestuffs containing toluidines. In experimental studies, significant increases of multiple-site tumor incidence have been observed in rats and/or mice on chronic administration of various toluidines in the diet.

22.0 **o**-Toluidine

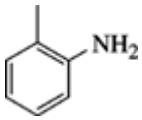
22.0.1 CAS Number: [*95-53-4*]

22.0.2–22.0.3 Synonyms and Trade Names: C.I. 37077, *o*-methylaniline, 2-methyl-1-aminobenzene, 2-methylaniline, 2-methylbenzenamine, 2-aminotoluene, 1-amino-2-methylbenzene, 2-amino-1-methylbenzene, 1-methyl-2-aminobenzene, *o*-tolylamine, and methyl-2-aminobenzene

22.0.4 Molecular Weight: 107.15

22.0.5 Molecular Formula: C_7H_9N

22.0.6 Molecular Structure:



22.1 Chemical and Physical Properties

o-Toluidine is a light yellow to reddish brown liquid. It has a density of 0.9984 (20/4°C), a melting point of –14.7°C, a boiling point of 200.2°C, a refractive index of 1.57276 (20°C), and a flash point of 86°C (closed cup). It is slightly soluble in water and soluble in alcohol and ether (155, 156).

22.2 Production and Use

Commercial production was first reported in the United States in 1922 for *o*-toluidine and in 1956 for *o*-toluidine hydrochloride. In 1983, U.S. production of *o*-toluidine was between 11 and 21 million pounds; 34 companies were identified as suppliers. In 1990, two suppliers of *o*-toluidine and ten suppliers of *o*-toluidine hydrochloride were identified; no production volumes are available (60). *o*-Toluidine and its hydrochloride salt are used primarily as an intermediate in the manufacture of dyes, including azo pigment dyes, triarylmethane dyes, sulfur dyes, and indigo compounds. These dyes are used primarily for printing textiles, in color photography, and as biologic stains. *o*-Toludine is also used as an intermediate for rubber vulcanizing chemicals, pharmaceuticals, and pesticides.

The greatest potential for exposure to *o*-toluidine and its hydrochloride salt are dyemakers and pigment makers through inhalation and dermal contact in the workplace. The National Occupational Hazard Survey estimated that from 1972 to 1974, 13,053 workers were potentially exposed to *o*-toluidine. The National Occupational Exposure Survey conducted from 1981 to 1983 indicated that 5,440 workers were exposed to *o*-toluidine. A total of 54,000 pounds of *o*-toluidine were reported to be released to the environment by 17 industrial facilities in the United States in 1990 (60). *o*-Toluidine is also present in cigarette smoke and is a metabolite of the local anesthetic prilocaine

(177).

22.3 Exposure Assessment

22.3.3 Workplace Methods The recommended method for determining workplace exposures to *o*-toluidine is NIOSH Analytical Method 2002 (111a).

22.3.5 Biomonitoring/Biomarkers An increased level of methemoglobin measured in blood of workers is a nonspecific indicator of exposure to methemoglobin-inducing chemicals, including *o*-toluidine. Investigations regarding other possible biomonitoring methods have recently demonstrated that *o*-toluidine binds to both albumin and hemoglobin and that a linear dose relationship exists for hemoglobin (178). Additionally, the biologic half-lives for the protein adducts are several times that reported for elimination of *o*-toluidine or its metabolites via the urine, thus providing evidence that these proteins may be valuable biomarkers of exposure to *o*-toluidine in the occupational setting (178). The formation of hemoglobin adduct has recently been developed as a biomonitoring method to assess worker exposure to *o*-toluidine in a chemical plant with known bladder cancer excess (93).

22.4 Toxic Effects

The oral LD_{50} in rats is reported to be 900–940 mg/kg; that of the hydrochloride salt, diluted in water, in rats is 2950 mg/kg (179). Oral, dermal, or respiratory tract absorption of *o*-toluidine can result in methemoglobinemia, reticulocytosis, hematuria, skin and eye irritation, and irritation of the epithelium of kidneys and bladder (163, 179).

o-Toluidine was reported to yield positive results in a variety of mutagenicity and related assays, which included Ames *Salmonella*, *in vitro* chromosome aberration, *in vitro* sister chromatid exchange (SCE), mouse lymphoma cell mutation, *in vitro* cell transformation, and *in vitro* unscheduled DNA synthesis tests (100, 116). It also caused somatic mutation in *Drosophila* but was negative in *in vivo* mouse micronucleus test (116).

An IARC working group (111) reported that there were not adequate data to evaluate the carcinogenicity of *o*-toluidine hydrochloride in humans. Although an excess of bladder tumors has often been found in workers exposed to varying combinations of dyestuffs, no population of workers exposed to *o*-toluidine alone has been described, and either the data were insufficient, or insufficient followup time has prevented a clear association being made with the exposure. An excess number of bladder cancers has recently been reported in workers exposed to *o*-toluidine and aniline; the authors concluded that it is more likely that *o*-toluidine is responsible for the observed excess number of cases of bladder cancer, although aniline may have played a role (93, 180).

There is sufficient evidence for the carcinogenicity of *o*-toluidine (as the hydrochloride salt) in experimental animals. When administered in the diet, *o*-toluidine induced various types of tumors in multiple sites, including hepatocellular carcinomas or adenomas in female mice and hemangiosarcomas at multiple sites in male mice of one strain, hemangiosarcomas and hemangiomas of the abdominal viscera in both sexes of another strain, increased incidences of sarcomas of multiple organs in rats of both sexes and mesotheliomas in male rats, and carcinomas of the urinary bladder in female rats (111).

22.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Forty-eight hours after the subcutaneous injection of a single dose of 400 mg/kg body weight *o*-[methy- ^{14}C]-toluidine hydrochloride to male Fischer 344 rats, 83.9% of the ^{14}C appeared in the urine, 3.3% in the feces, and 1.4% was exhaled as $^{14}CO_2$. Various hydroxy- and N-acetyl derivatives were identified as urinary metabolites (111).

22.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV-TWA adopted by ACGIH is 2 ppm with skin notation; the compound is considered a confirmed animal carcinogen with unknown relevance to humans (A3 classification) by the ACGIH (160). The OSHA exposure limit is 5 ppm. NIOSH considers this compound to be an occupational carcinogen (110) and recommends appropriate worker protection. The NIOSH immediately dangerous to life or health concentration (IDLH) is 50 ppm (110).

23.0 **m**-Toluidine
23.0.1 CAS Number: [*108-44-1*]

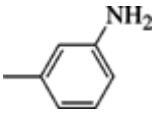
23.0.2 Synonyms: *m*-Tolylamine; 3-methylbenzenamine, 3-aminophenylmethane, 3-methylaniline, *m*-toluamine, and *m*-aminotoluene

23.0.3 Trade Names: NA

23.0.4 Molecular Weight: 107.15

23.0.5 Molecular Formula: C_7H_9N

23.0.6 Molecular Structure:



23.1 Chemical and Physical Properties
m-Toluidine is a liquid. It has a melting point of –30°C, a boiling point of 203.3°C, and a vapor pressure of 1 torr at 41°C. It is slightly soluble in water, soluble in alcohol, ether, acetone, and benzene (155, 156).
23.2 Production and Use
The major uses of *m*-toluidine and its hydrochloride are as intermediates in the manufacture of dyes and other chemicals. Production has been limited because its nonplanar configuration, due to steric hindrance, limits its use in direct dyes. It is used in only 12 dyes; none is of major importance (181).

Exposure to *m*-toluidine is primarily occupationally via inhalation and dermal contact. *m*-Toluidine may be released in wastewater during its production and use in the manufacture of dyes and other chemicals.
23.3 Exposure Assessment
23.3.5 Biomonitoring/Biomarkers An increased level of methemoglobin measured in blood of workers is a nonspecific indicator of exposure to methemoglobin-inducing chemicals including *m*-toluidine.
23.4 Toxic Effects
Clinical signs of intoxication in humans include methemoglobinemia and hematuria; it is absorbed orally, dermally, and via the respiratory tract. There are no epidemiologic studies on workers who have been exposed only to *m*-toluidine. The oral LD_{50} of *m*-toluidine (rats) is reported to be 974 mg/kg (179).

In an 18-mo carcinogenicity diet evaluation in male CD rats (8,000 ppm for 3 mo, then 4,000 ppm for an additional 15 mo; or 16,000 ppm for 3 mo, then 8,000 for an additional 15 mo), and male and female CD-1 mice (16,000 ppm for 5 mo, then 4,000 ppm in males and 8,000 ppm in females for an additional 13 mo; or 32,000 ppm in both sexes for 5 mo and then 8,000 ppm in males and 16,000 ppm in females for additional 13 mo), there was no evidence of a significant increase of incidence of any kind of tumor in the rats, and only a significant increase in liver tumors in male mice (182).
23.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV-TWA is 2 ppm, with a skin notation (160).
24.0 **p**-Toluidine
24.0.1 CAS Number: [*106-49-0*]

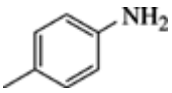
24.0.2–24.0.3 Synonyms and Trade Names: 4-Aminotoluene, 4-methylaniline, naphthol as-kgll, and

4-methylbenzenamine

24.0.4 Molecular Weight: 107.15

24.0.5 Molecular Formula: C_7H_9N

24.0.6 Molecular Structure:



24.1 Chemical and Physical Properties
p-Toluidine occurs in the form of plates or leaflets. It has a melting point of 43°C, a boiling point of 201.5°C, a refractive index of 1.5532 (59.1°C), a flash point of 86°C (closed cup), and a vapor pressure of 1 torr at 42°C. It is slightly soluble in water and soluble in alcohol, ether, acetone, methanol, or carbon disulfide. It has an aromatic, winelike odor and a burning taste (155, 156).
24.2 Production and Use
p-Toluidine and its hydrochloride are used primarily in the synthesis of dyes and in the preparation of ion exchange resins. No information on production volumes is available.

Exposure to *p*-toluidine is primarily occupationally via inhalation and dermal contact. *p*-Toluidine may be released in wastewater during its production and use in the manufacture of dyes and other chemicals. It is also released during the thermal degradation of polyurethane products.
24.3 Exposure Assessment
24.3.3 Biomonitoring/Biomarkers An increased level of methemoglobin measured in blood of workers is a nonspecific indicator of exposure to *p*-toluidine, which is a potent methemoglobin inducer.
24.4 Toxic Effects
Clinical signs of toxicity in humans include anoxic methemoglobinemia and hematuria. It is absorbed orally, dermal, and via the respiratory tract. There are no epidemiologic studies reported on workers who have been exposed only to *p*-toluidine. The oral LD_{50} of *p*-toluidine is 656 mg/kg in rats and 794 mg/kg in mice; its hydrochloride salt in water was 1285 mg/kg in rats; the LD_{50} (rabbit dermal) is 890 mg/kg (179).

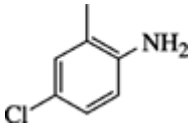
In an 18-mo *p*-toluidine hydrochloride diet carcinogenicity study, male CD rats (1000 and 2000 ppm for 18 mo) did not develop statistically significant increases of tumors; however, CD-1 male and female mice (1000 ppm for 6 mo and then 500 ppm for an additional 12 mo; or 2000 ppm for 6 mo and then 1000 ppm for an additional 12 mo) showed significant increases in liver carcinomas, in males in both dose levels and in females in the high-dose level (182).
24.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV-TWA is 2 ppm (approximately 9 mg/m^3) with skin notation; it is classified as a confirmed animal carcinogen with unknown relevance to humans (A3 classification) by the ACGIH (160).
25.0 4-Chloro-**o**-toluidine
25.0.1 CAS Number: [*95-69-2*]

25.0.2–25.0.3 Synonyms and Trade Names: para-Chloro-ortho-toluidine, 4-chloro-2-methylaniline, 4-chloro-2-methylbenzenamine, 2-amino-5-chlorotoluene, azoene fast red tr base, brentamine fast red tr base, 5-chloro-2-aminotolueue, 4-chloro-6-methylaniline, daiz red base tr, deval red k, deval red tr, deazo fast red tra, fast red base tr, fast red 5ci base, fast red tr 11, fast red tro base, kako red tr base, kambamine red tr, 2-methyl-4-chloroaniline, mitsui red tr base, red base nir, red tr base, sonya fast red tr base, and tula base fast red tr

25.0.4 Molecular Weight: 141.60

25.0.5 Molecular Formula: C_7H_8ClN

25.0.6 Molecular Structure:



25.1 Chemical and Physical Properties
4-Chloro-*o*-toluidine occurs in the form of leaflets. It has a melting point of 27°C and a boiling point of 241°C. It is soluble in alcohol (155, 156).
25.2 Production and Use
Commercial production of 4-chloro-*o*-toluidine was first reported in the United States in 1939. However, production has been stopped since 1979, and all importation was discontinued in 1986. The U.S. International Trade Commission (USITC) reported that 89,753 pounds of 4-chloro-*o*-toluidine and its hydrochloride salt were imported in 1980, 83,098 pounds in 1981, 31,747 pounds in 1982, and 44,147 pounds in 1983 (112). It is used as an azo coupler in the synthesis of azo dyes used in the textile industry and for the manufacture of the insecticide chlordimeform (3, 112).

The greatest potential for exposure to 4-chloro-*o*-toluidine and its hydrochloride salt are dyemakers, pigment makers, and manufacturers of chloridimeform through inhalation and dermal contact in the workplace. The National Occupational Hazard survey, conducted by NIOSH from 1972 to 1974, estimated that 1379 workers were potentially exposed to 4-chloro-*o*-toluidine. The National Occupational Exposure survey (1981–1983) indicated that 1357 workers, including 675 women, were potentially exposed to 4-chloro-*o*-toluidine and 4-chloro-*o*-toluidine hydrochloride. As a decomposition product of chlordimeform, 4-chloro-*o*-toluidine has been identified in field samples of plant materials treated with chlordimeform, a potential source of human exposure to 4-chloro-*o*-toluidine by the ingestion route (112).
25.3 Exposure Assessment
25.3.3 Biomonitoring/Biomarkers An increased level of methemoglobin measured in blood of workers is a nonspecific indicator of exposure to methemoglobin-inducing chemicals, including 4-chloro-*o*-toluidine. Hemoglobin adduct formation has been demonstrated in rats exposed to 4-chloro-*o*-toluidine and may be used as a dosimeter for human exposure to the chemical (73).
25.4 Toxic Effects
The intraperitoneal LD_{50} of 4-chloro-*o*-toluidine hydrochloride was 560–700 mg/kg in rats and 680–720 mg/kg in mice. Hematuria and hemorrhagic cystitis have been reported in workers exposed to 4-chloro-*o*-toluidine (112). 4-Chloro-*o*-toluidine has been demonstrated to be genotoxic in a variety of prokaryotic and mammalian *in vitro* and *in vivo* test systems (112).

According to the IARC working group, limited human evidence and sufficient animal data are available to classify this agent a Group 2A compound and therefore probably carcinogenic to humans (112, 116). Between 1982 and 1990, 7 cases of urinary bladder cancer were detected in a group of 49 workers producing the insecticide chlordimeform from 4-chloro-*o*-toluidine on an irregular basis for an average of 18 years. The incidence of bladder tumors in these workers was significantly higher than that of the cancer registers. In other studies, increased incidences of cancer were also observed in workers exposed to 4-chloro-*o*-toluidine and several other compounds that are known or suspected carcinogens.

In experimental studies, a significant increase in hemangiosarcomas or hemangiomas was observed in both sexes of two strain of mice on chronic administration of 4-chloro-*o*-toluidine hydrochloride

in the diet (112, 116).

25.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Following oral administration of [^{14}C-methyl]-4-chloro-*o*-toluidine to male and female rats, 71% of the administered radioactivity was eliminated in the urine and 24.5% in the faeces within 72 h. 4-Chloro-*o*-toluidine binding to DNA was demonstrated *in vitro* with calf thymus DNA and *in vivo* when it was administrated by intraperitoneal injection to rats (112).

25.5 Standards, Regulations, or Guidelines of Exposure

OSHA regulates 4-chloro-*o*-toluidine and 4-chloro-*o*-toluidine hydrochloride under Hazard Communication Standard. 4-Chloro-*o*-toluidine hydrochloride is regulated as a hazardous constituent of waste under the Resource Conservation and Recovery Act (RCRA) and is subject to reporting/recordkeeping requirements under RCRA and Section 313 of the Emergency Planning and Community Right-to-Know Act of EPA. The Toxic Substances Control Act (TSCA) of the EPA also subjects 4-chloro-*o*-toluidine and its hydrochloride salt to reporting requirements applicable to any significant new use (60).

26.0 5-Chloro-**o**-toluidine

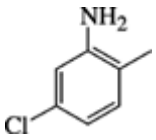
26.0.1 CAS Number: [*95-79-4*]

26.0.2–26.0.3 Synonyms and Trade Names: 5-Chloro-2-methylaniline, 5-chloro-2-methylbenzenamine, 2-amino-4-chlorotoluene, 1-amino-3-chloro-6-methylbenzene, 4-chloro-2-aminotoluene, 3-chloro-6-methylaniline, acco fast red kb base, ansibase red kb, azoic diazo component 32, azoene fast red kb base, fast red kb amine, fast red kb base, fast red kb salt, fast red kb salt supra, fast red kbs salt, genazo red kb soln, hiltonil fast red kb base, lake red bk base, metrogen red former kb soln, naphthosol fast red kb base, pharmazoid red kb, red kb base, spectrolene red kb, stable red kb base, C.I. Azoic Diazo Component No. 32, C.I. 37090, 2-methyl-5-chloroaniline, and 5-chloro-2-methyl-benzamine

26.0.4 Molecular Weight: 141.60

26.0.5 Molecular Formula: C_7H_8ClN

26.0.6 Molecular Structure:



26.1 Chemical and Physical Properties

5-Chloro-*o*-toluidine has a melting point of 22°C and a boiling point of 237°C (155, 156).

26.2 Production and Use

Specific production volumes for 5-chloro-*o*-toluidine are not available. In 1977, the compound and its hydrochloride salt were produced or sold in excess of 1,000 pounds by one U.S. company. In 1974, U.S. imports of 5-chloro-*o*-toluidine amounted to 42,163 pounds. 5-Chloro-*o*-toluidine is used as an azo coupler in the synthesis of azo dyes used in the textile industry (3).

The greatest potential for exposure to 5-chloro-*o*-toluidine is for workers in the chemical and dye manufacturing and textile industries.

26.3 Exposure Assessment

26.3.3 Biomonitoring/Biomarkers Hemoglobin adduct formation has been demonstrated in rats exposed to 5-chloro-*o*-toluidine and may be useful dosimeter for human exposure (73).

26.4 Toxic Effects

No specific acute toxicity data for 5-chloro-*o*-toluidine are available. The compound may induce a similar spectrum of toxicity as other toluidines. The chloro derivatives of toluidines are generally

more potent than toluidines in producing methemoglobinemia and hematuria.

A bioassay for the possible carcinogenicity of 5-chloro-*o*-toluidine was conducted using Fischer 344 rats and B6C3F$_1$ mice. Groups of 50 male and 50 female rats and mice were given 5-chloro-*o*-toluidine in the diet at 2500 or 5000 ppm for rats and 2000 or 4000 ppm for mice. The compound was administered for 78 wk to both rats and mice, followed by an observation period of up to 26 wk for rats and 13 wk for mice. Under the conditions of this bioassay, 5-chloro-*o*-toluidine was carcinogenic to the mice, inducing hemangiosarcomas and hepatocellular carcinomas in both males and females. There was no conclusive evidence of the carcinogenicity of the compound in the rats (183).

26.5 Standards, Regulations or Guidelines of Exposure

No information is available.

27.0 6-Chloro-**o**-toluidine

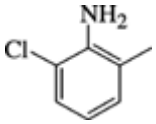
27.0.1 CAS Number: [*87-63-8*]

27.0.2–27.0.3 Synonyms and Trade Names: 6-Chloro-2-methylaniline, 2-chloro-6-methylaniline, 2-chloro-6-methylbenzenamine, 2-amino-3-chlorotoluene, and 6-chloro-2-toluidine

27.0.4 Molecular Weight: 141.60

27.0.5 Molecular Formula: C_7H_8ClN

27.0.6 Molecular Structure:



6-Chloro-*o*-toluidine has a melting point of 2°C, a boiling point of 215°C, and a flash point of 98°C. It is soluble in water and has a specific gravity of 1.152.

28.0 5-Nitro-**o**-toluidine

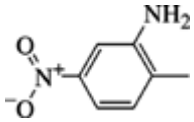
28.0.1 CAS Number: [*99-55-8*]

28.0.2–28.0.3 Synonyms and Trade Names: 2-methyl-5-nitrobenzenamine; 2-methyl-5-nitroaniline; 2-amino-4-nitrotoluene; 1-amino-2-methyl-5-nitrobenzene; 4-nitro-2-aminotoluene; amarthol fast scarlet g base; amarthol fast scarlet g; salt; azoene fast scarlet gc base; azoene fast scarlet gc salt; azofix scarlet g salt; azogene fast scarlet g; C.I. 371.05; C.I. azoic diazo component 12; dainichi fast scarlet g base; daito scarlet base g; devol scarlet b; devol scarlet g salt; diabase scarlet g; diazo fast scarlet g; fast red sg base; fast scarlet base g; fast scarlet base j; fast scarlet g; fast scarlet g base; fast scarlet gc base; fast scarlet j salt; fast scarlet mN4t base; fast scarlet t base; hiltonil fast scarlet g base; hiltonil fast scarlet gc base; hiltonil fast scarlet g salt; kayaku scarlet g base; lake scarlet g base; lithosol orange r base; mitsui scarlet g base; naphthanil scarlet g base; naphtoelan fast scarlet g base; naphtoelan fast scarlet g salt; PNOT; scarlet base ciba ii; scarlet base irga ii; scarlet base nsp; scarlet g base; sugai fast scarlet g base; symulon scarlet g base; Fast Red G Base; C.I. Azoic Diazo Component No. 12.

28.0.4 Molecular Weight: 152.15

28.0.5 Molecular Formula: $C_7H_8N_2O_2$

28.0.6 Molecular Structrure:



28.1 Chemical and Physical Properties
5-Nitro-*o*-toluidine occurs in the form of yellow monclinic prisms. It has a melting point of 107.5°C. It is soluble in acetone, benzene, chloroform, diethyl ether, and ethanol (155, 156).
28.2 Production and Use
Production of 5-nitro-*o*-toluidine in the United States was reported to 180 ton in 1972 and 57 ton in 1975 (112). It has been used as a precursor in the synthesis of a wide varieties of azo dyes. It is also used as a coupling component in the synthesis of organic textile dyes such as Naphthol Red M. The nitro moiety serves as a chromophore (in common with other groups such as nitroso, carbonyl, thiocarbonyl, azo, azoxy, azomethine, and ethenyl, in which the double bonds contribute to the absorption of visible light); the amino group serves as an auxochrome (in common with other groups such as alkylamino, dialkylamine, methoxy, or hydroxy), which functions by intensifying or modifying the color (184).

The greatest potential for exposure to 5-nitro-*o*-toluidine is for workers at dye manufacturing facilities.
28.3 Exposure Assessment
28.3.3 Biomonitoring/Biomarkers An increased level of methemoglobin measured in blood of workers is a nonspecific indi cator of exposure to methemoglobin-inducing chemicals, including 5-nitro-*o*-toluidine.
28.4 Toxic Effects
Methemoglobinemia was induced in guinea pigs and cats after IP injection of the compound (112). It is also the major toxic effect observed in workers following excessive exposure. In addition, upon dermal contact the compound may irritate the skin and cause dermatitis. 5-Nitro-*o*-toluidine has been demonstrated to be genotoxic in a variety of prokaryotic and mammalian *in vitro* and *in vivo* test systems (112). There are no data available for evaluating carcinogenic risk to humans. When 5-nitro-*o*-toluidine was administered as a dietary feeding study to F344 rats (50 or 100 ppm) and B6C3F1 mice (1200 or 2300 ppm) of both sexes, hepatocellular carcinomas were produced in mice but not in rats (185).
28.5 Standards, Regulations, or Guidelines of Exposure
No information is available.

Aromatic Amino and Nitro–Amino Compounds and their Halogenated Derivatives
Yin-Tak Woo, Ph.D., DABT, David Y. Lai, Ph.D., DABT

C. Aminophenols and Nitroaminophenols
Aminophenols and nitroaminophenols are widely used for manufacture of dyes and pharmaceuticals. They are also directly used, along with many other chemicals, as ingredients of hair dyes/colorants and related products and therefore may lead to occupational and consumer exposure. The International Agency for Research on Cancer (37) has extensively reviewed various epidemiological and case-control studies showing excess risk for cancer of the urinary bladder in male hairdressers and barbers and possible excess risk for cancer of the lung and other target sites and concluded that there is evidence, albeit somewhat limited, that occupation as a hairdresser or barber entails exposures that are probably carcinogenic (Group 2A). In contrast to professional exposure, there is inadequate evidence to evaluate the carcinogenic risk of personal use of hair dyes/colorants.

In general, the introduction of the hydrophilic hydroxy group to aromatic amines is expected to decrease its absorption and increase its excretion and therefore may appear to be detoxifying in nature. However, if the hydroxy group is *ortho* or *para* to the amino group, highly reactive and toxic quinoneimine intermediates may be generated after oxidation. The introduction of an additional nitro group to aminophenol may yield an additional amino group via reduction or may confer acute toxicity by acting as an uncoupler of oxidative phosphorylation.

29.0 **o**-Aminophenol

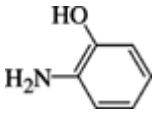
29.0.1 CAS Number: [*95-55-6*]

29.0.2–29.0.3 Synonyms and Trade Names: 2-Aminophenol, 2-amino-1-hydroxybenzene, basf ursol 3ga, benzofur gg, C.I. 76520, C.I. oxidation base 17, fouramine op, *o*-hydroxyaniline, nako yellow 3ga, paradone olive green b, pelagol 3ga, pelagol grey gg, zoba 3ga, and 2-aminobenzenol

29.0.4 Molecular Weight: 109.13

29.0.5 Molecular Formula: C_6H_7NO

29.0.6 Molecular Structure:



29.1 Chemical and Physical Properties

o-Aminophenol occurs as colorless, odorless rhombic needles or plates that readily become grayish or yellowish brown upon exposure to air and light. It has a molecular weight of 109.13, a density of 1.33 g/cm^3 and a melting point of 175°C and is sublimable. It is soluble in water (2 g/100 mL cold water), alcohol (5 g/100 mL), freely soluble in ether, and slightly soluble in benzene (155, 186).

29.2 Production and Use

There is a scarcity of production data on aminophenols because they are often reported as aniline derivatives (186). *o*-Aminophenol is used as an azo and sulfur dye intermediate and for dyeing fur and hair; it is widely used in the cosmetics, dye, and drug industries.

Occupational exposure may occur to hairdressers, barbers, and dye workers. Occasional exposure may also occur through personal use of hair dyes/colorants.

29.3 Exposure Assessment

Biomonitoring data are not available.

29.4 Toxic Effects

o-Aminophenol is not readily absorbed through intact skin but may prove to be a sensitizing agent with resultant contact dermatitis. When inhaled in excessive amounts, it may cause methemoglobinemia as well as bronchial asthma. Intraperitoneal administration (100–200 mg/kg) to Syrian golden hamsters on day 8 of gestation produced a significant teratogenic response similar to that of *p*-aminophenol (see section 31), including neural tube defects (exencephaly, encephalocele, and spina bifida), eye defects, and skeletal defects (129). However, no teratogenicity study by the oral route of administration was found. The compound was reported to be mutagenic in the Ames test (100).

29.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Aminophenols are generally metabolized by *N*-acetylation with the relative rate following the order *p*- > *m*- > *o*- (187). The phenolic group may also be conjugated (e.g., glucuronide) to facilitate excretion. Reactive electrophilic quinoneimine derivatives may be formed by oxidation of *o* or *p* isomer but not the *m* isomer. The oxidation product of *o*-aminophenol has been shown to bind to protein; however, there was no evidence of binding to nucleic acids (188).

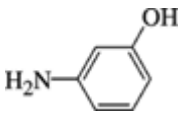
29.5 Standards, Regulations, or Guidelines of Exposure
There is no information on setting of hygienic standards of permissible exposure
30.0 **m**-Aminophenol
30.0.1 CAS Number: [*591-27-5*]

30.0.2–30.0.3 Synonyms and Trade Names: 3-Aminophenol, 3-amino-1-hydroxybenzene, 3-hydroxyaniline, *m*-hydroxyaminobenzene, basf ursol bg, C.I. 76545, C.I. oxidation base 7, fouramine eg, fourrine 65, fourrine eg, furro eg, futramine eg, nako teg, pelagal eg, renal eg, tetral eg, ursol eg, zoba eg, and *m*-hydroxyphenylamine

30.0.4 Molecular Weight: 109.13

30.0.5 Molecular Formula: C_6H_7NO

30.0.6 Molecular Structure:



30.1 Chemical and Physical Properties
m-Aminophenol occurs as colorless, odorless prisms at room temperature and is relatively more stable than its *o* or *p* isomer. It has a melting point of 125°C; it is soluble in cold water (2.5 g/100 mL) and very soluble in alcohol, petroleum ether, and hot water (155, 156, 186).
30.2 Production and Use
m-Aminophenol is used chiefly in the synthesis of dyes and occasionally as a hair dye [red-brown color obtained with *p*-phenylenediamine or light orange with *p*-aminophenol (189)] and in the manufacture of *p*-aminosalicylic acid.

Occupational exposure may occur to hairdressers, barbers, and dye workers. Occasional exposure may also occur through personal use of hair dyes/colorants.
30.3 Exposure Assessment
Biomonitoring data are not available.
30.4 Toxic Effects
Intraperitoneal administration (100–200 mg/kg) of *m*-aminophenol to Syrian golden hamsters on day 8 of gestation produced inconsistent results. A teratogenic response was demonstrated at the mid dose of 150 mg/kg, but not at the high dose of 200 mg/kg (129). In a followup teratology study in which Sprague–Dawley rats were fed a diet of 0.1, 0.25, and 1.0% *m*-aminophenol for 90 d prior to mating, maternal toxicity was demonstrated at the highest dose level, and a significant reduction in body weight was noted in the 0.25% group, but there was no evidence of teratogenic or embryo-fetal toxicity at any dose level tested. Accumulation of iron-positive pigment within the liver, kidneys, and spleen was observed in dams fed a 1% diet, together with significant reduction in red blood cell count and hemoglobin level, as well as an increase in mean corpuscular volume, indicating a hemolytic effect; histomorphologic appearance of the thyroid indicated hyperactive activity (at 0.25 and 1.0% diet) (190). In contrast to *o*- and *p*-aminophenol and their glucuronides, neither *m*-aminophenol nor its conjugate with glucuronic acid has been shown to form methemoblobin *in vitro* (191). The compound was reported to be mutagenic in the Ames test (100).

30.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Aminophenols are generally metabolized by *N*-acetylation, with the relative rate following the order *p*- > *m*- > *o*- (187). The phenolic group may also be conjugated (e.g., glucuronide) to facilitate excretion. Unlike its *o*- or *p*-isomer, *m*-aminophenol does not undergo oxidation to quinone imine derivative.
30.5 Standards, Regulations, or Guidelines of Exposure
Hygienic standards of permissible exposure levels have not been assigned.

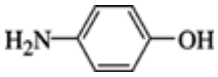
31.0 **p**-Aminophenol
31.0.1 CAS Number: [*123-30-8*]

31.0.2–31.0.3 Synonyms and Trade Names: 4-Aminophenol, *p*-hydroxyaniline, 4-amino-1-hydroxybenzene, Azol, Certinal, Citol, Paranol, Rodinal, Unal, Ursol P, paramidophenol, Kodelon, Energol, Freedol, Indianol, Kathol, basf ursol p base, benzofur p, C.I. oxidation base 6a, fouramine p, fourrine 84, PAP, pelagol grey p base, tertral p base, ursol p base, zoba brown p base C.I. 76550, durafur brown rb, fourrine p base, furro p base, nako brown r, pelagol p base, renal ac, 4-hydroxyaniline, and 4-aminobenzenol

31.0.4 Molecular Weight: 109.13

31.0.5 Molecular Formula: C_6H_7NO

31.0.6 Molecular Structure:



31.1 Chemical and Physical Properties
p-Aminophenol occurs as orthorhombic plates that deteriorate upon exposure to air and light. It has a melting point of 189°C and a boiling point of 284°C, and is sublimable. It is soluble in water (0.39% at 15°C, 0.65% at 24°C, 1.5% at 50°C, 8.5% at 90°C), very soluble in methyl ethyl ketone and absolute ethanol, but practically insoluble in benzene and chloroform (155, 156, 186).
31.2 Production and Use
p-Aminophenol is used in the manufacture of sulfur and azo dyes and in dyeing furs. The hydrochloride salt is used as a photographic developer in conjunction with sodium or potassium carbonates. *p*-Aminophenol was tried as an analgesic because of the belief that acetanilid was ultimately oxidized to *p*-aminophenol; however, it was found to be more toxic than its predecessor, acetanilid (192). Phenacetin, the ethyl ether of *N*-acetyl-*p*-aminophenol, also known as acetophenetidin, has been widely prescribed as an analgesic.

Occupational exposure may occur to hairdressers, barbers, and dye workers. Occasional exposure may also occur through personal use of hair dyes/colorants as well as through the use of OTC drugs that yield *p*-aminophenol as a metabolite.
31.3 Exposure Assessment
Biomonitoring data are not available.
31.4 Toxic Effects
31.4.1 Experimental Studies *p*-Aminophenol is a cytotoxic chemical; one mechanism associated with its cytotoxicity has been attributed to its activity as a tissue respiratory (oxidative phosphorylation) inhibitor (193).

Intraperitoneal administration (100–200 mg/kg) of the compound on day 8 of gestation to Syrian golden hamsters produced a significant teratogenic response including encephalocele and limb, tail, and eye defects; rare malformations observed included ectopic heart, cleft palate, occult cranioschisis, and abnormal genitalia. It was proposed that the mechanism may be related to the formation of a reactive quinone/quinoneimine. In contrast to IP administration, the compound was not teratogenic by the oral route at the same dosages (129).

p-Aminophenol was nonteratogenic in Sprague–Dawley rats fed a diet containing 0.07, 0.2, or 0.7% for up to 6 mo. After 13 wk, 25 females/group were mated to untreated males in a teratology study; after 20 wk, 20 males/group were mated to untreated virgin females in a dominant lethal mutagenicity study. Dose-related nephrosis was seen in both sexes after 13 and 27 wk and in the high-dose males that were removed from the test diet for a 7-wk recovery period. The authors noted

an increase in developmental variations associated with maternal toxicity at the mid- and high-dose levels. The dominant lethal study was equivocal (194).

p-Aminophenol has also been demonstrated to be nephrotoxic to rats. Administration of 25–100 mg/kg to male F344 rats resulted in a dose-related proximal nephropathy. The observed increased excretion of enzymes, glucose, and urine total protein, resulting in glycosuria and amino aciduria, indicated functional defects in the proximal tubule and reduced solute reabsorption efficiency (196). The necrosis is apparently restricted to the straight segment of the proximal tubule of the Fischer 344 rat; Sprague–Dawley rats, on the other hand, are more resistant to the nephrotoxicity of acetaminophen and its nephrotoxic metabolite *p*-aminophenol. The authors postulated that the strain differences in *p*-aminophenol-induced nephrotoxicity may be related to differences in the intrarenal activation of *p*-aminophenol (197).

Mutagenicity studies of *p*-aminophenol yielded mixed results: negative in Ames (100), positive in L5178 mouse lymphoma assay, and negative in CHO/HGPRT assay (51). Although a number of derivatives (e.g., phenacetin) of *p*-aminophenol have been reported to be carcinogenic (116, 198), there appears to be no evidence to indicate that *p*-aminophenol is carcinogenic.

31.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Aminophenols are generally metabolized by N-acetylation with the relative rate following the order *p*- > *m*- > *o*- (187). The phenolic group may also be conjugated (e.g., glucuronide) to facilitate excretion. Reactive electrophilic quinone imine derivatives may be formed by oxidation of the *o* or *p* isomer but not the *m* isomer.

31.4.2 Human Experience *p*-Aminophenol is considered a minor nephrotoxic metabolite of acetaminophen in humans. Long-term use of acetaminophen can result in an increased lipofuscin deposition in kidneys. *In vitro* studies have demonstrated that *p*-aminophenol can undergo oxidative polymerization to form melanin, a component of soluble lipofuscin. Hemolysis accompanies this process in whole blood. Long-term excessive use of phenacetin or acetaminophen has been associated with chronic renal disease, hemolytic anemia, and increased solid lipofuscin deposition in tissues (195).

31.5 Standards, Regulations, or Guidelines of Exposure

Hygienic standards of permissible exposures have not been assigned.

32.0 2-Amino-5-nitrophenol

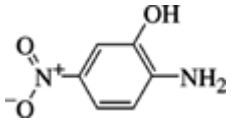
32.0.1 CAS Number: [*121-88-0*]

32.0.2–32.0.3 Synonyms and Trade Names: 2-Hydroxy-4-nitroaniline, 5-nitro-2-aminophenol, C.I. 76535, rodol yba, and ursol yellow brown a

32.0.4 Molecular Weight: 154.13

32.0.5 Molecular Formula: $C_6H_6N_2O_3$

32.0.6 Molecular Structure:



32.1 Chemical and Physical Properties

2-Amino-5-nitrophenol is an orange crystalline solid at room temperature. It has a melting point of 200°C; it is insoluble in water but soluble in alcohol, benzene, and most common organic solvents (155, 199).

32.2 Production and Use

2-Amino-5-nitrophenol is not produced in commercial quantities in the United States. The import volume between 1973 and 1979 was in the order of 13,400 kg per year. It is used as a colorant in semipermanent hair dyes and in the manufacture of azo dye (e.g., C.I. Solvent Red 8) for synthetic resins, lacquers, and wood stains (199).

In view of its widespread use in hair dyes, occupational (hairdressers and barbers) exposure is expected. A National Occupational Hazard Survey conducted by NIOSH in 1981–1983 estimated that a total of 14,512 U.S. workers, including 11,827 women, were potentially exposed to 2-amino-4-nitrophenol in 1339 beauty salons (105). Occasional consumer exposure may also occur through the personal use of hair dye products.

32.3 Exposure Assessment

Biomonitoring studies are not available.

32.4 Toxic Effects

The LD_{50} of 2-amino-5-nitrophenol in rats was reported to be greater than 4 g/kg by oral and 800 mg/kg by intraperitoneal administration (200). Mutagenicity and related genotoxicity studies indicated that the compound is positive in the Ames test with metabolic activation, positive in mouse lymphoma L5178Y assay without metabolic activation, positive in chromosomal aberrations and sister chromatid exchanges assays in CHO cells with and without metabolic activation (199), but negative in dominant lethal mutation in rats (200).

The potential carcinogenicity of 2-amino-5-nitrophenol was tested by NTP (199) by oral administration (gavage) in corn oil to F344/N rats (100 and 200 mg/kg) and $B6C3F_1$ mice (400 and 800 mg/kg) for 2 years. There was some evidence of carcinogenic activity in low-dose male rats, as indicated by increased incidence of acinar cell adenomas of the pancreas. No evidence of carcinogenic activity was found among female rats and the low-dose groups of male and female mice. The poor survival rates in the high-dose male rats and high-dose male and female mice reduced the sensitivity for detecting potential carcinogenic response.

32.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms There is no information on the disposition or metabolism of 2-amino-5-nitrophenol. However, the disposition of the closely related 2-amino-4-nitrophenol has been studied. Up to 1.67% of 2-amino-4-nitrophenol has been shown to be absorbed after dermal application to rats. Absorbed material was excreted in the urine within 24 h. Absorption has also been demonstrated after oral administration. Virtually all absorbed material was excreted in 5 d.

32.5 Standards, Regulations, or Guidelines of Exposure

Hygienic standards of permissible exposure have not been assigned. The use of 2-amino-5-nitrophenol in cosmetic products is prohibited in the European Economic Communities (36).

33.0 4-Amino-2-nitrophenol

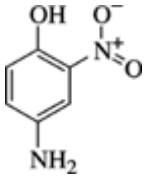
33.0.1 CAS Number: [*119-34-6*]

33.0.2–33.0.3 Synonyms and Trade Names: *p*-Aminonitrophenol, C.I. 76555, fourrine 57, fourrine brown pr, fourrine brown propyl, 4-hydroxy-3-nitroaniline, *o*-nitro-*p*-aminophenol, oxidation base 25, 3-nitro-4-hydroxyaniline, and C.I. oxidation base 25

33.0.4 Molecular Weight: 154.13

33.0.5 Molecular Formula: $C_6H_6N_2O_3$

33.0.6 Molecular Structure:



33.1 Chemical and Physical Properties
4-Amino-2-nitrophenol has a melting point of 131°C (155).
33.2 Production and Use
4-Amino-2-nitrophenol has been used in dyeing human hair and animal fur. The typical concentration in the "semi-permanent" hair dyes was estimated to be in the order of 0.1--1.0% (36).

In view of its use in hair dyes, occupational (hairdressers and barbers) exposure is expected. Occasional consumer exposure may also occur through the personal use of hair dye products.
33.3 Exposure Assessment
Biomonitoring studies are not available.
33.4 Toxic Effects
The LD_{50} of 4-amino-2-nitrophenol in rats was reported to be 3.3 g/kg by oral and 302 mg/kg by intraperitoneal administration (200). The compound was reported to be mutagenic in the Ames test and the mouse lymphoma L5178Y assay (100). The potential carcinogenicity of 4-amino-2-nitrophenol was tested by NCI (201) by dietary administration (1250 or 2500 ppm) to F344/N rats and $B6C3F_1$ mice for 2 years. Under the conditions of the bioassay, the compound was carcinogenic in male rats inducing transitional-cell carcinomas of the urinary bladder (controls 0/15, low dose 0/46, high dose 11/39). The same tumor was also observed in three dosed female rats and may have been associated with the administration of the chemical. No evidence of carcinogenic activity was found in the mice.

33.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms There is no information on the disposition or metabolism of 4-amino-2-nitrophenol. However, the disposition of its isomer 2-amino-4-nitrophenol has been studied. Up to 1.67% of 2-amino-4-nitrophenol has been shown to be absorbed after dermal application to rats. Absorbed material was excreted in the urine within 24 h. Absorption has also been demonstrated after oral administration. Virtually all absorbed material was excreted in 5 d.
33.5 Standards, Regulations, or Guidelines of Exposure
Hygienic standards of permissible exposure have not been assigned.

Aromatic Amino and Nitro–Amino Compounds and their Halogenated Derivatives
Yin-Tak Woo, Ph.D., DABT, David Y. Lai, Ph.D., DABT

D. Phenylenediamines and Derivatives
Phenylenediamines (PDAs) are aromatic amines with two amino groups attached to benzene. There are three possible isomers: *ortho-, meta-*, and *para*-phenylenediamine (*o-, m-*, and *p*-PDA). Their primary uses are in the synthesis of polymers (primarily polyurethanes) and dyestuffs, and as components of hair dye formulations. Several of their nitro and chloro derivatives are also widely used in the hair dye industry.

Phenylenediamines are methemoglobin-forming agents and skin sensitizers. Among the three isomers, *m*-PDA is the most potent methemoglobin-forming agent and *p*-PDA is more toxic and a stronger skin sensitizer than *o*- and *m*-PDA. 2-Nitro-*p*-PDA was reported to cause developmental toxicity in mice. All three isomers of PDA and a number of their nitro and chloro derivatives have

been shown to induce gene mutagen in bacteria and/or cultured mammalian cells. Many of them also induced chromosomal aberrations, sister chromatid exchange, and cell transformation in cultured mammalian cells. The *m* and *p* isomers of PDA did not show any carcinogenic effects in limited carcinogenicity studies in rodents. However, there is sufficient evidence of carcinogenicity in long-term animal studies for *o*-PDA, 2-nitro-*p*-PDA, 4-chloro-*o*-PDA, 4-chloro-*m*-PDA, and 2,6-dichloro-*p*-PDA. Addition of chlorine atom(s) in the phenyl ring appeared to increase the carcinogenicity of phenylenediamines.

Aromatic Amino and Nitro–Amino Compounds and their Halogenated Derivatives
Yin-Tak Woo, Ph.D., DABT, David Y. Lai, Ph.D., DABT

E. Toluenediamines
There are six possible isomers of toluenediamines (TDA), or diaminotoluenes. They are usually synthesized commercially by dinitration of toluene, yielding a mixture of approximately 76% 2,4-TDA, 19% 2,6-TDA, 2.5% 3,4-TDA, 1.5% 2,3-TDA, 0.7% 2,5-TDA, and traces of 3,5-TDA (85). Among these isomers, 2,4-TDA and 2,6-TDA (both also known as *m*-TDA) are the most widely used diamines principally as chemical intermediates for the manufacture of toluene diisocyante (TDI), the predominant diisocyanate in the flexible foam and elastomer industries. In addition, TDA isomers are also used in hair dyes and a variety of other uses.

Four isomers (2,4-, 2,5-, 2,6-, and 3,4-) of TDA have been shown to be mutagenic in the Ames assay. In addition, both 2,4-TDA and 2,6-TDA yielded positive results in *in vitro* chromosome aberration and sister chromatid exchange assays (100). In contrast to genotoxicity assays, differential results have been observed in carcinogenicity studies. Whereas several studies indicated 2,4-TDA to be clearly carcinogenic in rats and mice, bioassays of 2,5-TDA and 2,6-TDA gave negative results. Mechanistic studies (83) showed that although both 2,4-TDA and 2,6-TDA are capable of binding to DNA, 2,4-TDA is about 6500 times more effective than 2,6-TDA. In addition, 2,4-TDA has been shown to induce hepatocellular proliferation (227) and exhibit tumorigenesis-promoting activity inducing liver foci from diethylnitrosamine-initiated hepatocytes (83), whereas 2,6-TDA lacks such activities indicating that genotoxicity alone is insufficient to induce complete carcinogenesis.

NIOSH Analytical Method 5516 is recommended for determining workplace exposure for all toluenediamine isomers (111a).
44.0 2,3-Toluenediamine
44.0.1 CAS Number: [*2687-25-4*]

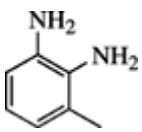
44.0.2 Synonyms: 3-Methyl-1,2-benzenediamine, toluene-2,3-diamine, and 2,3-diaminotoluene, and *o*-TDA

44.0.3 Trade Names: NA

44.0.4 Molecular Weight: 122.17

44.0.5 Molecular Formula: $C_7H_{10}N_2$

44.0.6 Molecular Structure:



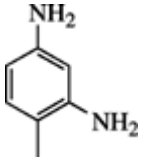
47.1 General
2,3-Toluenediamine has a boiling point of 255°C and a melting point of 63 to 64°C; it is soluble in water, alcohol, and ether. The most significant commercial use of *o*-TDA is in the manufacture of tolyltriazoles, which are used as corrosion inhibitors, photographic chemicals, and catalysts. It is also used as a chemical intermediate in the synthesis of polyols and antioxidants (85). No toxicology information was located in the literature. No hygienic standards of permissible exposure have been assigned. In the absence of data, NIOSH considers all TDA isomers as possible occupational carcinogens.
45.0 2,4-Toluenediamine
45.0.1 CAS Number: [*95-80-7*]

45.0.2–45.0.3 Synonyms and Trade Names: Toluene-2,4-diamine, toluenediamine, 2,4-diaminotoluene, 4-methyl-1,3-benzenediamine, 3-amino-*p*-toluidine, 5-amino-*o*-toluidine, tolylene-2,4-diamine, 1,3-diamino-4-methylbenzene, 2,4-diamino-1-methylbenzene, 2,4-diamino-1-toluene, 2,4-diaminotoluol, 4-methyl-*m*-phenylenediamine, C.I. 76035, C.I. oxidation base, C.I. oxidation base 20; C.I. oxidation base 35; C.I. oxidation base 200, developer 14, developer b, developer db, developer dbj, developer mc, developer mt, developer mt-cf, developer mtd, developer, azogen developer h, benzofur mt, eucanine gb, fouramine, fouramine j, fourrine 94, fourrine m, MTD, nako tmt, pelagol j, pelagol grey j, pontamine developer tn, renal md, Tertral g, zoba gke, zogen developer h, 4-methylphenylene-1,3-diamine, and 2,4-TDA

45.0.4 Molecular Weight: 122.17

45.0.5 Molecular Formula: $C_7H_{10}N_2$

45.0.6 Molecular Structure:



45.1 Chemical and Physical Properties
2,4-Toluenediamine has a boiling point of 292°C and melting point of 99°C; it is soluble in water, alcohol, and ether. It is a colorless to brown, needle-shaped crystal or powder that tends to darken on storage (85, 155).
45.2 Production and Use
2,4-Toluenediamine is a widely used industrial chemical intermediate. It is produced in very large volumes with worldwide production estimated to be 6.9×10^5 metric tons in 1991 (85). The major use for 2,4-TDA is in the manufacture of toluene diisocyanate (TDI), the predominant isocyanate in the flexible polyurethane foams and elastomers industry. It is also used as an intermediate for the synthesis of dyes and pigments and was used in hair dye formulations until 1971 (36).

Human exposure to 2,4-TDA may occur indirectly via exposure to 2,4-toluene diisocyanate, which is known to hydrolyze to 2,4-TDA rapidly upon contact with water. Workers in some plastics and elastomers industries may be exposed to atmospheres containing TDI (228). Direct exposure to 2,4-TDA *per se* could also occur to hairdressers and barbers through the use of hair dye formulations.
45.3 Exposure Assessment
Biomonitoring methods to measure hemoglobin adducts of 2,4-TDA as a dosimeter of exposure have been developed (95, 102). Immunoassays to measure DNA adducts with 2,4-TDA have also been developed (21).
45.4 Toxic Effects
Clinical effects in humans include methemoglobinemia, especially when red blood cell-reducing

mechanisms are impaired, such as in G6PD deficiency, which occurs in humans in the absence of glutathione reductase, glutathione, or glutathione peroxidase. It is an eye irritant that may cause corneal damage, and delayed skin irritation reportedly occurs, which can result in blistering (1).

45.4.1 Experimental Studies Reproductive toxicity in the rat has been demonstrated. Reduced fertility, arrested spermatogenesis, and diminished circulating testosterone levels have resulted in rats fed 0.03% 2,4-TDA; electron microscopy revealed degenerative changes in Sertoli cells and a decrease in epididymal sperm reserves; after 3 wk of 0.06% TDA feeding, sperm counts were further reduced and accompanied by a dramatic increase in testes weights, intense fluid accumulation, and ultrastructural changes in Sertoli cells (130). In previous studies testicular atrophy, hormonal effects, and aspermatogenesis were also observed in Sprague–Dawley rats given a 0.1% diet for 9 wk (131, 132).

2,4-TDA is mutagenic in the Ames assay with metabolic activation in the presence of S-9; it gave weakly positive results in the micronucleus test at near toxic doses (231, 232). *In vitro* chromosome aberration and sister chromatid exchange assays were reported to be positive (100). Its *in vivo* genotoxic activity has recently been demonstrated using the Big Blue transgenic mouse mutation assay (81).

When 2,4-TDA was administered in the diet to male and female F344 rats (79 or 170 ppm) or $B6C3F_1$ mice (100 or 200 ppm), hepatocellular carcinomas were produced in female mice, hepatocellular carcinomas in male rats, and mammary adenomas or carcinomas in female rats, but no carcinomas in the male mice (233). Also male Wistar rats have reportedly been shown to develop hepatocarcinomas following treatment with 2,4-TDA (234). A skin painting study in Swiss–Webster mice was reportedly noncarcinogenic (235). However, it has also been observed that mice appear to be less sensitive than rats; this difference may be based upon differences in metabolism (236).

45.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Metabolism studies (16, 21, 232, 236) indicated that 2,4-TDA is metabolically activated by N-hydroxylation followed by N-acetylation to yield the N-acetoxy derivative as the ultimate DNA reactive and mutagenic intermediate. Based on analysis of the DNA adducts, the 4-amino group appears to be the preferential (80%) site of metabolic activation (21). At an equimolar dose of 250 mg/kg, 2,4-TDA was shown to be 6500 times more active in binding to DNA in rats liver than its 2,6-isomer (83). In addition, 2,4-TDA has been shown to induce hepatocellular proliferation (227) and exhibit tumorigenesis-promoting activity inducing liver foci from diethylnitrosamine-initiated hepatocytes (83). In contrast, the mutagenic but noncarcinogenic 2,6-TDA lacks such tumorigenesis-promoting activities indicating that genotoxicity alone is insufficient to induce complete carcinogenesis.

45.4.2 Human Experience However, epidemiological studies of workers exposed to commercial mixtures of dinitrotoluene and/or toluenediamine at three chemical plants indicated that the fertility of men had not been reduced significantly and reported no observable effects on the fertility of workers (229, 230). However, other reports have suggested that human exposure may disrupt spermatogenesis and cause an excess of miscarriages (131, 132). Biliary tract cancer has been reported in industrial workers (237); however, it could not be determined whether 2,4-TDA played a significant role.

An IARC working group concluded that, despite the lack of human data, there are sufficient animal data to classify 2,4-TDA a Group 2B compound, an agent possibly carcinogenic to humans (116).
45.5 Standards, Regulations, or Guidelines of Exposure
NIOSH recommends that 2,4-TDA be treated as a possible occupational carcinogen.
46.0 2,5-Toluenediamine
46.0.1 CAS Number: [*95-70-5*]

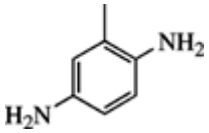
46.0.2–46.0.3 Synonyms and Trade Names: 2,5-Diaminotoluene, toluene-2,5-diamine, 2-methyl-1,4-

benzenediamine and 2,5-TDA

46.0.4 Molecular Weight: 122.17

46.0.5 Molecular Formula: $C_7H_{10}N_2$

46.0.6 Molecular Structure:



46.1 Chemical and Physical Properties
2,5-Toluenediamine has a boiling point of 273 to 274°C and a melting point of 64°C; it is soluble in water, alcohol, and ether (85, 155).
46.2 Production and Use
2,5-Toluenediamine is used primarily in hair dye formulations as one of the major oxidation dye precursors (36). It is also used in the synthesis of saframine, a family of dyes used as biological stain and may be present in indelible ink, antifreeze, and nail polish (238).

As may be expected from its use in hair dye formulations, hairdressers and barbers may be exposed to 2,5-TDA (36). Workers in the dye manufacturing industry may also be exposed.
46.3 Exposure Assessment
No biomonitoring data or studies are available.
46.4 Toxic Effects
2,5-Toluenediamine is toxic following oral, inhalation, and dermal exposure causing hepatotoxicity and hemolytic anemia. The compound is considered highly irritating to skin and eye (239). Myotoxicity (to both cardiac and skeletal muscle) has also been observed in rats exposed to 2,5-TDA; a number of more highly ring-methylated analogs (2,3,5,6-tetramethyl-, 2,5-dimethyl- and 2,6-dimetyl-*p*-phenylenediamine) are even more myotoxic (240). Ames test showed positive mutagenicity with metabolic activation (100).

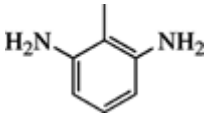
The possible carcinogenicity of 2,5-TDA (as sulfate salt, CAS # [*6369-59-1*]) was tested by the National Cancer Institute in a dietary feeding study (238). Groups of 50 male and female F344 rats (600 or 2000 ppm) and B6C3F_1 mice (600 or 1000 ppm) were given diets containing 2,5-TDA for 78 wk and then observed for an additional period of 28–31 wk for rats and 16–19 wk for mice. The only statistically significant increased incidence was in lung tumors in high-dose female mice, but the evidence was not convincing enough to be attributed to 2,5-TDA. Overall, the compound was considered noncarcinogenic (238).
46.5 Standards, Regulations, or Guidelines of Exposure
No hygienic standards of permissible exposure have been assigned.
47.0 2,6-Toluenediamine
47.0.1 CAS Number: [*823-40-5*]

47.0.2–47.0.3 Synonyms and Trade Names: Toluene-2,6-diamine, 2-methyl-1,3-benzenediamine, 2,6-diaminotoluene, 1,3-diamino-2-methylbenzene, 2,methyl-*m*-phenylenediamine, 2,6-diamino-1-methylbenzene, 2-methyl-1,3-phenylenediamine, 2,6-toluylenediamine, and 2,6-toluenediamine and 2,6-TDA

47.0.4 Molecular Weight: 122.17

47.0.5 Molecular Formula: $C_7H_{10}N_2$

47.0.6 Molecular Structure:



47.1 Chemical and Physical Properties
2,6-Toluenediamine has a melting point of 106°C; it is soluble in water and alcohol. The dihydrochloride of 2,6-TDA is usually more stable than the free amine (85, 155).
47.2 Production and Use
2,6-Toluenediamine is usually produced as a byproduct with 2,4-TDA in mixtures containing 20% 2,6- and 80% 2,4-isomer. It is used primarily in the manufacture of toluene diisocyanate (TDI), the predominant isocyanate in the flexible polyurethane foams and elastomers industry (228).

Human exposure to 2,6-TDA may occur indirectly via exposure to toluene diisocyanate mixture containing 2,6-toluenediisocyanate, which is known to hydrolyze to 2,6-TDA rapidly upon contact with water. Workers in some plastics and elastomers industries may be exposed to atmosphere containing TDI (228).
47.3 Exposure Assessment
Biomonitoring methods to measure hemoglobin adducts of 2,6-TDA as a dosimeter of exposure have been developed (102).
47.4 Toxic Effects
2,6-Toluenediamine is positive in the Ames test, *in vitro* chromosome aberration, and sister chromatid exchange assays (100). Long-term bioassay of 2,6-TDA (as dihydrochloride salt, CAS [*15481-70-6*]) in an NCI feeding study using male and female F344 rats (250 or 500 ppm) and B6C3F$_1$ mice (50 or 100 ppm) showed no evidence of carcinogenicity (241), although the doses used in the mosue study did not reach the maximum tolerated dose.

47.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Metabolism and mechanistic studies (83, 229, 242) showed that 2,6-TDA is metabolically activated to a mutagenic and reactive intermediate capable of binding to DNA. However, unlike its hepatocarcinogenic 2,4-isomer, 2,6-TDA lacks tumorigenesis promoting activities as indicated by its failure to induce hepatocellular proliferation (227) and promote development of liver foci from diethylnitrosamine-initiated hepatocytes (83). Thus the genotoxicity of 2,6-TDA alone is insufficient to confer complete carcinogenic activity.
47.5 Standards, Regulation, or Guidelines of Exposure
No hygienic standards of permissible exposure have been assigned.
48.0 3,4-Toluenediamine
48.0.1 CAS Number: [*496-72-0*]

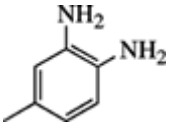
48.0.2 Synonyms: 3,4-Diaminotoluene, 4-methyl-1,2-benzenediamine, diaminotoluene, toluene-3,4-diamine, and 4-methyl-*o*-phenylenediamine

48.0.3 Trade Names: NA

48.0.4 Molecular Weight: 122.17

48.0.5 Molecular Formula: $C_7H_{10}N_2$

48.0.6 Molecular Structure:



3,4-Toluenediamine has a melting point of 88°C and a boiling point of 265°C (sublimes); it is soluble in water. The most significant commercial use of *o*-TDA is in the manufacture of tolyltriazoles, which are used as corrosion inhibitors, photographic chemicals, and catalysts. It is also used as chemical intermediate in the synthesis of polyols and antioxidants (85). The compound was reported to be mutagenic in the Ames test in one study (100), but negative in another (243). No hygienic standards of permissible exposure have been assigned. In the absence of data, NIOSH considers all TDA isomers as possible occupational carcinogens.

49.0 3,5-Toluenediamine

49.0.1 CAS Number: [*108-71-4*]

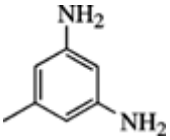
49.0.2 Synonyms: 5-Methyl-1,3-benzenediamine and 3,5-diaminotoluene

49.0.3 Trade Names: NA

49.0.4 Molecular Weight: 122.17

49.0.5 Molecular Formula: $C_7H_{10}N_2$

49.0.6 Molecular Structure:



There is no information available on this isomer in the open literature.

Aromatic Amino and Nitro–Amino Compounds and their Halogenated Derivatives
Yin-Tak Woo, Ph.D., DABT, David Y. Lai, Ph.D., DABT

F. Chlorinated Nitrobenzene Compounds

Chlorinated nitrobenzene compounds are important chemical intermediates for the synthesis of dyes, rubber, agricultural and pharmaceutical chemicals, as well as for some explosives. The chemical reactivity and toxicity of chlorinated nitrobenzene compounds depend on the number of chloro and nitro groups on the ring *and* their relative position. The ring nitro group(s) may contribute to toxicity either by reduction to aromatic amines or by activating the chloro group to become a leaving group, thereby yielding a direct-acting arylating agent. To yield an arylating agent, the electron-withdrawing nitro group(s) must be situated *ortho* or *para* to the chloro group. The strongest arylating agents are 1-fluoro-2,4-dinitrobenzene and 1-chloro-2,4-dinitrobenzene. There is good evidence that the mutagenicity of halogenated nitrobenzene compounds may be correlated to their arylating activity. A comparative mutagencity study (244), using Ames assay, of 21 chloro-/fluoronitrobenzene and 9 chloro-/fluorobenzene compounds indicated that mutagenicity (base-pair substitution only) was exhibited by all compounds having a chloro or fluoro group at the *ortho* or *para* position in the nitrobenzene nucleus. Chlorinated nitrobenzene compounds are also notorious as inducers of methemoglobinemia; this activity is less dependent on the relative positions of chloro

and nitro groups. All three isomers (*o-, m-, p-*) of chloronitrobenzene have been shown to be potent inducers of methemoglobinemia.

50.0 **o**-Chloronitrobenzene

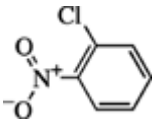
50.0.1 CAS Number: [*88-73-3*]

50.0.2–50.0.3 Synonyms and Trade Names: 1-Chloro-2-nitrobenzene, 2-chloro-1-nitrobenzene, Oncb, 2-nitrochlorobenzene, 2-CNB, and *o*-CNB

50.0.4 Molecular Weight: 157.56

50.0.5 Molecular Formula: $C_6H_4ClNO_2$

50.0.6 Molecular Structure:



50.1 Chemical and Physical Properties

o-Chloronitrobenzene usually occurs as oily yellow crystals at room temperature. It has a melting point of 34°C and a boiling point of 246°C; it is soluble in alcohol, benzene, ether, and acetone but insoluble in water. At room temperature, its vapor pressure is sufficiently high to lead to significant volatilization (62). As an aromatic nitro compound, it is easily reducible to corresponding aromatic amino compounds (26). The chlorine atom can be easily replaced by OH, OCH_3 OC_6H_5, etc., by nucleophilic attack.

50.2 Production and Use

The annual production of *o*-CNB in the United States in 1993 was 19,000 metric tons (2) and on the order of 50,000–70,000 metric tons in Germany (26). It is used as a chemical intermediate for the synthesis of *o*-aminophenol, which is used as a photographic developer. It is also used in the preparation of dyes, corrosion inhibitors, and agricultural chemicals.

Human exposure may occur to dyestuff workers but the extent is uncertain because of its use as a chemical intermediate. *o*-Chloronitrobenzene has been detected in the surface water of the Rhine River in a concentration range of 0.1–0.5 mg/L (26). Concentration levels of up to 1 mg/kg were reportedly found in fish in Europe (26).

50.3 Exposure Assessment

No biomonitoring studies are available.

50.4 Toxic Effects

o-Chloronitrobenzene has been reported to cause a variety of toxic effects, which include skin, eye, and respiratory tract irritation, pulmonary edema, methemoglobinemia, neurotoxicity, dermatitis, skin sensitization, and hepatic, pancreatic, and renal disorders (163, 245). Toxicity studies by NTP (62) showed that *o*-CNB is mutagenic in the Ames test, positive in the sister chromatid exchange assay, and capable of inducing chromosomal aberrations in Chinese hamster ovary cells but negative in sex-linked recessive lethal mutation assays in *Drosophila melanogaster*. Inhalation exposure of rats and mice to *o*-CNB resulted in methemoglobin formation and oxidative damage to red blood cells, leading to a regenerative anemia and a spectrum of tissue damage secondary to erythrocyte injury. Hyperplasia of the respiratory epithelium was also observed in rats exposed to *o*-CNB. The increase in methemoglobin occurred in rats exposed to as low as 1.1 ppm *o*-CNB. The NOAEL was 6 ppm for mice in a 13-wk inhalation study. Reproductive toxicity study indicated evidence of decreased spermatogenesis in rats exposed to *o*-CNB. A planned carcinogenicity study by NTP was cancelled.

50.4.1.3 Pharmacokinetics, Metabolism, amd Mechansims *o*-Chloronitrobenzene can be readily

absorbed by oral, dermal, and inhalation routes (62). It has been reported to be metabolized to *o*-chloroaniline, indicating nitroreduction, and conjugated with GSH to *S*-(2-nitrophenyl)glutathione, indicating the arylating activity (1).

50.5 Standards, Regulations, or Guidelines of Exposure

No hygienic standards of permissible exposure have been assigned. In Germany, this compound has been considered a substance suspected of having carcinogenic potential (246).

51.0 **m**-Chloronitrobenzene

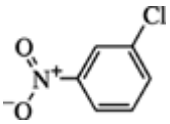
51.0.1 CAS Number: [*121-73-3*]

51.0.2–51.0.3 Synonyms and Trade Names: 3-Nitrochlorobenzene, 1-chloro-3-nitrobenzene; MNCB, nitrochlorobenzene, and *m*-CNB

51.0.4 Molecular Weight: 157.56

51.0.5 Molecular Formula: $C_6H_4ClNO_2$

51.0.6 Molecular Structure:



51.1 Chemical and Physical Properties

m-Chloronitrobenzene has a melting point of 43°C and a boiling point of 236°C. It is soluble in hot alcohol, chloroform, ether, carbon disulfide, and benzene, but relatively insoluble in water (2). Unlike the *o*- and *p*-isomers, the chlorine atom in *m*-CNB is not activated for nucleophilic substitution.

51.2 Production and Use

m-Chloronitrobenzene is of lesser economic importance than its *ortho* and *para* isomers, with no U.S. production reported (2). The annual production in Germany was reported to be in the order of 1000–3000 metric tons. It has limited use in the manufacturing of dyes and agricultural chemicals.

There is no information on potential exposure. Chloronitrobenzene has been detected in the surface water of the Rhine River with concentrations between 20 and 500 ng/L and in fish at levels of up to 1 mg/kg (26).

51.4 Toxic Effects

The main toxicological concern for *m*-CNB is the induction of methemoglobinemia, which could be observed in rats given dermal administration of 800–2000 mg/kg of the compound. Cats are substantially more susceptible to the methemoglobin-forming activity of *m*-CNB. A single IP dose of 5–10 mg *m*-CNB/kg body weight was sufficient to generate methemoglobinemia with the greatest effect observed 10 h after the administration (26). In contrast its *o* and *p* isomers, *m*-CNB has been basically shown to be nonmutagenic in the Ames test, sister chromatid exchange, and chromosome aberration assays (26, 100, 247).

51.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Absorption studies indicated that *m*-CNB may be absorbed via oral, dermal, and inhalation routes. Metabolism studies in rabbit showed *m*-chloroaniline and its phenolic derivatives as the major metabolites. There is no evidence of GSH conjugation indicating the lack of arylating activity. There is evidence that the mode of action of methemoglobinemia is most likely caused by the formation of hydroxylamine derivative during metabolism (26).

51.5 Standards, Regulations, or Guidelines of Exposure

No hygienic standards of permissible exposure have been assigned.

52.0 **p**-Chloronitrobenzene

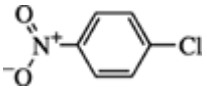
52.0.1 CAS Number: [*100-00-5*]

52.0.2–52.0.3 Synonyms and Trade Names: 4-Chloronitrobenzene, PNCB, nitrochlorobenzene, 1-chloro-4-nitrobenzene, 1,4-chloronitrobenzene, 4-nitrochlorobenzene, 4-chloro-1-nitrobenzene, *p*-nitrochlorobenzene, 1-chloro-4-nitrobenzene, and *p*-CNB

52.0.4 Molecular Weight: 157.56

52.0.5 Molecular Formula: $C_6H_4ClNO_2$

52.0.6 Molecular Structure:



52.1 Chemical and Physical Properties

p-Chloronitrobenzene occurs as yellow crystals at room temperature. It has a melting point of 83.6°C and a boiling point of 242°C; it is soluble in alcohol, benzene, ether, and acetone, but insoluble in water. At room temperature, its vapor pressure (0.009 torr at 25°C) is sufficiently high to lead to significant volatilization (62). As an aromatic nitro compound, it is easily reducible to the corresponding aromatic amino compound (26). The chlorine atom can be easily replaced by OH, OCH_3, OC_6H_5, etc. by nucleophilic attack.

52.2 Production and Use

The annual production of *p*-CNB in the United States in 1993 was 35,000 metric tons (2) and on the order of 50,000–70,000 metric tons in Germany (26). It is used as an intermediate in the manufacture of dyes, rubber, and agricultural chemicals.

Human exposure may occur to dyestuff workers but the extent is uncertain because of its use as a chemical intermediate. *p*-Chloronitrobenzene has been detected in the surface water of the Rhine River at a concentration range of 0.1–6.38 mg/L (26).

52.3 Exposure Assessment

52.3.3 Workplace Methods NIOSH Analytical Method 2005 is recommended for determining workplace exposures to *p*-CNB (111a)

The measurement of blood methemoglobin level has been used as a nonspecific indicator of biological exposure to *p*-CNB.

52.4 Toxic Effects

The most significant toxicity is methemoglobinemia, which may occur after oral, dermal, or inhalation exposure. Symptoms of methemoglobinemia, which include headache, dizziness, vomiting, weakness, cyanosis, and anemia, have been observed in workers exposed to *p*-CNB via skin contact or inhalation. Skin penetration is rapid, and *p*-CNB is more potent than aniline in terms of potential to produce cyanosis and anemia (26). Animal studies also indicated the methemoglobinemia-inducing capability of *p*-CNB (26). A recent NTP subchronic inhalation toxicity study showed evidence of methemoglobinemia in F344/N rats exposed to as low as 1.5 ppm *p*-CNB. No NOAEL could be achieved for rats in this study while a NOAEL of 6 ppm was established for B6C3F_1 mice (62). Mutagenicity studies by NTP (62) showed that *p*-CNB is mutagenic in the Ames test, positive in the sister chromatid exchange assay, and capable of inducing chromosomal aberrations in Chinese hamster ovary cells but negative in sex-linked recessive lethal mutation assay in *Drosophila melanogaster*.

A teratogenicity study of *p*-CNB was conducted in groups of Sprague–Dawley rats administered 5, 15, or 45 mg/kg/d by gavage on days 6 to 19 of gestation and in New Zealand rabbits dosed with 5, 15, or 40 mg/kg/d on gestation days 7 to 19 by gavage (168). In the rat study, there was evidence of

embryotoxicity (increased resorptions) and teratogenicity (increased incidences of skeletal anomalies) only at the high-dose group, which is slightly maternally toxic. In the rabbit study, the high dose was highly toxic to the dams, whereas the mid- and low-doses caused small increases in the incidences of skeletal malformations that were not statistically significant (168).

p-CNB was reported to be noncarcinogenic in Sprague–Dawley rats and equivocal in HaM/ICR mice given maximally tolerated dietary doses (rats: initially 4000 ppm, reduced to 500 ppm after 3 mo and then raised to 1000 ppm after 2 mo; mice: 6000 ppm) and half of those doses for 18 mo followed by 6 mo (rats) or 3 mo (mice) observation (182). In another long-term bioassay in which rats were given *p*-CNB orally at 0.1, 0.7, or 5.0 mg/kg/d, the only predominant adverse effect was apparently significant methemoglobinemia observed at mid- and high-dose levels (1). In view of the uncertainties, NTP originally planned a carcinogenicity bioassay but subsequently decided to discontinue after the subchronic toxicity studies.

52.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Absorption studies indicated that *p*-CNB can be readily absorbed by all routes of exposure (62). *In vitro* studies have demonstrated that *p*-CNB can be reduced to *p*-chloroacetanilide as well as *p*-chloroaniline, and that cytosolic GSH transferase is involved in the conjugation with GSH to form *S*-(4-nitrophenyl)glutathione. Urinary metabolites of male Sprague–Dawley rats following a single IP dose of 100 mg/kg of *p*-CNB diluted in olive oil included trace amounts of unchanged *p*-CNB, *p*-chloroaniline, 2,4-dichloroaniline, *p*-nitrothiophenol, 2-chloro-5-nitrophenol, 2-amino-5-chlorophenol, 4-chloro-2-hydroxyacetanilide, and a small amount of *p*-chloroacetanilide (248).

52.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV–TWA is 0.64 mg/m^3 (0.1 ppm) with skin notation. The ACGIH also considers *p*-CNB a confirmed animal carcinogen with unknown relevance to humans (160). NIOSH considers *p*-CNB as a potential occupational carcinogen. The current OSHA PEL is 1 mg/m^3 with skin notation. The NIOSH immediately dangerous to life or health concentration (IDLH) is 100 mg/m^3 (110). In Germany, *p*-CNB is considered a suspect carcinogen (246) and subject to a variety of legal regulations and orders with a maximum workplace concentration of 1 mg/m^3 assigned (26).

53.0 1-Chloro-2,4-dinitrobenzene

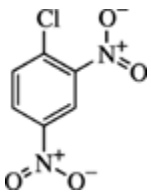
53.0.1 CAS Number: [*97-00-7*]

53.0.2–53.0.3 Synonyms and Trade Names: 2,4-Dinitro-1-chlorobenzene, 2,4-dinitrochlorobenzene, 1,3-dinitro-4-chlorobenzene, dinitrochlorobenzene, chlorodinitrobenzene, DNCB, and 4-chloro-1,3-dinitrobenzene

53.0.4 Molecular Weight: 202.55

53.0.5 Molecular Formula: $C_6H_3ClN_2O_4$

53.0.6 Molecular Structure:



53.1 Chemical and Physical Properties

1-Chloro-2,4-dinitrobenzene occurs as yellow crystals at room temperature. It has a melting point of 53–54°C (for a form) or 43°C (for b form) and a boiling point of 315°C; it is insoluble in water but readily soluble in ether, benzene, or hot alcohol. With two electron-withdrawing nitro groups situated at *ortho* and *para* positions, the chlorine is activated to become a good leaving group, thus

making the compound a good arylating agent (155, 156).
53.2 Production and Use
1-Chloro-2,4-dinitrobenzene is the best-known chlorodinitrobenzene isomer. It has been used in the manufacture of dyes, as a reagent for the detection of pyridine compounds, as an algicide in coolant water of air conditioning systems, and as a positive control in sensitization experiments.

Incidents of occupational exposure have been reported. The highly potent sensitizing activity of DNCB has limited its uses to closed systems.
53.4 Toxic Effects
Although not known to be a potent systemic toxicant with rat oral LD_{50} reported to be 1.07 g/kg (155), this chemical is a notoriously potent sensitizer. Dermal exposure can result in contact urticaria and yellow discoloration of the skin, as well as violent dermatitis (211). Adams et al. (249) reported a case in which DNCB had been used as an algicide in the coolant water of air conditioning systems. Four repairmen working on these systems suffered severe contact dermatitis that was very difficult to treat. The conclusion was that because DNCB is extremely allergenic and should be used only in closed systems that afford no human contact (167). In fact, DNCB has been used since 1927 for experimental induction of contact sensitivity and in allergenic cross-sensitization screening programs (137). A detailed review of the use of DNCB in experimental sensitization studies, including dose–response relationships and species differences, has been published (25).

1-Chloro-2,4-dinitrobenzene has been shown to be mutagenic in the Ames test without metabolic activation (244, 250). The presence of glutathione may reduce the direct-acting mutagenicity of DNCB by forming glutathione conjugate; however, the glutathione conjugate may be further activated by nitroreduction (250). A preliminary carcinogenicity study of DNCB in Charles River rats and Ham/ICR mice by dietary administration for 12–13 months was reported to be negative (182); however, in view of its being a direct-acting arylating agent, testing by dermal and inhalation routes may be more appropriate.

53.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Metabolism studies have demonstrated that DNCB depletes hepatic GSH levels by the biotransformation displacement of chlorine to yield 1-SG-2,4-dinitrobenzene (251). A reactive intermediate may be involved, for further studies have also demonstrated that DNCB was less mutagenic in a GSH-deficient derivative of *Salmonella typhimurium* TA100 (TA100/GSH-) than in TA100 itself, suggesting that the mutagenicity depends on GSH. Further investigations indicated that halogenated aromatics may react with bacterial DNA and produce premutagenic alterations according to two mechanisms: direct attack on the DNA through nucleophilic substitution (S_N2) of the halogen atoms, or activation through GSH conjugation and subsequent nitroreduction of the conjugate or its metabolic products to more reactive intermediates (250).
53.5 Standards, Regulations, or Guidelines of Exposure
1-Chloro-2,4-dinitroenzene is on OSHA's List of Highly Hazardous Chemicals. The highly potent sensitizing activity of DNCB has limited its uses to closed systems.
54.0 1-Chloro-2,5-dinitrobenzene
54.0.1 CAS Number: [*619-16-9*]

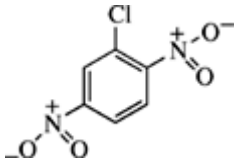
54.0.2 Synonyms: 2-Chloro-1,4-dinitrobenzene

54.0.3 Trade Names: NA

54.0.4 Molecular Weight: 202.55

54.0.5 Molecular Formula: $ClC_6H_3(NO_2)_2$

54.0.6 Molecular Structure:



1-chloro-2,5-dinitrobenzene occurs as light yellow crystals at room temperature, has a melting point of 64°C, and is soluble in alcohol, and ether (155). There is no specific information on its production. Its uses are reported to be identical with those of 1-chloro-2,4-dinitrobenzene, and its toxicity is assumed to be also similar. Information on exposure and regulations is not available.

55.0 1-Chloro-2,6-Dinitrobenzene

55.0.1 CAS Number: [*606-21-3*]

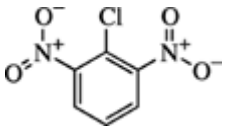
55.0.2 Synonyms: 2-Chloro-1,3-dinitrobenzene

55.0.3 Trade Names: NA

55.0.4 Molecular Weight: 202.55

55.0.5 Molecular Formula: $C_6H_3ClN_2O_4$

55.0.6 Molecular Structure:



1-Chloro-2,6-dinitrobenzene occurs as yellow crystals at room temperature; it has a melting point of 86–87°C and a boiling point of 315°C and is soluble in alcohol, ether, and toluene. With both nitro groups *ortho* to the chlorine, this compound is expected to be a good arylating agent. There is no specific information on its production and uses, although chlorodinitrobenzene isomers and mixtures have been used in the manufacture of dyestuffs, other dye intermediates, and certain explosives (167). Information on exposure, toxicology, and regulation is not available.

56.0 1-Chloro-2,3-dinitrobenzene

56.0.1 CAS Number: [*602-02-8*]

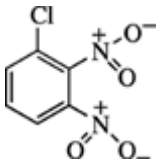
56.0.2 Synonyms: 3-Chloro-1,2-dinitrobenzene

56.0.3 Trade Names: NA

56.0.4 Molecular Weight: 202.55

56.0.5 Molecular Formula: $ClC_6H_3(NO_2)_2$

56.0.6 Molecular Structure:



1-chloro-2,3-dinitrobenzene has a melting point of 78°C and a boiling point of 315°C, is insoluble in water, and is soluble in alcohol and ether. There is no specific information on its production and uses, although chlorodinitrobenzene isomers and mixtures have been used in the manufacture of dyestuffs, other dye intemediates, and cartain explosives (167). Information on exposure, toxicology, and regulation is no available.

57.0 1-Chloro-3,4-dinitrobenzene

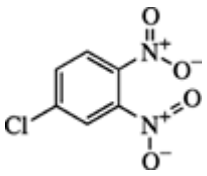
57.0.1 CAS Number: [*610-40-2*]

57.0.2–57.0.3 Synonyms and Trade Names: 1,2-Dinitro-4-chlorobenzene and 3,4-dinitrochlorobenzene

57.0.4 Molecular Weight: 202.55

57.0.5 Molecular Formula: $C_6H_3ClN_2O_4$

57.0.6 Molecular Structure:



1-chloro-3,4-dinitrobenzene occurs as monoclinic prisms and needles at room temperature, has melting points of 36°C (a form), 37°C (b form), 40–41°C (g form), a boiling point of 16° at 4 mm Hg; it is insoluble in water, but soluble in ether, benzene, carbon disulfide, and hot alcohol. There is no specific information on its production and uses, although chlorodinitrobenzene isomers and mixtures have been used in the manufacture of dyestuffs, other dye intermediates, and certain explosives (167). The compound was reported to be a skin sensitizer, causing contact dermatitis ranging from a few itching, vesicular papules to a generalized exfoliative dermatisis (167). Information on exposure and regulation is not available.

58.0 1-Chloro-3,5-dinitrobenzene

58.0.1 CAS Number: [*618-86-0*]

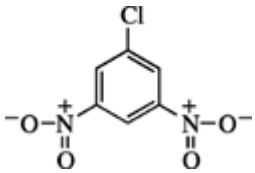
58.0.2 Synonyms: 1-Chloro-3,5-dinitrobenzene

58.0.3 Trade Names: NA

58.0.4 Molecular Weight: 202.55

58.0.5 Molecular Formula: $ClC_6H_3(NO_2)_2$

58.0.6 Molecular Structure:



1-chloro-3,5-dinitrobenzene occurs at colorless needles at room temperature; it has a melting point of 59°C, is insoluble is water, but is soluble in alcohol and ether. There is no specific information on its production and uses, although chlorodinitrobenzene isomers and mixtures have been used in

manufacture of dyestuffs, other dye intermediates, and certain explosives (167). Information on exposure, toxicology, and regulation is not available.

59.0 Pentachloronitrobenzene

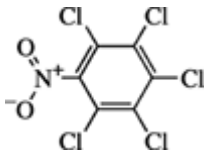
59.0.1 CAS Number: [*82-68-8*]

59.0.2–59.0.3 Synonyms and Trade Names: Avical, Eorthcicle, Fortox, Kobu, Marison Forte, Pkhnb, Terrafun, Tri PCNB, PCNB, Quintozine, quintobenzene, Terrachlor, Terraclor, Avicol, Botrilex, Earthcide, Kobutol, Pentagen, Tilcarex, SA Terraclor 2E, SA Terraclor, nitropentachlorobenzene, brassicol, quintocene, batrilex, fartox, formac 2, fungiclor, gc 3944-3-4, KP 2, olpisan, quintozen, saniclor 30, and tritisan

59.0.4 Molecular Weight: 295.34

59.0.5 Molecular Formula: $C_6Cl_5NO_2$

59.0.6 Molecular Structure:



59.1 Chemical and Physical Properties

Pentachloronitrobenzene is a colorless solid at room temperature. It has a melting point of 144°C (technical grade) and a boiling point of 328°C; it is slightly soluble in water (0.044 mg/L at 20°C; 2 mg/L at 25°C) and freely soluble in carbon disulfide, benzene, and chloroform. Technical-grade PCNB often contains impurities, which include hexachlorobenzene, pentachlorobenzene, and tetrachlorbenzene (155, 156, 252).

59.2 Production and Use

Approximately 2 million pounds of PCNB are used annually in the United States for agricultural purposes. It has been used as a soil or seed fungicide for the control of Botrytis disease, club root of crucifers, scab of potato, and Rhizoctonia damping-off disease of seedlings (253). It is also used as a turf fungicide to prevent root rotting.

As may be expected from its agricultural uses, occupational exposure may occur during its production and direct application as a soil fungicide. The general population may also be exposed through occasional consumer use or through ingestion of foods or drinking water containing PCNB residues.

59.3 Exposure Assessment

Biomonitoring data are not available.

59.4 Toxic Effects

Exposure to PCNB can induce contact sensitization (211). Methemoglobinemia has been demonstrated in cats, which have an unusually high sensitivity due to the low rate of methemoglobin reductase activity, following a single high oral dose of 1.6 g/kg (254). The reported oral LD_{50} for male rats (in corn oil) is 1.74 g/kg, and the LD_{50} (dermal) for rabbits was found to be >4 g/kg (255). The reported LC_{50} values are 1.4 g/m^3 for rats and 2.0 g/m^3 for mice (179).

Subchronic toxicity studies of PCNB by NTP (256) in rodents exposed to diets containing 33, 100, 333, 1000, or 2000 ppm of the compound indicated hyaline droplet nephropathy in male rats exposed to the two highest doses, minimal thyroid follicular cell hypertrophy in rats, and centrolobular hepatocellular hypertrophy in both rats and mice. The no-observed effect levels (NOELs) for histologic lesions were 33 ppm for male rats, 333 ppm for female rats, 100 ppm for female mice; no

NOEL could be determined for male mice in this study.

No adverse effects were reported in a three-generation reproductive study in which CD rats were administered a diet of PCNB at concentrations of 0, 5, 50, or 500 ppm (255). A followup teratogenic study in Charles River strain albino rats, administered PCNB at dosages of 100–1563 ppm in corn oil, did not demonstrate any treatment-related developmental effects (257). Nonteratogenicity was also confirmed in Wistar rats following oral administration (258). In a comparative study using contaminated PCNB (11% hexachlorobenzene) and purified PCNB (<20 ppm hexachlorobenzene), contaminated PCNB produced renal agenesis and cleft palates in C57B1/6 mice and cleft palates in CD-1 mice. Purified PCNB produced fewer cleft palates and no kidney malformations. Neither sample produced teratogenesis in CD rats (259).

Mutagenicity and related tests of PCNB showed that the compound is negative in most tests which include Ames, *E. coli* WP2, sister chromatid exchange, unscheduled DNA synthesis, and dominant lethal test in rats; there was only one report of induction of chromosome aberration in CHO cells both with and without metabolic activation (252).

A two-year dietary feeding study in four beagle dogs of each sex, at dietary levels of 0, 5, 30, 180, or 1080 ppm, demonstrated no treatment-related effect; 30 ppm was identified as the NOEL, and cholestatic hepatitis with secondary bile nephrosis was observed at 180 and 1080 ppm (255).

In a number of carcinogenesis assays, PCNB has not demonstrated carcinogenicity at 25, 100, 300, 1000, or 2500 ppm (diet of a commercial mixture of 20% PCNB) (260). A preliminary study showed that PCNB, (purity not specified) generated liver tumors in male B6AKF1 mice and female $B6C3F_1$ mice (261). A skin painting tumor initiation–promotion (croton oil) study in mice (purity not given) generated squamous cell carcinomas (262). An NCI bioassay on technical-grade PCNB (97% pure with 1% hexachlorobenzene) administered in the diet to Osborne–Mendel rats (5417 or 10,064 ppm for males, 7875 or 14,635 ppm for females) and $B6C3F_1$ mice (2606 or 5213 ppm for males, 4093 or 8187 for females) showed no evidence of carcinogenicity (253). In a second NCI/NTP study (252) in which $B6C3F_1$ male and female mice were fed diets containing 2500 and 5000 ppm, PCNB was also noncarcinogenic; however, infection in female mice may have reduced the sensitivity of the bioassay because of poor survival. In a recent industry-sponsored study submitted to the Office of Pesticide Program, PCNB was reported to induce slight but statistically significant increases in the incidences of follicular cell tumors in Charles River CD rats (263).

59.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Metabolism studies in a variety of animal species indicated that PCNB can be metabolized to (1) sulfur-containing metabolites after glutathione-*S*-transferase-catalyzed conjugation with glutathione, (2) pentachloroaniline after reduction, and (3) pentachlorophenol via denitration (252, 255). No information is available on mechanistic studies.

59.5 Standards, Regulations, or Guidelines of Exposure

A ACGH TLV–TWA is 0.5 mg/m^3 with A4 designation indicating that it is not classifiable as a human carcinogen (160). There are some restrictions on tolerance levels of this pesticide on peanuts and a variety of vegetables and fruits.

Aromatic Amino and Nitro–Amino Compounds and their Halogenated Derivatives

Yin-Tak Woo, Ph.D., DABT, David Y. Lai, Ph.D., DABT

G. Bicyclic and Tricyclic Aromatic Amines

Many bicyclic and tricyclic aromatic amines are potent carcinogens, with three of them (2-

naphthylamine, 4-aminobiphenyl, and benzidine) unequivocally shown to be human carcinogens and many of them considered occupational carcinogens (see Section 1.3.1) Compared to monocyclic aromatic amines, the additional aromatic ring(s) in the bicyclic and tricyclic aromatic amines confer greater capability for resonance stabilization of the metabolically activated reactive intermediate to allow more time to travel from the site of activation to reach DNA binding sites to initiate carcinogenesis. The structure–activity relationships of carcinogenic bicyclic and tricyclic aromatic amines have been extensively studied (44, 98, 198). The following structural features have been consistently observed across aromatic amines with various bicyclic and tricyclic aryl moieties: (1) aromatic amines with amino group(s) occupying the terminal end(s) (e.g., 2-position of naphthalene or aminofluorene, 4,4'-positions of biphenyl or diphenylmethane) of the longest conjugated chain of the aryl moiety are the most active carcinogens, (2) N-substitution with alkyl group(s) higher than methyl tends to be inhibitory especially if branched, (3) ring substitution with bulky group(s) tends to be inhibitory especially if flanking the amino group, (4) ring substitution with highly hydrophilic group(s) such as sulfonic acid tends to be inhibitory, and (5) ring substitution that distorts molecular planarity [e.g., at the 2-, 2'-, 6-, 6'-position(s) of biphenyl] may decrease or abolish activity. The structural formulas of the bicyclic and tricyclic aromatic amines covered in this chapter are depicted in Fig. 58.2 to provide an overview as well as under description of specific compound.

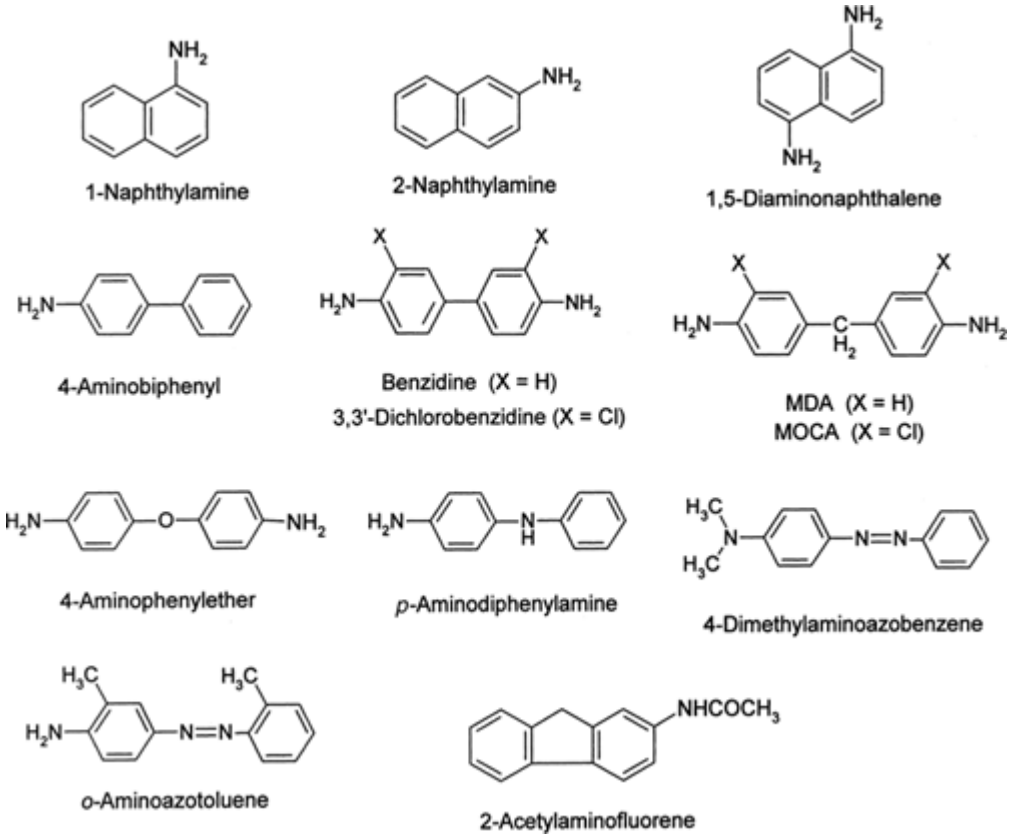


Figure 58.2. Overview of structural formulas of bicyclic and tricyclic aromatic amines.

Aliphatic and Aromatic Nitrogen Compounds

Henry J. Trochimowicz, Sc.D., Gerald L. Kennedy, Jr., Ph.D., CIH, Neil D. Krivanek, Ph.D.

1.0 Ethyleneimine

1.0.1 CAS Number:

[*151-56-4*]

1.0.2-1.0.3 Synonyms and Trade Names:

Aziridine; dimethyleneimine; azocyclopropane; azirane; dihydroazirine; EI; amenoethylene; ethyleneimine; and ethylimine

1.0.4 Molecular Weight:

43.8

1.0.5 Molecular Formula:

C_2H_5N

1.0.6 Molecular Structure:

1.1 Chemical and Physical Properties

1.1.1 General

Physical Form:	mobile, colorless liquid, very volatile fluid
Boiling Point	55–56°C
Freezing Point	–78°C
Specific Gravity	0.8321 (24°C)
Vapor Pressure	160 mmHg at 20°C
Flammability	
Flash Point	–11°C
Explosive Limits IEL	3.6%
UEL	46%
Ignition Temperature (auto)	320°C
Solubility	infinitely soluble in water; soluble in alkali, alcohol

1.1.2 Odor and Warning Properties Ethyleneimine (EI) is a volatile liquid at room temperature and has an ammonia-like odor that is detectable at 2 ppm (v/v). Although it is highly volatile, the liquid is rapidly absorbed through the skin, and it is considered to have poor warning properties.

1.2 Production and Use

Ethyleneimine is used to manufacture triethylenemelamine and is used in its polymeric form in paper and textile chemicals, adhesive binders, petroleum refining chemicals, fuels and lubricants, coating resins, varnishes, lacquers, agricultural chemicals, cosmetics, ion-exchange resins, photographic chemicals, colloid flocculants, and surfactants (1).

One producer of EI in the United States has estimated annual capacity of 2.2 million kg. There are other producers of ethyleneimine in Germany, Japan, and probably the former Soviet Union (2, 3).

1.3 Exposure Assessment

Several analytical methods have been described (2–4). Environmental atmospheres that may contain EI are sampled by drawing air through a Folin's reagent bubbler, extracting with chloroform, and analyzing by high-performance liquid chromatography (HPLC) with an ultraviolet (UV) detector; the range is 0.16 to 20 mg/m^3. NIOSH Analytical Method 3514(14a).

1.4 Toxic Effects

1.4.2 Experimental Studies Ethyleneimine is highly toxic on an acute basis by all routes of administration. It is treated as a Group 3 carcinogen (not classifiable as to its carcinogenicity to humans) by the International Agency for Research on Cancer (2, 3), as an A3 carcinogen (confirmed animal carcinogen with unknown relevance to humans) (5), a cancer-suspect agent (Group 3) by the Occupational Safety and Health Administration (OSHA), and is regulated when present in materials at concentrations of 1% or more (6). The National Institute for Occupational Safety of Health (NIOSH) also regards EI as a “potential human carcinogen” (7).

1.4.1.1 Acute Toxicity Ethylenimine on an acute basis is highly toxic by all routes of administration (Table 59.1) (8–10). Its oral LD_{50} in rats is only 15 mg/kg, and the free imine is also a potent skin irritant and vesicant (8). Application of 0.005 mL of the imine as the pure material or 0.5 mL of a 15% aqueous solution caused severe corneal damage (10).

Table 59.1. Acute Toxicity Response to Ethyleneimine–Animals

Species	Dose	Route	Response	Ref.

Rat	15 mg/kg	Oral	LD_{50}	8
Rat	100 mg/m^3 (~56 ppm)	Inhalation	2-hr LC_{50}	9
Rabbit	100 mg/m^3	Inhalation	2-hr LC_{50}	9
Mouse	400 mg/m^3 (~222 ppm)	Inhalation	2-hr LC_{50}	9
Guinea pig	25 ppm	Inhalation	8-h LC_{LO}	8
Guinea pig	0.014 mL/kg	Skin	LD_{50}, necrosis	8
Rabbit	13 mg/kg	Skin	LD_{50}	10
Rabbit	0.005 mL	Eye	Severe corneal damage	10
Rabbit	0.5 mL (15% aqueous)	Eye	Severe corneal damage	10

In a series of acute inhalation exposures for varying periods of time (5 to 480 min), the 8-h LC_{50} in guinea pigs was 25 ppm, a concentration that also produced one death out of six rats. Death was delayed, and both rats and guinea pigs showed extreme respiratory difficulty at concentrations higher than 10 ppm; evidence of eye and nose irritation occurred at 100 ppm and higher (8).

Cause of death from massive overexposure is due to central nervous system (CNS) effects. Clinical signs of toxicity include eye and respiratory irritation, vomiting, and CNS effects including convulsions.

1.4.1.2 Subchronic and Chronic Toxicity Based on repeated exposure, 7-h exposures to 1.65 ppm for several months caused essentially no effects in several species. However, similar exposures to 3.5 ppm caused illness and death.

Inhalation of ethyleneimine results in delayed lung damage, including congestion, edema, and hemorrhage. Kidney damage has also been observed. Proteinuria, hematuria, increased blood urea nitrogen, and a depression of all blood elements have also been seen following inhalation. Histopathological examination has shown necrotic degeneration of renal tubular epithelium (4).

1.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Specific data on the absorption of EI by various routes of exposure were not found. However, based on toxicity test results in animals, EI is readily absorbed by all routes.

Ethyleneimine injected intraperitoneally into rats was distributed widely through the body and slightly accumulated in the liver, spleen, kidneys, intestine, and cecum.

Ethyleneimine apparently undergoes oxidation, because recovered radiolabeled CO_2 appears in the expired air of rats dosed intraperitoneally. Several urinary metabolites were also reported but were not identified. Some of the intraperitoneal dose was not metabolized but was eliminated unchanged in the urine and expired air. Urinary excretion is the major route of elimination for EI and its metabolites and accounts for about 50% of the administered dose. Pulmonary excretion of CO_2 and unchanged EI accounted for 3 to 5% and 1 to 3% of the administered dose, respectively. Fecal elimination or other minor routes of excretion were not discussed (11).

1.4.1.4 Reproductive and Developmental Except for a limited Soviet study suggesting embryo and maternally toxic effects during a 20-day inhalation exposure at 10 mg/m^3 (12), no developmental toxicity studies or studies to evaluate reproductive performance in mammals have been reported for

EI.

1.4.1.5 Carcinogenesis The carcinogenicity of ethyleneimine was evaluated in two strains of mice, and both gave positive results (13, 14). Groups of 18 male and 18 female mice of $B6C3F_1$ or B6AKR strains were treated orally (initially by gavage, then in the diet) from age 7 days through 77 to 78 weeks. The time-weighted average (TWA) dose was about 1.8 mg/kg/day. The incidence of hepatomas and lung adenomas was significantly elevated in both strains and sexes. In $B6C3F_1$ mice, the incidence of hepatomas and pulmonary adenomas was 15/17 and 15/17 in males and 11/15 and 15/15 females, respectively. In the B6AKR strain, hepatomas and adenomas occurred in 9/16 and 12/16 males and in 2/11 and 10/11 females, respectively. In the control groups, hepatomas were 8/79 and 0/87 in male and female B6C3F1 mice and 5/90 and 1/82 in male and female B6AKR mice. The respective incidence of pulmonary adenomas was 5/79, 3/87, 10/90, and 3/82. The incidence of hepatomas and pulmonary adenomas (reported as combined tumors) was significantly ($p < .01$) elevated (13, 14).

In rats treated by subcutaneous injections, EI was associated with an increase in injection site tumors, but no pulmonary or liver tumors were reported (10). In suckling mice (age 7 days, 4.64 mg/kg body weight), the incidence of tumors was significantly ($p < .01$) greater among males of two strains than in controls (13). Seven of 18 $B6C3F_1$ mice and 6 of 18 B6AKR strain male mice developed tumors of the liver, lungs, or lymphatics. The incidence of tumors in female mice was not different from controls.

On the basis of these carcinogenicity studies and its mutagenic potential, OSHA (6) called EI a "cancer-suspect" agent. The International Agency for Cancer Research (2, 3) placed EI in its Group 3 category (the agent is not classifiable as to its carcinogenicty to humans). ACGIH (5) calls EI an A3 carcinogen (confirmed animal carcinogen with unknown relevance to humans). NIOSH (7) reported it as a "potential human carcinogen."

1.4.1.6 Genetic and Related Cellular Effects Studies Ethyleneimine is an extremely reactive alkylating agent that is very mutagenic in all test systems investigated.

Ethyleneimine induced gene mutation (in microorganisms, such as viruses and *Salmonella typhimurium* bacteria, in plants, and in mammals), mitotic recombination (in fungi), mitotic and/or meiotic chromosomal aberrations (in plants, in *Drosophila melanogaster*, and in mammals), and dominant and recessive lethal mutations (in *Drosophila melanogaster*). It was mutagenic in every investigation except in a few instances where negative results could clearly be attributed to a dosing regimen that was too low (15).

1.4.2 Human Experience Epidemiological studies of worker groups exposed chronically to EI have not been reported. Several case reports are available, however, that describe the effects of acute accidental exposure. When five students were exposed to EI for about 2 h in a poorly ventilated room, the effects of exposure, which were delayed several hours in their onset, included vomiting, persistent eye inflammation (3 months after the exposure), a profound hacking cough with mild obstructive pneumonopathy, and ulceration of the upper respiratory tract (16). Several fatalities resulted from inhalation (or combined inhalation and skin contamination) of EI (17). Death resulted from pneumonia and pulmonary edema within several hours after brief exposures or, in one case, from progressive respiratory obstruction caused by destruction of the tracheobronchial cartilage over a period of 2 months following a 5-min exposure.

An occupational hazard assessment of EI sponsored by the National Cancer Institute (NCI) and centered on its carcinogenic potential was recently reported (18).

1.5 Standards, Regulations, or Guidelines of Exposure

The IARC has classified EI as a Group 3 carcinogen (the agent is not classifiable as to its carcinogenicity to humans). OSHA calls EI a "cancer-suspect agent" (Group 3) and regulates it as an

occupational carcinogen when it is present in formulations at concentrations of 1% or more requiring protective clothing, respiratory protection. NIOSH regards EI as a “potential human carcinogen” and recommends that occupational exposures be limited to the lowest possible concentrations. ACGIH categorizes EI as A3 (confirmed animal carcinogen with unknown relevance to humans).

Ethyleneimine does not have adequate warning properties to avoid overexposure. However, industrial exposure to EI is rigidly controlled by OSHA regulations and, or ACGIH and exhaust fans threshold limit value (TLV) limits its exposure during a 40-h week to an 8-hr TWA of 0.88 mg/m^3 (0.5 ppm), with a “skin” notation to alert against cutaneous absorption (5). Manufacturer recommendations (U.S.) are very explicit and suggest that one should not attempt to handle EI until fully acquainted with the dangers involved (1).

Finally, EPA lists EI as a hazardous air pollutant (HAP) generally known or suspected to cause serious health problems. The Clean Air Act, as amended in 1990, directs the EPA to set standards that require major sources to sharply reduce routine emissions of toxic pollutants. EPA is required to establish and phase-in specific performance-based standards for all air emission sources that emit one or more of the listed pollutants. Ethyleneimine is included in this list (19).

1.6 Studies on Environmental Impact

Ethyleneimine may be released to the environment as emissions or in wastewater from its manufacture and use. It is a reactive molecule, but there are no data on its fate in environmental media. It should react in the atmosphere with hydroxyl radicals (estimated half-life 1.5 days). If released in water, it will hydrolyze at a neutral pH in about 5 months, but it is apt to be lost much faster by evaporation or chemical reactions with metal ions. It should rapidly evaporate from soil, but it may also leach into the soil or complex with metal ions in the soil. It would not be expected to bioconcentrate in fish. No environmental monitoring data could be found for EI. Human exposure would be primarily occupational (20).

Aliphatic and Aromatic Nitrogen Compounds

Henry J. Trochimowicz, Sc.D., Gerald L. Kennedy, Jr., Ph.D., CIH, Neil D. Krivanek, Ph.D.

2.0 Propyleneimine

2.0.1 CAS Number:

[*75-55-8*]

2.0.2–2.0.3 Synonyms and Trade Names:

2-Methylaziridine, PI, and 2-methyleneimine

2.0.4 Molecular Weight:

57.09

2.0.5 Molecular Formula:

C_3H_7N

2.0.6 Molecular Structure:

2.1 Chemical and Physical Properties

2.1.1 General

Physical Form	colorless, oily liquid
Boiling Point	66–67°C

Freezing Point	–65°C
Vapor Density	2.0 (air = 1)
Density	0.802 at 25°C
Refractive Index	1.409 e
Vapor Pressure	112 mmHg at 20°C
Flammability	flammable
Solubility	miscible in water, soluble in ethanol
Stability	polymerizes; hydrolyzes in water or solutions of HCl to give methylethanolamine

2.1.2 Odor and Warning Properties Similar to that of aliphatic amines (fishy).

2.2 Production and Use

Propyleneimine is used in limited quantities as a chemical intermediate in the modification of latex surface-coating resins, polymers in textile and paper industries, dyes, photography, gelatins, oil additives, and organic synthesis. It is also a co-monomer for polymers with methacrylic acid and esters. Propylene imine has been made commercially by combining 1,2-dichloropropane with ammonia at elevated temperatures. It can function chemically as a secondary amine yielding N-substituted PI or as a cyclic amine involving ring opening reactions (2, 3).

2.3 Exposure Assessment

Several analytical methods for PI in air have been described (2, 3). In addition, one recent method that involves HPLC and UV detection should also be considered (21). Because PI is used in limited quantities and is treated as a possible carcinogen by OSHA, the IARC, and ACGIH, its exposure potential would be expected to be very low.

2.4 Toxic Effects

2.4.1 Experimental Studies 2.4.1.1 Acute Toxicity Propyleneimine is highly toxic on an acute basis. However, relative to EI, it was one-fourth to one-eighth as toxic in a very limited acute inhalation study in rats (8). Acute toxicity data for PI are summarized in Table 59.2.

Table 59.2. Acute Toxicity Response to Propyleneimine–Animals (8)

Species	Dose	Route	Response
Rat	19 mg/kg	Oral	~LD_{50}
Guinea pig	0.043 mL/kg	Skin	~LD_{50}
Rabbit	0.005 ml	Eye	~LD_{50}
Rat	500 ppm, 2 hr	Inhalation	0 of 6 died
	500 ppm, 4 hr	Inhalation	5 of 6 died
Guinea pig	500 ppm, ½ hr	Inhalation	0 of 5 died
	500 ppm, 2 hr	Inhalation	3 of 5 died

2.4.1.2 Subchronic and Chronic Toxicity No subchronic or chronic inhalation toxicity studies were found. Repeated oral administration to assess carcinogenicity potential is discussed later.

2.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms No published studies on the absorption, distribution, metabolism, or excretion of PI were found.

2.4.1.4 Reproductive and Developmental No studies to evaluate PI's potential effects on the pregnant female or male and female reproductive performance were found.

2.4.1.5 Carcinogenesis The carcinogenicity of PI was evaluated in rats. When groups of 26 rats/sex were given oral doses of PI for 28 weeks, 28 of 52 rats dosed at 20 mg/kg and 45 of 52 rats dosed at 10 mg/kg developed tumors. Breast tumors, gliomas, ear duct tumors, leukemias, intestinal tumors, and miscellaneous tumors were reported. Both test groups experienced paralysis after 18 to 30 weeks of dosing, and mortality was high in the 20 mg/kg group. Therefore, this study, originally designed for a 60-week dosing regimen, was terminated after approximately 28 weeks. It was concluded that PI is a powerful carcinogen that affects a wide variety of organs (22).

2.4.1.6 Genetic and Related Cellular Effects Studies Like EI, PI is mutagenic in a variety of *in vitro* assays. It is positive in *Salmonella typhimurium* strains TA98 and TA100 (23) and in strains TA1535 and TA1538 with and without metabolic activation (24). Propyleneimine is also positive in *Saccharomyces cerevisiae* (25) in an unscheduled DNA synthesis (UDS) assay using human diploid fibroblasts (26), and in a rec-assay with *Escherichia coli* (27). In addition, PI was positive in several cell transformation assays (28).

PI was also positive *in vivo* in a rat micronucleus test using either bone marrow or peripheral blood as the target organ (29). It was also positive in the *Drosophila melanogaster* wing spot test (30).

2.4.2 Human Experience There are no human case reports or epidemiology studies available for PI. However, the acute toxic properties of PI are considered similar to those of ethyleneimine—irritation of skin, eye, and upper respiratory tract, nausea, and vomiting. Headache, dizziness, and shortness of breath might also occur.

2.5 Standards, Regulations, or Guidelines of Exposure

PI has been classified by the IARC as a Group 2B carcinogen (the agent is possibly carcinogenic to humans) (2, 3) and meets the criteria for OSHA's medical records rule (31). It has also been classified by the American Conference of Governmental Industrial Hygienists (ACGIH) as Group A3, a confirmed animal carcinogen with unknown relevance to humans (5).

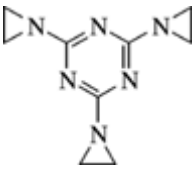
Occupational exposure limits were established for PI by both ACGIH (5) and OSHA (32): 2 ppm (4.7 mg/m^3) as an 8-h TWA, 40-h workweek, with a “skin notation” to alert against cutaneous absorption. In addition, exposure should be minimized due to IARC's classification of PI as a Group 2B carcinogen, ACGIH's classification as an A3 carcinogen, OSHA's medical record rules, and NIOSH's listing as a “potential human carcinogen.” Its occupational exposure limit (8-h TWA, skin notation), is 2 ppm (4.7 mg/m^3) as proposed by both OSHA (32) and the ACGIH (5).

2.6 Studies on Environmental Impact

The major sources of environmental release of propyleneimine are emissions and effluents from plants that manufacture or use this compound for surface coating resins to improve adhesion. If released to the soil, propyleneimine may be removed by chemical hydrolysis (half-life on the order of 17.5 days at neutral pH), ring-opening reactions with naturally occurring chemical species (i.e. humic materials), or fairly rapid volatilization from dry soil surfaces. If released to water, propyleneimine may undergo chemical hydrolysis (half-life 17.5 days at neutral pH), volatilization (half-life greater than or equal to 5 days in water 1 m deep flowing 1 m/s) or undergo ring-opening reactions with naturally occurring chemical species. Propyleneimine is not expected to photolyze, oxidize, or bioaccumulate significantly in aquatic organisms. If released to the atmosphere, propyleneimine, it is predicted, will exist almost entirely in the vapor phase. The primary removal mechanism is expected to be reaction with photochemically generated hydroxyl radicals (half-life on the order of 1.6 days). Human exposure to propyleneimine is probably due mainly to occupational exposure during production and use (20).

Aliphatic and Aromatic Nitrogen Compounds
Henry J. Trochimowicz, Sc.D., Gerald L. Kennedy, Jr., Ph.D., CIH, Neil D. Krivanek, Ph.D.

3.0 Triethylenemelamine
3.0.1 CAS Number:
[*51-18-3*]
3.0.2–3.0.3 Synonyms and Trade Names:
2,4,6-Triethylenimino-1,3,5-triazine; tetramine; TEM; Triamelin
3.0.4 Molecular Weight:
204.23
3.0.5 Molecular Formula:
$C_9H_{12}N_6$
3.0.6 Molecular Structure:



3.1 Chemical and Physical Properties
3.1.1 General

Physical Form	crystalline solid
Melting Point	160°C (decomposes)
Solubility	40% in water (w/w, 26°C) <0.1 g/100 mL at 16°C
Stability	aqueous solutions are stable for 3 months at 4°C; polymerizes at room temperature

3.1.2 Odor and Warning Properties None.
3.2 Production and Use
Triethylenemelamine (TEM) is a potent mutagen (33). It has little, if any, industrial application. TEM is used mainly in medicine as an antineoplastic agent and as a "positive control" in many *in vitro* and *in vivo* mutagenicity assays (34, 35).
3.3 Exposure Assessment
Because TEM has limited, if any, use in industry, no analytical methods have been developed to detect TEM in air, water, soil or biological specimens.
3.4 Toxic Effects
3.4.1 Experimental Studies 3.4.1.1 Acute Toxicity Triethylenemelamine is highly toxic on the basis of acute toxicity. Its oral LD_{50} is 13 mg/kg in the rat and 15 mg/kg in the mouse; in the dog, 1 mg/kg was lethal in 3 to 5 days (36). There are delayed gastrointestinal symptoms, diarrhea, and characteristic damage to lymphatic cells of the intestinal tract and elsewhere; bone marrow damage with depression of all blood elements; weakness, convulsions, respiratory failure, and death (36–38). No acute inhalation toxicity data were found. Acute toxicity responses by the oral and other routes of administration are tabulated in Table 59.3.

Table 59.3. Acute Toxicity of TEM in Animals (36)

Species	Dose (mg/kg)	Exposure Route	Response

Mouse	2.8	i.p.	LD_{50}
	15.0	Oral	LD_{50}
Rat	1.0	i.p.	LD_{50}
	13.0	Oral	LD_{50}
Dog	1.0	Oral	Lethal in 3–5 days
	0.4	i.v.	Lowest lethal dose
Cat	1.0	i.v.	Lethal in 7–12 days

3.4.1.2 Subchronic and Chronic Toxicity Very limited information about the general toxic response of animals to repeated dosing of TEM was found. Lethality occurred when rats and mice were given five daily intraperitoneal doses of TEM at 0.32 mg/kg and 1.1 mg/kg, respectively (36).

3.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Triethylenemelamine is well absorbed from the gastrointestinal tract and from the peritoneal cavity (36). Absorption through the skin or from the respiratory tract was not studied. In humans, blood levels of TEM fall rapidly after intravenous injection to a level of only 10% of the expected value in 2 min after dosing. No selective uptake by any tissue was reported. Eight percent of the ^{14}C ring-labeled TEM was excreted in the urine within 24 h as cyanuric acid (39). These results were very similar to those seen earlier in mice following intraperitoneal injection of a ^{14}C-labeled compound (40).

3.4.1.4 Reproductive and Developmental Toxicity Although no standard developmental toxicity or reproductive toxicity studies were found, TEM did induce fetal death and malformed offspring when pregnant rats were given intraperitoneal doses as low as 0.3 mg/kg (41). It is also a potent antifertility agent in mice dosed intraperitoneally at 0.25 to 1.0 mg/kg for 5 days (42).

3.4.1.5 Carcinogenesis In several older, limited studies, triethylenemelamine reportedly produced tumors in mice by the dermal and intraperitoneal routes and in rats by subcutaneous and/or intramuscular administration. These data were reviewed and evaluated by the IARC (2, 3) and judged as “limited evidence of carcinogenicity in animals.” As a result of this evaluation of the animal data and a lack of evidence of carcinogenicity in humans, the IARC placed TEM in its Group 3 category (2, 3).

3.4.1.6 Genetic and Related Cellular Effects Studies Triethylenemelamine is a potent mutagen (33). It evokes a positive response in almost every *in vitro* and *in vivo* mutagenicity assay in which it was tested. TEM was mutagenic in *Salmonella typhimurium, Saccharomyces cerevisiae, Neurospora crassa*, and cultured human lymphocytes, and it produced dominant lethal mutations in mice (2, 3, 33). It was also positive in the mouse micronucleus assay (43) and produced alterations in sperm-head morphology, as well as significant impairment of spermatogenesis in mice (42). In addition, it was positive in a recent rat micronucleus study using both bone marrow and peripheral blood as target organs (29) and produced specific locus mutations in *Neurospora crassa* (44). Because of its potent mutagenicity potential, TEM is used as an antineoplastic agent in treating a variety of human cancer types.

3.4.2 Human Experience The signs and symptoms produced in humans from therapeutic administration of TEM are briefly described. There are delayed gastrointestinal symptoms, diarrhea, and characteristic damage to the lymphatic cells of the intestinal tract and elsewhere; bone marrow

damage and depression of all blood elements (pancytopenia); tumor inhibition and cytotoxicity (chromosomal aberrations and inhibition of cell division); and antifertility effects. No injuries have been reported from the earlier, very limited use of TEM in industry (2, 3).

3.5 Standards, Regulations, or Guidelines of Exposure

Based on only limited evidence of carcinogenicity potential in rats and mice, the IARC placed TEM in its Group 3 category (the agent is not classifiable as to its carcinogenicity to humans). Neither OSHA nor NTP has classified TEM as a carcinogen. Because TEM has limited, if any, use in industry, no occupational exposure limits have been set. However, TEM is a highly toxic chemical and a potent mutagen, and exposure should be minimized.

3.6 Studies on Environmental Impact

None.

Aliphatic and Aromatic Nitrogen Compounds

Henry J. Trochimowicz, Sc.D., Gerald L. Kennedy, Jr., Ph.D., CIH, Neil D. Krivanek, Ph.D.

4.0 Chloroethylamines (Nitrogen Mustards)

4.0.1 CAS Number:

[*51-75-2*]

4.0.2–4.0.3 Synonyms and Trade Names:

MBA; Nitrogen Mustard; mechloroethamine; HN-2; Mustine Note; 2,2'-dichloro-*N*-methyldiethylamine; Dichloren; bis(2-chloroethyl)methylamine; 2-chloro-*N*-(2-chloroethyl)-*N*-methylethanamine; bis(beta-chloroethyl) methylamine; Caryolysine; mechlorethanamine; chlormethine

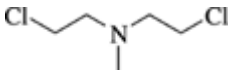
4.0.4 Molecular Weight:

156.05

4.0.5 Molecular Formula:

$C_5H_{11}Cl_2N$

4.0.6 Molecular Structure:



4.1.1 General

The information in this section describes the properties and toxicity of six of the simpler b-chloroethylamines in the following sections.

4.2 Production and Use

The nitrogen mustards are tertiary amines in which the halogen atom and the amine portion have reactivities similar to those of alkyl halides and alkyl amines. They are oily liquids that have limited water solubility but form readily soluble hydrochlorides. They are prepared by the action of thionyl chloride on the appropriate alkanolamine. Many of the actions of the nitrogen mustards resemble those of ethyleneimine derivatives because they are transformed in aqueous solutions into the highly reactive ethylenimonium intermediates: these ions can readily react with a variety of organic compounds *in vitro*, especially with amino, sulfhydro, and carboxyl groups of proteins and phosphate groups in nucleic acid, and therefore can alkylate biologically important macromolecules (36, 45).

The nitrogen mustards are not manufactured in significant commercial quantities in the United States. Some derivatives have been used in medicine as “antineoplastic agents,” and, to an even lesser extent, in treating a variety of nonmalignant diseases. No significant industrial uses of these chemicals in the United States were found.

Three b-chloroethylamine derivatives have been classified by the IARC as carcinogens. Studies of nitrogen mustard [2-chloro-*N*-(2-chloroethyl)-*N*-methylethanamine] reported "limited evidence of carcinogenicity in humans" and "sufficient evidence of carcinogenicity in animals," and it is classified by the IARC in Group 2A, (probably carcinogenic to humans). Nitrogen mustard N-oxide [2-chloro-*N*-(2-chloroethyl)-*N*-methylethanamine, *N*-oxide] and uracil mustard [5-bis(2-chloroethyl) amino-2,4(1*H*,3*H*)-pyrimidinedione] studies reported "sufficient evidence of carcinogenicity in animals," and they are classified by the IARC as Group 2B carcinogens (2, 3).

4.3 Exposure Assessment

Because there are no significant industrial uses of nitrogen mustards, no specific information to assess human exposure potential was found.

4.4 Toxic Effects

The important characteristic actions of the bis(b-chloroethyl)amines on biological systems are (1) severe local irritation of tissues and vesicant action on the skin and corneal damage in the eye; (2) delayed deaths for doses around the LD_{50}, prominent gastrointestinal effects and diarrhea; (3) cytotoxic effects and inhibition of cell division; (4) bone marrow and lymph node damage and leukopenia; (5) tumor inhibition; (6) antifertility effects, that is, impairment of menses and spermatogenesis; (7) mutagenic activity (*in vitro* and *in vivo*); (8) carcinogenicity or tumor irritation; and (9) pharmacological and neurotoxic activity (large doses). Their proclivity to damage actively proliferating cells (bone marrow, fetal tissue, germinal epithelium, neoplasms) is evident from the effects listed. Because many of these effects resemble those of ionizing radiation, the term "radiomimetic" is frequently used. Not all of the series produce all of these effects to the same degree; however, the differences among the polyfunctional b-chloroethylamines are minimal.

All of the preceding effects that have been observed in animals can presumably occur in humans. Most of these effects have been observed during the therapeutic use of these agents. Nearly all patients developed nausea, vomiting, headache, and diarrhea. A major toxic effect is depression of normal bone marrow function and a decrease in the total number of circulating leukocytes and platelets. Because the b-chloroethylamines have limited specialized use in industry and chemical laboratories and because their high degree of toxicity and serious effects are rather universally recognized, there have been few reports of injury from these sources. No case reports or epidemiology studies of exposure to nitrogen mustards were found.

The chloroethylamines in this group are discussed individually in sections 5.0 through 10.0

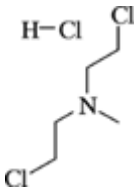
$C_5H_{12}Cl_3N$

5.0.6 Molecular Structure:



5.1 Chemical and Physical Properties

5.1.1 General

	Nitrogen Mustard	Nitrogen Mustard HCl
Chemical Formula	$C_5H_{11}Cl_2N$	$C_5H_{12}Cl_3N$
Physical State	liquid	white crystals
	none	none
Boiling Point	217°C at 10 mmHg	—
Melting Point	14.45°C	–60°C
Density	1.118 at 25/5°C	—
Solubility	miscible with DMF, CS_2, and CCl_4	soluble in H_2O and ethanol
Stability	reacts with H_2O; decomposes on standing	stable dry; unstable in H_2O

5.1.2 Odor and Warning Properties None.

5.2 Production and Use

See section 4.2.

5.3 Exposure Assessment

See section 4.3.

5.4 Toxic Effects

5.4.1 Experimental Studies

5.4.1.1 Acute Toxicity Nitrogen mustard (and its hydrochloride) is highly toxic on an acute basis and

produces all of the effects previously described. It has an oral LD_{50} of 10 mg/kg in rats and 20 mg/kg in mice (46). By the dermal route, its LD_{50} in rats is 12 mg/kg, indicating that it is readily absorbed (47). By the intravenous route, its LD_{50} was 1.1 mg/kg in rats, 2 mg/kg in mice, 1 mg/kg in dogs, and 1.6 mg/kg in rabbits (46). By inhalation, the only information found was for short exposure periods—a 2-min LC_{50} of 600 mg/m^3 in rats, a 30-min LC_{50} of 1500 mg/m^3 in mice, and a 10-min LC_{50} of 2000 mg/m^3 in dogs (48).

Nitrogen mustard in contact with the eye is reportedly severely damaging and acts similarly to sulfur mustard gas but with more immediate effect and greater tendency to injure deeper ocular structures, particularly the iris and lens (49). Relative to dermal exposure, it is reportedly a potent vesicant and local irritant.

5.4.1.2 Subchronic and Chronic Toxicity No specific repeated exposure studies were found.

5.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Oral absorption of nitrogen mustard and its hydrochloride salt is variable and less complete than absorption from subcutaneous injection, but these materials are readily absorbed dermally and by inhalation. An intravenous dose of 3 mg/kg administered to dogs readily disappeared from the blood: 0.01% was found in urine, low levels were found in various tissues, and bone marrow showed the highest concentration. Approximately 90% was metabolized within 4 min of incubation with whole blood (50). Within 30 sec after intravenous injection of ^{14}C-labeled nitrogen mustard, more than 90% disappeared from the blood in another study (39). The promptness with which these agents are transformed *in vivo* is also evident by their rapid action. Following its *in vivo* administration, nitrogen mustard or its hydrochloride is probably converted to an ethylenimonium ion which then reacts readily with a large number of biologically important macromolecules (36, 45).

5.4.1.4 Reproductive and Developmental Nitrogen mustard is reportedly an active developmental toxin in four species of laboratory animals: mice, rats, rabbits, and ferrets (51). It was also an antifertility agent in rodents (52–54). All of the preceding effects involved intraperitoneal or intravenous doses of less than 1 mg/kg.

5.4.1.5 Carcinogenesis Nitrogen mustard administered mainly as the hydrochloride salt is carcinogenic in mice and rats. Following its subcutaneous, intraperitoneal, or intravenous injection, it produced an increased incidence of lung tumors and thymic lymphomas in mice. It produced a variety of malignant tumors in rats following intravenous injection. On the basis of there studies, its mutagenic potential, and "limited evidence of carcinogenicity in humans," IARC has classified nitrogen mustard in Group 2A (probably carcinogenic to humans) (3).

5.4.1.6 Genetic and Related Cellular Effects Studies Nitrogen mustard, like many antineoplastic agents, is mutagenic in many *in vitro* and *in vivo* test systems. It induced dominant lethal mutations and induced micronuclei in bone marrow cells of mice exposed *in vivo* and alkylated DNA of ascites cells in experimental animals treated *in vivo*. It induced chromosomal aberrations, sister chromatid exchanges, and unscheduled DNA synthesis in human cells *in vitro*. It induced sister chromatid exchanges, chromosomal aberrations, and DNA damage in rodent cells *in vitro*; the latter studies on the induction of mutation were inconclusive. It also transformed mouse C3H10T1/2 cells. Nitrogen mustard induced aneuploidy and somatic mutation and recombination in *Drosophila*, chromosomal aberration in plants, mitotic recombination and mutation in fungi, and mutation and DNA damage in bacteria (3).

5.4.2 Human Experience See section 4.4.

5.5 Standards, Regulations, or Guidelines of Exposure

No workplace limits for industrial air have been proposed for nitrogen mustard (or its hydrochloride)

by OSHA, ACGIH, or AIHA.
5.6 Studies on Environmental Impact
Nitrogen mustard's production and use as an antineoplastic agent and its former production as a gas warfare agent may result in its release to the environment through various waste streams. If released to the atmosphere, nitrogen mustard will mainly exist in the vapor phase in the ambient atmosphere based on an estimated vapor pressure of 65 mmHg at 25°C. Vapor-phase nitrogen mustard is degraded in the atmosphere by reaction with photochemically produced hydroxyl radicals whose estimated half-life is about 2 days. An estimated K_{oc} of 74 suggests that nitrogen mustard will have high mobility in soil. Volatilization from dry soil surfaces may be an important fate process based on its vapor pressure; however, nitrogen mustard is not expected to volatilize from moist soil surfaces because of its low Henry's law constant. Nitrogen mustard is expected to hydrolyze rapidly in both moist soil and water. A hydrolysis half-life of 11 hours at 25°C was measured in water; methyldiethanolamine is the expected product from this reaction. Nitrogen mustard is not expected to adsorb to suspended matter in the water column based on its K_{oc} value or to volatilize from water surfaces given an estimated Henry's law constant of 8.5×10^{-8} atm-cu m/mole. Bioconcentration in aquatic organisms should not occur based on an estimated BCF value of 3 (20).

Aliphatic and Aromatic Nitrogen Compounds

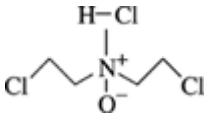
6.0 Nitrogen Mustard **N**-Oxide (Hydrochloride)
6.0.1 CAS number:
[*302-70-5*]
6.0.2 Synonyms:
Ethanamine; 2-chloro-*N*-(2-Chloroethyl)-*N*-methyl-,*N*-oxide(hydrochloride); 2,2-dichloro-*N*-methyldiethylamine, oxide (HCl); chlormethine *N*-oxide(HCl); HN2 Oxide Mustard; 2-chloro-*N*-(2-chloroethyl)-*N*-methyl-Ethanamine, *N*-oxide hydrochloride
6.0.3 Trade Names:
None
6.0.4 Molecular Weight:
172; 208.5(*HCl)
6.0.5 Molecular Formula:
$C_5H_{12}Cl_3NO$
6.0.6 Molecular Structure:



6.1 Chemical and Physical Properties
6.1.1 General:

Physical State	colorless, odorless crystals (*HCl)
Melting Point	109°C (*HCl)
Solubility	both forms are soluble in H_2O and ethanol

6.1.2 Odor and Warning Properties None.
6.2 Production and Use

See section 4.2.
6.3 Exposure Assessment
See section 4.3.
6.4 Toxic Effects
6.4.1 Experimental Studies 6.4.1.1 Acute Toxicity Nitrogen mustard N-oxide produces all of the biological effects described previously for this class of compound. Although few acute data were found, the N-oxide form is slightly less toxic than nitrogen mustard itself. Its intravenous LD_{50} in rats is 60 mg/kg (55) compared to 1.1 mg/kg for nitrogen mustard (46). By the oral route, an LD_{50} of 60 mg/kg in rats was reported for the N-oxide (56) compared to a 10 mg/kg LD_{50} for nitrogen mustard (46). No data related to dermal, eye, or inhalation toxicity were found.

6.4.1.2 Subchronic and Chronic Toxicity No specific toxicity studies of repeated exposure were found.

6.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms After intravenous injections of 5 mg/kg of radio-labeled N-oxide into dogs, almost no activity was found in blood after 1 h, suggesting rapid metabolism. The highest level of radioactivity in the urine was found between 5 and 20 min after injection and declined to zero after 4 h (57). No other information on absorption, distribution, or excretion of nitrogen mustard N-oxide in mammals was found.

6.4.1.4 Reproductive and Developmental No specific studies to evaluate developmental toxicity potential in animals were found. However, like other b-chloroethylamines, nitrogen mustard N-oxide has produced antifertility effects in male rats (58) and mice (59).

6.4.1.5 Carcinogenesis Nitrogen mustard N-oxide is reportedly carcinogenic in mice and rats. Following subcutaneous administration in mice, it produced lung tumors, thymic lymphomas, and Harderian gland adenomas. In rats given the material intravenously, it produced mainly lymphoreticular tumors and sarcomas. The preceding data were evaluated by the IARC and considered “sufficient evidence of carcinogenicity in animals.” Based on this evaluation and its mutagenic potential, the IARC classified nitrogen mustard N-oxide as Group 2B (possibly carcinogenic to humans) (3).

6.4.1.6 Genetic and Related Cellular Effects Studies In earlier studies, nitrogen mustard N-oxide was mutagenic in tumor cells and bacteria and also induced dominant lethal mutations in mice (2, 3). In more recent studies, this material was mutagenic in *Salmonella typhimurium, Escherichia coli*, and *Bacillus subtilis* (60). It also induced sister chromatid exchanges in human lymphocytes (61) and unscheduled DNA synthesis in various rat cell types (62).

6.4.2 Human Experience See section 4.4.
6.5 Standards, Regulations, or Guidelines of Exposure
No workplace limits for industrial air have been set by OSHA, ACGIH, or NIOSH for nitrogen mustard *N*-oxide(or its hydrochloride).
6.6 Studies on Environmental Impact
Because the substance is used only as an antineoplastic agent, health professionals (e.g., pharmacists, nurses, and physicians) involved in cancer chemotherapy are the principal personnel who may be exposed. Exposure may occur during drug preparation, administration, or cleanup (63).

7.0 Tris(b-chloroethyl)amine (hydrochloride)

7.0.1 CAS Number:
[*555-77-1*]; [*817-09-4*] (*HCl)
7.0.2 Synonyms:
Ethanamine, 2-chloro-*N*, *N*-bis(2-chloroethyl)*(hydrochloride); 2,2',2"-trichlorotriethylamine (*HCl); HN3(*HCl); trimustine(*HCl); trichloromethine- (*HCl)
7.0.3 Trade Name:
None
7.0.4 Molecular Weight:
204.53; 240.99 (*HCl)
7.0.5 Molecular Formula:
$C_6H_{12}NCl_3$
7.0.6 Molecular Structure:
$N(CH_2CH_2Cl)_3$(ĖHCl)
7.1 Chemical and Physical Properties
7.1.1 General

Physical State	liquid; white powder(*HCl)
Boiling Point	144°C at 15 mmHg
Solubility	Very soluble in water
Melting Point	131°C (HCL)

7.1.2 Odor and Warning Properties None.
7.2 Production and Use
See section 4.2.
7.3 Exposure Assessment
See section 4.3.
7.4 Toxic Effects
7.4.1 Experimental Studies 7.4.1.1 Acute Toxicity Tris(b-chloroethyl)amine produces the same biological effects as the preceding nitrogen mustards. This material is highly toxic on an acute basis. It is readily absorbed through the skin as indicated by dermal LD_{50}s of 7, 4.9, 19, and 1 mg/kg body weight, in mice, rats, rabbits, and dogs, respectively (46). By the oral route, a lowest lethal dose (LD_{LO}) of 5 mg/kg for rats (64) and an LD_{50} of 1.1 mg/kg for mice (65) were reported. The LD_{50} after intravenous injection was 0.7 mg/kg for rats and 2.5 mg/kg for rabbits (46).

In dogs, tris(b-chlorethyl)amine caused vomiting, anorexia, and blood in the feces a few hours after a single intravenous dose of 1 mg/kg. Coma preceded death by anoxia as a consequence of peripheral circulatory failure (66). In rabbits (67) injected intravenously and in mice (68) given a subcutaneous dose, the immediate response was a decreased peripheral lymphocyte count. Tris(b-chloroethyl) amine is reportedly a strong vesicant on skin and produces conjunctivitis (2, 3).

7.4.1.2 Subchronic and Chronic Toxicity No specific toxicity studies of repeated exposure were found for tris(b-chloroethyl)amine (or its hydrochloride).

7.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms No specific data on absorption, distribution, excretion, or metabolism were found. However, tris(b-chloroethyl)amine causes cross-links in membrane proteins and hemoglobin in human erythrocytes *in vitro* (69, 70), and it also alkylates nucleic acids *in vitro* (71).

7.4.1.4 Reproductive and Developmental No studies to assess developmental toxicity potential were found. However, like other nitrogen mustards, tris(b-chloroethyl)amine is probably an antifertility agent in male rats (2.4 mg/kg) by the intravenous route (72) and in male mice (1.5 mg/kg) by intraperitoneal administration (73).

7.4.1.5 Carcinogenesis Tris(b-chloroethyl)amine was tested for carcinogenic potential in mice and rats given the material by subcutaneous injection. The study in mice was considered inadequate for evaluation by the IARC. However, in rats, this material induced a high incidence of sarcomas (mostly spindle-cell type) in animals of each sex at the site of injection, as well as a few intestinal adenocarcinomas; neither tumor type was seen in controls. IARC considered the preceding data "sufficient evidence of carcinogenicity in experimental animals." Although no human carcinogenicity data were available, the IARC classified tris(b-chloroethyl)amine in Group 2B (the agent is possibly carcinogenic to humans). This classification was based on these animal studies, its mutagenic potential, and analogy to other nitrogen mustards (74).

7.4.1.6 Genetic and Related Cellular Effects Studies Tris(b-chloroethyl)amine, like other antineoplastic agents, is mutagenic *in vitro* and *in vivo*. It inhibited DNA synthesis and induced mutations at the hprt locus of Chinese hamster V79 cells (75) and produced DNA inhibition in human fibroblast cells (76). A single intraperitoneal treatment at 5 mg/kg also induced dominant lethal mutations in mice (77).

7.4.2 Human Experience See section 4.4.
7.5 Standards, Regulations, or Guidelines of Exposure
No workplace limits have been set by OSHA, ACGIH, or AIHA for tris(b-chloroethyl)amine (or its hydrochloride) in industrial air.
7.6 Studies on Environmental Impact
Tris(2-chloroethyl)amine belongs to the nitrogen mustard group of compounds. It is produced in small quantitities as the hydrochloride and may enter the waste stream as such during the production process. If released to either soil or water, hydrolysis is expected to be a major fate process for tris(2-chloroethyl)amine, especially under weakly alkaline conditions. An estimated Henry's law constant of 3×10^{-7} atm-cu m/mole indicates that this compound is essentially nonvolatile and thus volatilization from water and moist soil will not be an important environmental fate process. An estimated K_{oc} value of 672 suggests that tris(2-chloroethyl)amine has a low to moderate mobility potential through soil. However, as hydrolysis may proceed quickly, mobility of this compound through the soil is not expected to be a major fate process. An estimated BCF value of 30 suggests that this compound will not bioconcentrate in aquatic organisms and hydrolysis should preclude bioconcentration from being a major fate process. If released to the atmosphere, tris(2-chloroethyl) amine is expected to degrade rapidly based on a half-life of five hours. Insufficient data are available to predict the relative importance or rate of biodegradation in soil or water (20).

Aliphatic and Aromatic Nitrogen Compounds
Henry J. Trochimowicz, Sc.D., Gerald L. Kennedy, Jr., Ph.D., CIH, Neil D. Krivanek, Ph.D.

8.0 Dimethyl(b-chloroethyl)amine (hydrochloride)
8.0.1 CAS Number:
[*107-99-3*]; [*4584-46-7*](*HCl)
8.0.2 Synonyms:
Ethanamine, 2-chloro-*N*-*N*-dimethyl(hydrochloride); dimethylalminoethyl chloride; HN1; nitrogen half mustard
8.0.3 Trade Name:
None
8.0.4 Molecular Weight:
107.58; 144.04(*HCl)
8.0.5 Molecular Formula:
$C_4H_{10}NCl$

8.0.6 Molecular Structure:
$(CH_3)_2NCH_2CH_2Cl(\dot{c}HCl)$
8.1 Chemical and Physical Properties
8.1.1 General

Physical State	liquid
Boiling Point	109–110°C at 750 mmHg
Melting Point	205–208°C (HCl)

8.1.2 Odor and Warning Properties None.
8.2 Production and Use
See section 4.2.
8.3 Exposure Assessment
See section 4.3.
8.4 Toxic Effects
8.4.1 Experimental Studies 8.4.1.1 Acute Toxicity This monofunctional b-chloroethylamine does not have the cytotoxic and leukopenic potency of the nitrogen mustards. Its major actions are local irritation, effects on the autonomic nervous system, and neurotoxicity. The single dose LD_{50} in mice by subcutaneous injection was 200 mg/kg in one study (68) and 250 mg/kg (for the hydrochloride salt) in another study (78). The only other acute information found was an intraperitoneal LD_{50} in mice of 280 mg/kg (79).

8.4.1.2 Subchronic and Chronic Toxicity No specific toxicity studies of repeated exposure in animals were found for dimethyl(b-chloroethyl)amine or its hydrochloride salt.

8.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms No information for absorption, distribution, excretion, or metabolism in mammals was found.

8.4.1.4 Reproductive and Developmental No experimental studies of dimethyl(B-chloroethyl)amine were found to assess its potential to affect the unborn fetus or reproductive performance.

8.4.1.5 Carcinogenesis No studies by common exposure routes have been conducted. In addition, dimethyl(b-chloroethyl)amine (and its hydrochloride salt) has not been evaluated by the IARC for carcinogenic potential.

8.4.1.6 Genetic and Related Cellular Effects Studies Dimethyl(b-chloroethyl)amine was mutagenic in a variety of *in vitro* assays. It was positive in the Ames test, the L5178Y mouse lymphoma cell assay, and the hepatocyte primary culture-DNA repair test, tests designed to detect chemicals that interact with DNA (80). It was also positive in *E. coli* (81), induced sister chromatid exchanges in various rat cells (82), and produced sex chromosome loss and nondisjunction in *Drosophila melanogaster* (83).

8.4.2 Human Experience See section 4.4.
8.5 Standards, Regulations, or Guidelines of Exposure
No workplace limits have been set by OSHA, ACGIH, or AIHA for dimethyl(b-chloroethyl)amine in industrial air.
8.6 Studies on Environmental Impact
None.

Aliphatic and Aromatic Nitrogen Compounds

Henry J. Trochimowicz, Sc.D., Gerald L. Kennedy, Jr., Ph.D., CIH, Neil D. Krivanek, Ph.D.

9.0 Diethyl(b-chloroethyl)amine (Hydrochloride)
9.0.1 CAS Number:
[*100-35-6*]; [*869-24-9*](*HCl)
9.0.2 Synonyms:
Ethanamine, 2-chloro-*N*-*N*-diethyl(hydrochloride); 2-chlorotriethylamine (*HCl); diethylaminoethyl chloride (*HCl)
9.0.3 Trade Name:
None
9.0.4 Molecular Weight:
134.64; 172.10(*HCl)
9.0.5 Molecular Formula:
$C_6H_{14}NCl$
9.0.6 Molecular Structure:
$C_6H_{14}NCl(CH_3CH_2)_2NCH_2CH_2Cl(\cdot HCl)$
9.1 Chemical and Physical Properties
9.1.1 General

Physical State	liquid
Boiling Point	51–52°C at 16 mmHg
Melting Point	208–210°C (HCL)

9.1.2 Odor and Warning Properties None reported.
9.2 Production and Use
See section 4.2.
9.3 Exposure Assessment
See section 4.3.
9.4 Toxic Effects
9.4.1 Experimental Studies 9.4.1.1 Acute Toxicity The acute toxicological effects of diethyl(b-chloroethyl)amine are similar to those of the preceding dimethyl derivative in that it is not as cytotoxic or leukopenic as the other bifunctional nitrogen mustards. Its intravenous LD_{50} in mice and rabbits was 100 and 40 mg/kg, respectively, and its subcutaneous LD_{50} in mice was 100 mg/kg (46). In the rat, the oral LD_{50} is 17 mg/kg, and this material was also a moderate skin and severe eye irritant. Finally, its dermal LD_{50} in rabbits was 300 mg/kg (84).

9.4.1.2 Subchronic and Chronic Toxicity No animal toxicity studies of repeated exposure were found.

9.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms No information for absorption, distribution, excretion or metabolism of diethyl(b-chloroethyl)anime in mammals was found.

9.4.1.4 Reproductive and Developmental No studies to assess the effects of diethyl(b-chloroethyl) amine on the unborn fetus or on reproductive performance were found.

9.4.1.5 Carcinogenesis No studies to assess carcinogenic potential were found. In addition, this chemical has not been evaluated for carcinogenicity potential by the IARC or ACGIH. However, its dimethyl analog produced lung tumors in strain A mice following intraperitoneal injection (85).

9.4.1.6 Genetic and Related Cellular Effects Studies Like its dimethyl analog, diethyl(b-chlorethyl) amine is mutagenic in a variety of *in vitro* assays. It was positive in the Ames test, the L5178Y mouse lymphoma cell assay, and the hepatocyte primary-culture DNA-repair test (80). It was also

positive in *E. coli* (86) and induced sister chromatid exchanges in various types of rat cells (82).

9.4.2 Human Experience See section 4.4.
9.5 Standards, Regulations, or Guidelines of Exposure
No workplace limits have been set by OSHA, ACGIH, or AIHA for diethyl(b-chloroethyl)amine in industrial air.
9.6 Studies on Environmental Impact
None.

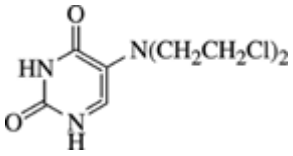
10.0 Uracil Mustard
10.0.1 CAS Number:
[*66-75-1*]
10.0.2–10.0.3 Synonyms and Trade Names:
5[Bis(2-chloroethyl)amino]-2, 4-(1H,3H)-pyrimidinedione; Uracil nitrogen mustard; Aminouracil mustard; Chlorethaminacil; CB-4835; Desmethyldopan; Nordopan; sk-19849; U-8344; Uracillost; Uracilmostaza; Uramustine; 2,6-dihydroxy-5-bis[2-chloroethyl]aminopyridimidine; 5-[bis(2-chloroethyl)amino]uracil; 5-[di(beta-chloroethyl)amino]uracil; 5-*N*,*N*-bis(2-chloroethyl)aminouracil
10.0.4 Molecular Weight:
252.10
10.0.5 Molecular Formula:
$C_8H_{11}Cl_2N_3O_2$
10.0.6 Molecular Structure:



10.1 Chemical and Physical Properties
10.1.1 General

Physical State	white, odorless crystals
Melting Point	206°C
Solubility	very slightly soluble in water; slightly soluble in methanol and acetone
Stability	unstable in water and acid solutions

10.1.2 Odor and Warning Properties None reported.
10.2 Production and Use
See section 4.2.
10.3 Exposure Assessment
See section 4.3.
10.4 Toxic Effects
10.4.1 Experimental Studies 10.4.1.1 Acute Toxicity Uracil mustard is highly toxic on an acute basis. Its oral LD_{50} in mice and rats ranges from 2 to 6 mg/kg and its LD_{50} by either intramuscular or intraperitoneal routes ranges from 1 to 3 mg/kg (86). In another study (87), the oral LD_{50} in rats

was 3.5 mg/kg, and rats exhibited sleepiness, muscle weakness, and gastrointestinal distress. Extensive damage to bone marrow and testis was also reported.

10.4.1.2 Subchronic and Chronic Toxicity No standard toxicity studies for repeated exposure were found. However, as part of a limited carcinogenicity study (88), mice injected intraperitoneally (0.18 to 12 mg/kg body weight) three times a week for 4 weeks and observed for several months showed liver damage such as early portal cirrhosis.

10.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Only a few limited studies were found. When ^{14}C-uracil mustard was given to Walker carcinosarcoma-bearing rats at a 4 mg/kg dose, incorporation of the ^{14}C-label into macromolecules in subcellular fractions of various tissues was maximal by 1 h after administration and was more extensive in RNA than in DNA or in protein (89). In one other study, when 0.2 mmol/ml uracil mustard was added to heparinized human blood *in vitro*, about 50% of it was no longer detectable (colorimetrically) after 30 min (90).

10.4.1.4 Reproductive and Developmental In a limited developmental toxicity study, administration of uracil mustard to female rats in doses of 0.3 and 0.6 mg/kg body weight on the 12th day of pregnancy produced retarded and clubbed appendages, exencephaly, and deformed paws and tails in the surviving offspring at 21 days (91). Although no standard studies to assess reproductive performance were found, uracil mustard, like other nitrogen mustards, probably is an antifertility agent. In one older study (87), rats given 3.5 mg/kg uracil mustard orally exhibited extensive damage to the testis.

10.4.1.5 Carcinogenesis Uracil mustard was reportedly carcinogenic in both mice and rats following multiple intraperitoneal injections. It produced a dose-related increase in lung tumor incidence in mice and tumors in a variety of other organs in both mice and rats. The IARC reviewed the preceding data and deemed it “sufficient evidence of carcinogenity in animals.” Based on this information, its mutagenic potential, analogy to other nitrogen mustards, and a lack of carcinogenicity data in humans, the IARC classified uracil mustard in Group 2B (possibly carcinogenic to humans) (2, 3). Uracil mustard compared to nitrogen mustard itself in the same assay (lung tumor assay in strain A mice, intraperitoneal dosing), was more potent a tumorigen than nitrogen mustard (92).

10.4.1.6 Genetic and Related Cellular Effects Studies Uracil mustard is mutagenic in several *in vitro* and *in vivo* assays. It is positive in *Salmonella typhimurium, E. coli*, and *Saccharomyces cerevisiae* and in a host-mediated assay using the mouse and *S. typhimurium* (93). It was also mutagenic in *Drosophila melanogaster* (94) and in a microsomal assay using mouse lymphocytes (95).

10.4.2 Human Experience See section 4.4.

10.5 Standards, Regulations, or Guidelines of Exposure

No workplace limits have been set by OSHA, ACGIH, or NIOSH for uracil mustard in industrial air.

10.6 Studies on Environmental Impact

Uracil mustard's production and use as an antineoplastic agent may result in its release to the environment through various waste streams. If released to soil, uracil mustard should have high mobility. Volatilization of uracil mustard should not be important from moist or dry soil surfaces. Insufficient data are available to determine the rate or importance of biodegradation of uracil mustard in soil or water. If released to water, uracil mustard would not adsorb to suspended solids and sediment. Uracil mustard will be essentially nonvolatile from aqueous surfaces. An estimated BCF value of 1.8 suggests that uracil mustard will not bioconcentrate in aquatic organisms. Uracil mustard will hydrolyze rapidly in water and moist soil. Experimental neutral and base-catalyzed hydrolysis rates in water at 25°C are 0.57/hour and 2.05/hour, respectively, which correspond to a calculated half-life of 1.2 hours at a pH of 7. If released to the atmosphere, uracil mustard will exist almost entirely in the particulate phase. Vapor-phase uracil mustard is degraded in the atmosphere by reaction with photochemically produced hydroxyl radicals and the estimated half-life is about 19

hours. Vapor-phase uracil mustard is also degraded in the atmosphere by reaction with atmospheric ozone, and then an estimated half-life is about 6.5 days. Particulate-phase uracil mustard may be physically removed from the air by wet deposition. Direct human exposure may occur by ingestion of the drug when dispensed in capsule form. Workers involved in formulating and dispensing the drug may be exposed through dermal contact or inhalation of dust (20).

Aliphatic and Aromatic Nitrogen Compounds
Henry J. Trochimowicz, Sc.D., Gerald L. Kennedy, Jr., Ph.D., CIH, Neil D. Krivanek, Ph.D.

11.0 Pyrrolidine
11.0.1 CAS Number:
[*123-75-1*]; [*25150-61-2*] (HCl)
11.0.2 Synonyms:
Tetrahydropyrrole; tetramethyleneimine; 1-azacyclopentane
11.0.3 Trade Names:
NA
11.0.4 Molecular Weight:
71.12
11.0.5 Molecular Formula:
C_4H_9N
11.0.6 Molecular Structure:

11.1 Chemical and Physical Properties
11.1.1 General

Physical Form	colorless liquid that fumes in air
Boiling Point	87°C
Freezing Point	–60°C
Specific Gravity	0.852
Vapor Pressure	128 mmHg at 39°C
Vapor Density	2.5
Flammability	
Flash Point	3°C
LEL	2.9% at –2°C
UEL	13.0% at 29.8°C

11.1.2 Odor and Warning Properties Unpleasant ammonia-like odor.
11.2 Production and Use
Pyrrolidine is a flammable alkaline liquid that undergoes reactions typical of secondary amines. It is used to prepare pesticides and rubber accelerators and as a chemical intermediate (usually the hydrochloride form) in the pharmaceutical industry. There is relatively limited industrial exposure to this material.
11.3 Exposure Assessment
Trace amounts (<0.1 ppm) of pyrrolidine are found in baked ham and frankfurters, and 0.06 to 6 ppm

pyrrolidine can be found in beverages such as wine, unpasteurized milk, and coffee (96).

Pyrrolidine can be detected in solids and liquids by using HPLC techniques (97).

No other data to assess human exposure were found.

A recent method for collection, desorption, and analysis of volatile organic compounds, including pyrrolidine, has been reported (107).

11.4 Toxic Effects

11.4.1 Experimental Studies 11.4.1.1 Acute Toxicity Pyrrolidine is moderately toxic on an acute toxicity basis. Its oral LD_{50} is 300 mg/kg in rats (98), 450 mg/kg in mice (99), and 250 mg/kg in rabbits and guinea pigs (8). By the intraperitoneal route, the LD_{50} in mice is 420 mg/kg for pyrrolidine itself (100) and 241 mg/kg for the hydrochloride salt (101). The mouse 2-hr LC_{50} was reported as 1300 mg/m^3 (98).

Lethal oral doses in rats affected gastrointestinal mucosa and caused vascular disorders. Inhalation exposures in mice resulted in irritation, excitement, and convulsions (98). Small intravenous doses (<1 mg/kg) in dogs and cats caused an increase in blood pressure and respiratory rate. This activity was reduced by ganglionic blocking agents or sympathectomy (102).

Finally, primary skin irritation studies on adult albino rabbits indicate pyrrolidine to be a severe skin irritant (103). Based on its alkaline characteristics, it is probably a severe eye irritant, even as a 20% solution (98).

11.4.1.2 Chronic and Subchronic Toxicity During or after 10 oral doses of 135 mg/kg, rats showed no evidence of toxicity (104). A limited chronic inhalation study with rats at 2.6 mg/m^3, 4 hr/day for 6 months resulted in increased excitability of the nervous system, decreased diuresis, and decreased hemoglobin (98). No other repeated exposure studies were found.

11.4.1.3 Pharmacokinetics, Metabolism, and Mechanism No information on absorption, distribution, metabolism and excretion of pyrrolidine in mammals was found.

11.4.1.4 Reproductive and Developmental Toxicity No studies on pyrrolidine were found to assess developmental or reproductive toxicity potential.

11.4.1.5 Carcinogenesis See reference 98 in Section 11.4.1.2.

11.4.1.6 Genetic and Related Cellular Effects Studies Pyrrolidine was negative for mutagenicity potential in a direct bacterial assay, a microsomal mutagenesis asssay, and a host-mediated assay, all using *Salmonella typhimurium* bacteria (105). It was also negative for aneuploidy induction in a *Saccharomyces cerevisiae* assay (106).

11.4.1.7 Other None

11.4.2 Human Experience No human exposure information, case histories, or epidemiological studies on pyrrolidine were found.

11.5 Standards, Regulations, or Guidelines of Exposure

No OSHA permissible exposure limit (PEL) or ACGIH TLV has been established for pyrrolidine.

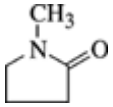
For routine handling, rubber gloves and safety glasses are recommended. Procedures for flammable solvents should be followed. For acute respiratory protections, organic vapor canister-type gas masks should be used (103).

11.6 Studies on Environmental Impact

None.
11.7 Summary
Pyrrolidine is moderately toxic on an acute basis with an oral LD_{50} in rats of 300 mg/kg and a 2-hr LC_{50} in mice of 1300 mg/m^3. It is also mutagenic in several *in vitro* assays. No other information was found relative to dermal and eye toxicity, repeated exposure responses, developmental/reproductive toxicity, carcinogenicity potential, or pharmacokinetics/metabolism.

Aliphatic and Aromatic Nitrogen Compounds
Henry J. Trochimowicz, Sc.D., Gerald L. Kennedy, Jr., Ph.D., CIH, Neil D. Krivanek, Ph.D.

12.0 **N**-Methyl-2-Pyrrolidinone
12.0.1 CAS Number:
[*872-50-4*]
12.0.2 Synonyms:
NMP, 2-Pyrrolidinone, N-Methyl-; and NMP
12.0.3 Trade Names:
NA
12.0.4 Molecular Weight:
99.13
12.0.5 Molecular Formula:
C_5H_9NO
12.0.6 Molecular Structure:



12.1 Chemical and Physical Properties
12.1.1 General

Physical Form	colorless to light yellow liquid
Boiling point	20°C
Density	1.026 at 25°C
Vapor Pressure	0.5 mmHg at 25°C

12.1.2 Odor and Warning Properties Mild, amine-like odor.
12.2 Production and Use
N-Methyl-2-pyrrolidinone (NMP) is a highly polar liquid. It is synthesized by combining acetylene and formaldehyde to form butynediol which is then converted to butanediol, which is further rearranged to butyrolactone and then NMP.

NMP has good chemical stability and is used by the chemical industry as a chemical reaction medium and in the petrochemical industry as a solvent for recovery/purification of aromatics, concentration of acetylene, and removal of sulfur from natural gas. It is also used as a formulating solvent for coating systems such as vinyl coatings, paints, and acrylic-styrene emulsion-type floor finishes. As a solvent, it also serves in stripping and cleaning systems for microelectronic components and various coating systems.
12.3 Exposure Assessment

No information to assess human exposure potential was found.

A method is available for simultaneous analytical determination of 2 NMP metabolites in urine using a GLC technique that has a detection limit of 0.2 mg/ml. This method can also be used to monitor NMP in the workplace (108). Another method to monitor wastewater uses GLC techniques following concentration on XAD-2 resin from NaCl solutions and elution with methanol (109).
12.4 Toxic Effects
12.4.1 Experimental Studies 12.4.1.1 Acute Toxicity NMP has slight acute oral toxicity and an LD_{50} of 4320 mg/kg in rats. NMP also has slight dermal toxicity and no deaths or symptoms of toxicity when 2000 mg/kg is administered onto the skin of rabbits (110), and in guinea pigs, it produced no irritation and was not a skin sensitizer (111). In the rabbit eye, NMP produced moderate irritation (111). By the inhalation route, NMP was moderately toxic to the rat exposed to a 4-h ALC of 1.7 mg/1 as an aerosol-vapor mixture (111).

12.4.1.2 Subchronic and Chronic Toxicity Rats were exposed to an aerosol-vapor mixture of NMP at concentrations of 0, 0.1, 0.5, and 1.0 mg/l for 6 h/day, 5 days/week for 4 weeks. At 0.1- and 0.5-mg/L levels, rats did not show any significant clinical signs or pathological lesions. However, lethargy, respiratory difficulty, and excessive mortality were found in rats exposed to 1.0 mg/L. These rats had focal pneumonia, bone marrow hypoplasia, and atrophy of lymphoid tissue in the spleen and thymus. The lesions were reversible in surviving rats following 2 weeks of recovery. Increases in the relative and absolute numbers of neutrophils were observed during exposure at 1.0 mg/L, but returned to normal limits after 2 weeks of recovery (111). In another subchronic inhalation study, exposure of rats to air saturated with NMP (370 ppm) had no adverse effects (112). Data from subchronic oral studies showed that NMP had a low level of toxicity and NOELs of 80 mg/kg/day in 90-day studies in rats and dogs (110).

Rats and mice were fed either 2,000, 6,000, 18,000, or 30,000 ppm NMP (rats) or 500, 2,500, 7,500, or 10,000 ppm (mice) for 28 days, and complete toxicological workups were conducted. The NOEL was 6,000 ppm for male rats and body weight decreases occurred at higher levels. The NOEL was 18,000 ppm for female rats (same end-point effects). Mild alterations in lipid, protein, and carbohydrate metabolism occurred at 18,000 ppm or higher. In mice, the NOEL in both sexes was 2,500 ppm, and kidney changes were seen at 7,500 ppm and higher (113).

Ninety-day feeding studies were also conducted in rats (3,000, 7,500, or 18,000 ppm NMP) and mice (1,000, 2,500, or 7,500 ppm NMP). A complete toxicity profile was obtained. Decreases in mean body weights were observed in male and female rats fed either 7,500 or 18,000 ppm NMP. Of 36 neurobehavioral parameters investigated, male rats in the 7,500- and 18,000-ppm groups showed an increase in foot splay, and 18,000-ppm males had a higher incidence of low arousal and slight palpebral closure suggestive of a sedative effect. Absolute and relative liver weights were increased in 18,000-ppm females, were associated with an increased incidence of centrilobular hepatocellular hypertrophy, and were considered to be an adaptive/physiological response. In mice, liver weight increases (considered an adaptive response) occurred at 2,500 and 7,500 ppm; no other NMP-related effects were seen (114).

12.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Studies to explore the metabolism of NMP in rats were performed with ^{14}C- and ^{3}H-labeled NMP. Half-lives of about 7 h for the ^{14}C isotope and 10 h for the ^{3}H isotope were measured. Urinary excretion accounted for about 70% of the total dose within 12 h. One major (70 to 75%) and two minor urinary metabolites were seen. The liver was the major organ for tissue distribution (115, 116).

The kinetics of NMP in nonpregnant and in pregnant rats and their fetuses were investigated in a study in which the animals were exposed by inhalation for 6 hours to 150 ppm on day 19 or 20 of pregnancy. Similar concentrations of *N*-methylpyrrolidone in fetal and maternal blood were measured. The half-life was more than 16 hours (117).

In one other limited study (118), the major urinary metabolite of NMP in rats was 5-hydroxy-*N*-methylpyrrolidinone based on thin-layer chromatography and MS comparisons with an authentic sample.

12.4.1.4 Reproductive and Developmental NMP has been tested for its developmental toxicity by the inhalation, oral, dermal, and intraperitoneal routes of administration. In an inhalation study, pregnant rats were exposed 6 h/day on days 6 to 15 of gestation to 0.1 or 0.36 mg/L of an NMP aerosol. Except for sporadic lethargy and irregular respiration in several rats at both exposure levels during the first three days of exposure, no clinical signs of toxicity were observed. NMP was not embryotoxic, and no major external or skeletal malformations were found in the fetuses (111).

In two limited inhalation studies, slight embryo and maternal toxicity was observed in rats exposed to 800 ppm (the maximum saturated concentration in air at 25°C), 6 h/day, on either days 4 to 8 or days 11 to 15 of gestation (119).

Groups of pregnant rats were orally administered either 332 or 997 mg/kg/day on days 6 to 15 of gestation. Embryolethality and marked fetal retardation were noted only at the high dose. A marked reduction in maternal body weight gain was also noted in the dams. At the low dose, a slight retardation of ossification was reported in the fetuses, and no maternal toxicity was noted (119).

Groups of pregnant mice were orally administered 1054 to 2637 mg/kg/day on days 11 to 15 of gestation. No maternal effects were reported. At the high dose, there was an increase in resorptions, decreased litter size, general toxic effects on fetal development, and an increase in cleft palate incidence (19.2 versus 9.5% in controls). No adverse effects were noted in the low-dose group (120).

Pregnant rats were dermally administered 75, 237, or 750 mg/kg/day of NMP on days 6 to 15 of gestation. Maternal toxicity was observed at 750 mg/kg manifested by reduced body weight gain during gestation. Fetal toxicity at 750 mg/kg was indicated by fewer live fetuses per dam, an increase in the percentage of resorption sites, reduced fetal body weights, and apparent retardation in skeletal development. No maternal or fetal toxicity was noted at either 75 or 237 mg/kg (121).

When three different strains of pregnant mice were given NMP by intraperitoneal injection during gestation, increased resorptions and malformations were seen at daily dose levels of 24 to 1568 mg/kg, but sensitivity to these effects varied widely among the different strains (120).

Groups of sexually immature male and female rats were exposed to 10.3, 50.8, or 116 ppm of NMP, 6 h/day, 7 days/week, from day 34 of age until they produced a litter. Clinical signs noted among male and female rats exposed to 116 ppm were lethargy and chromodacryorrhea. No reproductive effects were noted in the parents or in their offspring. Additionally, no effect on reproductive ability was noted in female rats exposed to 116 ppm of NMP and then mated with unexposed male rats or in male rats exposed to 116 ppm of NMP and then mated with unexposed female rats (122).

Prenatal exposure of pregnant rats to NMP at 165 ppm caused preimplantation loss, low fetal weights, and delayed ossification (123). In an earlier study, these authors reported that decreased fetal weight was related to impairments of neurobehavioral function in adults although no dose-response was seen and the end point examined did not necessarily indicate cause and effect (124).

In a two-generation reproduction study, rats were exposed by inhalation to 0, 10, 51 or 116 ppm NMP for 6 h/day, 5 days/week from premating through two generations. No evidence of altered reproductive function was seen. No developmental effects were seen although there was a slight decrease in fetal weight at the 116-ppm dose (125).

12.4.1.5 Carcinogenesis Rats were exposed to NMP vapor at either 0, 0.04 or 0.4 mg/L for 6 h/day, 5

days/week for 2 years. Male rats at 0.4 mg/L showed slightly reduced mean body weight. No life-shortening toxic or carcinogenic effects were observed in rats exposed for 2 years to either 0.04 or 0.4 mg/L of NMP. By the dermal route, a group of 32 mice received an initiation dose of 25 mg of NMP followed 2 weeks later by applications of the tumor promotor phorbol myristate acetate, three times a week, for more than 25 weeks. Dimethylcarbamoyl chloride and dimethylbenzanthracene served as positive controls. Although the NMP group had three skin tumors, this response was not considered significant when compared with that of the positive controls (122).

A group of mice received nine 25 mg subcutaneous injections of NMP during a 17-month period. Tumor incidence for the NMP treatment (21/49) was comparable to that of the untreated control group (28/49) (126).

12.4.1.6 Genetic and Related Cellular Effects Studies NMP was not mutagenic in the Ames test with or without metabolic activation (115, 122) or in the mouse lymphoma assay (122). NMP did induce aneuploidy in the yeast *Saccharomyces cerevisiae* (127). NMP at single oral doses up to 3,800 mg/kg body weight did not lead to an increase either in micronucleated erythrocytes or in structural or numerical chromosomal aberrations when bone marrow was sampled after 16, 24, and 48 hour later in the micronucleus test or after 24 and 48 hours for karyotype analysis (128).

12.4.2 Human Experience In one published industrial hygiene study in the semiconductor industry, headaches and chronic eye irritation were described in some employees exposed to levels as low as 0.7 ppm. Levels of 49 to 83 ppm were found unbearable by the workers (121). Repeat patch testing over 24 h showed no irritation (110).

Six male volunteers were exposed for eight hours on four different days to 0, 10, 25, and 50 mg/m^3. NMP was absorbed through the respiratory tract and readily eliminated from the body, mainly by biotransformation to other compounds. Exposure to 10, 25, or 50 mg/m^3 NMP did not cause nose, eye, or airway irritation (129).

A case report was presented of a pregnant laboratory technician who suffered intrauterine growth retardation and stillbirth following exposure to NMP (130). It is not clear that there is any cause and effect relationship.

Several workers in a small electrotechnical company in Norway experienced irritant reactions of the skin after a few days of working with NMP. The involved workers displayed acute irritant contact dermatitis of the hands (131).

12.5 Standards, Regulations, or Guidelines of Exposure

No workplace exposure limit for NMP has been set by OSHA or ACGIH, but a workplace environmental exposure level guide (WEEL) of 10 ppm, 8-h TWA, has been established by the American Industrial Hygiene Association (AIHA) WEEL Committee.

12.6 Studies on Environmental Impact

NMP may be released to the environment as a fugitive emission during production and use. If released to soil, NMP can biodegrade under aerobic conditions. It is expected to display very high mobility in soil. NMP may slowly volatilize from dry soil to the atmosphere, but it is not expected to volatilize significantly from moist soil. If released to water, screening studies indicate that NMP will biodegrade under aerobic conditions after a short lag. A calculated bioconcentration factor of 0.16 indicates that NMP is not expected to bioconcentrate significantly in fish and aquatic organisms, nor is it expected to significantly absorb to sediment or suspended organic matter. An estimated Henry's law constant of 1.56×10^{-8} atm-cu m/mole at 25°C indicates that NMP is not expected to volatilize significantly from water to the atmosphere. The estimated half-life for volatilization of NMP from a model river is 2335 days. If released to the atmosphere, NMP is expected to undergo a gas-phase reaction with photochemically produced hydroxyl radicals, and the estimated half-life is 5.2 hrs. It may undergo atmospheric removal by wet deposition processes (120).

Aliphatic and Aromatic Nitrogen Compounds

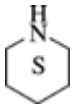
13.0.4 Molecular Weight:
85.15
13.0.5 Molecular Formula:
$C_5H_{11}N$
13.05 Molecular Structure:



13.1 Chemical and Physical Properties
13.1.1 General

Physical Form	colorless liquid that fumes in air
Boiling Point	106.3°C
Freezing Point	–13°C
Melting Point	–13°C
Specific Gravity	0.861
Vapor Pressure	40 mmHg at 29.2°C
Flash Point	16°C

13.1.2 Odor and Warning Properties Pepper-like odor, threshold <2 ppm (132); strong base; soapy consistency.
13.2 Production and Use
Piperidine is a clear, colorless, flammable liquid that has an amine-like pungent odor. It is strongly basic (pK_b = 2.88) and reacts vigorously with oxidizing agents. Piperidine and its derivatives are usually produced by reducing pyridine and corresponding derivatives. Chemically, piperidine has been closely identified with alkaloids because the piperidine nucleus occurs in a wide variety of these plant derivatives.

Piperidine is used in many active pharmaceuticals (analgesics, germicides, anesthetics), as a wetting agent, as a hardening agent for epoxy resins, as a rubber additive, and as a catalyst in silicone esters. Industrial exposure is limited. The chemical is highly basic making it reactive on contact with all tissues. It has an appreciable vapor pressure, so its reactivity, flammability, and volatility make it a serious potential hazard in the workplace.
13.3 Exposure Assessment
Trace amounts of piperidine (<0.2 ppm) have been found in baked ham, and 0.3 ppm can be found in beverages such as coffee or milk (96).

No other data to assess human exposure potential were found.

13.4 Toxic Effects

13.4.1 Experimental Studies 13.4.1.1 Acute Toxicity Piperidine has reported oral LD_{50}s in the rat of 133 mg/kg (133), 447 mg/kg, (134) or 337 mg/kg (135). Rats treated with 100 mg/kg in water showed weakness, respiratory distress, and convulsions (136). The corresponding oral value in the rabbit is 321 mg/kg (137), and therefore the chemical is considered highly to moderately toxic following acute oral exposure. No changes in liver biochemistry (hepatic DNA, ornithine decarboxylase and alanine aminotransferase activities, cytochrome P450 and glutathione content) were seen in rats following single oral exposures from 5 to 142 mg/kg (138). Injection studies have produced LD_{50} values of <50 mg/kg intraperitoneally in the rat; 330 mg/kg intraperitoneally, 30 mg/kg subcutaneously, and 160 mg/kg intravenously in the mouse; and 5 to 10 mg/kg in both the dog and cat (139). Like many secondary aliphatic amines, piperidine produces a significant hypertensive response (136), stimulates respiration, and increases the heart rate (102, 140, 141). A 4-h inhalation exposure of 4000 ppm killed all four rats tested (134). The 4-h LC_{50} in mice was 1723 ppm and the 1-h LC_{50} in guinea pigs was 3444 ppm (133).

Severe injury that involved nonreversible corneal damage was produced by instillation of piperidine into the rabbit eye (133, 134). The chemical is also severely irritating to the skin of rats, mice, and rabbits (136), and necrosis was seen in all six rabbits when the neat material was applied to the belly (134). The LD_{50} in the rabbit following dermal application ranges from 275 mg/kg (134) to 1000 mg/kg (133), which indicates that the material is moderately to highly toxic by the dermal route.

Other simple alkylpiperidine derivatives have been studied for their acute toxicity. 5-Ethyl-2-methylpiperidine was highly irritating to the rabbit eye and skin and, like piperidine, was readily absorbed through the skin (dermal LD_{50} in rabbits of 630 mg/kg); it also produced an oral LD_{50} in rats of 540 mg/kg. Five out of six rats exposed by inhalation to 250 ppm for 4 h died. This represents a greater degree of toxicity than determined in the same laboratory for 5-ethyl-2-methylpyridine, for which the oral LD_{50} in rats was 1540 mg/kg, the percutaneous LD_{50} in rabbits was 3420 mg/kg, and exposure to 1000 ppm for 4 h produced death in five of six rats (84). The 1-ethyl derivative of piperidine is also a strong skin irritant and highly toxic to rats when administered undiluted.

13.4.1.2 Chronic and Subchronic Toxicity Rats and rabbits were exposed by inhalation to either 0.57 to 2.87 ppm piperidine 4 h/day for 4 months. The authors reported that 0.57 was the “threshold” of chronic toxicity, and decreased arterial pressure, increased permeability of skin capillaries, and increased neuromuscular irritability were reported. At 2.87 ppm a number of additional observations were reported including altered brain electrical activity, cardiovascular system alterations and spermatogenesis, decreased body weight gain, and dystrophic changes in the liver and kidney (details not reported) (142). Ten doses of piperidine at 90 mg/kg during a 2-week period produced marked weight loss, necrosis of the liver, and possible kidney damage in rats (143).

13.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Piperidine has been identified in the urine of animals and humans (140). The presence of piperidine in the urine can be easily measured with HPLC and chemiluminescence (144) or gas–liquid chromatography (145). Derived from cadaverine and lysine, piperidine is excreted from humans at 3 to 20 mg/day. Oral administration of cadaverine to rabbits causes a severalfold increase in piperidine excretion. Injected into chickens or rabbits, the major portion is excreted unchanged (146). Piperidine is well absorbed from the gastrointestinal tracts, and the amount absorbed through skin is sufficient to produce death in laboratory animals.

13.4.1.4 Reproductive and Developmental Inhalation of 0.9, 4.3, or 28.7 ppm by pregnant rats produced no teratogenic effects, but embryo length and weight were reduced at the two higher levels tested (147).

13.4.1.5 Carcinogenesis No tumors were produced in rats given piperidine (0.09%) in drinking water for 1 year. Piperidine and sodium nitrite given together also failed to produce tumors. The failure of this treatment was surprising because nitrosopiperidine induced a high incidence of lung and esophageal tumors. The authors suggest that the relative strong basicity of piperidine reduced the rate of reaction with nitrite to such an extent that an ineffective amount of nitrosopiperidine was formed (148). In mice that had cholesterol pellets containing piperidine implanted in their bladders and were given sodium nitrite in their drinking water, an increase in bladder cancers was produced (149). Piperidine given as a series of 24 injections in groups of mice failed to produce lung tumors in the strain A mouse cancer screen (92). When piperidine and sodium nitrite were incubated in the isolated rat urinary bladder, nitrosopiperidine was detected in the bladder contents. No studies designed to evaluate the carcinogenic potential of piperidine alone following lifetime exposures have been reported.

13.4.1.6 Genetic and Related Cellular Effects Studies Piperidine did not produce an increase in mutational frequency in the host-mediated assay using the mouse following a series of intraperitoneal injections (105). No increase in mutational rate was seen in two *E. coli* strains incubated with 40 mM piperidine (150). In the mouse lymphoma assay, DNA strand breaks were seen following incubation with an S9 microsomal fraction. No response was seen without the microsomal fraction (151). Only high concentrations (5 to 7 $\times 10^{-3}$ mM) produced increased DNA breaks without the microsomal fraction, and no changes were reported with the S9 enzyme (152). Piperidine produced single-strand DNA breaks in rat liver DNA followed by repair (153). Chromosomal and mitotic abnormalities were produced by piperidine in onion plants at dose-related concentrations ranging from 50–1000 ppm (154).

13.4.2 Human Experience Skin exposure to liquid piperidine for less than 3 min produced severe epithelial damage and a chemical burn (155). In a workplace in which piperidine was being transferred from drums in a semi-closed system, airborne levels of 2 to 5 ppm were measured (132). The pungent odor could be tolerated by an unacclimated individual for only a brief time, although no actual irritation was perceived. Volunteers reported an irritation threshold of 26 ppm (156).

No other human exposure data, clinical case histories, or epidemiology studies of piperidine were located.

13.5 Standards, Regulations, or Guidelines of Exposure

A WEEL of 1 ppm as an 8-h TWA for a 40-h week has been recommended by AIHA (157). A skin notation is included and the value is based on piperidine vapor irritating the respiratory tract and the eyes. The liquid is corrosive to skin and may cause permanent eye injury; the odor is considered to be objectionable above 2 ppm. Good ventilation is essential to minimize inhalation exposure, and the use of personal protection to prevent accidental eye and skin contact is clearly indicated. Safety procedures to handle flammable materials should be followed.

13.6 Studies on Environmental Impact

Piperidine is found naturally in foods and fish. In soil and water, it is likely to biodegrade, and in soil, it is likely to leach. In water at neutral conditions, piperidine will be dissociated and therefore, evaporation will be pH dependent. In dry soil, its high vapor pressure would suggest significant evaporation. Because of its low octanol/water partition coefficient, bioconcentration of piperidine in fish is unlikely. Estimations of its fate in the atmosphere suggest a half-life of 3.4 days. Primary human exposure is due to food consumption (20).

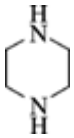
Aliphatic and Aromatic Nitrogen Compounds

Henry J. Trochimowicz, Sc.D., Gerald L. Kennedy, Jr., Ph.D., CIH, Neil D. Krivanek, Ph.D.

14.0 Piperazine

14.0.1 CAS Number:
[*110-85-0*] (anhydrous); [*142-63-2*] (hexahydrate)
14.0.2 Synonyms:
Hexahydropyrazine; diethylenediamine; piperazidine
14.0.3 Trade Name:
Lumbrical; Wurmirazin
14.0.4 Molecular Weight:
86.14 (anhydrous)

194.23 (hexahydrate)
14.0.5 Molecular Formula:
$C_4H_{10}N_2$, $C_4H_{22}N_2O_6$(hexahydrate)
14.0.6 Molecular Structure:



14.1 Chemical and Physical Properties
14.1.1 General

Physical Form	deliquescent solid (anhydrous); minute crystals (hexahydrate)
Boiling Point	146°C (anhydrous), 145–156°C (hexahydrate)
Melting Point	106°C (anhydrous), 44–45°C (hexahydrate)
Specific Gravity	1.1 (anhydrous)
Vapor Pressure	<1.0 mmHg at 20°C
Vapor Density	3.0 (anhydrous)
Flash Point	82°C (anhydrous); 87°C (hexahydrate)

14.1.2 Odor and Warning Properties Salty taste; no definable odor.
14.2 Production and Use
Piperazine is a transparent, deliquescent solid. Aqueous solutions of the base are strongly alkaline (pK_b = 4.19); the pH of a 10% aqueous solution is 11. It is used in medicinals, insecticides, and corrosion inhibitors, and as an accelerator for curing polychloroprene. Piperazine and several piperazine salts are used in humans and animals to treat parasitic infestations.

Industrial exposure is not extensive. The major producers make piperazine from higher amines (e.g., ethylenediamine or diethylenetriamine) and forms of triethanolamine. Formulations of 30 to 40% piperazine are sold to reprocessors, who make products of various salts or anhydrous and hexahydrate piperazine (158).

Primary routes of exposure are skin or eye contact or inhalation of vapors (or the dusts of salts). The salts are less hazardous than anhydrous or hexahydrate forms of piperazine.
14.3 Exposure Assessment
No information to assess human exposure potential to piperazine was found.

Piperazine can be detected in food crops at a concentration as low as 0.03 ppm (159). A method is applicable for aqueous solutions from the Association of Official Analytical Chemists (160).

Methods for detecting piperazine in human tissue have also been developed (161).

14.4 Toxic Effects

14.4.1 Experimental Studies 14.4.1.1 Acute Toxicity The oral LD_{50} of piperazine in the rat ranges from 2050 to 3000 mg/kg (147, 162, 163) and in the mouse from 600 (99) to 1900 mg/kg (147). In another study, the lowest concentration that produced mortality in the rat was 5000 mg/kg, and gastrointestinal irritation was noted at doses of 450 mg/kg or greater (164). No deaths occurred in groups of six rats exposed for 2 h to an aerosol that had a nominal concentration of approximately 40 mg/L. Clinical signs indicative of respiratory irritation were seen but no pathological changes were seen 14 days postexposure (165). Changes in motor activities and muscle contractions were seen in mice that inhaled 5400 mg/m^3 for 2 h. The animals apparently survived this exposure (147). Subcutaneous injection to mice produced LD_{50}s of 1100 mg/kg (166) and 2030 mg/kg (167). Intraperitoneal injection in the mouse produced an LD_{50} of approximately 1900 mg/kg (139, 168). Piperazine produced a biphasic effect on the rat cardiovascular system. This effect included an initial fall in blood pressure and heart rate followed by a transient rise in both. Atropine antagonized the initial reaction. Piperazine did not produce any electrocardiographic changes when injected (route unspecified) alone (169).

The dermal LD_{50} of piperazine is 4000 mg/kg in rabbits (163). Contact of rabbit skin with undiluted piperazine for 30 min produced slight irritation that became a chemical burn in 70 min (162). The reaction of the belly skin of rabbits was less marked, and only transient erythema was observed following application of approximately 500 mg piperazine (163). Only transient redness was seen in guinea pigs from a 50% aqueous solution, but necrosis was produced following immersion of the mouse tail in neat material (147). Mild irritation was produced in guinea pigs with 5 to 35% concentrations in water (170), but no evidence of dermal sensitization was seen (171, 172). Severe eye damage, presumed to be permanent, was produced in the rabbit eye following instillation of a single drop of the undiluted chemical (49, 162), and a 5% aqueous solution produced a score of 9 (out of 10). A dose of 250 mg placed in the conjunctival sac produced severe irritation in the rabbit eye (173).

14.4.1.2 Chronic and Subchronic Toxicity Inhalation of 100 ppm by guinea pigs (3 h exposure, seven exposures in 11 days) produced no effects (162). Rats were fed diets that contained 1000 ppm for 90 days without adverse effects. Liver and kidney damage was seen at both 3000 and 10,000 ppm (162). In another feeding study, rats fed 150 mg/kg/day for 30 days showed decreased serum and tissue lipid levels but little change in glucose tolerance, tissue glycogen levels, and liver DNA, RNA, and protein contents (174). No interference with the immune response was seen in mice treated with 5000 ppm piperazine for 2 weeks (175).

14.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Piperazine is partly metabolized in humans; only 15% of a 2-g dose was excreted unchanged. Piperazine itself is a metabolite of the antihistaminic agent chlorocyclizine (176).

Volunteers who inhaled 0.3 mg piperazine/m^3 for 4 to 16 h were given diets that contained nitrate and/or ascorbate. *N*-Mononitrosopiperazine, but not *N*, *N*-dinitrosopiperazine, was detected in the urine (177). This was also seen in workers exposed to concentrations of 0.06 to 1.7 mg/m^3 during a 12-h work shift (178). The mononitrosopiperazine metabolite was detected in gastric juice and urine following oral administration of 480 mg piperazine to four male volunteers (179).

14.4.1.4 Reproductive and Developmental No complete studies to evaluate the developmental toxicity potential of piperazine have been reported. No effects were produced in 13-day-old rat fetuses following intrauterine application of 50 mg piperazine (180). No effects in piglets were reported following oral administration (dose and duration unspecified) (181).

14.4.1.5 Carcinogenesis No increase in lung adenomas was produced in mice administered 0.69 to 18.75 mg of piperazine/kg in drinking water for 20 to 25 weeks and sacrificed 10 to 13 weeks later

(182, 183). An increase in lung adenomas was produced in this bioassay by administration of piperazine together with sodium nitrate, suggesting the formation of the active nitroso derivative (184). Sodium ascorbate inhibited tumor formation, in theory, by preventing piperazine nitrosation (185). Co-administration of 250 ppm piperazine and 500 ppm sodium nitrate in drinking water did not produce tumors in rats (172). None of these studies were conducted using currently accepted methods for evaluating carcinogenic potential but piperazine alone, in these assays, was noncarcinogenic.

14.4.1.6 Genetic and Related Cellular Effects Studies Piperazine dihydrochloride was not mutagenic in the mouse host-mediated assay. However, when tested in combination with sodium nitrate (to produce the N-nitroso derivative), a mutagenic response was seen (186). Piperazine was inactive when tested in four *Salmonella* strains in amounts ranging from 33 to 2167 mg (187). No evidence of genetic damage was reported in the LS1784 mouse lymphoma assay and the BALB/3T3 transformation assay (188). Administration of 50 mg/kg intraperitoneally to rats did not cause DNA strand breaks, although similar administration of the dinitroso derivative caused single-strand breakage that required 6 days or longer to repair (153). Urinary metabolites isolated from mice given oral doses of both piperazine and sodium nitrate were also mutagenic (189).

14.4.2 Human Experience Piperazine (as the hydrochloride salt) is used as a vermifuge in humans, and doses range from 75 to 3500 mg/kg. Side reactions have included hives, headaches, nausea and vomiting, diarrhea, lethargy, tremor, incoordination, and muscular weakness. These findings have been transient and disappear when medication is stopped (190). Severe thrombocytopenia was described in a male patient who took 2.25 g/day for 14 days followed by a single dose 14 days later. This reaction resolved and was attributed to hypersensitivity following a course of therapy 15 years earlier (191).

Severe, but reversible, neurological disorders accompanied by electroencephalographic changes, also reversible, have been seen following the medicinal use of piperazine (192). Three cases of occupational dermatitis attributed to piperazine, confirmed by patch testing, have been reported (193–195). Respiratory sensitization has also been reported (193, 196). Piperazine was the inducing agent in 29 cases of occupational asthma reported in 130 workers who handled amines and other chemicals. The TWA concentration of piperazine associated with induction of an asthmatic state was estimated at 1.2 mg/m^3 (197). A strong exposure–response relationship as to the frequency of work-related airway symptoms (including chronic bronchitis) that indicated asthma was detected in a cohort of 602 studied by a mailed questionnaire (198). In the highest exposed group (no quantitative exposure levels presented), one of four workers had chronic bronchitis. However, no association between specific IgE antibodies, occupational asthma, and piperazine exposure was determined in a cross-sectional study that involved 140 workers at a chemical plant, some of whom were exposed to this substance during the course of their work (199). Miosis is occasionally induced by interference with the sympathetic supply to the eye, and slight disturbances of accommodation may have the same basis (200, 201). Descriptions of the visual effects are vague, variously characterized as difficulty in vision, difficulty in focusing, disturbance in color vision, or occurrence of flashes on closing the eyes at night, usually associated with giddiness, lack of coordination, and a sense of detachment. In any case, the visual disturbances are rare and inconsequential (202). In contrast to the association of piperazine and asthma, workers who manufactured piperazine products showed no signs of any small airway disease (volume of trapped gas, forced expiratory volume, vital capacity, and total lung capacity measurements were all normal) (203).

No differences in chromosomal aberrations or micronuclei in lymphocytes were seen in peripheral blood in chemical factory workers. Piperazine was one of the many agents to which these workers were exposed (204). No association between exposure and other biochemical activities or mononuclear leukocytes was detected in these workers (205, 206). Although there was an increased frequency of b-lymphocyte tumors and lung cancer in 85 workers at this plant, no association with any specific chemical exposure in the plant could be established (179). In 30 workers employed in a

chemical plant where piperazine was used (not quantified), the micronucleus frequency in red blood cells was elevated (206).

14.5 Standards, Regulations, or Guidelines of Exposure

A TLV® of 5 mg/m^3 has been established for the dihydrochloride salt of piperazine. This limit is based on acute human exposures that produced mild to moderate skin burns and sensitization and mild to moderate asthma associated with inhalation of the dust. It was felt this exposure should prevent systemic toxicity (5). Anhydrous and hexahydrate piperazine must be handled with great care in view of the strongly basic nature of the material. Skin and eye contact should be minimized and immediate flushing with water is necessary to reduce damage. Minimizing inhalation exposure is essential, and piperazine should be used only in well-ventilated areas.

Methods are available to analyze piperazine in pharmaceuticals and animal feeds. Polarographic, titrimetric, colorimetric, and gas–liquid chromatographic methods have been published (207–210). Capillary gas chromatography may be used to determine piperazine in the air and in human urine (211). High-performance thin-layer chromatographic methods may also be helpful in separating piperazine from other polyethyleneamines (212).

14.6 Studies on Environmental Impact

None.

15.0 Morpholine

15.0.1 CAS Number:

[*110-91-8*]

15.0.2 Synonyms:

Diethyleneimide oxide; tetrahydro-1,4-oxazine; tetrahydro-*p*-oxazine

15.0.3 Trade Name:

None

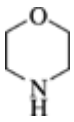
15.0.4 Molecular Weight:

87.12

15.0.5 Molecular Formula:

C_4H_9NO

15.0.6 Molecular Structure:



5.1 Chemical and Physical Properties

15.1.1 General

Physical Form	colorless, flammable, hygroscopic liquid
Boiling Point	128.9°C
Melting Point	–4.9°C
Specific Gravity	1.007
Vapor Pressure	6.6 mmHg at 20°C
Flash Point	35°C closed cup; 38°C open cup
Explosive Limits	LEL: 1.8%

UEL 11%

15.1.2 Odor and Warning Properties Weak ammonia-like odor.
15.2 Production and Use
Morpholine is made by dehydrating ethanolamines. Its main use is as a rubber accelerator in manufacturing tires. This process requires high temperature (300°F) and pressure, which increase the hazards. Morpholine is also used as a boiler water additive, brightener for detergents, and corrosion inhibitor, in the preservation of book paper, in waxes and polishes, and in organic synthesis.
15.3 Exposure Assessment
Morpholine is a natural constituent of tobacco smoke (213). It is also found in fish at concentrations ranging from <1 ppm to 9 ppm, in canned meats at 0.4 to 0.5 ppm, and in herrings at levels of 0.2 to 1 ppm (96).

Analytic methods for separating and/or determining morpholine include ion-exchange chromatography (214), mass spectrometry (96), thermogravimetric analysis (215), spectrophotometry (216), colorimetric analysis (217), and gas chromatography (213, 218, 219). Gas chromatography coupled with a thermal energy analyzer may also be used to determine traces of nitrosomorpholine resulting from the N-nitrosation of morpholine. The detection limit of this method is 2 ng/g (220).

High-performance liquid chromatography has been used to separate morpholine and its metabolites (*N*-hydroxymorpholine, *N*-methylmorpholine,*N*-methylmorpholine *N*-oxide) from biological fluids and tissue preparations (221). Morpholine also may be detected in such biological samples as urine, feces, blood, plasma, bile, and tissue by gas and gas–liquid chromatography (222, 223).

NIOSH Analytical Method 5150 is recommended for determining workplace exposure (1223a).

No other human exposure information relative to workplace levels or other background concentrations of morpholine was found.
15.4 Toxic Effects
15.4.1 Experimental Studies 15.4.1.1 Acute Toxicity Morpholine is moderately to slightly toxic in animals following single acute exposures by various routes (Table 59.4) (224–233). Single doses from 100 to 10,000 mg/kg fed to rats and guinea pigs produced hemorrhage in the small intestine and, in some animals, the nasal area. These doses were not tolerated and produced some mortality (226). Rabbits given dermal doses showed necrotic epithelium and inflamed edematous dermis. Morpholine is corrosive to the skin (226).

Table 59.4. Acute Toxicity of Morpholine

Route	Species	LD_{50} (mg/kg)	Ref.
Oral	Rat	1050	224
		1420	225
		1610	179
		1600	226

	Unspecified	365[b]	233
Intraperitoneal			
	Mouse	413	79
	Mouse	1350	139

[a] ppm, 4-h exposure.
[b] ppm, 2-h exposure.

Rats exposed by inhalation to 73 ppm for 4 h showed an increase in respiratory rate and lung irritation; this irritation was minimal at 11 ppm and not seen at 1 ppm (224). A 1-h exposure of rats to 6283 ppm produced lacrimation, rhinitis, and inactivity, but all rats survived (234).

Undiluted morpholine is necrotic to rabbit skin (235). Using standardized methodologies, skin irritation scores from 6.6 to 8.0 (maximum possible) have been reported (229).

No dermal sensitization or irritation was seen in guinea pigs tested with a 10% solution of morpholine in a system where two morpholine derivatives were sensitizers (228). No dermal irritation was seen in rabbits treated with a formulation containing 1% morpholine (236). Severe corneal necrosis is produced by treatment with 0.009 mL of 40% solution of morpholine (173). The irritation seen with 10 or 20% solutions was considerably less (49). Only slight conjunctival redness was seen in rabbits following instillation of a 1% morpholine-containing formulation into the eye (236).

15.4.1.2 Subchronic and Chronic Toxicity Rats fed 323 mg morpholine/kg for 4 weeks showed lowered weight gains but no gross pathological changes. No effects were seen at either 27.6 or 93 mg/kg, but clinical laboratory tests and microscopic pathology were not conducted (234). Rats given large doses of 120 to 800 mg/kg for 30 days showed lethargy, weight loss, irritation of the intestinal tract, and congestion of the gastric mucosa. Microscopic changes were seen in the liver, kidneys, spleen, stomach, and lungs, and considerable mortality occurred (226). Guinea pigs did not tolerate feeding of 450 mg/kg for 30 days. Liver, kidney, stomach, and lung lesions were seen at these doses, but only kidney and liver changes were seen at 90 mg/kg (226). Guinea pigs were also given daily dermal applications of morpholine, and survival was reduced at doses from 90 to 2780 mg/kg. Skin lesions were pronounced, as were the changes in the kidney and liver (226).

Rats have been used to study the effects of morpholine following inhalation for varying periods of time. Rats that inhaled 25 ppm, 6 h/day, 5 days/week for 13 weeks showed no compound-related changes. At 100 ppm, focal necrosis and necrotic cell debris were seen in the nasal cavity in 2 of 20 rats. Exposure at 250 ppm produced more severe irritation to the upper respiratory tract, and the damage (including increased Harderian gland secretion) at 13 weeks was more severe than that seen at 7 weeks (237).

Exposures to either 950 or 2000 ppm, 4 h/day, 5 days/week for 30 days produced lung and body weight changes (238). Feed consumption decreases, increased lung and kidney weights, and irritation of the eyes and nose were reported in rats that inhaled 450 ppm, 6 h/day, 5 days/week for 8 weeks (231). Irritation of the eyes, nose, and respiratory tract were seen following inhalation of

18,000 ppm (226).

Male and female rats exposed at 10, 50, or 150 ppm, 6 h/day, 5 days/week for 104 weeks showed normal growth, survival, hematology, and clinical chemistries. Rats exposed at 150 ppm had focal erosion and squamous metaplasia of the epithelium of the anterior of the nasal cavity. Signs of eye changes including corneal irritation, uveitis, and corneal damage were seen only in rats exposed at 150 ppm. The distribution of ocular changes in the lower exposure groups was similar to that in the controls (239).

15.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Morpholine given to animals is excreted primarily in the urine. Morpholine is not readily metabolized in the rat (221, 222, 240, 241) or rabbit (242). N-methylation and N-oxidation have been reported in the guinea pig; this occurs to a much smaller extent in the rat and hamster (221). A distribution study suggests that morpholine goes preferentially to the kidney in rabbits (243) and rats (222).

Approximately 92% of an orally administered morpholine dose to rats appeared unchanged in the urine within 48 h. Only 1.4% was excreted in the feces. At 24 h, 1.1, 0.5, 0.05, 0.05, and 0.6% remained in the stomach, intestine, liver, kidney, and blood, respectively (241). The urinary metabolite identified in the hamster, and to a much lesser extent the rat, was *N*-methylmorpholine *N*-oxide (221).

In humans, morpholine reportedly appears predominantly unchanged in the urine (244).

15.4.1.4 Reproductive and Developmental No studies to evaluate the reproductive or developmental toxicity of morpholine have been found, but no evidence of reproductive system damage has been reported in repeated-exposure toxicity studies in animals.

15.4.1.5 Carcinogenesis Morpholine did not produce an increase in tumors in rats that inhaled from 10 to 150 ppm for 2 years (239). No tumors were seen in rats fed 5000 ppm morpholine for 8 weeks and observed for their lifetime (245). Morpholine fed concurrently with sodium nitrate increased the numbers of hepatocellular carcinomas and sarcomas of the liver and lungs of rats and mice, probably mediated through the formation of N-nitrosomorpholine (246–248). The authors concluded that morpholine itself was either weakly carcinogenic or that a nitrate from an unknown source was present.

No cancers were produced when 6330 ppm morpholine was added to the drinking water of mice for their lifetimes (182). Concurrent exposure of morpholine plus nitrite or nitrogen dioxide increased the tumor incidence in a variety of species (182, 249–252). In a recent feeding study (253) where morpholine (0.5% in diet) and sodium nitrate were given concurrently for 23 weeks, rats showed no evidence of cancer.

15.4.1.6 Genetic and Related Cellular Effects Studies Genetic testing has produced both positive and negative findings (Table 59.5) (254–261). In general, *in vivo* assays such as the dominant lethal and host-mediated assays have been either negative or weakly positive. However, chromosomal aberrations were reported in mice (260). In microbial test systems, incubation of morpholine with sodium nitrite produces a strongly positive response, presumably by generating nitrosomorpholine (258).

Table 59.5. Genetic Toxicology of Morpholine

Assay/End Point	Result	Ref.
Salmonella	Negative	254, 255

Mouse lymphoma	Positive	188
Sister chromatid exchange	Positive	188
DNA repair/rat hepatocyte	Negative	256
Mouse host-mediated assay		
Oral	Negative	257
Intravenous	Weakly positive	258
Intramuscular	Weakly positive	186, 259
Chromosomal aberrations		
Mouse	Positive	260
Rat	Negative	261
Dominant lethal—rat	Negative	261

15.4.2 Human Experience Shea (49) reported nose irritation to himself after a 1-min exposure at 12,000 ppm and coughing after 1.5 min. The transfer of morpholine by pipette caused a severe sore throat and reddened mucous membranes. These symptoms cleared when exposure ceased.

The maximum allowable concentration for morpholine is 1400 ppm (v/v) based on 10% of a lower exposure limit. However, relevant toxicological data indicates that irreversible health effects and impairment of escape occur only at concentrations higher than 1400 ppm.

Concentrated morpholine readily permeates the skin. The undiluted compound is very irritating to the eyes and is moderately irritating to the skin (173). The irritation diminishes as the product is diluted to less than 25% with water. No serious chronic effects from morpholine have been observed in humans, although irritation to the skin or respiratory tract has been noted in a few instances of exposures to fumes from the material when heated or in contact with high concentrations (262).

Cosmetic products containing morpholine (1% generally) have been widely tested and are neither irritants (eye or skin) nor sensitizers (263).

No other human exposure data, case histories, or epidemiology studies on morpholine were found.

15.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH (5) has a TLV® of 20 ppm (8 hour TWA) to protect against both the irritating and systemic effects of morpholine. The OSHA PEL and NIOSH REL are also 20 ppm.

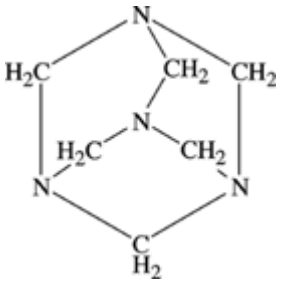
15.6 Studies on Environmental Impact

Morpholine may be released to the environment in effluents and emissions as a result of its manufacture, transport, storage, disposal, and use as a chemical intermediate (catalysts, antioxidants, pharmaceuticals, bactericides), in textile chemicals, photographic developers, hair conditioners, waxes and polishes, and in preservation of book paper. Total demand of morpholine was 11,000 metric tons (1975) and the U.S. estimated morpholine emissions into the atmosphere (as of 1978) were about 10 million pounds/year. If released to soil, morpholine may volatilize from dry soil surfaces but not from moist soil. Morpholine in soil will move with soil moisture and is expected to leach extensively. Based on screening test results, biodegradation may be significant but only after a long adaptation period. Morpholine released to natural waters will not tend to bioconcentrate, volatilize, or adsorb to sediment or organic particulate matter in the water column. Morpholine is biodegradable in screening tests, but it is unlikely that significant morpholine degradation will occur because of the long lag required (264). Morpholine reacts with photochemically produced hydroxyl radicals in the atmosphere and that results in an estimated half-life of 2.6 hours. The general population may be exposed to morpholine by eating foods such as baked ham and fish and breathing

cigarette smoke. Occupational exposure would occur via inhalation and dermal contact (20).

Aliphatic and Aromatic Nitrogen Compounds
Henry J. Trochimowicz, Sc.D., Gerald L. Kennedy, Jr., Ph.D., CIH, Neil D. Krivanek, Ph.D.

16.0 Hexamethylenetetramine
16.0.1 CAS Number:
[*100-97-0*]
16.0.2 Synonyms:
HMTA; HEXA; hexamine; methenamine; formamine
16.0.3 Trade Name:
Urotropin
16.0.4 Molecular Weight:
140.19
16.0.5 Molecular Formula:
$C_6H_{12}N_4$
16.0.6 Molecular Structure:



16.1 Chemical and Physical Properties
16.1.1 General

Physical Form	hygroscopic, white crystalline solid
Melting Point	280°C
Density	1.33
Flammability	Flammable
Vapor Pressure	4.0×10^{-3} mmHg at 20°C
Flash Point	250°C
Water Solubility	≥10 g/100 mL at 20°C

16.1.2 Odor and Warning Properties Slight ammonia-like odor.
16.2 Production and Use
HMTA is a tertiary aliphatic amine made by reacting aqueous formaldehyde with liquid or gaseous ammonia. HMTA is used in the rubber industry to prevent vulcanized rubber from blocking and as an accelerator, as a curing agent for thermosetting resins (particularly phenyl-formaldehyde and urea-formaldehyde resins); in foundry mold castings as part of binder resins, in the production of nitrilotriacetic acid; in the manufacture of adhesives and coatings; in firelogs and briquettes for camping; and in flame-retardant materials. Because of its unique ability to hydrolyze to formaldehyde and ammonia under acidic conditions, it is also used in pharmaceuticals, for intestinal infection, and as a preservative in the food industry.

Industrial exposure potential to HMTA is quite large. Primary routes of exposure would be skin or eye contact with powder and inhalation of the dust. Ingestion of HMTA should be a minor route of exposure.

16.3 Exposure Assessment

No information to assess the human exposure potential of hexamethylenetetramine was found.

A method using GC combined with quadruple MS has been used to analyze air samples (265).

HMTA in air can also be analyzed by HPLC (266). Detection of 0.1 mg/sample is reported using thin-layer chromatography and spectrophotometry (267). Urinary concentration following separation can be accomplished using ion-pair extraction and spectrophotometric techniques (268).

16.4 Toxic Effects

16.4.1 Experimental Studies 16.4.1.1 Acute Toxicity The dose at which mice begin to die following acute oral exposure is reportedly 512 mg/kg (269). Injection (intravenous, intraperitoneal, subcutaneous) LD_{50}s in rats, mice, cats, and guinea pigs range from 200 to 512 mg/kg (270–272). This limited information suggests that HMTA is moderately toxic following acute exposure.

No skin irritation was seen from a neoprene sponge containing an unspecified concentration of HMTA (273), and mild irritation occurred when a 5% solution of a mixture that contained 40% HMTA was placed on the skin of guinea pigs. No sensitization was observed (274). No specific data relating to the effects in or on the eyes have been found.

16.4.1.2 Chronic and Subchronic Toxicity Rats fed diets that contained 1600 ppm HMTA for their lifetimes showed no effects in body weight, life span, cause of death, organ weights, or fertility (275). No adverse effects were seen in rats given 400 mg HMTA by gavage for 90 to 333 days (276). Mice fed 5 g/kg/day for 10 days showed no toxic effects (277). No major adverse effects were seen in mice given 5000 or 10,000 ppm in drinking water for 60 weeks or 50,000 ppm for 30 weeks; rats were unaffected following exposure to 10,000 ppm for 2 years or 50,000 ppm for 2 weeks (278, 279). Rats given daily intramuscular injections of 200 mg HMTA for 90 days showed no signs of systemic toxicity (276).

16.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The absorption, metabolism, and excretion of HMTA have not been adequately characterized. In human acid media (such as stomach contents and urine), HMTA slowly decomposes to form formaldehyde (280). However, the quantity found in the urine is minimal (281). Both HMTA and formaldehyde were seen in the urine of human volunteers (136). Most of ingested HMTA was reportedly excreted unchanged within 3 h (species unspecified) (282).

HMTA reportedly produces formic acid when it reacts with acidic sweat, water, and air on the skin (283, 284).

The bioavailability of HMTA was studied in 10 healthy human volunteers. HMTA taken orally was recovered in the urine (82%) within 24 h, and the serum elimination half-time was 4.3 h (285). A similar response was seen over a dosage range of 100 to 500 mg (286). More recent oral data (287) are confirmatory.

16.4.1.4 Reproductive and Developmental No differences in fertility were seen in rats given 10,000 ppm HMTA before and during mating (288). In a second study, no effects on fertility were seen in rats fed 6600 ppm (275). In addition, five generations of rats given up to 50 mg/kg daily in drinking water were unaffected (289). Similarly, no reproductive effects were seen in dogs fed either 600 or 1250 ppm after mating although the percentage of stillborn pups increased slightly, and the survival and weight gain were reduced (290).

No effects were seen in a developmental toxicity screening study in which small groups of mice were given oral doses of 1 g/kg from gestation days 7 through 16 inclusive (291).

16.4.1.5 Carcinogenesis No significantly increased incidence of tumors was observed in rats or mice given HMTA for their lifetimes. Exposures in rats included 400 mg/day for 1 year (276), 10,000 ppm in drinking water for 2 years in each of three generations (288), 10,000 ppm in water for a lifetime (148), and up to 1000 ppm in the diet for 2 years (292). In mice, testing conditions included up to 10,000 ppm in drinking water for 60 weeks or 50,000 ppm for 30 weeks and a lifetime holding period (277, 278), and up to 10,000 ppm in the diet for 2 years (293).

Injection of 25 to 30 g subcutaneously per mouse led to an increase in subcutaneous sarcomas in two experiments (293, 294) but not in two other studies (295). The relevance of this methodology to the workplace condition is questionable.

16.4.1.6 Genetic and Related Cellular Effects Studies HMTA is generally positive in microbial assays that examined the mutagenic potential of the chemical. HMTA was positive in the *Salmonella typhimurium assay* (296, 297), in *E. coli* (298), in *Drosophila* (299), and in onion cells (300). Sublethal doses (not specified) slightly increased the number of meiotic abnormalities in male mice (31).

Conversely, HMTA was reportedly negative in *Salmonella typhimurium* and in *E. coli* (302, 303). No mutagenic activity was detected *in vivo* in the bone marrow of mice exposed to HMTA (304).

HMTA was not mutagenic *in vivo* in the mouse dominant lethal test following both oral (305) and intraperitoneal doses (31) of 25 g/kg.

16.4.2 Human Experience HMTA is a skin sensitizer, and vapors or solutions have produced skin irritation (306, 307). Inhalation may cause asthma-like reactions in previously sensitized individuals (308). Rash and inflammation have been seen in workers, and in severe cases blisters with watery flow result (309–311). Some workers develop a tolerance to further irritation (310, 311). Hypersensitivity of the airways has been related to exposure to HMTA in foundry workers, although exposure to other potential irritants was certainly possible (312). One death in a 10-day-old infant was reported following administration of an aqueous solution (concentration, amount unspecified) in which ammonia and formaldehyde were detected in the major organs (313).

HMTA has been suggested as a potential cause of the higher incidences of gastrointestinal and skin cancer, because it is used as one of several accelerators in the rubber industry (314). This link was made because of HMTA's ability to cause dermatitis and skin sensitization but there are no definitive studies.

No other human exposure data or epidemiological studies of HMTA were found.

16.5 Standards, Regulations, or Guidelines of Exposure

Because HMTA has been consumed in small amounts as a food preservative and has been used medically as a urinary antibacterial-antiseptic, the World Health Organization suggested a temporary acceptance level of 5 mg/kg as an estimate of the acceptable daily intake of HMTA in humans (315). No workplace airborne control-level guidance value has been proposed.

16.6 Studies on Environmental Impact

HMTA's production and use as an ammonia or formaldehyde donor may result in its release to the environment through various waste streams. If released to air, HMTA's vapor pressure of 4.0×10^{-3} mmHg at 25°C indicates that it will exist solely as a vapor in the ambient atmosphere. Vapor-phase HMTA will be degraded in the atmosphere by reaction with photochemically-produced hydroxyl radicals; the half-life for this reaction in air is estimated at 15 minutes. If released to soil, HMTA is expected to have high mobility based upon an estimated K_{oc} of 55. Volatilization from moist soil and dry soil surfaces is not expected to be an important fate process based upon an estimated Henry's law

constant of 1.6×10^{-9} atm-cu m/mole and this compound's vapor pressure, respectively. Hydrolysis may be important in some soils. HMTA hydrolyzes in water at pH 3 to 7; the half-life in each case is slightly more than 1 day. If released into water, it is not expected to adsorb to suspended solids and sediment in water based upon the estimated K_{oc}. Volatilization from water surfaces is not expected to be an important fate process based upon this compound's estimated Henry's law constant. An estimated BCF of 0.40 suggests that the potential for bioconcentration in aquatic organisms is low. In a semicontinuous activated sludge system, HMTA removal ranged from 1.1% after 5 days to 52.5% after 50 days; removal was attributed to acid hydrolysis to formaldehyde and ammonia followed by biodegradation of these two compounds. Removal of 70 to 87% was observed after 28 days using an activated sludge inoculum. In a 5-day BOD test using a sewage seed, HMTA reached 2.02% of its theoretical BOD. Occupational exposure to HMTA may occur through inhalation of dust particles and dermal contact with this compound at workplaces where it is produced or used (20).

Aliphatic and Aromatic Nitrogen Compounds
Henry J. Trochimowicz, Sc.D., Gerald L. Kennedy, Jr., Ph.D., CIH, Neil D. Krivanek, Ph.D.

17.0 Pyrrole
17.0.1 CAS Number:
[*109-97-7*]
17.0.2 Synonyms:
Azile; Divinylenimine; imidole
17.0.3 Trade Name:
None
17.0.4 Molecular Weight:
67.09
17.0.5 Molecular Formula:
C_4H_5N
17.0.6 Molecular Structure:

17.1 Chemical and Physical Properties
17.1.1 General

Physical Form	colorless liquid
Boiling Point	129–131°C
Freezing Point	–24°C
Melting Point	–23°C
Specific Gravity	0.967
Vapor Density	2.31 (air = 1)
Flash Point	33°C

17.1.2 Odor and Warning Properties Chloroform-like odor.
17.2 Production and Use
Pyrrole is a constituent of coal tar and bone oil. It is a weakly basic (pK = 13.6), colorless liquid that

darkens with exposure to air. It is used in drug manufacture. Industrial exposure is limited.
17.3 Exposure Assessment
17.4 Toxic Effects
17.4.1 Experimental Studies 17.4.1.1 Acute Toxicity Acute toxicity data are scarce. The subcutaneous LD_{50} in mice is 61 mg/kg. LD_{LO}s in rabbits are reported for the oral (147 mg/kg), subcutaneous (250 mg/kg), and intraperitoneal (150 mg/kg) routes (316). Intraperitoneal injections of large doses into dogs caused convulsions and liver injury. Pyrrole generally causes discoloration of urine and lung and liver injury in mammals. Death that follows large doses is accompanied by acute emphysema and pulmonary stasis (11). Pyrrole did not produce an increase in mutational frequency in several strains of *S. typhimurium* (Ames test) (317) and was negative in the rat hepatocyte DNA-repair test (318).

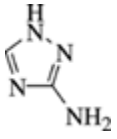
Somewhat more data are available for *N*-methylpyrrole. The minimum oral lethal dose in rats is about 2.5 mL/kg. Repeated oral doses to rats (five per week for 6 weeks) of 0.1 mL caused practically no effects. Fatal oral doses (>2.5 mL/kg) to rats produced interstitial hemorrhages in the lungs and hemorrhagic necrosis in the liver. *N*-Methylpyrrole did not produce skin irritation or sensitization in guinea pigs (319).

17.4.1.2 Chronic and Subchronic Toxicity No other toxicity information was found for pyrrole relative to repeated exposure toxicity, pharmacokinetics/metabolism, reproductive and developmental toxicity, carcinogenicity, or mutagenicity.

17.4.2 Human Experience No human experience data, case histories, or epidemiology studies of pyrrole were found.
17.5 Standards, Regulations, or Guidelines of Exposure
No occupational exposure standards have been established.
17.6 Studies on Environmental Impact
No information was found.

Aliphatic and Aromatic Nitrogen Compounds
Henry J. Trochimowicz, Sc.D., Gerald L. Kennedy, Jr., Ph.D., CIH, Neil D. Krivanek, Ph.D.

18.0 Aminotriazole
18.0.1 CAS Number:
[*61-82-5*]
18.0.2 Synonyms:
3-AT; Amitrole; ATA; 3-Aminotriazole; 2-Amino-1,3,4 triazole; 3-Amino-1,2,4-triazole
18.0.3 Trade Name:
Amitrole
18.0.4 Molecular Weight:
84.08
18.0.5 Molecular Formula:
$C_2H_4N_4$
18.0.6 Molecular Structure:



18.1 Chemical and Physical Properties
18.1.1 General

Physical Form	white to colorless crystals
Melting Point	159°C
Boiling Point	200°C
Specific Gravity	1.138
Vapor Pressure	0.055 mmHg at 20°C
Solubility	soluble in water, alcohol; insoluble in acetone, benzene

18.1.2 Odor and Warning Properties None.
18.2 Production and Use
Amitrole is synthesized by condensing formic acid with aminoguanidine and can be purified by recrystallization from methanol. The chemical is effective in killing mostly woody plants, including hardwood and coniferous species. Amitrole is an effective contact spray for controlling herbaceous perennials, as well as most annual broadleaf weeds and grasses. It is applied as a foliar spray or as crystals or concentrated solution to cut surfaces. Human exposures are primarily by dermal contact or by inhalation following spray applications. This is the chemical responsible for the cranberry crisis in the United States in 1959 (320) in which the crop of that year was reportedly contaminated by amitrole, a chemical that could produce cancer of the thyroid when fed to rats.
18.3 Exposure Assessment
Amitrole residues can be measured to 0.1 mg (321, 322), and these techniques can be used to determine airborne concentrations.

Aminotriazole may be measured in the workplace using NIOSH Analytical Method 0500(4a).
18.4 Toxic Effects
18.4.1 Experimental Studies 18.4.1.1 Acute Toxicity Amitrole is very low in acute toxicity. The oral LD_{50} in mice is 11,000 mg/kg and in sheep is 4000 mg/kg (323). Other reported LD_{50} values in rodents include 24,600 mg/kg in the rat, 15,000 mg/kg in the mouse (324), and >4080 mg/kg in both young and old rats (325). Depending on the dose, the symptoms of overexposure include extreme depression, difficulty in breathing, clonic spasms, and coma (323). One dog tolerated a single oral dose of 2150 mg/kg, but vomiting was seen at 4640 mg/kg (326). Dermal exposures of 10,000 mg/kg to rabbits and 2500 mg/kg to rats were nonlethal (327). When amitrole was injected, the LD_{50} in mice was >5000 mg/kg both intraperitoneally (25) and intravenously (328). No adverse signs were seen after intravenous injection of 1750 mg/kg in cats and 1200 mg/kg in dogs (329). Doses of 1000 mg/kg in narcotized cats and dogs produced death due to cardiac or circulatory failure (323). Amitrole in the acid form produced mild irritation, reversible in 48 h, in the rabbit eye (324).

18.4.1.2 Subchronic and Chronic Toxicity Rats given 29 mg/kg in the diet for 2 weeks showed decreases in thyroid hormone levels (330). Kidney weight decreases were detected in rats given 500 mg/kg in the diet for 4 weeks, an effect that could be blocked by injection of thyroid hormone (331). Thyroid growth was modified by treatment of rats for 80 days with amitrole (332). No thyroid hyperplasia was seen in rats fed 2000 ppm for 12 weeks (333), although thyroid changes were seen in rats fed 50 ppm for 90 days (334). Serum T3/T4 ratios and thyroid weights were altered in rats fed amitrole (concentration not specified) for 5 months (332). Body weights were reduced in rats given 1000 ppm in drinking water for 1 year but nonneoplastic lesions were not discussed in the report (332).

Hyperplasia of the thyroid occurred in rats fed 100 ppm but not in rats fed 25 ppm for extended periods. Atrophy of the thymus and spleen was also reported at feeding levels of 500 and 1000 ppm (325). Similar changes have been confirmed in rats (335) and mice (336). Goiter was seen in dogs treated for 50 weeks but no other specific organ toxicity was seen (337). No toxicological changes

were seen in a 2-year inhalation study in which rats were exposed to 2000 mg/m^3 for 1 hour each week (338).

Liver enzymes, including cytochrome P450, d-aminolevulenic acid dehydrase, and peroxidase, have been affected following repeated exposures to amitrole (339–343). The short-term effects on the thyroid gland are striking and have been extensively studied and reported (335, 344–346).

18.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms 18.4.1.3.1 Absorption Amitrole is rapidly absorbed from the stomach. The highest tissue levels were reached in 1 h and declined after 2 to 6 h (347).

18.4.1.3.2 Distribution After intravenous injection to mice, amitrole was distributed to many soft tissues and reached higher concentrations in actively growing parts of transplanted tumors than in normal tissue.

18.4.1.3.3 Excretion Following oral administration of ^{14}C-amitrole to rats, most of the radioactivity that appeared in the urine during the first 24 h was unmetabolized amitrole, but 3-amino-5-mercapto-1,2,4-triazole and 3-amino-1,2,4-triazolyl-*S*-mercapturic acid were also present (348).

Only insignificant traces of ^{14}C were seen in the expired air of rats 3 days after an oral exposure. In the first 24 h, 70 to 95% of the radioactivity was in the urine. Radioactivity in the body after 6 days ranged from 0.28 to 1.47% of the dose, and most activity was in the liver (349).

18.4.1.4 Reproductive and Developmental Reproductive organs were not the target tissue in the repeated-exposure toxicity studies reported earlier, although it is not certain that appropriate evaluation was always conducted. In a two-generation study in rats, the number of pups per litter and the pup weight were reduced at 500 or 1000 ppm. Most of these pups died from a condition resembling runt disease and, upon autopsy, had atrophic thymuses and spleens. These effects were not seen at either 25 or 100 ppm. No developmental effects were seen in pups following administration to pregnant rats of up to 100 mg/kg via gavage from gestation days 7 through 15 (325). Marked retardation of development without structural defects has been seen in mice (350).

Amitrole did not induce abnormal sperm morphology in mice given five daily intraperitoneal injections at doses ranging from 50 to 500 mg/kg (351).

18.4.1.5 Carcinogenesis A dose-related increase in thyroid adenomas was seen in rats fed 10, 50, and 100 ppm for 2 years (352). A high incidence of thyroid and liver tumors was seen in rats given amitrole either in drinking water (20 to 25 mg/day) or in food (250 or 500 mg/day) for 10 to 32 months (353). Mice given 1000 mg/kg by gavage early in life, followed by 53 to 60 weeks feeding of 2192 ppm, showed carcinomas of the thyroid and liver hepatomas (14). However, mice fed 1, 10, or 110 ppm for 21 to 23 months showed no carcinogenic response (354). No changes in tumor incidence or types were seen in hamsters following lifetime (900 days) feeding of either 1, 10, or 100 ppm (354). No tumors were reported in dogs fed 10, 50, 100, or 200 ppm for 1 year (348). No tumors were seen in rats that inhaled 2000 mg/m^3 amitrole for 1 h/week for 2 years (338). No skin tumors were seen in mice that received weekly applications of either 0.1 or 10 mg for their lifetimes (355).

18.4.1.6 Genetic and Related Cellular Effects Studies Amitrole was negative in short-term bioassays, including the Ames *Salmonella* test (329), in *in vitro* human lymphocyte clastogenicity (330), and a mouse lymphomas cell forward-mutation assay (331) (Table 59.6) (356–397). Additionally, amitrole did not induce any gene expression in *Salmonella typhimurium* (322). Amitrole did not cause a dominant lethal effect and did not cause chromosomal aberrations in mice (2, 3, 324). Amitrole was positive in three *in vitro* mammalian cell assays: unscheduled DNA synthesis, sister chromatid exchange, and cell transformation (334). A positive response was also seen in Syrian hamster

embryo cells; a dose-dependent increase in morphological transformation, as well as a dose-dependent increase in gene mutations, was observed (398). Amitrole was also positive for intrachromosomal recombination that results in genome rearrangement in the yeast *S. cerevisiae* (337).

Table 59.6. Mutagenicity Tests with Aminotriazole

Assay/end point	Result	Ref.
Salmonella	Negative	24, 331, 337, 356–366, 339
	Positive	366
E. coli	Negative	362, 363, 367–372
	Positive	362
Saccharomyces	Negative	373–377
	Positive	378–380
Bacillus	Negative—5 strains	381
	Positive—1 strain	381
Drosophila	Negative	382
Unscheduled DNA synthesis	Negative	383, 384
Sister chromatid exchange	Negative	383, 385
	Positive	386
Bone marrow—mouse	Negative	387
Cytogenetics—rat	Negative	388
Mouse micronucleus	Negative	389
Dominant lethal—mouse	Negative	390, 391
Mouse lymphoma	Negative	392–394
Cell transformation	Negative	395–397

Amitrole was studied in the International Collaborative Program for evaluating short-term tests for carcinogenicity (356). These data were reviewed and evaluated by the IARC (320), who concluded that amitrole had a limited degree of evidence for genetic activity in short-term tests.

18.4.2 Human Experience A single oral dose of 100 mg inhibited the uptake of ^{131}I by the thyroid gland for 24 h in healthy subjects and in patients with hyperthyroidism. A dose of 10 mg had only a very weak effect (399). In an attempted suicide, a 39-year-old woman ingested a mixture that included amitrole; the amount ingested was 20 mg/kg. She did not become ill, although unchanged amitrole at a concentration of 1000 ppm was isolated from the urine (400).

A study was made of railroad workers who had been exposed to one or more herbicides for a total of 46 days or more within the period from 1957 to 1971. Of a total of 324 workers, 143 had been exposed mainly to amitrole. The incidence of cancer among these 143 persons was 7 (each in a different organ), compared to the 1.9 expected on the basis of national statistics adjusted for age and sex. In addition, there were two cancers of the lung, whereas 0.24 cancers were expected. However, both patients with lung cancer had smoked, and the tumors were of different cell types (41, 402). The lack of a similar report regarding persons heavily exposed to amitrole in its manufacture is noteworthy.

18.5 Standards, Regulations, or Guidelines of Exposure

An 8-hour Time Weighted Average of 0.2 mg/m^3 has been established by the ACGIH TLV® Committee. It has been placed in Group A3 (confirmed animal carcinogen with unknown relevance to humans) by that committee (5). The NIOSH REL is 0.2 mg/m^3.

18.6 Studies on Environmental Impact

Amitrole is released into the environment primarily from its applications as a herbicide. If released to soil, amitrole will degrade microbially and possibly chemically with a resultant average persistence of 2 to 4 weeks at recommended herbicidal concentrations. The degree of leaching in soil may depend upon the chemical and organic content of an individual soil. Loss of amitrole from soil by volatilization or photodegradation is minor. If released to the aquatic environment, amitrole is not expected to hydrolyze, directly photolyze, volatilize, or bioconcentrate significantly in aquatic organisms. Amitrole degradation in natural waters may be possible by oxidation with photochemically produced peroxy radicals or by photosensitized photolysis; biodegradation is not a rapid removal process from water. Adorption of amitrole to hydrosoil may be an important transport mechanism. An initial maximum half-life of 68 days was observed for amitrole applied to an outdoor pond, and persistence exceeded 200 days. If released to the atmosphere, vapor-phase amitrole reacts rapidly with photochemically produced hydroxyl radicals (estimated half-life of 3.8 days at 25°C), but does not react with ozone or directly photolyze (20).

Aliphatic and Aromatic Nitrogen Compounds

19/20/21.1 Chemical and Physical Properties
19/20/21.1.1 General

	Captan	Captafol	Folpet
Physical Form	Yellow amorphous powder	White crystals	White crystals
Melting Point (°C)	178°C(pure)	159–161°C	177–180°C
Vapor Pressure (mmHg)	1.3 mPa (25°C)	—	—
Water Solubility	Insoluble	Insoluble	Practically

19/20/21.1.2 Odor and Warning Properties Captan: none (pure); pungent (tech). Captafol: pungent. Folpet: None

19/20/21.2 Production and Use

These *N*-sulfenyl phthalimide fungicides are used in large quantities worldwide. They became commercially available in 1950. Two producers make these fungicides in the United States (403). All three are primarily agricultural fungicides, but they do find some use in preventing fungal growth in industrial applications (e.g., paints and plastics). Captan is registered for use on more than 80 different crops including many foods, field crops, and ornamentals. Captafol and Folpet have similar uses on crops and are used for seed and plant bed treatment as well. Captan and Folpet are available in wettable powder formulations. All three are available as dusts, and captan and captafol are available in flowable formulations (404). These are broad-spectrum fungicides that inhibit mycelial growth from germinating fungus spores. They have effective protective action but will not eradicate a preexisting infection and are not systemically active.

Industrial exposure in manufacturing is limited. Agricultural workers are exposed to the wettable powders, dusts, and flowable formulations, as well as to aqueous emulsions, by inhalation and by skin contact with dusts, emulsions, and sprays.

19/20/21.3 Exposure Assessment

Several methods are available to measure these compounds in air (405–407). The recommended workplace method for determining these comparative NIOSH method 0500 (4a).

19/20/21.4 Toxic Effects

19/20/21.4.1 Experimental Studies 19/20/21.4.1.1 Acute Toxicity Acute toxicity data on Captan, Captafol and Folpet are summarized in Table 59.7 (408–410).

Table 59.7. Acute Toxicity (408–410)

Study	Captan	Captafol	Folpet
Rat, oral LD_{50}	12,500 mg/kg	6200 mg/kg 2500 mg/kg (80% WP)	>10,000 mg/kg
Rabbit, skin LD_{50}	>9000 mg/kg	>15,400 mg/kg (80% WP)	22,600 mg/kg
Rat, inhalation LC_{50} (2-h)	>5.7 mg/L	—	>5.0 mg/L
Mouse, inhalation LC_{50} (2-h)	4.5 mg/L	5.0 mg/L	>6.0 mg/L
Mouse, i.p. LD_{50}	518 mg/kg	462 mg/L	200 mg/kg

Mouse, oral LD_{50}	7840 mg/kg	7000 mg/kg	—

19/20/21.4.1.2 Chronic and Subchronic Toxicity Captan is a moderate skin sensitizer in guinea pigs (411). Captan was tested in subchronic studies in rats and mice to determine dose levels for chronic studies in the NCI Bioassay Program. Both male and female rats and male and female mice showed transient weight depression at both 2100 and 16,000 ppm (412).

A 54-week feeding study of both technical and recrystallized captan at 10,000 ppm was conducted using both male and female rats. Both sexes exhibited growth depression but no signs of systemic toxicity. At autopsy, testicular atrophy was found in three animals (411).

In two 17-month feeding studies in rats and dogs with folpet, the animals showed high tolerance to this compound (413) (See section 19/20/21.4.1.5).

Captafol apparently is not as well tolerated as captan and folpet after chronic administration, although no effects of tumor incidence were observed (413) (See section 19/20/21.4.1.5).

19/20/21.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Captan and folpet are quite similar. Extensive studies of captan have shown that it is readily absorbed from the gastrointestinal tract, rapidly metabolized, and eliminated from the body. The probable metabolic pathways of both the tetrahydrophthalimide and trichloromethylthio moieties have been elucidated. In rats, the tetrahydrophthalamide moiety is excreted, 92% in 48 h and 97% in 96 h (85% in the urine and 12% in the feces) (414). The trichloromethylthio moiety is converted to thiophosgene, which is further metabolized to thiazolidine-2-thione-4-carboxylic acid, which is excreted in the urine of orally dosed rats; carbon dioxide is also a product of the metabolism of thiophosgene through the intermediate formation of carbonyl sulfide. Thiophosgene is also detoxified by sulfites present in the gut and is excreted in the urine of orally dosed rats to yield dithiobis(methanesulfonic acid) and its disulfide monooxide derivative (415).

Captan is metabolized *in vitro* by liver mixed-function oxidases to carbonyl sulfide, suggesting a pathway similar to that which occurs *in vivo* (416). The metabolic fate of folpet is the same for the trichloromethylthio moiety, and the phthalamide product is hydrolyzed to phthalic acid and ammonia. Folpet is degraded extremely rapidly in the presence of sulfhydryl compounds, giving the same products as from hydrolysis (413).

When hydrolyzed, captafol yields tetrahydrophthalimide, chloride ion, dichloroacetic acid, and inorganic sulfur. No organochlorine is formed in the presence of sulhydryl groups (other products are the same). This reaction with sulfhydryl compounds is much faster than the hydrolytic reaction (413). The fate of the tetrahydrophthalimide moiety is the same as for captan (414).

19/20/21.4.1.4 Reproductive and Developmental The phthalimide moiety of captan, folpet, and captafol is structurally similar to thalidomide, which has produced birth defects. Consequently, many studies have been done on these chemicals to address this toxic end point.

Developmental studies have been conducted with captan, folpet, and captafol in several mammalian species, including nonhuman primates (417–419). In most studies, where these compounds were administered throughout organogenesis, lack of developmental effects was demonstrated. However, results of studies with rabbits were contradictory. There have been two studies with no malformed fetuses and one in which 9 of 75 fetuses were malformed (420). Further investigation did not produce a significant increase in the number of abnormalities (411).

In a study of golden hamsters, effects from a single administration of these compounds were compared with effects from repeated administration throughout organogenesis. At the highest doses (single and multiple with folpet and single with captafol), maternal mortality increased, and some abnormal fetuses were produced. There were no indications of teratogenic activity at the lowest single doses (captafol and folpet) and at all multiple doses (captafol) (419).

19/20/21.4.1.5 Carcinogenesis An NCI bioassay of technical-grade captan was conducted to determine carcinogenicity by administering captan in the feed to Osborne–Mendel rats and $B6C3F_1$ mice. The major outcome was that tumors of the duodenum of $B6C3F_1$ mice were associated with the captan treatment. There was no evidence that the tumors observed in Osborne–Mendel rats were treatment-related (412).

In the NCI study, groups of 50 rats of each sex were fed average doses of 2520 or 6050 ppm captan in the diet for 80 weeks. Groups of 50 mice of each sex were fed 8000 or 16,000 ppm captan in the diet for 80 weeks. These doses are approximately 250 (male) and 450 (female) mg/kg/day (high dose) and 50 (male) to 100 (female) mg/kg/day (low dose) in rats. In mice, these doses are approximately 2100 mg/kg/day (high dose) and 1000 mg/kg/day (low dose).

Other studies to determine the carcinogenic potential of captan reported negative findings. In one study (14), mice were administered 215 mg/kg/day for 3 weeks and then fed a diet containing 560 ppm for the remainder of 18 months. Two feeding studies were conducted, 18 months in mice and 2 years in rats. Doses in mice were 3750 and 7500 ppm technical-grade captan in the diet (414).

Folpet was also tested for carcinogenic potential (14). Mice were administered 215 mg/kg/day for 3 weeks and then fed a diet that contained 603 ppm for the remainder of 18 months. Folpet did not cause a significant increase in tumors in this study. In other chronic studies of folpet, rats were fed 1000, 3200, and 10,000 ppm for 17 months, and dogs were fed 10,000, 40,000, and 60,000 ppm for 17 months. In the rats, neither the incidence nor the character of tumors in test animals differed from those observed in the controls, and the mortality rate of test groups did not differ from those in the controls. There was slight growth retardation at 10,000 ppm. Clinical laboratory tests were normal, and no histological alterations were noted that could be attributed to the feeding of folpet. The dogs all survived. Body weights were normal, as were clinical laboratory tests and histopathological examination of tissues (413).

In a 2-year rat study of captafol added to the diet at 0 (70 males and 70 females), 250, 500, 1500, and 5000 ppm (35 females and 35 males at each test level), there was growth depression at the 1500- and 5000-ppm levels. Mortality was increased in the 5000-ppm group, and no males were alive after 23 months. A lymphocyte-to-neutrophil shift was observed in the surviving males of this group after 21 months. There was an increase in the liver-to-body weight ratio at the 500, 1500, and 5000-ppm levels at 12 months. An increase in this ratio was also seen in males at 250 ppm. At the end of the experiment, there was no longer a significant difference at the two lower test levels. Significant increases were also observed in organ weight and organ to body weight ratios for kidney and adrenal glands of rats fed at 1500 and 5000 ppm. Histopathology revealed liver changes characterized by degeneration of hepatic cells, vacuolization, incipient fat alteration, and infiltration by mononuclear cells. Kidney changes were characterized by alterations in proximal and distal tubular cells, and many giant forms with large irregular nuclei were present.

These changes in liver and kidney were seen only in rats fed the two highest dose levels. No other histopathogical changes were associated with the administration of captafol. No effects on tumor incidence were observed (413).

19/20/21.4.1.6 Genetic and Related Cellular Effects Studies Captan, captafol, and folpet have been tested extensively for mutagenic potential as shown in Table 59.8 (421–426). All have demonstrated

the ability to induce gene mutations in some of the test systems, usually without metabolic activation. In studies with and without activation or added sulfhydryl groups (L-cysteine), it has been shown that these compounds lost mutagenic activity rapidly in the presence of the S-9 activation system or the sulfhydryl groups (414, 427–429).

Table 59.8. Studies to Determine Genotoxicity of Captan, Captafol, and Folpet[ab]

Test-Gene Mutations	Captan	Captafol	Folpet
Aspergillus nidulans	421	421	
Neurospora crassa	422		
E. coli.			
Without activation	423	423	423
With activation	423	423	423

[a] + = positive result; – = negative result.
[b] Reference numbers in parentheses.

Captan, folpet, and captafol produced mutations in bacteria and yeast and other cellular systems, but were inactive in *in vivo* mutagenicity tests (430, 431).

19/20/21.4.2 Human Experience Captafol has caused occupational dermatitis in both agricultural workers and nonagricultural workers (408, 432, 433). Sensitization to captafol, it is estimated, occurs in 10 to 40% of those who use this chemical.

In a nonagricultural exposure (432), a welder frequently brushed against large bags of captafol while working at a distributing plant. After 1½ years with no problems, he suddenly developed marked vesiculation and edema of his face and hands and associated wheezing.

In California in 1974 through 1976, 22 cases of skin exposure incidents, three cases of eye exposure incidents, and five eye and skin exposure incidents were reported. The skin exposure incidents were mainly allergic dermatitis. The eye and skin exposure incidents resulted primarily in chemical conjunctivitis, allergic conjunctivitis, and dermatitis. In most of these cases, safety equipment was not required or used (433).

No other human experience data or epidemiology studies were found for these fungicides.

19/20/21.5 Standards, Regulations, or Guidelines of Exposure

A TLV® for captan is 5 mg/m^3 for an 8-hour exposure. The TLV® Committee lists captan in Group A3 (confirmed animal carcinogen with unknown relevance to humans). The TLV for captafol is 0.1 mg/m^3 for an 8-hour exposure. It also has a skin notation and is in Group A4 (not classifiable as a human carcinogen) (5). An exposure limit for folpet has not been established by the TLV Committee. The NIOSH REL for captan is 5 mg/m^3 and for captafol is 0.1 mg/m^3.

19/20/21.6 Studies on Environmental Impact

Captan released to soil is not expected to leach extensively, but evaporation from near the surface of soils may be significant. Captan readily hydrolyzes in water, and it will probably also hydrolyze in

soil, depending upon the pH. Captan half-lives in moist soil range from 1 to 12 days. Captan released to water will have a moderate tendency to adsorb to suspended sediments, biota, and sediments and a low-to-medium tendency to bioconcentrate (BCF = 36 – 900). Volatilization may be significant from shallow rivers and streams but will be slower from lakes and ponds. The primary degradative process for captan in water is hydrolysis. Hydrolysis half-lives will be on the order of hours. Direct photolysis of captan is not important in relatively clear water; indirect photooxidation appears to be important in water with high humic content. A computer estimated half-life for captan in the vapor phase of the atmosphere based upon reaction with hydroxyl radicals is about one hour. Captan may also be present in the atmosphere adsorbed to particulate matter. Captan has been found in food composites at concentrations up to 0.178 ppm. The average daily intake of captan in the U.S. diet in 1979 was 0.005 mg/kg/body weight/day.

Folpet is released to the environment through its use as a fungicide. If released to soil, folpet is not expected to be mobile and, therefore, very little leaching in soil is expected. Folpet is expected to degrade in the ambient atmosphere by reaction with photochemically produced hydroxyl radicals, and the half-life is 0.37 days. If released to water, neither volatilization nor bioconcentration are expected to be important fate processes. In alkaline aqueous media, folpet undergoes rapid hydrolysis. Absorption of folpet to sediments will be important. Exposure of folpet to the general population is possible by inhalation of air or ingestion of food contaminated by release during its use as a fungicide.

Captafol strongly adsorbs to soil and should therefore remain in the upper layers of soil. In soil, biodegradation and hydrolysis transform captafol. The half-life of captafol in soil is about 11 days. Both biodegradation and hydrolysis are expected to be the major pathways for the loss of captafol in water. The half-life of captafol in river water was estimated at 0.3 day. Volatilization from water or soil should be negligible. The bioconcentration of captafol in aquatic organisms should not be important. Reaction of captafol with photochemically produced hydroxyl radicals and ozone will be the important loss process in the atmosphere. The half-life of captafol in air can be estimated at less than 1.4 h. Partial removal of captafol will also occur as a result of dry and wet deposition. Captafol has rarely been detected in surface water and groundwater in the United States. It has been detected at very low levels in some foods. The applicators of the fungicide and farm workers are the most likely people to be exposed to captafol by inhalation and dermal routes (20).

Other	Converts to MBC with moisture	Stable	Converts to MBC with moisture

22/23/24.1.2 Odor and Warning Properties Negligible.
22/23/24.2 Production and Use
There are three major benzimidazole fungicides used worldwide. All are primarily agricultural and turf-ornamental rather than industrial fungicides. They produce their fungicidal effect by systemic action. Benomyl has the largest share of U.S. use and is applied on many food and ornamental plant crops (427). MBC is registered in more than 15 countries for use on at least 25 food crops as well as turf-ornamentals, but is not registered in the United States (414). Thiophanate-methyl, whose major metabolite is a benzimidazole, is a Japanese product that is also used widely. Residue tolerances have been established for nine food crops in the United States.

All three fungicides are available in wettable powder formulations or dispersions that contain from 6 to 70% active ingredient, the balance is either inert ingredients or other fungicides. Industrial exposure at the manufacturing level is limited. However, agricultural workers are exposed to the wettable powders and dispersions, as well as to dilute aqueous emulsions. There are two primary routes of exposure: inhalation of the dusts and skin contact with dusts, emulsions, and sprays. All have similar uses, mechanisms of action, and toxicity. Because MBC is considered the major metabolite of benomyl and thiophanate-methyl is found in and on plant material after use of both products, these three chemicals are discussed together.
22/23/24.3 Exposure Assessment
Analytical methods for determining residues of benomyl are based on conversion to MBC or to 2-aminobenzimidazole. These methods can be easily adapted for determining MBC and thiophanate-methyl and for analyzing air samples (434, 435).

Benomyl-derived residues can be determined by HPL chromatography.

NIOSH Analytical Method 0500 or 6000 is recommended for determining workplace exposure (4a).
22/23/24.4 Toxic Effects
22/23/24.4.1 Experimental Studies 22/23/24.4.1.1 Acute Toxicity Table 59.9 is a compilation of the acute toxicity of benomyl, MBC, and thiophanate-methyl (414). These compounds have very low mammalian toxicity. By most routes of exposure, the maximum feasible dose killed no animals. Clinical signs of acute toxicity from high doses of thiophanate-methyl were tremors leading to tonic or clinic convulsions, nose bleeding and lacrimation in rats; and decreased respiratory rate, lethargy, disappearance of tonus of abdominal muscle, discharge from eyes, and mydriasis in rabbits and dogs (414).

Table 59.9. Acute Toxicity of Benzimidazole Fungicides (435–437)

Species	Sex	Route	Study	Benomyl	MBC	Thiophanate-methyl
Rat	M	Oral	LD_{50}	>10,000 mg/kg	>10,000 mg/kg	7500 mg/kg
	F	Oral	LD_{50}		>10,000 mg/kg	6640 mg/kg

22/23/24.4.1.2 Chronic and Subchronic Toxicity In 2-year feeding studies of benomyl (2500 ppm, the highest dietary level), the no observable effect level (NOEL) was 2500 ppm for rats and 500 ppm for dogs. In dogs fed 2500 ppm, there was biochemical evidence of impaired liver function and histological evidence of liver cirrhosis. No oncogenic effects were observed in rats.

In a 2-year feeding study with mice, the NOEL was 500 ppm except for changes in the liver. This NOEL was based on reduced body weights, weight effects in the liver and testis, and microscopic changes in these tissues at 1500 and 5000 ppm. Oncogenic effects were observed in the liver of male and female mice at all dietary levels (500 to 5000 ppm). Other studies of the active metabolite of benomyl in similar mouse strains produced similar results; however, oncogenicity was not observed at exposures below 500 ppm. When an unrelated strain of mice was used, that is, one with a much lower background of liver tumor incidence among untreated animals, an oncogenic response was not produced. This was true for exposures up to and including 5000 ppm (438).

For MBC, toxic effects described in animals from exposures by inhalation, ingestion, or skin contact include liver, bone marrow, and testicular effects (436).

Thiophanate-methyl was not irritating or toxic in a 30-day skin absorption study of guinea pigs. The material was applied daily to the abraded dorsum at 2, 20, and 200 mg/kg (414). Mice (CR-SCL strain) were fed thiophanate-methyl for 2 years at doses of 10, 40, 160, and 640 ppm in their diet. Except for slightly retarded growth in males at 640 ppm, no effects were detected (414).

22/23/24.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms As stated previously, MBC is the major metabolite of benomyl and thiophanate-methyl in plants. Subsequent metabolic products are hydroxylated derivatives and 2-aminobenzimidazole.

Benomyl and MBC are rapidly metabolized and eliminated in urine of rats and dogs as methyl 5-hydroxy-2-benzimidazolecarbamate (5HBC) (439). Residue data on dog and rat tissues from 2-year feeding studies indicate that benomyl and MBC and/or metabolites do not accumulate in animal tissue. Data on the metabolism of thiophanate-methyl in animals were not available.

22/23/24.4.1.4 Reproductive and Developmental Benomyl was not embryotoxic or teratogenic to rats by dietary administration at levels as high as 5000 ppm (equivalent to approximately 373 mg/kg/day). No teratogenic effects were found in studies with rabbits fed 500 ppm in the diet (equivalent to approximately 20 mg/kg/day). By gavage administration, a statistically significant teratogenic response was obtained at dose levels of 62.5 mg/kg/day and higher, but not at 30 mg/kg/day and less (438).

Excessive exposure of laboratory animals to benomyl has produced testicular weight, lowered sperm counts, and reduced fertility. These effects were accompanied by other indicators of general toxicity and were reversible in studies that evaluated effects after exposure was discontinued. In two- and three-generation dietary studies of rats, the overall NOEL for parents and their offspring was 500 ppm (20 to 30 mg/kg/day). Reduced body weights, testicular weights, and sperm counts were observed at 3000 and 10,000 ppm. However, there were no compound-related effects on fertility, mating behavior, or length of gestation. Benomyl is not considered to have selective effects on the reproductive system. The effects occur at doses that also produce general toxicity in laboratory animals (438, 440).

The developmental toxicity of MBC was observed in animals dosed by stomach tube; however, when higher doses were administered in the animals' feed, developmental toxicity was observed only at dose levels that were also toxic to pregnant animals. MBC produced reproductive toxicity in studies of male rats and mice; however, the reproductive ability of females was not affected by this material (436).

Groups of pregnant rats were administered MBC by gavage on days 6 to 15 of gestation at dose levels up to 80 mg/kg/day. Groups of pregnant rabbits were similarly administered up to 160 mg/kg/day on days 6 to 18 of gestation. In the rats, dead and resorbed fetuses accounted for 29% of conceptions in controls, 48% at 20 mg/kg of MBC, 64% at 40 mg/kg, and 73% at 80 mg/kg. In rabbits, no dead or resorbed fetuses were seen in controls whereas 15 to 33% were found in MBC-treated rabbits. There were no differences among groups of rats or rabbits in mean weight of live fetuses, and there were no malformations (441).

MBC was administered by gavage to pregnant rats at doses of 25, 50, 100, 200, 400, or 1000 mg/kg/day on days 1 through 8 of gestation. When MBC doses of up to 400 mg/kg/day were administered during early pregnancy, MBC had no significant effect on the number of implantation sites, body weight gain, uterine weight, implantation site size, and serum ovarian and pituitary hormone activity; however, a trend toward increased resorptions was evident. At 100 mg/kg/day, MBC produced reductions in body weight gain, implantation site weights, and serum luteinizing hormone and an increase in serum estradiol. When administered during pseudopregnancy, 400 mg/kg/day of MBC partially reduced uterine decidual growth but affected no other parameter (442).

MBC was orally administered by gavage to male rats at 400 mg/kg/day for 10 days. On the third day of treatment they were mated with unexposed females. Testicular weights were 58% less than those of the control rats. Sixteen of the 24 males in the treatment group were infertile by the fifth week after exposure, and 12 of the 16 never regained fertility. Most of the male rats exposed to MBC had testes that showed atrophy of the seminiferous tubules, which were lined by Sertoli cells and contained spermatogonia (443).

Groups of male and female rats were administered by gavage 50, 100, 200, or 400 mg/kg/day of MBC from weaning through puberty, gestation, and lactation. A similar study was conducted with hamsters administered 400 mg/kg/day. The growth, viability, and reproductive function of the offspring (FI) were observed during a 4-month period of continuous breeding. MBC did not alter pubertal development, growth, or viability.

The reproductive function of rats administered 200 or 400 mg/kg/day of MBC was reduced due to effects on sperm production and fetal viability. In the male rats, MBC markedly altered sperm morphology, testicular and epididymal weights, sperm numbers, and testicular histology. Fertility, sperm motility, and hormone levels were altered primarily in the males that had low sperm counts. The ability to conceive did not involve a female factor. In the female rats, MBC administration caused postimplantation losses in the high-dose group, and a few malformed rat pups were found in the litters from the 100- and 200-mg/kg/day groups. MBC was less toxic to the hamster than the rat, and the only reproductive effects induced by MBC administration were sperm measures. Fetal and

neonatal (F1) viability were not affected (444).

Thiophanate-methyl was fed to CR rats (10 males, 20 females/group) at 0, 40, 160, and 640 ppm in a three-generation (two litters/generation) reproductive study. There was an effect on growth at 640 ppm, but no apparent effects were noted on reproduction parameters. Tissues and organs of 3-week-old F3b animals were examined histopathologically. Cleared specimens were also examined for skeletal anomalies. No effects were detected (414).

22/23/24.4.1.5 Carcinogenesis Long-term testing for the carcinogenic potential of benomyl and MBC is discussed in the section on Chronic and Subchronic Toxicity. Those long-term studies evaluated a variety of toxicity end points including carcinogenicity. Both benomyl and MBC were weak carcinogens in some *in vivo* studies.

Two-year feeding studies with thiophanate-methyl in ICR-SCL mice (see Chronic and Subchronic Toxicity, earlier) a strain of mouse especially susceptible to tumors, showed a variety of tumors in all groups, including controls, but the compound was not considered carcinogenic (414).

22/23/24.4.1.6 Genetic and Related Cellular Effects Studies Benomyl has been evaluated in numerous tests for mutagenicity and genotoxicity. The vast majority of these tests were negative. The weight of evidence from all studies indicates that benomyl is not a heritable gene mutagen. It does not interact with cellular DNA nor induced point or germ cell mutations. Benomyl is not considered clastogenic. The only genotoxic end point for which benomyl produces specific responses is numerical chromosomal aberrations or aneuploidy. This is the mechanism by which benomyl exerts its fungicidal activity (438).

Dominant lethal studies were conducted for all three compounds. Benomyl was fed to male rats for 7 days at 250, 1250, and 2500 ppm in the diet. The rats were bred to three females each week for six of the 10 weeks required for spermatogenetic processes. No toxicity was observed in the males. The control group had higher incidences of preimplantation losses and early resorptions. Benomyl was not mutagenic in the dominant lethal assay (440).

MBC was administered in single doses to male mice at 1280 mg/kg (intraperitoneally). These mice were bred to three females each week during an 8-week period. Except for slight growth depression the first week, no effects on the males were noted. MBC was not mutagenic in this dominant lethal assay (414).

Thiophanate-methyl was administered intraperitoneally in single doses to groups of 10 male ICR-strain mice at 8 to 500 mg/kg. The animals were then mated during an 8-week period. No mutagenic effects were noted (i.e., no increased early fetal death or preimplantation losses) (445).

Tests in bacterial or mammalian cell cultures and in animals indicate that MBC does not interact with DNA. This material does cause an increase in chromosomal numbers (aneuploidy). Currently available animal data indicate that this material does not cause permanent genetic damage in the reproductive cells of mammals.

22/23/24.4.1.7 Other: Neurological, Pulmanary, Skin Sensitization No other human experience data or epidemiology studies were found for these fungicides.

22/23/24.4.2 Human Experience There is no evidence of adverse long-term health effects in humans from exposure to these chemicals. Temporary allergic skin reactions in a few susceptible persons are mentioned in the benomyl material safety data sheet (MSDS) from Du Pont (438).

Ten strawberry harvesters were monitored during working hours for dermal exposure, and the average exposure was 5.39 mg/h/person (446).
22/23/24.5 Standards, Regulations, or Guidelines of Exposure

These three compounds are considered nuisance dust particulates. Benomyl has an ACGIH TLV of 10 mg/m^3, and the OSHA PEL TWA is 15 mg/m^3 for total and 5 mg/m^3 for respective benomyl. There are no occupational exposure standards for carbendazim and thiophanate-methyl.

22/23/24.6 Studies on Environmental Impact

Benomyl released to soil does not leach, but volatilization of benomyl from soil can occur. Hydrolysis of benomyl in soil is probably the most significant removal process although biodegradation may also be significant, especially for the benomyl hydrolytic products. When applied to turf, benomyl has a half-life of 3 to 6 months and up to twice that in bare soil. Benomyl released to water has a low to moderate tendency to adsorb to sediments, suspended sediments, and biota and does not bioconcentrate to any significant extent. Volatilization of benomyl from water is probably insignificant. Hydrolysis is probably the most significant removal process for benomyl from water ($t_{1/2}$ < 1 week), although biodegradation and photolysis may also be important. A computer estimated half-life for the reaction of benomyl in the vapor phase with photochemically produced hydroxyl radicals in the atmosphere is 1.6 hours. The half-life of carbendazim is in the 1-to-2 month range, depending upon media (20).

No significant information was found for thiophanate-methyl.

Aliphatic and Aromatic Nitrogen Compounds

Henry J. Trochimowicz, Sc.D., Gerald L. Kennedy, Jr., Ph.D., CIH, Neil D. Krivanek, Ph.D.

25.0 Benzotriazole

25.0.1 CAS Number:

[*95-14-7*]

25.0.2 Synonyms:

1,2,3-Benzotriazole

25.0.3 Trade Name:

NA

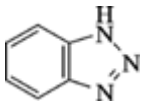
25.0.4 Molecular Weight:

119.12

25.0.5 Molecular Formula:

$C_6H_5N_3$

25.0.6 Molecular Structure:



25.1 Chemical and Physical Properties

25.1.1 General

Physical Form	White to lighten crystals
Boiling Point	350°C
Melting Point	98.5°C
Water Solubility	0.1–0.5 g/100 mL at 23.7°C
Other	May explode during vacuum distillation
Vapor Density	4.1

25.1.2 Odor and Warning Properties None.

25.2 Production and Use

1-H-Benzotriazole is manufactured in the United States. Its main use is as an anticorrosive in metalworking, in art restoration, and as a tarnish remover and protective coating in the construction industry. It is used as a corrosion inhibitor in water-cooling systems and in dry-cleaning equipment. It is also used in some formulations of automatic dishwasher detergents to prevent tarnishing of metal utensils. 1-*H*-Benzotraizole forms covalent linkages with metals thereby preventing attack by corrosive agents. It is used in other capacities in electrolytic and photographic processing.

25.3 Exposure Assessment

To analyze for 1-*H*-benzotraizole, HPLC, thin-layer chromatography, and nonaqueous titration of the amine function with perchloric acid are acceptable (447). One or more of these methods could be adapted to analyze for 1-*H*-benzotriazole in air.

ind59-108 Toxic Effects

25.4.1 Experimental Studies 25.4.1.1 Acute Toxicity The acute toxicity of 1-*H*-benzotriazole is moderate to slight.

Oral ALD (rats)	500 to 670 mg/kg (448, 449)
Intraperitoneal LD_{50} (mice)	1000 mg/kg (450)
Intravenous LD_{50} (mice)	238 mg/kg (451)
Inhalation LC_{50} (rats), 3 hr.	1900 mg/m^3 (452)

In a test for primary skin irritation and sensitization on guinea pigs, 1-*H*-benzotriazole was at most, mildly irritating in concentrations up to 50% in ethanol and was not a sensitizer. The dry powder is severely irritating to rabbit eyes (0.1 mL, unwashed) but prompt water washing reduces irritation considerably (448).

25.4.1.2 Subchronic and Chronic Toxicity A 56-day feeding study was conducted in rats and mice to determine maximum tolerated doses for the bioassay of 1-*H*-benzotriazole (447). Toxicity (i.e., weight depression) was observed in rats at 300 to 30,000 ppm, but not in mice, except at 30,000 ppm (not at 10,000 ppm).

25.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms 1-*H*-Benzotriazole was metabolized by rat liver microsomes *in vitro* to 4-hydroxybenzotriazole and 5-hydroxybenzotriazole (453).

No data for absorption, distribution, metabolism, or excretion of benzotriazole in mammals were found.

25.4.1.4 Reproductive and Developmental No relevant studies were found.

25.4.1.5 Carcinogenesis Chronic (2-year) feeding studies were conducted. Rats were given 0, 6,700, or 12,000 ppm in feed for 78 weeks and held for an additional 26 weeks. Mice were given 0, 11,700, or 23,500 ppm in feed in 104 weeks. The authors concluded that under the conditions of this study, there were no convincing evidence that 1-H-benzotriazole was carcinogenic in rats or mice (447).

25.4.1.6 Genetic and Related Cellular Effects Studies 1-H-Benzotriazole was positive in the *S. typhimurium* and in *E. coli* mutagenicity assays (454).

25.4.2 Human Experience A report showed that two metalworkers developed contact dermatitis from exposure to lubricating oil that contained 1-*H*-benzotriazole (455).

No other human experience data, case histories, or epidemiology studies were found for benzotriazole.

25.4 Standards, Regulations, or Guidelines of Exposure
No occupational exposure standards have been established.
25.6 Studies on Environmental Impact
No information was found.
